About the Author

Laura E. Berk is a distinguished professor of psychology at Illinois State University, where she has taught human development to both undergraduate and graduate students for more than three decades. She received her bachelor's degree in psychology from the University of California, Berkeley, and her master's and doctoral degrees in child development and educational psychology from the University of Chicago. She has been a visiting scholar at Cornell University, UCLA, Stanford University, and the University of South Australia.

Berk has published widely on the effects of school environments on children's development, the development of private speech, and the role of make-believe play in development. Her research has been funded by the U.S. Office of Education and the National Institute of Child Health and Human Development. It has appeared in many prominent journals, including *Child Development*, *Developmental Psychology*, *Merrill-Palmer Quarterly*, *Journal of Abnormal Child Psychology*, *Development and Psychopathology*, and *Early Childhood Research Quarterly*. Her empirical studies have attracted the attention of the general public, leading to contributions to *Psychology Today* and *Scientific American*. She has also been featured on National Public Radio's *Morning Edition* and in *Parents Magazine*, *Wondertime*, and *Reader's Digest*.

Berk has served as a research editor of *Young Children* and as a consulting editor for *Early Childhood Research Quarterly*. Currently, she is associate editor of the *Journal of Cognitive Education and Psychology*. She is a frequent contributor to edited volumes on early childhood development, having recently authored chapters on the importance of parenting, on make-believe play, and on the kindergarten child. She has also written the article on social development for *The Child: An Encyclopedic Companion*; the article on Vygotsky for the *Encyclopedia of Cognitive Science*; and the chapter on storytelling as a teaching strategy for *Voices of Experience: Memorable Talks from the National Institute on the Teaching of Psychology* (Association for Psychological Science). She is coauthor of the forthcoming chapter on make-believe play and self-regulation in the *Sage Handbook of Play in Early Childhood*.

Berk's books include *Private Speech: From Social Interaction to Self-Regulation*; *Scaffolding Children's Learning: Vygotsky and Early Childhood Education*; *Landscapes of Development: An Anthology of Readings*; and *A Mandate for Playful Learning in Preschool: Presenting the Evidence*. In addition to *Development Through the Lifespan*, she is author of the best-selling texts *Child Development* and *Infants, Children, and Adolescents*, published by Pearson. Her book for parents and teachers is *Awakening Children's Minds: How Parents and Teachers Can Make a Difference*.

Berk is active in work for children's causes. In addition to service in her home community, she is a member of the national board of directors and chair of the Chicago advisory board of Jumpstart, a nonprofit organization that provides intensive literacy intervention to thousands of low-income preschoolers across the United States, using college and university students as interveners. Berk is a fellow of the American Psychological Association, Division 7: Developmental Psychology.

Brief Contents

PART I: Theory and Research in Human Development

- 1** History, Theory, and Research Strategies 2

PART II: Foundations of Development

- 2** Genetic and Environmental Foundations 44
- 3** Prenatal Development, Birth, and the Newborn Baby 78

PART III: Infancy and Toddlerhood: The First Two Years

- 4** Physical Development in Infancy and Toddlerhood 118
- 5** Cognitive Development in Infancy and Toddlerhood 150
- 6** Emotional and Social Development in Infancy and Toddlerhood 182

PART IV: Early Childhood: Two to Six Years

- 7** Physical and Cognitive Development in Early Childhood 214
- 8** Emotional and Social Development in Early Childhood 254

PART V: Middle Childhood: Six to Eleven Years

- 9** Physical and Cognitive Development in Middle Childhood 288
- 10** Emotional and Social Development in Middle Childhood 328

PART VI: Adolescence: The Transition to Adulthood

- 11** Physical and Cognitive Development in Adolescence 360
- 12** Emotional and Social Development in Adolescence 400

PART VII: Early Adulthood

- 13** Physical and Cognitive Development in Early Adulthood 430
- 14** Emotional and Social Development in Early Adulthood 462

PART VIII: Middle Adulthood

- 15** Physical and Cognitive Development in Middle Adulthood 500
- 16** Emotional and Social Development in Middle Adulthood 530

PART IX: Late Adulthood

- 17** Physical and Cognitive Development in Late Adulthood 562
- 18** Emotional and Social Development in Late Adulthood 602

PART X: The End of Life

- 19** Death, Dying, and Bereavement 638

Features at a Glance

SOCIAL ISSUES: HEALTH

- Family Chaos Undermines Children's Well-Being 26
- The Pros and Cons of Reproductive Technologies 54
- The Nurse–Family Partnership: Reducing Maternal Stress and Enhancing Child Development Through Social Support 94
- A Cross-National Perspective on Health Care and Other Policies for Parents and Newborn Babies 104
- Does Child Care in Infancy Threaten Attachment Security and Later Adjustment? 202
- Emotional Intelligence 313
- Children's Eyewitness Testimony 355
- Lesbian, Gay, and Bisexual Youths: Coming Out to Oneself and Others 376
- The Obesity Epidemic: How Americans Became the Heaviest People in the World 440
- Childhood Attachment Patterns and Adult Romantic Relationships 474
- Partner Abuse 482
- Generative Adults Tell Their Life Stories 534
- Grandparents Rearing Grandchildren: The Skipped-Generation Family 548
- Interventions for Caregivers of Older Adults with Dementia 586
- Elder Suicide 612
- Voluntary Active Euthanasia: Lessons from Australia and the Netherlands 657

SOCIAL ISSUES: EDUCATION

- Baby Learning from TV and Video: The Video Deficit Effect 159
- Children's Questions: Catalyst for Cognitive Development 232
- Young Children Learn About Gender Through Mother–Child Conversations 275
- School Recess—A Time to Play, a Time to Learn 298
- Magnet Schools: Equal Access to High-Quality Education 321
- Media Multitasking Disrupts Attention and Learning 394
- Development of Civic Engagement 413
- Masculinity at Work: Men Who Choose Nontraditional Careers 458
- The Art of Acting Improves Memory in Older Adults 523

BIOLOGY AND ENVIRONMENT

- Resilience 10
- A Case of Epigenesis: Smoking During Pregnancy Alters Gene Expression 74
- The Mysterious Tragedy of Sudden Infant Death Syndrome 110
- Brain Plasticity: Insights from Research on Brain-Damaged Children and Adults 126
- “Tuning In” to Familiar Speech, Faces, and Music: A Sensitive Period for Culture-Specific Learning 141
- Infantile Amnesia 164
- Parental Depression and Child Development 186
- Development of Shyness and Sociability 192
- “Mindblindness” and Autism 241
- Children with Attention-Deficit Hyperactivity Disorder 304
- Bullies and Their Victims 342
- Sex Differences in Spatial Abilities 390
- Two Routes to Adolescent Delinquency 424
- Telomere Length: A Marker of the Impact of Life Circumstances on Biological Aging 433
- Anti-Aging Effects of Dietary Calorie Restriction 505
- What Factors Promote Psychological Well-Being in Midlife? 540
- What Can We Learn About Aging from Centenarians? 566
- Religious Involvement and Quality of Life in the Final Year 609
- Music as Palliative Care for Dying Patients 653

CULTURAL INFLUENCES

- The Baby Boomers Reshape the Life Course 12
- Immigrant Youths: Adapting to a New Land 32
- The African-American Extended Family 66
- Cultural Variation in Infant Sleeping Arrangements 129
- Social Origins of Make-Believe Play 168
- The Powerful Role of Paternal Warmth in Development 204
- Children in Village and Tribal Cultures Observe and Participate in Adult Work 236
- Cultural Variations in Personal Storytelling: Implications for Early Self-Concept 257
- Ethnic Differences in the Consequences of Physical Punishment 267
- Impact of Ethnic and Political Violence on Children 353
- Identity Development Among Ethnic Minority Adolescents 406
- Is Emerging Adulthood Really a Distinct Period of Development? 467
- Menopause as a Biocultural Event 508
- Cultural Variations in Sense of Usefulness in Late Life 576
- The New Old Age 607
- Cultural Variations in Mourning Behavior 664

APPLYING WHAT WE KNOW

- Steps Prospective Parents Can Take Before Conception to Increase the Chances of a Healthy Baby 57
- Do's and Don'ts for a Healthy Pregnancy 96
- Soothing a Crying Baby 111
- Reasons to Breastfeed 131
- Features of a High-Quality Home Life: The HOME Infant–Toddler Subscales 171
- Signs of Developmentally Appropriate Infant and Toddler Child Care 172
- Supporting Early Language Learning 179
- Encouraging Affectionate Ties Between Infants and Their Preschool Siblings 205
- Helping Toddlers Develop Compliance and Self-Control 209
- Features of a High-Quality Home Life for Preschoolers: The HOME Early Childhood Subscales 244
- Signs of Developmentally Appropriate Early Childhood Programs 247
- Helping Children Manage Common Fears of Early Childhood 259
- Positive Parenting 268
- Regulating TV and Computer Use 272
- Providing Developmentally Appropriate Organized Sports in Middle Childhood 297
- Signs of High-Quality Education in Elementary School 319
- Fostering a Mastery-Oriented Approach to Learning 335
- Helping Children Adjust to Their Parents' Divorce 349
- Handling Consequences of Teenagers' New Cognitive Capacities 386
- Supporting High Achievement in Adolescence 393
- Supporting Healthy Identity Development 405
- Preventing Sexual Coercion 449
- Resources That Foster Resilience in Emerging Adulthood 468
- Keeping Love Alive in a Romantic Partnership 475
- Strategies That Help Dual-Earner Couples Combine Work and Family Roles 495
- Reducing Cancer Incidence and Deaths 511
- Reducing the Risk of Heart Attack 512
- Managing Stress 515
- Facilitating Adult Reentry to College 527
- Ways Middle-Aged Parents Can Promote Positive Ties with Their Adult Children 546
- Relieving the Stress of Caring for an Aging Parent 551
- Ingredients of Effective Retirement Planning 557
- Increasing the Effectiveness of Educational Experiences for Older Adults 598
- Fostering Adaptation to Widowhood in Late Adulthood 624
- Discussing Concerns About Death with Children and Adolescents 644
- Communicating with Dying People 650
- Suggestions for Resolving Grief After a Loved One Dies 663

Contents

A Personal Note to Students xv
Preface for Instructors xvi

PART I

Theory and Research in Human Development

chapter 1

History, Theory, and Research Strategies 2

A Scientific, Applied, and Interdisciplinary Field 5

Basic Issues 5

- Continuous or Discontinuous Development? 6
- One Course of Development or Many? 6
- Relative Influence of Nature and Nurture? 7

The Lifespan Perspective: A Balanced Point of View 7

- Development Is Lifelong 8
- Development Is Multidimensional and Multidirectional 9
- Development Is Plastic 9

■ **BIOLOGY AND ENVIRONMENT** *Resilience* 10

- Development Is Influenced by Multiple, Interacting Forces 10

■ **CULTURAL INFLUENCES** *The Baby Boomers Reshape the Life Course* 12

Scientific Beginnings 14

- Darwin: Forefather of Scientific Child Study 14
- The Normative Period 14
- The Mental Testing Movement 15

Mid-Twentieth-Century Theories 15

- The Psychoanalytic Perspective 15
- Behaviorism and Social Learning Theory 17
- Piaget's Cognitive-Developmental Theory 18

Recent Theoretical Perspectives 20

- Information Processing 20
- Developmental Cognitive Neuroscience 21
- Ethology and Evolutionary Developmental Psychology 22
- Vygotsky's Sociocultural Theory 23
- Ecological Systems Theory 24

■ **SOCIAL ISSUES: HEALTH** *Family Chaos Undermines Children's Well-Being* 26

Comparing and Evaluating Theories 27

Studying Development 27

- Common Research Methods 28

■ **CULTURAL INFLUENCES** *Immigrant Youths: Adapting to a New Land* 32

- General Research Designs 34
- Designs for Studying Development 35

Ethics in Lifespan Research 39
Summary 41
Important Terms and Concepts 43

PART II

Foundations of Development

chapter 2

Genetic and Environmental Foundations 44

Genetic Foundations 46

- The Genetic Code 46
- The Sex Cells 46
- Boy or Girl? 47
- Multiple Offspring 47
- Patterns of Genetic Inheritance 48
- Chromosomal Abnormalities 52

Reproductive Choices 53

- Genetic Counseling 53

■ **SOCIAL ISSUES: HEALTH** *The Pros and Cons of Reproductive Technologies* 54

- Prenatal Diagnosis and Fetal Medicine 56
- Adoption 57

Environmental Contexts for Development 59

- The Family 59
- Socioeconomic Status and Family Functioning 61
- Poverty 61
- Affluence 62
- Beyond the Family: Neighborhoods, Towns, and Cities 63
- The Cultural Context 65

■ **CULTURAL INFLUENCES** *The African-American Extended Family* 66

Understanding the Relationship Between Heredity and Environment 69

- The Question, "How Much?" 70
- The Question, "How?" 71

■ **BIOLOGY AND ENVIRONMENT** *A Case of Epigenesis: Smoking During Pregnancy Alters Gene Expression* 74

Summary 75

Important Terms and Concepts 77

chapter 3

Prenatal Development, Birth, and the Newborn Baby 78

Prenatal Development 80

- Conception 80
- Period of the Zygote 80

Period of the Embryo 82

Period of the Fetus 83

Prenatal Environmental Influences 85

Teratogens 85

Other Maternal Factors 92

- **SOCIAL ISSUES: HEALTH** *The Nurse–Family Partnership: Reducing Maternal Stress and Enhancing Child Development Through Social Support* 94

The Importance of Prenatal Health Care 95

Childbirth 96

The Stages of Childbirth 96

The Baby’s Adaptation to Labor and Delivery 97

The Newborn Baby’s Appearance 97

Assessing the Newborn’s Physical Condition: The Apgar Scale 98

Approaches to Childbirth 98

Natural, or Prepared, Childbirth 99

Home Delivery 99

Medical Interventions 100

Fetal Monitoring 100

Labor and Delivery Medication 100

Cesarean Delivery 101

Preterm and Low-Birth-Weight Infants 101

Preterm versus Small-for-Date Infants 102

Consequences for Caregiving 102

Interventions for Preterm Infants 102

- **SOCIAL ISSUES: HEALTH** *A Cross-National Perspective on Health Care and Other Policies for Parents and Newborn Babies* 104

Birth Complications, Parenting, and Resilience 105

The Newborn Baby’s Capacities 106

Reflexes 106

States 108

- **BIOLOGY AND ENVIRONMENT** *The Mysterious Tragedy of Sudden Infant Death Syndrome* 110

Sensory Capacities 112

Neonatal Behavioral Assessment 114

Adjusting to the New Family Unit 115

Summary 115

Important Terms and Concepts 117

PART III

Infancy and Toddlerhood: The First Two Years

chapter 4

Physical Development in Infancy and Toddlerhood 118

Body Growth 120

Changes in Body Size and Muscle–Fat Makeup 120

Individual and Group Differences 121

Changes in Body Proportions 121

Brain Development 121

Development of Neurons 121

Neurobiological Methods 122

Development of the Cerebral Cortex 124

Sensitive Periods in Brain Development 125

- **BIOLOGY AND ENVIRONMENT** *Brain Plasticity: Insights from Research on Brain-Damaged Children and Adults* 126

Changing States of Arousal 128

- **CULTURAL INFLUENCES** *Cultural Variation in Infant Sleeping Arrangements* 129

Influences on Early Physical Growth 130

Heredity 130

Nutrition 130

Malnutrition 132

Learning Capacities 133

Classical Conditioning 133

Operant Conditioning 134

Habituation 134

Imitation 135

Motor Development 136

The Sequence of Motor Development 137

Motor Skills as Dynamic Systems 137

Fine-Motor Development: Reaching and Grasping 139

Perceptual Development 140

Hearing 140

- **BIOLOGY AND ENVIRONMENT** *“Tuning In” to Familiar Speech, Faces, and Music: A Sensitive Period for Culture-Specific Learning* 141

Vision 142

Intermodal Perception 145

Understanding Perceptual Development 146

Summary 148

Important Terms and Concepts 149

chapter 5

Cognitive Development in Infancy and Toddlerhood 150

Piaget’s Cognitive-Developmental Theory 152

Piaget’s Ideas About Cognitive Change 152

The Sensorimotor Stage 153

Follow-Up Research on Infant Cognitive Development 155

Evaluation of the Sensorimotor Stage 158

- **SOCIAL ISSUES: EDUCATION** *Baby Learning from TV and Video: The Video Deficit Effect* 159

Information Processing 161

A General Model of Information Processing 161

Attention 163

Memory 163

- **BIOLOGY AND ENVIRONMENT** *Infantile Amnesia* 164

Categorization 164

Evaluation of Information-Processing Findings 166

The Social Context of Early Cognitive Development 167

- **CULTURAL INFLUENCES** *Social Origins of Make-Believe Play* 168

Individual Differences in Early Mental Development 169

- Infant and Toddler Intelligence Tests 169
- Early Environment and Mental Development 170
- Early Intervention for At-Risk Infants and Toddlers 173

Language Development 174

- Theories of Language Development 174
- Getting Ready to Talk 175
- First Words 176
- The Two-Word Utterance Phase 177
- Individual and Cultural Differences 177
- Supporting Early Language Development 178

Summary 180**Important Terms and Concepts** 181**chapter 6****Emotional and Social Development in Infancy and Toddlerhood** 182**Erikson's Theory of Infant and Toddler Personality** 184

- Basic Trust versus Mistrust 184
- Autonomy versus Shame and Doubt 184

Emotional Development 185

- Development of Basic Emotions 185

- **BIOLOGY AND ENVIRONMENT** *Parental Depression and Child Development* 186

- Understanding and Responding to the Emotions of Others 188
- Emergence of Self-Conscious Emotions 188
- Beginnings of Emotional Self-Regulation 189

Temperament and Development 190

- The Structure of Temperament 190
- Measuring Temperament 191
- Stability of Temperament 191

- **BIOLOGY AND ENVIRONMENT** *Development of Shyness and Sociability* 192

- Genetic and Environmental Influences 193
- Temperament and Child Rearing: The Goodness-of-Fit Model 194

Development of Attachment 195

- Bowlby's Ethological Theory 196
- Measuring the Security of Attachment 197
- Stability of Attachment 198
- Cultural Variations 198
- Factors That Affect Attachment Security 199
- Multiple Attachments 201

- **SOCIAL ISSUES: HEALTH** *Does Child Care in Infancy Threaten Attachment Security and Later Adjustment?* 202

- **CULTURAL INFLUENCES** *The Powerful Role of Paternal Warmth in Development* 204

- Attachment and Later Development 206

Self-Development 206

- Self-Awareness 206
- Categorizing the Self 208
- Self-Control 208

Summary 210**Important Terms and Concepts** 211**MILESTONES**

Development in Infancy and Toddlerhood 212

PART IV**Early Childhood: Two to Six Years****chapter 7****Physical and Cognitive Development in Early Childhood** 214**PHYSICAL DEVELOPMENT** 216**A Changing Body and Brain** 216

- Skeletal Growth 217
- Brain Development 217

Influences on Physical Growth and Health 219

- Heredity and Hormones 219
- Nutrition 219
- Infectious Disease 220
- Childhood Injuries 221

Motor Development 223

- Gross-Motor Development 223
- Fine-Motor Development 224
- Individual Differences in Motor Skills 225

COGNITIVE DEVELOPMENT 226**Piaget's Theory: The Preoperational Stage** 226

- Advances in Mental Representation 226
- Make-Believe Play 226
- Symbol–Real-World Relations 227
- Limitations of Preoperational Thought 228
- Follow-Up Research on Preoperational Thought 230
- Evaluation of the Preoperational Stage 231

- **SOCIAL ISSUES: EDUCATION** *Children's Questions: Catalyst for Cognitive Development* 232

- Piaget and Education 233

Vygotsky's Sociocultural Theory 233

- Private Speech 233
- Social Origins of Early Childhood Cognition 234
- Vygotsky and Education 235
- Evaluation of Vygotsky's Theory 235

- **CULTURAL INFLUENCES** *Children in Village and Tribal Cultures Observe and Participate in Adult Work* 236

Information Processing 236

- Attention 236
- Memory 237
- The Young Child's Theory of Mind 238
- Early Childhood Literacy 240

- **BIOLOGY AND ENVIRONMENT** “Mindblindness” and Autism 241
 - Early Childhood Mathematical Reasoning 242
- Individual Differences in Mental Development** 243
 - Home Environment and Mental Development 244
 - Preschool, Kindergarten, and Child Care 244
 - Educational Media 246
- Language Development** 248
 - Vocabulary 248
 - Grammar 249
 - Conversation 250
 - Supporting Language Development in Early Childhood 250
- Summary** 251
- Important Terms and Concepts** 253

chapter 8

Emotional and Social Development in Early Childhood 254

- Erikson’s Theory: Initiative versus Guilt** 256
- Self-Understanding** 256
 - Foundations of Self-Concept 256
- **CULTURAL INFLUENCES** *Cultural Variations in Personal Storytelling: Implications for Early Self-Concept* 257
 - Emergence of Self-Esteem 257
- Emotional Development** 258
 - Understanding Emotion 258
 - Emotional Self-Regulation 259
 - Self-Conscious Emotions 259
 - Empathy and Sympathy 260
- Peer Relations** 261
 - Advances in Peer Sociability 261
 - First Friendships 262
 - Peer Relations and School Readiness 263
 - Parental Influences on Early Peer Relations 263
- Foundations of Morality** 264
 - The Psychoanalytic Perspective 264
 - Social Learning Theory 265
- **CULTURAL INFLUENCES** *Ethnic Differences in the Consequences of Physical Punishment* 267
 - The Cognitive-Developmental Perspective 268
 - The Other Side of Morality: Development of Aggression 269
- Gender Typing** 273
 - Gender-Stereotyped Beliefs and Behavior 273
 - Biological Influences on Gender Typing 273
 - Environmental Influences on Gender Typing 274
- **SOCIAL ISSUES: EDUCATION** *Young Children Learn About Gender Through Mother–Child Conversations* 275
 - Gender Identity 276
 - Reducing Gender Stereotyping in Young Children 278

- Child Rearing and Emotional and Social Development** 278
 - Styles of Child Rearing 278
 - What Makes Authoritative Child Rearing Effective? 280
 - Cultural Variations 280
 - Child Maltreatment 281

Summary 284

Important Terms and Concepts 285

PART V

Middle Childhood: Six to Eleven Years

chapter 9

Physical and Cognitive Development in Middle Childhood 288

PHYSICAL DEVELOPMENT 290

Body Growth 290

Common Health Problems 290

- Nutrition 291
- Overweight and Obesity 291
- Vision and Hearing 293
- Illnesses 293
- Unintentional Injuries 294

Motor Development and Play 294

- Gross-Motor Development 294
- Fine-Motor Development 295
- Sex Differences 296
- Games with Rules 296
- Shadows of Our Evolutionary Past 297

■ **SOCIAL ISSUES: EDUCATION** *School Recess—A Time to Play, a Time to Learn* 298

Physical Education 298

COGNITIVE DEVELOPMENT 299

Piaget’s Theory: The Concrete Operational Stage 299

- Concrete Operational Thought 299
- Limitations of Concrete Operational Thought 301
- Follow-Up Research on Concrete Operational Thought 301
- Evaluation of the Concrete Operational Stage 302

Information Processing 302

- Working-Memory Capacity 302
- Executive Function 303
- Attention 303

■ **BIOLOGY AND ENVIRONMENT** *Children with Attention-Deficit Hyperactivity Disorder* 304

- Memory Strategies 304
- Knowledge and Memory 305

- Culture, Schooling, and Memory Strategies 306
- The School-Age Child's Theory of Mind 306
- Cognitive Self-Regulation 307
- Applications of Information Processing to Academic Learning 307

Individual Differences in Mental Development 309

- Defining and Measuring Intelligence 309
- Recent Efforts to Define Intelligence 310
- Explaining Individual and Group Differences in IQ 312

■ **SOCIAL ISSUES: HEALTH** *Emotional Intelligence* 313

Language Development 316

- Vocabulary 316
- Grammar 316
- Pragmatics 316
- Learning Two Languages 317

Learning in School 318

- Class Size 318
- Educational Philosophies 319
- Teacher–Student Interaction 320

■ **SOCIAL ISSUES: EDUCATION** *Magnet Schools: Equal Access to High-Quality Education* 321

- Grouping Practices 321
- Teaching Children with Special Needs 322
- How Well Educated Are U.S. Children? 323

Summary 325

Important Terms and Concepts 327

chapter 10

Emotional and Social Development in Middle Childhood 328

Erikson's Theory: Industry versus Inferiority 330

Self-Understanding 330

- Self-Concept 330
- Self-Esteem 331
- Influences on Self-Esteem 331

Emotional Development 335

- Self-Conscious Emotions 335
- Emotional Understanding 335
- Emotional Self-Regulation 336

Moral Development 336

- Moral and Social-Conventional Understanding 336
- Understanding Individual Rights 337
- Understanding Diversity and Inequality 337

Peer Relations 339

- Peer Groups 339
- Friendships 340
- Peer Acceptance 341

■ **BIOLOGY AND ENVIRONMENT** *Bullies and Their Victims* 342

Gender Typing 343

- Gender-Stereotyped Beliefs 343
- Gender Identity and Behavior 344

Family Influences 345

- Parent–Child Relationships 345
- Siblings 345
- Only Children 346
- Divorce 346
- Blended Families 349
- Maternal Employment and Dual-Earner Families 350

Some Common Problems of Development 352

- Fears and Anxieties 352
- Child Sexual Abuse 352

■ **CULTURAL INFLUENCES** *Impact of Ethnic and Political Violence on Children* 353

- Fostering Resilience in Middle Childhood 354

■ **SOCIAL ISSUES: HEALTH** *Children's Eyewitness Testimony* 355

A Personal Note to Students

My more than 30 years of teaching human development have brought me in contact with thousands of students like you—students with diverse college majors, future goals, interests, and needs. Some are affiliated with my own field, psychology, but many come from other related fields—education, sociology, anthropology, family studies, social service, nursing, and biology, to name just a few. Each semester, my students' aspirations have proved to be as varied as their fields of study. Many look toward careers in applied work—counseling, caregiving, nursing, social work, school psychology, and program administration. Some plan to teach, and a few want to do research. Most hope someday to become parents, whereas others are already parents who come with a desire to better understand and rear their children. And almost all arrive with a deep curiosity about how they themselves developed from tiny infants into the complex human beings they are today.

My goal in preparing this sixth edition of *Development Through the Lifespan* is to provide a textbook that meets the instructional goals of your course as well as your personal interests and needs. To achieve these objectives, I have grounded this book in a carefully selected body of classic and current theory and research. In addition, the text highlights the lifespan perspective on development and the interacting contributions of biology and environment to the developing person. It also illustrates commonalities and differences among ethnic groups and cultures and discusses the broader social contexts in which we develop. I have provided a unique pedagogical program that will assist you in mastering information, integrating various aspects of development, critically examining controversial issues, applying what you have learned, and relating the information to your own life.

I hope that learning about human development will be as rewarding for you as I have found it over the years. I would like to know what you think about both the field of human development and this book. I welcome your comments; please feel free to send them to me at Department of Psychology, Box 4620, Illinois State University, Normal, IL 61790.

Laura E. Berk

Preface for Instructors

My decision to write *Development Through the Lifespan* was inspired by a wealth of professional and personal experiences. First and foremost were the interests and concerns of hundreds of students of human development with whom I have worked in over three decades of college teaching. Each semester, their insights and questions have revealed how an understanding of any single period of development is enriched by an appreciation of the entire lifespan. Second, as I moved through adult development myself, I began to think more intensely about factors that have shaped and reshaped my own life course—family, friends, mentors, co-workers, community, and larger society. My career well-established, my marriage having stood the test of time, and my children launched into their adult lives, I felt that a deeper grasp of these multiple, interacting influences would help me better appreciate where I had been and where I would be going in the years ahead. I was also convinced that such knowledge could contribute to my becoming a better teacher, scholar, family member, and citizen. And because teaching has been so central and gratifying to my work life, I wanted to bring to others a personally meaningful understanding of lifespan development.

The years since *Development Through the Lifespan* first appeared have been a period of considerable expansion and change in theory and research. This sixth edition represents these rapidly transforming aspects of the field, with a wealth of new content and teaching tools:

- *Diverse pathways of change are highlighted.* Investigators have reached broad consensus that variations in biological makeup and everyday tasks lead to wide individual differences in paths of change and resulting competencies. This edition pays more attention to variability in development and to recent theories—including ecological, sociocultural, and dynamic systems—that attempt to explain it. Multicultural and cross-cultural findings, including international comparisons, are enhanced throughout the text. Biology and Environment and Cultural Influences boxes also accentuate the theme of diversity in development.
- *The lifespan perspective is emphasized.* As in previous editions, the lifespan perspective—development as lifelong, multidimensional, multidirectional, plastic, and embedded in multiple contexts—continues to serve as a unifying approach to understanding human change and is woven thoroughly into the text.
- *The complex bidirectional relationship between biology and environment is given greater attention.* Accumulating evidence on development of the brain, motor skills, cognitive and language competencies, temperament and personality, emotional and social understanding, and developmental problems underscores the way biological factors emerge in, are modified by, and share power with experience. Interconnections between biology and environment are integral to the lifespan perspective and are

revisited throughout the text narrative and in the Biology and Environment boxes with new and updated topics.

- *Inclusion of interdisciplinary research is expanded.* The move toward viewing thoughts, feelings, and behavior as an integrated whole, affected by a wide array of influences in biology, social context, and culture, has motivated developmental researchers to strengthen their ties with other fields of psychology and with other disciplines. Topics and findings included in this edition increasingly reflect the contributions of educational psychology, social psychology, health psychology, clinical psychology, neurobiology, pediatrics, geriatrics, sociology, anthropology, social service, and other fields.
- *The links among theory, research, and applications are strengthened.* As researchers intensify their efforts to generate findings relevant to real-life situations, I have placed even greater weight on social policy issues and sound theory- and research-based applications. Further applications are provided in the Applying What We Know tables, which give students concrete ways of building bridges between their learning and the real world.
- *The role of active student learning is made more explicit.* **TAKE A MOMENT...**, a feature built into the chapter narrative, asks students to think deeply and critically or to engage in an exercise or application as they read. Ask Yourself questions at the end of each major section have been thoroughly revised and expanded to promote four approaches to engaging actively with the subject matter—*Review, Connect, Apply, and Reflect*. This feature assists students in thinking about what they have learned from multiple vantage points. A new **LOOK AND LISTEN** feature asks students to observe what real children, adolescents, and adults say and do; speak with them or with professionals invested in their well-being; and inquire into community programs and practices that influence lifespan development. In addition, highlighting of key terms within the text narrative reinforces student learning in context.

Text Philosophy

The basic approach of this book has been shaped by my own professional and personal history as a teacher, researcher, and parent. It consists of seven philosophical ingredients that I regard as essential for students to emerge from a course with a thorough understanding of lifespan development. Each theme is woven into every chapter:

1. **An understanding of the diverse array of theories in the field and the strengths and shortcomings of each.** The first chapter begins by emphasizing that only knowledge of multiple theories can do justice to the richness of human

development. As I take up each age period and domain of development, I present a variety of theoretical perspectives, indicate how each highlights previously overlooked aspects of development, and discuss research that evaluates it. Consideration of contrasting theories also serves as the context for an evenhanded analysis of many controversial issues.

2. **A grasp of the lifespan perspective as an integrative approach to development.** I introduce the lifespan perspective as an organizing framework in the first chapter and refer to and illustrate its assumptions throughout the text, in an effort to help students construct an overall vision of development from conception to death.
3. **Knowledge of both the sequence of human development and the processes that underlie it.** Students are provided with a discussion of the organized sequence of development along with processes of change. An understanding of process—how complex combinations of biological and environmental events produce development—has been the focus of most recent research. Accordingly, the text reflects this emphasis. But new information about the timetable of change has also emerged. In many ways, the very young and the old have proved to be far more competent than they were believed to be in the past. In addition, many milestones of adult development, such as finishing formal education, entering a career, getting married, having children, and retiring, have become less predictable. Current evidence on the sequence and timing of development, along with its implications for process, is presented for all periods of the lifespan.
4. **An appreciation of the impact of context and culture on human development.** A wealth of research indicates that people live in rich physical and social contexts that affect all domains of development. Throughout the book, students travel to distant parts of the world as I review a growing body of cross-cultural evidence. The text narrative also discusses many findings on socioeconomically and ethnically diverse people within the United States. Furthermore, the impact of historical time period and cohort membership receives continuous attention. In this vein, gender issues—the distinctive but continually evolving experiences, roles, and life paths of males and females—are granted substantial emphasis. Besides highlighting the effects of immediate settings, such as family, neighborhood, and school, I make a concerted effort to underscore the influence of larger social structures—societal values, laws, and government policies and programs—on lifelong well-being.
5. **An understanding of the joint contributions of biology and environment to development.** The field recognizes more powerfully than ever before the joint roles of hereditary/constitutional and environmental factors—that these contributions to development combine in complex ways and cannot be separated in a simple manner. Numerous

examples of how biological dispositions can be maintained as well as transformed by social contexts are presented throughout the book.

6. **A sense of the interdependency of all domains of development—physical, cognitive, emotional, and social.** Every chapter emphasizes an integrated approach to human development. I show how physical, cognitive, emotional, and social development are interwoven. Within the text narrative, and in a special series of Ask Yourself questions at the end of major sections, students are referred to other sections of the book to deepen their grasp of relationships among various aspects of change.
7. **An appreciation of the interrelatedness of theory, research, and applications.** Throughout this book, I emphasize that theories of human development and the research stimulated by them provide the foundation for sound, effective practices with children, adolescents, and adults. The link among theory, research, and applications is reinforced by an organizational format in which theory and research are presented first, followed by practical implications. In addition, a current focus in the field—harnessing knowledge of human development to shape social policies that support human needs throughout the lifespan—is reflected in every chapter. The text addresses the current condition of children, adolescents, and adults in the United States and elsewhere in the world and shows how theory and research have combined with public interest to spark successful interventions. Many important applied topics are considered, such as family planning, infant mortality, maternal employment and child care, teenage pregnancy and parenthood, domestic violence, exercise and adult health, religiosity and well-being, lifelong learning, grandparents rearing grandchildren, caring for aging adults with dementia, adjustment to retirement, optimal aging, and palliative care for the dying.

Text Organization

I have chosen a chronological organization for *Development Through the Lifespan*. The book begins with an introductory chapter that describes the scientific history of the field, influential theories, and research strategies. It is followed by two chapters on the foundations of development. Chapter 2 combines an overview of genetic and environmental contexts into a single integrated discussion of these multifaceted influences on development. Chapter 3 is devoted to prenatal development, birth, and the newborn baby. With this foundation, students are ready to look closely at seven major age periods: infancy and toddlerhood (Chapters 4, 5, and 6), early childhood (Chapters 7 and 8), middle childhood (Chapters 9 and 10), adolescence (Chapters 11 and 12), early adulthood (Chapters 13 and 14), middle adulthood (Chapters 15 and 16), and late adulthood (Chapters 17 and 18). Topical chapters within each chronological division cover

physical development, cognitive development, and emotional and social development. The book concludes with a chapter on death, dying, and bereavement (Chapter 19).

The chronological approach assists students in thoroughly understanding each age period. It also eases the task of integrating the various domains of development because each is discussed in close proximity. At the same time, a chronologically organized book requires that theories covering several age periods be presented piecemeal. This creates a challenge for students, who must link the various parts together. To assist with this task, I frequently remind students of important earlier achievements before discussing new developments, referring back to related sections with page references. Also, chapters or sections devoted to the same topic (for example, cognitive development) are similarly organized, making it easier for students to draw connections across age periods and construct an overall view of developmental change.

New Coverage in the Sixth Edition

Lifespan development is a fascinating and ever-changing field of study, with constantly emerging new discoveries and refinements in existing knowledge. The sixth edition represents this burgeoning contemporary literature, with over 2,000 new citations. Cutting-edge topics throughout the text underscore the book's major themes. Here is a sampling:

CHAPTER 1: Updated Biology and Environment box on resilience • Updated section on developmental cognitive neuroscience • Increased coverage of evolutionary developmental psychology, with special attention to the adaptiveness of human longevity • Expanded illustrations at all levels of Bronfenbrenner's ecological model • New Social Issues: Health box on how family chaos undermines children's well-being • Updated Cultural Influences box on immigrant youths • Clarified explanation of sequential designs

CHAPTER 2: Updated Social Issues: Health box on the pros and cons of reproductive technologies • Updated section on development of adopted children • Enhanced attention to the impact of poverty on development • Expanded introduction to family influences on development, including the importance of coparenting • Updated research on neighborhood influences on children's physical and mental health • Current statistics on the condition of children, families, and the aged in the United States compared with other Western nations • Introduction to the concept of gene–environment interaction, with illustrative research findings • Expanded section on epigenesis, including new examples of environmental influences on gene expression • New Biology and Environment box highlighting a case of epigenesis—prenatal smoking modifies gene expression

CHAPTER 3: Enhanced attention to fetal brain development, sensory capacities, and behavior • Expanded and updated consideration of a wide range of teratogens • New evidence on the long-term consequences of emotional stress during pregnancy • New findings on older maternal age and prenatal and birth complications • Updated evidence on the contributions of doula support to the birth process and to newborn adjustment • New research on parenting and development of pre-term and low-birth-weight infants • Expanded and updated Social Issues: Health box on health care and other policies for parents and newborn babies, including cross-national infant mortality rates and the importance of generous parental leave • New Social Issues: Health box on the Nurse–Family Partnership—reducing maternal stress and enhancing child development through social support • Updated findings on the roles of impaired brain functioning, maternal smoking, and maternal drug abuse in sudden infant death syndrome (SIDS) • New evidence on the role of sleep in infant learning • New research on the impact of “proximal care”—extensive holding of young babies—in reducing infant crying • Updated research on touch sensitivity in newborns, including techniques for reducing infant stress to painful medical procedures

CHAPTER 4: Updated introduction to major methods of assessing brain functioning, including the EEG geodesic sensor net (GSN) and near-infrared spectroscopy (NIRS) • Updated discussion of advances in brain development, with special attention to the prefrontal cortex • New research on children adopted from Romanian orphanages, including neurobiological evidence bearing on the question of whether infancy is a sensitive period of development • Updated Cultural Influences box on cultural variation in infant sleeping arrangements • Updated section on breastfeeding • New dynamic systems research on development of walking and reaching • Updated evidence on how caregiving practices and physical surroundings contribute to development of infant motor skills • Enhanced attention to cultural influences—including infant sleep and motor development • New evidence on the perceptual narrowing effect in speech, music, and species-related face perception, and in gender- and race-related face perception • Expanded and updated section on intermodal perception, including its contributions to all aspects of psychological development

CHAPTER 5: Revised and updated section on infant and toddler imitation, revealing toddlers' ability to infer others' intentions • New section on symbolic understanding, including toddlers' developing grasp of words and pictures as symbolic tools • New Social Issues: Education box on baby learning from TV and video, including discussion of the video deficit effect • Revised section introducing information-processing concepts, including working memory, automatic processes, speed of processing, and executive function • New evidence on similarity of infant and toddler recall memory to memory processing in older children and adults • Revised and updated section on infant and toddler

categorization skills • New research on babies' joint attention and preverbal gestures, revealing their developing capacity to participate in cooperative processes necessary for effective communication • Updated findings on toddlers' earliest spoken words, including cultural variations • New findings on adult-child conversation and early vocabulary development, with special attention to SES differences

CHAPTER 6: New research on consequences of effortful control—the self-regulatory dimension of temperament—for cognitive, emotional, and social development • Special attention to the role of child genotype in parenting effects on temperament • Updated evidence on contextual factors that contribute to changes in attachment pattern over time • Revised and updated section on consequences of early availability of a consistent caregiver for attachment security, emotion processing, and adjustment, highlighting studies of children adopted from Eastern European orphanages • New evidence on contributions of fathers' play to attachment security and emotional and social adjustment • Updated findings on employed fathers' increased involvement in caregiving • Revised and updated Social Issues: Health box on child care, attachment, and later development • New evidence on toddlers' scale errors, with implications for body self-awareness • Updated research on the impact of sensitive caregiving on early self-development

CHAPTER 7: Increased attention to brain development in early childhood, with special attention to the prefrontal cortex and executive function • Updated statistics and research on the health status of U.S. young children, including tooth decay, childhood immunizations, and overall health status • New research on development of handedness, including cultural variations • Expanded attention to the impact of adult mealtime practices on children's eating behavior • New evidence on preschoolers' magical beliefs • Revised and updated section on preschoolers' understanding of symbol-real-world relations • New research on cultural variations in effective scaffolding • New Social Issues: Education box on children's questions as a catalyst for cognitive development • Updated discussion of gains in executive function in early childhood, including attention, inhibition, and planning • Recent findings on toddlers' early, implicit false-belief understanding and its relationship to preschoolers' explicit grasp of false belief • New evidence on cognitive attainments and social experiences that contribute to mastery of false belief • Enhanced discussion of SES differences in emergent literacy and math knowledge • Updated discussion of the effects of television and computers on academic learning • New research on preschoolers' strategies for word learning, including cultural variations

CHAPTER 8: Updated consideration of emotional self-regulation in early childhood, including the influence of temperament and parenting • Enhanced Cultural Influences box on ethnic differences in the consequences of physical punish-

ment • New section on the role of positive peer relations in school readiness • New longitudinal evidence on the relationship of early corporal punishment to later behavior problems • Enhanced attention to aggressive children's distorted view of the social world • Updated discussion of parent training programs to reduce child conduct problems, with special attention to Incredible Years • New Social Issues: Education box on young children's learning about gender through mother-child conversations • New section on cultural variations in communication within gender-segregated peer groups • New findings on the harmful impact of parental psychological control on children's adjustment • Updated consideration of consequences of child maltreatment, including new evidence on central nervous system damage

CHAPTER 9: Revised and updated section on overweight and obesity, including current U.S. prevalence rates, international comparisons, and coverage of contributing factors and consequences • Updated statistics on physical activity and fitness among U.S. school-age children • New sections on working-memory capacity and executive function in middle childhood, with implications for academic learning • Revised and updated Biology and Environment box on children with attention-deficit hyperactivity disorder • New research on development of planning in middle childhood • Updated evidence on the school-age child's theory of mind • Updated Social Issues: Education box on emotional intelligence • Discussion of secular trends in IQ, including implications for understanding ethnic variations in IQ • Attention to the impact of the U.S. No Child Left Behind Act on quality of U.S. education • Updated research on academic achievement of U.S. children with limited English proficiency • Expanded consideration of the impact of biased teacher judgments on ethnic minority children's academic achievement • New research on educational consequences of widespread SES and ethnic segregation in American schools • New Social Issues: Education box on magnet schools as a means of attaining equal access to high-quality education • Revised and updated section on U.S. academic achievement in international perspective, including comparisons with high-performing nations

CHAPTER 10: Enhanced attention to cultural variations in self-concept, with special attention to Asian versus U.S. comparisons • Updated research on parenting practices and children's achievement-related attributions, including the influence of cultural values on likelihood of developing learned helplessness • Expanded and updated section on children's understanding of diversity and inequality, development of racial and ethnic prejudice, and strategies for reducing prejudice • New findings on peer acceptance, including implications of peer-acceptance categories for bullying and victimization • Updated Biology and Environment box on bullies and their victims • New evidence on sex differences in development of gender identity in middle childhood • Expanded attention to the role of effective coparenting in children's

adjustment to parental divorce and remarriage • New research on the implications of self-care and after-school programs for school-age children's adjustment • Revised and updated Cultural Influences box on impact of ethnic and political violence on children • Updated findings on the consequences of child sexual abuse

CHAPTER 11: New section on adolescent brain development, focusing on the imbalance between the cognitive control network and the emotional/social network, with implications for teenage reward-seeking, emotional reactivity, and risk-taking • Updated evidence on teenage pregnancy and parenthood prevention and intervention strategies • New findings on key elements of effective sex education programs • Expanded and updated research on adolescent decision making • Updated consideration of factors contributing to sex differences in spatial and mathematical abilities, including cultural valuing of gender equality • New research on the impact of school transitions on adolescent adjustment • Enhanced consideration of teacher and peer supports for academic achievement • Updated discussion of factors contributing to dropping out of school • New Social Issues: Education box on the impact of “media multitasking” on learning

CHAPTER 12: New research on personal and social factors contributing to identity development in adolescence • Updated Social Issues: Health box on adolescent suicide • Updated evidence on adolescents' capacity to integrate moral, social-conventional, and personal concerns • Enhanced consideration of factors that promote moral identity, along with its relationship to moral behavior • Updated Social Issues: Education box on development of civic engagement • New evidence on gender intensification in adolescence • Updated section on parenting and adolescent autonomy, including research on immigrant families • Expanded and updated section on Internet friendships, with special attention to teenagers' use of social networking sites • New evidence on associations among parent, friend, and dating-partner relationships • New findings on long-term outcomes of multisystemic therapy for violent juvenile offenders

CHAPTER 13: Updated Biology and Environment box on telomere length as a marker of the impact of life circumstances on biological aging • New controversial evidence on the role of free radicals in aging • New research on SES variations in adult health • Updated statistics on the continued worldwide rise in adult overweight and obesity, including a revised Social Issues: Health box on environmental factors contributing to the U.S. obesity epidemic • New findings on negative stereotyping and discrimination experienced by overweight adults • Enhanced discussion of treatment of adult obesity • New evidence on the Internet as a contemporary way to initiate dating relationships • Updated research on psychological stress and unfavorable health outcomes • Enhanced discussion of the psychological impact of attending college, including bene-

fits of opportunities to interact with racially and ethnically diverse peers • New findings on the role of gender stereotypes in women's likelihood of choosing STEM careers • Updated Social Issues: Education box on men who choose nontraditional careers

CHAPTER 14: Revised and updated section on emerging adulthood, including new findings on emerging adults' religiosity, spirituality, and commitment to community service • Enhanced discussion of the controversy over whether emerging adulthood really is a distinct period of development • Special attention to parenting of emerging adults, including “helicopter parenting” • Updated consideration of increasingly flexible age-graded expectations for early adulthood life events • Updated consideration of factors that contribute to enduring romantic relationships • New findings on social networking sites as contexts for early adulthood friendship • Expanded discussion of the rise in average age of leaving the parental home • Increased attention to parent–young-adult child relationships • New findings on sharing of household tasks in dual-earner marriages, including cross-national evidence • Updated research on relationship qualities and communication skills contributing to marital satisfaction • Attention to the role of American individualism in the high U.S. divorce and remarriage rates • Updated consideration of the dramatic increase in never-married single parents, including SES and ethnic variations • New findings on career development in early adulthood, with special attention to obstacles to success faced by women and ethnic minorities • Enhanced discussion of combining work and family

CHAPTER 15: Updated Biology and Environment box on anti-aging effects of dietary calorie restriction • Updated evidence on the risks of hormone therapy to reduce physical discomforts of menopause • New survey findings on sexual activity of U.S. middle-aged adults • Updated sections on risk of cancer and heart disease in midlife • New research on gains in effective coping in middle adulthood • Updated evidence on the neurobiological basis of declines in processing speed with age • New findings on midlife changes in attention and memory • New Social Issues: Education box on how lessons in the art of acting improve memory in older adults

CHAPTER 16: Enhanced consideration of the contribution of parenting to generativity in midlife • New research on cultural variations in the link between midlife physical changes and psychological well-being • Updated Social Issues: Health box on grandparents rearing grandchildren in skipped-generation families • Updated evidence on relationships between middle-aged adults and their aging parents, including ethnic variations • New findings on midlife intergenerational assistance to both children and aging parents • Enhanced discussion of care of aging parents in poor health, with emphasis on gender disparities, ethnic variations, and emotional, physical, and financial consequences • New research on middle-aged

adults' use of social networking sites • Updated discussion of the glass ceiling in career advancement faced by women and ethnic minorities • New evidence on career change at midlife, with special attention to blue-collar workers • Discussion of the impact of the late-2000s recession on delayed retirement

CHAPTER 17: Updated statistics on life expectancy in late adulthood, including gender and SES variations • Updated international comparisons in healthy life expectancy • New research on brain development, including neurological changes that enable older adults to compensate for declines in central nervous system functioning • Updated findings on risk and protective factors associated with various aspects of physical aging • New evidence on cultural variations in older adults' sense of personal control, with implications for coping with physical impairments • Updated section on assistive technologies • Expanded and updated discussion of stereotypes of aging, including stereotype threat, with implications for physical and cognitive performance • Updated consideration of SES and ethnic variations in health in late adulthood • Expanded consideration of progress in compression of morbidity • Updated survey findings on sexual activity in late adulthood • New findings on neurological changes associated with Alzheimer's disease, including efforts to understand how abnormal amyloid and tau damage neurons • New evidence on genetic and environmental risks for Alzheimer's, and on protective factors, with special emphasis on diet, education, and physical activity • Updated Social Issues: Health box on interventions for caregivers of older adults with dementia, with increased attention to respite and caregiving skills • Enhanced attention to use of selective optimization with compensation in adapting to cognitive changes • Expanded discussion of episodic memory and prospective memory in late adulthood • Updated research on everyday problem solving in late adulthood • Enhanced consideration of the impact of cognitive

training on older adults' mental functioning, including broadening programs to target self-efficacy • New evidence on the rapid rise in use of computers and the Internet among older people

CHAPTER 18: Updated research on reminiscence in late adulthood • New findings on personality development in late adulthood, with special attention to openness to experience • Enhanced consideration of the benefits of spirituality and religiosity in late life, including a new Biology and Environment box on religious involvement and quality of life in the final year • Consideration of sustaining an effective person–environment fit in older adults' social contexts, including caregiving and housing arrangements • Updated discussion of socioemotional selectivity theory and related research • New research on divorce, remarriage, and cohabitation in late adulthood, including aging baby boomers' use of online dating services • Updated findings on late-life friendships • New evidence on retirement as a dynamic process with multiple transitions and wide individual variation

CHAPTER 19: Updated research on diverse factors influencing people's adaptation to dying • Updated discussion of dying at home, in hospitals, and in nursing homes • New findings on hospice, including reducing patient suffering, improving family functioning, and increasing ability to sustain patient care at home • Updated statistics on public attitudes toward passive euthanasia, voluntary active euthanasia, and assisted suicide • Updated statistics on Oregon residents dying by legalized assisted suicide • New research on the role of expressions of happiness and humor in bereavement adjustment • New evidence on bereavement interventions, with special attention to support groups based on the dual-process model of coping with loss

Acknowledgments

The dedicated contributions of many individuals helped make this book a reality and contributed to refinements and improvements in this sixth edition. An impressive cast of reviewers provided many helpful suggestions, constructive criticisms, and enthusiasm for the organization and content of the text. I am grateful to each one of them.

I cannot begin to express what a great pleasure it has been, once again, to work with Tom Pauken, Managing Editor, who oversaw the preparation of the third and fifth editions of *Development Through the Lifespan* and who returned to edit this sixth edition. His careful review of manuscript, keen organizational skills, responsive day-to-day communication, insightful suggestions, astute problem solving, interest in the subject matter, and thoughtfulness greatly enhanced the quality of the text and eased the immense challenges that arose during its preparation. Judy Ashkenaz, Development Editor, carefully reviewed and commented on each chapter, helping to ensure that every thought and concept would be clearly expressed and well-

developed. She also assisted with preparation of photo specifications, drafting of photo captions and chapter summaries, and, as needs arose, graciously took on extra tasks, including updating of diverse aspects of the Instructor's Resource Manual. Rachel Trapp, editorial assistant, has been extraordinary. In addition to spending countless hours searching, gathering, and organizing scholarly literature, she assisted with an array of editorial and production tasks. In a pinch, she diligently took over the responsibility of preparing and editing many of the assessments in MyDevelopmentLab (MDL).

The supplements package benefited from the talents and dedication of several other individuals. Leah Shriro revised the IRM brief summaries and lecture outlines. Kimberly Michaud prepared a superb Test Bank and many of the MDL assessments. Judy Ashkenaz designed and wrote a highly attractive PowerPoint presentation. Maria Henneberry and Phil Vandiver of Contemporary Visuals in Bloomington, IL, prepared an artistic and inspiring set of new video segments addressing diverse topics in lifespan development.

Donna Simons, Senior Production Project Manager, coordinated the complex production tasks that resulted in an exquisitely beautiful sixth edition. I am grateful for her keen aesthetic sense, attention to detail, flexibility, efficiency, and thoughtfulness. I thank Sarah Evertson for photo research that contributed to the exceptional photographs that illustrate the text narrative. Margaret Pinette provided outstanding copyediting and careful compilation of the references list, and Julie Hotchkiss offered meticulous proofreading.

Wendy Albert, Executive Marketing Manager, prepared the beautiful print ads and informative e-mails to the field about *Development Through the Lifespan*, Sixth Edition. She has also ensured that accurate and clear information reached Pearson Education's sales force and that the needs of prospective and current adopters were met.

A final word of gratitude goes to my family, whose love, patience, and understanding have enabled me to be wife, mother, teacher, researcher, and text author at the same time. My sons, David and Peter, grew up with my texts, passing from childhood to adolescence and then to adulthood as successive editions were written. David has a special connection with the books' subject matter as an elementary school teacher. Peter is now an experienced attorney, and his vivacious and talented wife Melissa joins a new generation of university faculty dedicated to creative teaching and research. All three continue to enrich my understanding through reflections on events and progress in their own lives. Last, but certainly not least, I thank my husband, Ken, for joining me on a wonderfully fulfilling lifespan journey. Over the past two decades, he willingly made room in our lives for the immensely demanding endeavor of authoring six editions of *Development Through the Lifespan*. His reflections, support, and astute counsel made all the difference during the project's final months.

Laura E. Berk

About the Cover Art

© KEN KASHIAN

Growing up in Depression-era Detroit, Harold Gregor displayed passion for and talent in art as a child. As early as kindergarten, he drew—so much so that he recalls being placed in the corner for wasting paper. He earned his bachelor’s degree from Wayne State University, master’s degree from Michigan State University, and Ph.D. in painting from Ohio State University. After a decade of teaching and experimentation with diverse artistic styles in southern California, he moved to the American heartland, joining the faculty at Illinois State University in 1970.

The Illinois farm and prairie landscape quickly became a compelling source of inspiration, and Gregor gained national prominence as one of the foremost American Photo-realist painters. Starting with close-up views of corn cribs, an indigenous form of architecture that fascinated him, he soon moved to panoramas and aerial views of prairie farm scenes, introducing imaginative colors that accentuated the unique and varied beauty of the Midwestern landscape.

In 2004, while climbing a cliff trail in Italy, he fell and broke his right wrist. With his right arm in a cast, he transformed an obstacle into an opportunity: He began to paint with his left hand. Once his right arm healed, he refined his left-handed paintings, eventually arriving at brilliantly colorful, abstract stylistic innovations he calls Vibrascapes, of which the dazzling, energetic image on the cover of this text is an example.

Now a distinguished professor emeritus, Harold Gregor is the epitome of “optimal aging.” At age 83, he continues to paint prolifically, prepare new exhibitions, and teach. On his studio wall can be found a Chinese proverb, which reads, “What happiness to wake alive again into this same gray world of winter rain.” He says the proverb reminds him that although growing older is accompanied by unforeseen challenges, he feels blessed each day to do what he enjoys most: painting and teaching.

Harold Gregor’s paintings have been shown at the White House, the American Embassy in Moscow, and the Art Institute of Chicago. They have won numerous prestigious awards and can be viewed in galleries across the United States. To learn more about his life and work, visit www.hgregor.com; and watch the video segment, *Creativity in Late Life*, that accompanies this text.

Legend for Photos Accompanying Sofie's Story

Sofie's story is told in Chapters 1 and 19, from her birth to her death. The photos that appear at the beginning of Chapter 1 follow her through her lifespan and include family members of two succeeding generations.

Page 2

1. Sofie, age 18, high school graduation in 1926.
2. Sofie as a baby, with her mother in 1908.
3. Sofie, age 6, with her brother, age 8, in 1914.
4. Sofie's German passport.
5. Sofie, age 60, and daughter Laura on Laura's wedding day in 1968.
6. Sofie and Phil in 1968, less than two years before Sofie died.
7. Sofie's grandsons, David and Peter, ages 5 and 2, children of Laura and Ken.
8. Laura, Ken, and sons Peter and David, ages 10 and 13, on the occasion of David's Bar Mitzvah in 1985.
9. Peter and Melissa on their wedding day in 2007.
10. Laura, Ken, sons David and Peter, and Peter's wife Melissa, with acclaimed pianist Awadagin Pratt, at the naming of a Pratt Foundation piano scholarship in Sofie's memory.

*Development
Through the
Lifespan*

chapter 1

This photo essay chronicles the life course and family legacy of Sofie Lentschner. It begins in 1908 with Sofie's infancy and concludes in 2012, four decades after Sofie's death, at an event celebrating the naming of a piano scholarship in her memory. For a description of each photo, see the legend on page xxv.

History, Theory, and Research Strategies

Sofie Lentschner was born in 1908, the second child of Jewish parents who made their home in Leipzig, Germany, a city of thriving commerce and cultural vitality. Her father was a successful businessman and community leader, her mother a socialite well-known for her charm, beauty, and hospitality. As a baby, Sofie displayed the determination and persistence that would be sustained throughout her life. She sat for long periods inspecting small objects with her eyes and hands. The single event that consistently broke her gaze was the sound of the piano in the parlor. As soon as Sofie could crawl, she steadfastly pulled herself up to finger its keys and marveled at the tinkling sounds.

By the time Sofie entered elementary school, she was an introspective child, often ill at ease at the festive parties that girls of her family's social standing were expected to attend. She immersed herself in schoolwork, especially in mastering foreign languages—a regular part of German elementary and secondary education. Twice a week, she took piano lessons from the finest teacher in Leipzig. By the time Sofie graduated from high school, she spoke English and French fluently and had become an accomplished pianist. Whereas most German girls of her time married by age 20, Sofie postponed serious courtship in favor of entering the university. Her parents began to wonder whether their intense, studious daughter would ever settle into family life.

Sofie wanted marriage as well as education, but her plans were thwarted by the political turbulence of her times. When Hitler rose to power in the early 1930s, Sofie's father, fearing for the safety of his wife and children, moved the family to Belgium. Conditions for Jews in Europe quickly worsened. The Nazis plundered Sofie's family home and confiscated her father's business. By the end of the 1930s, Sofie had lost contact with all but a handful of her aunts, uncles, cousins, and childhood friends, many of whom (she later learned) were herded into cattle cars and transported to Nazi death camps at Auschwitz and Chelmno, Poland. In 1939, as anti-Jewish laws and atrocities intensified, Sofie's family fled to the United States.

As Sofie turned 30, her parents, convinced that she would never marry and would need a career for financial security, agreed to support her return to school. Sofie earned two master's degrees, one in music and the other in librarianship. Then, on a blind date, she met Philip, a U.S. army officer. Philip's calm, gentle nature complemented Sofie's intensity and worldliness. Within six months they married. During the next four

years, two daughters and a son were born. Soon Sofie's father became ill, his health shattered by the strain of uprooting his family and losing his home and business. After months of being bedridden, he died of heart failure.

When World War II ended, Philip left the army and opened a small men's clothing store. Sofie divided her time between

COURTESY OF LAURA E. BERK

caring for the children and helping Philip in the store. Now in her forties, she was a devoted mother, but few women her age were still rearing young children. As Philip struggled with the business, he spent longer hours at work, and Sofie often felt lonely. She rarely touched the piano, which brought back painful memories of youthful life plans shattered by war.

Sofie's sense of isolation and lack of fulfillment frequently left her short-tempered. Late at night, she and Philip could be heard arguing.

As Sofie's children grew older, she returned to school again, this time to earn a teaching credential. Finally, at age 50, she launched a career. For the next decade, she taught German and French to high school students and English to newly arrived immigrants. Besides easing her family's financial difficulties, she felt a gratifying sense of accomplishment and creativity. These years were among the most energetic and satisfying of Sofie's life. She had an unending enthusiasm for teaching—for transmitting her facility with language, her first-hand knowledge of the consequences of hatred and oppression, and her practical understanding of how to adapt to life in a new land. She watched her children, whose young lives were free of the trauma of war, adopt many of her values and commitments and begin their marital and vocational lives at the expected time.

Sofie approached age 60 with an optimistic outlook. Released from the financial burden of paying for their children's college education, she and Philip looked forward to greater leisure. Their affection and respect for each other deepened.

Once again, Sofie began to play the piano. But this period of contentment was short-lived.

One morning, Sofie awoke and felt a hard lump under her arm. Several days later, her doctor diagnosed cancer. Sofie's spirited disposition and capacity to adapt to radical life changes helped her meet the illness head on. She defined it as an enemy to be fought and overcome. As a result, she lived five more years. Despite the exhaustion of chemotherapy, Sofie maintained a full schedule of teaching duties and continued to visit and run errands for her elderly mother. But as she weakened physically, she no longer had the stamina to meet her classes. Bedridden for the last few weeks, she slipped quietly into death with Philip at her side. The funeral chapel overflowed with hundreds of Sofie's students. She had granted each a memorable image of a woman of courage and caring.

One of Sofie's three children, Laura, is the author of this book. Married a year before Sofie died, Laura and her husband, Ken, often think of Sofie's message, spoken privately to them on the eve of their wedding day: "I learned from my own life and marriage that you must build a life together but also a life apart. You must grant each other the time, space, and support to forge your own identities, your own ways of expressing yourselves and giving to others. The most important ingredient of your relationship must be respect."

Laura and Ken settled in a small midwestern city, near Illinois State University, where they have served on the faculty for many years—Laura in the Department of Psychology, Ken in the Department of Mathematics. They have two sons, David and Peter, to whom Laura has related many stories about Sofie's life and who carry her legacy forward. David shares his grandmother's penchant for teaching; he is a second-grade teacher. Peter, a lawyer, shares his grandmother's love of music, and his wife Melissa—much like Sofie—is both a talented linguist and a musician. When Peter asked Melissa to marry him, he placed a family heirloom on her finger—an engagement ring that had belonged to Sofie's aunt, who perished in a Nazi death camp. In the box that held the ring, Melissa found a written copy of the story of Sofie and her family.

Sofie also had a lifelong impact on many of her students. A professor of human development wrote to Laura:

I have been meaning to contact you for a while. I teach a class in lifespan development. When I opened the textbook and saw the pictures of your mother, I was very surprised. I took high school German classes from her. I remember

her as a very tough teacher who both held her students accountable and cared about each and every one of us. That she was an incredible teacher did not really sink in until I went to Germany during my [college] years and was able to both understand German and speak it.

Sofie's story raises a wealth of fascinating issues about human life histories:

- What determines the features that Sofie shares with others and those that make her unique—in physical characteristics, mental capacities, interests, and behaviors?
- What led Sofie to retain the same persistent, determined disposition throughout her life but to change in other essential ways?
- How do historical and cultural conditions—for Sofie, the persecution that destroyed her childhood home, caused the death of family members and friends, and led her family to flee to the United States—affect well-being throughout life?
- How does the timing of events—for example, Sofie's early exposure to foreign languages and her delayed entry into marriage, parenthood, and career—affect development?
- What factors—both personal and environmental—led Sofie to die sooner than expected?

These are central questions addressed by **developmental science**, a field of study devoted to understanding constancy and change throughout the lifespan (Lerner, 2006; Lerner et al., 2011). Great diversity characterizes the interests and concerns of investigators who study development. But all share a single goal: to identify those factors that influence consistencies and transformations in people from conception to death. ●

A Scientific, Applied, and Interdisciplinary Field

The questions just listed are not merely of scientific interest. Each has *applied*, or practical, importance as well. In fact, scientific curiosity is just one factor that led the study of development to become the exciting field it is today. Research about development has also been stimulated by social pressures to improve people's lives. For example, the beginning of public education in the early twentieth century led to a demand for knowledge about what and how to teach children of different ages. The interest of the medical profession in improving people's

health required an understanding of physical development, nutrition, and disease. The social service profession's desire to treat emotional problems and to help people adjust to major life events, such as divorce, job loss, war, natural disasters, or the death of loved ones, required information about personality and social development. And parents have continually sought expert advice about child-rearing practices and experiences that would promote their children's well-being.

Our large storehouse of information about development is *interdisciplinary*. It has grown through the combined efforts of people from many fields of study. Because of the need for solutions to everyday problems at all ages, researchers from psychology, sociology, anthropology, biology, and neuroscience have joined forces in research with professionals from education, family studies, medicine, public health, and social service, to name just a few. Together, they have created the field as it exists today—a body of knowledge that is not just scientifically important but also relevant and useful.

Basic Issues

Developmental science is a relatively recent endeavor. Studies of children did not begin until the late nineteenth and early twentieth centuries. Investigations into adult development, aging, and change over the life course emerged only in the 1960s and 1970s (Elder & Shanahan, 2006). But speculations about how people grow and change have existed for centuries. As they combined with research, they inspired the construction of *theories* of development. A **theory** is an orderly, integrated set of statements that describes, explains, and predicts behavior. For example, a good theory of infant-caregiver attachment would (1) *describe* the behaviors of babies of 6 to 8 months of age as they seek the affection and comfort of a familiar adult, (2) *explain* how and why infants develop this strong desire to bond with a caregiver, and (3) *predict* the consequences of this emotional bond for future relationships.

Theories are vital tools for two reasons. First, they provide organizing frameworks for our observations of people. In other words, they *guide and give meaning* to what we see. Second, theories that are verified by research provide a sound basis for practical action. Once a theory helps us *understand* development, we are in a much better position to know *how to improve* the welfare and treatment of children and adults.

As we will see, theories are influenced by the cultural values and belief systems of their times. But theories differ in one important way from mere opinion or belief: A theory's continued existence depends on *scientific verification*. Every theory must be tested using a fair set of research procedures agreed on by the scientific community, and the findings must endure, or be replicated over time.

Within the field of developmental science, many theories exist, offering very different ideas about what people are like and

how they change. The study of development provides no ultimate truth because investigators do not always agree on the meaning of what they see. Also, humans are complex beings; they change physically, mentally, emotionally, and socially. No single theory has explained all these aspects. But the existence of many theories helps advance knowledge as researchers continually try to support, contradict, and integrate these different points of view.

This chapter introduces you to major theories of human development and research strategies used to test them. In later chapters, we will return to each theory in greater detail and will also introduce other important but less grand theories. Although there are many theories, we can easily organize them by looking at the stand they take on three basic issues: (1) Is the course of development continuous or discontinuous? (2) Does one course of development characterize all people, or are there many possible courses? (3) What are the roles of genetic and environmental factors—nature and nurture—in development? Let's look closely at each of these issues.

Continuous or Discontinuous Development?

How can we best describe the differences in capacities among infants, children, adolescents, and adults? As Figure 1.1 illustrates, major theories recognize two possibilities.

One view holds that infants and preschoolers respond to the world in much the same way as adults do. The difference between the immature and mature being is simply one of *amount or complexity*. For example, when Sofie was a baby, her perception of a piano melody, memory for past events, and ability to categorize objects may have been much like our own. Perhaps her only limitation was that she could not perform

these skills with as much information and precision as we can. If this is so, then changes in her thinking must be **continuous**—a process of gradually augmenting the same types of skills that were there to begin with.

According to a second view, infants and children have *unique ways of thinking, feeling, and behaving*, ones quite different from adults. If so, then development is **discontinuous**—a process in which new ways of understanding and responding to the world emerge at specific times. From this perspective, Sofie could not yet perceive, remember, and categorize experiences as a mature person can. Rather, she moved through a series of developmental steps, each of which has unique features, until she reached the highest level of functioning.

Theories that accept the discontinuous perspective regard development as taking place in **stages**—*qualitative* changes in thinking, feeling, and behaving that characterize specific periods of development. In stage theories, development is like climbing a staircase, with each step corresponding to a more mature, reorganized way of functioning. The stage concept also assumes that people undergo periods of rapid transformation as they step up from one stage to the next. In other words, change is fairly sudden rather than gradual and ongoing.

Does development actually occur in a neat, orderly sequence of stages? This ambitious assumption has faced significant challenges. Later in this chapter, we will review some influential stage theories.

One Course of Development or Many?

Stage theorists assume that people everywhere follow the same sequence of development. Yet the field of human development is becoming increasingly aware that children and adults live in

FIGURE 1.1 Is development continuous or discontinuous? (a) Some theorists believe that development is a smooth, continuous process. Individuals gradually add more of the same types of skills. (b) Other theorists think that development takes place in discontinuous stages. People change rapidly as they step up to a new level and then change very little for a while. With each new step, the person interprets and responds to the world in a reorganized, qualitatively different way. As we will see later, still other theorists believe that development is characterized by both continuous and discontinuous change.

distinct **contexts**—unique combinations of personal and environmental circumstances that can result in different paths of change. For example, a shy individual who fears social encounters develops in very different contexts from those of an outgoing agemate who readily seeks out other people (Kagan, 2003, 2008a). Children and adults in non-Western village societies have experiences in their families and communities that differ sharply from those of people in large Western cities. These different circumstances foster different intellectual capacities, social skills, and feelings about the self and others (Shweder et al., 2006).

As you will see, contemporary theorists regard the contexts that shape development as many-layered and complex. On the personal side, they include heredity and biological makeup. On the environmental side, they include both immediate settings—home, school, and neighborhood—and circumstances more remote from people’s everyday lives: community resources, societal values, and historical time period. Finally, researchers today are more conscious than ever before of cultural diversity in development.

Relative Influence of Nature and Nurture?

In addition to describing the course of human development, each theory takes a stand on a major question about its underlying causes: Are genetic or environmental factors more important? This is the age-old **nature–nurture controversy**. By *nature*, we mean the hereditary information we receive from our parents at the moment of conception. By *nurture*, we mean the complex forces of the physical and social world that influence our biological makeup and psychological experiences before and after birth.

Although all theories grant roles to both nature and nurture, they vary in emphasis. Consider the following questions: Is the developing person’s ability to think in more complex ways largely the result of a built-in timetable of growth, or is it primarily influenced by stimulation from parents and teachers? Do children acquire language rapidly because they are genetically predisposed to do so or because parents teach them from an early age? And what accounts for the vast individual differences among people—in height, weight, physical coordination, intelligence, personality, and social skills? Is nature or nurture more responsible?

A theory’s position on the roles of nature and nurture affects how it explains individual differences. Theorists who emphasize *stability*—that individuals who are high or low in a characteristic (such as verbal ability, anxiety, or sociability) will remain so at later ages—typically stress the importance of *heredity*. If they regard environment as important, they usually point to *early experiences* as establishing a lifelong

pattern of behavior. Powerful negative events in the first few years, they argue, cannot be fully overcome by later, more positive ones (Bowlby, 1980; Sroufe, Coffino, & Carlson, 2010). Other theorists, taking a more optimistic view, see development as having substantial **plasticity** throughout life—as open to change in response to influential experiences (Baltes, Lindenberger, & Staudinger, 2006; Overton, 2010).

Throughout this book, you will see that investigators disagree, often sharply, on the question of *stability versus plasticity*. Their answers often vary across *domains*, or aspects, of development. Think back to Sofie’s story, and you will see that her linguistic ability and persistent approach to challenges were stable over the lifespan. In contrast, her psychological well-being and life satisfaction fluctuated considerably.

The Lifespan Perspective: A Balanced Point of View

So far, we have discussed basic issues of human development in terms of extremes—solutions favoring one side or the other. But as we trace the unfolding of the field, you will see that the positions of many theorists have softened. Today, some theorists believe that both continuous and discontinuous changes occur. Many acknowledge that development has both universal features and features unique to each individual and his or her contexts. And a growing number regard heredity and environment as inseparably interwoven, each affecting the potential of the other to modify the child’s traits and capacities (Gottlieb, 2007; Overton, 2010; Rutter, 2007).

These balanced visions owe much to the expansion of research from a nearly exclusive focus on the first two decades

Since the 1960s, researchers have moved from focusing only on child development to investigating development over the entire life course. This woman and her companions on a river rafting trip illustrate the health, vitality, and life satisfaction of many contemporary older adults.

of life to include development during adulthood. In the first half of the twentieth century, it was widely assumed that development stopped at adolescence. Infancy and childhood were viewed as periods of rapid transformation, adulthood as a plateau, and aging as a period of decline. The changing character of the North American population awakened researchers to the idea that gains in functioning are lifelong.

Because of improvements in nutrition, sanitation, and medical knowledge, *average life expectancy* (the number of years an individual born in a particular year can expect to live) gained more in the twentieth century than in the preceding 5,000 years. In 1900, life expectancy was just under age 50; today, it is 78.5 years in the United States and even higher in most other industrialized nations, including neighboring Canada. Life expectancy continues to increase; in the United States, it is predicted to reach 84 years in 2050. Consequently, there are more older adults—a worldwide trend that is especially striking in developed countries. People age 65 and older accounted for about 4 percent of the U.S. population in 1900, 7 percent in 1950, and 13 percent in 2010 (U.S. Census Bureau, 2012b).

Older adults are not only more numerous but also healthier and more active. Challenging the earlier stereotype of the withering person, they have contributed to a profound shift in our view of human change and the factors that underlie it. Increasingly, researchers are envisioning *development as a dynamic system*—a perpetually ongoing process, extending

from conception to death, that is molded by a complex network of biological, psychological, and social influences (Lerner et al., 2011). A leading dynamic systems approach is the **lifespan perspective**. Four assumptions make up this broader view: that development is (1) lifelong, (2) multidimensional and multidirectional, (3) highly plastic, and (4) affected by multiple, interacting forces (Baltes, Lindenberger, & Staudinger, 2006; Smith & Baltes, 1999; Staudinger & Lindenberger, 2003).

Development Is Lifelong

According to the lifespan perspective, no single age period is supreme in its impact on the life course. Rather, events occurring during each major period, summarized in Table 1.1, can have equally powerful effects on future change. Within each period, change occurs in three broad domains: *physical*, *cognitive*, and *emotional/social*, which we separate for convenience of discussion (see Figure 1.2 for a description of each). Yet, as you already know from reading the first part of this chapter, these domains are not really distinct; they overlap and interact.

Every age period has its own agenda, its unique demands and opportunities that yield some similarities in development across many individuals. Nevertheless, throughout life, the challenges people face and the adjustments they make are highly diverse in timing and pattern, as the remaining assumptions make clear.

TABLE 1.1 Major Periods of Human Development

PERIOD	APPROXIMATE AGE RANGE	BRIEF DESCRIPTION
Prenatal	Conception to birth	The one-celled organism transforms into a human baby with remarkable capacities to adjust to life outside the womb.
Infancy and toddlerhood	Birth–2 years	Dramatic changes in the body and brain support the emergence of a wide array of motor, perceptual, and intellectual capacities and first intimate ties to others.
Early childhood	2–6 years	During the “play years,” motor skills are refined, thought and language expand at an astounding pace, a sense of morality is evident, and children establish ties with peers.
Middle childhood	6–11 years	The school years are marked by improved athletic abilities; more logical thought processes; mastery of basic literacy skills; advances in self-understanding, morality, and friendship; and the beginnings of peer-group membership.
Adolescence	11–18 years	Puberty leads to an adult-sized body and sexual maturity. Thought becomes abstract and idealistic and school achievement more serious. Adolescents begin to establish autonomy from the family and to define personal values and goals.
Early adulthood	18–40 years	Most young people leave home, complete their education, and begin full-time work. Major concerns are developing a career, forming an intimate partnership, and marrying, rearing children, or establishing other lifestyles.
Middle adulthood	40–65 years	Many people are at the height of their careers and attain leadership positions. They must also help their children begin independent lives and their parents adapt to aging. They become more aware of their own mortality.
Late adulthood	65 years–death	People adjust to retirement, to decreased physical strength and health, and often to the death of a spouse. They reflect on the meaning of their lives.

FIGURE 1.2 Major domains of development. The three domains are not really distinct. Rather, they overlap and interact.

Development Is Multidimensional and Multidirectional

Think back to Sofie's life and how she continually faced new demands and opportunities. From a lifespan perspective, the challenges and adjustments of development are *multidimensional*—affected by an intricate blend of biological, psychological, and social forces.

Lifespan development is also *multidirectional*, in at least two ways. First, development is not limited to improved performance. Rather, at every period, it is a joint expression of growth and decline. When Sofie directed her energies toward mastering languages and music as a school-age child, she gave up refining other skills to their full potential. Later, when she chose to become a teacher, she let go of other career options. Although gains are especially evident early in life, and losses during the final years, people of all ages can improve current skills and develop new ones, including skills that compensate for reduced functioning (Lang, Rohr, & Williger, 2010; Scheibe, Freund, & Baltes, 2007). Most older adults, for example, devise compensatory techniques for dealing with their increasing memory failures. They may rely more on external aids, such as calendars and lists, or generate new internal strategies, such as visualizing exactly where they will be and what they will be doing when they must keep an appointment or take medication (de Frias & Dixon, 2005).

Second, besides being multidirectional over time, change is multidirectional within each domain of development. Although some qualities of Sofie's cognitive functioning (such as memory) probably declined in her mature years, her knowledge of both English and French undoubtedly grew throughout her life. And she also developed new forms of thinking. For example, Sofie's wealth of experience and ability to cope with diverse problems led her to become expert in practical matters—a quality of reasoning called *wisdom*. Recall Sofie's wise advice to Laura and Ken on the eve of their wedding day. We will consider the development of wisdom in Chapter 17. Notice in these examples how the lifespan perspective includes both continuous and discontinuous change.

Development Is Plastic

Lifespan researchers emphasize that development is plastic at all ages. Consider Sofie's social reserve in childhood and her decision to study rather than marry as a young adult. As new opportunities arose, Sofie moved easily into marriage and child-bearing in her thirties. And although parenthood and financial difficulties posed challenges to Sofie's and Philip's happiness, their relationship gradually became richer and more fulfilling. In Chapter 17, we will see that intellectual performance also remains flexible with advancing age. Older adults respond to

Biology and Environment

Resilience

John and his best friend, Gary, grew up in a rundown, crime-ridden, inner-city neighborhood. By age 10, each had experienced years of family conflict followed by parental divorce. Reared from then on in mother-headed households, John and Gary rarely saw their fathers. Both dropped out of high school and were in and out of trouble with the police.

Then their paths diverged. By age 30, John had fathered two children with women he never married, had spent time in prison, was unemployed, and drank alcohol heavily. In contrast, Gary had returned to finish high school, had studied auto mechanics at a community college, and had become manager of a gas station and repair shop. Married with two children, he had saved his earnings and bought a home. He was happy, healthy, and well-adapted to life.

A wealth of evidence shows that environmental risks—poverty, negative family interactions and parental divorce, job loss, mental illness, and drug abuse—predispose children to future problems (Masten & Gewirtz, 2006; Sameroff, 2006; Wadsworth & Santiago, 2008). Why did

Gary “beat the odds” and come through unscathed?

Research on **resilience**—the ability to adapt effectively in the face of threats to development—is receiving increased attention as investigators look for ways to protect young people from the damaging effects of stressful life conditions (Masten & Powell, 2003). This interest has been inspired by long-term studies on the relationship of life stressors in childhood to competence and adjustment in adolescence and adulthood (Werner, 2013). In each study, some individuals were shielded from negative outcomes, whereas others had lasting problems. Four broad factors offered protection from the damaging effects of stressful life events.

Personal Characteristics

A child’s genetically influenced characteristics can reduce exposure to risk or lead to experiences that compensate for early stressful events. High intelligence and socially valued talents (in music or athletics, for example) increase the chances that a child will have rewarding experiences in school and in the community that offset the impact of a stressful home life. Temperament is particularly

This boy’s close, affectionate relationship with his father promotes resilience. A strong bond with at least one parent who combines warmth with appropriate expectations for maturity can shield children from the damaging effects of stressful life conditions.

powerful. Children who have easygoing, sociable dispositions and who can readily inhibit negative emotions and impulses tend to have an optimistic outlook on life and a special capacity to adapt to change—

special training with substantial (but not unlimited) gains in a wide variety of mental abilities (Stine-Morrow & Basak, 2011).

Evidence on plasticity reveals that aging is not an eventual “shipwreck,” as has often been assumed. Instead, the metaphor of a “butterfly”—of metamorphosis and continued potential—provides a far more accurate picture of lifespan change. Still, development gradually becomes less plastic, as both capacity and opportunity for change are reduced. And plasticity varies greatly across individuals. Some children and adults experience more diverse life circumstances. Also, as the Biology and Environment box above indicates, some adapt more easily than others to changing conditions.

Development Is Influenced by Multiple, Interacting Forces

According to the lifespan perspective, pathways of change are highly diverse because *development is influenced by multiple*

forces: biological, historical, social, and cultural. Although these wide-ranging influences can be organized into three categories, they work together, combining in unique ways to fashion each life course.

Age-Graded Influences. Events that are strongly related to age and therefore fairly predictable in when they occur and how long they last are called **age-graded influences**. For example, most individuals walk shortly after their first birthday, acquire their native language during the preschool years, reach puberty around age 12 to 14, and (for women) experience menopause in their late forties or early fifties. These milestones are influenced by biology, but social customs—such as starting school around age 6, getting a driver’s license at age 16, and entering college around age 18—can create age-graded influences as well. Age-graded influences are especially prevalent in childhood and adolescence, when biological changes are rapid and cultures impose many age-related experiences to ensure

qualities that elicit positive responses from others. In contrast, emotionally reactive and irritable children often tax the patience of people around them (Vanderbilt-Adriance & Shaw, 2008; Wang & Deater-Deckard, 2013). For example, both John and Gary moved several times during their childhoods. Each time, John became anxious and angry. Gary looked forward to making new friends and exploring a new neighborhood.

A Warm Parental Relationship

A close relationship with at least one parent who provides warmth, appropriately high expectations, monitoring of the child's activities, and an organized home environment fosters resilience (Masten & Shaffer, 2006; Taylor, 2010). But this factor (as well as the next one) is not independent of children's personal characteristics. Children who are relaxed, socially responsive, and able to deal with change are easier to rear and more likely to enjoy positive relationships with parents and other people. At the same time, some children develop more attractive dispositions as a result of parental warmth and attention (Gulotta, 2008).

Social Support Outside the Immediate Family

The most consistent asset of resilient children is a strong bond with a competent,

caring adult. For children who do not have a close bond with either parent, a grandparent, aunt, uncle, or teacher who forms a special relationship with the child can promote resilience (Masten & Reed, 2002). Gary received support in adolescence from his grandfather, who listened to Gary's concerns and helped him solve problems. In addition, Gary's grandfather had a stable marriage and work life and handled stressors skillfully. Consequently, he served as a model of effective coping.

Associations with rule-abiding peers who value school achievement are also linked to resilience (Tiet, Huizinga, & Byrnes, 2010). But children who have positive relationships with adults are far more likely to establish these supportive peer ties.

Community Resources and Opportunities

Community supports—good schools, convenient and affordable health care and social services, libraries, and recreation centers—foster both parents' and children's well-being. In addition, opportunities to participate in community life help older children and adolescents overcome adversity. Extracurricular activities at school, religious youth groups, scouting, and other organizations

teach important social skills, such as cooperation, leadership, and contributing to others' welfare. As participants acquire these competencies, they gain in self-reliance, self-esteem, and community commitment (Benson et al., 2006). As a college student, Gary volunteered for Habitat for Humanity, joining a team building affordable housing in low-income neighborhoods. Community involvement offered Gary opportunities to form meaningful relationships, which further strengthened his resilience.

Research on resilience highlights the complex connections between heredity and environment. Armed with positive characteristics, which stem from native endowment, favorable rearing experiences, or both, children and adolescents can act to reduce stressful situations.

But when many risks pile up, they are increasingly difficult to overcome (Obradović et al., 2009). To inoculate children against the negative effects of risk, interventions must not only reduce risks but also enhance children's protective relationships at home, in school, and in the community. This means attending to both the person and the environment—strengthening the individual's capacities while also reducing hazardous experiences.

For these 18-year-olds, moving into their college dorm is a major life transition, offering new freedoms and responsibilities. Entering college is an age-graded influence, occurring at about the same age for most young people.

that young people acquire the skills they need to participate in their society.

History-Graded Influences. Development is also profoundly affected by forces unique to a particular historical era. Examples include epidemics, wars, and periods of economic prosperity or depression; technological advances, such as the introduction of television, computers, and the Internet; and changes in cultural values, such as attitudes toward women and ethnic minorities. These **history-graded influences** explain why people born around the same time—called a *cohort*—tend to be alike in ways that set them apart from people born at other times.

Consider the *baby boomers*, a term used to describe people born between 1946 and 1964, the post-World War II period during which birth rates soared in most Western nations. This population increase was especially sharp in the United States: By 1960, the prewar birth rate had nearly doubled, yielding the

Cultural Influences

The Baby Boomers Reshape the Life Course

From 1946 to 1964, 92 percent of all American women of childbearing age gave birth, averaging almost four children each—a new baby every 8 seconds (Croker, 2007). This splurge of births, which extended for nearly two decades, yielded a unique generation often credited with changing the world. Today, the baby boomers comprise more than 80 million adults—nearly 30 percent of the U.S. population (U.S. Census Bureau, 2012). Most are middle aged, with the oldest having recently entered late adulthood.

Several interrelated factors sparked the post–World War II baby boom. Many people who had postponed marriage and parenthood throughout the Great Depression of the 1930s started families in the 1940s, once the economy had improved. With the end of World War II, returning GIs also began to have children. As these two cohorts focused on childbearing, they gave birth to babies who otherwise would have been spaced out over 10 to 15 years. And as economic prosperity accelerated in the 1950s, making larger families affordable, more people

married at younger ages and had several children closely spaced, which led the baby boom to persist into the 1960s (Stewart & Malley, 2004). Finally, after a war, the desire to make babies generally strengthens. Besides replacing massive loss of life, new births signify hope that “human life will continue” (Croker, 2007, p. 9).

Compared with the previous generation, many more young baby boomers were economically privileged. They were also the recipients of deep emotional investment from their parents, who—having undergone the deprivations of depression and war—often ranked children as the most enduring benefit of their adult lives. These factors may have engendered optimism, confidence, even a sense of entitlement (Elder, Nguyen, & Caspi, 1985). At the same time, their huge numbers—evident in overflowing school classrooms—may have sparked an intense struggle for individual recognition. By the time the boomers reached early adulthood, this set of traits led critics to label them a narcissistic, indulged, “me” generation.

Rock star Bono, born in 1960, is a “trailing edge” baby boomer who, like many in his cohort, has a strong sense of social responsibility. Here he holds a child at a health clinic in Lesotho. Bono is a leader in the fight against AIDS and poverty in Africa.

From the mid-1960s to the early 1970s, the “leading-edge” baby boomers (born in the late 1940s and early 1950s) entered colleges and universities in record numbers, becoming better educated than any previous generation. This cohort—self-focused, socially aware, and in search of distinction—broke away from their parents’

largest gain in the nation’s history. The sheer size of the baby-boom generation made it a powerful social force from the time its members became young adults; today, the baby boomers are redefining our view of middle and late adulthood (see the Cultural Influences box above).

LOOK AND LISTEN

Identify a history-graded influence in your life, and speculate about its impact on people your age. Then ask someone a generation older than you to identify a history-graded influence in his or her life and to reflect on its impact. ●

Nonnormative Influences. Age-graded and history-graded influences are *normative*—meaning typical, or average—because each affects large numbers of people in a similar way. **Nonnormative influences** are events that are irregular: They happen to just one person or a few people and do not follow a

predictable timetable. Consequently, they enhance the multidirectionality of development. Nonnormative influences that had a major impact on the direction of Sofie’s life included piano lessons in childhood with an inspiring teacher; delayed marriage, parenthood, and career entry; and a battle with cancer. Because they occur haphazardly, nonnormative events are difficult for researchers to capture and study. Yet, as each of us can attest from our own experiences, they can affect us in powerful ways.

Nonnormative influences have become more powerful and age-graded influences less so in contemporary adult development. Compared with Sofie’s era, much greater diversity exists today in the ages at which people finish their education, enter careers, get married, have children, and retire. Indeed, Sofie’s “off-time” accomplishments would have been less unusual had she been born two generations later! Age remains a powerful organizer of everyday experiences, and age-related expectations have certainly not disappeared. But age markers have blurred, and they vary across ethnic groups and cultures. The increasing

family- and marriage-centered lifestyles. Starting in the mid-sixties, marriage rates declined, age of first marriage rose, and divorce rates increased. And the baby boomers responded to the turbulence of those times—the assassination of President Kennedy in 1963, the Vietnam War, and growing racial tensions—by mobilizing around the antiwar, civil rights, and women’s movements, yielding a generation of student activists.

By the time the “trailing-edge” boomers (born in the late 1950s and early 1960s) came of age, these movements had left an enduring mark. Even as they turned toward family life and career development, the boomers continued to search for personal meaning, self-expression, and social responsibility. By midlife, the generation had produced an unusually large number of socially concerned writers, teachers, filmmakers, and labor and community organizers, as well as innovative musicians and artists (Cole & Stewart, 1996; Dickstein, 1992). And a multitude of ordinary citizens worked to advance social causes.

In addition, as baby-boom women entered the labor market and struggled for career advancement and equal pay, their self-confidence grew, and they paved the

way for the next generation: On average, younger women attained this same level of self-confidence at a much earlier age (Stewart & Ostrove, 1998; Twenge, 1997, 2001). And as baby-boom activists pressed for gender and racial equality, they influenced national policy. The 1960s saw laws passed that banned discrimination in employment practices, in racial access to public accommodations, and in sale or rental of housing. By the 1970s, progress in civil rights served as the springboard for the gay and lesbian rights movement.

Today, the baby boomers are the largest generation ever to have entered middle age, and they are healthier, better educated, and financially better off than any previous midlife cohort (Whitbourne & Willis, 2006). Their sense of self-empowerment and innovativeness is bringing new vitality to this period of the lifespan, including efforts to increase the personal meaningfulness of their careers and to deepen their lifelong engagement with social causes. Yet another concern of baby-boom midlifers is an intense desire to control the physical changes of aging (Hooymann & Kiyak, 2011). Far more than their predecessors, they resist growing old, as indicated by their interest in a wide array of anti-aging products and

procedures—from cosmetics to Botox to plastic surgery—that are now a multi-billion-dollar U.S. industry.

Nevertheless, it is important to note that the baby boomers—though advantaged as a generation—are diverse in health status and sense of control over their lives. Those higher in education and income considerably better off. And because retirement savings were heavily hit by the economic recession of 2007 to 2009, many are working longer than they otherwise had planned.

What lies ahead as this gigantic population bulge moves into late adulthood? Most analysts focus on societal burdens, such as rising social security and health-care costs. At the same time, as the boomers continue to build on the foundation laid in middle age, they could become “our only increasing natural resource” (Freedman, 1999). After retirement, they will have more time to care about others—and more relevant experience and years left to do so—than any previous generation. Policies and programs aimed at recruiting older adults into volunteer and service roles may be one of the most effective ways to “channel good will into good deeds,” combat social ills, and enhance development during all periods of life.

role of nonnormative events in the life course adds to the fluid nature of lifespan development.

Notice that instead of a single line of development, the lifespan perspective emphasizes many potential pathways and outcomes—an image more like tree branches extending in diverse directions, which may undergo both continuous and stagewise transformations (see Figure 1.3). Now let’s turn to scientific foundations of the field as a prelude to major theories that address various aspects of change.

FIGURE 1.3 The lifespan view of development. Rather than envisioning a single line of stagewise or continuous change (see Figure 1.1 on page 6), lifespan theorists conceive of development as more like tree branches extending in diverse directions. Many potential pathways are possible, depending on the contexts that influence the individual’s life course. Each branch in this treelike image represents a possible skill within one of the major domains of development. The crossing of the branches signifies that the domains—physical, cognitive, emotional, and social—are interrelated.

Scientific Beginnings

Scientific study of human development dates back to the late nineteenth and early twentieth centuries. Early observations of human change were soon followed by improved methods and theories. Each advance contributed to the firm foundation on which the field rests today.

Darwin: Forefather of Scientific Child Study

British naturalist Charles Darwin (1809–1882) observed the infinite variation among plant and animal species. He also saw that within a species, no two individuals are exactly alike. From these observations, he constructed his famous *theory of evolution*.

The theory emphasized two related principles: *natural selection* and *survival of the fittest*. Darwin explained that certain species survive in particular environments because they have characteristics that fit with, or are adapted to, their surroundings. Other species die off because they are less well-suited to their environments. Individuals within a species who best meet the environment's survival requirements live long enough to reproduce and pass their more beneficial characteristics to future generations. Darwin's (1859/1936) emphasis on the adaptive value of physical characteristics and behavior found its way into important developmental theories.

During his explorations, Darwin discovered that early prenatal growth is strikingly similar in many species. Other scientists concluded from Darwin's observations that the development of the human child follows the same general plan as the

evolution of the human species. Although this belief eventually proved inaccurate, efforts to chart parallels between child growth and human evolution prompted researchers to make careful observations of all aspects of children's behavior. Out of these first attempts to document an idea about development, scientific child study was born.

The Normative Period

G. Stanley Hall (1844–1924), one of the most influential American psychologists of the early twentieth century, is generally regarded as the founder of the child study movement (Cairns & Cairns, 2006). He also foreshadowed lifespan research by writing one of the few books of his time on aging. Inspired by Darwin's work, Hall and his well-known student Arnold Gesell (1880–1961) devised theories based on evolutionary ideas. They regarded development as a *maturational process*—a genetically determined series of events that unfold automatically, much like a flower (Gesell, 1933; Hall, 1904).

Hall and Gesell are remembered less for their one-sided theories than for their intensive efforts to describe all aspects of

Darwin's theory of evolution emphasizes the adaptive value of physical characteristics and behavior. Affection and care in families promote survival and psychological well-being throughout the lifespan. Here, a son helps his father adjust to using a walker.

development. This launched the **normative approach**, in which measures of behavior are taken on large numbers of individuals, and age-related averages are computed to represent typical development. Using this procedure, Hall constructed elaborate questionnaires asking children of different ages almost everything they could tell about themselves—interests, fears, imaginary playmates, dreams, friendships, everyday knowledge, and more. Similarly, through careful observations and parent interviews, Gesell collected detailed normative information on the motor achievements, social behaviors, and personality characteristics of infants and children.

Gesell was also among the first to make knowledge about child development meaningful to parents by informing them of what to expect at each age. If the timetable of development is the product of millions of years of evolution, as Gesell believed, then children are naturally knowledgeable about their needs. His child-rearing advice recommended sensitivity to children's cues (Thelen & Adolph, 1992). Along with Benjamin Spock's *Baby and Child Care*, Gesell's books became a central part of a rapidly expanding child development literature for parents.

The Mental Testing Movement

While Hall and Gesell were developing their theories and methods in the United States, French psychologist Alfred Binet (1857–1911) was also taking a normative approach to child development, but for a different reason. In the early 1900s, Binet and his colleague Theodore Simon were asked by Paris school officials to find a way to identify children with learning problems who needed to be placed in special classes. To address these practical educational concerns, Binet and Simon constructed the first successful intelligence test.

In 1916, at Stanford University, Binet's test was adapted for use with English-speaking children. Since then, the English version has been known as the *Stanford-Binet Intelligence Scale*. Besides providing a score that could successfully predict school achievement, the Binet test sparked tremendous interest in individual differences in development. Comparisons of the scores of people who vary in gender, ethnicity, birth order, family background, and other characteristics became a major focus of research. And intelligence tests moved quickly to the forefront of the nature–nurture controversy.

Mid-Twentieth-Century Theories

In the mid-twentieth century, the study of human development expanded into a legitimate discipline. As it attracted increasing interest, a variety of theories emerged, each of which continues to have followers today. In these theories, the European concern with the individual's inner thoughts and feelings contrasts sharply with the North American academic focus on scientific precision and concrete, observable behavior.

The Psychoanalytic Perspective

In the 1930s and 1940s, as more people sought help from professionals to deal with emotional difficulties, a new question had to be addressed: How and why do people become the way they are? To treat psychological problems, psychiatrists and social workers turned to an emerging approach to personality development that emphasized each individual's unique life history.

According to the **psychoanalytic perspective**, people move through a series of stages in which they confront conflicts between biological drives and social expectations. How these conflicts are resolved determines the person's ability to learn, to get along with others, and to cope with anxiety. Among the many individuals who contributed to the psychoanalytic perspective, two were especially influential: Sigmund Freud, founder of the psychoanalytic movement, and Erik Erikson.

Freud's Theory. Freud (1856–1939), a Viennese physician, sought a cure for emotionally troubled adults by having them talk freely about painful events of their childhoods. Working with these recollections, he examined the unconscious motivations of his patients and constructed his **psychosexual theory**, which emphasizes that how parents manage their child's sexual and aggressive drives in the first few years is crucial for healthy personality development.

In Freud's theory, three parts of the personality—id, ego, and superego—become integrated during five stages, summarized in Table 1.2 on page 16. The *id*, the largest portion of the mind, is the source of basic biological needs and desires. The *ego*, the conscious, rational part of personality, emerges in early infancy to redirect the id's impulses so they are discharged in acceptable ways.

Between 3 and 6 years of age, the *superego*, or conscience, develops as parents insist that children conform to the values of society. Now the ego faces the increasingly complex task of reconciling the demands of the id, the external world, and conscience (Freud, 1923/1974). For example, when the id impulse to grab an attractive toy from a playmate confronts the superego's warning that such behavior is wrong, the ego must mediate between these two forces, deciding which will win the inner struggle or, alternatively, work out a compromise, such as asking for a turn with the toy. According to Freud, the relations established among the id, ego, and superego during the preschool years determine the individual's basic personality.

Freud (1938/1973) believed that during childhood, sexual impulses shift their focus from the oral to the anal to the genital regions of the body. In each stage, parents walk a fine line between permitting too much or too little gratification of their child's basic needs. If parents strike an appropriate balance, then children grow into well-adjusted adults with the capacity for mature sexual behavior and investment in family life.

Freud's theory was the first to stress the influence of the early parent–child relationship on development. But his perspective was eventually criticized. First, it overemphasized the influence of sexual feelings in development. Second, because it

TABLE 1.2 Freud's Psychosexual Stages and Erikson's Psychosocial Stages Compared

APPROXIMATE AGE	FREUD'S PSYCHOSEXUAL STAGE	ERIKSON'S PSYCHOSOCIAL STAGE
Birth–1 year	Oral: The new ego directs the baby's sucking activities toward breast or bottle. If oral needs are not met, the individual may develop such habits as thumb sucking, fingernail biting, overeating, or smoking.	Basic trust versus mistrust: From warm, responsive care, infants gain a sense of trust, or confidence, that the world is good. Mistrust occurs if infants are neglected or handled harshly.
1–3 years	Anal: Toddlers and preschoolers enjoy holding and releasing urine and feces. If parents toilet train before children are ready or make too few demands, conflicts about anal control may appear in the form of extreme orderliness or disorder.	Autonomy versus shame and doubt: Using new mental and motor skills, children want to decide for themselves. Parents can foster autonomy by permitting reasonable free choice and not forcing or shaming the child.
3–6 years	Phallic: As preschoolers take pleasure in genital stimulation, Freud's Oedipus conflict for boys and Electra conflict for girls arise: Children feel a sexual desire for the other-sex parent. To avoid punishment, they give up this desire and adopt the same-sex parent's characteristics and values. As a result, the superego is formed, and children feel guilty when they violate its standards.	Initiative versus guilt: Through make-believe play, children gain insight into the person they can become. Initiative—a sense of ambition and responsibility—develops when parents support their child's sense of purpose. But if parents demand too much self-control, children experience excessive guilt.
6–11 years	Latency: Sexual instincts die down, and the superego strengthens as the child acquires new social values from adults and same-sex peers.	Industry versus inferiority: At school, children learn to work and cooperate with others. Inferiority develops when negative experiences at home, at school, or with peers lead to feelings of incompetence.
Adolescence	Genital: With puberty, sexual impulses reappear. Successful development during earlier stages leads to marriage, mature sexuality, and child rearing.	Identity versus role confusion: By exploring values and vocational goals, the young person forms a personal identity. The negative outcome is confusion about future adult roles.
Early adulthood	 <p>© OLIVE PIERCE/BLACK STAR</p> <p>Erik Erikson</p>	Intimacy versus isolation: Young adults establish intimate relationships. Because of earlier disappointments, some individuals cannot form close bonds and remain isolated.
Middle adulthood		Generativity versus stagnation: Generativity means giving to the next generation through child rearing, caring for others, or productive work. The person who fails in these ways feels an absence of meaningful accomplishment.
Old age		Integrity versus despair: Integrity results from feeling that life was worth living as it happened. Older people who are dissatisfied with their lives fear death.

was based on the problems of sexually repressed, well-to-do adults in nineteenth-century Viennese society, it did not apply in other cultures. Finally, Freud had not studied children directly.

Erikson's Theory. Several of Freud's followers took what was useful from his theory and improved on his vision. The most important of these neo-Freudians is Erik Erikson (1902–1994), who expanded the picture of development at each stage. In his **psychosocial theory**, Erikson emphasized that in addition to mediating between id impulses and superego demands, the ego makes a positive contribution to development, acquiring attitudes and skills that make the individual an active, contribut-

ing member of society. A basic psychosocial conflict, which is resolved along a continuum from positive to negative, determines healthy or maladaptive outcomes at each stage. As Table 1.2 shows, Erikson's first five stages parallel Freud's stages, but Erikson added three adult stages.

Unlike Freud, Erikson pointed out that normal development must be understood in relation to each culture's life situation. For example, in the 1940s, he observed that Yurok Indians of the northwest coast of the United States deprived babies of breastfeeding for the first 10 days after birth and instead fed them a thin soup. At age 6 months, infants were abruptly weaned—if necessary, by having the mother leave for a few days.

ANTONIA TOZER/GETTY IMAGES/AWL IMAGES RM

A child of the Kazakh people of Mongolia observes closely as her grandfather demonstrates how to train an eagle to hunt small animals, essential for the heavily meat-based Kazakh diet. As Erikson recognized, this parenting practice is best understood in relation to the competencies valued and needed in Kazakh culture.

From our cultural vantage point, these practices seem cruel. But Erikson explained that because the Yurok depended on salmon, which fill the river just once a year, the development of considerable self-restraint was essential for survival. In this way, he showed that child rearing is responsive to the competencies valued and needed by an individual's society.

Contributions and Limitations of the Psychoanalytic Perspective. A special strength of the psychoanalytic perspective is its emphasis on the individual's unique life history as worthy of study and understanding. Consistent with this view, psychoanalytic theorists accept the *clinical*, or *case study*, *method*, which synthesizes information from a variety of sources into a detailed picture of the personality of a single person. (We will discuss this method further at the end of this chapter.) Psychoanalytic theory has also inspired a wealth of research on many aspects of emotional and social development, including infant–caregiver attachment, aggression, sibling relationships, child-rearing practices, morality, gender roles, and adolescent identity.

Despite its extensive contributions, the psychoanalytic perspective is no longer in the mainstream of human development research. Psychoanalytic theorists may have become isolated from the rest of the field because they were so strongly committed to in-depth study of individuals that they failed to consider other methods. In addition, many psychoanalytic ideas, such as psychosexual stages and ego functioning, are so vague that they are difficult or impossible to test empirically (Crain, 2005; Thomas, 2005).

Nevertheless, Erikson's broad outline of lifespan change captures the essence of psychosocial attainments during each major period of the life course. We will return to it, along with other perspectives inspired by Erikson's theory, in later chapters.

Behaviorism and Social Learning Theory

As the psychoanalytic perspective gained in prominence, the study of development was also influenced by a very different perspective. According to **behaviorism**, directly observable events—stimuli and responses—are the appropriate focus of study. North American behaviorism began in the early twentieth century with the work of John Watson (1878–1958), who, rejecting the psychoanalytic concern with the unseen workings of the mind, set out to create an objective science of psychology.

Traditional Behaviorism. Watson was inspired by Russian physiologist Ivan Pavlov's studies of animal learning. Pavlov knew that dogs release saliva as an innate reflex when they are given food. But he noticed that his dogs were salivating before they tasted any food—when they saw the trainer who usually fed them. The dogs, Pavlov reasoned, must have learned to associate a neutral stimulus (the trainer) with another stimulus (food) that produces a reflexive response (salivation). Because of this association, the neutral stimulus alone could bring about a response resembling the reflex. Eager to test this idea, Pavlov successfully taught dogs to salivate at the sound of a bell by pairing it with the presentation of food. He had discovered *classical conditioning*.

Watson wanted to find out if classical conditioning could be applied to children's behavior. In a historic experiment, he taught Albert, an 11-month-old infant, to fear a neutral stimulus—a soft white rat—by presenting it several times with a sharp, loud sound, which naturally scared the baby. Little Albert, who at first had reached out eagerly to touch the furry rat, began to cry and turn his head away at the sight of it (Watson & Raynor, 1920). In fact, Albert's fear was so intense that researchers eventually challenged the ethics of studies like this one. Watson concluded that environment is the supreme force in development and that adults can mold children's behavior by carefully controlling stimulus–response associations. He viewed development as a continuous process—a gradual increase with age in the number and strength of these associations.

Another form of behaviorism was B. F. Skinner's (1904–1990) *operant conditioning theory*. According to Skinner, the frequency of a behavior can be increased by following it with a wide variety of *reinforcers*, such as food, praise, or a friendly smile. It can also be decreased through *punishment*, such as disapproval or withdrawal of privileges. As a result of Skinner's work, operant conditioning became a broadly applied learning principle. We will consider these conditioning techniques further in Chapter 4.

Social Learning Theory. Psychologists wondered whether behaviorism might offer a more direct and effective explanation of the development of social behavior than the less precise concepts of psychoanalytic theory. This sparked approaches that built on the principles of conditioning, offering expanded views of how children and adults acquire new responses.

Several kinds of **social learning theory** emerged. The most influential, devised by Albert Bandura (1925–), emphasizes *modeling*, also known as *imitation* or *observational learning*, as a powerful source of development. The baby who claps her hands after her mother does so, the child who angrily hits a playmate in the same way that he has been punished at home, and the teenager who wears the same clothes and hairstyle as her friends at school are all displaying observational learning. In his early work, Bandura found that diverse factors affect children’s motivation to imitate: their own history of reinforcement or punishment for the behavior, the promise of future reinforcement or punishment, and even vicarious reinforcement or punishment (observing the model being reinforced or punished).

Bandura’s work continues to influence much research on social development. But today, his theory stresses the importance of *cognition*, or thinking. In fact, the most recent revision of Bandura’s (1992, 2001) theory places such strong emphasis on how we think about ourselves and other people that he calls it a *social-cognitive* rather than a social learning approach.

In Bandura’s revised view, children gradually become more selective in what they imitate. From watching others engage in self-praise and self-blame and through feedback about the worth of their own actions, children develop *personal standards* for behavior and a *sense of self-efficacy*—the belief that their

own abilities and characteristics will help them succeed. These cognitions guide responses in particular situations (Bandura, 1999, 2001). For example, imagine a parent who often remarks, “I’m glad I kept working on that task, even though it was hard,” who explains the value of persistence, and who encourages it by saying, “I know you can do a good job on that homework!” Soon the child starts to view herself as hardworking and high-achieving and selects people with these characteristics as models. In this way, as individuals acquire attitudes, values, and convictions about themselves, they control their own learning and behavior.

Contributions and Limitations of Behaviorism and Social Learning Theory.

Behaviorism and social learning theory have been helpful in treating a wide range of adjustment problems. **Behavior modification** consists of procedures that combine conditioning and modeling to eliminate undesirable behaviors and increase desirable responses. It has been used to relieve a wide range of difficulties in children and adults, ranging from poor time management and unwanted habits to serious problems, such as language delays, persistent aggression, and extreme fears (Martin & Pear, 2011).

Nevertheless, many theorists believe that behaviorism and social learning theory offer too narrow a view of important environmental influences, which extend beyond immediate reinforcement, punishment, and modeled behaviors to people’s rich physical and social worlds. Behaviorism and social learning theory have also been criticized for underestimating people’s contributions to their own development. Bandura, with his emphasis on cognition, is unique among theorists whose work grew out of the behaviorist tradition in granting children and adults an active role in their own learning.

Social learning theory recognizes that children acquire many skills through modeling. By observing and imitating her mother, this Vietnamese preschooler learns to use chopsticks.

Piaget’s Cognitive-Developmental Theory

If one individual has influenced research on child development more than any other, it is Swiss cognitive theorist Jean Piaget (1896–1980). North American investigators had been aware of Piaget’s work since 1930. But they did not grant it much attention until the 1960s, mainly because Piaget’s ideas were at odds with behaviorism, which dominated North American psychology in the mid-twentieth century (Cairns & Cairns, 2006). Piaget did not believe that children’s learning depends on reinforcers, such as rewards from adults. According to his **cognitive-developmental theory**, children actively construct knowledge as they manipulate and explore their world.

Piaget’s Stages. Piaget’s view of development was greatly influenced by his early training in biology. Central to his theory is the biological concept of *adaptation* (Piaget, 1971). Just as structures of the body are adapted to fit with the environment, so structures of the mind develop to better fit with, or represent,

TABLE 1.3 Piaget's Stages of Cognitive Development

STAGE	PERIOD OF DEVELOPMENT	DESCRIPTION
Sensorimotor	Birth–2 years	Infants “think” by acting on the world with their eyes, ears, hands, and mouth. As a result, they invent ways of solving sensorimotor problems, such as pulling a lever to hear the sound of a music box, finding hidden toys, and putting objects into and taking them out of containers.
Preoperational	2–7 years	Preschool children use symbols to represent their earlier sensorimotor discoveries. Development of language and make-believe play takes place. However, thinking lacks the logic of the two remaining stages.
Concrete operational	7–11 years	Children’s reasoning becomes logical. School-age children understand that a certain amount of lemonade or play dough remains the same even after its appearance changes. They also organize objects into hierarchies of classes and subclasses. However, children think in a logical, organized fashion only when dealing with concrete information they can perceive directly.
Formal operational	11 years on	The capacity for abstract, systematic thinking enables adolescents, when faced with a problem, to start with a hypothesis, deduce testable inferences, and isolate and combine variables to see which inferences are confirmed. Adolescents can also evaluate the logic of verbal statements without referring to real-world circumstances.

**Jean Piaget**

the external world. In infancy and early childhood, Piaget claimed, children’s understanding is different from adults’. For example, he believed that young babies do not realize that an object hidden from view—a favorite toy or even the mother—continues to exist. He also concluded that preschoolers’ thinking is full of faulty logic. For example, children younger than age 7 commonly say that the amount of a liquid changes when it is poured into a different-shaped container. According to Piaget, children eventually revise these incorrect ideas in their ongoing efforts to achieve an *equilibrium*, or balance, between internal structures and information they encounter in their everyday worlds.

In Piaget’s theory, as the brain develops and children’s experiences expand, they move through four broad stages, each characterized by qualitatively distinct ways of thinking. Table 1.3 provides a brief description of Piaget’s stages. Cognitive development begins in the *sensorimotor stage* with the baby’s use of the senses and movements to explore the world. These action patterns evolve into the symbolic but illogical thinking of the preschooler in the *preoperational stage*. Then cognition is transformed into the more organized, logical reasoning of the school-age child in the *concrete operational stage*. Finally, in the *formal operational stage*, thought becomes the abstract, systematic reasoning system of the adolescent and adult.

Piaget devised special methods for investigating how children think. Early in his career, he carefully observed his three infant children and presented them with everyday problems, such as an attractive object that could be grasped, mouthed,

In Piaget’s concrete operational stage, school-age children think in an organized, logical fashion about concrete objects. This 7-year-old understands that the quantity of pie dough remains the same after he changes its shape from a ball to a flattened circle.

kicked, or searched for. From their responses, Piaget derived his ideas about cognitive changes during the first two years. To study childhood and adolescent thought, Piaget adapted the clinical method of psychoanalysis, conducting open-ended *clinical interviews* in which a child's initial response to a task served as the basis for Piaget's next question. We will look more closely at this technique when we discuss research methods later in this chapter.

Contributions and Limitations of Piaget's Theory. Piaget convinced the field that children are active learners whose minds consist of rich structures of knowledge. Besides investigating children's understanding of the physical world, Piaget explored their reasoning about the social world. His stages have sparked a wealth of research on children's conceptions of themselves, other people, and human relationships. In practical terms, Piaget's theory encouraged the development of educational philosophies and programs that emphasize discovery learning and direct contact with the environment.

Despite Piaget's overwhelming contributions, his theory has been challenged. Research indicates that Piaget underestimated the competencies of infants and preschoolers. When young children are given tasks scaled down in difficulty and relevant to their everyday experiences, their understanding appears closer to that of the older child and adult than Piaget assumed. Also, adolescents generally reach their full intellectual potential only in areas of endeavor in which they have had extensive education and experience (Kuhn, 2008). These findings have led many researchers to conclude that cognitive maturity depends heavily on the complexity of knowledge sampled and the individual's familiarity with the task.

Furthermore, many studies show that children's performance on Piagetian problems can be improved with training—findings that call into question Piaget's assumption that discovery learning rather than adult teaching is the best way to foster development (Klahr & Nigam, 2004; Siegler & Svetina, 2006). Critics also point out that Piaget's stagewise account pays insufficient attention to social and cultural influences on development. Finally, some lifespan theorists disagree with Piaget's conclusion that no major cognitive changes occur after adolescence. Several have proposed important transformations in adulthood (Labouvie-Vief, 2006; Moshman, 2011; Perry, 1970/1998).

Today, the field of developmental science is divided over its loyalty to Piaget's ideas (Desrochers, 2008). Those who continue to find merit in Piaget's stages often accept a modified view—one in which changes in thinking take place more gradually than Piaget believed (Case, 1998; Demetriou et al., 2002; Fischer & Bidell, 2006; Halford & Andrews, 2006). Among those who disagree with Piaget's stage sequence, some have embraced an approach that emphasizes continuous gains in children's cognition: information processing. And still others have been drawn to theories that focus on the role of children's social and cultural contexts. We take up these approaches in the next section.

ASK YOURSELF

REVIEW What aspect of behaviorism made it attractive to critics of the psychoanalytic perspective? How did Piaget's theory respond to a major limitation of behaviorism?

CONNECT Although social learning theory focuses on social development and Piaget's theory on cognitive development, each has enhanced our understanding of other domains. Mention an additional domain addressed by each theory.

APPLY A 4-year-old becomes frightened of the dark and refuses to go to sleep at night. How would a psychoanalyst and a behaviorist differ in their views of how this problem developed?

REFLECT Describe a personal experience in which you received feedback from another person that strengthened your sense of self-efficacy—belief that your abilities and characteristics will help you succeed.

Recent Theoretical Perspectives

New ways of understanding the developing person are constantly emerging—questioning, building on, and enhancing the discoveries of earlier theories. Today, a burst of fresh approaches and research emphases is broadening our understanding of lifespan development.

Information Processing

In the 1970s and 1980s, researchers turned to the field of cognitive psychology for ways to understand the development of thinking. The design of digital computers that use mathematically specified steps to solve problems suggested to psychologists that the human mind might also be viewed as a symbol-manipulating system through which information flows—a perspective called **information processing** (Klahr & MacWhinney, 1998; Munakata, 2006). From the time information is presented to the senses at *input* until it emerges as a behavioral response at *output*, information is actively coded, transformed, and organized.

Information-processing researchers often design flowcharts to map the precise steps individuals use to solve problems and complete tasks, much like the plans devised by programmers to get computers to perform a series of “mental operations.” They seek to clarify how both task characteristics and cognitive limitations—for example, memory capacity or available knowledge—influence performance (Birney & Sternberg, 2011). To see the usefulness of this approach, let's look at an example.

In a study of problem solving, a researcher provided a pile of blocks varying in size, shape, and weight and asked school-age

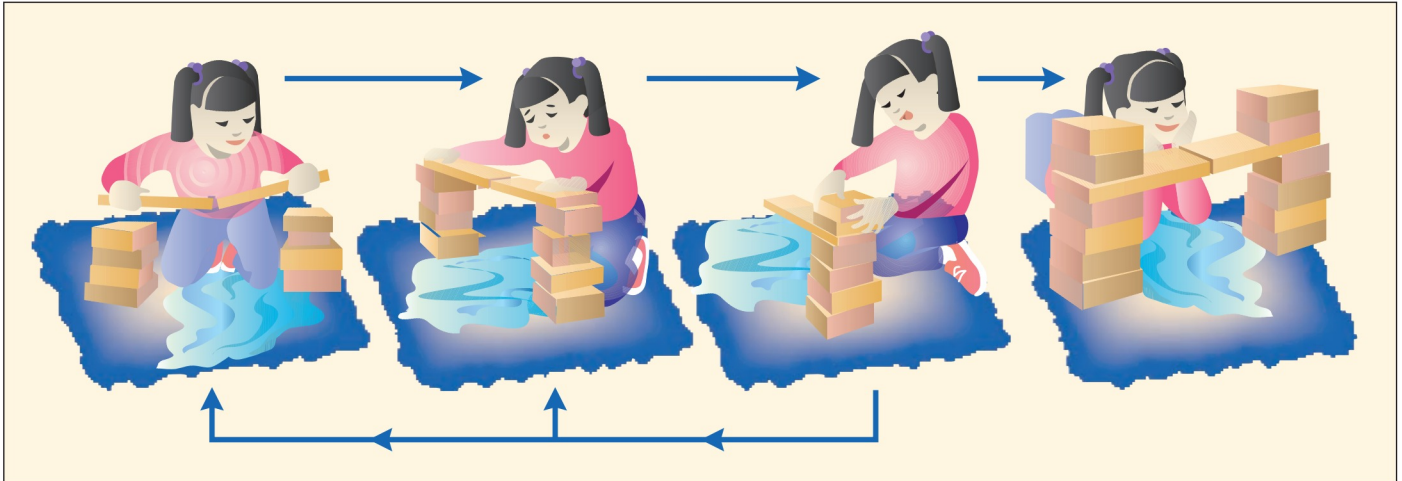

FIGURE 1.4 Information-processing flowchart showing the steps that a 5-year-old used to solve a bridge-building problem. Her task was to use blocks varying in size, shape, and weight, some of which were planklike, to construct a bridge across a “river” (painted on a floor mat) too wide for any single block to span. The child discovered how to counterweight and balance the bridge. The arrows reveal that, even after building a successful counterweight, she returned to earlier, unsuccessful strategies, which seemed to help her understand why the counterweight approach worked. (Adapted from Thornton, 1999.)

children to build a bridge across a “river” (painted on a floor mat) that was too wide for any single block to span (Thornton, 1999). Figure 1.4 shows one solution: Two planklike blocks span the water, each held in place by the counterweight of heavy blocks on the bridge’s towers. Whereas older children easily built successful bridges, only one 5-year-old did. Careful tracking of her efforts revealed that she repeatedly tried unsuccessful strategies, such as pushing two planks together and pressing down on their ends to hold them in place. But eventually, her experimentation triggered the idea of using the blocks as counterweights. Her mistaken procedures helped her understand why the counterweight approach worked.

Many information-processing models exist. Some, like the one just considered, track children’s mastery of one or a few tasks. Others describe the human cognitive system as a whole (Gopnik & Tenenbaum, 2007; Johnson & Mareschal, 2001; Westermann et al., 2006). These general models are used as guides for asking questions about broad changes in thinking: Does a child’s ability to solve problems become more organized and “planful” with age? Why is information processing slower among older than younger adults? Are declines in memory during old age evident on all types of tasks or only some?

Like Piaget’s theory, the information-processing approach regards people as actively making sense of their own thinking (Halford, 2005; Munakata, 2006). But unlike Piaget’s theory, it does not divide development into stages. Rather, most information-processing researchers regard the thought processes studied—perception, attention, memory, planning strategies, categorization of information, and comprehension of written and spoken prose—as similar at all ages but present to a lesser or greater extent. Their view of development is one of continuous change.

A great strength of the information-processing approach is its commitment to rigorous research methods. Because it has

provided precise accounts of how children and adults tackle many cognitive tasks, its findings have important implications for education (Blumenfeld, Marx, & Harris, 2006; Siegler, 2009). But information processing has fallen short in some respects. It has been better at analyzing thinking into its components than at putting them back together into a comprehensive theory. And it has little to say about aspects of cognition that are not linear and logical, such as imagination and creativity.

Developmental Cognitive Neuroscience

Over the past three decades, as information-processing research has expanded, a new area of investigation arose, called **developmental cognitive neuroscience**. It brings together researchers from psychology, biology, neuroscience, and medicine to study the relationship between changes in the brain and the developing person’s cognitive processing and behavior patterns.

Improved methods for analyzing brain activity while children and adults perform various tasks have greatly enhanced knowledge of relationships between brain functioning, cognitive capacities, and behavior (Pennington, Snyder, & Roberts, 2007; Westermann et al., 2007). Armed with these brain-imaging techniques (which we will consider in Chapter 4), neuroscientists are tackling questions like these: How does genetic makeup combine with specific experiences at various ages to influence the growth and organization of the young child’s brain? What transformations in the brain make it harder for adolescents and adults than for children to acquire a second language? What neurological changes are related to declines in speed of thinking, memory, and other aspects of cognitive processing in old age?

During the first five years, the brain is highly plastic—especially open to growth as a result of experience. But it retains

considerable plasticity throughout life. Neuroscientists are making rapid progress in identifying the types of experiences that support or undermine brain development at various ages. They are also clarifying the brain bases of many learning and behavior disorders, and they are contributing to effective interventions by examining the impact of various intervention techniques on both brain functioning and behavior (Durstun & Conrad, 2007; Luciana, 2007; Schlaggar & McCandliss, 2007). Although much remains to be discovered, developmental cognitive neuroscience is already transforming our understanding of development and yielding major practical applications throughout the lifespan.

An advantage of having many theories is that they encourage researchers to attend to previously neglected dimensions of people's lives. The final three perspectives we will discuss focus on *contexts* for development. The first of these views emphasizes that the development of many capacities is influenced by our long evolutionary history.

Ethology and Evolutionary Developmental Psychology

Ethology is concerned with the adaptive, or survival, value of behavior and its evolutionary history. Its roots can be traced to the work of Darwin. Two European zoologists, Konrad Lorenz and Niko Tinbergen, laid its modern foundations. Watching diverse animal species in their natural habitats, Lorenz and Tinbergen observed behavior patterns that promote survival. The best known of these is *imprinting*, the early following behavior of certain baby birds, such as geese, that ensures that the young will stay close to the mother and be fed and protected from danger. Imprinting takes place during an early, restricted period of development (Lorenz, 1952). If the mother goose is absent

MARTIN HARVEY/GETTY IMAGES/PETER ARNOLD

Ethology focuses on the adaptive, or survival, value of behavior and on similarities between human behavior and that of other species, especially our primate relatives. Observing this chimpanzee mother cuddling her infant helps us understand the human caregiver–infant relationship.

during this time but an object resembling her in important features is present, young goslings may imprint on it instead.

Observations of imprinting led to a major concept in human development: the *critical period*. It refers to a limited time span during which the individual is biologically prepared to acquire certain adaptive behaviors but needs the support of an appropriately stimulating environment. Many researchers have investigated whether complex cognitive and social behaviors must be learned during certain time periods. For example, if children are deprived of adequate food or physical and social stimulation during their early years, will their intelligence be impaired? If language learning is impeded in childhood due to limited parent–child communication, is the capacity to acquire language later reduced?

In later chapters, we will see that the term *sensitive period* applies better to human development than the strict notion of a critical period (Bornstein, 1989). A **sensitive period** is a time that is optimal for certain capacities to emerge and in which the individual is especially responsive to environmental influences. However, its boundaries are less well-defined than those of a critical period. Development can occur later, but it is harder to induce.

Inspired by observations of imprinting, British psychoanalyst John Bowlby (1969) applied ethological theory to the understanding of the human infant–caregiver relationship. He argued that infant smiling, babbling, grasping, and crying are built-in social signals that encourage the caregiver to approach, care for, and interact with the baby. By keeping the parent near, these behaviors help ensure that the infant will be fed, protected from danger, and provided with stimulation and affection necessary for healthy growth. The development of attachment in humans is a lengthy process that leads the baby to form a deep affectionate tie with the caregiver (Thompson, 2006). Bowlby believed that this bond has lifelong consequences for human relationships. In later chapters, we will consider research that evaluates this assumption.

Observations by ethologists have shown that many aspects of social behavior, including emotional expressions, aggression, cooperation, and social play, resemble those of our primate relatives. Recently, researchers have extended this effort in a new area of research called **evolutionary developmental psychology**. It seeks to understand the adaptive value of specieswide cognitive, emotional, and social competencies as those competencies change with age (Geary, 2006b; King & Bjorklund, 2010). Evolutionary developmental psychologists ask questions like these: What role does the newborn's visual preference for facelike stimuli play in survival? Does it support older infants' capacity to distinguish familiar caregivers from unfamiliar people? Why do children play in gender-segregated groups? What do they learn from such play that might lead to adult gender-typed behaviors, such as male dominance and female investment in caregiving?

© KIDSTOCK/BLEND IMAGES/CORBIS

Human longevity may have adaptive value. It enables younger family members to draw on older adults' knowledge and sage advice when tackling life's challenges.

As these examples suggest, evolutionary psychologists are not just concerned with the genetic and biological roots of development. They recognize that humans' large brain and extended childhood resulted from the need to master an increasingly complex environment, so they are also interested in learning (Bjorklund, Causey, & Periss, 2009). And they realize that today's lifestyles differ so radically from those of our evolutionary ancestors that certain evolved behaviors—such as life-threatening risk taking in adolescents and male-to-male violence—are no longer adaptive (Blasi & Bjorklund, 2003).

Recently, evolutionary psychologists have begun to address the adaptiveness of human longevity—why adults live as much as one-fourth to one-third of their years after their children are grown (Greve & Bjorklund, 2009). The most common explanation involves the support that grandparents (especially grandmothers) offer in rearing young grandchildren, which is associated with higher birth and child-survival rates. Another view emphasizes the adaptive value of older adults' vast knowledge, experience, and sage advice—a rich resource for younger members of the family or social group as they tackle life's many challenges.

In sum, evolutionary developmental psychology aims to understand the *person–environment system* throughout the lifespan. The next contextual perspective we will discuss, Vygotsky's sociocultural theory, serves as an excellent complement to the evolutionary viewpoint because it highlights social and cultural contexts for development.

Vygotsky's Sociocultural Theory

The field of human development has recently seen a dramatic increase in studies addressing the cultural context of people's lives. Investigations that make comparisons across cultures,

and between ethnic groups within cultures, provide insight into whether developmental pathways apply to all people or are limited to particular environmental conditions (Goodnow, 2010).

Today, much research is examining the relationship of *culturally specific beliefs and practices* to development. The contributions of Russian psychologist Lev Vygotsky (1896–1934) have played a major role in this trend. Vygotsky's (1934/1987) perspective, called **sociocultural theory**, focuses on how *culture*—the values, beliefs, customs, and skills of a social group—is transmitted to the next generation. According to Vygotsky, *social interaction*—in particular, cooperative dialogues with more knowledgeable members of society—is necessary for children to acquire the ways of thinking and behaving that make up a community's culture. Vygotsky believed that as adults and more expert peers help children master culturally meaningful activities, the communication between them becomes part of children's thinking. As children internalize the features of these dialogues, they can use the language within them to guide their own thought and actions and to acquire new skills (Berk & Harris, 2003; Winsler, Fernyhough, & Montero, 2009). The young child instructing herself while working a puzzle or setting a table for dinner has begun to produce the same kind of guiding comments that an adult previously used to help her master important tasks.

Vygotsky's theory has been especially influential in the study of cognitive development. Vygotsky agreed with Piaget that children are active, constructive beings. But whereas Piaget emphasized children's independent efforts to make sense of their world, Vygotsky viewed cognitive development as a *socially mediated process*, in which children depend on assistance from adults and more-expert peers as they tackle new challenges.

A Cambodian girl learns traditional dance forms from her grandmother. She acquires a culturally valued skill by interacting with an older, more experienced member of her culture.

In Vygotsky's theory, children undergo certain stagewise changes. For example, when they acquire language, they gain in ability to participate in dialogues with others, and mastery of culturally valued competencies surges forward. When children enter school, they spend much time discussing language, literacy, and other academic concepts—experiences that encourage them to reflect on their own thinking (Bodrova & Leong, 2007; Kozulin, 2003). As a result, they advance dramatically in reasoning and problem solving.

At the same time, Vygotsky stressed that dialogues with experts lead to continuous changes in cognition that vary greatly from culture to culture. Consistent with this view, a major finding of cross-cultural research is that cultures select tasks for their members, and social interaction surrounding those tasks leads to competencies essential for success in a particular culture. For example, in industrialized nations, teachers help people learn to read, drive a car, or use a computer. Among the Zinacanteco Indians of southern Mexico, adult experts guide young girls as they master complicated weaving techniques (Greenfield, 2004; Greenfield, Maynard, & Childs, 2000). In Brazil and other developing nations, child candy sellers with little or no schooling develop sophisticated mathematical abilities as the result of buying candy from wholesalers, pricing it in collaboration with adults and experienced peers, and bargaining with customers on city streets (Saxe, 1988).

Research stimulated by Vygotsky's theory reveals that people in every culture develop unique strengths. But Vygotsky's emphasis on culture and social experience led him to neglect the biological side of development. Although he recognized the importance of heredity and brain growth, he said little about

their role in cognitive change. Furthermore, Vygotsky's focus on social transmission of knowledge meant that, compared with other theorists, he placed less emphasis on children's capacity to shape their own development. Followers of Vygotsky grant the individual and society more balanced, mutually influential roles (Nelson, 2007a; Rogoff, 2003).

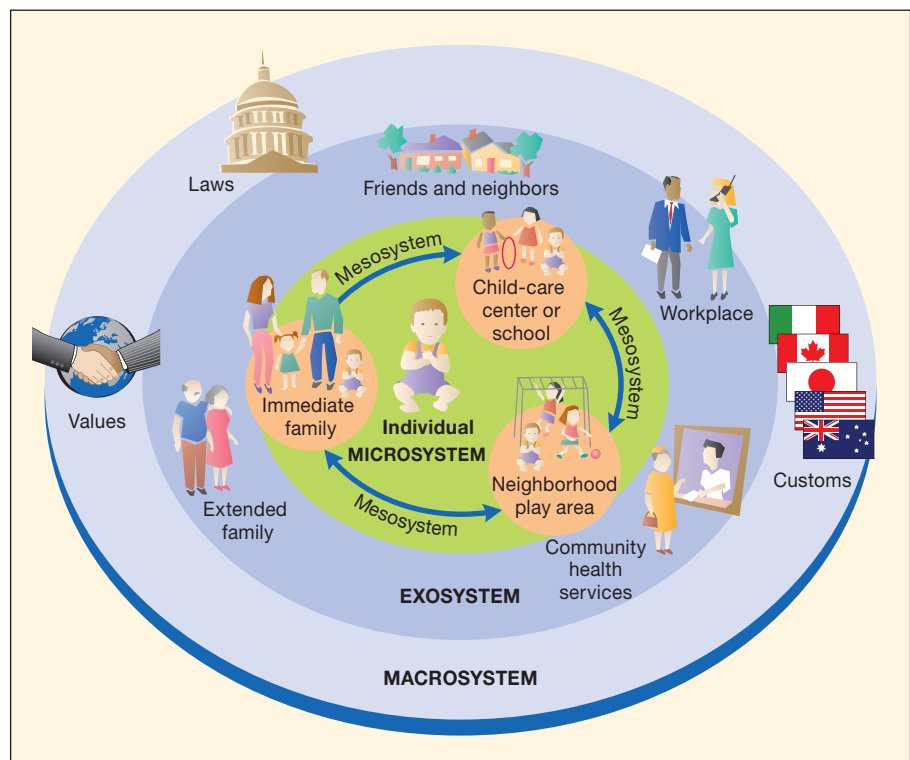

Ecological Systems Theory

Urie Bronfenbrenner (1917–2005) is responsible for an approach that has moved to the forefront of the field because it offers the most differentiated and complete account of contextual influences on development. **Ecological systems theory** views the person as developing within a complex *system* of relationships affected by multiple levels of the surrounding environment. Because the child's biologically influenced dispositions join with environmental forces to mold development, Bronfenbrenner characterized his perspective as a *bioecological model* (Bronfenbrenner, 2005; Bronfenbrenner & Morris, 2006).

Bronfenbrenner envisioned the environment as a series of nested structures, including but also extending beyond the home, school, neighborhood, and workplace settings in which people spend their everyday lives (see Figure 1.5). Each layer of the environment joins with the others to powerfully affect development.

The Microsystem. The innermost level of the environment, the **microsystem**, consists of activities and interaction patterns in the person's immediate surroundings. Bronfenbrenner emphasized that to understand development at this level, we

FIGURE 1.5 Structure of the environment in ecological systems theory. The *microsystem* concerns relations between the developing person and the immediate environment; the *mesosystem*, connections among immediate settings; the *exosystem*, social settings that affect but do not contain the developing person; and the *macrosystem*, the values, laws, customs, and resources of the culture that affect activities and interactions at all inner layers. The *chronosystem* (not pictured) is not a specific context. Instead, it refers to the dynamic, ever-changing nature of the person's environment.

© ELLEN B. SENISI PHOTOGRAPHY

A father says good-bye to his daughter at the start of the school day. The child's experiences at school (microsystem) and the father's experiences at work (exosystem) affect the father–daughter relationship.

must keep in mind that all relationships are *bidirectional*. For example, adults affect children's behavior, but children's biologically and socially influenced characteristics—their physical attributes, personalities, and capacities—also affect adults' behavior. A friendly, attentive child is likely to evoke positive, patient reactions from parents, whereas an irritable or distractible child is more likely to receive impatience, restriction, and punishment. When these reciprocal interactions occur often over time, they have an enduring impact on development (Crockenberg & Leerkes, 2003).

Third parties—other individuals in the microsystem—also affect the quality of any two-person relationship. If they are supportive, interaction is enhanced. For example, when parents encourage each other in their child-rearing roles, each engages in more effective parenting. In contrast, marital conflict is associated with inconsistent discipline and hostile reactions toward children. In response, children often react with fear and anxiety or with anger and aggression, and the well-being of both parent and child suffers (Caldera & Lindsey, 2006; Low & Stocker, 2012).

The Mesosystem. The second level of Bronfenbrenner's model, the **mesosystem**, encompasses connections between microsystems. For example, a child's academic progress depends not just on activities that take place in classrooms but also on parent involvement in school life and on the extent to which academic learning is carried over into the home (Jeynes, 2012). Among adults, how well a person functions as spouse and parent at home is affected by relationships in the workplace, and vice versa (Gottfried, Gottfried, & Bathurst, 2002).

The Exosystem. The **exosystem** consists of social settings that do not contain the developing person but nevertheless affect experiences in immediate settings. These can be formal organizations, such as the board of directors in the individual's workplace, religious institution, or community health and welfare services. Flexible work schedules, paid maternity and paternity leave, and sick leave for parents whose children are ill are examples of ways that work settings can help parents rear children and, indirectly, enhance the development of both adult and child. Exosystem supports can also be informal. Children are affected by their parents' social networks—friends and extended-family members who provide advice, companionship, and even financial assistance. Research confirms the negative impact of a breakdown in exosystem activities. Families who are socially isolated, with few personal or community-based ties, show increased rates of conflict and child abuse (Coulton et al., 2007). Refer to the Social Issues: Health box on page 26 for an additional illustration of the power of the exosystem to affect family functioning and children's development.

The Macrosystem. The outermost level of Bronfenbrenner's model, the **macrosystem**, consists of cultural values, laws, customs, and resources. The priority that the macrosystem gives to the needs of children and adults affects the support they receive at inner levels of the environment. For example, in countries that require generous workplace benefits for employed parents and set high standards for the quality of child care, children are more likely to have favorable experiences in their immediate settings. And when the government provides a generous pension plan for retirees, it supports the well-being of older people.

LOOK AND LISTEN

Ask a parent to explain his or her most worrisome child-rearing challenge. Cite one source of support at each level of Bronfenbrenner's model that could ease parental stress and promote child development. ●

A Dynamic, Ever-Changing System. According to Bronfenbrenner, the environment is not a static force that affects people in a uniform way. Instead, it is ever-changing. Whenever individuals add or let go of roles or settings in their lives, the breadth of their microsystems changes. These shifts in contexts—or *ecological transitions*, as Bronfenbrenner called them—are often important turning points in development. Starting school, entering the workforce, marrying, becoming a parent, getting divorced, moving, and retiring are examples.

Bronfenbrenner called the temporal dimension of his model the **chronosystem** (the prefix *chrono* means “time”). Life changes can be imposed externally or, alternatively, can arise from within the person, since individuals select, modify, and create many of their own settings and experiences. How they do so depends on their age; their physical, intellectual, and personality characteristics; and their environmental opportunities. Therefore, in ecological systems theory, development is neither

Social Issues: Health

Family Chaos Undermines Children's Well-Being

Virtually all of us can recall days during our childhoods when family routines—regular mealtime, bedtime, homework time, and parent–child reading and playtimes—were disrupted, perhaps because of a change in a parent’s job, a family illness, or a busy season of after-school sports. In some families, however, absence of daily structure is nearly constant, yielding a chaotic home life that interferes with healthy development (Fiese & Winter, 2010). An organized family life provides a supportive context for warm, involved parent–child interaction, which is essential to children’s well-being.

Family chaos is linked to economic disadvantage—especially, single mothers with limited incomes struggling to juggle the challenges of transportation, shift jobs, unstable child-care arrangements, and other daily hassles. But chaos is not limited to such families.

Surveys reveal that among U.S. families as a whole, mothers’ time with children has remained fairly stable over the past three decades, and fathers’ time has increased (Galinsky, Aumann, & Bond, 2009). But the way many parents spend that time has changed. Across income levels and ethnic groups, both mothers and fathers report more multitasking while caring for children—for example, using mealtimes not just to eat but also to check homework, read to children, and plan family outings and celebrations (Bianchi & Raley, 2005; Serpell et al., 2002). Consequently, disruption in one family routine can disrupt others.

Possibly because of this compression of family routines, today’s parents and children consistently say they have too little time together (Opinion Research Corporation, 2009). For example, only slightly more than half of U.S. families report eating together three to five times per week (CASA, 2006). Frequency of family meals is

associated with wide-ranging positive outcomes—in childhood, enhanced language development and academic achievement, fewer behavior problems, and time spent sleeping; and in adolescence, reduced sexual risk taking, alcohol and drug use, and mental health problems. Shared mealtimes also increase the likelihood of a healthy diet and protect against obesity and adolescent eating disorders (Adam, Snell, & Pendry, 2007; Fiese & Schwartz, 2008). As these findings suggest, regular mealtimes are a general indicator of an organized family life and positive parent involvement.

But family chaos can prevail even when families do engage in joint activities. Unpredictable, disorganized family meals involving harsh or lax parental discipline and hostile, disrespectful communication are associated with children’s adjustment difficulties (Fiese, Foley, & Spagnola, 2006). As family time becomes pressured and overwhelming, its orderly structure diminishes, and warm parent–child engagement disintegrates.

Diverse circumstances can trigger a pileup of limited parental emotional resources, breeding family chaos. In addition to *microsystem* and *mesosystem* influences (parents with mental health problems, parental separation and divorce, single parents with few or no supportive relationships), the *exosystem* is powerful: When family time is at the mercy of external forces—parents commuting several hours a day to and from work, child-care

arrangements often failing, parents experiencing excessive workplace pressures or job loss—family routines are threatened.

Family chaos contributes to children’s behavior problems, above and beyond its negative impact on parenting effectiveness (Coldwell, Pike, & Dunn, 2008; Fiese & Winter, 2010). Chaotic surroundings induce in children a sense of being hassled and feelings of powerlessness, which engender anxiety and low self-esteem.

Exosystem and macrosystem supports—including work settings with favorable family policies and high-quality child care that is affordable and reliable—can help prevent escalating demands on families that give way to chaos (Repetti & Wang, 2010). In one community, a child-care center initiated a take-home dinner program. Busy parents could special-order a healthy, reasonably priced family meal, ready to go at day’s end to aid in making the family dinner a routine that enhances children’s development.

A chaotic home life interferes with warm, relaxed parent–child interaction and contributes to behavior problems. Exosystem influences, such as excessive workplace pressures, can trigger disorganized family routines.

controlled by environmental circumstances nor driven solely by inner dispositions. Rather, people are both products and producers of their environments: The person and the environment form a network of interdependent effects. Our discussion of resilience on pages 10–11 illustrates this idea. We will see many more examples in later chapters.

ASK YOURSELF

REVIEW Explain how each recent theoretical perspective regards children and adults as active contributors to their own development.

CONNECT Is ecological systems theory compatible with assumptions of the lifespan perspective—development as lifelong, multidirectional, highly plastic, and influenced by multiple, interacting forces? Explain.

APPLY Mario wants to find out precisely how children of different ages recall stories. Anna is interested in how adult–child communication in different cultures influences children’s storytelling. Which theoretical perspective has Mario probably chosen? How about Anna? Explain.

REFLECT To illustrate the chronosystem in ecological systems theory, select an important event from your childhood, such as a move to a new neighborhood, a class with an inspiring teacher, or parental divorce. How did the event affect you? How might its impact have differed had you been five years younger? How about five years older?

Comparing and Evaluating Theories

In the preceding sections, we reviewed major theoretical perspectives in human development research. They differ in many respects. First, they focus on different domains of development. Some, such as the psychoanalytic perspective and ethology, emphasize emotional and social development. Others, such as Piaget’s cognitive-developmental theory, information processing, and Vygotsky’s sociocultural theory, stress changes in thinking. The remaining approaches—behaviorism, social learning theory, evolutionary developmental psychology, ecological systems theory, and the lifespan perspective—discuss many aspects of human functioning. Second, every theory contains a point of view about development. **TAKE A MOMENT...** As we conclude our review of theoretical perspectives, identify the stand each theory takes on the controversial issues presented at the beginning of this chapter. Then check your analysis against Table 1.4 on page 28.

Finally, we have seen that every theory has strengths and limitations. Perhaps you are attracted to some theories but have

doubts about others. As you read more about development in later chapters, you may find it useful to keep a notebook in which you test your theoretical likes and dislikes against the evidence. Don’t be surprised if you revise your ideas many times, just as theorists have done since scientific study of development began.

Studying Development

In every science, research is usually based on a *hypothesis*—a prediction about behavior drawn from a theory. Theories and hypotheses, however, merely initiate the many activities that result in sound evidence on human development. Conducting research according to scientifically accepted procedures involves many steps and choices. Investigators must decide which participants, and how many, to include. Then they must figure out what the participants will be asked to do and when, where, and how many times each will be seen. Finally, they must examine and draw conclusions from their data.

In the following sections, we look at research strategies commonly used to study human development. We begin with common *research methods*—the specific activities of participants, such as taking tests, answering questionnaires, responding to interviews, or being observed. Then we turn to *research designs*—overall plans for research studies that permit the best possible test of the investigator’s hypothesis. Finally, we discuss ethical issues involved in doing research with human participants.

Why learn about research strategies? Why not leave these matters to research specialists and concentrate, instead, on what is known about the developing person and how this knowledge can be applied? There are two reasons. First, each of us must be a wise and critical consumer of knowledge. Knowing the strengths and limitations of various research strategies is important in separating dependable information from misleading results. Second, individuals who work directly with children or adults may be in a unique position to build bridges between research and practice by conducting studies, either on their own or in partnership with experienced investigators. Community agencies such as schools, mental health facilities, and parks and recreation programs are increasingly collaborating with researchers in designing, implementing, and evaluating interventions aimed at enhancing development (Guerra, Graham, & Tolan, 2011). To broaden these efforts, a basic understanding of the research process is essential.

LOOK AND LISTEN

Ask a teacher, counselor, social worker, or nurse to describe a question about development he or she would like researchers to address. After reading the rest of this chapter, recommend research strategies best suited to answering that question, citing their strengths and limitations. ●

TABLE 1.4 Stances of Major Theories on Basic Issues in Human Development

THEORY	CONTINUOUS OR DISCONTINUOUS DEVELOPMENT?	ONE COURSE OF DEVELOPMENT OR MANY?	RELATIVE INFLUENCE OF NATURE AND NURTURE?
Psychoanalytic perspective	<i>Discontinuous:</i> Psychosexual and psychosocial development takes place in stages.	<i>One course:</i> Stages are assumed to be universal.	<i>Both nature and nurture:</i> Innate impulses are channeled and controlled through child-rearing experiences. <i>Early experiences</i> set the course of later development.
Behaviorism and social learning theory	<i>Continuous:</i> Development involves an increase in learned behaviors.	<i>Many possible courses:</i> Behaviors reinforced and modeled may vary from person to person.	<i>Emphasis on nurture:</i> Development is the result of conditioning and modeling. <i>Both early and later experiences</i> are important.
Piaget's cognitive-developmental theory	<i>Discontinuous:</i> Cognitive development takes place in stages.	<i>One course:</i> Stages are assumed to be universal.	<i>Both nature and nurture:</i> Development occurs as the brain grows and children exercise their innate drive to discover reality in a generally stimulating environment. <i>Both early and later experiences</i> are important.
Information processing	<i>Continuous:</i> Children and adults change gradually in perception, attention, memory, and problem-solving skills.	<i>One course:</i> Changes studied characterize most or all children and adults.	<i>Both nature and nurture:</i> Children and adults are active, sense-making beings who modify their thinking as the brain grows and they confront new environmental demands. <i>Both early and later experiences</i> are important.
Ethology and evolutionary developmental psychology	<i>Both continuous and discontinuous:</i> Children and adults gradually develop a wider range of adaptive behaviors. Sensitive periods occur in which qualitatively distinct capacities emerge fairly suddenly.	<i>One course:</i> Adaptive behaviors and sensitive periods apply to all members of a species.	<i>Both nature and nurture:</i> Evolution and heredity influence behavior, and learning lends greater flexibility and adaptiveness to it. In sensitive periods, <i>early experiences</i> set the course of later development.
Vygotsky's sociocultural theory	<i>Both continuous and discontinuous:</i> Language development and schooling lead to stagewise changes. Dialogues with more expert members of society also lead to continuous changes that vary from culture to culture.	<i>Many possible courses:</i> Socially mediated changes in thought and behavior vary from culture to culture.	<i>Both nature and nurture:</i> Heredity, brain growth, and dialogues with more expert members of society jointly contribute to development. <i>Both early and later experiences</i> are important.
Ecological systems theory	<i>Not specified.</i>	<i>Many possible courses:</i> Biologically influenced dispositions join with environmental forces at multiple levels to mold development in unique ways.	<i>Both nature and nurture:</i> The individual's characteristics and the reactions of others affect each other in a bidirectional fashion. <i>Both early and later experiences</i> are important.
Lifespan perspective	<i>Both continuous and discontinuous:</i> Continuous gains and declines and discontinuous, stagewise emergence of new skills occur.	<i>Many possible courses:</i> Development is influenced by multiple, interacting biological, psychological, and social forces, many of which vary from person to person, leading to diverse pathways of change.	<i>Both nature and nurture:</i> Development is multidimensional, affected by an intricate blend of hereditary and environmental factors. Emphasizes plasticity at all ages. <i>Both early and later experiences</i> are important.

Common Research Methods

How does a researcher choose a basic approach to gathering information? Common methods include systematic observation, self-reports (such as questionnaires and interviews), clinical or case studies of a single individual, and ethnographies of the life circumstances of a specific group of people. Table 1.5 summarizes the strengths and limitations of each of these methods.

Systematic Observation. Observations of the behavior of children and adults can be made in different ways. One approach is to go into the field, or natural environment, and record the behavior of interest—a method called **naturalistic observation**.

A study of preschoolers' responses to their peers' distress provides a good example (Farver & Branstetter, 1994). Observing 3- and 4-year-olds in child-care centers, the researchers recorded each instance of crying and the reactions of nearby

TABLE 1.5 Strengths and Limitations of Common Research Methods

METHOD	DESCRIPTION	STRENGTHS	LIMITATIONS
SYSTEMATIC OBSERVATION			
Naturalistic observation	Observation of behavior in natural contexts	Reflects participants' everyday lives.	Cannot control conditions under which participants are observed.
Structured observation	Observation of behavior in a laboratory, where conditions are the same for all participants	Grants each participant an equal opportunity to display the behavior of interest.	May not yield observations typical of participants' behavior in everyday life.
SELF-REPORTS			
Clinical interview	Flexible interviewing procedure in which the investigator obtains a complete account of the participant's thoughts	Comes as close as possible to the way participants think in everyday life. Great breadth and depth of information can be obtained in a short time.	May not result in accurate reporting of information. Flexible procedure makes comparing individuals' responses difficult.
Structured interview, questionnaires, and tests	Self-report instruments in which each participant is asked the same questions in the same way	Permits comparisons of participants' responses and efficient data collection. Researchers can specify answer alternatives that participants might not think of in an open-ended interview.	Does not yield the same depth of information as a clinical interview. Responses are still subject to inaccurate reporting.
CLINICAL, OR CASE STUDY, METHOD			
	A full picture of one individual's psychological functioning, obtained by combining interviews, observations, and test scores	Provides rich, descriptive insights into factors that affect development.	May be biased by researchers' theoretical preferences. Findings cannot be applied to individuals other than the participant.
ETHNOGRAPHY			
	Participant observation of a culture or distinct social group. By making extensive field notes, the researcher tries to capture the culture's unique values and social processes	Provides a more complete description than can be derived from a single observational visit, interview, or questionnaire.	May be biased by researchers' values and theoretical preferences. Findings cannot be applied to individuals and settings other than the ones studied.

children—whether they ignored, watched, commented on the child's unhappiness, scolded or teased, or shared, helped, or expressed sympathy. Caregiver behaviors—explaining why a child was crying, mediating conflict, or offering comfort—were noted to see if adult sensitivity was related to children's caring responses. A strong relationship emerged. The great strength of naturalistic observation is that investigators can see directly the everyday behaviors they hope to explain.

Naturalistic observation also has a major limitation: Not all individuals have the same opportunity to display a particular behavior in everyday life. In the study just described, some children might have witnessed a child crying more often than others or been exposed to more cues for positive social responses from caregivers. For these reasons, they might have displayed more compassion.

Researchers commonly deal with this difficulty by making **structured observations**, in which the investigator sets up a laboratory situation that evokes the behavior of interest so that every participant has equal opportunity to display the response. In one such study, 2-year-olds' emotional reactions to harm that

they thought they had caused were observed by asking each of them to take care of a rag doll that had been modified so its leg would fall off when the child picked it up. To make the child feel at fault, once the leg detached, an adult "talked for" the doll by saying, "Ow!" Researchers recorded children's facial expressions of sadness and concern for the injured doll, efforts to help the doll, and body tension—responses that indicated remorse and a desire to make amends for the mishap. In addition, mothers were asked to engage in brief conversations about emotions with their children (Garner, 2003). Toddlers whose mothers more often explained the causes and consequences of emotion were more likely to express concern for the injured doll.

The procedures used to collect systematic observations vary, depending on the research problem posed. Sometimes investigators choose to analyze the entire stream of behavior—everything said and done over a certain time period. In one study, researchers wanted to find out whether maternal sensitivity in infancy and early childhood contributes to readiness for formal schooling at age 6 (Hirsh-Pasek & Burchinal, 2006). Between ages 6 months and 4½ years, the investigators periodically

© ELLEN B. SENISI PHOTOGRAPHY

In naturalistic observation, the researcher goes into the field and records the behavior of interest. Here, a researcher observes children at preschool. She may be focusing on their playmate choices, cooperation, helpfulness, or conflicts.

videotaped mother-child 15-minute play sessions. Then they rated each session for many behaviors—maternal positive emotion, support, stimulating play, and respect for the child's autonomy. These ingredients of sensitivity did predict better language and academic progress when the children reached kindergarten.

Researchers have devised ingenious ways of observing difficult-to-capture behaviors. For example, to record instances of bullying, a group of investigators set up video cameras overlooking a classroom and a playground and had fourth to sixth graders wear small, remote microphones and pocket-sized transmitters (Craig, Pepler, & Atlas, 2000). Results revealed that bullying occurred often—at rates of 2.4 episodes per hour in the classroom and 4.5 episodes per hour on the playground. Yet only 15 to 18 percent of the time did teachers take steps to stop the harassment.

Systematic observation provides invaluable information on how children and adults actually behave, but it tells us little about the reasoning behind their responses. For that information, researchers must turn to self-report techniques.

Self-Reports. Self-reports ask research participants to provide information on their perceptions, thoughts, abilities, feelings, attitudes, beliefs, and past experiences. They range from relatively unstructured interviews to highly structured interviews, questionnaires, and tests.

In a **clinical interview**, researchers use a flexible, conversational style to probe for the participant's point of view. In the following example, Piaget questioned a 5-year-old child about his understanding of dreams:

Where does the dream come from?—I think you sleep so well that you dream.—Does it come from us or from outside?—From outside.—When you are in bed and you dream, where is the

dream?—In my bed, under the blanket. I don't really know. If it was in my stomach, the bones would be in the way and I shouldn't see it.—Is the dream there when you sleep?—Yes, it is in the bed beside me. (Piaget, 1926/1930, pp. 97–98)

Although a researcher conducting clinical interviews with more than one participant would typically ask the same first question to establish a common task, individualized prompts are used to provide a fuller picture of each person's reasoning.

The clinical interview has two major strengths. First, it permits people to display their thoughts in terms that are as close as possible to the way they think in everyday life. Second, the clinical interview can provide a large amount of information in a fairly brief period. For example, in an hour-long session, we can obtain a wide range of information on child rearing from a parent or on life circumstances from an older adult—much more than we could capture by observing for the same amount of time.

A major limitation of the clinical interview has to do with the accuracy with which people report their thoughts, feelings, and experiences. Some participants, wishing to please the interviewer, may make up answers that do not represent their actual thinking. When asked about past events, some may have trouble recalling exactly what happened. And because the clinical interview depends on verbal ability and expressiveness, it may underestimate the capacities of individuals who have difficulty putting their thoughts into words.

The clinical interview has also been criticized because of its flexibility. When questions are phrased differently for each participant, responses may reflect the manner of interviewing rather than real differences in the way people think about a topic. **Structured interviews** (including tests and questionnaires), in which each participant is asked the same set of questions in the same way, eliminate this problem. These instruments are also much more efficient. Answers are briefer, and researchers can obtain written responses from an entire group simultaneously. Furthermore, by listing answer alternatives, researchers can specify the activities and behaviors of interest—ones that participants might not think of in an open-ended clinical interview. For example, when parents were asked what they considered “the most important thing for children to prepare them for life,” 62 percent checked “to think for themselves” when this choice appeared on a list. Yet only 5 percent thought of this during a clinical interview (Schwarz, 1999).

Nevertheless, structured interviews do not yield the same depth of information as a clinical interview. And they can still be affected by the problem of inaccurate reporting. Currently, more researchers are combining the two approaches to see if they yield consistent findings (Yoshikawa et al., 2008). And blending the two methods is likely to offer a clearer picture than either method can alone.

The Clinical, or Case Study, Method. An outgrowth of psychoanalytic theory, the **clinical, or case study, method** brings together a wide range of information on one person,

© LAURA DWIGHT PHOTOGRAPHY

Using the clinical, or case study, method, this researcher interacts with a 3-year-old during a home visit. Interviews and observations will contribute to an in-depth picture of this child's psychological functioning.

including interviews, observations, and test scores. The aim is to obtain as complete a picture as possible of that individual's psychological functioning and the experiences that led up to it.

The clinical method is well-suited to studying the development of certain types of individuals who are few in number but vary widely in characteristics. For example, the method has been used to find out what contributes to the accomplishments of *prodigies*—extremely gifted children who attain adult competence in a field before age 10 (Moran & Gardner, 2006). Consider Adam, a boy who read, wrote, and composed musical pieces before he was out of diapers. By age 4, Adam was deeply involved in mastering human symbol systems—French, German, Russian, Sanskrit, Greek, the computer programming language BASIC, ancient hieroglyphs, music, and mathematics. Adam's parents provided a home rich in stimulation and reared him with affection, firmness, and humor. They searched for schools in which he could both develop his abilities and form rewarding social relationships. He graduated from college at age 18 and continued to pursue musical composition (Goldsmith, 2000). Would Adam have realized his abilities without the chance combination of his special gift and nurturing, committed parents? Probably not, researchers concluded (Feldman, 2004).

The clinical method yields richly detailed case narratives that offer valuable insights into the many factors influencing development. Nevertheless, like all other methods, it has drawbacks. Because information often is collected unsystematically and subjectively, researchers' theoretical preferences may bias their observations and interpretations. In addition, investigators cannot assume that their conclusions apply, or generalize, to anyone other than the person studied (Stanovich, 2013). Even

when patterns emerge across several cases, it is wise to confirm these with other research strategies.

Methods for Studying Culture. To study the impact of culture, researchers adjust the methods just considered or tap procedures specially devised for cross-cultural and multicultural research (Triandis, 2007). Which approach investigators choose depends on their research goals.

Sometimes researchers are interested in characteristics that are believed to be universal but that vary in degree from one society to the next: Are parents warmer or more directive in some cultures than others? How strong are gender stereotypes in different nations? In each instance, several cultural groups will be compared, and all participants must be questioned or observed in the same way. Therefore, researchers draw on the observational and self-report procedures we have already considered, adapting them through translation so they can be understood in each cultural context. For example, to study cultural variation in parenting practices, the same questionnaire, asking for ratings on such items as “I often hug and kiss my child” or “I scold my child when his/her behavior does not meet my

Cultural Influences

Immigrant Youths: Adapting to a New Land

Over the past several decades, a rising tide of immigrants has come to North America, fleeing war and persecution in their homelands or seeking better life chances. Today, nearly one-fourth of U.S. children and adolescents have foreign-born parents, making them the fastest growing sector of the U.S. youth population. About 20 percent of these young people are foreign-born themselves, mostly from Latin America, the Caribbean, and Asia (Hernandez, Denton, & Macartney, 2008; Suárez-Orozco, Todorova, & Qin, 2006).

How well are immigrant youths adapting to their new country? To find out, researchers use multiple research methods—academic testing, questionnaires assessing psychological adjustment, and in-depth ethnographies.

Academic Achievement and Adjustment

Although educators and laypeople often assume that the transition to a new country has a negative impact on psychological well-being, evidence reveals that children of immigrant parents adapt well. Students who are first-generation (foreign-born) and

second-generation (American-born, with immigrant parents) often achieve in school as well as or better than students of native-born parents (Fuligni, 2004; Hao & Woo, 2012; Hernandez, Denton, & Macartney, 2008). Findings on psychological adjustment are similar. Compared with their age mates, adolescents from immigrant families are less likely to commit delinquent and violent acts, to use drugs and alcohol, or to have early sex. They are also less likely to be obese or to have missed school because of illness. And they tend to report just as high, and at times higher, self-esteem as young people with native-born parents (Fuligni, 1998; Saucier et al., 2002; Supple & Small, 2006).

These outcomes are strongest for Chinese, Filipino, Japanese, Korean, and East Indian youths, less dramatic for other ethnicities (Fuligni, 2004; Louie, 2001; Portes & Rumbaut, 2005). Variation in

adjustment is greater among Mexican, Central American, and Southeast Asian (Hmong, Cambodian, Laotian, Thai, and Vietnamese) young people, who show elevated rates of school failure and dropout, delinquency, teenage parenthood, and drug use. Disparities in parental economic resources, education, English-language proficiency, and support of children contribute

expectations,” is given to all participants (Wu et al., 2002). Still, investigators must be mindful of cultural differences in familiarity with being observed and with responding to self-report instruments, which may bias their findings (Van de Vijver, Hofer, & Chasiotis, 2010).

At other times, researchers want to uncover the *cultural meanings* of children’s and adults’ behaviors by becoming as familiar as possible with their way of life. To achieve this goal, investigators rely on a method borrowed from the field of anthropology—**ethnography**. Like the clinical method, ethnographic research is a descriptive, qualitative technique. But instead of aiming to understand a single individual, it is directed toward understanding a culture or a distinct social group through *participant observation*. Typically, the researcher spends months, and sometimes years, in the cultural community, participating in its daily life. Extensive field notes are

gathered, consisting of a mix of observations, self-reports from members of the culture, and careful interpretations by the investigator (Miller, Hengst, & Wang, 2003; Shweder et al., 2006). Later, these notes are put together into a description of the community that tries to capture its unique values and social processes.

The ethnographic method assumes that entering into close contact with a social group will allow researchers to understand the beliefs and behaviors of its members in a way that is not possible with an observational visit, interview, or questionnaire. Some ethnographies take in many aspects of experience, as one team of researchers did in describing what it is like to grow up in a small American town. Others focus on one or a few settings and issues—for example, barriers to effective parent–school communication in a Mexican–American community or African–Caribbean adults’ reactions to a diagnosis

to these trends (García Coll & Marks, 2009; Pong & Landale, 2012).

Still, many first- and second-generation youths whose parents face considerable financial hardship and who speak little English are successful (Hao & Woo, 2012; Hernandez, Denton, & Macartney, 2008). Factors other than income are responsible—notably, family values and strong ethnic-community ties.

Family and Community Influences

Ethnographies reveal that immigrant parents view education as the surest way to improve life chances (García Coll & Marks, 2009; Goldenberg et al., 2001). Aware of the challenges their children face, they typically emphasize trying hard. They remind their children that, because educational opportunities were not available in their native countries, they themselves are often limited to menial jobs. And while preserving their culture's values, these parents also make certain adaptations—for example, supporting education for daughters even though their culture of origin endorses it only for sons.

Adolescents from these families internalize their parents' valuing of education, endorsing it more strongly than agemates with native-born parents (Fuligni, 2004;

Su & Costigan, 2008). Because minority ethnicities usually stress allegiance to family and community over individual goals, first- and second-generation young people feel a strong sense of obligation to their parents. They view school success as both their own and their parents' success and as a way of repaying their parents for the hardships they have endured (Bacallao & Smokowski, 2007; Fuligni, Yip, & Tseng, 2002). Both family relationships and school achievement protect these youths from delinquency, early pregnancy and drug use, and other risky behaviors (see the Biology and Environment box on resilience on pages 10–11).

Immigrant parents of successful youths typically develop close ties to an ethnic community, which exerts additional control through a high consensus on values and constant monitoring of young people's activities. The following comments capture the power of these family and community forces:

Elizabeth, age 16, from Vietnam, straight-A student, like her two older sisters: My parents know pretty much all the kids in the neighborhood. . . . Everybody here knows everybody else. It's hard to get away with much. (Zhou & Bankston, 1998, pp. 93, 130)

Juan, teenager from Mexico: A really big part of the Hispanic population [is] being close to family, and the family being a priority all the time. I hate people who say, "Why do you want to go to a party where your family's at? Don't you want to get away from them?" You know, I don't really get tired of them. I've always been really close to them. That connection to my parents, that trust that you can talk to them, that makes me Mexican. (Bacallao & Smokowski, 2007, p. 62)

The experiences of well-adjusted immigrant youths are not problem-free. Chinese adolescents who had arrived in the United States within the previous year described their adjustment as very difficult because they were not proficient in English and, as a result, found many everyday tasks challenging and felt socially isolated (Yeh et al., 2008). Young immigrants also encounter racial and ethnic prejudices and experience tensions between family values and the new culture—challenges we will take up in Chapter 12. In the long term, however, family and community cohesion, supervision, and high expectations promote favorable outcomes.

of high blood pressure, signaling elevated risk for heart disease (Higginbottom, 2006; Peshkin, 1997; Valdés, 1998). Notice how such ethnographic evidence is vital in designing effective educational and health interventions. Increasingly, researchers are supplementing traditional self-report and observational methods with ethnography when they suspect that unique meanings underlie cultural differences, as the Cultural Influences box above reveals.

Ethnographers strive to minimize their own influence on the culture they are studying by becoming part of it. Nevertheless, as with clinical studies, investigators' cultural values and theoretical commitments sometimes lead them to observe selectively or misinterpret what they see. In addition, the findings of ethnographic studies cannot be assumed to generalize beyond the people and settings in which the research was conducted.

General Research Designs

In deciding on a research design, investigators choose a way of setting up a study that permits them to test their hypotheses with the greatest certainty possible. Two main types of designs are used in all research on human behavior: *correlational* and *experimental*.

Correlational Design. In a correlational design, researchers gather information on individuals, generally in natural life circumstances, without altering their experiences. Then they look at relationships between participants' characteristics and their behavior or development. Suppose we want to answer such questions as, Do parents' styles of interacting with their children have any bearing on children's intelligence? Does the arrival of a baby influence a couple's marital satisfaction? Does the death of a spouse in old age affect the surviving partner's physical health and psychological well-being? In these and many other instances, the conditions of interest are difficult or impossible to arrange and control and must be studied as they currently exist.

Correlational studies have one major limitation: We cannot infer cause and effect. For example, if we were to find that parental interaction is related to children's intelligence, we would not know whether parents' behavior actually *causes* intellectual differences among children. In fact, the opposite is possible: The behaviors of highly intelligent children may be so attractive that they cause parents to interact more favorably. Or a third variable that we did not even consider, such as the amount of noise and distraction in the home, may cause changes in both parental interaction and children's intelligence.

In correlational studies and in other types of research designs, investigators often examine relationships by using a

FIGURE 1.6 The meaning of correlation coefficients.

The magnitude of the number indicates the *strength* of the relationship. The sign of the number (+ or -) indicates the *direction* of the relationship.

correlation coefficient—a number that describes how two measures, or variables, are associated with each other. We will encounter the correlation coefficient in discussing research findings throughout this book, so let's look at what it is and how it is interpreted. A correlation coefficient can range in value from +1.00 to -1.00. The *magnitude*, or *size*, of the number shows the *strength of the relationship*. A zero correlation indicates no relationship; the closer the value is to +1.00 or -1.00, the stronger the relationship (see Figure 1.6). For instance, a correlation of -0.78 is high, -0.52 is moderate, and -0.18 is low. Note, however, that correlations of $+0.52$ and -0.52 are equally strong. The *sign of the number* (+ or -) refers to the *direction of the relationship*. A positive sign (+) means that as one variable *increases*, the other also *increases*. A negative sign (-) indicates that as one variable *increases*, the other *decreases*.

Let's look at some examples of how a correlation coefficient works. One researcher reported a $+0.55$ correlation between a measure of maternal language stimulation and the size of children's vocabularies at 2 years of age (Hoff, 2003). This is a moderate correlation, which indicates that mothers who spoke more to their toddlers had children who were more advanced in language development. In two other studies, maternal sensitivity was modestly associated with children's cooperativeness in consistent ways. First, maternal warmth and encouragement during play correlated positively with 2-year-olds' willingness to comply with their mother's directive to clean up toys, at $+0.34$ (Feldman & Klein, 2003). Second, the extent to which mothers spoke harshly, interrupted, and controlled their 4-year-olds' play correlated negatively with children's compliance, at -0.31 for boys and -0.42 for girls (Smith et al., 2004).

All these investigations found correlations between parenting and young children's behavior. **TAKE A MOMENT...** Are you tempted to conclude that the maternal behaviors influenced children's responses? Although the researchers in these studies suspected this was so, they could not be sure of cause and effect.

Will the death of her husband affect this elderly widow's physical health and psychological well-being? A correlational design can be used to answer this question, but it does not permit researchers to determine the precise cause of their findings.

Can you think of other possible explanations? Finding a relationship in a correlational study does suggest that tracking down its cause—using a more powerful experimental strategy, if possible—would be worthwhile.

Experimental Design. An experimental design permits inferences about cause and effect because researchers use an evenhanded procedure to assign people to two or more treatment conditions. In an experiment, the events and behaviors of interest are divided into two types: independent and dependent variables. The **independent variable** is the one the investigator expects to cause changes in another variable. The **dependent variable** is the one the investigator expects to be influenced by the independent variable. Cause-and-effect relationships can be detected because the researcher directly *controls* or *manipulates* changes in the independent variable by exposing participants to the treatment conditions. Then the researcher compares their performance on measures of the dependent variable.

In one *laboratory experiment*, investigators explored the impact of adults' angry interactions on children's adjustment (El-Sheikh, Cummings, & Reiter, 1996). They hypothesized that the way angry encounters end (independent variable) affects children's emotional reactions (dependent variable). Four- and 5-year-olds were brought to a laboratory one at a time, accompanied by their mothers. One group was exposed to an *unresolved-anger treatment*, in which two adult actors entered the room and argued but did not work out their disagreements. The other group witnessed a *resolved-anger treatment*, in which the adults ended their disputes by apologizing and compromising. When witnessing a follow-up adult conflict, children in the resolved-anger treatment showed less distress, as measured by fewer anxious facial expressions, less freezing in place, and less seeking of closeness to their mothers. The experiment revealed that anger resolution can reduce the stressful impact of adult conflict on children.

In experimental studies, investigators must take special precautions to control for participants' characteristics that could reduce the accuracy of their findings. For example, in the study just described, if a greater number of children from homes high in parental conflict ended up in the unresolved-anger treatment, we could not tell what produced the results—the independent variable or the children's backgrounds. To protect against this problem, researchers engage in **random assignment** of participants to treatment conditions. By using an unbiased procedure, such as drawing numbers out of a hat or flipping a coin, investigators increase the chances that participants' characteristics will be equally distributed across treatment groups.

Modified Experimental Designs: Field and Natural Experiments. Most experiments are conducted in laboratories, where researchers can achieve the maximum possible control over treatment conditions. But, as we have already indicated, findings obtained in laboratories may not always apply to everyday situations. In *field experiments*, investigators capitalize on opportunities to assign participants

randomly to treatment conditions in natural settings. In the experiment just described, we can conclude that the emotional climate established by adults affects children's behavior in the laboratory. But does it also do so in daily life?

Another study helps answer this question. Ethnically diverse, poverty-stricken families with a 2-year-old child were scheduled for a home visit, during which researchers assessed family functioning and child problem behaviors by asking parents to respond to questionnaires and videotaping parent-child interaction. Then the families were randomly assigned to either a brief intervention condition, called the Family Check-Up, or a no-intervention control group. The intervention consisted of three home-based sessions in which a consultant gave parents feedback about their child-rearing practices and their child's adjustment, explored parents' willingness to improve, and identified community services appropriate to each family's needs (Dishion et al., 2008). Findings showed that families assigned to the Family Check-Up (but not controls) gained in positive parenting, which predicted a reduction in child problem behaviors—sometimes still evident a year later, when participating children were reassessed at age 3. Highly problematic children benefited most from this brief, early intervention.

Often researchers cannot randomly assign participants and manipulate conditions in the real world. Sometimes they can compromise by conducting *natural, or quasi-, experiments*, comparing treatments that already exist, such as different family environments, schools, workplaces, or retirement villages. These studies differ from correlational research only in that groups of participants are carefully chosen to ensure that their characteristics are as much alike as possible. In this way, investigators do their best to rule out alternative explanations for their treatment effects. But, despite these efforts, natural experiments cannot achieve the precision and rigor of true experimental research.

To help you compare correlational and experimental designs, Table 1.6 on page 36 summarizes their strengths and limitations. It also includes an overview of designs for studying development, to which we turn next.

Designs for Studying Development

Scientists interested in human development require information about the way research participants change over time. To answer questions about development, they must extend correlational and experimental approaches to include measurements at different ages. Longitudinal and cross-sectional designs are special *developmental* research strategies. In each, age comparisons form the basis of the research plan.

The Longitudinal Design. In a **longitudinal design**, participants are studied repeatedly, and changes are noted as they get older. The time spanned may be relatively short (a few months to several years) or very long (a decade or even a lifetime). The longitudinal approach has two major strengths. First, because it tracks the performance of each person over time,

TABLE 1.6 Strengths and Limitations of Research Designs

DESIGN	DESCRIPTION	STRENGTHS	LIMITATIONS
GENERAL			
Correlational	The investigator obtains information on participants without altering their experiences.	Permits study of relationships between variables.	Does not permit inferences about cause-and-effect relationships.
Experimental	Through random assignment of participants to treatment conditions, the investigator manipulates an independent variable and examines its effect on a dependent variable. Can be conducted in the laboratory or the natural environment.	Permits inferences about cause-and-effect relationships.	When conducted in the laboratory, findings may not generalize to the real world. In <i>field experiments</i> , control over the treatment is usually weaker than in the laboratory. In <i>natural, or quasi-, experiments</i> , lack of random assignment substantially reduces the precision of research.
DEVELOPMENTAL			
Longitudinal	The investigator studies the same group of participants repeatedly at different ages.	Permits study of common patterns and individual differences in development and relationships between early and later events and behaviors.	Age-related changes may be distorted because of participant dropout, practice effects, and cohort effects.
Cross-sectional	The investigator studies groups of participants differing in age at the same point in time.	More efficient than the longitudinal design. Not plagued by such problems as participant dropout and practice effects.	Does not permit study of individual developmental trends. Age differences may be distorted because of cohort effects.
Sequential	The investigator conducts several similar cross-sectional or longitudinal studies (called sequences). These might study participants over the same ages but in different years, or they might study participants over different ages but during the same years.	When the design includes longitudinal sequences, permits both longitudinal and cross-sectional comparisons. Also reveals cohort effects. Permits tracking of age-related changes more efficiently than the longitudinal design.	May have the same problems as longitudinal and cross-sectional strategies, but the design itself helps identify difficulties.

researchers can identify common patterns as well as individual differences in development. Second, longitudinal studies permit investigators to examine relationships between early and later events and behaviors. Let's illustrate these ideas.

A group of researchers wondered whether children who display extreme personality styles—either angry and explosive or shy and withdrawn—retain the same dispositions when they become adults. In addition, the researchers wanted to know what kinds of experiences promote stability or change in personality and what consequences explosiveness and shyness have for long-term adjustment. To answer these questions, the researchers delved into the archives of the Guidance Study, a well-known longitudinal investigation initiated in 1928 at the University of California, Berkeley, and continued for several decades (Caspi, Elder, & Bem, 1987, 1988).

Results revealed that the two personality styles were moderately stable. Between ages 8 and 30, a good number of individuals remained the same, whereas others changed substantially. When stability did occur, it appeared to be due to a “snowballing effect,” in which children evoked responses from adults and peers that acted to maintain their dispositions. Explosive

youngsters were likely to be treated with anger, whereas shy children were apt to be ignored. As a result, the two types of children came to view their social worlds differently. Explosive children regarded others as hostile; shy children regarded them as unfriendly (Caspi & Roberts, 2001). Together, these factors led explosive children to sustain or increase their unruliness and shy children to continue to withdraw.

Persistence of extreme personality styles affected many areas of adult adjustment. For men, the results of early explosiveness were most apparent in their work lives, in the form of conflicts with supervisors, frequent job changes, and unemployment. Since few women in this sample of an earlier generation worked after marriage, their family lives were most affected. Explosive girls grew up to be hotheaded wives and mothers who were especially prone to divorce. Sex differences in the long-term consequences of shyness were even greater. Men who had been withdrawn in childhood were delayed in marrying, becoming fathers, and developing stable careers. However, perhaps because a withdrawn, unassertive style was socially acceptable for females in the mid-twentieth century, women who had shy personalities showed no special adjustment problems.

Problems in Conducting Longitudinal Research.

Despite their strengths, longitudinal investigations pose a number of problems. For example, participants may move away or drop out of the research for other reasons. This biases the sample so that it no longer represents the population to whom researchers would like to generalize their findings. Also, from repeated study, people may become more aware of their own thoughts, feelings, and actions and revise them in ways that have little to do with age-related change. In addition, they may become “test-wise.” Their performance may improve as a result of *practice effects*—better test-taking skills and increased familiarity with the test—not because of factors commonly associated with development.

The most widely discussed threat to longitudinal findings is **cohort effects** (see page 11): Individuals born in the same time period are influenced by a particular set of historical and cultural conditions. Results based on one cohort may not apply to people developing at other times. For example, unlike the findings on female shyness described in the preceding section, which were gathered in the 1950s, today’s shy adolescent girls and young women tend to be poorly adjusted—a difference that may be due to changes in gender roles in Western societies. Shy young people, whether male or female, feel more anxious, depressed, and lonely and may do less well in educational and career attainment than their agetates (Caspi et al., 2003; Karevold et al., 2012; Mounts et al., 2006). Similarly, a longitudinal study of lifespan development would probably result in quite different findings if it were carried out in the first decade of the twenty-first century, around the time of World War II, or during the Great Depression of the 1930s.

Cohort effects don’t just operate broadly on an entire generation. They also occur when specific experiences influence some groups of individuals but not others in the same generation. For example, children who witnessed the terrorist attacks of September 11, 2001 (either because they were near Ground Zero or because they saw injury and death on TV), or who lost a parent in the disaster, were far more likely than other children to display persistent emotional problems, including intense fear, anxiety, and depression (Mullett-Hume et al., 2008; Pfeffer et al., 2007; Rosen & Cohen, 2010). A study of one New York City sample suggested that as many as one-fourth of the city’s children were affected (Hoven et al., 2005).

The Cross-Sectional Design. The length of time it takes for many behaviors to change, even in limited longitudinal studies, has led researchers to turn toward a more convenient strategy for studying development. In the **cross-sectional design**, groups of people differing in age are studied at the same point in time. The cross-sectional design is an efficient strategy for describing age-related trends. And because participants are measured only once, researchers need not be concerned about such difficulties as participant dropout or practice effects.

A study in which students in grades 3, 6, 9, and 12 filled out a questionnaire about their sibling relationships provides a good illustration (Buhrmester & Furman, 1990). Findings revealed that

AP IMAGES/CHRIS CARLSON

Cohort effects are particular historical and cultural conditions that affect individuals born in the same time period. Young people who witnessed Barack Obama and his family celebrating his election victory in 2008 and again in 2012 came away with a new sense of what is possible for members of America’s ethnic minorities.

sibling interaction was characterized by greater equality and less power assertion with age. Also, feelings of sibling companionship declined in adolescence. The researchers thought that several factors contributed to these age differences. As later-born children become more competent and independent, they no longer need, and are probably less willing to accept, direction from older siblings. And as adolescents move from psychological dependence on the family to greater involvement with peers, they may have less time and emotional need to invest in siblings. As you will see in Chapter 12, subsequent research has confirmed these intriguing ideas about the development of sibling relationships.

Problems in Conducting Cross-Sectional Research.

Despite its convenience, cross-sectional research does not provide evidence about development at the level at which it actually occurs: the individual. For example, in the cross-sectional study of sibling relationships just discussed, comparisons are limited to age-group averages. We cannot tell if important individual differences exist. Indeed, longitudinal findings reveal that adolescents vary considerably in the changing quality of their sibling relationships. Although many become more distant, others become more supportive and intimate, still others more rivalrous and antagonistic (Branje et al., 2004; Kim et al., 2006; Whiteman & Loken, 2006).

Cross-sectional studies—especially those that cover a wide age span—have another problem. Like longitudinal research, they can be threatened by cohort effects. For example,

comparisons of 10-year-old cohorts, 20-year-old cohorts, and 30-year-old cohorts—groups born and reared in different years—may not really represent age-related changes. Instead, they may reflect unique experiences associated with the historical period in which the age groups were growing up.

Improving Developmental Designs. Researchers have devised ways of building on the strengths and minimizing the weaknesses of longitudinal and cross-sectional approaches. Several modified developmental designs have resulted.

Sequential Designs. To overcome some of the limitations of traditional developmental designs, investigators sometimes use **sequential designs**, in which they conduct several similar cross-sectional or longitudinal studies (called *sequences*). The sequences might study participants over the same ages but in different years, or they might study participants over different ages but during the same years. Figure 1.7 illustrates the first of these options. As it also reveals, some sequential designs combine longitudinal and cross-sectional strategies, an approach that has two advantages:

- We can find out whether cohort effects are operating by comparing participants of the same age who were born in different years. In the example in Figure 1.7, we can compare the three longitudinal samples at ages 20, 30, and 40. If they do not differ, we can rule out cohort effects.
- We can make longitudinal and cross-sectional comparisons. If outcomes are similar in both, then we can be especially confident about our findings.

In a study that used the design in Figure 1.7, researchers wanted to find out whether adult personality development progresses as Erikson's psychosocial theory predicts (Whitbourne et al., 1992). Questionnaires measuring Erikson's stages were

given to three cohorts of 20-year-olds, each born a decade apart. The cohorts were reassessed at ten-year intervals. Consistent with Erikson's theory, longitudinal and cross-sectional gains in identity and intimacy occurred between ages 20 and 30—a trend unaffected by historical time period. But a powerful cohort effect emerged for consolidation of the sense of industry: At age 20, Cohort 1 scored substantially below Cohorts 2 and 3. Look at Figure 1.7 again and notice that members of Cohort 1 reached age 20 in the mid-1960s. As college students, they were part of an era of political protest that reflected disenchantment with the work ethic. Once out of college, they caught up with the other cohorts in industry, perhaps as a result of experiencing the pressures of the work world. Followed up in 2001 at age 54, Cohort 1 showed a decline in focus on identity issues and a gain in ego integrity over middle adulthood—trends expected to continue through late adulthood (Sneed, Whitbourne, & Culang, 2006). Future tracking of Cohorts 2 and 3 will reveal whether they, too, follow this Erikson-predicted psychosocial path.

By uncovering cohort effects, sequential designs help explain diversity in development. Yet to date only a small number of sequential studies have been conducted.

Combining Experimental and Developmental Designs.

Perhaps you noticed that all the examples of longitudinal and cross-sectional research we have considered permit only correlational, not causal, inferences. Yet causal information is desirable, both for testing theories and for finding ways to enhance development. Sometimes researchers can explore the causal link between experiences and development by experimentally manipulating the experiences. If, as a result, development improves, then we have strong evidence for a causal association. Today, research that combines an experimental strategy with either a longitudinal or a cross-sectional approach is becoming increasingly common.

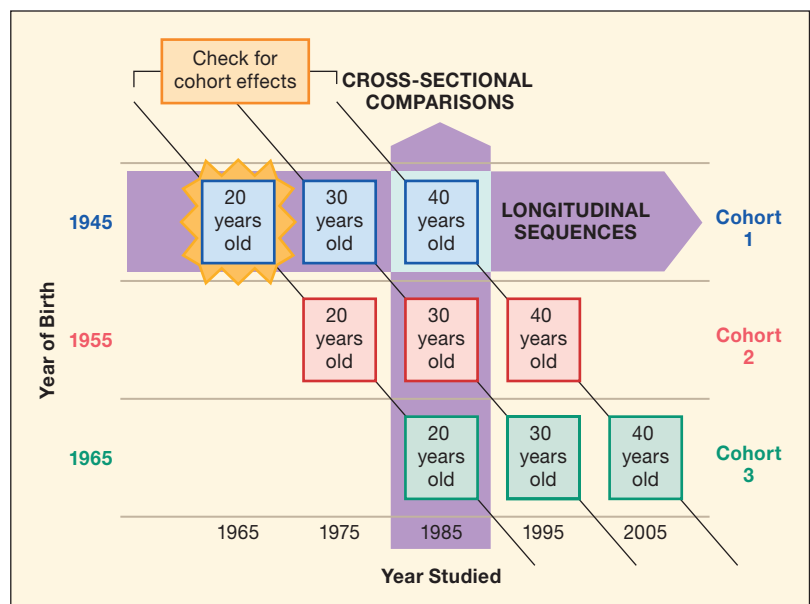

FIGURE 1.7 Example of a sequential design.

Three cohorts, born in 1945 (blue), 1955 (pink), and 1965 (green), are followed longitudinally from 20 to 40 years of age. The design permits the researcher to check for cohort effects by comparing people of the same age who were born in different years. In a study that used this design, the 20-year-olds in Cohort 1 differed substantially from the 20-year-olds in Cohorts 2 and 3, indicating powerful history-graded influences. This design also permits longitudinal and cross-sectional comparisons. Similar findings lend additional confidence in the results.

ASK YOURSELF

REVIEW Explain how cohort effects can affect the findings of both longitudinal and cross-sectional studies. How do sequential designs reveal cohort effects?

CONNECT Review the study of the Family Check-Up, described on page 35. Explain how it combines an experimental with a developmental design. What are the independent and dependent variables? Is its developmental approach longitudinal or cross-sectional?

APPLY A researcher compares older adults with chronic heart disease to those with no major health problems and finds that the first group scores lower on mental tests. Can the researcher conclude that heart disease causes a decline in intellectual functioning in late adulthood? Explain.

REFLECT Suppose a researcher asks you to enroll your baby in a 10-year longitudinal study. What factors would lead you to agree and stay involved? Do your answers shed light on why longitudinal studies often have biased samples?

agencies, and by research-oriented associations, such as the American Psychological Association (2002) and the Society for Research in Child Development (2007). Table 1.7 presents a summary of basic research rights drawn from these guidelines. **TAKE A MOMENT...** After examining them, read about the following research situations, each of which poses a serious ethical dilemma. What precautions do you think should be taken in each instance?

- In a study of moral development, an investigator wants to assess children's ability to resist temptation by videotaping their behavior without their knowledge. She promises 7-year-olds a prize for solving difficult puzzles but tells them not to look at a classmate's correct solutions, which are deliberately placed at the back of the room. Informing children ahead of time that cheating is being studied or that their behavior is being monitored will destroy the purpose of the study.
- A researcher wants to study the impact of mild daily exercise on the physical and mental health of elderly patients in nursing homes. He consults each resident's doctor to make sure that the exercise routine will not be harmful. But when he seeks the residents' consent, he finds that many do not comprehend the purpose of the research. And some appear to agree simply to relieve feelings of isolation and loneliness.

As these examples indicate, when children or the aged take part in research, the ethical concerns are especially complex. Immaturity makes it difficult or impossible for children to evaluate for themselves what participation in research will mean. And because mental impairment rises with very advanced age, some older adults cannot make voluntary and informed choices (Dubois et al., 2011; Society for Research in Child Development, 2007). And the life circumstances of others make them unusually vulnerable to pressure for participation.

Ethics in Lifespan Research

Research into human behavior creates ethical issues because, unfortunately, the quest for scientific knowledge can sometimes exploit people. For this reason, special guidelines for research have been developed by the federal government, by funding

TABLE 1.7 Rights of Research Participants

RESEARCH RIGHT	DESCRIPTION
Protection from harm	Participants have the right to be protected from physical or psychological harm in research. If in doubt about the harmful effects of research, investigators should seek the opinion of others. When harm seems possible, investigators should find other means for obtaining the desired information or abandon the research.
Informed consent	All participants, including children and the elderly, have the right to have explained to them, in language appropriate to their level of understanding, all aspects of the research that may affect their willingness to participate. When children are participants, informed consent of parents as well as of others who act on the child's behalf (such as school officials) should be obtained, preferably in writing. Older adults who are cognitively impaired should be asked to appoint a surrogate decision maker. If they cannot do so, then someone should be named by an institutional review board (IRB) after careful consultation with relatives and professionals who know the person well. All participants have the right to discontinue participation in the research at any time.
Privacy	Participants have the right to concealment of their identity on all information collected in the course of research. They also have this right with respect to written reports and any informal discussions about the research.
Knowledge of results	Participants have the right to be informed of the results of research in language that is appropriate to their level of understanding.
Beneficial treatments	If experimental treatments believed to be beneficial are under investigation, participants in control groups have the right to alternative beneficial treatments if they are available.

Sources: American Psychological Association, 2002; Society for Research in Child Development, 2007.

PIERRE ANDRIEU/AFP/GETTY IMAGES

Older adults should not be arbitrarily excluded from research. Most require only typical informed-consent procedures, and their participation brings both personal and scientific benefits. But for some elders, including those who reside in settings for the chronically ill, informed consent may necessitate the assistance of a surrogate decision maker.

Virtually every organization that has devised ethical principles for research has concluded that conflicts arising in research situations often do not have simple right-or-wrong answers. The ultimate responsibility for the ethical integrity of research lies with the investigator. But researchers are advised—and often required—to seek advice from others. Committees for this purpose exist in colleges, universities, and other institutions. These *institutional review boards (IRBs)* weigh the costs of the research to participants in terms of inconvenience and possible psychological or physical injury against the study's value for advancing knowledge and improving conditions of life. If there are any risks to participants' safety and welfare that the research does not justify, then preference is always given to the participants' interests.

The ethical principle of *informed consent* requires special interpretation when participants cannot fully appreciate the research goals and activities. Parental consent is meant to protect the safety of children, whose ability to decide is not yet mature. But as soon as children are old enough to appreciate the purpose of the research, and certainly by age 7, their own informed consent should be obtained in addition to parental consent. Around this age, changes in children's thinking permit them to better understand basic scientific principles and the needs of others. Researchers should respect and enhance these new capacities by giving school-age children a full explanation of research activities in language they can understand (Fisher, 1993). Extra care must be taken when telling children that the information they provide will be kept confidential and that they can end their participation at any time. Even adolescents may not understand, and sometimes do not believe, these promises (Bruzzese & Fisher, 2003; Ondrusek et al., 1998).

Most older adults require no more than the usual informed-consent procedures. Yet many investigators set upper age limits in studies relevant to the elderly, thereby excluding the oldest

adults (Bayer & Tadd, 2000). Older adults should not be stereotyped as incompetent to decide about their own participation or to engage in research activities. Nevertheless, extra measures must be taken to protect those who are cognitively impaired or who reside in settings for the chronically ill. As noted, some individuals may agree to participate simply to engage in rewarding social interaction. Yet participation should not be automatically withheld, since it can result in personal as well as scientific benefits. In these instances, potential participants should be asked to appoint a surrogate decision maker. If they cannot do so, then someone should be named by an IRB, after careful consultation with relatives and professionals who know the person well. As an added precaution, if the elderly person is incapable of consenting and the risks of the research are more than minimal, then the study should not be done unless it is likely to benefit the participant directly (Dubois et al., 2011).

Finally, all ethical guidelines advise that special precautions be taken in the use of deception and concealment, as occurs when researchers observe people from behind one-way mirrors, give them false feedback about their performance, or do not tell them the truth about the real purpose of the research. When these kinds of procedures are used, *debriefing*, in which the investigator provides a full account and justification of the activities, occurs after the research session is over. But young children often lack the cognitive skills to understand the reasons for deceptive procedures, and despite explanations, even older children may leave the research situation with their belief in the honesty of adults undermined. Ethical standards permit deception if investigators satisfy IRBs that a study's potential benefits to society are great enough to justify infringing on participants' right to informed consent and risking other harm (Fisher, 2005). Nevertheless, because deception may have serious emotional consequences for some youngsters, many experts in research ethics believe that investigators should use it with children only if the risk of harm is minimal.

ASK YOURSELF

REVIEW What special steps must investigators take in conducting studies of children and the aged to ensure protection from harm and informed consent?

CONNECT In the field experiment on the Family Check-Up (see page 35), why is it ethically important for the researchers to offer the intervention, or a beneficial alternative, to the no-intervention control group after completion of the study?

APPLY As a researcher gathered observations of the activities of several elderly adults with cognitive impairments in a nursing home, one resident said, "Stop watching me!" How should the researcher respond, and why?

REFLECT What ethical safeguards do you regard as vital in conducting research that requires deception of children?

SUMMARY

A Scientific, Applied, and Interdisciplinary Field

(p. 5)

What is developmental science, and what factors stimulated expansion of the field?

- **Developmental science** is an interdisciplinary field devoted to understanding human constancy and change throughout the lifespan. Research on human development has been stimulated by both scientific curiosity and social pressures to improve people's lives.

Basic Issues (p. 5)

Identify three basic issues on which theories of human development take a stand.

- Each **theory** of human development takes a stand on three basic issues: (1) Is development a **continuous** process, or does it proceed in a series of **discontinuous stages**? (2) Does one general course of development characterize all individuals, or do many possible courses exist, depending on the distinct **contexts** in which children and adults live? (3) Is development determined primarily by genetic or environmental factors (the **nature–nurture controversy**), and are individual differences stable or characterized by substantial **plasticity**?

The Lifespan Perspective: A Balanced Point of View

(p. 7)

Describe the lifespan perspective on development.

- The **lifespan perspective** is a balanced view that envisions development as a dynamic system. It is based on assumptions that development is lifelong, multidimensional (affected by biological, psychological, and social forces), multidirectional (a joint expression of growth and decline), and plastic (open to change through new experiences).

© AURORA PHOTOS/ROBERT HARDING

- According to the lifespan perspective, the life course is influenced by multiple, interacting forces, which can be organized into three categories: (1) **age-graded influences**, which are predictable in timing and duration; (2) **history-graded influences**, unique to a particular historical era; and (3) **nonnormative influences**, unique to one or a few individuals.

Scientific Beginnings (p. 14)

Describe the major early influences on the scientific study of development.

- Darwin's theory of evolution influenced important developmental theories and inspired scientific child study. In the early twentieth century, Hall and Gesell introduced the **normative approach**, which produced a large body of descriptive facts about development.

© LISA F. YOUNG/ALAMY

- Binet and Simon constructed the first successful intelligence test, which sparked interest in individual differences in development and led to a heated controversy over nature versus nurture.

Mid-Twentieth-Century Theories (p. 15)

What theories influenced human development research in the mid-twentieth century?

- In the 1930s and 1940s, psychiatrists and social workers turned to the **psychoanalytic perspective** for help in treating people's emotional problems. In Freud's **psychosexual theory**, the individual moves through five stages, during which three portions of the personality—id, ego, and superego—become integrated. Erikson's **psychosocial theory** expands Freud's theory by emphasizing the development of culturally relevant attitudes and skills and the lifespan nature of development.

ANTONIA TOZER/GETTY IMAGES/AWL IMAGES RM

- As the psychoanalytic perspective gained in prominence, **behaviorism** and **social learning theory** emerged, emphasizing the study of directly observable events—stimuli and responses—and the principles of conditioning and modeling. These approaches led to the use of **behavior modification** to eliminate undesirable behaviors and increase desirable responses.
- In contrast to behaviorism, Piaget's **cognitive-developmental theory** emphasizes children's active role in constructing knowledge as they manipulate and explore their world. According to Piaget, children move through four stages, from the baby's sensorimotor action patterns to the adolescent's capacity for abstract, systematic thinking. Piaget's work has stimulated a wealth of research on children's thinking and encouraged educational programs that emphasize discovery learning.

Recent Theoretical Perspectives (p. 20)

Describe recent theoretical perspectives on human development.

- **Information processing** views the mind as a complex symbol-manipulating system, much like a computer. Because this approach provides precise accounts of how children and adults tackle cognitive tasks, its findings have important implications for education.
- Researchers in **developmental cognitive neuroscience** study the relationship between changes in the brain and the development of cognitive processing and behavior patterns. They have made progress in identifying the types of experiences to which the brain is sensitive at various ages and in clarifying the brain bases of many learning and behavior disorders.

- Three contemporary perspectives emphasize contexts of development. **Ethology** stresses the adaptive value of behavior and inspired the **sensitive period** concept. In **evolutionary developmental psychology**, which extends this emphasis, researchers seek to understand the person–environment system throughout the lifespan.

- Vygotsky's **sociocultural theory**, which focuses on how culture is transmitted from one generation to the next through social interaction, views cognitive development as a socially mediated process. Through cooperative dialogues with more expert members of society, children come to use language to guide their own thought and actions and acquire culturally relevant knowledge and skills.
- **Ecological systems theory** views the individual as developing within a complex system of relationships affected by multiple, nested layers of the surrounding environment—**microsystem**, **mesosystem**, **exosystem**, and **macrosystem**. The **chronosystem** represents the dynamic, ever-changing nature of individuals and their experiences.

Comparing and Evaluating Theories (p. 27)

Identify the stand taken by each major theory on the three basic issues of human development.

- Theories vary in their focus on different domains of development, in their view of how development occurs, and in their strengths and weaknesses. (For a full summary, see Table 1.4 on page 28.)

Studying Development (p. 27)

Describe methods commonly used in research on human development.

- **Naturalistic observations**, gathered in everyday environments, permit researchers to see directly the everyday behaviors they hope to explain. In contrast, **structured observations**, which take place in laboratories, give every participant an equal opportunity to display the behaviors of interest.
- Self-report methods can be flexible and open-ended like the **clinical interview**, which permits participants to express their thoughts in ways similar to their thinking in everyday life. Alternatively, **structured interviews** (including tests and questionnaires) are more efficient, permitting researchers to ask about activities and behaviors that participants may not think of in an open-ended interview. Investigators use the **clinical**, or **case study**, method to gain an in-depth understanding of a single individual.
- Researchers have adapted observational and self-report methods to permit direct comparisons of cultures. To uncover the cultural meanings of behavior, they rely on **ethnography**, engaging in participant observation.

Distinguish between correlational and experimental research designs, noting the strengths and limitations of each.

- The **correlational design** examines relationships between variables without altering people's experiences. The **correlation coefficient** is often used to measure the association between variables. Correlational studies do not permit inferences about cause and effect, but they can identify relationships that are worth exploring with a more powerful experimental strategy.
- An **experimental design** permits cause-and-effect inferences. Researchers manipulate an **independent variable** by exposing participants to two or more treatment conditions. Then they determine what effect this variable has on a **dependent variable**. **Random assignment** to treatment conditions reduces the chances that participant characteristics will affect the accuracy of experimental findings.
- Field and natural, or quasi-, experiments compare treatments in natural environments. However, these approaches are less rigorous than laboratory experiments.

Describe designs for studying development, noting the strengths and limitations of each.

- In the **longitudinal design**, participants are studied repeatedly over time, permitting researchers to identify common patterns and individual differences in development and to examine relationships between early and later events and behaviors. Longitudinal research poses several problems, including biased sampling, practice effects, and **cohort effects**—difficulty generalizing to people developing at other historical times.

- The **cross-sectional design**, in which groups of people differing in age are studied at the same point in time, is an efficient way to study age-related trends, but it is limited to comparisons of age-group averages. Cross-sectional studies, especially those that cover a wide age span, are also vulnerable to cohort effects.
- By comparing participants of the same age who were born in different years, investigators use **sequential designs** to discover whether cohort effects are operating. When sequential designs combine longitudinal and cross-sectional strategies, researchers can see if outcomes are similar, adding confidence to their findings.
- When researchers combine experimental and developmental designs, they can examine causal influences on development.

Ethics in Lifespan Research (p. 39)

What special ethical concerns arise in research on human development?

- Because the quest for scientific knowledge has the potential to exploit people, the ethical principle of informed consent requires special safeguards for children and for elderly people who are cognitively impaired or who live in settings for the care of the chronically ill. The use of deception in research with children is especially risky because it may undermine their basic faith in the honesty of adults.

Important Terms and Concepts

age-graded influences (p. 10)	ecological systems theory (p. 24)	normative approach (p. 15)
behavior modification (p. 18)	ethnography (p. 32)	plasticity (p. 7)
behaviorism (p. 17)	ethology (p. 22)	psychoanalytic perspective (p. 15)

chapter 2

© ELLEN B. SENISI PHOTOGRAPHY

Heredity and environment combine in intricate ways, making members of this large extended family both alike and different in physical characteristics and behavior.

Genetic and Environmental Foundations

“It’s a girl!” announces the doctor, holding up the squalling newborn baby as her parents gaze with amazement at their miraculous creation.

“A girl! We’ve named her Sarah!” exclaims the proud father to eager relatives waiting for news of their new family member.

As we join these parents in thinking about how this wondrous being came into existence and imagining her future, we are struck by many questions. How could this baby, equipped with everything necessary for life outside the womb, have developed from the union of two tiny cells? What ensures that Sarah will, in due time, roll over, walk, talk, make friends, learn, imagine, and create—just like other typical children born before her? Why is she a girl and not a boy, dark-haired rather than blond, calm and cuddly instead of wiry and energetic? What difference will it make that Sarah is given a name and place in one family, community, nation, and culture rather than another?

To answer these questions, this chapter takes a close look at the foundations of development: heredity and environment. Because nature has prepared us for survival, all humans have features in common. Yet each of us is also unique. **TAKE A MOMENT...** Think about several of your friends, and jot down the most obvious physical and behavioral similarities between them and their parents. Did you find that one person shows combined features of both parents, another resembles just one parent, whereas a third is not like either parent? These directly observable characteristics are called **phenotypes**. They depend in part on the individual’s **genotype**—the complex blend of genetic information that determines our species and influences all our unique characteristics. Yet phenotypes are also affected by each person’s lifelong history of experiences.

We begin our discussion with a review of basic genetic principles that help explain similarities and differences among us in appearance and behavior. Then we turn to aspects of the environment that play powerful roles throughout the lifespan. Finally, we consider the question of how nature and nurture *work together* to shape the course of development. ●

Understanding the Relationship Between Heredity and Environment

The Question, “How Much?” • The Question, “How?”

■ **BIOLOGY AND ENVIRONMENT** A Case of Epigenesis: Smoking During Pregnancy Alters Gene Expression

Genetic Foundations

Each of us is made up of trillions of units called *cells*. Within every cell (except red blood cells) is a control center, or *nucleus*, containing rodlike structures called **chromosomes**, which store and transmit genetic information. Human chromosomes come in 23 matching pairs (an exception is the XY pair in males, which we will discuss shortly). Each member of a pair corresponds to the other in size, shape, and genetic functions, with one chromosome inherited from the mother and one from the father (see Figure 2.1).

The Genetic Code

Chromosomes are made up of a chemical substance called **deoxyribonucleic acid**, or **DNA**. As Figure 2.2 shows, DNA is a long, double-stranded molecule that looks like a twisted ladder. Each rung of the ladder consists of a specific pair of chemical substances called *bases*, joined together between the two sides. It is this sequence of base pairs that provides genetic instructions. A **gene** is a segment of DNA along the length of the chromosome. Genes can be of different lengths—perhaps 100 to several thousand ladder rungs long. An estimated 20,000 to 25,000 genes lie along the human chromosomes (Human Genome Project, 2008).

We share some of our genetic makeup with even the simplest organisms, such as bacteria and molds, and most of it with other mammals, especially primates. Between 98 and 99 percent of chimpanzee and human DNA is identical. This means that only a small portion of our heredity is responsible for the traits that make us human, from our upright gait to our extraordinary language and cognitive capacities. And the genetic variation from one human to the next is even less! Individuals around the world are about 99.1 percent genetically identical (Gibbons et al., 2004). But it takes a change in only a single base pair to influence human traits. And such tiny changes can combine

in unique ways across multiple genes, thereby amplifying variability within the human species.

A unique feature of DNA is that it can duplicate itself through a process called **mitosis**. This special ability permits the one-celled fertilized ovum to develop into a complex human being composed of a great many cells. Refer again to Figure 2.2, and you will see that during mitosis, the chromosomes copy themselves. As a result, each new body cell contains the same number of chromosomes and genetic information.

Genes accomplish their task by sending instructions for making a rich assortment of proteins to the *cytoplasm*, the area surrounding the cell nucleus. Proteins, which trigger chemical reactions throughout the body, are the biological foundation on which our characteristics are built. How do humans, with far fewer genes than scientists once thought (only twice as many as the worm or fly), manage to develop into such complex beings? The answer lies in the proteins our genes make, which break up and reassemble in staggering variety—about 10 to 20 million altogether. Simpler species have far fewer proteins. Furthermore, the communication system between the cell nucleus and cytoplasm, which fine-tunes gene activity, is more intricate in humans than in simpler organisms. Within the cell, wide-ranging environmental factors modify gene expression (Lashley, 2007). So even at this microscopic level, biological events are the result of *both* genetic and nongenetic forces.

The Sex Cells

New individuals are created when two special cells called **gametes**, or sex cells—the sperm and ovum—combine. A gamete contains only 23 chromosomes, half as many as a regular body cell. Gametes are formed through a cell division process called **meiosis**, which halves the number of chromosomes normally present in body cells. When sperm and ovum unite at conception, the resulting cell, called a **zygote**, will again have 46 chromosomes.

FIGURE 2.1 A karyotype, or photograph, of human chromosomes. The 46 chromosomes shown on the left were isolated from a human cell, stained, greatly magnified, and arranged in pairs according to decreasing size of the upper “arm” of each chromosome. The twenty-third pair, XY, reveals that the cell donor is a male. In a female, this pair would be XX. (© CNRI/Science Photo Library/Photo Researchers, Inc.)

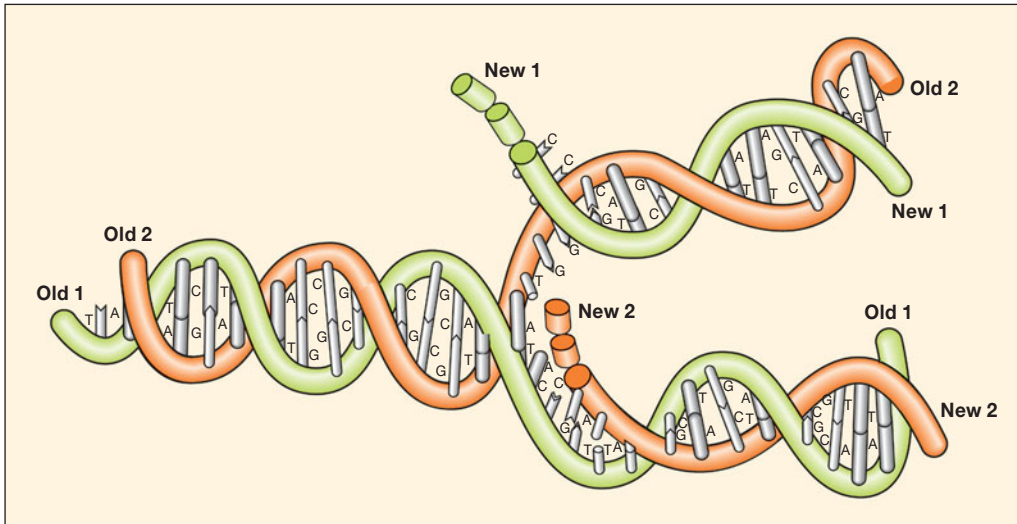

FIGURE 2.2 DNA's ladder-like structure. This figure shows that the pairings of bases across the rungs of the ladder are very specific: Adenine (A) always appears with thymine (T), and cytosine (C) always appears with guanine (G). Here, the DNA ladder duplicates by splitting down the middle of its ladder rungs. Each free base picks up a new complementary partner from the area surrounding the cell nucleus.

In meiosis, the chromosomes pair up and exchange segments, so that genes from one are replaced by genes from another. Then chance determines which member of each pair will gather with others and end up in the same gamete. These events make the likelihood extremely low—about 1 in 700 trillion—that nontwin siblings will be genetically identical (Gould & Keeton, 1996). The genetic variability produced by meiosis is adaptive: It increases the chances that at least some members of a species will cope with ever-changing environments and will survive.

In the male, four sperm are produced when meiosis is complete. Also, the cells from which sperm arise are produced continuously throughout life. For this reason, a healthy man can father a child at any age after sexual maturity. In the female, meiosis results in just one ovum. In addition, the female is born with a bank of ova already present in her ovaries, though recent findings suggest that new ova may arise from ovarian stem cells later on (White et al., 2012). Nevertheless, females can bear children for only three to four decades. Still, there are plenty of female sex cells. About 1 to 2 million are present at birth, 40,000 remain at adolescence, and approximately 350 to 450 will mature during a woman's childbearing years (Moore, Persaud, & Torchia, 2013).

Boy or Girl?

Return to Figure 2.1 and note that 22 of the 23 pairs of chromosomes are matching pairs, called **autosomes** (meaning *not* sex chromosomes). The twenty-third pair consists of **sex chromosomes**. In females, this pair is called XX; in males, it is called XY. The X is a relatively large chromosome, whereas the Y is short and carries little genetic material. When gametes form in males, the X and Y chromosomes separate into different sperm cells. The gametes that form in females all carry an X chromosome. Therefore, the sex of the new organism is determined by whether an X-bearing or a Y-bearing sperm fertilizes the ovum.

Multiple Offspring

Ruth and Peter, a couple I know well, tried for several years to have a child, without success. When Ruth reached age 33, her doctor prescribed a fertility drug, and twins—Jeannie and Jason—were born. Jeannie and Jason are **fraternal, or dizygotic, twins**, the most common type of multiple offspring, resulting from the release and fertilization of two ova. Genetically, they are no more alike than ordinary siblings. Table 2.1 summarizes genetic and environmental factors that

TABLE 2.1 Maternal Factors Linked to Fraternal Twinning

FACTOR	DESCRIPTION
Ethnicity	Occurs in 4 per 1,000 births among Asians, 8 per 1,000 births among whites, 12 to 16 per 1,000 births among blacks ^a
Family history of twinning	Occurs more often among women whose mothers and sisters gave birth to fraternal twins
Age	Rises with maternal age, peaking between 35 and 39 years, and then rapidly falls
Nutrition	Occurs less often among women with poor diets; occurs more often among women who are tall and overweight or of normal weight as opposed to slight body build
Number of births	Is more likely with each additional birth
Fertility drugs and in vitro fertilization	Is more likely with fertility hormones and in vitro fertilization (see page 54), which also increase the chances of bearing triplets, quadruplets, or quintuplets

^aWorldwide rates, not including multiple births resulting from use of fertility drugs. Sources: Hall, 2003; Hoekstra et al., 2008; Lashley, 2007.

© FAFOTO/ALAMY

These identical, or monozygotic, twins were created when a duplicating zygote separated into two clusters of cells, which developed into two individuals with the same genetic makeup.

increase the chances of giving birth to fraternal twins. Older maternal age, fertility drugs, and in vitro fertilization (to be discussed shortly) are major causes of the dramatic rise in fraternal twinning and other multiple births in industrialized nations over the past several decades (Machin, 2005; Russell et al., 2003). Currently, fraternal twins account for 1 in about every 60 births in the United States (U.S. Department of Health and Human Services, 2010a).

Twins can be created in another way. Sometimes a zygote that has started to duplicate separates into two clusters of cells that develop into two individuals. These are called **identical, or monozygotic, twins** because they have the same genetic makeup. The frequency of identical twins is the same around the world—about 1 in every 330 births (Hall, 2003). Animal research has uncovered a variety of environmental influences that prompt this type of twinning, including temperature changes, variation in oxygen levels, and late fertilization of the ovum. In a minority of cases, the identical twinning runs in families, suggesting a genetic influence (Lashley, 2007).

During their early years, children of single births often are healthier and develop more rapidly than twins. Jeannie and Jason, like most twins, were born early—three weeks before Ruth's due date. And, like other premature infants—as you will see in Chapter 3—they required special care after birth. When the twins came home from the hospital, Ruth and Peter had to divide time between them. Perhaps because neither baby received as much attention as the average single infant, Jeannie and Jason walked and talked several months later than most other children their age, though both caught up by middle childhood (Lytton & Gallagher, 2002). Parental energies are further strained after the birth of triplets, whose early development is slower than that of twins (Feldman, Eidelman, & Rotenberg, 2004).

Patterns of Genetic Inheritance

Jeannie has her parents' dark, straight hair; Jason is curly-haired and blond. Patterns of genetic inheritance—the way genes from each parent interact—explain these outcomes. Recall that, except for the XY pair in males, all chromosomes come in matching pairs. Two forms of each gene occur at the same place on the chromosomes, one inherited from the mother and one from the father. Each form of a gene is called an **allele**. If the alleles from both parents are alike, the child is **homozygous** and will display the inherited trait. If the alleles differ, then the child is **heterozygous**, and relationships between the alleles determine the phenotype.

Dominant–Recessive Inheritance. In many heterozygous pairings, **dominant–recessive inheritance** occurs: Only one allele affects the child's characteristics. It is called *dominant*; the second allele, which has no effect, is called *recessive*. Hair color is an example. The allele for dark hair is dominant (we can represent it with a capital *D*), whereas the one for blond hair is recessive (symbolized by a lowercase *b*). A child who inherits a homozygous pair of dominant alleles (*DD*) and a child who inherits a heterozygous pair (*Db*) will both be dark-haired, even though their genotypes differ. Blond hair (like Jason's) can result only from having two recessive alleles (*bb*). Still, heterozygous individuals with just one recessive allele (*Db*) can pass that trait to their children. Therefore, they are called **carriers** of the trait.

Some human characteristics that follow the rules of dominant–recessive inheritance are listed in Tables 2.2 and 2.3.

TABLE 2.2 Examples of Dominant and Recessive Characteristics

DOMINANT	RECESSIVE
Dark hair	Blond hair
Normal hair	Pattern baldness
Curly hair	Straight hair
Nonred hair	Red hair
Facial dimples	No dimples
Normal hearing	Some forms of deafness
Normal vision	Nearsightedness
Farsightedness	Normal vision
Normal vision	Congenital eye cataracts
Normally pigmented skin	Albinism
Double-jointedness	Normal joints
Type A blood	Type O blood
Type B blood	Type O blood
Rh-positive blood	Rh-negative blood

Note: Many normal characteristics that were previously thought to be due to dominant–recessive inheritance, such as eye color, are now regarded as due to multiple genes. For the characteristics listed here, there still seems to be general agreement that the simple dominant–recessive relationship holds.

TABLE 2.3 Examples of Dominant and Recessive Diseases

DISEASE	DESCRIPTION	MODE OF INHERITANCE	INCIDENCE	TREATMENT
AUTOSOMAL DISEASES				
Cooley's anemia	Pale appearance, retarded physical growth, and lethargic behavior begin in infancy.	Recessive	1 in 500 births to parents of Mediterranean descent	Frequent blood transfusion; death from complications usually occurs by adolescence.
Cystic fibrosis	Lungs, liver, and pancreas secrete large amounts of thick mucus, leading to breathing and digestive difficulties.	Recessive	1 in 2,000 to 2,500 Caucasian births; 1 in 16,000 births to North Americans of African descent	Bronchial drainage, prompt treatment of respiratory infection, dietary management. Advances in medical care allow survival with good life quality into adulthood.
Phenylketonuria (PKU)	Inability to metabolize the amino acid phenylalanine, contained in many proteins, causes severe central nervous system damage in the first year of life.	Recessive	1 in 8,000 births	Placing the child on a special diet results in average intelligence and normal lifespan. Subtle deficits in memory, planning, decision making, and problem solving are often present.
Sickle cell anemia	Abnormal sickling of red blood cells causes oxygen deprivation, pain, swelling, and tissue damage. Anemia and susceptibility to infections, especially pneumonia, occur.	Recessive	1 in 500 births to North Americans of African descent	Blood transfusions, painkillers, prompt treatment of infection. No known cure; 50 percent die by age 55.
Tay-Sachs disease	Central nervous system degeneration, with onset at about 6 months, leads to poor muscle tone, blindness, deafness, and convulsions.	Recessive	1 in 3,600 births to Jews of European descent and to French Canadians	None. Death occurs by 3 to 4 years of age.
Huntington disease	Central nervous system degeneration leads to muscular coordination difficulties, mental deterioration, and personality changes. Symptoms usually do not appear until age 35 or later.	Dominant	1 in 18,000 to 25,000 births to North Americans	None. Death occurs 10 to 20 years after symptom onset.
Marfan syndrome	Tall, slender build; thin, elongated arms and legs; and heart defects and eye abnormalities, especially of the lens. Excessive lengthening of the body results in a variety of skeletal defects.	Dominant	1 in 5,000 to 10,000 births	Correction of heart and eye defects is sometimes possible. Death from heart failure in young adulthood is common.
X-LINKED DISEASES				
Duchenne muscular dystrophy	Degenerative muscle disease. Abnormal gait, loss of ability to walk between 7 and 13 years of age.	Recessive	1 in 3,000 to 5,000 male births	None. Death from respiratory infection or weakening of the heart muscle usually occurs in adolescence.
Hemophilia	Blood fails to clot normally; can lead to severe internal bleeding and tissue damage.	Recessive	1 in 4,000 to 7,000 male births	Blood transfusions. Safety precautions to prevent injury.
Diabetes insipidus	Insufficient production of the hormone vasopressin results in excessive thirst and urination. Dehydration can cause central nervous system damage.	Recessive	1 in 2,500 male births	Hormone replacement.

Note: For recessive disorders listed, carrier status can be detected in prospective parents through a blood test or genetic analyses. For all disorders listed, prenatal diagnosis is available (see page 56).

Sources: Kliegman et al., 2008; Lashley, 2007; McKusick, 2011.

As you can see, many disabilities and diseases are the product of recessive alleles. One of the most frequently occurring recessive disorders is *phenylketonuria*, or *PKU*, which affects the way the body breaks down proteins contained in many foods. Infants born with two recessive alleles lack an enzyme that converts one of the basic amino acids that make up proteins (phenylalanine) into a byproduct essential for body functioning (tyrosine). Without this enzyme, phenylalanine quickly builds to toxic levels that damage the central nervous system. By 1 year, infants with PKU are permanently mentally retarded.

Despite its potentially damaging effects, PKU provides an excellent illustration of the fact that inheriting unfavorable genes does not always lead to an untreatable condition. All U.S. states require that each newborn be given a blood test for PKU. If the disease is found, doctors place the baby on a diet low in phenylalanine. Children who receive this treatment nevertheless show mild deficits in certain cognitive skills, such as memory, planning, decision making, and problem solving, because even small amounts of phenylalanine interfere with brain functioning (DeRoche & Welsh, 2008). But as long as dietary treatment begins early and continues, children with PKU usually attain an average level of intelligence and have a normal lifespan.

In dominant–recessive inheritance, if we know the genetic makeup of the parents, we can predict the percentage of children in a family who are likely to display or carry a trait. Figure 2.3 illustrates this for PKU. For a child to inherit the condition, each parent must have a recessive allele.

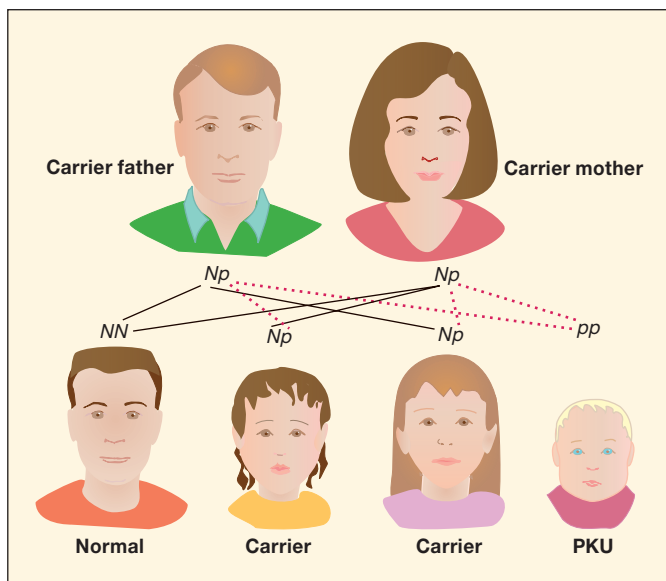

FIGURE 2.3 Dominant–recessive mode of inheritance, as illustrated by PKU. When both parents are heterozygous carriers of the recessive gene (p), we can predict that 25 percent of their offspring are likely to be normal (NN), 50 percent are likely to be carriers (Np), and 25 percent are likely to inherit the disorder (pp). Notice that the PKU-affected child, in contrast to his siblings, has light hair. The recessive gene for PKU affects more than one trait. It also leads to fair coloring.

Only rarely are serious diseases due to dominant alleles. Think about why this is so. Children who inherit the dominant allele always develop the disorder. They seldom live long enough to reproduce, so the harmful dominant allele is eliminated from the family's heredity in a single generation. Some dominant disorders, however, do persist. One is *Huntington disease*, a condition in which the central nervous system degenerates. Why has this disorder endured? Its symptoms usually do not appear until age 35 or later, after the person has passed the dominant gene to his or her children.

Incomplete Dominance. In some heterozygous circumstances, the dominant–recessive relationship does not hold completely. Instead, we see **incomplete dominance**, a pattern of inheritance in which both alleles are expressed in the phenotype, resulting in a combined trait, or one that is intermediate between the two.

The *sickle cell trait*, a heterozygous condition present in many black Africans, provides an example. *Sickle cell anemia* (see Table 2.3) occurs in full form when a child inherits two recessive genes. They cause the usually round red blood cells to become sickle (crescent-moon) shaped, especially under low-oxygen conditions. The sickled cells clog the blood vessels and block the flow of blood, causing intense pain, swelling, and tissue damage. Despite medical advances that today allow 85 percent of affected children to survive to adulthood, North Americans with sickle cell anemia have an average life expectancy of only 55 years (Driscoll, 2007). Heterozygous individuals are protected from the disease under most circumstances. However, when they experience oxygen deprivation—for example, at high altitudes or after intense physical exercise—the single recessive allele asserts itself, and a temporary, mild form of the illness occurs.

The sickle cell allele is common among black Africans for a special reason. Carriers of it are more resistant to malaria than are individuals with two alleles for normal red blood cells. In Africa, where malaria is common, these carriers survived and reproduced more frequently than others, leading the gene to be maintained in the black population. But in regions of the world where the risk of malaria is low, the frequency of the gene is declining. For example, only 8 percent of African Americans are carriers, compared with 20 percent of black Africans (National Center for Biotechnology Information, 2007).

X-Linked Inheritance. Males and females have an equal chance of inheriting recessive disorders carried on the autosomes, such as PKU and sickle cell anemia. But when a harmful allele is carried on the X chromosome, **X-linked inheritance** applies. Males are more likely to be affected because their sex chromosomes do not match. In females, any recessive allele on one X chromosome has a good chance of being suppressed by a dominant allele on the other X. But the Y chromosome is only about one-third as long and therefore lacks many corresponding genes to override those on the X. A well-known example is *hemophilia*, a disorder in which the blood fails to clot normally.

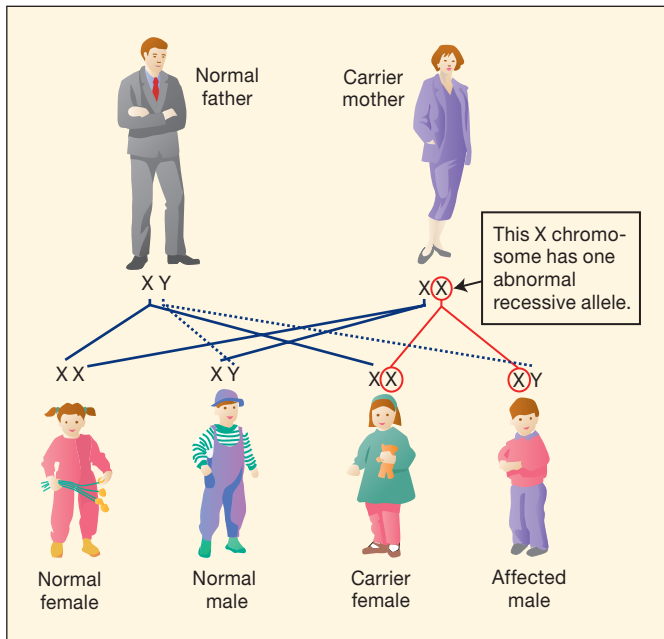

FIGURE 2.4 X-linked inheritance. In the example shown here, the allele on the father's X chromosome is normal. The mother has one normal and one abnormal recessive allele on her X chromosomes. By looking at the possible combinations of the parents' alleles, we can predict that 50 percent of these parents' male children are likely to have the disorder and 50 percent of their female children are likely to be carriers of it.

Figure 2.4 shows its greater likelihood of inheritance by male children whose mothers carry the abnormal allele.

Besides X-linked disorders, many sex differences reveal the male to be at a disadvantage. Rates of miscarriage, infant and childhood deaths, birth defects, learning disabilities, behavior disorders, and mental retardation all are higher for boys (Butler & Meaney, 2005). It is possible that these sex differences can be traced to the genetic code. The female, with two X chromosomes, benefits from a greater variety of genes. Nature, however, seems to have adjusted for the male's disadvantage. Worldwide, about 106 boys are born for every 100 girls, and judging from miscarriage and abortion statistics, an even greater number of males are conceived (United Nations, 2011).

Nevertheless, in recent decades the proportion of male births has declined in many industrialized countries, including the United States, Canada, and European nations (Jongbloet et al., 2001). Some researchers attribute the trend to a rise in stressful living conditions, which heighten spontaneous abortions, especially of male fetuses (Catalano et al., 2010). In support of this hypothesis, a California study spanning the decade of the 1990s revealed that the percentage of male fetal deaths increased in months in which unemployment (a major stressor) also rose above its typical level (Catalano et al., 2009).

Genomic Imprinting. More than 1,000 human characteristics follow the rules of dominant–recessive and incomplete-dominance inheritance (McKusick, 2011). In these cases,

whichever parent contributes a gene to the new individual, the gene responds in the same way. Geneticists, however, have identified some exceptions. In **genomic imprinting**, alleles are *imprinted*, or chemically *marked*, so that one pair member (either the mother's or the father's) is activated, regardless of its makeup (Hirasawa & Feil, 2010). The imprint is often temporary; it may be erased in the next generation, and it may not occur in all individuals.

Imprinting helps us understand certain puzzling genetic patterns. For example, children are more likely to develop diabetes if their father, rather than their mother, suffers from it. And people with asthma or hay fever tend to have mothers, not fathers, with the illness. Imprinting is involved in several childhood cancers and in *Prader-Willi syndrome*, a disorder with symptoms of mental retardation and severe obesity (Butler, 2009). It may also explain why Huntington disease, when inherited from the father, tends to emerge at an earlier age and to progress more rapidly (Gropman & Adams, 2007).

Genomic imprinting can also operate on the sex chromosomes, as *fragile X syndrome*—the most common inherited cause of mental retardation—reveals. In this disorder, which affects about 1 in 4,000 males and 1 in 6,000 females, an abnormal repetition of a sequence of DNA bases occurs on the X chromosome, damaging a particular gene. About 25 to 30 percent of individuals with fragile X syndrome also have symptoms of *autism*, a serious disorder usually diagnosed in early childhood that involves impaired social interaction, delayed or absent language and communication, and repetitive motor behavior (Schwartz, 2008). The defective gene at the fragile site is expressed only when it is passed from mother to child (Hagerman et al., 2009). Because the disorder is X-linked, males are more severely affected.

Mutation. Although less than 3 percent of pregnancies result in the birth of a baby with a hereditary abnormality, these children account for about 20 percent of infant deaths and contribute substantially to lifelong impaired physical and mental functioning (U.S. Department of Health and Human Services, 2010a). How are harmful genes created in the first place? The answer is **mutation**, a sudden but permanent change in a segment of DNA. A mutation may affect only one or two genes, or it may involve many genes, as in the chromosomal disorders we will discuss shortly. Some mutations occur spontaneously, simply by chance. Others are caused by hazardous environmental agents.

Although nonionizing forms of radiation—electromagnetic waves and microwaves—have no demonstrated impact on DNA, ionizing (high-energy) radiation is an established cause of mutation. Women who receive repeated doses before conception are more likely to miscarry or to give birth to children with hereditary defects. The incidence of genetic abnormalities, such as physical malformations and childhood cancer, is also higher in children whose fathers are exposed to radiation in their occupation. However, infrequent and mild exposure to radiation does not cause genetic damage (Jacquet, 2004). Rather, high doses over a long period impair DNA.

The examples just given illustrate *germline mutation*, which takes place in the cells that give rise to gametes. When the affected individual mates, the defective DNA is passed on to the next generation. In a second type, called *somatic mutation*, normal body cells mutate, an event that can occur at any time of life. The DNA defect appears in every cell derived from the affected body cell, eventually becoming widespread enough to cause disease (such as cancer) or disability.

It is easy to see how disorders that run in families can result from germline mutation. But somatic mutation may be involved in these disorders as well. Some people harbor a genetic susceptibility that causes certain body cells to mutate easily in the presence of triggering events (Weiss, 2005). This helps explain why some individuals develop serious illnesses as a result of smoking, exposure to pollutants, or psychological stress, while others do not.

Somatic mutation shows that each of us does not have a single, permanent genotype. Rather, the genetic makeup of each cell can change over time. Somatic mutation increases with age, raising the possibility that it contributes to the age-related rise in disease and to the aging process itself (Salvioli et al., 2008).

Finally, although virtually all mutations that have been studied are harmful, some spontaneous ones (such as the sickle cell allele in malaria-ridden regions of the world) are necessary and desirable. By increasing genetic variation, they help individuals adapt to unexpected environmental challenges. Scientists, however, seldom go looking for mutations that underlie favorable traits, such as an exceptional talent or sturdy immune system. They are far more concerned with identifying and eliminating unfavorable genes that threaten health and survival.

Polygenic Inheritance. So far, we have discussed patterns of inheritance in which people either display a particular trait or do not. These cut-and-dried individual differences are much easier to trace to their genetic origins than are characteristics that vary on a continuum among people, such as height, weight, intelligence, and personality. These traits are due to **polygenic inheritance**, in which many genes influence the characteristic in question. Polygenic inheritance is complex, and much about it is still unknown. In the final section of this chapter, we will discuss how researchers infer the influence of heredity on human attributes when they do not know the precise patterns of inheritance.

Chromosomal Abnormalities

Besides harmful recessive alleles, abnormalities of the chromosomes are a major cause of serious developmental problems. Most chromosomal defects result from mistakes occurring during meiosis, when the ovum and sperm are formed. A chromosome pair does not separate properly, or part of a

chromosome breaks off. Because these errors involve far more DNA than problems due to single genes, they usually produce many physical and mental symptoms.

Down Syndrome. The most common chromosomal disorder, occurring in 1 out of every 770 live births, is *Down syndrome*. In 95 percent of cases, it results from a failure of the twenty-first pair of chromosomes to separate during meiosis, so the new individual receives three of these chromosomes rather than the normal two. For this reason, Down syndrome is sometimes called *trisomy 21*. In other, less frequent forms, an extra broken piece of a twenty-first chromosome is attached to another chromosome (called *translocation* pattern). Or an error occurs during the early stages of mitosis, causing some but not all body cells to have the defective chromosomal makeup (called *mosaic* pattern) (U.S. Department of Health and Human Services, 2012a). Because the mosaic type involves less genetic material, symptoms may be less extreme.

The consequences of Down syndrome include mental retardation, memory and speech problems, limited vocabulary, and slow motor development. Affected individuals also have distinct physical features—a short, stocky build, a flattened face, a protruding tongue, almond-shaped eyes, and (in 50 percent of cases) an unusual crease running across the palm of the hand. In addition, infants with Down syndrome are often born with eye cataracts, hearing loss, and heart and intestinal defects (U.S. Department of Health and Human Services, 2012a). Because of medical advances, fewer individuals with Down syndrome die early than was the case in the past. Many survive into their fifties and a few into their sixties to eighties. However, more than half of affected individuals who live past age 40 show symptoms of *Alzheimer's disease*, the most common form of dementia (Wiseman et al., 2009). Genes on chromosome 21 are linked to this disorder.

© ROBIN NELSON/PHOTOFEST

Despite impaired development, this toddler with Down syndrome benefits from growing up in a stimulating, caring environment. As his physical therapist engages him in water play, he benefits intellectually, physically, and emotionally.

FIGURE 2.5 Risk of Down syndrome and all chromosomal abnormalities by maternal age. Risk rises sharply after age 35. (From R. L. Schonberg & C. J. Tift, 2007, “Birth Defects and Prenatal Diagnosis,” from *Children with Disabilities*, 6/e, M. L. Batshaw, L. Pellegrino, & N. J. Roizen, editors, p. 85. Baltimore: Paul H. Brookes Publishing Co, Inc. Adapted by permission.)

Infants with Down syndrome smile less readily, show poor eye-to-eye contact, have weak muscle tone, and explore objects less persistently (Slonims & McConachie, 2006). But when parents encourage them to engage with their surroundings, Down syndrome children develop more favorably. They also benefit from infant and preschool intervention programs, although emotional, social, and motor skills improve more than intellectual performance (Carr, 2002). Clearly, environmental factors affect how well children with Down syndrome fare.

As Figure 2.5 shows, the risk of bearing a Down syndrome baby rises dramatically with maternal age. But exactly why older mothers are more likely to release ova with meiotic errors is not yet known (Martin, 2008). In about 5 to 10 percent of cases, the extra genetic material originates with the father. Some studies suggest a role for advanced paternal age, while others show no age effects (De Souza, Alberman, & Morris, 2009; Dzurova & Pikhart, 2005; Sherman et al., 2005).

Abnormalities of the Sex Chromosomes. Disorders of the autosomes other than Down syndrome usually disrupt development so severely that miscarriage occurs. When such babies are born, they rarely survive beyond early childhood. In contrast, sex chromosome disorders often are not recognized until adolescence when, in some deviations, puberty is delayed. The most common problems involve the presence of an extra chromosome (either X or Y) or the absence of one X in females.

Research has discredited a variety of myths about individuals with sex chromosome disorders. For example, males with *XXY syndrome* are not necessarily more aggressive and antisocial than XY males. And most children with sex chromosome disorders do not suffer from mental retardation. Rather, their intellectual problems are usually very specific. Verbal difficulties—for

example, with reading and vocabulary—are common among girls with *triple X syndrome* and boys with *Klinefelter syndrome*, both of whom inherit an extra X chromosome. In contrast, girls with *Turner syndrome*, who are missing an X, have trouble with spatial relationships—for example, drawing pictures, telling right from left, following travel directions, and noticing changes in facial expressions (Kesler, 2007; Lawrence et al., 2003; J. L. Simpson et al., 2003). Brain-imaging evidence confirms that adding to or subtracting from the usual number of X chromosomes alters the development of certain brain structures, yielding particular intellectual deficits (Cutter et al., 2006; Itti et al., 2006).

REVIEW Cite evidence indicating that both heredity and environment contribute to the development of individuals with PKU and Down syndrome.

REVIEW Using your knowledge of X-linked inheritance, explain why males are more vulnerable than females to miscarriage, infant death, genetic disorders, and other problems.

CONNECT Referring to ecological systems theory (Chapter 1, pages 24–27), explain why parents of children with genetic disorders often experience increased stress. What factors, within and beyond the family, can help these parents support their children’s development?

APPLY Gilbert’s genetic makeup is homozygous for dark hair. Jan’s is homozygous for blond hair. What proportion of their children are likely to be dark-haired? Explain.

Reproductive Choices

Two years after they married, Ted and Marianne gave birth to their first child. Kendra appeared to be a healthy infant, but by 4 months her growth had slowed, and she was diagnosed with Tay-Sachs disease (see Table 2.3 on page 49). When Kendra died at 2 years of age, Ted and Marianne were devastated. Although they did not want to bring another infant into the world who would endure such suffering, they badly wanted to have a child.

In the past, many couples with genetic disorders in their families chose not to bear a child at all rather than risk the birth of an abnormal baby. Today, genetic counseling and prenatal diagnosis help people make informed decisions about conceiving, carrying a pregnancy to term, or adopting a child.

Genetic Counseling

Genetic counseling is a communication process designed to help couples assess their chances of giving birth to a baby with a hereditary disorder and choose the best course of action in view of risks and family goals (Resta et al., 2006). Individuals

Social Issues: Health

The Pros and Cons of Reproductive Technologies

Some couples decide not to risk pregnancy because of a history of genetic disease. Many others—in fact, one-sixth of all couples who try to conceive—discover that they are infertile. And some never-married adults and gay and lesbian partners want to bear children. Today, increasing numbers of individuals are turning to alternative methods of conception—technologies that, although they fulfill the wish for parenthood, have become the subject of heated debate.

Donor Insemination and In Vitro Fertilization

For several decades, *donor insemination*—injection of sperm from an anonymous man into a woman—has been used to overcome male reproductive difficulties. In recent years, it has also permitted women without a male partner to become pregnant. Donor insemination is 70 to 80 percent successful, resulting in about 40,000 deliveries and 52,000 newborn babies in the United States each year (Wright et al., 2008).

In vitro fertilization is another reproductive technology that has become increasingly common. Since the first “test tube” baby was born in England in 1978, 1 percent of all children in developed countries—about 60,000 babies in the United States—have been conceived through this technique annually (Centers for Disease Control and Prevention, 2011e). With *in vitro* fertilization, a woman is given hormones that stimulate the ripening of several ova. These are removed surgically and placed in a dish of nutrients, to which sperm are added. Once an ovum is fertilized and begins to

duplicate into several cells, it is injected into the mother’s uterus.

By mixing and matching gametes, pregnancies can be brought about when either or both partners have a reproductive problem. Usually, *in vitro* fertilization is used to treat women whose fallopian tubes are permanently damaged. But a recently developed technique permits a single sperm to be injected directly into an ovum, thereby overcoming most male fertility problems. And a “sex sorter” method helps ensure that couples who carry X-linked diseases (which usually affect males) have a daughter. Fertilized ova and sperm can even be frozen and stored in embryo banks for use at some future time, thereby guaranteeing healthy zygotes should age or illness lead to fertility problems.

The overall success rate of *in vitro* fertilization is about 35 percent. However, success declines steadily with age, from 40 percent in women younger than age 35 to 8 percent in women age 43 and older (Pauli et al., 2009).

Children conceived through these methods may be genetically unrelated to one or both of their parents. In addition, most parents who have used *in vitro* fertilization do not tell their children about their origins. Does lack of genetic ties or secrecy surrounding these techniques interfere with parent–child relationships? Perhaps because of a strong desire for parenthood, caregiving is actually somewhat warmer for young children conceived through donor insemination or *in vitro* fertilization. Also, *in vitro* infants are as securely attached to their parents, and *in vitro* children and adolescents as well-adjusted, as their counterparts who were naturally conceived

(Golombok et al., 2004; Punamaki, 2006; Wagenaar et al., 2011).

Although reproductive technologies have many benefits, serious questions have arisen about their use. In many countries, including the United States, doctors are not required to keep records of donor characteristics, though information about the child’s genetic background might be crucial in the case of serious disease (Adamson, 2005). Another concern is that the *in vitro* “sex sorter” method will lead to parental sex selection, thereby eroding the moral value that boys and girls are equally precious.

Furthermore, about 50 percent of *in vitro* procedures result in multiple births. Most are twins, but 9 percent are triplets and higher-order multiples. Consequently, among *in vitro* babies, the rate of low birth weight is nearly three times as high as in the general population (Wright et al., 2008). Risk of major birth defects also doubles because of many factors, including drugs used to induce ripening of ova and delays in fertilizing the ova outside the womb (Machin, 2005; Neri, Takeuchi, & Palermo, 2008). In sum, *in vitro* fertilization poses greater risks than natural conception to infant survival and healthy development.

Surrogate Motherhood

An even more controversial form of medically assisted conception is *surrogate motherhood*. In this procedure, *in vitro* fertilization may be used to impregnate a woman (called a surrogate) with a couple’s fertilized ovum. Alternatively, sperm from a man whose partner is infertile may be used to inseminate the surrogate, who agrees to turn the baby over to the natural father. The child is then adopted by his partner. In both cases, the surrogate is paid a fee for her childbearing services.

likely to seek counseling are those who have had difficulties bearing children—for example, repeated miscarriages—or who know that genetic problems exist in their families. In addition, women who delay childbearing past age 35 are often candidates for genetic counseling. After this time, the overall rate of chromosomal abnormalities rises sharply (refer again to Figure 2.5). But because younger mothers give birth in far greater numbers

than older mothers, they bear the majority of babies with genetic defects. Therefore, some experts argue that maternal needs, not age, should determine referral for genetic counseling (Berkowitz, Roberts, & Minkoff, 2006).

If a family history of mental retardation, psychological disorders, physical defects, or inherited diseases exists, the genetic counselor interviews the couple and prepares a *pedigree*,

Although most of these arrangements proceed smoothly, those that end up in court highlight serious risks for all concerned. In one case, both parties rejected the infant with severe disabilities who resulted from the pregnancy. In several others, the surrogate mother wanted to keep the baby, or the couple changed their mind during the pregnancy. These children came into the world in the midst of conflict that threatened to last for years.

Because surrogacy usually involves the wealthy as contractors for infants and the less economically advantaged as surrogates, it may promote exploitation of financially needy women. In addition, most surrogates already have children of their own, and knowledge that their mother would give away a baby may cause these children to worry about the security of their own family circumstances.

New Reproductive Frontiers

Reproductive technologies are evolving faster than societies can weigh the ethics of these procedures. Doctors have used donor ova from younger women in combination with in vitro fertilization to help postmenopausal women become pregnant. Most recipients are in their forties, but several women in their fifties and sixties, and a few at age 70, have given birth. These cases raise questions about bringing children into the world whose parents may not live to see them reach adulthood. Based on U.S. life expectancy data, 1 in 3 mothers and 1 in 2 fathers having a baby at age 55 will die before their child enters college (U.S. Census Bureau, 2012).

Currently, experts are debating other reproductive options. At donor banks, customers can select ova or sperm on the basis of physical characteristics and even IQ. And scientists are devising ways to alter the

GETTY IMAGES

Fertility drugs and in vitro fertilization often result in multiple births. These quadruplets are healthy, but babies born with the aid of reproductive technologies are at high risk for low birth weight and major birth defects.

DNA of human ova, sperm, and embryos to protect against hereditary disorders—techniques that could be used to engineer other desired characteristics. Many worry that these practices are dangerous steps toward selective breeding through “designer babies”—controlling offspring characteristics by manipulating genetic makeup.

Although new reproductive technologies permit many barren couples to rear healthy newborn babies, laws are needed to regulate such practices. In Australia, New Zealand, Sweden, and Switzerland, individuals conceived with donated gametes have a right to information about their genetic origins (Frith, 2001). Pressure from those working in the field of assisted reproduction may soon lead to a similar policy in the United States. Australia, Canada, and the Netherlands prohibit any genetic alteration of human gametes, with other nations following suit (Isasi,

Nguyen, & Knoppers, 2006). But some scientists argue that this total ban is too restrictive because it interferes with serving therapeutic needs.

In the case of surrogate motherhood, the ethical problems are so complex that 11 U.S. states and the District of Columbia have sharply restricted the practice (Human Rights Campaign, 2008). Australia, Canada, and many European nations have banned it, arguing that the status of a baby should not be a matter of commercial arrangement. Denmark, France, and Italy have prohibited in vitro fertilization for women past menopause. At present, little is known about the psychological consequences of being a product of these procedures. Research on how such children grow up, including later-appearing medical conditions and knowledge and feelings about their origins, is important for weighing the pros and cons of these techniques.

a picture of the family tree in which affected relatives are identified. The pedigree is used to estimate the likelihood that parents will have an abnormal child, using the genetic principles discussed earlier in this chapter. For many disorders, molecular genetic analyses (in which DNA is examined) can reveal whether the parent is a carrier of the harmful gene. Carrier detection is possible for all the recessive diseases listed

in Table 2.3 on page 49, as well as others, and for fragile X syndrome.

When all the relevant information is in, the genetic counselor helps people consider appropriate options. These include taking a chance and conceiving, choosing from among a variety of reproductive technologies (see the Social Issues: Health box above), or adopting a child.

Prenatal Diagnosis and Fetal Medicine

If couples who might bear an abnormal child decide to conceive, several **prenatal diagnostic methods**—medical procedures that permit detection of developmental problems before birth—are available (see Table 2.4). Women of advanced maternal age are prime candidates for *amniocentesis* or *chorionic villus sampling*. Except for *maternal blood analysis*, however, prenatal diagnosis should not be used routinely because of injury risks to the developing organism.

Prenatal diagnosis has led to advances in fetal medicine. For example, by inserting a needle into the uterus, doctors can administer drugs to the fetus. Surgery has been performed to repair such problems as heart, lung, and diaphragm malformations, urinary tract obstructions, and neural defects. Fetuses with blood disorders have been given blood transfusions. And those with immune deficiencies have received bone marrow

transplants that succeeded in creating a normally functioning immune system (Deprest et al., 2010).

These techniques frequently result in complications, the most common being premature labor and miscarriage (Schonberg & Tift, 2007). Yet parents may be willing to try almost any option, even one with only a slim chance of success. Currently, the medical profession is struggling with how to help parents make informed decisions about fetal surgery.

Advances in *genetic engineering* also offer hope for correcting hereditary defects. As part of the Human Genome Project—an ambitious international research program aimed at deciphering the chemical makeup of human genetic material (genome)—researchers have mapped the sequence of all human DNA base pairs. Using that information, they are “annotating” the genome—identifying all its genes and their functions, including their protein products and what these products do. A major goal is to understand the estimated 4,000 human disorders, those due to single genes and those resulting from a complex interplay of multiple genes and environmental factors.

TABLE 2.4 Prenatal Diagnostic Methods

METHOD	DESCRIPTION
Amniocentesis	The most widely used technique. A hollow needle is inserted through the abdominal wall to obtain a sample of fluid in the uterus. Cells are examined for genetic defects. Can be performed by the 14th week after conception; 1 to 2 more weeks are required for test results. Small risk of miscarriage.
Chorionic villus sampling	A procedure that can be used if results are desired or needed very early in pregnancy. A thin tube is inserted into the uterus through the vagina, or a hollow needle is inserted through the abdominal wall. A small plug of tissue is removed from the end of one or more chorionic villi, the hairlike projections on the chorion, the membrane surrounding the developing organism. Cells are examined for genetic defects. Can be performed at 9 weeks after conception; results are available within 24 hours. Entails a slightly greater risk of miscarriage than amniocentesis. Also associated with a small risk of limb deformities, which increases the earlier the procedure is performed.
Fetoscopy	A small tube with a light source at one end is inserted into the uterus to inspect the fetus for defects of the limbs and face. Also allows a sample of fetal blood to be obtained, permitting diagnosis of such disorders as hemophilia and sickle cell anemia, as well as neural defects (see below). Usually performed between 15 and 18 weeks after conception but can be done as early as 5 weeks. Entails some risk of miscarriage.
Ultrasound	High-frequency sound waves are beamed at the uterus; their reflection is translated into a picture on a video screen that reveals the size, shape, and placement of the fetus. By itself, permits assessment of fetal age, detection of multiple pregnancies, and identification of gross physical defects. Also used to guide amniocentesis, chorionic villus sampling, and fetoscopy. Sometimes combined with magnetic resonance imaging (see page 123 in Chapter 4) to detect physical abnormalities with greater accuracy. When used five or more times, may increase the chances of low birth weight.
Maternal blood analysis	By the second month of pregnancy, some of the developing organism's cells enter the maternal bloodstream. An elevated level of alpha-fetoprotein may indicate kidney disease, abnormal closure of the esophagus, or neural tube defects, such as anencephaly (absence of most of the brain) and spina bifida (bulging of the spinal cord from the spinal column). Isolated cells can be examined for genetic defects.
Ultrafast magnetic resonance imaging (MRI)	Sometimes used as a supplement to ultrasound, where brain or other abnormalities are detected and MRI can provide greater diagnostic accuracy. The ultrafast technique overcomes image blurring due to fetal movements. No evidence of adverse effects.
Preimplantation genetic diagnosis	After in vitro fertilization and duplication of the zygote into a cluster of about 8 to 10 cells, 1 or 2 cells are removed and examined for hereditary defects. Only if that sample is free of detectable genetic disorders is the fertilized ovum implanted in the woman's uterus.

Applying What We Know

Steps Prospective Parents Can Take Before Conception to Increase the Chances of a Healthy Baby

Recommendation	Explanation
Arrange for a physical exam.	A physical exam before conception permits detection of diseases and other medical problems that might reduce fertility, be difficult to treat during pregnancy, or affect the developing organism.
Consider your genetic makeup.	Find out if anyone in your family has had a child with a genetic disease or disability. If so, seek genetic counseling before conception.
Reduce or eliminate toxins under your control.	Because the developing organism is highly sensitive to damaging environmental agents during the early weeks of pregnancy (see Chapter 3), couples trying to conceive should avoid drugs, alcohol, cigarette smoke, radiation, pollution, chemical substances in the home and workplace, and infectious diseases. Furthermore, they should stay away from ionizing radiation and some industrial chemicals that are known to cause mutations.
Ensure proper nutrition.	A doctor-recommended vitamin–mineral supplement, begun before conception, helps prevent many prenatal problems. It should include folic acid, which reduces the chances of neural tube defects, prematurity, and low birth weight (see Chapter 3, page 92).
Consult your doctor after 12 months of unsuccessful efforts at conception.	Long periods of infertility may be due to undiagnosed spontaneous abortions, which can be caused by genetic defects in either partner. If a physical exam reveals a healthy reproductive system, seek genetic counseling.

© ELLEN B. SEMIS PHOTOGRAPHY

This 10-year-old has Duchenne muscular dystrophy, a hereditary degenerative muscle disease that is likely to lead to early death. In the future, such children may benefit from gene-based treatments for hereditary disorders.

Already, thousands of genes have been identified, including those involved in hundreds of diseases, such as cystic fibrosis; Duchenne muscular dystrophy; Huntington disease; Marfan syndrome; heart, digestive, blood, eye, and nervous system abnormalities; and many forms of cancer (National Institutes of Health, 2012). As a result, new treatments are being explored, such as *gene therapy*—correcting genetic abnormalities by delivering DNA carrying a functional gene to the cells. In recent experiments, gene therapy relieved symptoms in hemophilia patients and in patients with severe immune system dysfunction. A few, however, experienced serious side effects (Gillet et al., 2009). In another approach, called *proteomics*, scientists modify gene-specified proteins involved in biological aging and disease (Van Eyk & Dunn, 2008).

Genetic treatments seem some distance in the future for most single-gene defects, however, and even farther off for diseases involving multiple genes that combine in complex ways with each other and the environment. Applying What We Know above summarizes steps that prospective parents can take before conception to protect the genetic health of their child.

Adoption

Adults who are infertile, who are likely to pass along a genetic disorder, or who are older and single but want a family are turning to adoption in increasing numbers. Those who have children by birth, too, sometimes choose to expand their families through adoption. Adoption agencies try to ensure a good fit

Memuna, adopted at age 6, and her American parents and siblings visit Memuna's extended family in Sierra Leone. Several years earlier, civil-war militia attacks took the lives of Memuna's birth parents. Her adoptive parents are helping her forge an identity that blends her Sierra Leone and U.S. backgrounds.

by seeking parents of the same ethnic and religious background as the child and, where possible, trying to choose parents who are the same age as typical biological parents. Because the availability of healthy babies has declined (fewer young unwed mothers give up their babies than in the past), more people in North America and Western Europe are adopting from other countries or accepting children who are past infancy or who have known developmental problems (Schweiger & O'Brien, 2005).

Adopted children and adolescents—whether or not they are born in their adoptive parents' country—tend to have more learning and emotional difficulties than other children, a difference that increases with the child's age at time of adoption (van den Dries et al., 2009; van IJzendoorn, Juffer, & Poelhuis, 2005; Verhulst, 2008). Various explanations exist for adoptees' more problematic childhoods. The biological mother may have been unable to care for the child because of problems believed to be partly genetic, such as alcoholism or severe depression, and may have passed this tendency to her offspring. Or perhaps she experienced stress, poor diet, or inadequate medical care during pregnancy—factors that can affect the child (as we will see in Chapter 3). Furthermore, children adopted after infancy often have a preadoptive history of conflict-ridden family relationships, lack of parental affection, neglect and abuse, or deprived institutional rearing. Finally, adoptive parents and children, who are genetically unrelated, are less alike in intelligence and personality than are biological relatives—differences that may threaten family harmony.

Despite these risks, most adopted children fare well, and those with preexisting problems usually make rapid progress (Arcus & Chambers, 2008; Bimmel et al., 2003). In a study of internationally adopted children in the Netherlands, sensitive maternal care and secure attachment in infancy predicted

cognitive and social competence at age 7 (Stams, Juffer, & van IJzendoorn, 2002). And children with troubled family histories who are adopted at older ages generally improve in feelings of trust and affection for their adoptive parents, as they come to feel loved and supported (Veríssimo & Salvaterra, 2006). As we will see in Chapter 4, however, later-adopted children—especially those with multiple early-life adversities—are more likely than their age-mates to have persistent cognitive, emotional, and social problems.

By adolescence, adoptees' lives are often complicated by unresolved curiosity about their roots. Some have difficulty accepting the possibility that they may never know their birth parents. Others worry about what they would do if their birth parents suddenly reappeared. Adopted teenagers also face a more challenging process of defining themselves as they try to integrate aspects of their birth family and their adoptive family into their emerging identity. Nevertheless, the decision to search for birth parents is usually postponed until early adulthood, when marriage and childbirth may trigger it.

Despite concerns about their origins, most adoptees appear well-adjusted as adults. When parents have been warm, open, and supportive in their communication about adoption, their children typically forge a positive sense of self (Brodzinsky, 2011). And as long as their parents took steps to help them learn about their heritage in childhood, young people adopted into a different ethnic group or culture generally develop identities that are healthy blends of their birth and rearing backgrounds (Nickman et al., 2005; Thomas & Tessler, 2007).

As we conclude our discussion of reproductive choices, perhaps you are wondering how things turned out for Ted and Marianne. Through genetic counseling, Marianne discovered a history of Tay-Sachs disease on her mother's side of the family. Ted had a distant cousin who died of the disorder. The genetic

counselor explained that the chances of giving birth to another affected baby were 1 in 4. Ted and Marianne took the risk. Their son Douglas is now 12 years old. Although Douglas is a carrier of the recessive allele, he is a normal, healthy boy. In a few years, Ted and Marianne will tell Douglas about his genetic history and explain the importance of seeking genetic counseling and testing before he has children of his own.

ASK YOURSELF

REVIEW Why is genetic counseling called a *communication process*? Who should seek it?

CONNECT How does research on adoption reveal resilience? Which factor related to resilience (see Chapter 1, pages 10–11) is central in positive outcomes for adoptees?

APPLY Imagine that you must counsel a couple considering in vitro fertilization using donor ova to overcome infertility. What medical and ethical risks would you raise?

REFLECT Suppose you are a carrier of fragile X syndrome and want to have children. Would you choose pregnancy, adoption, or surrogacy? If you became pregnant, would you opt for prenatal diagnosis? Explain your decisions.

Environmental Contexts for Development

Just as complex as genetic inheritance is the surrounding environment—a many-layered set of influences that combine to help or hinder physical and psychological well-being. **TAKE A MOMENT...** Think back to your childhood, and jot down a brief description of events and people that you believe significantly influenced your development. Next, do the same for your adult life. Do the items on your list resemble those of my students, who mostly mention experiences that involve their families? This emphasis is not surprising, since the family is the first and longest-lasting context for development. Other influences that make most students' top ten are friends, neighbors, school, workplace, and community and religious organizations.

Return to Bronfenbrenner's ecological systems theory, discussed in Chapter 1. It emphasizes that environments extending beyond the *microsystem*—the immediate settings just mentioned—powerfully affect development. Indeed, my students rarely mention one important context. Its impact is so pervasive that we seldom stop to think about it in our daily lives. This is the *macrosystem*, or broad social climate of society—its values and programs that support and protect human development. All people need help with the demands of each period of the

lifespan—through affordable housing and health care, safe neighborhoods, good schools, well-equipped recreational facilities, and high-quality child care and other services that permit them to meet both work and family responsibilities. And some people, because of poverty or individual tragedies, need considerably more help than others.

In the following sections, we take up these contexts for development. Because they affect every age and aspect of change, we will return to them in later chapters. For now, our discussion emphasizes that environments, as well as heredity, can enhance or create risks for development.

The Family

In power and breadth of influence, no other microsystem context equals the family. The family creates unique bonds among people. Attachments to parents and siblings are usually lifelong and serve as models for relationships in the wider world. Within the family, children learn the language, skills, and social and moral values of their culture. And people of all ages turn to family members for information, assistance, and pleasurable interaction. Warm, gratifying family ties predict physical and psychological health throughout development. In contrast, isolation or alienation from the family is often associated with developmental problems (Deković & Buist, 2005; Parke & Buriel, 2006).

Contemporary researchers view the family as a network of interdependent relationships (Bornstein & Sawyer, 2006; Bronfenbrenner & Morris, 2006). Recall from ecological systems theory that *bidirectional influences* exist in which the behaviors of each family member affect those of others. Indeed, the very term *system* implies that the responses of family members are related. These system influences operate both directly and indirectly.

Direct Influences. The next time you have a chance to observe family members interacting, watch carefully. You are likely to see that kind, patient communication evokes cooperative, harmonious responses, whereas harshness and impatience engender angry, resistive behavior. Each of these reactions, in turn, forges a new link in the interactive chain. In the first instance, a positive message tends to follow; in the second, a negative or avoidant one is likely.

LOOK AND LISTEN

Observe several parent–young child pairs in a context where parents are likely to place limits on children's behavior. How does quality of parent communication seem to influence the child's response? How does the child's response affect the parent's subsequent interaction? ●

These observations fit with a wealth of research on the family system. Studies of families of diverse ethnicities show that when parents are firm but warm, children tend to comply

© LAURA DWIGHT PHOTOGRAPHY

Family relationships are bidirectional, in that each member's behaviors affect those of others. This father's affectionate involvement evokes attentiveness and cooperation from his son, which promote further parental warmth and caring.

with their requests. And when children cooperate, their parents are likely to be warm and gentle in the future. In contrast, children whose parents discipline harshly and impatiently are likely to refuse and rebel. And because children's misbehavior is stressful, parents may increase their use of punishment, leading to more unruliness by the child (Stormshak et al., 2000; Whiteside-Mansell et al., 2003). This principle also applies to other two-person family relationships—siblings, marital partners, parent and adult child. In each case, the behavior of one family member helps sustain a form of interaction in the other that either promotes or undermines psychological well-being.

Indirect Influences. The impact of family relationships on development becomes even more complicated when we consider that interaction between any two members is affected by others present in the setting. Recall from Chapter 1 that Bronfenbrenner calls these indirect influences the effect of *third parties*.

Third parties can serve as supports for or barriers to development. For example, when a marital relationship is warm and considerate, mothers and fathers are more likely to engage in effective **coparenting**, mutually supporting each other's parenting behaviors. Such parents are warmer, praise and stimulate their children more, and nag and scold them less. Effective coparenting, in turn, fosters a positive marital relationship (Morrill et al., 2010). In contrast, parents whose marriage is tense and hostile often interfere with one another's child-rearing efforts, are less responsive to children's needs, and are more likely to criticize, express anger, and punish (Caldera & Lindsey, 2006; McHale et al., 2002b).

Children who are chronically exposed to angry, unresolved parental conflict have serious emotional problems resulting from disrupted emotional security (Cummings & Merrilees, 2010; Schacht, Cummings, & Davies, 2009). These include both *internalizing difficulties* (especially among girls), such as feeling worried and fearful and trying to repair their parents' relationship; and *externalizing difficulties* (especially among boys), including anger and aggression (Cummings, Goeke-Morey, & Papp, 2004). These child problems can further disrupt parents' marital relationship.

Yet even when third parties strain family ties, other members may help restore effective interaction. Grandparents, for example, can promote children's development both directly, by responding warmly to the child, and indirectly, by providing parents with child-rearing advice, models of child-rearing skill, and even financial assistance. Of course, as with any indirect influence, grandparents can sometimes be harmful. When relations between grandparents and parents are quarrelsome, parent-child communication may suffer.

Adapting to Change. Think back to the *chronosystem* in Bronfenbrenner's theory (see page 25 in Chapter 1). The interplay of forces within the family is dynamic and ever-changing. Important events, such as the birth of a baby, a change of jobs, or the addition to the household of an elderly parent in declining health, create challenges that modify existing relationships. The way such events affect family interaction depends on the support other family members provide and on the developmental status of each participant. For example, the arrival of a new baby prompts very different reactions in a toddler than in a school-age child. And caring for an ill elderly parent is more stressful for a middle-aged adult still rearing children than for an adult of the same age who has no child-rearing responsibilities.

Historical time period also contributes to a dynamic family system. In recent decades, a declining birth rate, a high divorce rate, expansion of women's roles, and postponement of parenthood have led to a smaller family size. This, combined with a longer lifespan, means that more generations are alive, with fewer members in the youngest ones, leading to a "top-heavy" family structure. Young people today are more likely to have older relatives than at any time in history—a circumstance that

can be enriching as well as a source of tension. In sum, as this complex intergenerational system moves through time, relationships are constantly revised as members adjust to their own and others' development as well as to external pressures.

Nevertheless, some general patterns in family functioning do exist. In the United States and other industrialized nations, one important source of these consistencies is socioeconomic status.

Socioeconomic Status and Family Functioning

People in industrialized nations are stratified on the basis of what they do at work and how much they earn for doing it—factors that determine their social position and economic well-being. Researchers assess a family's standing on this continuum through an index called **socioeconomic status (SES)**, which combines three related, but not completely overlapping, variables: (1) years of education and (2) the prestige of one's job and the skill it requires, both of which measure social status; and (3) income, which measures economic status. As SES rises and falls, people face changing circumstances that profoundly affect family functioning.

SES is linked to timing of marriage and parenthood and to family size. People who work in skilled and semiskilled manual occupations (for example, construction workers, truck drivers, and custodians) tend to marry and have children earlier as well as give birth to more children than people in professional and technical occupations. The two groups also differ in values and expectations. For example, when asked about personal qualities they desire for their children, lower-SES parents tend to emphasize external characteristics, such as obedience, politeness, neatness, and cleanliness. In contrast, higher-SES parents emphasize psychological traits, such as curiosity, happiness, self-direction, and cognitive and social maturity (Duncan & Magnuson, 2003; Hoff, Laursen, & Tardif, 2002; Tudge et al., 2000).

These differences are reflected in family interaction. Parents higher in SES talk to, read to, and otherwise stimulate their infants and preschoolers more. With older children and adolescents, they use more warmth, explanations, and verbal praise; set higher academic and other developmental goals; and allow their children to make more decisions. Commands ("You do that because I told you to"), criticism, and physical punishment all occur more often in low-SES households (Bush & Peterson, 2008; Mandara et al., 2009).

Education contributes substantially to these variations in child rearing. Higher-SES parents' interest in providing verbal stimulation and nurturing inner traits is supported by years of schooling, during which they learned to think about abstract, subjective ideas and, thus, to invest in their children's cognitive and social development (Mistry et al., 2008; Vernon-Feagins et al., 2008). At the same time, greater economic security enables parents to devote more time, energy, and material resources

to fostering their children's psychological characteristics (Cheadle & Amato, 2011; Votruba-Drzal, 2003). In contrast, high levels of stress sparked by economic insecurity contribute to low-SES parents' reduced provision of stimulating interaction and activities as well as greater use of coercive discipline (Chen & Phillips, 2004; Conger & Donnellan, 2007). Because of limited education and low social status, many lower-SES parents feel a sense of powerlessness in their relationships beyond the home. At work, for example, they must obey rules of others in positions of authority. When they get home, their parent-child interaction seems to duplicate these experiences—but now they are in authority. Higher-SES parents, in contrast, typically have more control over their own lives. At work, they are used to making independent decisions and convincing others of their point of view. At home, they are more likely to teach these skills to their children (Greenberger, O'Neil, & Nagel, 1994).

Poverty

When families slip into poverty, development is seriously threatened. Consider Zinnia Mae, who grew up in a close-knit black community located in a small southeastern American city (Heath, 1990). As unemployment struck the community and citizens moved away, 16-year-old Zinnia Mae caught a ride to Atlanta. Two years later, she was the mother of a daughter and twin boys, and she had moved into high-rise public housing.

Zinnia Mae worried constantly about scraping together enough money to put food on the table, finding babysitters so she could go to the laundry or grocery, freeing herself from rising debt, and finding the twins' father, who had stopped sending money. The children had only one set meal—breakfast; otherwise, they ate whenever they were hungry or bored. Their play space was limited to the living room sofa and a mattress on the floor. Toys consisted of scraps of a blanket, spoons and food cartons, a small rubber ball, a few plastic cars, and a roller skate abandoned in the building. At a researcher's request, Zinnia Mae agreed to tape record her interactions with her children. Cut off from family and community ties and overwhelmed by financial strain and feelings of helplessness, she found herself unable to join in activities with her children. In 500 hours of tape, she started a conversation with them only 18 times.

Although poverty rates in the United States declined slightly in the 1990s, in recent years they have risen. Today, about 15 percent—46 million Americans—are affected. Those hit hardest are parents under age 25 with young children and older adults who live alone. Poverty is also magnified among ethnic minorities and women. For example, more than 21 percent of U.S. children are poor, a rate that climbs to 32 percent for Hispanic children, 34 percent for Native-American children, and 38 percent for African-American children. For single mothers with preschool children and elderly women on their own, the poverty rate is close to 50 percent (DeNavas-Walt, Proctor, & Smith, 2011; U.S. Census Bureau, 2012).

AP IMAGES/JENNI GIRTMAN

At a homeless shelter, a mother helps her 7-year-old with a homework assignment. But many homeless children suffer from developmental delays and emotional stress that interfere with school achievement.

Joblessness, a high divorce rate, a lower remarriage rate among women than men, widowhood, and (as we will see later) inadequate government programs to meet family needs are responsible for these disheartening statistics. The poverty rate is higher among children than any other age group. And of all Western nations, the United States has the highest percentage of extremely poor children. Nearly 10 percent of U.S. children live in deep poverty (at less than half the poverty threshold, the income level judged necessary for a minimum living standard). In contrast, in Denmark, Finland, Norway, and Sweden, child poverty rates have remained at 5 percent or less for two decades, and deep child poverty is rare (UNICEF, 2007, 2010b). The earlier poverty begins, the deeper it is, and the longer it lasts, the more devastating are its effects. Children of poverty are more likely than other children to suffer from lifelong poor physical health, persistent deficits in cognitive development and academic achievement, high school dropout, mental illness, and antisocial behavior (Aber, Jones, & Raver, 2007; Morgan et al., 2009; Ryan, Fauth, & Brooks-Gunn, 2006).

The constant stressors that accompany poverty gradually weaken the family system. Poor families have many daily hassles—bills to pay, the car breaking down, loss of welfare and unemployment payments, something stolen from the house, to name just a few. When daily crises arise, family members become depressed, irritable, and distracted; and hostile interactions increase (Conger & Donnellan, 2007; Kohen et al., 2008).

Negative outcomes are especially severe in single-parent families and families who must live in poor housing and dangerous neighborhoods—conditions that make everyday existence even more difficult, while reducing social supports that help people cope with economic hardship (Hart, Atkins, & Matsuba, 2008; Leventhal & Brooks-Gunn, 2003).

Besides poverty, another problem—one that has become more common in the past 30 years—has reduced the life chances of many children and adults. Approximately 3.5 million people in the United States experience homelessness in a given year. The majority are adults on their own, many of whom suffer from serious mental illness. But about 38 percent of the homeless are children (National Coalition for the Homeless, 2009). The rise in homelessness is mostly due to two factors: a decline in the availability of government-supported, low-cost housing and the release of large numbers of mentally ill people from institutions, without an increase in community treatment programs to help them adjust to ordinary life and get better.

Most homeless families consist of women with children under age 5. Besides health problems (which affect the majority of homeless people), many homeless children suffer from developmental delays and chronic emotional stress due to harsh, insecure daily lives (Pardeck, 2005). An estimated 25 to 30 percent who are old enough do not go to school. Those who do enroll achieve less well than other poverty-stricken children because of poor attendance and health and emotional difficulties (Obradović et al., 2009; Shinn et al., 2008).

Affluence

Despite their advanced education and great material wealth, affluent parents—those in prestigious and high-paying occupations—too often fail to engage in family interaction and parenting that promote favorable development. In several studies, researchers tracked the adjustment of youths growing up in high-SES suburbs (Luthar & Latendresse, 2005a). By seventh grade, many showed serious problems that worsened in high school. Their school grades were poor, and they were more likely than low-SES youths to engage in alcohol and drug use and to report high levels of anxiety and depression (Luthar & Becker, 2002; Luthar & Goldstein, 2008). Furthermore, among affluent (but not low-SES) teenagers, substance use was correlated with anxiety and depression, suggesting that wealthy youths took drugs to self-medicate—a practice that predicts persistent abuse (Luthar & Sexton, 2004).

Why are so many affluent youths troubled? Compared to their better-adjusted counterparts, poorly adjusted affluent young people report less emotional closeness and supervision from their parents, who lead professionally and socially demanding lives. As a group, wealthy parents are nearly as physically and emotionally unavailable to their youngsters as parents coping

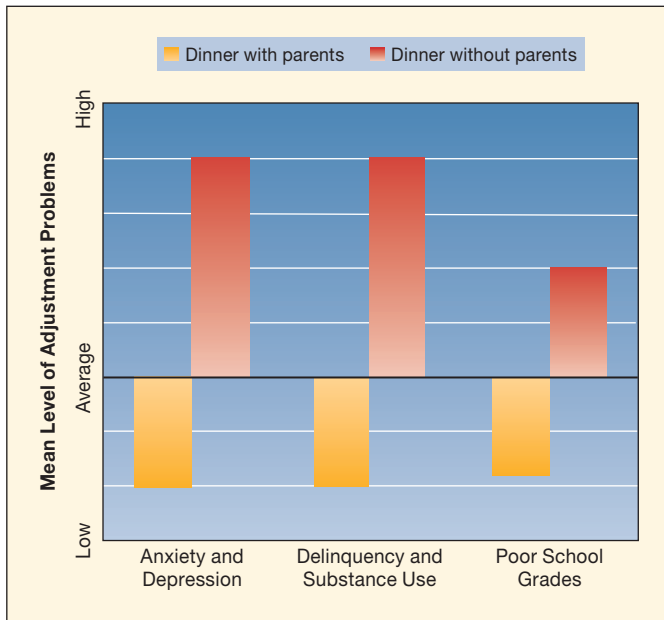

FIGURE 2.6 Relationship of regularly eating dinner with parents to affluent youths' adjustment problems. Compared with sixth graders who often ate dinner with their parents, those who rarely did so were far more likely to display anxiety and depression, delinquency and substance use, and poor school grades, even after many other aspects of parenting were controlled. In this study, frequent family mealtimes also protected low-SES youths from delinquency and substance use and from classroom learning problems. (Adapted from Luthar & Latendresse, 2005b.)

with serious financial strain. At the same time, these parents often make excessive demands for achievement (Luthar & Becker, 2002). Adolescents whose parents value their accomplishments more than their character are more likely to have academic and emotional problems.

For both affluent and low-SES youths, a simple routine—eating dinner with parents—is associated with a reduction in adjustment difficulties, even after many other aspects of parenting are controlled (see Figure 2.6) (Luthar & Latendresse, 2005b). Interventions that make wealthy parents aware of the high costs of a competitive lifestyle and minimal family time are badly needed.

Beyond the Family: Neighborhoods, Towns, and Cities

As the concepts of *mesosystem* and *exosystem* in ecological systems theory make clear, connections between family and community are vital for psychological well-being. From our discussion of poverty, perhaps you can see why: In poverty-stricken urban areas, community life is usually disrupted. Families move often, parks and playgrounds are in disarray, and community centers providing organized leisure time activities do not exist. In such neighborhoods, family violence, child abuse and neglect, child and youth internalizing and externalizing difficulties, adult criminal behavior, and depression and declines in cognitive

functioning in older adults are especially high (Aneshensel et al., 2007; Chen, Howard, & Brooks-Gunn, 2011; Dunn, Schaefer-McDaniel, & Ramsay, 2010; Lang et al., 2008). In contrast, strong family ties to the surrounding social context—as indicated by frequent contact with friends and relatives and regular church, synagogue, or mosque attendance—reduce stress and enhance adjustment.

Neighborhoods. Let's look closely at the functions of communities in the lives of children and adults by beginning with the neighborhood. **TAKE A MOMENT...** What were your childhood experiences like in the yards, streets, and parks surrounding your home? How did you spend your time, whom did you get to know, and how important were these moments to you?

Neighborhoods offer resources and social ties that play an important part in children's development. In several studies, low-SES families were randomly assigned vouchers to move out of public housing into neighborhoods varying widely in affluence. Compared with their peers who remained in poverty-stricken areas, children and youths who moved into low-poverty neighborhoods showed substantially better physical and mental health and school achievement (Goering, 2003; Leventhal & Brooks-Gunn, 2003).

Neighborhood resources have a greater impact on economically disadvantaged than well-to-do young people. Higher-SES families are less dependent on their immediate surroundings for social support, education, and leisure pursuits. They can afford to transport their children to lessons and entertainment and, if necessary, to better-quality schools in distant parts of the community. In low-income neighborhoods, in-school and after-school programs that substitute for lack of other resources by providing art, music, sports, scouting, and other enrichment activities are associated with improved academic performance and a reduction in emotional and behavior problems in middle childhood (Peters, Petrunka, & Arnold, 2003; Vandell, Reisner, & Pierce, 2007). Neighborhood organizations and informal social activities contribute to favorable development in adolescence, including increased self-confidence, school achievement, and educational aspirations (Barnes et al., 2007; Gonzales et al., 1996).

Yet in dangerous, disorganized neighborhoods, high-quality activities for children and adolescents are scarce. Even when they are available, crime and social disorder limit young people's access, and parents overwhelmed by financial and other stressors are less likely to encourage their children to participate (Dearing et al., 2009; Dynarski et al., 2004). Thus, the neediest children and youths are especially likely to miss out on these development-enhancing activities.

LOOK AND LISTEN

Ask several parents to list their school-age children's regular lessons and other enrichment activities. Then inquire about home and neighborhood factors that either encourage or impede their children's participation. ●

The Better Beginnings, Better Futures Project of Ontario, Canada, is a government-sponsored set of pilot programs aimed at preventing the dire consequences of neighborhood poverty. The most successful of these efforts, using a local elementary school as its base, provided children with in-class, before- and after-school, and summer enrichment activities. Workers also visited each child's parents regularly, informed them about community resources, and encouraged their involvement in the child's school and neighborhood life. And a communitywide component focused on improving the quality of the neighborhood as a place to live, by offering leadership training and adult education programs and organizing safety initiatives and special events and celebrations (Peters, 2005; Peters, Petrunka, & Arnold, 2003). Evaluations as children reached grades 3, 6, and 9 revealed wide-ranging benefits compared with children and families living in other poverty neighborhoods without this set of programs (Peters et al., 2010). Among these were parents' sense of improved marital satisfaction, family functioning, effective child rearing, and community involvement, and gains in children's academic achievement and social adjustment, including positive relationships with peers and adults and a reduction in emotional and behavior problems.

As these outcomes suggest, neighborhoods also affect adults' well-being. An employed parent who can rely on a caring neighbor or community program for child-rearing assistance and who lives in a safe area gains access to valuable information and services, effective child-rearing role models, and peace of mind essential for productive work. In low-SES areas with high resident stability and social cohesion, where neighbors collaborate in keeping the environment clean and watching out for vandalism and other crimes, adults report less stress, which in turn predicts substantially better physical health (Boardman, 2004; Feldman & Steptoe, 2004).

During late adulthood, neighborhoods become increasingly important because people spend more time in their homes. Despite the availability of planned housing for older adults, about 90 percent remain in regular housing, usually in the same neighborhood where they lived during their working lives (U.S. Census Bureau, 2012b). Proximity to relatives and friends is a significant factor in the decision to move or stay put late in life. In the absence of nearby family members, older adults mention neighbors and nearby friends as resources they rely on most for physical and social support (Hooyman & Kiyak, 2011).

Towns and Cities. Neighborhoods are embedded in towns and cities, which also mold children's and adults' daily lives. In rural areas and small towns, children and youths

This 5-year-old enjoys working with volunteers at a community garden sponsored by the Boys & Girls Clubs of America. Neighborhood resources are especially important for the development of economically disadvantaged children and youths.

are more likely to be given important work tasks—caring for livestock, operating the snowplow, or playing in the town band. They usually perform these tasks alongside adults, who instill in them a strong sense of responsibility and teach them practical and social skills needed to sustain their community. Compared with large urban areas, small towns also offer stronger connections between settings that influence children's lives. For example, because most citizens know each other and schools serve as centers of community life, contact between teachers and parents occurs often—an important factor in promoting children's academic achievement (Hill & Taylor, 2004).

Adults in small towns participate in more civic groups, such as school board or volunteer fire brigade. And they are more likely to occupy positions of leadership because a greater proportion of residents are needed to meet community needs (Elder & Conger, 2000). In late adulthood, people residing in small towns and suburbs have neighbors who are more willing to provide assistance. As a result, they form a greater number of warm relationships with nonrelatives.

Of course, small-town residents cannot visit museums, go to professional baseball games, or attend orchestra concerts on a regular basis. The variety of settings is not as great as in a large city. In small towns, however, active involvement in the community is likely to be greater throughout the lifespan. Also,

public places in small towns are relatively safe and secure. Responsible adults are present in almost all settings to keep an eye on children and youths. And older adults feel safer—a strong contributor to how satisfied they are with their place of residence (Shields et al., 2002). These conditions are hard to match in today’s urban environments.

The Cultural Context

Our discussion in Chapter 1 emphasized that human development can be fully understood only when viewed in its larger cultural context. In the following sections, we expand on this theme by taking up the role of the *macrosystem* in development. First, we discuss ways that cultural values and practices affect environmental contexts for development. Second, we consider how healthy development depends on laws and government programs that shield people from harm and foster their well-being.

Cultural Values and Practices. Cultures shape family interaction and community settings beyond the home—in short, all aspects of daily life. Many of us remain blind to aspects of our own cultural heritage until we see them in relation to the practices of others.

TAKE A MOMENT... Consider the question, Who should be responsible for rearing young children? How would you answer it? Here are some typical responses from my students: “If parents decide to have a baby, then they should be ready to care for it.” “Most people are not happy about others intruding into family life.” These statements reflect a widely held opinion in the United States—that the care and rearing of children, and paying for that care, are the duty of parents, and only parents. This view has a long history—one in which independence, self-reliance, and the privacy of family life emerged as central American values (Halfon & McLern, 2002). It is one reason, among others, that the public has been slow to endorse government-supported benefits for all families, such as high-quality child care and paid employment leave for meeting family needs. And it has also contributed to the large number of U.S. families who remain poor, even though family members are gainfully employed (Gruendel & Aber, 2007; UNICEF, 2007, 2010).

Although the culture as a whole may value independence and privacy, not all citizens share the same values. Some belong to **subcultures**—groups of people with beliefs and customs that differ from those of the larger culture. Many ethnic minority groups in the United States have cooperative family structures, which help protect their members from the harmful effects of poverty. As the Cultural Influences box on page 66 indicates, the African-American tradition of **extended-family households**, in which three or more generations live together, is a vital feature of black family life that has enabled its members to survive, despite a long history of prejudice and economic deprivation. Within the extended family, grandparents play meaningful

roles in guiding younger generations; adults who face employment, marital, or child-rearing difficulties receive assistance and emotional support; and caregiving is enhanced for children and the elderly. Active, involved extended families also characterize other minorities, such as Asian, Native-American, and Hispanic subcultures (Becker et al., 2003; Harwood et al., 2002).

Our discussion so far reflects a broad dimension on which cultures and subcultures differ: the extent to which *collectivism* versus *individualism* is emphasized. In **collectivist societies**, people define themselves as part of a group and stress group goals over individual goals. In **individualistic societies**, people think of themselves as separate entities and are largely concerned with their own personal needs (Triandis, 1995, 2005). As these definitions suggest, the two cultural patterns are associated with two distinct views of the self. Collectivist societies value an *interdependent self*, which stresses social harmony, obligations and responsibility to others, and collaborative endeavors. In contrast, individualistic societies value an *independent self*, which emphasizes personal exploration, discovery, achievement, and individual choice in relationships. Both interdependence and independence, in varying mixtures, are part of the makeup of every person (McAdams & Cox, 2010; Tamis-LeMonda et al., 2008). But societies vary greatly in the extent to which they emphasize each alternative and—as later chapters will reveal—instill it in their young.

Although individualism tends to increase as cultures become more complex, cross-national differences remain. The United States is strongly individualistic, whereas most Western European countries lean toward collectivism. As we will see next, collectivist versus individualistic values have a powerful impact on a nation’s approach to protecting the well-being of its children, families, and aging citizens.

Public Policies and Lifespan Development. When widespread social problems arise, such as poverty, homelessness, hunger, and disease, nations attempt to solve them through **public policies**—laws and government programs designed to improve current conditions. For example, when poverty increases and families become homeless, a country might decide to build more low-cost housing, provide economic aid to homeowners having difficulty making mortgage payments, raise the minimum wage, and increase welfare benefits. When reports indicate that many children are not achieving well in school, federal and state governments might grant more tax money to school districts, strengthen teacher preparation, and make sure that help reaches children who need it most. And when senior citizens have difficulty making ends meet because of inflation, a nation might increase its social security benefits.

Nevertheless, U.S. public policies safeguarding children and youths have lagged behind policies for older adults. And compared with other industrialized nations, both sets of policies have been especially slow to emerge in the United States.

Cultural Influences

The African-American Extended Family

The African-American extended family can be traced to the African heritage of most black Americans. In many African societies, newly married couples do not start their own households. Instead, they live with a large extended family, which assists its members with all aspects of daily life. This tradition of maintaining a broad network of kin ties traveled to North America during the period of slavery. Since then, it has served as a protective shield against the destructive impact of poverty and racial prejudice on African-American family life. Today, more black than white adults have relatives other than their own children living in the same household. African-American parents also live closer to kin, often establish family-like relationships with friends and neighbors, see more relatives during the week, and perceive them as more important figures in their lives (Boyd-Franklin, 2006; McAdoo & Younge, 2009).

By providing emotional support and sharing essential resources, the African-American extended family helps reduce the stress of poverty and single parenthood. Extended-family members often help with child rearing, and adolescent mothers living in extended families are more likely to complete high school and get a job and less likely to be on welfare than mothers living on their own—factors that in turn benefit children’s well-being (Gordon, Chase-Lansdale, & Brooks-Gunn, 2004; Trent & Harlan, 1994).

For single mothers who were very young at the time of their child’s birth, extended-family living continues to be associated with more positive mother–child interaction during the preschool years. Otherwise, establishing an independent household with the help of nearby relatives is related to improved child rearing. Perhaps this arrangement permits the more mature teenage mother who has developed effective parenting skills to implement them (Chase-Lansdale, Brooks-Gunn, & Zamsky, 1994). In families rearing adolescents, kinship support increases the likelihood of effective parenting, which is related to adolescents’ self-reliance, emotional well-being, and reduced antisocial behavior (Simons et al., 2006; Taylor, 2010).

Finally, the extended family plays an important role in transmitting African-American culture. Compared with nuclear-family households (which include only parents and their children), extended-family arrangements place more emphasis on cooperation and on moral and religious

values. And older black adults, such as grandparents and great-grandparents, regard educating children about their African heritage as especially important (Mosely-Howard & Evans, 2000; Taylor, 2000). Family reunions—sometimes held in grandparents’ and great-grandparents’ hometowns in the South—are especially common among African Americans, giving young people a strong sense of their roots (Boyd-Franklin, 2006). These influences strengthen family bonds, protect children’s development, and increase the chances that the extended-family lifestyle will carry over to the next generation.

Policies for Children, Youths, and Families. We have already seen that although many U.S. children fare well, a large number grow up in environments that threaten their development. As Table 2.5 reveals, the United States does not rank well on any key measure of children’s health and well-being.

© JEFF GREENBERG/THE IMAGE WORKS

Three generations celebrate together at a neighborhood festival. Strong bonds with extended family members have helped protect many African-American children against the destructive impact of poverty and racial prejudice.

The problems of children and youths extend beyond the indicators in the table. Despite improved health-care provisions signed into law in 2010, the United States remains the only industrialized nation in the world without a universal, publicly funded health-care system. Approximately 10 percent

TABLE 2.5 How Does the United States Compare to Other Nations on Indicators of Children's Health and Well-Being?

INDICATOR	U.S. RANK ^a	SOME COUNTRIES THE UNITED STATES TRAILS
Childhood poverty (among 24 industrialized nations considered)	24th	Canada, Czech Republic, Germany, United Kingdom, Norway, Sweden, Poland, Spain ^b
Infant deaths in the first year of life (worldwide)	28th	Canada, Hong Kong, Ireland, Singapore, Spain
Teenage birth rate (among 28 industrialized nations considered)	28th	Australia, Canada, Czech Republic, Denmark, Hungary, Iceland, Poland, Slovakia
Public expenditure on education as a percentage of gross domestic product ^c (among 22 industrialized nations considered)	12th	Belgium, France, Iceland, New Zealand, Portugal, Spain, Sweden
Public expenditure on early childhood education and child care as a percentage of gross domestic product ^c (among 14 industrialized nations considered)	9th	Austria, Germany, Italy, Netherlands, France, Sweden
Public expenditure on health as a percentage of total health expenditure, public plus private (among 27 industrialized nations considered)	26th	Austria, Australia, Canada, France, Hungary, Iceland, Switzerland, New Zealand

^a1 = highest, or best, rank.

^bU.S. childhood poverty and, especially, deep poverty rates greatly exceed poverty in these nations. For example, the poverty rate is 12 percent in the United Kingdom, 9.5 percent in Canada, 6 percent in the Czech Republic, 4 percent in Norway, and 2.5 percent in Sweden. Deep poverty affects just 2.5 percent of children in Canada, and a fraction of 1 percent in the other countries just listed.

^cGross domestic product is the value of all goods and services produced by a nation during a specified time period. It provides an overall measure of a nation's wealth.

Sources: Canada Campaign 2000, 2009; OECD, 2010a, 2010b; U.S. Census Bureau, 2012; U.S. Department of Education, 2012b.

of U.S. children—most in low-income families—have no health insurance (Kenney et al., 2010). Furthermore, the United States has been slow to move toward national standards and funding for child care. Affordable care is in short supply, and much of it is substandard in quality (Lamb & Ahnert, 2006; Muenchow & Marsland, 2007). In families affected by divorce, weak enforcement of child support payments heightens poverty in mother-headed households. When non-college-bound young people finish high school, many lack the vocational preparation they need to contribute fully to society. And 8 percent of 16- to 24-year-olds who dropped out of high school have not returned to earn a diploma (U.S. Department of Education, 2012b).

Why have attempts to help children and youths been difficult to realize in the United States? A complex set of political and economic forces is involved. Cultural values of self-reliance and privacy have made government hesitant to become involved in family matters. Furthermore, good social programs are expensive, and they must compete for a fair share of a country's economic resources. Children can easily remain unrecognized in this process because they cannot vote or speak out to protect their own interests, as adult citizens do (Ripple & Zigler, 2003). Instead, they must rely on the goodwill of others to become an important government priority.

Policies for Older Adults. Until well into the twentieth century, the United States had few policies in place to protect its aging population. For example, Social Security benefits, which address the income needs of retired citizens who contributed

to society through prior employment, were not awarded until the late 1930s. Yet most Western nations had social security systems in place a decade or more earlier (Karger & Stoesz, 2010). In the 1960s, U.S. federal spending on programs for older adults expanded rapidly. Medicare, a national health insurance program for older people that pays partial health-care costs, was initiated. But it mainly covers acute care services and requires participants to pay part of those costs, too. This leaves about half of elderly health spending to be covered by supplemental private insurance, government health insurance for the poor, or out-of-pocket payments (U.S. Department of Health and Human Services, 2011g).

Social Security and Medicare consume 96 percent of the U.S. federal budget for the elderly; only 4 percent is devoted to other programs. Consequently, U.S. programs for the aged have been criticized for neglecting social services (Hooymann & Kiyak, 2011). To meet this need, a national network for planning, coordinating, and delivering assistance to the aged has been established. Approximately 630 Area Agencies on Aging operate at regional and local levels, assessing community needs and offering communal and home-delivered meals, self-care education, elder abuse prevention, and a wide range of other social services. But limited funding means that the Area Agencies help far too few people in need.

As noted earlier, many senior citizens—especially women, ethnic minorities, and those living alone—remain in dire economic straits. Those who had interrupted employment histories, held jobs without benefits, or suffered lifelong poverty are

Many U.S. ethnic-minority older adults are poverty-stricken. This Native American, who lives in a remote Alaskan village, depends on an itinerant nurse for routine medical care.

not eligible for Social Security. Although all Americans age 65 and older are guaranteed a minimum income, the guaranteed amount is below the poverty line—the amount judged necessary for bare subsistence by the federal government. Furthermore, Social Security benefits are rarely adequate as a sole source of retirement income; they must be supplemented through other pensions and family savings. But a substantial percentage of U.S. aging citizens do not have access to these resources. Therefore, they are more likely than other age groups to be among the “near poor” (U.S. Department of Health and Human Services, 2010f).

Nevertheless, the U.S. aging population is financially much better off now than in the past. Today, older adults are a large, powerful, well-organized constituency, far more likely than children or low-income families to attract the support of politicians. As a result, the number of aging poor has declined from 1 out of 3 people in 1960 to 1 out of 10 in the early twenty-first century (U.S. Census Bureau, 2012). And senior citizens are healthier and more independent than ever before. Still, as Figure 2.7 shows, aging adults in the United States are less well off than those in many other Western nations, which provide more generous, government-funded income supplements to older adults.

Looking Toward the Future. Despite the worrisome state of many children, families, and aging citizens, efforts are being made to improve their condition. Throughout this book, we will discuss many successful programs that could be expanded. Also, growing awareness of the gap between what we know and what we do to better people’s lives has led experts

in developmental science to join with concerned citizens as advocates for more effective policies. As a result, several influential interest groups devoted to the well-being of children or older adults have emerged.

In the United States, the Children’s Defense Fund (CDF)—a private, nonprofit organization founded by Marian Wright Edelman in 1973—engages in public education, legal action, drafting of legislation, congressional testimony, and community organizing. It also publishes many reports on U.S. children’s condition, government-sponsored programs that serve children and families, and research-based proposals for improving those programs. To learn more about the Children’s Defense Fund, visit its website at www.childrensdefense.org. Another energetic advocacy organization is the National Center for Children in Poverty, dedicated to advancing the economic security, health, and welfare of U.S. children in low-income families by informing policy makers of relevant research. To explore its activities, visit www.nccp.org.

FIGURE 2.7 Percentage of older adults living in poverty in 20 industrialized nations. Among the countries listed, the United States has the highest rate of older adults living in poverty. Public expenditures on social security and other income guarantees for senior citizens are far greater in the highly ranked nations than in the United States. (Adapted from Luxembourg Income Study, 2011.)

About half of Americans over age 50, both retired and employed, are members of AARP (originally known as the American Association of Retired Persons). Founded by Ethel Percy Andrus in 1958, AARP has a large and energetic lobbying staff that works for increased government benefits of all kinds for the aged. Every two years, it releases *The Policy Book*, an in-depth compilation of AARP policy positions that form the basis for advocacy activities in diverse areas, including income, health care, social services, housing, and personal and legal rights. Among AARP's programs is an effort to mobilize elderly voters, an initiative that keeps lawmakers highly sensitive to policy proposals affecting older Americans. A description of AARP and its activities can be found at www.aarp.org.

Besides strong advocacy, public policies that enhance development depend on policy-relevant research that documents needs and evaluates programs to spark improvements. Today, more researchers are collaborating with community and government agencies to enhance the social relevance of their investigations. They are also doing a better job of disseminating their findings in easily understandable, compelling ways, through reports to government officials, websites aimed at increasing public understanding, and collaborations with the media to ensure accurate and effective reporting in newspaper stories, magazine articles, and radio and television documentaries (Shonkoff & Bales, 2011). In these ways, researchers are helping to create the sense of immediacy about the condition of children, families, and the aged that is necessary to spur a society into action.

ASK YOURSELF

REVIEW Links between family and community foster development throughout the lifespan. Provide examples from our discussion that support this idea.

CONNECT How does poverty affect the family system, placing all aspects of development at risk?

APPLY Check your local newspaper or one or two national news magazines or news websites to see how often articles on the condition of children, families, and the aged appear. Why is it important for researchers to communicate with the general public about the well-being of these sectors of the population?

REFLECT Do you agree with the widespread American sentiment that government should not become involved in family life? Explain.

Understanding the Relationship Between Heredity and Environment

So far in this chapter, we have discussed a wide variety of genetic and environmental influences, each of which has the power to alter the course of development. Yet people who are born into the same family (and who therefore share both genes and environments) are often quite different in characteristics. We also know that some individuals are affected more than others by their homes, neighborhoods, and communities. How do scientists explain the impact of heredity and environment when they seem to work in so many different ways?

Behavioral genetics is a field devoted to uncovering the contributions of nature and nurture to this diversity in human traits and abilities. All contemporary researchers agree that both heredity and environment are involved in every aspect of development. But for polygenic traits (those due to many genes), such as intelligence and personality, scientists are a long way from knowing the precise hereditary influences involved. Although they are making progress in identifying variations in DNA sequences associated with complex traits, so far these genetic markers explain only a small amount of variation in human behavior, and a minority of cases of most psychological disorders (Plomin & Davis, 2009). For the most part, scientists are still limited to investigating the impact of genes on complex characteristics indirectly.

Some believe that it is useful and possible to answer the question of *how much each factor contributes* to differences among people. A growing consensus, however, regards that question as unanswerable. These investigators believe that heredity and

© DAVID BACON/THE IMAGE WORKS

At this California resource center, low-income families learn about healthy eating and also receive food. Policy-relevant research helps make the case for programs like this one by documenting pressing needs of children and families.

environment are inseparable (Gottlieb, Wahlsten, & Lickliter, 2006; Lerner & Overton, 2008). The important question, they maintain, is *how nature and nurture work together*. Let's consider each position in turn.

The Question, "How Much?"

To infer the role of heredity in complex human characteristics, researchers use special methods, the most common being the *heritability estimate*. Let's look closely at the information this procedure yields, along with its limitations.

Heritability. Heritability estimates measure the extent to which individual differences in complex traits in a specific population are due to genetic factors. We will take a brief look at heritability findings on intelligence and personality here and will return to them in later chapters, when we consider these topics in greater detail. Heritability estimates are obtained from **kinship studies**, which compare the characteristics of family members. The most common type of kinship study compares identical twins, who share all their genes, with fraternal twins, who, on average, share only half. If people who are genetically more alike are also more similar in intelligence and personality, then the researcher assumes that heredity plays an important role.

Kinship studies of intelligence provide some of the most controversial findings in the field of developmental science. Some experts claim a strong genetic influence, whereas others believe that heredity is barely involved. Currently, most kinship findings support a moderate role for heredity. When many twin studies are examined, correlations between the scores of identical twins are consistently higher than those of fraternal twins. In a summary of more than 10,000 twin pairs, the correlation for intelligence was .86 for identical twins and .60 for fraternal twins (Plomin & Spinath, 2004).

Researchers use a complex statistical procedure to compare these correlations, arriving at a heritability estimate ranging from 0 to 1.00. The value for intelligence is about .50 for child and adolescent twin samples in Western industrialized nations. This suggests that differences in genetic makeup explain half the variation in intelligence. However, heritability increases through middle adulthood, with some estimates as high as .80 (Baird & Bergeman, 2011; Haworth et al., 2010). As we will see later, one explanation is that, compared to children, adults exert greater personal control over their intellectual experiences—for example, how much time they spend reading or solving challenging problems. Adopted children's mental test scores are more strongly related to their biological parents' scores than to those of their adoptive parents, offering further support for the role of heredity (Petrill & Deater-Deckard, 2004).

Heritability research also reveals that genetic factors are important in personality. For frequently studied traits, such as sociability, anxiety, agreeableness, and activity level, heritability estimates obtained on child, adolescent, and young adult

twins are moderate, in the .40s and .50s (Caspi & Shiner, 2006; Rothbart & Bates, 2006; Wright et al., 2008). Unlike intelligence, however, heritability of personality does not increase over the lifespan (Heiman et al., 2003; Loehlin et al., 2005).

Twin studies of schizophrenia—a psychological disorder involving delusions and hallucinations, difficulty distinguishing fantasy from reality, and irrational and inappropriate behaviors—consistently yield high heritabilities, around .80. The role of heredity in antisocial behavior and major depression, though still apparent, is less strong, with heritabilities in the .30s and .40s (Faraone, 2008). Again, adoption studies support these results. Biological relatives of schizophrenic and depressed adoptees are more likely than adoptive relatives to share the same disorder (Plomin et al., 2001; Ridenour, 2000; Tienari et al., 2003).

Limitations of Heritability. The accuracy of heritability estimates depends on the extent to which the twin pairs studied reflect genetic and environmental variation in the population. Within a population in which all people have very similar home, school, and community experiences, individual differences in intelligence and personality would be largely genetic, and heritability estimates would be close to 1.00. Conversely, the more environments vary, the more likely they are to account for individual differences, yielding lower heritability estimates. In twin studies, most of the twin pairs are reared together under highly similar conditions. Even when separated twins are available for study, social service agencies have often placed them in advantaged homes that are alike in many ways (Rutter et al.,

© JACQUIE HEMMERDINGER/THE NEW YORK TIMES/REDUX

Adriana and Tamara, identical twins separated at birth by adoption, were unaware of each other's existence. When they met at age 20, they discovered many similarities—academic achievement, love of dancing, and even taste in clothing. Clearly, heredity contributes to psychological characteristics. Nevertheless, generalizing from twin evidence to the population is controversial.

2001). Because the environments of most twin pairs are less diverse than those of the general population, heritability estimates are likely to exaggerate the role of heredity.

Heritability estimates are controversial measures because they can easily be misapplied. For example, high heritabilities have been used to suggest that ethnic differences in intelligence, such as the poorer performance of black children compared to white children, have a genetic basis (Jensen, 1969, 1998, 2001; Rushton & Jensen, 2005, 2006). Yet this line of reasoning is widely regarded as incorrect. Heritabilities computed on mostly white twin samples do not tell us what causes test score differences between ethnic groups. We have already seen that large economic and cultural differences are involved. In Chapter 9, we will discuss research indicating that when black children are adopted into economically advantaged homes at an early age, their scores are well above average and substantially higher than those of children growing up in impoverished families.

Perhaps the most serious criticism of heritability estimates has to do with their limited usefulness. Though interesting, these statistics give us no precise information on how intelligence and personality develop or how children might respond to environments designed to help them develop as far as possible (Baltes, Lindenberger, & Staudinger, 2006). Indeed, the heritability of children's intelligence increases as parental education and income increase—that is, as children grow up in conditions that allow them to make the most of their genetic endowment. In impoverished environments, children are prevented from realizing their potential. Consequently, enhancing experiences through interventions—such as increasing parent education and income and providing high-quality preschool or child care—has a greater impact on development (Bronfenbrenner & Morris, 2006; Turkheimer et al., 2003).

In sum, although heritability estimates confirm that heredity contributes to a broad array of complex traits, they tell us nothing about how environment can modify genetic influences. Still, scientists often rely on positive heritabilities before initiating more costly molecular analyses in search of specific genes that contribute to personality traits and disorders.

The Question, “How?”

Today, most researchers view development as the result of a dynamic interplay between heredity and environment. How do nature and nurture work together? Several concepts shed light on this question.

Gene–Environment Interaction. The first of these ideas is **gene–environment interaction**, which means that because of their genetic makeup, individuals differ in their responsiveness to qualities of the environment (Rutter, 2011). In other words, people have unique, genetically influenced reactions to particular experiences. Let's explore this idea in Figure 2.8. Gene–environment interaction can apply to any characteristic; here it is illustrated for intelligence. Notice that

when environments vary from extremely unstimulating to highly enriched, Ben's intelligence increases steadily, Linda's rises sharply and then falls off, and Ron's begins to increase only after the environment becomes modestly stimulating.

Gene–environment interaction highlights two important points. First, it shows that because each of us has a unique genetic makeup, we respond differently to the same environment. Notice in Figure 2.8 how a poor environment results in similarly low scores for all three individuals. But when the environment provides a moderate level of stimulation, Linda is by far the best-performing child. And in a highly enriched environment, Ben does best, followed by Ron, both of whom now outperform Linda. Second, sometimes different gene–environment combinations can make two people look the same! For example, if Linda is reared in a minimally stimulating environment, her score will be about 100—average for people in general. Ben and Ron can also obtain this score, but to do so, they must grow up in a fairly enriched home (Gottlieb, Wahlsten, & Lickliter, 2006).

Recently, researchers have made strides in identifying gene–environment interactions in personality development. In Chapter 6 we will see that young children with a gene that increases their risk of an emotionally reactive temperament respond especially strongly to variations in parenting quality (Pluess & Belsky, 2011). When parenting is favorable, they gain control over their emotions and adjust as well or better than other children. But when parenting is unfavorable, they become increasingly irritable, difficult, and poorly adjusted, more so than children not at genetic risk.

FIGURE 2.8 Gene–environment interaction, illustrated for intelligence by three children who differ in responsiveness to quality of the environment. As environments vary from extremely unstimulating to highly enriched, Ben's intelligence test score increases steadily, Linda's rises sharply and then falls off, and Ron's begins to increase only after the environment becomes modestly stimulating.

Canalization. Another way of understanding how heredity and environment combine comes from the concept of **canalization**—the tendency of heredity to restrict the development of some characteristics to just one or a few outcomes. A behavior that is strongly canalized develops similarly in a wide range of environments; only strong environmental forces can change it (Waddington, 1957). For example, infant perceptual and motor development seems to be strongly canalized because all normal human babies eventually roll over, reach for objects, sit up, crawl, and walk. It takes extreme conditions to modify these behaviors or cause them not to appear. In contrast, intelligence and personality are less strongly canalized; they vary much more with changes in the environment.

When we look at behaviors constrained by heredity, we can see that canalization is highly adaptive. Through it, nature ensures that children will develop certain species-typical skills under many rearing conditions, thereby promoting survival.

Gene–Environment Correlation. A major problem in trying to separate heredity and environment is that they are often correlated (Rutter, 2011; Scarr & McCartney, 1983). According to the concept of **gene–environment correlation**, our genes influence the environments to which we are exposed. The way this happens changes with age.

Passive and Evocative Correlation. At younger ages, two types of gene–environment correlation are common. The first is called *passive* correlation because the child has no control over it. Early on, parents provide environments influenced by their own heredity. For example, parents who are good athletes emphasize outdoor activities and enroll their children in swimming and gymnastics. Besides being exposed to an “athletic environment,” the children may have inherited their parents’ athletic ability. As a result, they are likely to become good athletes for both genetic and environmental reasons.

The second type of gene–environment correlation is *evocative*. Children evoke responses that are influenced by the child’s heredity, and these responses strengthen the child’s original style. For example, an active, friendly baby is likely to receive more social stimulation than a passive, quiet infant. And a cooperative, attentive child probably receives more patient and sensitive interactions from parents than an inattentive, distractible child. In support of this idea, the less genetically alike siblings are, the more their parents treat them differently, in both warmth and negativity. Thus, parents’ treatment of identical twins is highly similar, whereas their treatment of fraternal twins and nontwin biological siblings is only moderately so. And little resemblance exists in parents’ warm and negative interactions with unrelated stepsiblings (see Figure 2.9) (Reiss, 2003).

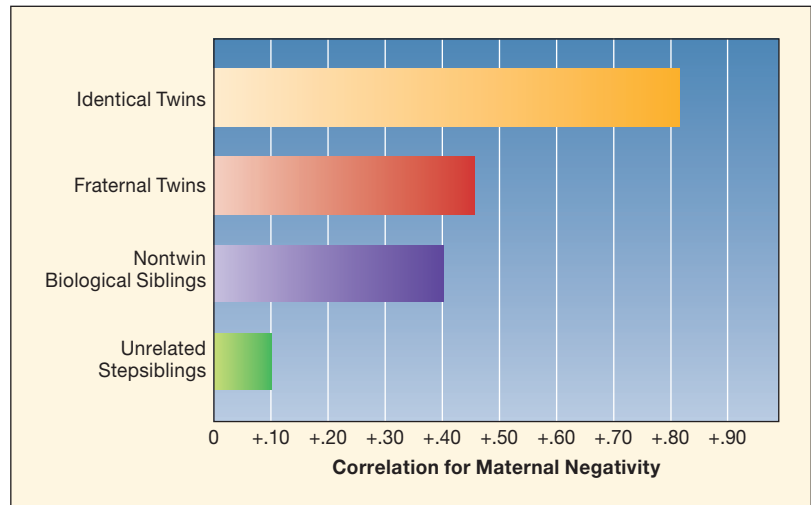

FIGURE 2.9 Similarity in mothers’ interactions for pairs of siblings differing in genetic relatedness. The correlations shown are for maternal negativity. The pattern illustrates evocative gene–environment correlation. Identical twins evoke similar maternal treatment because of their identical heredity. As genetic resemblance between siblings declines, the strength of the correlation drops. Mothers vary their interactions as they respond to each child’s unique genetic makeup. (Adapted from Reiss, 2003.)

Active Correlation. At older ages, *active* gene–environment correlation becomes common. As children extend their experiences beyond the immediate family and are given the freedom to make more choices, they actively seek environments that fit with their genetic tendencies. The well-coordinated, muscular child spends more time at after-school sports, the musically talented child joins the school orchestra and practices his violin, and the intellectually curious child is a familiar patron at her local library.

This tendency to actively choose environments that complement our heredity is called **niche-picking** (Scarr & McCartney, 1983). Infants and young children cannot do much niche-picking because adults select environments for them. In contrast, older children, adolescents, and adults are increasingly in charge of their environments.

Niche-picking explains why pairs of identical twins reared apart during childhood and later reunited may find, to their surprise, that they have similar hobbies, food preferences, and vocations—a trend that is especially marked when twins’ environmental opportunities are similar (Plomin, 1994). Niche-picking also helps us understand why identical twins become somewhat more alike, and fraternal twins and adopted siblings less alike, in intelligence with age (Bouchard, 2004; Loehlin, Horn, & Willerman, 1997). And niche-picking sheds light on why adult identical twins, compared to fraternal twins and other adults, select more similar spouses and best friends—in height, weight, personality, political attitudes, and other characteristics (Rushton & Bons, 2005).

The influence of heredity and environment is not constant but changes over time. With age, genetic factors may become more important in influencing the environments we experience and choose for ourselves.

© LOU CYPHER/CORBIS

This mother shares her love of the piano with her daughter, who also may have inherited her mother's musical talent. When heredity and environment are correlated, the influence of one cannot be separated from the influence of the other.

Environmental Influences on Gene Expression.

Notice how, in the concepts just considered, heredity is granted priority. In gene–environment interaction, it affects responsiveness to particular environments. In canalization, it restricts the development of certain behaviors. Similarly, gene–environment correlation is viewed as driven by genetics, in that children's genetic makeup causes them to receive, evoke, or seek experiences that actualize their hereditary tendencies (Plomin, 2009; Rutter, 2011).

A growing number of researchers take issue with the supremacy of heredity, arguing that it does not dictate children's experiences or development in a rigid way. In one study, boys with a genetic tendency toward antisocial behavior (based on the presence of a gene on the X chromosome known to predispose both animals and humans to aggression) were no more aggressive than boys without this gene, *unless* they also had a history of severe child abuse (Caspi et al., 2002). Boys with and without the gene did not differ in their experience of abuse, indicating that the “aggressive genotype” did not increase exposure to abuse. And in a large Finnish adoption study, children whose biological mothers had schizophrenia but who were being reared by healthy adoptive parents showed little mental

illness—no more than a control group with healthy biological and adoptive parents. In contrast, schizophrenia and other psychological impairments piled up in adoptees whose biological and adoptive parents were both disturbed (Tienari et al., 2003; Tienari, Wahlberg, & Wynne, 2006).

Furthermore, parents and other caring adults can *uncouple* unfavorable gene–environment correlations by providing children with positive experiences that modify the expression of heredity, yielding favorable outcomes. For example, in a study that tracked the development of 5-year-old identical twins, pair members tended to resemble each other in level of aggression. And the more aggression they displayed, the more maternal anger and criticism they received (a gene–environment correlation). Nevertheless, some mothers treated their twins differently. When followed up at age 7, twins who had been targets of more maternal negativity engaged in even more antisocial behavior. In contrast, their better-treated, genetically identical counterparts showed a reduction in disruptive acts (Caspi et al., 2004). Good parenting protected them from a spiraling, antisocial course of development.

Accumulating evidence reveals that the relationship between heredity and environment is not a one-way street, from genes to environment to behavior. Rather, like other system influences considered in this and the previous chapter, it is *bidirectional*: Genes affect people's behavior and experiences, but their experiences and behavior also affect gene expression (Diamond, 2009; Gottlieb, 2003; Rutter, 2007). Researchers call this view of the relationship between heredity and environment the *epigenetic framework* (Gottlieb, 1998, 2007). It is depicted in Figure 2.10. **Epigenesis** means development resulting from ongoing, bidirectional exchanges between heredity and all levels of the environment. To illustrate, providing a baby with a

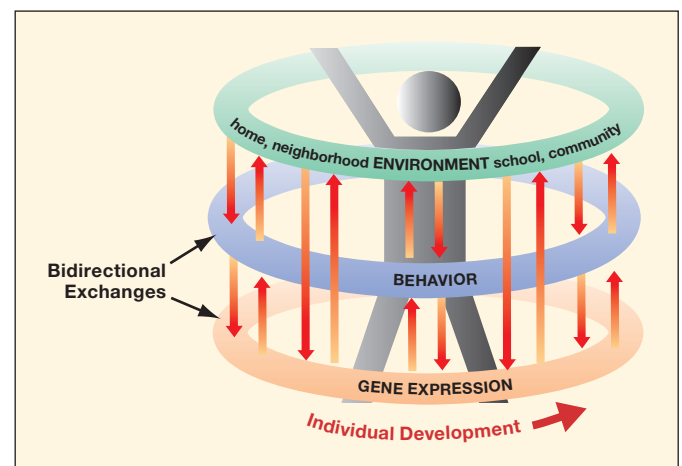

FIGURE 2.10 The epigenetic framework. Development takes place through ongoing, bidirectional exchanges between heredity and all levels of the environment. Genes affect behavior and experiences. Experiences and behavior also affect gene expression. (Adapted from Gottlieb, 2007.)

Biology and Environment

A Case of Epigenesis: Smoking During Pregnancy Alters Gene Expression

A wealth of experimental research with animals confirms that environment can modify the genome in ways that have no impact on a gene's sequence of base pairs but nevertheless affect the operation of that gene (Zhang & Meaney, 2010). This epigenetic interplay, in which a gene's impact on the individual's phenotype depends on the gene's context, is now being vigorously investigated in humans.

Maternal smoking during pregnancy is among the risk factors for *attention-deficit hyperactivity disorder (ADHD)*—one of the most common disorders of childhood, which we will take up in greater detail in Chapter 9. ADHD symptoms—inattention, impulsivity, and overactivity—typically result in serious academic and social problems. Some studies report that individuals who are homozygous for a chromosome-5 gene (DD) containing a special repeat of base pairs are at increased risk for ADHD, though other research has not confirmed any role for this gene (Fisher et al., 2002; Gill et al., 1997; Waldman et al., 1998).

Animal evidence suggests that one reason for this inconsistency may be that

environmental influences associated with ADHD—such as prenatal exposure to toxins—modify the gene's activity. To test this possibility, researchers recruited several hundred mothers and their 6-month-old babies, obtaining infant blood samples for molecular genetic analysis and asking mothers whether they smoked regularly during pregnancy (Kahn et al., 2003). At a 5-year follow-up, parents responded to a widely used behavior rating scale that assesses children for ADHD symptoms.

Findings revealed that by itself, the DD genotype was unrelated to impulsivity, overactivity, or oppositional behavior. But children whose mothers had smoked during pregnancy scored higher in these behaviors than children of nonsmoking mothers. Furthermore, as Figure 2.11 shows, 5-year-olds with both prenatal nicotine exposure and the DD genotype obtained substantially higher impulsivity, overactivity, and oppositional scores than all other groups—outcomes that persisted even after a variety of other factors (quality of the home environment and maternal ethnicity, marital status, and postbirth smoking) had been controlled.

Another investigation following participants into adolescence yielded similar findings, suggesting that the epigenetic effect persists (Becker et al.,

IMAGE SOURCE/GETTY IMAGES

Because his mother smoked during pregnancy, this baby may be at risk for attention-deficit hyperactivity disorder (ADHD). Prenatal nicotine exposure seems to alter expression of a chromosome-5 gene in ways that greatly heighten impulsivity, overactivity, and oppositional behavior.

2008). What processes might account for it? In animal research, tobacco smoke stimulates the DD genotype to release chemicals in the brain that promote impulsivity and overactivity (Ernst, Moolchan, & Robinson, 2001). These behaviors, in turn, often evoke harsh, punitive parenting, which triggers defiance in children.

The DD genotype is widespread, present in more than 50 percent of people. Thus, the majority of children prenatally exposed to nicotine are at high risk for learning and behavior problems (refer to page 88 in Chapter 3). Growing evidence indicates that other genes, in epigenetic interplay with as yet unknown environmental factors, also contribute to ADHD symptoms (Hudziak & Rettew, 2009).

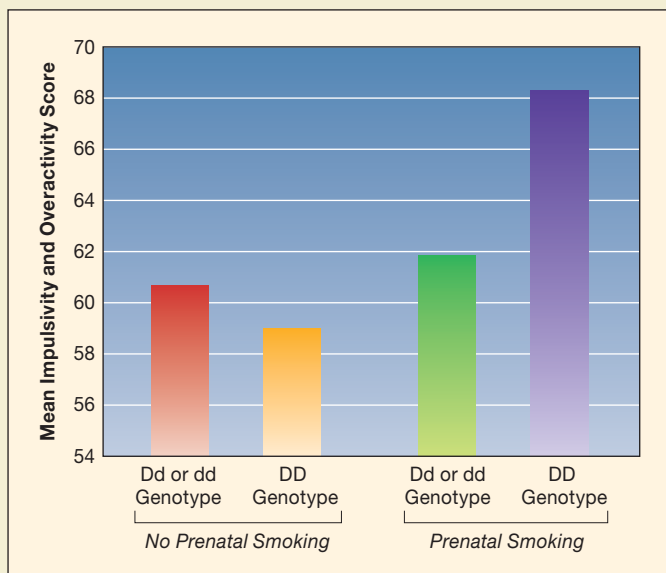

FIGURE 2.11 Combined influence of maternal prenatal smoking and genotype on impulsivity and overactivity at age 5. In the absence of prenatal smoking, 5-year-olds who were homozygous for a chromosome-5 gene (DD) showed no elevation in impulsivity and overactivity (orange bar) compared with children of other genotypes (Dd or dd) (red bar). Among children of all genotypes, prenatal smoking was associated with an increase in these behaviors (green and purple bars). And the combination of prenatal smoking and DD genotype greatly magnified impulsivity and overactivity (purple bar). Children's oppositional behavior followed a similar epigenetic pattern. (Adapted from Kahn et al., 2003.)

healthy diet increases brain growth, leading to new connections between nerve cells, which transform gene expression. This opens the door to new gene–environment exchanges—for example, advanced exploration of objects and interaction with caregivers, which further enhance brain growth and gene expression. These ongoing, bidirectional influences foster cognitive and social development. In contrast, harmful environments can negatively affect gene expression (see the Biology and Environment box on page 74 for an example) (Blair & Raver, 2012). And at times, the impact is so profound that later experiences can do little to change characteristics (such as intelligence and personality) that originally were flexible.

A major reason that researchers are interested in the nature–nurture issue is that they want to improve environments so that people can develop as far as possible. The concept of epigenesis reminds us that development is best understood as a series of complex exchanges between nature and nurture. Although people cannot be changed in any way we might desire, environments can modify genetic influences. The success of any attempt to improve development depends on the characteristics we want to change, the genetic makeup of the individual, and the type and timing of our intervention.

ASK YOURSELF

REVIEW What is epigenesis, and how does it differ from gene–environment interaction and gene–environment correlation? Provide an example of epigenesis.

CONNECT Explain how each of the following concepts supports the conclusion that genetic influences on human characteristics are not constant but change over time: somatic mutation (page 52), niche-picking (page 72), and epigenesis (page 73).

APPLY Bianca's parents are accomplished musicians. At age 4, Bianca began taking piano lessons. By age 10, she was accompanying the school choir. At age 14, she asked to attend a special music high school. Explain how gene–environment correlation promoted Bianca's talent.

REFLECT What aspects of your own development—for example, interests, hobbies, college major, or vocational choice—are probably due to niche-picking? Explain.

SUMMARY

Genetic Foundations (p. 46)

What are genes, and how are they transmitted from one generation to the next?

- Each individual's **phenotype**, or directly observable characteristics, is a product of both **genotype** and environment. **Chromosomes**, rodlike structures within the cell nucleus, contain our hereditary endowment. Along their length are **genes**, segments of **deoxyribonucleic acid (DNA)** that send instructions for making a rich assortment of proteins to the cell's cytoplasm.
- **Gametes**, or sex cells, result from a cell division process called **meiosis**, in which each individual receives a unique set of genes from each parent. Once sperm and ovum unite, the resulting **zygote** starts to develop into a complex human being through cell duplication, or **mitosis**.
- If the fertilizing sperm carries an X chromosome, the child will be a girl; if it contains a Y chromosome, a boy. **Fraternal**, or **dizygotic**, **twins** result when two ova are released from the mother's ovaries and each is fertilized. **Identical**, or **monozygotic**, **twins** develop when a zygote divides in two during the early stages of cell duplication.

© FIFOTO/ALAMY

Describe various patterns of genetic inheritance.

- **Homozygous** individuals have two identical **alleles**, or forms of a gene. If the alleles differ, the individual is **heterozygous**, and relationships between the alleles determine the phenotype. In **dominant–recessive inheritance**, only individuals with two recessive alleles display the recessive trait. Heterozygous individuals display only the dominant trait and are **carriers** of the recessive trait. In **incomplete dominance**, both alleles are expressed in the phenotype.

- In **X-linked inheritance**, a harmful allele is carried on the X chromosome and, therefore, is more likely to affect males. In **genomic imprinting**, one parent's allele is activated, regardless of its makeup.
- Harmful genes arise from **mutation**, which can occur spontaneously or be caused by hazardous environmental agents. Germline mutation affects the cells that give rise to gametes; somatic mutation can occur in body cells at any time of life.
- Human traits that vary on a continuum, such as intelligence and personality, result from **polygenic inheritance**—the effects of many genes.

Describe major chromosomal abnormalities, and explain how they occur.

- Most chromosomal abnormalities result from errors during meiosis. The most common, Down syndrome, results in physical defects and mental retardation. **Sex chromosome disorders**, such as XYY, triple X, Klinefelter, and Turner syndromes, are milder than defects of the **autosomes**, usually causing specific intellectual problems but not mental retardation.

Reproductive Choices

(p. 53)

What procedures can assist prospective parents in having healthy children?

- **Genetic counseling** helps couples at risk for giving birth to children with genetic abnormalities decide whether or not to conceive. **Prenatal diagnostic methods** permit early detection of developmental problems.
- Reproductive technologies such as donor insemination, in vitro fertilization, surrogate motherhood, and postmenopausal-assisted childbirth enable individuals to become parents who otherwise would not, but they raise serious legal and ethical concerns.
- Many parents who are infertile or at high risk of transmitting a genetic disorder decide to adopt. Although adopted children have more learning and emotional problems than children in general, most fare well in the long run. Warm, sensitive parenting predicts favorable development.

COURTESY OF THE MCSHANE FAMILY

Environmental Contexts for Development

(p. 59)

Describe family functioning from the perspective of ecological systems theory, along with aspects of the environment that support family well-being and development.

- The first and foremost context for development is the family, a dynamic system characterized by bidirectional influences, in which each member's behaviors affect those of others. Both direct and indirect influences operate within the family system, which must continually adjust to new events and changes in its members.

AP IMAGES/JENNI GIRTMAN

- **Socioeconomic status (SES)** profoundly affects family functioning. Higher-SES families tend to be smaller, to emphasize psychological traits, and to engage in warm, verbally stimulating interaction with children. Lower-SES families often stress external characteristics and use more commands, criticism, and physical punishment. Many affluent parents are physically and emotionally unavailable, thereby impairing their children's adjustment. Poverty and homelessness can seriously undermine development.
- Connections between family and community are vital for psychological well-being. Stable, socially cohesive neighborhoods in which residents have access to social support and enrichment activities promote favorable development in both children and adults. Compared with urban environments, small towns foster greater community involvement, warm ties among nonrelatives, and a sense of safety among the elderly.

RICHARD W. RODRIGUEZ/AP IMAGES FOR BOYS & GIRLS CLUBS OF AMERICA

- The values and practices of cultures and **subcultures** affect all aspects of daily life. **Extended-family households**, which are common among many ethnic minority groups, help protect family members from the negative effects of poverty and other stressful life conditions.

- **Collectivist societies**, which emphasize group needs and goals, and **individualistic societies**, which emphasize individual well-being, take different approaches to devising **public policies** to address social problems. Largely because of its strongly individualistic values, U.S. policies safeguarding children and families, as well as those safeguarding older adults, lag behind those of other Western nations.

Understanding the Relationship Between Heredity and Environment

(p. 69)

Explain the various ways heredity and environment may combine to influence complex traits.

- **Behavioral genetics** is a field that examines the contributions of nature and nurture to diversity in human traits and abilities. Researchers use **kinship studies** to compute **heritability estimates**, which measure the extent to which genetic factors influence complex traits such as intelligence and personality. However, the accuracy and usefulness of heritability estimates have been challenged.
- According to the concepts of **gene–environment interaction** and **canalization**, heredity influences each individual's unique response to varying environments. **Gene–environment correlation** and **niche-picking** describe how genes affect the environments to which individuals are exposed. **Epigenesis** reminds us that development is best understood as a series of complex exchanges between heredity and all levels of the environment.

chapter 3

ELIZABETH FLORES/MCT/NEWS.COM

An expectant mother reacts with amazement on hearing the robust heartbeat of her nearly full-term fetus. High-quality prenatal care and preparation for the events of childbirth enable her to approach labor and delivery with confidence and excitement.

Prenatal Development, Birth, and the Newborn Baby

When I met Yolanda and Jay one fall in my child development class, Yolanda was just two months pregnant. Approaching age 30, married for several years, and their careers well under way, they had decided to have a baby. To prepare for parenthood, they enrolled in my evening section, arriving once a week after work full of questions: “How does the baby grow before birth?” “When is each organ formed?” “Has its heart begun to beat?” “Can it hear, feel, or sense our presence?”

Most of all, Yolanda and Jay wanted to do everything possible to make sure their baby would be born healthy. Yolanda started to wonder about her diet and whether she should keep up her daily aerobic workout. And she asked me whether an aspirin for a headache, a glass of wine at dinner, or a few cups of coffee during work and study hours might be harmful.

In this chapter, we answer Yolanda and Jay’s questions, along with a great many more that scientists have asked about the events before birth. First, we trace prenatal development, paying special attention to environmental supports for healthy growth, as well as damaging influences that threaten the child’s health and survival. Next, we turn to the events of childbirth. Today, women in industrialized nations have many choices about where and how they give birth, and hospitals go to great lengths to make the arrival of a new baby a rewarding, family-centered event.

Yolanda and Jay’s son Joshua reaped the benefits of his parents’ careful attention to his needs during pregnancy. He was strong, alert, and healthy at birth. Nevertheless, the birth process does not always go smoothly. We will consider the pros and cons of medical interventions, such as pain-relieving drugs and surgical deliveries, designed to ease a difficult birth and protect the health of mother and baby. Our discussion also addresses the development of infants born underweight or too early. We conclude with a close look at the remarkable capacities of newborns. ●

chapter outline

Prenatal Development

- Conception • Period of the Zygote • Period of the Embryo • Period of the Fetus

Prenatal Environmental Influences

- Teratogens • Other Maternal Factors • The Importance of Prenatal Health Care

- **SOCIAL ISSUES: HEALTH** The Nurse–Family Partnership: Reducing Maternal Stress and Enhancing Child Development Through Social Support

Childbirth

- The Stages of Childbirth • The Baby’s Adaptation to Labor and Delivery • The Newborn Baby’s Appearance • Assessing the Newborn’s Physical Condition: The Apgar Scale

Approaches to Childbirth

- Natural, or Prepared, Childbirth • Home Delivery

Medical Interventions

- Fetal Monitoring • Labor and Delivery Medication • Cesarean Delivery

Preterm and Low-Birth-Weight Infants

- Preterm versus Small-for-Date Infants • Consequences for Caregiving • Interventions for Preterm Infants

- **BIOLOGY AND ENVIRONMENT** The Mysterious Tragedy of Sudden Infant Death Syndrome

Adjusting to the New Family Unit

Prenatal Development

The sperm and ovum that unite to form the new individual are uniquely suited for the task of reproduction. The ovum is a tiny sphere, measuring $\frac{1}{175}$ inch in diameter—barely visible to the naked eye as a dot the size of the period at the end of this sentence. But in its microscopic world, it is a giant—the largest cell in the human body. The ovum’s size makes it a perfect target for the much smaller sperm, which measure only $\frac{1}{500}$ inch.

Conception

About once every 28 days, in the middle of a woman’s menstrual cycle, an ovum bursts from one of her *ovaries*, two walnut-sized organs located deep inside her abdomen, and is drawn into one of two *fallopian tubes*—long, thin structures that lead to the hollow, soft-lined uterus (see Figure 3.1). While the ovum is traveling, the spot on the ovary from which it was released, now called the *corpus luteum*, secretes hormones that prepare the lining of the uterus to receive a fertilized ovum. If pregnancy does not occur, the corpus luteum shrinks, and the lining of the uterus is discarded two weeks later with menstruation.

The male produces sperm in vast numbers—an average of 300 million a day—in the *testes*, two glands located in the *scrotum*, sacs that lie just behind the penis. In the final process of maturation, each sperm develops a tail that permits it to

swim long distances, upstream in the female reproductive tract, through the *cervix* (opening of the uterus) and into the fallopian tube, where fertilization usually takes place. The journey is difficult, and many sperm die. Only 300 to 500 reach the ovum, if one happens to be present. Sperm live for up to 6 days and can lie in wait for the ovum, which survives for only 1 day after being released into the fallopian tube. However, most conceptions result from intercourse occurring during a three-day period—on the day of ovulation or during the 2 days preceding it (Wilcox, Weinberg, & Baird, 1995).

With conception, the story of prenatal development begins to unfold. The vast changes that take place during the 38 weeks of pregnancy are usually divided into three phases: (1) the period of the zygote, (2) the period of the embryo, and (3) the period of the fetus. As we look at what happens in each, you may find it useful to refer to Table 3.1, which summarizes milestones of prenatal development.

Period of the Zygote

The period of the zygote lasts about two weeks, from fertilization until the tiny mass of cells drifts down and out of the fallopian tube and attaches itself to the wall of the uterus. The zygote’s first cell duplication is long and drawn out; it is not complete until about 30 hours after conception. Gradually, new cells are added at a faster rate. By the fourth day, 60 to 70 cells exist that form a hollow, fluid-filled ball

FIGURE 3.1 Female reproductive organs, showing fertilization, early cell duplication, and implantation. (From *Before We Are Born*, 6th ed., by K. L. Moore & T. V. N. Persaud, p. 87. Copyright © 2003, reprinted with permission from Elsevier, Inc.)

TABLE 3.1 Milestones of Prenatal Development

TRIMESTER	PERIOD	WEEKS	LENGTH AND WEIGHT	MAJOR EVENTS
First	Zygote 	1		The one-celled zygote multiplies and forms a blastocyst.
		2		The blastocyst burrows into the uterine lining. Structures that feed and protect the developing organism begin to form— <i>amnion, chorion, yolk sac, placenta, and umbilical cord.</i>
	Embryo 	3–4	¼ inch (6 mm)	A primitive brain and spinal cord appear. Heart, muscles, ribs, backbone, and digestive tract begin to develop.
		5–8	1 inch (2.5 cm); ½ ounce (4 g)	Many external body structures (face, arms, legs, toes, fingers) and internal organs form. The sense of touch begins to develop, and the embryo can move.
	Fetus 	9–12	3 inches (7.6 cm); less than 1 ounce (28 g)	Rapid increase in size begins. Nervous system, organs, and muscles become organized and connected, and new behavioral capacities (kicking, thumb sucking, mouth opening, and rehearsal of breathing) appear. External genitals are well-formed, and the fetus's sex is evident.
Second		13–24	12 inches (30 cm); 1.8 pounds (820 g)	The fetus continues to enlarge rapidly. In the middle of this period, fetal movements can be felt by the mother. Vernix and lanugo keep the fetus's skin from chapping in the amniotic fluid. Most of the brain's neurons are in place by 24 weeks. Eyes are sensitive to light, and the fetus reacts to sound.
Third		25–38	20 inches (50 cm); 7.5 pounds (3,400 g)	The fetus has a good chance of survival if born during this time. Size increases. Lungs mature. Rapid brain development causes sensory and behavioral capacities to expand. In the middle of this period, a layer of fat is added under the skin. Antibodies are transmitted from mother to fetus to protect against disease. Most fetuses rotate into an upside-down position in preparation for birth.

called a *blastocyst* (refer again to Figure 3.1). The cells on the inside, called the *embryonic disk*, will become the new organism; the outer ring of cells, termed the *trophoblast*, will become the structures that provide protective covering and nourishment.

Implantation. Between the seventh and ninth days, **implantation** occurs: The blastocyst burrows deep into the uterine lining. Surrounded by the woman's nourishing blood, it starts to grow in earnest. At first, the trophoblast (protective outer layer) multiplies fastest. It forms a membrane, called the **amnion**, that encloses the developing organism in *amniotic*

fluid, which helps keep the temperature of the prenatal world constant and provides a cushion against any jolts caused by the woman's movement. A *yolk sac* emerges that produces blood cells until the liver, spleen, and bone marrow are mature enough to take over this function (Moore, Persaud, & Torchia, 2013).

The events of these first two weeks are delicate and uncertain. As many as 30 percent of zygotes do not survive this period. In some, the sperm and ovum do not join properly. In others, cell duplication never begins. By preventing implantation in these cases, nature eliminates most prenatal abnormalities (Sadler, 2010).

© LENNART NILSSON, A CHILD IS BORN/SCANPIX

Period of the zygote: seventh to ninth day. The fertilized ovum duplicates rapidly, forming a hollow ball of cells, or blastocyst, by the fourth day after fertilization. Here the blastocyst, magnified thousands of times, burrows into the uterine lining between the seventh and ninth day.

The Placenta and Umbilical Cord. By the end of the second week, cells of the trophoblast form another protective membrane—the **chorion**, which surrounds the amnion. From the chorion, tiny hairlike *villi*, or blood vessels, emerge.¹ As these villi burrow into the uterine wall, the *placenta* starts to develop. By bringing the embryo's and mother's blood close together, the **placenta** permits food and oxygen to reach the organism and waste products to be carried away. A membrane forms that allows these substances to be exchanged but prevents the mother's and embryo's blood from mixing directly.

The placenta is connected to the developing organism by the **umbilical cord**, which first appears as a tiny stalk and, during the course of pregnancy, grows to a length of 1 to 3 feet. The umbilical cord contains one large vein that delivers blood loaded with nutrients and two arteries that remove waste products. The force of blood flowing through the cord keeps it firm, so it seldom tangles while the embryo, like a space-walking astronaut, floats freely in its fluid-filled chamber (Moore, Persaud, & Torchia, 2013).

By the end of the period of the zygote, the developing organism has found food and shelter. These dramatic beginnings take place before most mothers know they are pregnant.

¹Recall from Table 2.4 on page 56 that *chorionic villus sampling* is the prenatal diagnostic method that can be performed earliest, at nine weeks after conception.

Period of the Embryo

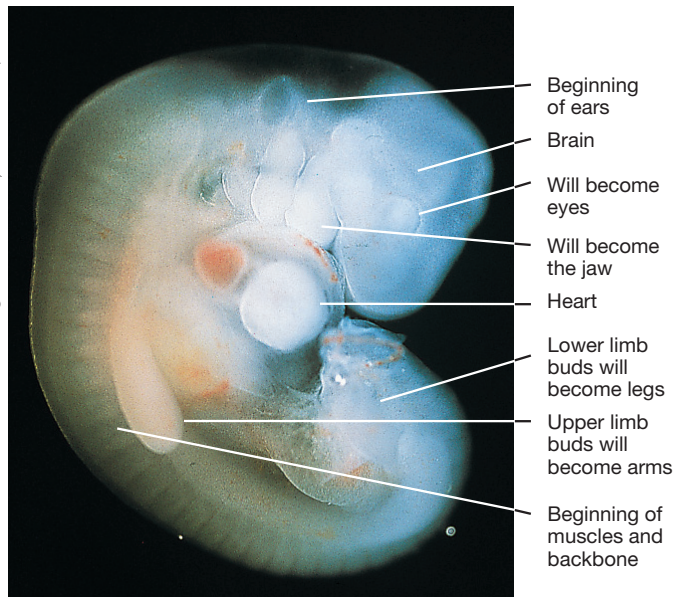

The period of the **embryo** lasts from implantation through the eighth week of pregnancy. During these brief six weeks, the most rapid prenatal changes take place as the **groundwork** is laid for all body structures and internal organs.

Last Half of the First Month. In the first week of this period, the embryonic disk forms three layers of cells: (1) the *ectoderm*, which will become the nervous system and skin; (2) the *mesoderm*, from which will develop the muscles, skeleton, circulatory system, and other internal organs; and (3) the *endoderm*, which will become the digestive system, lungs, urinary tract, and glands. These three layers give rise to all parts of the body.

At first, the nervous system develops fastest. The ectoderm folds over to form the **neural tube**, or primitive spinal cord. At 3½ weeks, the top swells to form the brain. While the nervous system is developing, the heart begins to pump blood, and the muscles, backbone, ribs, and digestive tract appear. At the end of the first month, the curled embryo—only ¼ inch long—consists of millions of organized groups of cells with specific functions.

The Second Month. In the second month, growth continues rapidly. The eyes, ears, nose, jaw, and neck form. Tiny buds become arms, legs, fingers, and toes. Internal organs are more distinct: The intestines grow, the heart develops separate chambers, and the liver and spleen take over production of blood cells so that the yolk sac is no longer needed. Changing body proportions cause the embryo's posture to become more upright.

Period of the embryo: fourth week. This 4-week-old embryo is only ¼-inch long, but many body structures have begun to form. The primitive tail will disappear by the end of the embryonic period.

© LENNART NILSSON, A CHILD IS BORN/SCANPIX

Period of the embryo: seventh week. The embryo's posture is more upright. Body structures—eyes, nose, arms, legs, and internal organs—are more distinct. An embryo this age responds to touch. It can also move, although at less than one inch long and one ounce in weight, it is still too tiny to be felt by the mother.

At 7 weeks, production of *neurons* (nerve cells that store and transmit information) begins deep inside the neural tube at the astounding pace of more than 250,000 per minute (Nelson, 2011). Once formed, neurons begin traveling along tiny threads to their permanent locations, where they will form the major parts of the brain.

At the end of this period, the embryo—about 1 inch long and $\frac{1}{2}$ ounce in weight—can already sense its world. It responds to touch, particularly in the mouth area and on the soles of the feet. And it can move, although its tiny flutters are still too light to be felt by the mother (Moore, Persaud, & Torchia, 2013).

Period of the Fetus

The period of the **fetus**, from the ninth week to the end of pregnancy, is the longest prenatal period. During this “growth and finishing” phase, the organism increases rapidly in size.

The Third Month. In the third month, the organs, muscles, and nervous system start to become organized and connected. When the brain signals, the fetus kicks, bends its arms, forms a fist, curls its toes, turns its head, opens its mouth, and even sucks its thumb, stretches, and yawns. Body position changes occur as often as 25 times per hour (Einspieler, Marschik, & Prechtel, 2008). The tiny lungs begin to expand and contract in

an early rehearsal of breathing movements. By the twelfth week, the external genitals are well-formed, and the sex of the fetus can be detected with ultrasound (Sadler, 2010). Other finishing touches appear, such as fingernails, toenails, tooth buds, and eyelids. The heartbeat can now be heard through a stethoscope.

Prenatal development is sometimes divided into **trimesters**, or three equal time periods. At the end of the third month, the *first trimester* is complete.

The Second Trimester. By the middle of the second trimester, between 17 and 20 weeks, the new being has grown large enough that the mother can feel its movements. A white, cheeselike substance called **vernix** protects its skin from chapping during the long months spent bathing in the amniotic fluid. White, downy hair called **lanugo** also appears over the entire body, helping the vernix stick to the skin.

At the end of the second trimester, many organs are well-developed. And most of the brain's billions of neurons are in place; few will be produced after this time. However, *glial cells*, which support and feed the neurons, continue to increase rapidly throughout the remaining months of pregnancy, as well as after birth. Consequently, brain weight increases tenfold from the twentieth week until birth (Roelfsema et al., 2004). At the same time, neurons begin forming *synapses*, or connections, at a rapid pace.

© LENNART NILSSON, A CHILD IS BORN/SCANPIX

Period of the fetus: eleventh week. The fetus grows rapidly. At 11 weeks, the brain and muscles are better connected. The fetus can kick, bend its arms, and open and close its hands and mouth, and suck its thumb. Notice the yolk sac, which shrinks as the internal organs take over its function of producing blood cells.

Brain growth means new behavioral capacities. The 20-week-old fetus can be stimulated as well as irritated by sounds. And if a doctor looks inside the uterus using fetoscopy (see Table 2.4 on page 56), fetuses try to shield their eyes from the light with their hands, indicating that sight has begun to emerge (Moore, Persaud, & Torchia, 2013). Still, a fetus born at this time cannot survive. Its lungs are immature, and the brain cannot yet control breathing and body temperature.

The Third Trimester. During the final trimester, a fetus born early has a chance for survival. The point at which the baby can first survive, called the **age of viability**, occurs sometime between 22 and 26 weeks (Moore, Persaud, & Torchia, 2013). A baby born between the seventh and eighth months, however, usually needs oxygen assistance to breathe. Although the brain's respiratory center is now mature, tiny air sacs in the lungs are not yet ready to inflate and exchange carbon dioxide for oxygen.

The brain continues to make great strides. The *cerebral cortex*, the seat of human intelligence, enlarges. As neural connectivity and organization improve, the fetus spends more time awake. At 20 weeks, fetal heart rate reveals no periods of

alertness. But by 28 weeks, fetuses are awake about 11 percent of the time, a figure that rises to 16 percent just before birth (DiPietro et al., 1996). Between 30 and 34 weeks, fetuses show rhythmic alternations between sleep and wakefulness that gradually increase in organization (Rivkees, 2003). Around this time, synchrony between fetal heart rate and motor activity peaks: A rise in heart rate is usually followed within 5 seconds by a burst of motor activity (DiPietro et al., 2006). These are clear signs that coordinated neural networks are beginning to form in the brain.

By the end of pregnancy, the fetus also takes on the beginnings of a personality. Fetal activity is linked to infant temperament. In one study, more active fetuses during the third trimester became 1-year-olds who could better handle frustration and 2-year-olds who were less fearful, in that they more readily interacted with toys and with an unfamiliar adult in a laboratory (DiPietro et al., 2002). Perhaps fetal activity is an indicator of healthy neurological development, which fosters adaptability in childhood. The relationships just described, however, are only modest. As we will see in Chapter 6, sensitive caregiving can modify the temperaments of children who have difficulty adapting to new experiences.

Period of the fetus: twenty-second week. This fetus is almost one foot long and weighs slightly more than one pound. Its movements can be felt easily by the mother and by other family members who place a hand on her abdomen. If born now, the fetus has a slim chance of surviving.

© LENNART NILSSON, A CHILD IS BORN/SCANPIX

Period of the fetus: thirty-sixth week. This fetus fills the uterus. To nourish it, the umbilical cord and placenta have grown large. Notice the vernix (a cheeselike substance) on the skin, which protects it from chapping. The fetus has accumulated fat to aid temperature regulation after birth. In two more weeks, it will be full-term.

The third trimester brings greater responsiveness to stimulation. Between 23 and 30 weeks, connections form between the cerebral cortex and brain regions involved in pain sensitivity. By this time, painkillers should be used in any surgical procedures (Lee et al., 2005). Around 28 weeks, fetuses blink their eyes in reaction to nearby sounds (Kisilevsky & Low, 1998; Saffran, Werker, & Werner, 2006). And at 30 weeks, fetuses presented with a repeated auditory stimulus against the mother's abdomen initially react with a rise in heart rate and body movements. But over the next 5 to 6 minutes, responsiveness gradually declines, indicating *habituation* (adaptation) to the sound. If the stimulus is reintroduced after a 10-minute delay, heart rate falls off far more quickly (Dirix et al., 2009). This suggests that fetuses can remember for at least a brief period.

Within the next six weeks, fetuses distinguish the tone and rhythm of different voices and sounds. They show systematic heart rate changes to a male versus a female speaker, to the mother's voice versus a stranger's, to a stranger speaking their native language (English) versus a foreign language (Mandarin Chinese), and to a simple familiar melody (descending tones) versus an unfamiliar melody (ascending tones) (Granier-Deferre et al., 2003; Huotilainen et al., 2005; Kisilevsky et al., 2003, 2009; Lecanuet et al., 1993). And in one clever study, mothers read aloud Dr. Seuss's lively book *The Cat in the Hat* for the last six weeks of pregnancy. After birth, their infants learned to turn on recordings of the mother's voice by sucking on nipples. They sucked hardest to hear *The Cat in the Hat*—the sound they had come to know while still in the womb (DeCasper & Spence, 1988).

In the final three months, the fetus gains more than 5 pounds and grows 7 inches. In the eighth month, a layer of fat is added to assist with temperature regulation. The fetus also receives antibodies from the mother's blood that protect against illnesses, since the newborn's own immune system will not work well until several months after birth. In the last weeks, most fetuses assume an upside-down position, partly because of the shape of the uterus and also because the head is heavier than the feet. Growth slows, and birth is about to take place.

ASK YOURSELF

REVIEW Why is the period of the embryo regarded as the most dramatic prenatal period? Why is the period of the fetus called the "growth and finishing" phase?

CONNECT How is brain development related to fetal capacities and behavior?

APPLY Amy, two months pregnant, wonders how the embryo is being fed and what parts of the body have formed. "I don't look pregnant yet, so does that mean not much development has taken place?" she asks. How would you respond to Amy?

Prenatal Environmental Influences

Although the prenatal environment is far more constant than the world outside the womb, many factors can affect the embryo and fetus. Yolanda and Jay learned that parents—and society as a whole—can do a great deal to create a safe environment for development before birth.

Teratogens

The term **teratogen** refers to any environmental agent that causes damage during the prenatal period. Scientists chose this label (from the Greek word *teras*, meaning "malformation" or "monstrosity") because they first learned about harmful prenatal influences from cases in which babies had been profoundly damaged. But the harm done by teratogens is not always simple and straightforward. It depends on the following factors:

- **Dose.** As we discuss particular teratogens, you will see that larger doses over longer time periods usually have more negative effects.
- **Heredity.** The genetic makeup of the mother and the developing organism plays an important role. Some individuals are better able than others to withstand harmful environments.
- **Other negative influences.** The presence of several negative factors at once, such as additional teratogens, poor nutrition, and lack of medical care, can worsen the impact of a harmful agent.
- **Age.** The effects of teratogens vary with the age of the organism at time of exposure. To understand this last idea, think of the *sensitive period* concept introduced in Chapter 1. A sensitive period is a limited time span in which a part of the body or a behavior is biologically prepared to develop rapidly. During that time, it is especially sensitive to its surroundings. If the environment is harmful, then damage occurs, and recovery is difficult and sometimes impossible.

Figure 3.2 on page 86 summarizes prenatal sensitive periods. In the *period of the zygote*, before implantation, teratogens rarely have any impact. If they do, the tiny mass of cells is usually so damaged that it dies. The *embryonic period* is the time when serious defects are most likely to occur because the foundations for all body parts are being laid down. During the *fetal period*, teratogenic damage is usually minor. However, organs such as the brain, ears, eyes, teeth, and genitals can still be strongly affected.

The effects of teratogens go beyond immediate physical damage. Some health effects are delayed and may not show up for decades. Furthermore, psychological consequences may occur indirectly, as a result of physical damage. For example, a defect resulting from drugs the mother took during pregnancy can affect others' reactions to the child as well as the child's

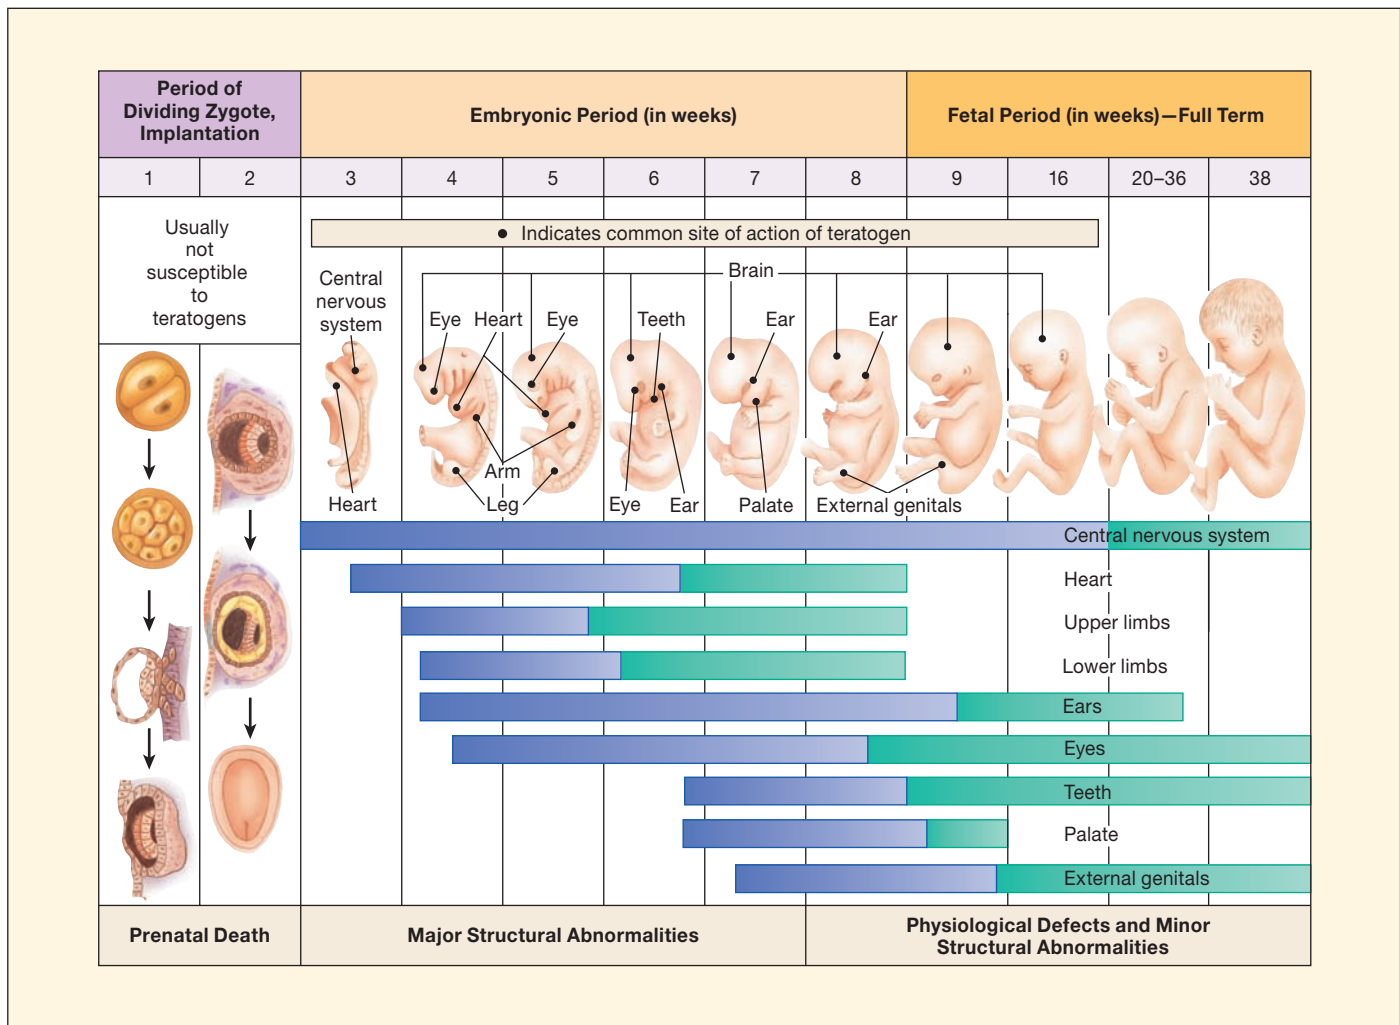

FIGURE 3.2 Sensitive periods in prenatal development. Each organ or structure has a sensitive period, during which its development may be disturbed. Blue horizontal bars indicate highly sensitive periods. Green horizontal bars indicate periods that are somewhat less sensitive to teratogens, although damage can occur. (Adapted from *Before We Are Born*, 7th ed., by K. L. Moore and T. V. N. Persaud, p. 313. Copyright © 2008, reprinted with permission from Elsevier, Inc.)

ability to explore the environment. Over time, parent–child interaction, peer relations, and cognitive, emotional, and social development may suffer. Furthermore, prenatally exposed children may be less resilient in the face of environmental risks, such as single parenthood, parental emotional disturbance, or maladaptive parenting (Yumoto, Jacobson, & Jacobson, 2008). As a result, their long-term adjustment may be compromised.

Notice how an important idea about development discussed in earlier chapters is at work here: *bidirectional influences* between child and environment. Now let’s look at what scientists have discovered about a variety of teratogens.

Prescription and Nonprescription Drugs. In the early 1960s, the world learned a tragic lesson about drugs and prenatal development. At that time, a sedative called *thalidomide* was widely available in Canada, Europe, and South America. When taken by mothers 4 to 6 weeks after conception, thalidomide produced gross deformities of the embryo’s arms

and legs and, less frequently, damage to the ears, heart, kidneys, and genitals. About 7,000 infants worldwide were affected (Moore, Persaud, & Torchia, 2013). As children exposed to thalidomide grew older, many scored below average in intelligence. Perhaps the drug damaged the central nervous system directly. Or the child-rearing conditions of these severely deformed youngsters may have impaired their intellectual development.

Another medication, a synthetic hormone called *diethylstilbestrol (DES)*, was widely prescribed between 1945 and 1970 to prevent miscarriages. As daughters of these mothers reached adolescence and young adulthood, they showed unusually high rates of cancer of the vagina, malformations of the uterus, and infertility. When they tried to have children, their pregnancies more often resulted in prematurity, low birth weight, and miscarriage than those of non-DES-exposed women. Young men showed an increased risk of genital abnormalities and cancer of the testes (Goodman, Schorge, & Greene, 2011; Hammes & Laitman, 2003).

Currently, the most widely used potent teratogen is a vitamin A derivative called *Accutane* (known by the generic name *isotretinoin*), prescribed to treat severe acne and taken by hundreds of thousands of women of childbearing age in industrialized nations. Exposure during the first trimester results in eye, ear, skull, brain, heart, and immune system abnormalities (Honein, Paulozzi, & Erickson, 2001). *Accutane*'s packaging warns users to avoid pregnancy by using two methods of birth control, but many women do not heed this advice (Garcia-Bournissen et al., 2008).

Indeed, any drug with a molecule small enough to penetrate the placental barrier can enter the embryonic or fetal bloodstream. Yet many pregnant women continue to take over-the-counter medications without consulting their doctors. Aspirin is one of the most common. Several studies suggest that regular aspirin use is linked to low birth weight, infant death around the time of birth, poorer motor development, and lower intelligence scores in early childhood, although other research fails to confirm these findings (Barr et al., 1990; Kozer et al., 2003; Streissguth et al., 1987). Coffee, tea, cola, and cocoa contain another frequently consumed drug, caffeine. High doses increase the risk of low birth weight (Brent, Christian, & Diener, 2011). And persistent intake of antidepressant medication is linked to an elevated incidence of premature delivery and birth complications, including respiratory distress, and to high blood pressure in infancy (Lund, Pedersen, & Henriksen, 2009; Roca et al., 2011; Udechuku et al., 2010).

Because children's lives are involved, we must take findings like these seriously. At the same time, we cannot be sure that these frequently used drugs actually cause the problems just mentioned. Often mothers take more than one drug. If the embryo or fetus is injured, it is hard to tell which drug might be responsible or whether other factors correlated with drug taking are at fault. Until we have more information, the safest course of action is the one Yolanda took: Avoid these drugs entirely. Unfortunately, many women do not know that they are pregnant during the early weeks of the embryonic period, when exposure to medications (and other teratogens) can be of greatest threat.

Illegal Drugs. The use of highly addictive mood-altering drugs, such as cocaine and heroin, has become more widespread, especially in poverty-stricken inner-city areas, where these drugs provide a temporary escape from a daily life of hopelessness. Nearly 4 percent of U.S. pregnant women take these substances (Substance Abuse and Mental Health Services Administration, 2011).

Babies born to users of cocaine, heroin, or methadone (a less addictive drug used to wean people away from heroin) are at risk for a wide variety of problems, including prematurity, low birth weight, physical defects, breathing difficulties, and death around the time of birth (Bandstra et al., 2010; Howell, Coles, & Kable, 2008; Schuetze & Eiden, 2006). In addition, these infants are born drug-addicted. They are often feverish and irritable and have trouble sleeping, and their cries are

abnormally shrill and piercing—a common symptom among stressed newborns (Bauer et al., 2005). When mothers with many problems of their own must care for these babies, who are difficult to calm down, cuddle, and feed, behavior problems are likely to persist.

Throughout the first year, heroin- and methadone-exposed infants are less attentive to the environment than nonexposed babies, and their motor development is slow. After infancy, some children get better, while others remain jittery and inattentive. The kind of parenting they receive may explain why problems persist for some but not for others (Hans & Jeremy, 2001).

Evidence on cocaine suggests that some prenatally exposed babies develop lasting difficulties. Cocaine constricts the blood vessels, causing oxygen delivered to the developing organism to fall for 15 minutes following a high dose. It also can alter the production and functioning of neurons and the chemical balance in the fetus's brain. These effects may contribute to an array of cocaine-associated physical defects, including eye, bone, genital, urinary tract, kidney, and heart deformities; brain hemorrhages and seizures; and severe growth retardation (Covington et al., 2002; Feng, 2005; Salisbury et al., 2009). Several studies report perceptual, motor, attention, memory, language, and impulse-control problems that persist into the preschool and school years (Bandstra et al., 2011; Dennis et al., 2006; Lester & Lagasse, 2010; Linares et al., 2006).

Other investigations, however, reveal no major negative effects of prenatal cocaine exposure (Behnke et al., 2006; Frank et al., 2005; Hurt et al., 2009). These contradictory findings indicate how difficult it is to isolate the precise damage caused by illegal drugs. Cocaine users vary greatly in the amount, potency, and purity of the cocaine they ingest. Also, they often take several drugs, display other high-risk behaviors, suffer from poverty and other stresses, and engage in insensitive caregiving—factors that worsen outcomes for children (Jones,

JOHN JAMES WOOD/GETTY IMAGES/PHOTOLIBRARY

This infant, born many weeks before his due date, breathes with the aid of a respirator. Prematurity and low birth weight can result from a variety of environmental influences during pregnancy, including maternal drug and tobacco use.

2006). But researchers have yet to determine exactly what accounts for findings of cocaine-related damage in some studies but not in others.

Another illegal drug, marijuana, is used more widely than heroin and cocaine. Researchers have linked prenatal marijuana exposure to smaller head size (a measure of brain growth); attention, memory, and academic achievement difficulties; impulsivity and overactivity; and depression as well as anger and aggression in childhood and adolescence (Goldschmidt et al., 2004; Gray et al., 2005; Huizink & Mulder, 2006; Jutras-Aswad et al., 2009). As with cocaine, however, lasting consequences are not well-established. Overall, the effects of illegal drugs are far less consistent than the impact of two legal substances to which we now turn: tobacco and alcohol.

Tobacco. Although smoking has declined in Western nations, an estimated 14 percent of U.S. women smoke during their pregnancies (Tong et al., 2009). The best-known effect of smoking during the prenatal period is low birth weight. But the likelihood of other serious consequences, such as miscarriage, prematurity, cleft lip and palate, blood vessel abnormalities, impaired heart rate and breathing during sleep, infant death, and asthma and cancer later in childhood, also increases (Geerts et al., 2012; Howell, Coles, & Kable, 2008; Jaakkola & Gissler, 2004; Mossey et al., 2009). The more cigarettes a mother smokes, the greater the chances that her baby will be affected. And if a pregnant woman stops smoking at any time, even during the third trimester, she reduces the likelihood that her infant will be born underweight and suffer from future problems (Klesges et al., 2001).

Even when a baby of a smoking mother appears to be born in good physical condition, slight behavioral abnormalities may threaten the child's development. Newborns of smoking mothers are less attentive to sounds, display more muscle tension, are more excitable when touched and visually stimulated, and more often have colic (persistent crying). These findings suggest subtle negative effects on brain development (Law et al., 2003; Sondergaard et al., 2002). Consistent with this view, prenatally exposed children and adolescents tend to have shorter attention spans, difficulties with impulsivity and overactivity, poorer memories, lower mental test scores, and higher levels of disruptive, aggressive behavior (Espy et al., 2011; Fryer, Crocker, & Mattson, 2008; Lindblad & Hjern, 2010).

Exactly how can smoking harm the fetus? Nicotine, the addictive substance in tobacco, constricts blood

vessels, lessens blood flow to the uterus, and causes the placenta to grow abnormally. This reduces the transfer of nutrients, so the fetus gains weight poorly. Also, nicotine raises the concentration of carbon monoxide in the bloodstreams of both mother and fetus. Carbon monoxide displaces oxygen from red blood cells, damaging the central nervous system and slowing body growth in the fetuses of laboratory animals (Friedman, 1996). Similar effects may occur in humans.

From one-third to one-half of nonsmoking pregnant women are “passive smokers” because their husbands, relatives, or co-workers use cigarettes. Passive smoking is also related to low birth weight, infant death, childhood respiratory illnesses, and possible long-term attention, learning, and behavior problems (Best, 2009; Pattenden et al., 2006). Clearly, expectant mothers should avoid smoke-filled environments.

Alcohol. In his moving book *The Broken Cord*, Michael Dorris (1989), a Dartmouth College anthropology professor, described what it was like to rear his adopted son Abel (called Adam in the book), whose biological mother drank heavily throughout pregnancy and died of alcohol poisoning shortly after his birth. A Sioux Indian, Abel was born with **fetal alcohol spectrum disorder (FASD)**, a term that encompasses a range of physical, mental, and behavioral outcomes caused by prenatal alcohol exposure. Children with FASD are given one of three diagnoses, which vary in severity:

1. **Fetal alcohol syndrome (FAS)**, distinguished by (a) slow physical growth, (b) a pattern of three facial abnormalities (short eyelid openings; a thin upper lip; a smooth or flattened philtrum, or indentation running from the bottom of the nose to the center of the upper lip), and (c) brain injury,

Left photo: This 5-year-old's mother drank heavily during pregnancy. Her widely spaced eyes, thin upper lip, and flattened philtrum are typical of fetal alcohol syndrome (FAS). Right photo: This 12-year-old has the small head and facial abnormalities of FAS. She also shows the mental impairments and slow growth that accompany the disorder.

evident in a small head and impairment in at least three areas of functioning—for example, memory, language and communication, attention span and activity level (overactivity), planning and reasoning, motor coordination, or social skills. Other defects—of the eyes, ears, nose, throat, heart, genitals, urinary tract, or immune system—may also be present. Abel was diagnosed as having FAS. As is typical for this disorder, his mother drank heavily throughout pregnancy.

2. **Partial fetal alcohol syndrome (p-FAS)**, characterized by (a) two of the three facial abnormalities just mentioned and (b) brain injury, again evident in at least three areas of impaired functioning. Mothers of children with p-FAS generally drank alcohol in smaller quantities, and children's defects vary with the timing and length of alcohol exposure. Furthermore, recent evidence suggests that paternal alcohol use around the time of conception can alter gene expression (see page 73 in Chapter 2), thereby contributing to symptoms (Ouko et al., 2009).
3. **Alcohol-related neurodevelopmental disorder (ARND)**, in which at least three areas of mental functioning are impaired, despite typical physical growth and absence of facial abnormalities. Again, prenatal alcohol exposure, though confirmed, is less pervasive than in FAS (Chudley et al., 2005; Loock et al., 2005).

Even when provided with enriched diets, FAS babies fail to catch up in physical size during infancy and childhood. Mental impairment associated with all three FASD diagnoses is also permanent: In his teens and twenties, Abel Dorris had trouble concentrating and keeping a routine job, and he suffered from poor judgment. For example, he would buy something and not wait for change or would wander off in the middle of a task. He died at age 23, after being hit by a car.

The more alcohol a woman consumes during pregnancy, the poorer the child's motor coordination, speed of information processing, reasoning, and intelligence and achievement test scores during the preschool and school years (Burden, Jacobson, & Jacobson, 2005; Korkman, Kettunen, & Autti-Raemoe, 2003; Mattson, Calarco, & Lang, 2006). In adolescence and early adulthood, FASD is associated with persisting attention and motor-coordination deficits, poor school performance, trouble with the law, inappropriate social and sexual behaviors, alcohol and drug abuse, and lasting mental health problems, including depression and high emotional reactivity to stress (Barr et al., 2006; Fryer, Crocker, & Mattson, 2008; Hellemans et al., 2010; Howell et al., 2006; Streissguth et al., 2004).

How does alcohol produce its devastating effects? First, it interferes with production and migration of neurons in the primitive neural tube. Brain-imaging research reveals reduced brain size, damage to many brain structures, and abnormalities in brain functioning, including the electrical and chemical activity involved in transferring messages from one part of the brain to another (Coles et al., 2011; Haycock, 2009). Second, the body uses large quantities of oxygen to metabolize alcohol. A pregnant woman's heavy drinking draws away oxygen that the developing organism needs for cell growth.

About 25 percent of U.S. mothers report drinking at some time during their pregnancies. As with heroin and cocaine, alcohol abuse is higher in poverty-stricken women. On some Native-American reservations, the incidence of FAS is as high as 10 to 20 percent (Szlemko, Wood, & Thurman, 2006; Tong et al., 2009). Unfortunately, when affected girls later become pregnant, the poor judgment caused by the syndrome often prevents them from understanding why they themselves should avoid alcohol. Thus, the tragic cycle is likely to be repeated in the next generation.

How much alcohol is safe during pregnancy? Even mild drinking, less than one drink per day, is associated with reduced head size and body growth among children followed into adolescence (Jacobson et al., 2004; Martinez-Frias et al., 2004). Recall that other factors—both genetic and environmental—can make some fetuses more vulnerable to teratogens. Therefore, no amount of alcohol is safe. Couples planning a pregnancy and expectant mothers should avoid alcohol entirely.

Radiation. Defects due to ionizing radiation were tragically apparent in children born to pregnant women who survived the bombing of Hiroshima and Nagasaki during World War II. Similar abnormalities surfaced in the nine months following the 1986 Chernobyl, Ukraine, nuclear power plant accident. After each disaster, the incidence of miscarriage and babies born with underdeveloped brains, physical deformities, and slow physical growth rose dramatically (Double et al., 2011; Schull, 2003). Evacuation of residents in areas near the Japanese

© CAROLINE PENN/CORBIS

This child's deformities are linked to radiation exposure early in pregnancy, caused by the Chernobyl nuclear power plant disaster in 1986. She is also at risk for low intelligence and language and emotional disorders.

nuclear facility damaged by the March 2011 earthquake and tsunami was intended to prevent these devastating outcomes.

Even when a radiation-exposed baby seems normal, problems may appear later. For example, even low-level radiation, resulting from industrial leakage or medical X-rays, can increase the risk of childhood cancer (Fattibene et al., 1999). In middle childhood, prenatally exposed Chernobyl children had abnormal brain-wave activity, lower intelligence test scores, and rates of language and emotional disorders two to three times greater than those of nonexposed Russian children. Furthermore, the more tension parents reported, due to forced evacuation from their homes and worries about living in irradiated areas, the poorer their children's emotional functioning (Loganovskaja & Loganovsky, 1999; Loganovsky et al., 2008). Stressful rearing conditions seemed to combine with the damaging effects of prenatal radiation to impair children's development.

Environmental Pollution. In industrialized nations, an astounding number of potentially dangerous chemicals are released into the environment. More than 75,000 are in common use in the United States, and many new pollutants are introduced each year. When 10 newborns were randomly selected from U.S. hospitals for analysis of umbilical cord blood, researchers uncovered a startling array of industrial contaminants—287 in all (Houlihan et al., 2005). They concluded that many babies are “born polluted” by chemicals that not only impair prenatal development but increase the chances of health problems and life-threatening diseases later on.

Certain pollutants cause severe prenatal damage. In the 1950s, an industrial plant released waste containing high levels of *mercury* into a bay providing seafood and water for the town of Minamata, Japan. Many children born at the time displayed physical deformities, mental retardation, abnormal speech, difficulty in chewing and swallowing, and uncoordinated movements. High levels of prenatal mercury exposure disrupt production and migration of neurons, causing widespread brain damage (Clarkson, Mago, & Myers, 2003; Hubbs-Tait et al., 2005). Prenatal mercury exposure from maternal seafood diets predicts deficits in speed of cognitive processing and motor, attention, and verbal test performance during the school years (Boucher et al., 2010; Debes et al., 2006). Pregnant women are wise to avoid eating long-lived predatory fish, such as swordfish, albacore tuna, and shark, which are heavily contaminated with mercury.

For many years, *polychlorinated biphenyls (PCBs)* were used to insulate electrical equipment until research showed that, like mercury, they entered waterways and the food supply. In Taiwan, prenatal exposure to high levels of PCBs in rice oil resulted in low birth weight, discolored skin, deformities of the gums and nails, brain-wave abnormalities, and delayed cognitive development (Chen & Hsu, 1994; Chen et al., 1994). Steady, low-level PCB exposure is also harmful. Women who frequently ate PCB-contaminated fish, compared with those who ate little or no fish, had infants with lower birth weights, smaller heads, persisting attention and memory difficulties, and

lower intelligence test scores in childhood (Boucher, Muckle, & Bastien, 2009; Jacobson & Jacobson, 2003; Stewart et al., 2008).

Another teratogen, *lead*, is present in paint flaking off the walls of old buildings and in certain materials used in industrial occupations. High levels of prenatal lead exposure are related to prematurity, low birth weight, brain damage, and a wide variety of physical defects. Even at low levels, affected infants and children show slightly poorer mental and motor development (Bellinger, 2005; Jedrychowski et al., 2009).

Finally, prenatal exposure to dioxins—toxic compounds resulting from incineration—is linked to brain, immune system, and thyroid damage in babies and to an increased incidence of breast and uterine cancers in women, perhaps through altering hormone levels (ten Tusscher & Koppe, 2004). Even tiny amounts of dioxin in the paternal bloodstream cause a dramatic change in sex ratio of offspring: Affected men father nearly twice as many girls as boys (Ishihara et al., 2007). Dioxin seems to impair the fertility of Y-bearing sperm prior to conception.

Infectious Disease. About 5 percent of women in industrialized nations catch an infectious disease while pregnant. Although most of these illnesses, such as the common cold, seem to have no impact, a few—as Table 3.2 illustrates—can cause extensive damage.

Viruses. In the mid-1960s, a worldwide epidemic of *rubella* (three-day, or German, measles) led to the birth of more than 20,000 American babies with serious defects and to 13,000 fetal and newborn deaths. Consistent with the sensitive-period concept, the greatest damage occurs when rubella strikes during the embryonic period. More than 50 percent of infants whose mothers become ill during that time show deafness; eye deformities, including cataracts; heart, genital, urinary, intestinal, bone, and dental defects; and mental retardation. Infection during the fetal period is less harmful, but low birth weight, hearing loss, and bone defects may still occur. The organ damage inflicted by prenatal rubella often leads to lifelong health problems, including severe mental illness, diabetes, cardiovascular disease, and thyroid and immune-system dysfunction in adulthood (Brown, 2006; Duszak, 2009).

Routine vaccination in infancy and childhood has made new rubella outbreaks unlikely in industrialized nations. But an estimated 100,000 cases of prenatal infection continue to occur worldwide, primarily in developing countries in Africa and Asia with weak or absent immunization programs (Bale, 2009).

The *human immunodeficiency virus (HIV)*, which can lead to *acquired immune deficiency syndrome (AIDS)*, a disease that destroys the immune system, has infected increasing numbers of women over the past three decades. In developing countries, where 95 percent of new infections occur, more than half affect women. In South Africa, for example, nearly 30 percent of all pregnant women are HIV-positive (South African Department of Health, 2009). Untreated HIV-infected expectant mothers pass the deadly virus to the developing organism 20 to 30 percent of the time.

TABLE 3.2 Effects of Some Infectious Diseases During Pregnancy

DISEASE	MISCARRIAGE	PHYSICAL MALFORMATIONS	MENTAL RETARDATION	LOW BIRTH WEIGHT AND PREMATURITY

AIDS progresses rapidly in infants. By 6 months, weight loss, diarrhea, and repeated respiratory illnesses are common. The virus also causes brain damage, as indicated by seizures, gradual loss in brain weight, and delayed mental and motor development. Nearly half of prenatal AIDS babies die by 1 year of age and 90 percent by age 3 (Devi et al., 2009). Antiretroviral drug therapy reduces prenatal AIDS transmission by as much as 95 percent, with no harmful consequences of drug treatment for children. These medications have led to a dramatic decline in prenatally acquired AIDS in Western nations. Although distribution is increasing, antiretroviral drugs are still not widely available in impoverished regions of the world (UNICEF, 2010a).

As Table 3.2 reveals, the developing organism is especially sensitive to the family of herpes viruses, for which no vaccine or treatment exists. Among these, *cytomegalovirus* (the most frequent prenatal infection, transmitted through respiratory or sexual contact) and *herpes simplex 2* (which is sexually transmitted) are especially dangerous. In both, the virus invades the mother’s genital tract, infecting babies either during pregnancy or at birth.

Babies are tested for the HIV virus in a clinic in Mozambique, Africa. Prenatal treatment with antiretroviral drugs reduces transmission of AIDS from mother to child by as much as 95 percent.

Bacterial and Parasitic Diseases. Table 3.2 also includes several bacterial and parasitic diseases. Among the most common is *toxoplasmosis*, caused by a parasite found in many animals. Pregnant women may become infected from eating raw or undercooked meat or from contact with the feces of infected cats. About 40 percent of women who have the disease transmit it to the developing organism. If it strikes during the first trimester, it is likely to cause eye and brain damage. Later infection is linked to mild visual and cognitive impairments (Jones, Lopez, & Wilson, 2003). Expectant mothers can avoid toxoplasmosis by making sure that the meat they eat is well-cooked, having pet cats checked for the disease, and turning over the care of litter boxes to other family members.

Other Maternal Factors

Besides avoiding teratogens, expectant parents can support the development of the embryo and fetus in other ways. In healthy, physically fit women, regular moderate exercise, such as walking, swimming, biking, or an aerobic workout, is related to increased birth weight (Olson et al., 2009). However, frequent, vigorous exercise, especially late in pregnancy, results in lower birth weight than in healthy, nonexercising controls (Clapp et al., 2002; Leet & Flick, 2003). Most women, however, do not engage in sufficient moderate exercise during pregnancy to promote their own and their baby's health (Poudevigne & O'Connor, 2006). An expectant mother who remains fit experiences fewer physical discomforts in the final weeks.

In the following sections, we examine other maternal factors—nutrition, emotional stress, blood type, age, and previous births.

Nutrition. During the prenatal period, when children are growing more rapidly than at any other time, they depend totally on the mother for nutrients. A healthy diet that results in a weight gain of 25 to 30 pounds (10 to 13.5 kilograms) helps ensure the health of mother and baby.

Prenatal malnutrition can cause serious damage to the central nervous system. The poorer the mother's diet, the greater the loss in brain weight, especially if malnutrition occurred during the last trimester. During that time, the brain is increasing rapidly in size, and a maternal diet high in all the basic nutrients is necessary for it to reach its full potential. An inadequate diet during pregnancy can also distort the structure of the liver, kidney, pancreas, and other organs, resulting in lifelong health problems, including cardiovascular disease and diabetes in adulthood (Barker, 2008; Whincup et al., 2008).

Because poor nutrition suppresses development of the immune system, prenatally malnourished babies frequently catch respiratory illnesses (Chandra, 1991). In addition, they are often irritable and unresponsive to stimulation. In poverty-stricken families, these effects quickly combine with a stressful home life. With age, low intelligence and serious learning problems become more apparent (Pollitt, 1996).

Many studies show that providing pregnant women with adequate food has a substantial impact on the health of their newborn babies. Yet the growth demands of the prenatal period require more than just increased quantity of food. Vitamin–mineral enrichment is also crucial. For example, taking a folic acid supplement around the time of conception greatly reduces by more than 70 percent abnormalities of the neural tube, such as *anencephaly* and *spina bifida* (see Table 2.4 on page 56). Folic acid supplementation early in pregnancy also reduces the risk of other physical defects, including cleft lip and palate, urinary tract abnormalities, and limb deformities. Furthermore, adequate folic acid intake during the last 10 weeks of pregnancy cuts in half the risk of premature delivery and low birth weight (Goh & Koren, 2008; MCR Vitamin Study Research Group, 1991; Scholl, Hediger, & Belsky, 1996).

Because of these findings, U.S. government guidelines recommend that all women of childbearing age consume 0.4 milligrams of folic acid per day. For women who have previously had a pregnancy affected by neural tube defect, the recommended amount is 4 to 5 milligrams (dosage must be carefully monitored, as excessive intake can be harmful) (American Academy of Pediatrics, 2006). About half of U.S. pregnancies are unplanned, so government regulations mandate that bread, flour, rice, pasta, and other grain products be fortified with folic acid.

When poor nutrition persists throughout pregnancy, infants usually require more than dietary improvement. Successful interventions must also break the cycle of apathetic mother–baby interactions. Some do so by teaching parents how to interact effectively with their infants, while others focus on stimulating infants to promote active engagement with their physical and social surroundings (Grantham-McGregor et al., 1994; Grantham-McGregor, Schofield, & Powell, 1987).

Although prenatal malnutrition is highest in poverty-stricken regions of the world, it is not limited to developing countries. The U.S. Special Supplemental Food Program for Women, Infants, and Children (WIC), which provides food packages to low-income pregnant women, reaches about 90 percent of those who qualify because of their extremely low incomes (U.S. Department of Agriculture, 2011b). But many U.S. women who need nutrition intervention are not eligible for WIC.

Emotional Stress. When women experience severe emotional stress during pregnancy, their babies are at risk for a wide variety of difficulties. Intense anxiety—especially during the first two trimesters—is associated with higher rates of miscarriage, prematurity, low birth weight, infant respiratory and digestive illnesses, colic (persistent infant crying), sleep disturbances, and irritability during the child's first three years (Field, 2011; Lazinski, Shea, & Steiner, 2008; van der Wal, van Eijsden, & Bonsel, 2007).

How can maternal stress affect the fetus? **TAKE A MOMENT...** To understand this process, list the changes you sensed in your own body the last time you were under stress.

When we experience fear and anxiety, stress hormones released into our bloodstream—such as *epinephrine* (adrenaline) and *cortisol*, known as the “flight or fight” hormones—cause us to be “poised for action.” Large amounts of blood are sent to parts of the body involved in the defensive response—the brain, the heart, and the muscles in the arms, legs, and trunk. Blood flow to other organs, including the uterus, is reduced. As a result, the fetus is deprived of a full supply of oxygen and nutrients.

Maternal stress hormones also cross the placenta, causing a dramatic rise in fetal stress hormones (evident in the amniotic fluid) and, therefore, in fetal heart rate, blood pressure, blood glucose, and activity level (Kinsella & Monk, 2009; Weinstock, 2008). Excessive fetal stress may permanently alter fetal neurological functioning, thereby heightening stress reactivity in later life. In several studies, infants and children of mothers who experienced severe prenatal anxiety displayed cortisol levels that were either abnormally high or abnormally low, both of which signal reduced physiological capacity to manage stress. Consistent with these findings, such children are more upset than their agemates when faced with novel or challenging experiences—effects that persist into adolescence and early adulthood (Entringer et al., 2009; Van den Bergh et al., 2008).

Furthermore, maternal emotional stress during pregnancy predicts childhood weakened immune system functioning and increased susceptibility to infectious disease (Nielsen et al., 2011). It is also associated with diverse negative behavioral outcomes, including anxiety, short attention span, anger, aggression, overactivity, and lower mental test scores, above and beyond the impact of other risks, such as maternal prenatal smoking, low birth weight, postnatal maternal anxiety, and low SES (de Weerth & Buitelaar, 2005; Gutteling et al., 2006; Lazinski, Shea, & Steiner, 2008; Loomans et al., 2011).

But stress-related prenatal complications are greatly reduced when mothers have partners, other family members, and friends who offer social support (Glover, Bergman, & O’Connor, 2008). The relationship of social support to positive pregnancy outcomes and subsequent child development is particularly strong for low-income women, who often lead highly stressful lives (see the Social Issues: Health box on page 94).

Rh Factor Incompatibility. When inherited blood types of mother and fetus differ, serious problems sometimes result. The most common cause of these difficulties is **Rh factor incompatibility**. When the mother is Rh-negative (lacks the Rh blood protein) and the father is Rh-positive (has the protein), the baby may inherit the father’s Rh-positive blood type. If even a little of a fetus’s Rh-positive blood crosses the placenta into the Rh-negative mother’s bloodstream, she begins to form antibodies to the foreign Rh protein. If these enter the fetus’s system, they destroy red blood cells, reducing the oxygen supply to organs and tissues. Mental retardation, miscarriage, heart damage, and infant death can occur.

It takes time for the mother to produce Rh antibodies, so firstborn children are rarely affected. The danger increases with each additional pregnancy. Fortunately, Rh incompatibility can

be prevented in most cases. After the birth of each Rh-positive baby, Rh-negative mothers are routinely given a vaccine to prevent the buildup of antibodies.

Maternal Age. In Chapter 2, we noted that women who delay childbearing until their thirties or forties face increased risk of infertility, miscarriage, and babies born with chromosomal defects. Are other pregnancy complications more common for older mothers? Research indicates that healthy women in their thirties have about the same rates as those in their twenties (Bianco et al., 1996; Dildy et al., 1996; Prysak, Lorenz, & Kisly, 1995). Thereafter, as Figure 3.3 reveals, complication rates increase, with a sharp rise among women age 50 to 55—an age at which because of menopause (end of menstruation) and aging reproductive organs, few women can conceive naturally (Salihu et al., 2003; Usta & Nassar, 2008).

In the case of teenage mothers, does physical immaturity cause prenatal complications? As we will see in Chapter 11, nature tries to ensure that once a girl can conceive, she is physically ready to carry and give birth to a baby. Infants born to teenagers have a higher rate of problems, but not directly because of maternal age. Most pregnant teenagers come from low-income backgrounds, where stress, poor nutrition, and health problems are common. Also, many are afraid to seek medical care or, in the United States, do not have access to care because they lack health insurance (U.S. Department of Health and Human Services, 2011a).

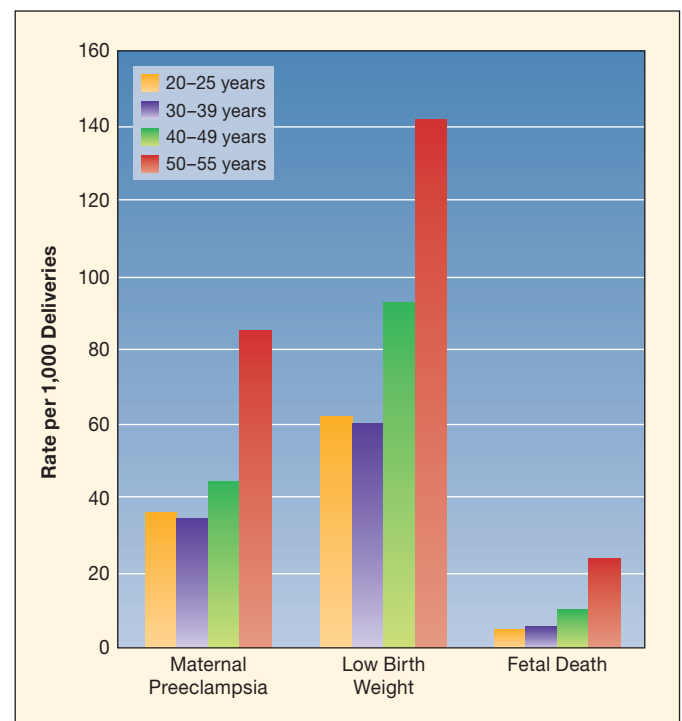

FIGURE 3.3 Relationship of maternal age to prenatal and birth complications. Complications increase after age 40, with a sharp rise between 50 and 55 years. See page 95 for a description of preeclampsia. (Adapted from Salihu et al., 2003.)

Social Issues: Health

The Nurse–Family Partnership: Reducing Maternal Stress and Enhancing Child Development Through Social Support

At age 17, Denise—an unemployed high-school dropout living with her disapproving parents—gave birth to Tara. Having no one to turn to for help during pregnancy and beyond, Denise felt overwhelmed and anxious much of the time. Tara was premature and cried uncontrollably, slept erratically, and suffered from frequent minor illnesses throughout her first year. When she reached school age, she had trouble keeping up academically, and her teachers described her as distractible, unable to sit still, angry, and uncooperative.

The Nurse–Family Partnership, currently implemented in hundreds of counties across 42 U.S. states, is a voluntary home visiting program for first-time, low-income expectant mothers like Denise. Its goals are to reduce pregnancy and birth complications, promote competent early caregiving, and improve family conditions, thereby protecting children from lasting adjustment difficulties. A registered nurse visits the home weekly during the first month after enrollment, twice a month during the remainder of pregnancy and through the middle of the child’s second year, and then monthly until age 2. In these sessions, the nurse provides the mother with intensive social support—a sympathetic ear; assistance in accessing health and other community services (especially fathers and grandmothers); and encouragement to finish high school, find work, and engage in future family planning.

To evaluate the program’s effectiveness, researchers randomly assigned large samples of mothers at risk for high prenatal stress (due to teenage pregnancy, poverty, and other negative life conditions) to nurse-visiting or comparison conditions (just prenatal care, or prenatal care plus infant referral for developmental problems). Families were followed through

their child’s school-age years and, in one experiment, into adolescence (Kitzman et al., 2010; Olds et al., 2004, 2007; Rubin et al., 2011).

As kindergartners, Nurse–Family Partnership children obtained higher language and intelligence test scores. And at both ages 6 and 9, the children of home-visited mothers in the poorest mental health during pregnancy exceeded comparison children in academic achievement and displayed fewer behavior problems. Furthermore, from their baby’s birth on, home-visited mothers were on a more favorable life course: They had fewer subsequent births, longer intervals between their first and second births, more frequent contact with the child’s father, more stable intimate partnerships, less welfare dependence, and a greater sense of control over their lives—key factors in reducing subsequent prenatal stress and in protecting children’s development. Perhaps for these reasons, 12-year-old children of home-visited mothers continued to be advantaged in academic achievement

and reported less alcohol use and drug-taking than comparison-group agemates.

Other findings revealed that professional nurses, compared with trained paraprofessionals, were far more effective in preventing outcomes associated with prenatal stress, including high infant fearfulness to novel stimuli and delayed mental development (Olds et al., 2002). Nurses were probably more proficient in individualizing program guidelines to fit the strengths and challenges faced by each family. They also might have had unique legitimacy as experts in the eyes of stressed mothers, more easily convincing them to take steps to reduce pregnancy complications that can trigger persisting developmental problems—such as those Tara displayed.

The Nurse–Family Partnership is highly cost-effective (Dawley, Loch, & Bindrich, 2007). For \$1 spent, it saves more than \$5 in public spending on pregnancy complications, preterm births, and child and youth learning and behavior problems.

COURTESY OF NURSE-FAMILY PARTNERSHIP

The Nurse–Family Partnership provides this first-time mother with regular home visits from a registered nurse. In follow-up research, children of home-visited mothers developed more favorably—cognitively, emotionally, and socially—than comparison children.

The Importance of Prenatal Health Care

Yolanda had her first prenatal appointment three weeks after missing her menstrual period. After that, she visited the doctor's office once a month until she was seven months pregnant, then twice during the eighth month. As birth grew near, Yolanda's appointments increased to once a week. The doctor kept track of her general health, her weight gain, the capacity of her uterus and cervix to support the fetus, and the fetus's growth.

Yolanda's pregnancy, like most others, was free of complications. But unexpected difficulties can arise, especially if mothers have health problems. For example, the 5 percent of pregnant women who have diabetes need careful monitoring. Extra glucose in the diabetic mother's bloodstream causes the fetus to grow larger than average, making pregnancy and birth problems more common. Maternal high blood glucose also compromises prenatal brain development: It is linked to poorer memory and learning in infancy and early childhood (deRegnier et al., 2007). Another complication, experienced by 5 to 10 percent of pregnant women, is *preeclampsia* (sometimes called *toxemia*), in which blood pressure increases sharply and the face, hands, and feet swell in the last half of pregnancy. If untreated, preeclampsia can cause convulsions in the mother and fetal death. Usually, hospitalization, bed rest, and drugs can lower blood pressure to a safe level (Vidaeff, Carroll, & Ramin, 2005). If not, the baby must be delivered at once.

Unfortunately, 6 percent of pregnant women in the United States wait until after the first trimester to seek prenatal care or receive none at all. Inadequate care is far more common among adolescent and low-income, ethnic-minority mothers. Their infants are three times as likely to be born underweight and five times as likely to die as are babies of mothers who receive early medical attention (Child Trends, 2012). Although the poorest of these mothers are eligible for government-sponsored health services, many low-income women do not qualify. As we will see when we take up birth complications, in nations where affordable medical care is universally available, such as Australia, Canada, Japan, and European countries, late-care pregnancies and maternal and infant health problems are greatly reduced.

LOOK AND LISTEN

List prenatal environmental factors that can compromise later academic performance and social adjustment. Ask several adults who hope someday to be parents to explain what they know about each factor. How great is their need for prenatal education? ●

Besides financial hardship, some mothers have other reasons for not seeking early prenatal care. These include *situational barriers* (difficulty finding a doctor, getting an appointment, and arranging transportation) and *personal barriers* (psychological

During a routine prenatal visit, this couple views an ultrasound image of their twins. All pregnant women need regular prenatal care to protect their health and that of their babies.

stress, the demands of taking care of other young children, family crises, and ambivalence about the pregnancy). Many also engage in high-risk behaviors, such as smoking and drug abuse, which they do not want to reveal to health professionals (Daniels, Noe, & Mayberry, 2006; Maupin et al., 2004). These women, who receive little or no prenatal care, are among those who need it most!

Clearly, public education about the importance of early and sustained prenatal care for all pregnant women is badly needed. Refer to Applying What We Know on page 96, which lists “do’s and don’ts” for a healthy pregnancy, based on our discussion of the prenatal environment.

ASK YOURSELF

REVIEW Why is it difficult to determine the prenatal effects of many environmental agents, such as drugs and pollution?

CONNECT How do teratogens illustrate the notion of epigenesis, presented in Chapter 2, that environments can affect gene expression (see page 73 to review)?

APPLY Nora, pregnant for the first time, believes that a few cigarettes and a glass of wine a day won't be harmful. Provide Nora with research-based reasons for not smoking or drinking.

REFLECT If you had to choose five environmental influences to publicize in a campaign aimed at promoting healthy prenatal development, which ones would you choose, and why?

Applying What We Know

Do's and Don'ts for a Healthy Pregnancy

Do

Do make sure that you have been vaccinated against infectious diseases that are dangerous to the embryo and fetus, such as rubella, before you get pregnant. Most vaccinations are not safe during pregnancy.

Do see a doctor as soon as you suspect that you are pregnant, and continue to get regular medical checkups throughout pregnancy.

Do eat a well-balanced diet and take vitamin–mineral supplements, as prescribed by your doctor, both prior to and during pregnancy. Gain 25 to 30 pounds gradually.

Do obtain literature from your doctor, library, or bookstore about prenatal development. Ask your doctor about anything that concerns you.

Do keep physically fit through moderate exercise. If possible, join a special exercise class for expectant mothers.

Do avoid emotional stress. If you are a single expectant mother, find a relative or friend on whom you can rely for emotional support.

Do get plenty of rest. An overtired mother is at risk for pregnancy complications.

Do enroll in a prenatal and childbirth education class with your partner or other companion. When parents know what to expect, the nine months before birth can be one of the most joyful times of life.

Don't

Don't take any drugs without consulting your doctor.

Don't smoke. If you have already smoked during part of your pregnancy, cut down or, better yet, quit. If other members of your family smoke, ask them to quit or to smoke outside.

Don't drink alcohol from the time you decide to get pregnant.

Don't engage in activities that might expose your embryo or fetus to environmental hazards, such as radiation or chemical pollutants. If you work in an occupation that involves these agents, ask for a safer assignment or a leave of absence.

Don't engage in activities that might expose your embryo or fetus to harmful infectious diseases, such as toxoplasmosis.

Don't choose pregnancy as a time to go on a diet.

Don't gain too much weight during pregnancy. A very large weight gain is associated with complications.

Childbirth

Although Yolanda and Jay completed my course three months before their baby was born, both agreed to return the following spring to share their experiences with my next class. Two-week-old Joshua came along as well. Yolanda and Jay's story revealed that the birth of a baby is one of the most dramatic and emotional events in human experience. Jay was present throughout Yolanda's labor and delivery. Yolanda explained:

By morning, we knew I was in labor. It was Thursday, so we went in for my usual weekly appointment. The doctor said, yes, the baby was on the way, but it would be a while. He told us to go home and relax and come to the hospital in three or four hours. We checked in at 3 in the afternoon; Joshua arrived at 2 o'clock the next morning. When, finally, I was ready to deliver, it went quickly; a half hour or so and some good hard pushes, and there he was! His face was red and puffy, and his head was misshapen, but I thought, "Our son! I can't believe he's really here."

Jay was also elated by Joshua's birth. "I wanted to support Yolanda and to experience as much as I could. It was awesome, indescribable," he said, holding Joshua over his shoulder and patting and kissing him gently. In the following sections, we explore the experience of childbirth, from both the parents' and the baby's point of view.

The Stages of Childbirth

It is not surprising that childbirth is often referred to as labor. It is the hardest physical work a woman may ever do. A complex series of hormonal changes between mother and fetus initiates the process, which naturally divides into three stages (see Figure 3.4):

1. *Dilation and effacement of the cervix.* This is the longest stage of labor, lasting an average of 12 to 14 hours with a first birth and 4 to 6 hours with later births. Contractions of the uterus gradually become more frequent and powerful, causing the cervix, or uterine opening, to widen and thin to nothing, forming a clear channel from the uterus into the birth canal, or vagina.
2. *Delivery of the baby.* This stage is much shorter, lasting about 50 minutes for a first birth and 20 minutes in later births. Strong contractions of the uterus continue, but the mother also feels a natural urge to squeeze and push with her abdominal muscles. As she does so with each contraction, she forces the baby down and out.
3. *Delivery of the placenta.* Labor comes to an end with a few final contractions and pushes. These cause the placenta to separate from the wall of the uterus and be delivered in about 5 to 10 minutes.

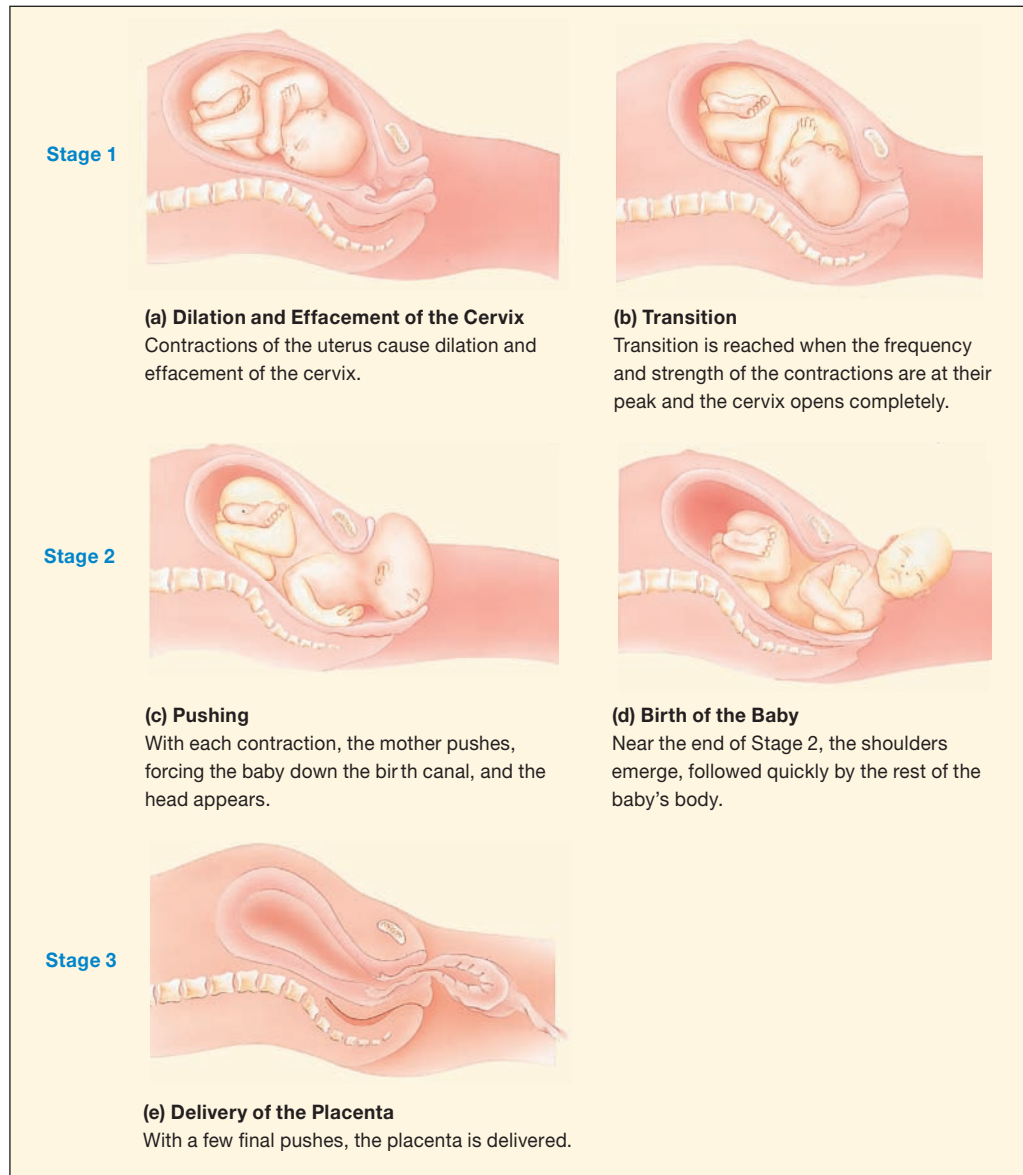

FIGURE 3.4 The three stages of labor.

The Baby's Adaptation to Labor and Delivery

At first glance, labor and delivery seem like a dangerous ordeal for the baby. The strong contractions exposed Joshua's head to a great deal of pressure, and they squeezed the placenta and the umbilical cord repeatedly. Each time, Joshua's supply of oxygen was temporarily reduced.

Fortunately, healthy babies are well-equipped to withstand these traumas. The force of the contractions causes the infant to produce high levels of stress hormones. Unlike during pregnancy, when excessive stress endangers the fetus, during childbirth high levels of infant cortisol and other stress hormones are adaptive. They help the baby withstand oxygen deprivation by

sending a rich supply of blood to the brain and heart (Gluckman, Sizonenko, & Bassett, 1999). In addition, stress hormones prepare the baby to breathe by causing the lungs to absorb any remaining fluid and by expanding the bronchial tubes (passages leading to the lungs). Finally, stress hormones arouse the infant into alertness. Joshua was born wide awake, ready to interact with the surrounding world.

The Newborn Baby's Appearance

Parents are often surprised at the odd-looking newborn—a far cry from the storybook image they may have had in their minds. The average newborn is 20 inches long and $7\frac{1}{2}$ pounds in weight; boys tend to be slightly longer and heavier than girls.

© LILLIAN WILSON/GETTY IMAGES/RISEK

To accommodate the well-developed brain, a newborn's head is large in relation to the trunk and legs. This newborn's body readily turns pink as she takes her first few breaths.

The head is large in comparison to the trunk and legs, which are short and bowed. This combination of a large head (with its well-developed brain) and a small body means that human infants learn quickly in the first few months of life. But, unlike most other mammals, they cannot get around on their own until much later.

Even though newborn babies may not match parents' idealized image, some features do make them attractive (Luo, Li, & Lee, 2011). Their round faces, chubby cheeks, large foreheads, and big eyes make adults feel like picking them up and cuddling them.

Assessing the Newborn's Physical Condition: The Apgar Scale

Infants who have difficulty making the transition to life outside the uterus require special help at once. To assess the newborn's

physical condition quickly, doctors and nurses use the **Apgar Scale**. As Table 3.3 shows, a rating of 0, 1, or 2 on each of five characteristics is made at 1 minute and again at 5 minutes after birth. A combined Apgar score of 7 or better indicates that the infant is in good physical condition. If the score is between 4 and 6, the baby needs assistance in establishing breathing and other vital signs. If the score is 3 or below, the infant is in serious danger and requires emergency medical attention. Two Apgar ratings are given because some babies have trouble adjusting at first but do quite well after a few minutes (Apgar, 1953).

Approaches to Childbirth

Childbirth practices, like other aspects of family life, are molded by the society of which mother and baby are a part. In many village and tribal cultures, expectant mothers are well-acquainted with the childbirth process. For example, the Jarara of South America and the Pukapukans of the Pacific Islands treat birth as a vital part of daily life. The Jarara mother gives birth in full view of the entire community, including small children. The Pukapukan girl is so familiar with the events of labor and delivery that she frequently can be seen playing at it. Using a coconut to represent the baby, she stuffs it inside her dress, imitates the mother's pushing, and lets the nut fall at the proper moment. In most nonindustrialized cultures, women are assisted—though often not by medical personnel—during labor and delivery. Among the Mayans of the Yucatán, the mother leans against the body of a woman called the “head helper,” who supports her weight and breathes with her during each contraction (Jordan, 1993; Mead & Newton, 1967).

In Western nations, childbirth has changed dramatically over the centuries. Before the late 1800s, birth usually took place at home and was a family-centered event. The industrial revolution brought greater crowding to cities, along with new health

TABLE 3.3 The Apgar Scale

SIGN ^a	RATING		
	0	1	2
Heart rate	No heartbeat	Under 100 beats per minute	100 to 140 beats per minute
Respiratory effort	No breathing for 60 seconds	Irregular, shallow breathing	Strong breathing and crying
Reflex irritability (sneezing, coughing, and grimacing)	No response	Weak reflexive response	Strong reflexive response
Muscle tone	Completely limp	Weak movements of arms and legs	Strong movements of arms and legs
Color ^b	Blue body, arms, and legs	Body pink with blue arms and legs	Body, arms, and legs completely pink

^aTo remember these signs, you may find it helpful to use a technique in which the original labels are reordered and renamed as follows: color = Appearance; heart rate = Pulse; reflex irritability = Grimace; muscle tone = Activity; and respiratory effort = Respiration. Together, the first letters of the new labels spell **Apgar**.

^bThe skin tone of nonwhite babies makes it difficult to apply the “pink” color criterion. However, newborns of all races can be rated for pinkish glow resulting from the flow of oxygen through body tissues.

In this Peruvian health clinic, families are encouraged to incorporate practices of their village culture into the birth experience. Here, a familiar attendant soothes a new mother as her baby is delivered.

problems. As a result, childbirth moved from home to hospital, where the health of mothers and babies could be protected. Once doctors assumed responsibility for childbirth, women's knowledge of it declined, and relatives and friends no longer participated (Borst, 1995).

By the 1950s and 1960s, women had begun to question the medical procedures that had come to be used routinely during labor and delivery. Many felt that routine use of strong drugs and delivery instruments had robbed them of a precious experience and was often neither necessary nor safe for the baby. Gradually, a natural childbirth movement arose in Europe and spread to North America. Its purpose was to make hospital birth as comfortable and rewarding for mothers as possible. Today, most hospitals offer birth centers that are family-centered and homelike. *Freestanding birth centers*, which permit greater maternal control over labor and delivery, including choice of delivery positions, presence of family members and friends, and early contact between parents and baby, also exist. And a small number of North American women reject institutional birth entirely and choose to have their babies at home.

Natural, or Prepared, Childbirth

Yolanda and Jay chose **natural, or prepared, childbirth**—a group of techniques aimed at reducing pain and medical intervention and making childbirth a rewarding experience. Most natural childbirth programs draw on methods developed by Grantly Dick-Read (1959) in England and Fernand Lamaze (1958) in France. These physicians recognized that cultural attitudes had taught women to fear the birth experience. An anxious, frightened woman in labor tenses muscles, turning the mild pain that sometimes accompanies strong contractions into intense pain.

In a typical natural childbirth program, the expectant mother and a companion (a partner, relative, or friend) participate in three activities:

- *Classes.* Yolanda and Jay attended a series of classes in which they learned about the anatomy and physiology of labor and delivery. Knowledge about the birth process reduces a mother's fear.
- *Relaxation and breathing techniques.* During each class, Yolanda was taught relaxation and breathing exercises aimed at counteracting the pain of uterine contractions.
- *Labor coach.* Jay learned how to help Yolanda during childbirth by reminding her to relax and breathe, massaging her back, supporting her body, and offering encouragement and affection.

Social support is important to the success of natural childbirth techniques. In Guatemalan and American hospitals that routinely isolated patients during childbirth, some mothers were randomly assigned a *doula*—a Greek word referring to a trained lay attendant—who stayed with them throughout labor and delivery, talking to them, holding their hands, and rubbing their backs to promote relaxation. These mothers had fewer birth complications, and their labors were several hours shorter than those of women who did not have supportive companionship. Guatemalan mothers who received doula support also interacted more positively with their babies after delivery, talking, smiling, and gently stroking (Kennell et al., 1991; Sosa et al., 1980).

Other studies indicate that mothers who are supported during labor and delivery—either by a lay birth attendant or by a relative or friend with doula training—less often have cesarean (surgical) deliveries or need medication to control pain. Also, their babies' Apgar scores are higher, and they are more likely to be breastfeeding at a two-month follow-up (Campbell et al., 2006, 2007; Hodnett et al., 2003; McGrath & Kennell, 2008). Social support also makes Western hospital-birth customs more acceptable to women from parts of the world where assistance from family and community members is the norm (Dundek, 2006).

LOOK AND LISTEN

Talk to several mothers about social supports available to them during labor and delivery. From the mothers' perspectives, how did those supports (or lack of support) affect the birth experience? ●

Home Delivery

Home birth has always been popular in certain industrialized nations, such as England, the Netherlands, and Sweden. The number of American women choosing to have their babies at home rose during the 1970s and 1980s but remains small, at less than 1 percent (U.S. Department of Health and Human Services, 2011a). Although some home births are attended by

ANDERSEN ROSS/GETTY IMAGES/BRAND X PICTURES

After a home birth, the midwife and a lay attendant provide support to the new mother. For healthy women attended by a well-trained doctor or midwife, home birth is as safe as hospital birth.

doctors, many more are handled by *certified nurse-midwives*, who have degrees in nursing and additional training in child-birth management.

Is it just as safe to give birth at home as in a hospital? For healthy women who are assisted by a well-trained doctor or midwife, it seems so because complications rarely occur (Fullerton, Navarro, & Young, 2007; Wax, Pinette, & Cartin, 2010). However, if attendants are not carefully trained and prepared to handle emergencies, the rate of infant death is high (Mehlmadrone & Madrone, 1997). When mothers are at risk for any kind of complication, the appropriate place for labor and delivery is the hospital, where life-saving treatment is available.

Medical Interventions

Four-year-old Melinda walks with a halting, lumbering gait and has difficulty keeping her balance. She has *cerebral palsy*, a general term for a variety of impairments in muscle coordination caused by brain damage before, during, or just after birth. For about 10 percent of these children, including Melinda, brain damage was caused by **anoxia**, or inadequate oxygen supply, during labor and delivery (Bracci, Perrone, & Buonocore, 2006). Melinda was also in **breech position**, turned so that the buttocks or feet would be delivered first, and the umbilical

cord was wrapped around her neck. Her mother had gotten pregnant accidentally, was frightened and alone, and arrived at the hospital at the last minute. Had she come to the hospital earlier, doctors could have monitored Melinda's condition and delivered her surgically as soon as squeezing of the umbilical cord led to distress, thereby reducing the damage or preventing it entirely.

In cases like Melinda's, medical interventions are clearly justified. But in others, they can interfere with delivery and even pose new risks. In the following sections, we examine some commonly used medical procedures during childbirth.

Fetal Monitoring

Fetal monitors are electronic instruments that track the baby's heart rate during labor. An abnormal heartbeat may indicate that the baby is in distress due to anoxia and needs to be delivered immediately. Continuous fetal monitoring, which is required in most U.S. hospitals, is used in over 80 percent of American births (Natale & Dodman, 2003). The most popular type of monitor is strapped across the mother's abdomen throughout labor. A second, more accurate method involves threading a recording device through the cervix and placing it directly under the baby's scalp.

Fetal monitoring is a safe medical procedure that has saved the lives of many babies in high-risk situations. But in healthy pregnancies, it does not reduce the already low rates of infant brain damage and death (Haws et al., 2009). Furthermore, most infants have some heartbeat irregularities during labor, so critics worry that fetal monitors identify many babies as in danger who, in fact, are not. Monitoring is linked to an increase in the number of cesarean (surgical) deliveries, which we will discuss shortly (Thacker & Stroup, 2003). In addition, some women complain that the devices are uncomfortable, prevent them from moving easily, and interfere with the normal course of labor.

Still, fetal monitors will probably continue to be used routinely in the United States, even though they are not necessary in most cases. Doctors fear that they will be sued for malpractice if an infant dies or is born with problems and they cannot show that they did everything possible to protect the baby.

Labor and Delivery Medication

Some form of medication is used in more than 80 percent of U.S. births (Althaus & Wax, 2005). *Analgesics*, drugs used to relieve pain, may be given in mild doses during labor to help a mother relax. *Anesthetics* are a stronger type of painkiller that blocks sensation. Currently, the most common approach to controlling pain during labor is *epidural analgesia*, in which a regional pain-relieving drug is delivered continuously through a catheter into a small space in the lower spine. Unlike older spinal block procedures, which numb the entire lower half of the body, epidural analgesia limits pain reduction to the pelvic

region. Because the mother retains the capacity to feel the pressure of the contractions and to move her trunk and legs, she is able to push during the second stage of labor.

Although pain-relieving drugs help women cope with childbirth and enable doctors to perform essential medical interventions, they also can cause problems. Epidural analgesia, for example, weakens uterine contractions. As a result, labor is prolonged, and the chances of cesarean (surgical) delivery increase (Nguyen et al., 2010). And because drugs rapidly cross the placenta, exposed newborns tend to have lower Apgar scores, to be sleepy and withdrawn, to suck poorly during feedings, and to be irritable when awake (Caton et al., 2002; Eltzschig, Lieberman, & Camann, 2003; Emory, Schlackman, & Fiano, 1996). Although no confirmed long-term consequences for development exist, the negative impact of these drugs on the newborn's adjustment supports the current trend to limit their use.

Cesarean Delivery

A **cesarean delivery** is a surgical birth; the doctor makes an incision in the mother's abdomen and lifts the baby out of the uterus. Forty years ago, cesarean delivery was rare. Since then, cesarean rates have climbed internationally, reaching 16 percent in Finland, 23 percent in New Zealand, 26 percent in Canada, 30 percent in Australia, and 32 percent in the United States (OECD, 2011b).

Cesareans have always been warranted by medical emergencies, such as Rh incompatibility, premature separation of the placenta from the uterus, or serious maternal illness or infection (for example, the herpes simplex 2 virus, which can infect the baby during a vaginal delivery). Cesareans are also justified in breech births, in which the baby risks head injury or anoxia (as in Melinda's case). But the infant's exact position makes a difference: Certain breech babies fare just as well with a normal delivery as with a cesarean (Giuliani et al., 2002). Sometimes the doctor can gently turn the baby into a head-down position during the early part of labor.

Until recently, many women who have had a cesarean have been offered the option of a vaginal birth in subsequent pregnancies. But new evidence indicates that compared with repeated cesareans, a natural labor after a cesarean is associated with slightly increased rates of rupture of the uterus and infant death (Cahill & Macones, 2007). As a result, the rule, "Once a cesarean, always a cesarean," has made a comeback.

Repeated cesareans, however, do not explain the worldwide rise in cesarean deliveries. Instead, medical control over childbirth is largely responsible. Because many needless cesareans are performed, pregnant women should ask questions about the procedure before choosing a doctor. Although the operation itself is safe, mother and baby require more time for recovery. Anesthetic may have crossed the placenta, making cesarean newborns sleepy and unresponsive and at increased risk for breathing difficulties (McDonagh, Osterweil, & Guise, 2005).

ASK YOURSELF

REVIEW Describe the features and benefits of natural childbirth. What aspect contributes greatly to favorable outcomes, and why?

REFLECT If you were an expectant parent, would you choose home birth? Why or why not?

Preterm and Low-Birth-Weight Infants

Babies born three weeks or more before the end of a full 38-week pregnancy or who weigh less than 5½ pounds (2,500 grams) have for many years been referred to as "premature." A wealth of research indicates that premature babies are at risk for many problems. Birth weight is the best available predictor of infant survival and healthy development. Many newborns who weigh less than 3½ pounds (1,500 grams) experience difficulties that are not overcome, an effect that becomes stronger as length of pregnancy and birth weight decrease (see Figure 3.5 on page 102) (Baron & Rey-Casserly, 2010; Bolisetty et al., 2006; Dombrowski, Noonan, & Martin, 2007). Brain abnormalities, frequent illness, inattention, overactivity, sensory impairments, poor motor coordination, language delays, low intelligence test scores, deficits in school learning, and emotional and behavior problems are some of the difficulties that persist through childhood and adolescence and into adulthood (Aarnoudse-Moens, Weiglas-Kuperus, & van Goudoever, 2009; Clark et al., 2008; Delobel-Ayoub et al., 2009; Nosarti et al., 2011).

About 1 in 13 American infants is born underweight. Although the problem can strike unexpectedly, it occurs especially often among poverty-stricken women (U.S. Department of Health and Human Services, 2011a). These mothers, as noted earlier, are more likely to be undernourished and to be exposed to other harmful environmental influences. In addition, they often do not receive adequate prenatal care.

Recall from Chapter 2 that prematurity is also common in multiple births. About 60 percent of twins and more than 90 percent of triplets are born early and low birth weight (U.S. Department of Health and Human Services, 2011a). Because space inside the uterus is restricted, multiples gain less weight than singletons in the second half of pregnancy.

FIGURE 3.5 Rates of infant survival and child disabilities by length of pregnancy. In a follow-up of more than 2,300 babies born between 23 and 28 weeks gestation, the percentage who survived decreased and the percentage who displayed moderate to severe disabilities (assessed during the preschool years) increased with reduced length of pregnancy. Severe disabilities included cerebral palsy (unlikely to ever walk), severely delayed mental development, deafness, and blindness. Moderate disabilities included cerebral palsy (able to walk with assistance), moderately delayed mental development, and hearing impairments partially correctable with a hearing aid. (Adapted from Bolisetty et al., 2006.)

Preterm versus Small-for-Date Infants

Although low-birth-weight infants face many obstacles to healthy development, most go on to lead normal lives; about half of those born at 23 to 24 weeks gestation and weighing only a couple of pounds at birth have no disability (refer again to Figure 3.5). To better understand why some babies do better than others, researchers divide them into two groups. **Preterm infants** are those born several weeks or more before their due date. Although they are small, their weight may still be appropriate, based on time spent in the uterus. **Small-for-date infants** are below their expected weight considering length of the pregnancy. Some small-for-date infants are actually full-term. Others are preterm infants who are especially underweight.

Of the two types of babies, small-for-date infants usually have more serious problems. During the first year, they are more likely to die, catch infections, and show evidence of brain damage. By middle childhood, they are smaller in stature, have lower intelligence test scores, are less attentive, achieve more poorly in school, and are socially immature (Hediger et al., 2002; O’Keefe et al., 2003; Sullivan et al., 2008). Small-for-date infants probably experienced inadequate nutrition before birth. Perhaps their mothers did not eat properly, the placenta did not function normally, or the babies themselves had defects that prevented them from growing as they should. Consequently, small-for-date infants are especially likely to suffer from prenatal neurological impairments that permanently weaken their capacity to manage stress (Wust et al., 2005).

Even among preterm newborns whose weight is appropriate for length of pregnancy, just seven more days—from

34 to 35 weeks—greatly reduces rates of illness, costly medical procedures, and lengthy hospital stays (Gladstone & Katz, 2004). And despite being relatively low-risk for disabilities, a substantial number of 34-week preterms are below average in physical growth and mildly to moderately delayed in cognitive development in early and middle childhood (Morse et al., 2009; Pietz et al., 2004; Stephens & Vohr, 2009). And in an investigation of over 120,000 New York City births, babies born even 1 or 2 weeks early showed slightly lower reading and math scores at a third-grade follow-up than children who experienced a full-length prenatal period (Noble et al., 2012). These outcomes persisted even after controlling for other factors linked to achievement, such as birth weight and SES. Yet doctors often induce births several weeks preterm, under the misconception that these babies are developmentally “mature.”

Consequences for Caregiving

Imagine a scrawny, thin-skinned infant whose body is only a little larger than the size of your hand. You try to play with the baby by stroking and talking softly, but he is sleepy and unresponsive. When you feed him, he sucks poorly. During the short, unpredictable periods in which he is awake, he is usually irritable.

The appearance and behavior of preterm babies can lead parents to be less sensitive in caring for them. Compared with full-term infants, preterm babies—especially those who are very ill at birth—are less often held close, touched, and talked to gently. At times, mothers of these infants resort to interfering pokes and verbal commands in an effort to obtain a higher level of response from the baby (Barratt, Roach, & Leavitt, 1996; Feldman, 2007). This may explain why preterm babies as a group are at risk for child abuse.

Research reveals that distressed, emotionally reactive preterm infants are especially susceptible to the effects of parenting quality: Among a sample of preterm 9-month-olds, the combination of infant negativity and angry or intrusive parenting yielded the highest rates of behavior problems at 2 years of age. But with warm, sensitive parenting, distressed preterm babies’ rates of behavior problems were the lowest (Poehlmann et al., 2011). When they are born to isolated, poverty-stricken mothers who cannot provide good nutrition, health care, and parenting, the likelihood of unfavorable outcomes increases. In contrast, parents with stable life circumstances and social supports usually can overcome the stresses of caring for a preterm infant (Ment et al., 2003). In these cases, even sick preterm babies have a good chance of catching up in development by middle childhood.

These findings suggest that how well preterm infants develop has a great deal to do with the parent–child relationship. Consequently, interventions directed at supporting both sides of this tie are more likely to help these infants recover.

Interventions for Preterm Infants

A preterm baby is cared for in a special Plexiglas-enclosed bed called an *isolette*. Temperature is carefully controlled because these babies cannot yet regulate their own body temperature

effectively. To help protect the baby from infection, air is filtered before it enters the isolette. When a preterm infant is fed through a stomach tube, breathes with the aid of a respirator, and receives medication through an intravenous needle, the isolette can be very isolating indeed! Physical needs that otherwise would lead to close contact and other human stimulation are met mechanically.

Special Infant Stimulation. In proper doses, certain kinds of stimulation can help preterm infants develop. In some intensive care nurseries, preterm babies can be seen rocking in suspended hammocks or lying on waterbeds designed to replace the gentle motion they would have received while still in the mother's uterus. Other forms of stimulation have also been used—an attractive mobile or a tape recording of a heartbeat, soft music, or the mother's voice. These experiences promote faster weight gain, more predictable sleep patterns, and greater alertness (Arnon et al., 2006; Marshall-Baker, Lickliter, & Cooper, 1998).

Touch is an especially important form of stimulation. In baby animals, touching the skin releases certain brain chemicals that support physical growth—effects believed to occur in humans as well. When preterm infants were massaged several times each day in the hospital, they gained weight faster and, at the end of the first year, were advanced in mental and motor development over preterm babies not given this stimulation (Field, 2001; Field, Hernandez-Reif, & Freedman, 2004).

In developing countries where hospitalization is not always possible, skin-to-skin “kangaroo care” is the most readily available intervention for promoting the survival and recovery of preterm babies. It involves placing the infant in a vertical position between the mother's breasts or next to the father's chest (under the parent's clothing) so the parent's body functions as a human incubator. Kangaroo care offers fathers a unique opportunity to increase their involvement in caring for the preterm newborn. Because of its many physical and psychological benefits, the technique is often used in Western nations as a supplement to hospital intensive care.

Kangaroo skin-to-skin contact fosters improved oxygenation of the baby's body, temperature regulation, sleep, breastfeeding, alertness, and infant survival (Conde-Agudelo, Belizan, & Diaz-Rossello, 2011; Lawn et al., 2010). In addition, the kangaroo position provides the baby with gentle stimulation of all sensory modalities: hearing (through the parent's voice), smell (through proximity to the parent's body), touch (through skin-to-skin contact), and visual (through the upright position). Mothers and fathers practicing kangaroo care feel more confident about caring for their fragile babies and interact more sensitively and affectionately with them (Dodd, 2005; Feldman, 2007).

Together, these factors may explain why preterm babies given many hours of kangaroo care in their early weeks, compared to those given little or no such care, score higher on measures of mental and motor development during the first year (Charpak, Ruiz-Peláez, & Figueroa, 2005; Feldman, 2007). Because of its diverse benefits, more than 80 percent of U.S. hospitals now offer kangaroo care to preterm newborns (Field et al., 2006).

Training Parents in Infant Caregiving Skills.

Interventions that support parents of preterm infants generally teach them about the infant's characteristics and promote caregiving skills. For parents with adequate economic and personal resources to care for a preterm infant, just a few sessions of coaching in recognizing and responding to the baby's needs are linked to enhanced parent–infant interaction, reduced infant crying and improved sleep, more rapid language development in the second year, and steady gains in mental test scores that equal those of full-term children by middle childhood (Achenbach et al., 1990; Newnham, Milgrom, & Skouteris, 2009).

When preterm infants live in stressed, low-income households, long-term, intensive intervention is required to reduce developmental problems. In the Infant Health and Development

Social Issues: Health

A Cross-National Perspective on Health Care and Other Policies for Parents and Newborn Babies

Infant mortality—the number of deaths in the first year of life per 1,000 live births—is an index used around the world to assess the overall health of a nation's children. Although the United States has the most up-to-date health-care technology in the world, it has made less progress in reducing infant deaths than many other countries. Over the past three decades, it has slipped in the international rankings, from seventh in the 1950s to twenty-eighth in 2012. Members of America's poor ethnic minorities are at greatest risk. African-American and Native-American babies are nearly twice as likely as white infants to die in the first year of life (U.S. Census Bureau, 2012a, 2012b).

Neonatal mortality, the rate of death within the first month of life, accounts for 67 percent of the infant death rate in the United States. Two factors are largely responsible for neonatal mortality. The first is serious physical defects, most of which cannot be prevented. The percentage of babies born with physical defects is about the same in all ethnic and income groups. The second leading cause of neonatal mortality is low birth weight, which is largely preventable. African-American and Native-American babies are twice as likely as white infants to be born early and underweight (U.S. Census Bureau, 2012b).

Widespread poverty and weak health-care programs for mothers and young children are largely responsible for these trends.

Each country in Figure 3.6 that outranks the United States in infant survival provides all its citizens with government-sponsored health-care benefits. And each takes extra steps to make sure that pregnant mothers and babies have access to good nutrition, high-quality medical care, and social and economic supports that promote effective parenting.

For example, all Western European nations guarantee women a certain number of prenatal visits at very low or no cost. After a baby is born, a health professional routinely visits the home to provide counseling about infant care and to arrange continuing medical services. Home assistance is especially extensive in the Netherlands. For a token fee, each mother is granted a specially trained maternity helper, who assists with infant care, shopping, housekeeping, meal preparation, and the care of other children during the days after delivery (Zwart, 2007).

Paid, job-protected employment leave is another vital societal intervention for new parents. Canadian mothers are eligible for 15 weeks' maternity leave at 55 percent of prior earnings (up to a maximum of

© MICHEL SETBOUN/CORBIS

These fathers in Stockholm take advantage of Sweden's parental leave program, the most generous in the world, which provides them with two weeks of birth leave followed by 16 months of paid leave at 80 percent of prior earnings.

\$485 per week), and Canadian mothers or fathers can take an additional 35 weeks of parental leave at the same rate. Paid leave is widely available in other industrialized nations as well. Sweden has the most generous parental leave program in the world. Mothers can begin maternity leave 60 days prior to expected delivery, extending it to six weeks after birth; fathers are granted two weeks of birth leave. In addition, either parent can take full leave for 16 months at 80 percent of prior earnings, followed by an additional three months at a modest flat rate. Each parent is also entitled to another 18 months of unpaid leave. Furthermore, many countries supplement basic paid

Program, preterm babies born into poverty received a comprehensive intervention that combined medical follow-up, weekly parent training sessions, and cognitively stimulating child care from 1 to 3 years of age. More than four times as many intervention children as controls (39 versus 9 percent) were within normal range at age 3 in intelligence, psychological adjustment, and physical growth (Bradley et al., 1994). In addition, mothers in the intervention group were more affectionate and more often encouraged play and cognitive mastery in their children—one reason their 3-year-olds may have been developing so favorably (McCarton, 1998).

At ages 5 and 8, children who had attended the child-care program regularly—for more than 350 days over the three-year period—continued to show better intellectual functioning. The more they attended, the higher they scored, with greater gains among those whose birth weights were higher—between 4½ and 5½ pounds (2,001 to 2,500 grams). In contrast, children who attended only sporadically gained little or even lost ground (Hill, Brooks-Gunn, & Waldfogel, 2003). These findings confirm that babies who are both preterm and economically disadvantaged require *intensive* intervention. And special strategies, such

leave. In Germany, for example, after a fully paid three-month leave, a parent may take one more year at a flat rate and three additional years at no pay (OECD, 2006; Waldfogel, 2001).

Yet in the United States, the federal government mandates *only 12 weeks of unpaid leave* for employees in businesses with at least 50 workers. Most women, however, work in smaller businesses, and many of those who work in large enough companies cannot afford to take unpaid leave (Hewlett, 2003). Similarly, though paternal leave predicts fathers' increased involvement in infant care at the end of the first year, many fathers take little or none at all (Nepomnyaschy & Waldfogel, 2007; OECD, 2006). In 2002, California became the first state to guarantee a mother or father paid leave—up to six weeks at half salary, regardless of the size of the company. Since then, Hawaii, New Jersey, New York, Rhode Island, and the territory of Puerto Rico have passed similar legislation.

Nevertheless, six weeks of childbirth leave (the norm in the United States) is not enough. When a family is stressed by a baby's arrival, leaves of six weeks or less are linked to increased maternal anxiety, depression, marital dissatisfaction, sense of role overload (conflict between work and family responsibilities), and negative interactions with the baby. A longer leave (12 weeks or more) predicts favorable

maternal mental health, supportive marital interaction, and sensitive caregiving (Feldman, Sussman, & Zigler, 2004; Hyde et al., 2001). Single women and their babies are most hurt by the absence of a generous national paid-leave policy. These mothers, who are usually the sole source of support for their families, can least afford to take time from their jobs.

In countries with low infant mortality rates, expectant parents need not wonder how or where they will get health care and other resources to support their baby's development. The powerful impact of universal, high-quality health care, generous parental leave, and other social services on maternal and infant well-being provides strong justification for these policies.

FIGURE 3.6 Infant mortality in thirty nations. Despite its advanced health-care technology, the United States ranks poorly. It is twenty-eighth in the world, with a death rate of 6.1 infants per 1,000 births. (Adapted from U.S. Census Bureau, 2012a.)

as extra adult-child interaction, may be necessary to achieve lasting changes in children with the lowest birth weights.

Nevertheless, even the best caregiving environments cannot “fix” the enormous biological risks associated with extremely low birth weight. A better course of action would be to prevent this serious threat to infant survival and development. The high rate of underweight babies in the United States—one of the worst in the industrialized world—could be greatly reduced by improving the health and social conditions described in the Social Issues: Health box above.

Birth Complications, Parenting, and Resilience

In the preceding sections, we considered a variety of birth complications. Now let's try to put the evidence together. Can any general principles help us understand how infants who survive a traumatic birth are likely to develop? A landmark study carried out in Hawaii provides some answers.

In 1955, Emmy Werner and Ruth Smith began to follow nearly 700 infants on the island of Kauai who had experienced mild, moderate, or severe birth complications. Each was matched, on the basis of SES and ethnicity, with a healthy newborn (Werner & Smith, 1982). Findings showed that the likelihood of long-term difficulties increased if birth trauma was severe. But among mildly to moderately stressed children, those growing up in stable families did almost as well on measures of intelligence and psychological adjustment as those with no birth problems. Children exposed to poverty, family disorganization, and mentally ill parents often developed serious learning difficulties, behavior problems, and emotional disturbance.

The Kauai study tells us that as long as birth injuries are not overwhelming, a supportive home environment can restore children's growth. But the most intriguing cases in this study were the handful of exceptions. A few children with both fairly serious birth complications and troubled family environments grew into competent adults who fared as well as controls in career attainment and psychological adjustment. Werner and Smith found that these children relied on factors outside the family and within themselves to overcome stress. Some had attractive personalities that drew positive responses from relatives, neighbors, and peers. In other instances, a grandparent, aunt, uncle, or babysitter provided the needed emotional support (Werner, 1989, 2001; Werner & Smith, 1992).

Do these outcomes remind you of the characteristics of resilient children, discussed in Chapter 1? The Kauai study and other similar investigations reveal that the impact of early biological risks often wanes as children's personal characteristics and social experiences contribute increasingly to their functioning (Laucht, Esser, & Schmidt, 1997; Resnick et al., 1999). In sum, when the overall balance of life events tips toward the favorable side, children with serious birth problems can develop successfully.

ASK YOURSELF

REVIEW Sensitive care can help preterm infants recover, but they are less likely than full-term newborns to receive such care. Explain why.

CONNECT List factors discussed in this chapter that increase the chances that an infant will be born underweight. How many of these factors could be prevented by better health care for expectant mothers?

APPLY Cecilia and Adena each gave birth to a 3-pound baby seven weeks preterm. Cecilia is single and on welfare. Adena and her partner are happily married and earn a good income. Plan an intervention appropriate for helping each baby develop.

REFLECT Many people object to the use of extraordinary medical measures to save extremely low-birth-weight babies because of their high risk for serious developmental problems. Do you agree or disagree? Explain.

The Newborn Baby's Capacities

Newborn infants have a remarkable set of capacities that are crucial for survival and for evoking attention and care from parents. In relating to the physical and social world, babies are active from the very start.

Reflexes

A **reflex** is an inborn, automatic response to a particular form of stimulation. Reflexes are the newborn baby's most obvious organized patterns of behavior. As Jay placed Joshua on a table in my classroom, we saw several. When Jay bumped the side of the table, Joshua reacted by flinging his arms wide and bringing them back toward his body. As Yolanda stroked Joshua's cheek, he turned his head in her direction. **TAKE A MOMENT...** Look at Table 3.4 and see if you can name the newborn reflexes that Joshua displayed.

Some reflexes have survival value. The rooting reflex helps a breastfed baby find the mother's nipple. Babies display it only when hungry and touched by another person, not when they touch themselves (Rochat & Hespos, 1997). At birth, babies adjust their sucking pressure to how easily milk flows from the nipple (Craig & Lee, 1999). And if sucking were not automatic, our species would be unlikely to survive for a single generation!

A few reflexes form the basis for complex motor skills that will develop later. The stepping reflex looks like a primitive walking response. Unlike other reflexes, it appears in a wide range of situations—with the newborn's body in a sideways or upside-down position, with feet touching walls or ceilings, and even with legs dangling in the air (Adolph & Berger, 2006).

© LAURA DWIGHT PHOTOGRAPHY

In the Moro reflex, loss of support or a sudden loud sound causes the baby to extend the legs and throw the arms outward in an “embracing” motion.

TABLE 3.4 Some Newborn Reflexes

REFLEX	STIMULATION	RESPONSE	AGE OF DISAPPEARANCE	FUNCTION
Eye blink	Shine bright light at eyes or clap hand near head.	Infant quickly closes eyelids.	Permanent	Protects infant from strong stimulation
Rooting	Stroke cheek near corner of mouth.	Head turns toward source of stimulation.	3 weeks (becomes voluntary turning at this time)	Helps infant find the nipple
Sucking	Place finger in infant's mouth.	Infant sucks finger rhythmically.	Replaced by voluntary sucking after 4 months	Permits feeding
Moro	Hold infant horizontally on back and let head drop slightly, or produce a sudden loud sound against surface supporting infant.	Infant makes an "embracing" motion by arching back, extending legs, throwing arms outward, and then bringing arms in toward the body.	6 months	In human evolutionary past, may have helped infant cling to mother
Palmar grasp	Place finger in infant's hand and press against palm.	Infant spontaneously grasps finger.	3–4 months	Prepares infant for voluntary grasping
Tonic neck	Turn head to one side while infant is lying awake on back.	Infant lies in a "fencing position." One arm is extended in front of eyes on side to which head is turned, other arm is flexed.	4 months	May prepare infant for voluntary reaching
Stepping	Hold infant under arms and permit bare feet to touch a flat surface.	Infant lifts one foot after another in stepping response.	2 months in infants who gain weight quickly; sustained in lighter infants	Prepares infant for voluntary walking
Babinski	Stroke sole of foot from toe toward heel.	Toes fan out and curl as foot twists in.	8–12 months	Unknown

Sources: Knobloch & Pasamanick, 1974; Prechtl & Beintema, 1965; Thelen, Fisher, & Ridley-Johnson, 1984.

One reason that babies frequently engage in the alternating leg movements of stepping is their ease compared with other movement patterns; repetitive movement of just one leg or of both legs at once requires more effort.

In infants who gain weight quickly in the weeks after birth, the stepping reflex drops out because thigh and calf muscles are not strong enough to lift the baby's chubby legs. But if the lower part of the infant's body is dipped in water, the reflex reappears because the buoyancy of the water lightens the load on the baby's muscles (Thelen, Fisher, & Ridley-Johnson, 1984). When stepping is exercised regularly, babies make more reflexive stepping movements and are likely to walk several weeks earlier than if stepping is not practiced (Zelazo et al., 1993). However, there is no special need for infants to practice the stepping reflex because all normal babies walk in due time.

Several reflexes help parents and infants establish gratifying interaction. A baby who searches for and successfully finds the nipple, sucks easily during feedings, and grasps when the hand is touched encourages parents to respond lovingly and feel competent as caregivers. Reflexes can also help caregivers comfort the baby because they permit infants to control distress and amount of stimulation. For example, on short trips with Joshua to the grocery store, Yolanda brought along a pacifier. If he became fussy, sucking helped quiet him until she could feed, change, or hold him.

When held upright under the arms, newborns show a reflexive stepping response, which forms the basis for later walking.

© LAURA DWIGHT PHOTOGRAPHY

The palmar grasp reflex is so strong during the first week after birth that many infants can use it to support their entire weight.

Refer to Table 3.4 again, and you will see that most newborn reflexes disappear during the first six months. Researchers believe that this is due to a gradual increase in voluntary control over behavior as the cerebral cortex develops. Pediatricians test reflexes carefully because reflexes can reveal the health of the baby's nervous system. Weak or absent reflexes, overly rigid or exaggerated reflexes, and reflexes that persist beyond the point in development when they should normally disappear can signal brain damage (Schott & Rossor, 2003; Zafeiriou, 2000).

States

Throughout the day and night, newborn infants move in and out of five **states of arousal**, or degrees of sleep and wakefulness, described in Table 3.5. During the first month, these states alternate frequently. The most fleeting is quiet alertness, which usually moves quickly toward fussing and crying. Much to the relief of their fatigued parents, newborns spend the greatest amount of time asleep—about 16 to 18 hours a day. Because the fetus tends to synchronize periods of rest and activity with those of the mother, newborns sleep more at night than during the day (Heraghty et al., 2008). Nevertheless, young babies' sleep-wake cycles are affected more by fullness-hunger than by darkness-light (Davis, Parker, & Montgomery, 2004).

However, striking individual differences in daily rhythms exist that affect parents' attitudes toward and interactions with the baby. A few newborns sleep for long periods, increasing the energy their well-rested parents have for sensitive, responsive care. Other babies cry a great deal, and their parents must exert great effort to soothe them. If these parents do not succeed, they may feel less competent and less positive toward their infant.

Furthermore, from birth on, arousal patterns have implications for cognitive development. Babies who spend more time alert probably receive more social stimulation and opportunities

to explore and, therefore, may have a slight advantage in mental development (Sadeh et al., 2007; Smart & Hiscock, 2007). And as with adults, sleep enhances babies' learning and memory. In one study, eye-blink responses and brain-wave recordings revealed that sleeping newborns readily learned that a tone would be followed by a puff of air to the eye (Fifer et al., 2010). Because young infants spend so much time sleeping, the capacity to learn about external stimuli during sleep may be essential for adaptation to their surroundings.

Of the states listed in Table 3.5, the two extremes—sleep and crying—have been of greatest interest to researchers. Each tells us something about normal and abnormal early development.

Sleep. Observing Joshua as he slept, Yolanda and Jay wondered why his eyelids and body twitched and his rate of breathing varied. Sleep is made up of at least two states. During irregular, or **rapid-eye-movement (REM)**, sleep, brain-wave activity is remarkably similar to that of the waking state. The eyes dart beneath the lids; heart rate, blood pressure, and breathing are uneven; and slight body movements occur. In contrast, during regular, or **non-rapid-eye-movement (NREM)**, sleep, the body is almost motionless, and heart rate, breathing, and brain-wave activity are slow and even.

Like children and adults, newborns alternate between REM and NREM sleep. However, they spend far more time in the REM state than they ever will again. REM sleep accounts for 50 percent of a newborn baby's sleep time. By 3 to 5 years, it has declined to an adultlike level of 20 percent (Louis et al., 1997).

Why do young infants spend so much time in REM sleep? In older children and adults, the REM state is associated with dreaming. Babies probably do not dream, at least not in the same way we do. But researchers believe that the stimulation of REM sleep is vital for growth of the central nervous system. Young infants seem to have a special need for this stimulation because they spend little time in an alert state, when they can

TABLE 3.5 Infant States of Arousal

STATE	DESCRIPTION	DAILY DURATION IN NEWBORN
Regular, or NREM, sleep	The infant is at full rest and shows little or no body activity. The eyelids are closed, no eye movements occur, the face is relaxed, and breathing is slow and regular.	8–9 hours
Irregular, or REM, sleep	Gentle limb movements, occasional stirring, and facial grimacing occur. Although the eyelids are closed, occasional rapid eye movements can be seen beneath them. Breathing is irregular.	8–9 hours
Drowsiness	The infant is either falling asleep or waking up. Body is less active than in irregular sleep but more active than in regular sleep. The eyes open and close; when open, they have a glazed look. Breathing is even but somewhat faster than in regular sleep.	Varies
Quiet alertness	The infant's body is relatively inactive, with eyes open and attentive. Breathing is even.	2–3 hours
Waking activity and crying	The infant shows frequent bursts of uncoordinated body activity. Breathing is very irregular. Face may be relaxed or tense and wrinkled. Crying may occur.	1–4 hours

Source: Wolff, 1966.

get input from the environment. In support of this idea, the percentage of REM sleep is especially great in the fetus and in preterm babies, who are even less able than full-term newborns to take advantage of external stimulation (de Weerd & van den Bossche, 2003; Peirano, Algarin, & Uauy, 2003).

Because newborns' normal sleep behavior is organized and patterned, observations of sleep states can help identify central nervous system abnormalities. In infants who are brain-damaged or who have experienced birth trauma, disturbed REM–NREM sleep cycles are often present. Babies with poor sleep organization are likely to be behaviorally disorganized and, therefore, to have difficulty learning and evoking caregiver interactions that enhance their development. In the preschool years, they show delayed motor, cognitive, and language development (de Weerd & van den Bossche, 2003; Feldman, 2006; Holditch-Davis, Belyea, & Edwards, 2005). And the brain-functioning problems that underlie newborn sleep irregularities may culminate in sudden infant death syndrome, a major cause of infant mortality (see the Biology and Environment box on page 110).

Crying. Crying is the first way that babies communicate, letting parents know they need food, comfort, or stimulation. During the weeks after birth, all infants have some fussy periods when they are difficult to console. But most of the time, the nature of the cry, combined with the experiences leading up to it, helps guide parents toward its cause. The baby's cry is a complex stimulus that varies in intensity, from a whimper to a message of all-out distress (Gustafson, Wood, & Green, 2000; Wood, 2009). As early as the first few weeks, infants can be identified by the unique vocal “signature” of their cries, which helps parents locate their baby from a distance (Gustafson, Green, & Cleland, 1994).

Young infants usually cry because of physical needs. Hunger is the most common cause, but babies may also cry in response to temperature change when undressed, a sudden noise, or a painful stimulus. Newborns (as well as older babies) often cry at the sound of another crying baby (Dondi, Simion, & Caltran, 1999; Geangu et al., 2010). Some researchers believe that this response reflects an inborn capacity to react to the suffering of others. Furthermore, crying typically increases during the early weeks, peaks at about 6 weeks, and then declines (Barr, 2001). Because this trend appears in many cultures with vastly different infant care practices, researchers believe that normal readjustments of the central nervous system underlie it. **TAKE A MOMENT...** The next time you hear an infant cry, notice your own reaction. The sound stimulates strong feelings of arousal and discomfort in men and women, parents and nonparents alike (Murray, 1985). This powerful response is probably innately programmed in humans to make sure that babies receive the care and protection they need to survive.

Soothing Crying Infants. Although parents do not always interpret their baby's cry correctly, their accuracy improves with experience. At the same time, they vary widely in responsiveness.

© LAURA DWIGHT PHOTOGRAPHY

To soothe his crying infant, this father rocks her gently while talking softly.

Parents who are high in empathy (ability to take the perspective of others in distress) and who hold “child-centered” attitudes toward infant care (for example, believe that babies cannot be spoiled by being picked up) are more likely to respond quickly and sensitively to a crying baby (Leerkes, 2010; Zeifman, 2003).

Fortunately, there are many ways to soothe a crying baby when feeding and diaper changing do not work (see Applying What We Know on page 111). The technique that Western parents usually try first, lifting the baby to the shoulder and rocking or walking, is highly effective. Another common soothing method is swaddling—wrapping the baby snugly in a blanket. The Quechua, who live in the cold, high-altitude desert regions of Peru, dress young babies in layers of clothing and blankets that cover the head and body, a practice that reduces crying and promotes sleep (Tronick, Thomas, & Daltabuit, 1994). It also allows the baby to conserve energy for early growth in the harsh Peruvian highlands.

In a public setting, watch several parents soothe their crying babies. What techniques did the parents use, and how successful were they? ●

Biology and Environment

The Mysterious Tragedy of Sudden Infant Death Syndrome

Millie awoke with a start one morning and looked at the clock. It was 7:30, and Sasha had missed both her night waking and her early morning feeding. Wondering if she was all right, Millie and her husband Stuart tiptoed into the room. Sasha lay still, curled up under her blanket. She had died silently during her sleep.

Sasha was a victim of **sudden infant death syndrome (SIDS)**, the unexpected death, usually during the night, of an infant under 1 year of age that remains unexplained after thorough investigation. In industrialized nations, SIDS is the leading cause of infant mortality between 1 and 12 months, accounting for about 20 percent of these deaths in the United States (Mathews & MacDorman, 2008).

SIDS victims usually show physical problems from the beginning. Early medical records of SIDS babies reveal higher rates of prematurity and low birth weight, poor Apgar scores, and limp muscle tone. Abnormal heart rate and respiration and disturbances in sleep–wake activity and in REM–NREM cycles while asleep are also involved (Cornwell & Feigenbaum, 2006; Kato et al., 2003). At the time of death, many SIDS babies have a mild respiratory infection (Blood-Siegfried, 2009). This seems to increase the chances of respiratory failure in an already vulnerable baby.

Mounting evidence suggests that impaired brain functioning is a major contributor to SIDS. Between 2 and 4 months, when SIDS is most likely to occur, reflexes decline and are replaced by voluntary, learned responses. Neurological weaknesses may prevent SIDS babies from acquiring behaviors that replace defensive reflexes (Lipsitt, 2003). As a result, when breathing difficulties occur during sleep, infants do not wake up, shift their position, or cry out for help. Instead, they simply give in to oxygen

deprivation and death. In support of this interpretation, autopsies reveal that the brains of SIDS babies contain unusually low levels of serotonin (a brain chemical that assists with arousal when survival is threatened) as well as other abnormalities in centers that control breathing and arousal (Duncan et al., 2010).

Several environmental factors are linked to SIDS. Maternal cigarette smoking, both during and after pregnancy, as well as smoking by other caregivers, doubles risk of the disorder. Babies exposed to cigarette smoke arouse less easily from sleep and have more respiratory infections (Richardson, Walker, & Horne, 2009; Shah, Sullivan, & Carter, 2006). Prenatal abuse of drugs that depress central nervous system functioning (alcohol, opiates, and barbiturates) increases the risk of SIDS as much as fifteenfold (Hunt & Hauck, 2006). Babies of drug-abusing mothers are especially likely to display SIDS-related brain abnormalities (Kinney, 2009).

SIDS babies are also more likely to sleep on their stomachs than on their backs and often are wrapped very warmly in clothing and blankets. Infants who sleep on their stomachs less often wake when their breathing is disturbed (Richardson, Walker, & Horne, 2008). In other cases, healthy babies sleeping face down on soft bedding may die from continually breathing their own exhaled breath.

Quitting smoking and drug taking, changing an infant's sleeping position, and removing a few bedclothes can reduce the incidence of SIDS. For example, if women refrained from smoking while pregnant, an estimated 30 percent of SIDS cases would be prevented. Public education campaigns that encourage parents to put their infants down on their backs have cut the incidence of SIDS in half in many Western nations (Moon, Horne, & Hauck, 2007). Another

Public education campaigns encouraging parents to put their infants down on their backs to sleep have helped reduce the incidence of SIDS by more than half in many Western nations.

protective measure is pacifier use: Sleeping babies who suck arouse more easily in response to breathing and heart-rate irregularities (Li et al., 2006). Nevertheless, compared with white infants, SIDS rates are two to six times as high in poverty-stricken minority groups, where parental stress, substance abuse, reduced access to health care, and lack of knowledge about safe sleep practices are widespread (Colson et al., 2009; Pickett, Luo, & Lauderdale, 2005).

When SIDS does occur, surviving family members require a great deal of help to overcome a sudden and unexpected death. As Millie commented six months after Sasha's death, "It's the worst crisis we've ever been through. What's helped us most are the comforting words of others who've experienced the same tragedy."

Applying What We Know

Soothing a Crying Baby

Method	Explanation
Talk softly or play rhythmic sounds.	Continuous, monotonous, rhythmic sounds (such as a clock ticking, a fan whirring, or peaceful music) are more effective than intermittent sounds.
Offer a pacifier.	Sucking helps babies control their own level of arousal.
Massage the baby's body.	Stroking the baby's torso and limbs with continuous, gentle motions relaxes the baby's muscles.
Swaddle the baby.	Restricting movement and increasing warmth often soothe a young infant.
Lift the baby to the shoulder and rock or walk.	This combination of physical contact, upright posture, and motion is an effective soothing technique, causing young infants to become quietly alert.
Take the baby for a short car ride or a walk in a baby carriage; swing the baby in a cradle.	Gentle, rhythmic motion of any kind helps lull the baby to sleep.
Combine several of the methods just listed.	Stimulating several of the baby's senses at once is often more effective than stimulating only one.
If these methods do not work, let the baby cry for a short period.	Occasionally, a baby responds well to just being put down and, after a few minutes, will fall asleep.

Sources: Campos, 1989; Evano, 2007; Lester, 1985; Reisman, 1987.

In many tribal and village societies and non-Western developed nations (such as Japan), babies are in physical contact with their caregivers almost continuously. Infants in these cultures show shorter bouts of crying than their American counterparts (Barr, 2001). When Western parents choose to practice “proximal care” by holding their babies extensively, amount of crying

in the early months is reduced by about one-third (St James-Roberts et al., 2006).

But not all research indicates that rapid parental responsiveness reduces infant crying (van IJzendoorn & Hubbard, 2000). Parents must make reasoned choices about what to do on the basis of culturally accepted practices, the suspected reason for the cry, and the context in which it occurs—for example, in the privacy of their own home or while having dinner at a restaurant. Fortunately, with age, crying declines. Virtually all researchers agree that parents can lessen older babies’ need to cry by encouraging more mature ways of expressing their desires, such as gestures and vocalizations.

Abnormal Crying. Like reflexes and sleep patterns, the infant’s cry offers a clue to central nervous system distress. The cries of brain-damaged babies and those who have experienced prenatal and birth complications are often shrill, piercing, and shorter in duration than those of healthy infants (Boukydis & Lester, 1998; Green, Irwin, & Gustafson, 2000). Even newborns with a fairly common problem—*colic*, or persistent crying—tend to have high-pitched, harsh-sounding cries (Zeskind & Barr, 1997). Although the cause of colic is unknown, certain newborns, who react especially strongly to unpleasant stimuli, are susceptible. Because their crying is intense, they find it harder to calm down than other babies (Barr et al., 2005; St James-Roberts et al., 2003). Colic generally subsides between 3 and 6 months.

© DEAN CONGER/CORBIS

Like the Quechua of Peru, the Mongol people of Central Asia heavily swaddle their babies, a practice that reduces crying and promotes sleep while also protecting infants from the region’s harsh winters.

Most parents try to respond to a crying baby with extra care and attention, but sometimes the cry is so unpleasant and the infant so difficult to soothe that parents become frustrated, resentful, and angry. Preterm and ill babies are more likely to be abused by highly stressed parents, who sometimes mention a high-pitched, grating cry as one factor that caused them to lose control and harm the baby (St James-Roberts, 2007). We will discuss a host of additional influences on child abuse in Chapter 8.

Sensory Capacities

On his visit to my class, Joshua looked wide-eyed at my bright pink blouse and turned to the sound of his mother's voice. During feedings, he lets Yolanda know through his sucking rhythm that he prefers the taste of breast milk to plain water. Clearly, Joshua has some well-developed sensory capacities. In the following sections, we explore the newborn's responsiveness to touch, taste, smell, sound, and visual stimulation.

Touch. In our discussion of preterm infants, we saw that touch helps stimulate early physical growth. As we will see in Chapter 6, it is vital for emotional development as well. Therefore, it is not surprising that sensitivity to touch is well-developed at birth. The reflexes listed in Table 3.4 on page 107 reveal that the newborn baby responds to touch, especially around the mouth, on the palms, and on the soles of the feet (Humphrey, 1978). Newborns even use touch to investigate their world. When small objects are placed in their palms, they can distinguish shape (prism versus cylinder) and texture (smooth versus rough), as indicated by their tendency to hold on longer to objects with an unfamiliar shape or texture (Sann & Streri, 2007, 2008).

At birth, infants are highly sensitive to pain. If male newborns are circumcised, anesthetic is sometimes not used because of the risk of giving drugs to a very young infant. Babies often respond with a high-pitched, stressful cry and a dramatic rise in heart rate, blood pressure, palm sweating, pupil dilation, and muscle tension (Lehr et al., 2007; Warnock & Sandrin, 2004). Brain-imaging research suggests that because of central nervous system immaturity, preterm babies, particularly males, feel the pain of a medical injection especially intensely (Bartocci et al., 2006).

Recent research establishing the safety of certain local anesthetics for newborns promises to ease the pain of these procedures. Offering a nipple that delivers a sugar solution is also helpful; it quickly reduces crying and discomfort in young babies, preterm and full-term alike. Breast milk may be especially effective: Even the smell of the milk of the baby's mother reduces infant distress to a routine blood-test heelstick more effectively than the odor of another mother's milk or of formula (Nishitani et al., 2009). And combining sweet liquid with gentle holding by the parent lessens pain even more. Research on infant mammals indicates that physical touch releases *endorphins*—painkilling chemicals in the brain (Axelin, Salanterä, & Lehtonen, 2006; Gormally et al., 2001).

Allowing a baby to endure severe pain overwhelms the nervous system with stress hormones, which can disrupt the child's developing capacity to handle common, everyday stressors. The result is heightened pain sensitivity, sleep disturbances, feeding problems, and difficulty calming down when upset (Mitchell & Boss, 2002).

Taste and Smell. Facial expressions reveal that newborns can distinguish several basic tastes. Like adults, they relax their facial muscles in response to sweetness, purse their lips when the taste is sour, and show a distinct archlike mouth opening when it is bitter (Steiner, 1979; Steiner et al., 2001). These reactions are important for survival: The food that best supports the infant's early growth is the sweet-tasting milk of the mother's breast. Not until 4 months do babies prefer a salty taste to plain water, a change that may prepare them to accept solid foods (Mennella & Beauchamp, 1998).

Nevertheless, newborns can readily learn to like a taste that at first evoked either a neutral or a negative response. For example, babies allergic to cow's-milk formula who are given a soy- or other vegetable-based substitute (typically very strong and bitter-tasting) soon prefer it to regular formula (Harris, 1997). A taste previously disliked can come to be preferred when it is paired with relief of hunger.

As with taste, certain odor preferences are present at birth. For example, the smell of bananas or chocolate causes a relaxed, pleasant facial expression, whereas the odor of rotten eggs makes the infant frown (Steiner, 1979). During pregnancy, the amniotic fluid is rich in tastes and smells that vary with the mother's diet—early experiences that influence newborns' preferences. In a study carried out in the Alsatian region of France, where anise is frequently used to flavor foods, researchers tested newborns for their reaction to the anise odor (Schaal, Marlier, & Soussignan, 2000). The mothers of some babies had regularly consumed anise during the last two weeks of pregnancy; the other mothers had never consumed it. When presented with the anise odor on the day of birth, the babies of non-anise-consuming mothers were far more likely to turn away with a negative facial expression (see Figure 3.7). These different reactions were still apparent four days later, even though all mothers had refrained from consuming anise during this time.

In many mammals, the sense of smell plays an important role in feeding and in protecting the young from predators by helping mothers and babies identify each other. Although smell is less well-developed in humans, traces of its survival value remain.

Immediately after birth, babies placed face down between their mother's breasts spontaneously latch on to a nipple and begin sucking within an hour. If one breast is washed to remove its natural scent, most newborns grasp the unwashed breast, indicating that they are guided by smell (Varendi & Porter, 2001). At 4 days of age, breastfed babies prefer the smell of their own mother's breast to that of an unfamiliar lactating mother (Cernoch & Porter, 1985). And both breast- and bottle-fed 3- to 4-day-olds orient more to the smell of unfamiliar human milk than to formula milk, indicating that (even without postnatal

FIGURE 3.7 Examples of facial expressions of newborns exposed to the odor of anise whose mothers' diets differed in anise-flavored foods during late pregnancy. (a) Babies of anise-consuming mothers spent more time turning toward the odor and sucking, licking, and chewing. (b) Babies of non-anise-consuming mothers more often turned away with a negative facial expression. (From B. Schaal, L. Marlier, & R. Soussignan, 2000, "Human Foetuses Learn Odours from Their Pregnant Mother's Diet," *Chemical Senses*, 25, p. 731. © 2000 Oxford University Press. Reprinted by permission of Oxford University Press and Dr. Benoist Schaal.)

exposure) the odor of human milk is more attractive to newborns (Marlier & Schaal, 2005). Newborns' dual attraction to the odor of their mother and to that of breast milk helps them locate an appropriate food source and, in the process, begin to distinguish their caregiver from other people.

Hearing. Newborn infants can hear a wide variety of sounds, and their sensitivity improves greatly over the first few months (Saffran, Werker, & Werner, 2006; Tharpe & Ashmead, 2001). At birth, infants prefer complex sounds, such as noises and voices, to pure tones. And babies only a few days old can tell the difference between a variety of sound patterns: a series of tones arranged in ascending versus descending order; tone sequences with a rhythmic downbeat (as in music) versus those without; utterances with two versus three syllables; the stress patterns of words ("ma-ma" versus "ma-ma"); happy-sounding speech as opposed to speech with negative or neutral emotional qualities; and even two languages spoken by the same bilingual speaker, as long as those languages differ in their rhythmic features—for example, French versus Russian (Mastropieri & Turkewitz, 1999; Ramus, 2002; Sansavini, Bertocchini, & Giovanelli, 1997; Trehub, 2001; Winkler et al., 2009).

Young infants listen longer to human speech than structurally similar nonspeech sounds (Vouloumanos & Werker,

2004). And they can detect the sounds of any human language. Newborns make fine-grained distinctions among many speech sounds. For example, when given a nipple that turns on a recording of the "ba" sound, babies suck vigorously and then slow down as the novelty wears off. When the sound switches to "ga," sucking picks up, indicating that infants detect this subtle difference. Using this method, researchers have found only a few speech sounds that newborns cannot discriminate. Their ability to perceive sounds not found in their own language is more precise than an adult's (Aldridge, Stillman, & Bower, 2001; Jusczyk & Luce, 2002). These capacities reveal that the baby is marvelously prepared for the awesome task of acquiring language.

TAKE A MOMENT... Listen carefully to yourself the next time you talk to a young baby. You will probably speak in ways that highlight important parts of the speech stream—use a slow, high-pitched, expressive voice with a rising tone at the ends of phrases and sentences and a pause before continuing. Adults probably communicate this way because they notice that infants are more attentive when they do so. Indeed, newborns prefer speech with these characteristics (Saffran, Werker, & Werner, 2006). In addition, they will suck more on a nipple to hear a recording of their mother's voice than that of an unfamiliar woman and to hear their native language as opposed to a foreign language (Moon, Cooper, & Fifer, 1993; Spence & DeCasper, 1987). These preferences may have developed from hearing the muffled sounds of the mother's voice before birth.

Vision. Vision is the least-developed of the newborn baby's senses. Visual structures in both the eye and the brain are not yet fully formed. For example, cells in the *retina*, the membrane lining the inside of the eye that captures light and transforms it into messages that are sent to the brain, are not as mature or densely packed as they will be in several months. The optic nerve that relays these messages, and the visual centers in the brain that receive them, will not be adultlike for several years. And the muscles of the *lens*, which permit us to adjust our visual focus to varying distances, are weak (Kellman & Arterberry, 2006).

As a result, newborns cannot focus their eyes well, and **visual acuity**, or fineness of discrimination, is limited. At birth, infants perceive objects at a distance of 20 feet about as clearly as adults do at 600 feet (Slater et al., 2010). In addition, unlike adults (who see nearby objects most clearly), newborn babies see unclearly across a wide range of distances (Banks, 1980; Hainline, 1998). As a result, images such as the parent's face, even from close up, look quite blurred.

Although they cannot yet see well, newborns actively explore their environment by scanning it for interesting sights and tracking moving objects. However, their eye movements are slow and inaccurate (von Hofsten & Rosander, 1998). Joshua's captivation with my pink blouse reveals that he is attracted to bright objects. But although newborns prefer to look at colored rather than gray stimuli, they are not yet good at discriminating colors. It will take about four months for color vision to become adultlike (Kellman & Arterberry, 2006).

Neonatal Behavioral Assessment

A variety of instruments permit doctors, nurses, and researchers to assess the behavior of newborn babies. The most widely used, T. Berry Brazelton's **Neonatal Behavioral Assessment Scale (NBAS)**, evaluates the newborn's reflexes, muscle tone, state changes, responsiveness to physical and social stimuli, and other reactions (Brazelton & Nugent, 1995). An instrument consisting of similar items, the Neonatal Intensive Care Unit Network Neurobehavioral Scale (NNNS), is specially designed for use with newborns at risk for developmental problems because of low birth weight, preterm delivery, prenatal substance exposure, or other conditions (Lester & Tronick, 2004). Scores are used to recommend appropriate interventions and to guide parents in meeting their baby's unique needs.

The NBAS has been given to many infants around the world. As a result, researchers have learned about individual and cultural differences in newborn behavior and how child-rearing practices can maintain or change a baby's reactions. For example, NBAS scores of Asian and Native-American babies reveal that they are less irritable than Caucasian infants. Mothers in these cultures often encourage their babies' calm dispositions through holding and nursing at the first signs of discomfort (Muret-Wagstaff & Moore, 1989; Small, 1998). The Kipsigis of rural Kenya, who highly value infant motor maturity, massage babies regularly and begin exercising the stepping reflex shortly after birth. These customs contribute to Kipsigis babies' strong but flexible muscle tone at 5 days of age (Super & Harkness, 2009). In Zambia, Africa, close mother–infant contact throughout the day quickly changes the poor NBAS scores of undernourished newborns. When reassessed at 1 week of age, a once unresponsive newborn appears alert and contented (Brazelton, Koslowski, & Tronick, 1976).

TAKE A MOMENT... Using these examples, can you explain why a single neonatal assessment score is not a good predictor of later development? Because newborn behavior and parenting combine to influence development, *changes in scores* over the first week or two of life (rather than a single score) provide the best estimate of the baby's ability to recover from the stress of birth. NBAS “recovery curves” predict intelligence and absence of emotional and behavior problems with moderate success well into the preschool years (Brazelton, Nugent, & Lester, 1987; Ohgi et al., 2003a, 2003b).

In some hospitals, health professionals use the NBAS or the NNNS to help parents get to know their newborns through discussion or demonstration of the capacities these instruments assess. Parents who participate in these programs, compared with no-intervention controls, interact more confidently and effectively with their babies (Browne & Talmi, 2005; Bruschiweiler-Stern, 2004). Although lasting effects on development have not been demonstrated, NBAS-based interventions are useful in helping the parent–infant relationship get off to a good start.

© JEFFREY L. ROTMAN/CORBIS

Similar to women in the Zambian culture, this mother of the El Molo people of northern Kenya carries her baby all day, providing close physical contact, a rich variety of stimulation, and ready feeding.

ASK YOURSELF

REVIEW What functions does REM sleep serve in young infants? Can sleep tell us anything about the health of the newborn's central nervous system? Explain.

CONNECT How do the diverse capacities of newborn babies contribute to their first social relationships? Provide as many examples as you can.

APPLY After a difficult delivery, Jackie observes her 2-day-old daughter Kelly being given the NBAS. Kelly scores poorly on many items. Seeing this, Jackie wonders if Kelly will develop normally. How would you respond to Jackie's concern?

REFLECT Are newborns more competent than you thought they were before you read this chapter? Which of their capacities most surprised you?

Adjusting to the New Family Unit

Because effective parental care is crucial for infant survival and optimal development, nature helps prepare expectant mothers and fathers for their new role. Toward the end of pregnancy, mothers begin producing the hormone oxytocin, which stimulates uterine contractions; causes the breasts to “let down” milk; induces a calm, relaxed mood; and promotes responsiveness to the baby (Russell, Douglas, & Ingram, 2001). And fathers show hormonal changes around the time of birth that are compatible with those of mothers—specifically, slight increases in *prolactin* (a hormone that stimulates milk production in females) and *estrogens* (sex hormones produced in larger quantities in females) and a drop in *androgens* (sex hormones produced in larger quantities in males) (Numan & Insel, 2003; Wynne-Edwards, 2001). These changes, which are induced by fathers’ contact with the mother and baby, predict positive emotional reactions to infants and paternal caregiving (Feldman et al., 2010; Leuner, Glasper, & Gould, 2010).

Although birth-related hormones can facilitate caregiving, their release and effects may depend on experiences, such as a positive couple relationship. Furthermore, humans can parent effectively without experiencing birth-related hormonal changes, as successful adoption reveals. And as we have seen, a great many factors—from family functioning to social policies—are involved in good infant care.

Indeed, the early weeks after the baby’s arrival are full of profound challenges. The mother needs to recuperate from childbirth. If she is breastfeeding, energies must be devoted to

working out this intimate relationship. The father must become a part of this new threesome while supporting the mother in her recovery. At times, he may feel ambivalent about the baby, who constantly demands and gets the mother’s attention. And as we will see in Chapter 6, siblings—especially those who are young and firstborn—understandably feel displaced. They sometimes react with jealousy and anger.

While all this is going on, the tiny infant is assertive about his urgent physical needs, demanding to be fed, changed, and comforted at odd times of the day and night. The family schedule becomes irregular and uncertain. Yolanda spoke candidly about the changes she and Jay experienced:

When we brought Joshua home, he seemed so small and helpless, and we worried about whether we would be able to take proper care of him. It took us 20 minutes to change the first diaper! I rarely feel rested because I’m up two to four times every night, and I spend a good part of my waking hours trying to anticipate Joshua’s rhythms and needs. If Jay weren’t so willing to help by holding and walking Joshua, I think I’d find it much harder.

How long does this time of adjustment to parenthood last? In Chapter 14, we will see that when marital relationships are positive, social support is available, and families have sufficient income, the stress caused by the birth of a baby remains manageable. Nevertheless, as one pair of counselors who have worked with many new parents pointed out, “As long as children are dependent on their parents, those parents find themselves preoccupied with thoughts of their children. This does not keep them from enjoying other aspects of their lives, but it does mean that they never return to being quite the same people they were before they became parents” (Colman & Colman, 1991, p. 198).

SUMMARY

Prenatal Development

(p. 80)

List the three periods of prenatal development, and describe the major milestones of each.

- The period of the zygote lasts about two weeks, from fertilization until **implantation** of the blastocyst in the uterine lining. During this time, structures that will support prenatal growth begin to form, including the **placenta** and the **umbilical cord**.
- During the period of the **embryo**, weeks 2 through 8, the groundwork is laid for all body structures. The **neural tube** forms and the nervous system starts to develop. Other organs follow rapidly. By the end of this period, the embryo responds to touch and can move.

- The period of the **fetus**, lasting until the end of pregnancy, involves dramatic increase in body size and completion of physical structures. At the end of the second **trimester**, most of the brain’s neurons are in place.
- The fetus reaches the **age of viability** at the beginning of the third trimester, between 22 and 26 weeks. The brain continues to develop rapidly, and new sensory and behavioral capacities emerge. Gradually the lungs mature, the fetus fills the uterus, and birth is near.

Prenatal Environmental Influences (p. 85)

Cite factors that influence the impact of teratogens, noting agents that are known teratogens.

- The impact of **teratogens** varies with the amount and length of exposure, genetic makeup of mother and fetus, presence or absence of other harmful agents, and age of the organism at time of exposure. The developing organism is especially vulnerable during the embryonic period.

JOHN JAMES WOOD/
GETTY IMAGES/PHOTOLIBRARY

- The most widely used potent teratogen is Accutane, a drug used to treat severe acne. The prenatal impact of other commonly used medications, such as aspirin and caffeine, is hard to separate from other factors correlated with drug taking.
- Babies born to users of cocaine, heroin, or methadone are at risk for a wide variety of problems, including prematurity, low birth weight, physical defects, breathing difficulties, and death around the time of birth.
- Infants whose parents use tobacco are often born underweight, may have physical defects, and are at risk for long-term attention, learning, and behavior problems. Maternal alcohol consumption can lead to **fetal alcohol spectrum disorder (FASD)**. **Fetal alcohol syndrome (FAS)** involves slow physical growth, facial abnormalities, and mental impairments. Milder forms—**partial fetal alcohol syndrome (p-FAS)** and **alcohol-related neurodevelopmental disorder (ARND)**—affect children whose mothers consumed smaller quantities of alcohol.

© SHUTTERSTOCK

- Prenatal exposure to high levels of ionizing radiation, mercury, PCBs, lead, and dioxins leads to physical malformations and severe brain damage. Low-level exposure has been linked to cognitive deficits and emotional and behavioral disorders.
- Among infectious diseases, rubella causes a wide range of abnormalities. Babies with prenatally transmitted HIV rapidly develop AIDS, leading to brain damage and early death. Cytomegalovirus, herpes simplex 2, and toxoplasmosis can also be devastating to the embryo and fetus.

Describe the impact of additional maternal factors on prenatal development.

- Prenatal malnutrition can lead to low birth weight, organ damage, and suppression of immune system development. Vitamin–mineral enrichment, including folic acid, can prevent prenatal and birth complications.

- Severe emotional stress is linked to many pregnancy complications and may permanently alter fetal neurological functioning, thereby magnifying future stress reactivity. Its negative impact can be reduced by providing the mother with social support. **Rh factor incompatibility**—an Rh-negative mother carrying an Rh-positive fetus—can lead to oxygen deprivation, brain and heart damage, and infant death.
- Other than the risk of chromosomal abnormalities in older women, maternal age through the thirties is not a major cause of prenatal problems. Poor health and environmental risks associated with poverty are the strongest predictors of pregnancy complications.

Why is early and regular health care vital during the prenatal period?

- Unexpected difficulties, such as preeclampsia, can arise, especially in mothers with preexisting health problems. Prenatal health care is especially critical for women unlikely to seek it, including those who are young and poor.

Childbirth (p. 96)

Describe the three stages of childbirth, the baby's adaptation to labor and delivery, and the newborn baby's appearance.

- In the first stage of childbirth, contractions widen and thin the cervix. In the second stage, the mother feels an urge to push the baby through the birth canal. In the final stage, the placenta is delivered. During labor, infants produce high levels of stress hormones, which help them withstand oxygen deprivation, clear the lungs for breathing, and arouse them into alertness at birth.
- Newborn babies have large heads, small bodies, and facial features that make adults feel like cuddling them. The **Apgar Scale** assesses the baby's physical condition at birth.

Approaches to Childbirth

(p. 98)

Describe natural childbirth and home delivery, noting benefits and concerns associated with each.

- In **natural**, or **prepared**, **childbirth**, the expectant mother and a companion attend classes about labor and delivery, master relaxation and breathing techniques to counteract pain, and prepare for coaching during childbirth. Social support from a partner, relative, or doula reduces the length of labor and the incidence of birth complications.
- Home birth is safe for healthy mothers who are assisted by a well-trained doctor or midwife, but mothers at risk for complications are safer giving birth in a hospital.

Medical Interventions

(p. 100)

List common medical interventions during childbirth, circumstances that justify their use, and any dangers associated with each.

- **Fetal monitors** help save the lives of many babies at risk for **anoxia** because of pregnancy and birth complications. When used routinely, however, they may identify infants as in danger who, in fact, are not.
- Use of analgesics and anesthetics to control pain, though necessary in complicated deliveries, can prolong labor and may have negative effects on the newborn's adjustment.
- **Cesarean deliveries** are warranted by medical emergency or serious maternal illness and for many babies who are in **breach position**. However, many unnecessary cesareans are performed.

Preterm and Low-Birth-Weight Infants (p. 101)

Describe risks associated with preterm birth and low birth weight, along with effective interventions.

- Low birth weight, most common in infants born to poverty-stricken women, is a major cause of neonatal and **infant mortality** and many developmental problems. Compared with **preterm infants**, whose weight is appropriate for time spent in the uterus, **small-for-date infants** usually have longer-lasting difficulties.

© ERNESTO BONILLA/XINHUA PRESS/CORBIS

- Some interventions provide special stimulation in the intensive care nursery. Others teach parents how to care for and interact with their babies. Preterm infants in stressed, low-income households need long-term, intensive intervention.

Birth Complications, Parenting, and Resilience

(p. 105)

What factors predict positive outcomes in infants who survive a traumatic birth?

- When infants experience birth trauma, a supportive home environment can help restore their growth. Even infants with fairly serious birth complications can recover with the help of favorable experiences with parents, relatives, neighbors, and peers.

The Newborn Baby's Capacities

(p. 106)

Describe the newborn baby's reflexes and states of arousal, including sleep characteristics and ways to soothe a crying baby.

- **Reflexes** are the newborn baby's most obvious organized patterns of behavior. Some have survival value, others provide the foundation for voluntary motor skills, and still others help parents and infants establish gratifying interaction.

© LAURA DWIGHT PHOTOGRAPHY

- Newborns move in and out of five **states of arousal** but spend most of their time asleep. Sleep includes at least two states, **rapid-eye-movement (REM) sleep** and **non-rapid-eye-movement (NREM) sleep**. Newborns spend about 50 percent of sleep time in REM sleep, which provides them with stimulation essential for central nervous system development.
- A crying baby stimulates strong feelings of discomfort in nearby adults. The intensity of the cry and the experiences that led up to it help parents identify what is wrong. Once feeding and diaper changing have been tried, a highly effective soothing technique is lifting the baby to the shoulder and rocking and walking.

Describe the newborn baby's sensory capacities.

- The senses of touch, taste, smell, and sound are well-developed at birth. Newborns use touch to investigate their world, are sensitive to pain, prefer sweet tastes and smells, and orient toward the odor of their own mother's lactating breast.
- Newborns can distinguish a variety of sound patterns and prefer complex sounds. They are especially responsive to human speech, can detect the sounds of any human language, and prefer their mother's voice.
- Vision is the least developed of the newborn's senses. At birth, focusing ability and **visual acuity** are limited. In exploring the visual field, newborn babies are attracted to bright objects but have difficulty discriminating colors.

Why is neonatal behavioral assessment useful?

- The most widely used instrument for assessing the behavior of the newborn infant, Brazelton's **Neonatal Behavioral Assessment Scale (NBAS)**, has helped researchers understand individual and cultural differences in newborn behavior. Sometimes it is used to teach parents about their newborn's capacities.

© JEFFREY L. ROTMAN/CORBIS

Adjusting to the New Family Unit

(p. 115)

Describe typical changes in the family after the birth of a new baby.

- The new baby's arrival is exciting but stressful, as the mother recuperates from childbirth and the family schedule becomes irregular and uncertain. When parents have a positive relationship as well as social support and adequate income, adjustment problems are usually temporary.

Physical Development in Infancy and Toddlerhood

On a brilliant June morning, 16-month-old Caitlin emerged from her front door, ready for the short drive to the child-care home where she spent her weekdays while her mother, Carolyn, and her father, David, worked. Clutching a teddy bear in one hand and her mother's arm with the other, Caitlin descended the steps. "One! Two! Threeee!" Carolyn counted as she helped Caitlin down. "How much she's changed," Carolyn thought to herself, looking at the child who, not long ago, had been a newborn. With her first steps, Caitlin had passed from *infancy* to *toddlerhood*—a period spanning the second year of life. At first, Caitlin did, indeed, "toddle" with an awkward gait, tipping over frequently. But her face reflected the thrill of conquering a new skill.

As they walked toward the car, Carolyn and Caitlin spotted 3-year-old Eli and his father, Kevin, in the neighboring yard. Eli dashed toward them, waving a bright yellow envelope. Carolyn bent down to open the envelope and took out a card. It read, "Announcing the arrival of Grace Ann. Born: Cambodia. Age: 16 months." Carolyn turned to Kevin and Eli. "That's wonderful news! When can we see her?"

"Let's wait a few days," Kevin suggested. "Monica's taken Grace to the doctor this morning. She's underweight and malnourished." Kevin described Monica's first night with Grace in a hotel room in Phnom Penh. Grace lay on the bed, withdrawn and fearful. Eventually she fell asleep, gripping crackers in both hands.

Carolyn felt Caitlin's impatient tug at her sleeve. Off they drove to child care, where Vanessa had just dropped off her 18-month-old son, Timmy. Within moments, Caitlin and Timmy were in the sandbox, shoveling sand into plastic cups and buckets with the help of their caregiver, Ginette.

A few weeks later, Grace joined Caitlin and Timmy at Ginette's child-care home. Although still tiny and unable to crawl or walk, she had grown taller and heavier, and her sad, vacant gaze had given way to an alert expression, a ready smile, and an enthusiastic desire to imitate and explore. When Caitlin headed for the sandbox, Grace stretched out her arms, asking Ginette to carry her there, too. Soon Grace was pulling herself up at every opportunity. Finally, at age 18 months, she walked!

This chapter traces physical growth during the first two years—one of the most remarkable and busiest times of development. We will see how rapid changes in the

infant's body and brain support learning, motor skills, and perceptual capacities. Caitlin, Grace, and Timmy will join us along the way to illustrate individual differences and environmental influences on physical development. ●

Body Growth

TAKE A MOMENT... The next time you're walking in your neighborhood park or at the mall, note the contrast between infants' and toddlers' physical capabilities. One reason for the vast changes in what children can do over the first two years is that their bodies change enormously—faster than at any other time after birth.

Changes in Body Size and Muscle–Fat Makeup

By the end of the first year, a typical infant's height is about 32 inches—more than 50 percent greater than at birth. By 2 years, it is 75 percent greater (36 inches). Similarly, by 5 months of age, birth weight has doubled, to about 15 pounds. At 1 year it has tripled, to 22 pounds, and at 2 years it has quadrupled, to about 30 pounds.

Figure 4.1 illustrates this dramatic increase in body size. But rather than making steady gains, infants and toddlers grow in little spurts. In one study, children who were followed over the first 21 months of life went for periods of 7 to 63 days with no growth, then added as much as half an inch in a 24-hour period! Almost always, parents described their babies as irritable and

FIGURE 4.1 Body growth during the first two years. These photos depict the dramatic changes in body size and proportions during infancy and toddlerhood in two individuals—a boy, Chris, and a girl, Mai. In the first year, the head is quite large in proportion to the rest of the body, and height and weight gain are especially rapid. During the second year, the lower portion of the body catches up. Notice, also, how both children added “baby fat” in the early months of life and then slimmed down, a trend that continues into middle childhood.

very hungry on the day before the spurt (Lampl, 1993; Lampl, Veldhuis, & Johnson, 1992).

One of the most obvious changes in infants' appearance is their transformation into round, plump babies by the middle of the first year. This early rise in “baby fat,” which peaks at about 9 months, helps the small infant maintain a constant body temperature. In the second year, most toddlers slim down, a trend that continues into middle childhood (Fomon & Nelson, 2002). In contrast, muscle tissue increases very slowly during infancy and will not reach a peak until adolescence. Babies are not very muscular; their strength and physical coordination are limited.

Individual and Group Differences

In infancy, girls are slightly shorter and lighter than boys, with a higher ratio of fat to muscle. These small sex differences persist throughout early and middle childhood and are greatly magnified at adolescence. Ethnic differences in body size are apparent as well. Grace was below the *growth norms* (height and weight averages for children her age). Early malnutrition contributed, but even after substantial catch-up, Grace—as is typical for Asian children—remained below North American norms. In contrast, Timmy is slightly above average, as African-American children tend to be (Bogin, 2001).

Children of the same age also differ in *rate* of physical growth; some make faster progress toward a mature body size than others. But current body size is not enough to tell us how quickly a child's physical growth is moving along. Although Timmy is larger and heavier than Caitlin and Grace, he is not physically more mature. In a moment, you will see why.

The best estimate of a child's physical maturity is *skeletal age*, a measure of bone development. It is determined by X-raying the long bones of the body to see the extent to which soft, pliable cartilage has hardened into bone, a gradual process that is completed in adolescence. When skeletal ages are examined, African-American children tend to be slightly ahead of Caucasian children at all ages, and girls are considerably ahead of boys. At birth, the sexes differ by about 4 to 6 weeks, a gap that widens over infancy and childhood (Tanner, Healy, & Cameron, 2001). This greater physical maturity may contribute to girls' greater resistance to harmful environmental influences. As noted in Chapter 2, girls experience fewer developmental problems than boys and have lower infant and childhood mortality rates.

Changes in Body Proportions

As the child's overall size increases, different parts of the body grow at different rates. Two growth patterns describe these changes. The first is the **cephalocaudal trend**—from the Latin for “head to tail.” During the prenatal period, the head develops more rapidly than the lower part of the body. At birth, the head takes up one-fourth of total body length, the legs only one-third. Notice how, in Figure 4.1, the lower portion of the body catches up. By age 2, the head accounts for only one-fifth and the legs for nearly one-half of total body length.

In the second pattern, the **proximodistal trend**, growth proceeds, literally, from “near to far”—from the center of the body outward. In the prenatal period, the head, chest, and trunk grow first, then the arms and legs, and finally the hands and feet. During infancy and childhood, the arms and legs continue to grow somewhat ahead of the hands and feet.

Brain Development

At birth, the brain is nearer to its adult size than any other physical structure, and it continues to develop at an astounding pace throughout infancy and toddlerhood. We can best understand brain growth by looking at it from two vantage points: (1) the microscopic level of individual brain cells and (2) the larger level of the cerebral cortex, the most complex brain structure and the one responsible for the highly developed intelligence of our species.

Development of Neurons

The human brain has 100 to 200 billion **neurons**, or nerve cells that store and transmit information, many of which have thousands of direct connections with other neurons. Unlike other body cells, neurons are not tightly packed together. Between them are tiny gaps, or **synapses**, where fibers from different neurons come close together but do not touch (see Figure 4.2). Neurons send messages to one another by releasing chemicals called **neurotransmitters**, which cross the synapse.

© ASAP/CNRI/SCIENCE SOURCE/PHOTO RESEARCHERS, INC.

FIGURE 4.2 Neurons and their connective fibers. This photograph of several neurons, taken with the aid of a powerful microscope, shows the elaborate synaptic connections that form with neighboring cells.

FIGURE 4.3 Major milestones of brain development. Formation of synapses is rapid during the first two years, especially in the auditory, visual, and language areas of the cerebral cortex. The prefrontal cortex undergoes more extended synaptic growth. In each area, overproduction of synapses is followed by synaptic pruning. The prefrontal cortex is among the last regions to attain adult levels of synaptic connections—in mid- to late adolescence. Myelination occurs at a dramatic pace during the first two years, more slowly through childhood, followed by an acceleration at adolescence and then a reduced pace in early adulthood. The multiple yellow lines indicate that the timing of myelination varies among different brain areas. For example, neural fibers myelinate over a longer period in the language areas, and especially in the prefrontal cortex, than in the visual and auditory areas. (Adapted from Thompson & Nelson, 2001.)

The basic story of brain growth concerns how neurons develop and form this elaborate communication system. Figure 4.3 summarizes major milestones of brain development. In the prenatal period, neurons are produced in the embryo's primitive neural tube. From there, they migrate to form the major parts of the brain (see Chapter 3, page 82). Once neurons are in place, they differentiate, establishing their unique functions by extending their fibers to form synaptic connections with neighboring cells. During the first two years, neural fibers and synapses increase at an astounding pace (Huttenlocher, 2002; Moore, Persaud, & Torchia, 2013). A surprising aspect of brain growth is **programmed cell death**, which makes space for these connective structures: As synapses form, many surrounding neurons die—20 to 80 percent, depending on the brain region (de Haan & Johnson, 2003; Stiles, 2008). Fortunately, during the prenatal period, the neural tube produces far more neurons than the brain will ever need.

As neurons form connections, *stimulation* becomes vital to their survival. Neurons that are stimulated by input from the surrounding environment continue to establish synapses, forming increasingly elaborate systems of communication that support more complex abilities. At first, stimulation results in a massive overabundance of synapses, many of which serve identical functions, thereby ensuring that the child will acquire the motor, cognitive, and social skills that our species needs to survive. Neurons that are seldom stimulated soon lose their synapses, in a process called **synaptic pruning** that returns neurons not needed at the moment to an uncommitted state so they can support future development. In all, about 40 percent of synapses are pruned during childhood and adolescence to reach the adult level (Webb, Monk, & Nelson, 2001). For this process to advance, appropriate stimulation of the child's brain is vital during periods in which the formation of synapses is at its peak (Bryk & Fisher, 2012).

If few new neurons are produced after the prenatal period, what causes the dramatic increase in brain size during the first two years? About half the brain's volume is made up of **glial cells**, which are responsible for **myelination**, the coating of neural fibers with an insulating fatty sheath (called *myelin*) that improves the efficiency of message transfer. Glial cells multiply rapidly from the fourth month of pregnancy through the second year of life—a process that continues at a slower pace through middle childhood and accelerates again in adolescence. Gains in neural fibers and myelination are responsible for the extraordinary gain in overall size of the brain—from nearly 30 percent of its adult weight at birth to 70 percent by age 2 (Johnson, 2011; Knickmeyer et al., 2008).

Brain development can be compared to molding a “living sculpture.” First, neurons and synapses are overproduced. Then, cell death and synaptic pruning sculpt away excess building material to form the mature brain—a process jointly influenced by genetically programmed events and the child's experiences. The resulting “sculpture” is a set of interconnected regions, each with specific functions—much like countries on a globe that communicate with one another (Johnston et al., 2001). This “geography” of the brain permits researchers to study its developing organization and the activity of its regions using neurobiological methods.

Neurobiological Methods

Table 4.1 describes major measures of brain functioning. The first two methods detect changes in *electrical activity* in the cerebral cortex. In an *electroencephalogram (EEG)*, researchers examine *brain-wave patterns* for stability and organization—signs of mature functioning of the cortex. And as the person

TABLE 4.1
Methods for Measuring Brain Functioning

METHOD	DESCRIPTION
Electroencephalogram (EEG)	Electrodes embedded in a head cap record electrical brain-wave activity in the brain's outer layers—the cerebral cortex. Today, researchers use an advanced tool called a geodesic sensor net (GSN) to hold interconnected electrodes (up to 128 for infants and 256 for children and adults) in place through a cap that adjusts to each person's head shape, yielding improved brain-wave detection.
Event-related potentials (ERPs)	Using the EEG, the frequency and amplitude of brain waves in response to particular stimuli (such as a picture, music, or speech) are recorded in multiple areas of the cerebral cortex. Enables identification of general regions of stimulus-induced activity.
Functional magnetic resonance imaging (fMRI)	While the person lies inside a tunnel-shaped apparatus that creates a magnetic field, a scanner magnetically detects increased blood flow and oxygen metabolism in areas of the brain as the individual processes particular stimuli. The scanner typically records images every 1 to 4 seconds; these are combined into a computerized moving picture of activity anywhere in the brain (not just its outer layers). Not appropriate for children younger than age 5 to 6, who cannot remain still during testing.
Positron emission tomography (PET)	After injection or inhalation of a radioactive substance, the person lies on an apparatus with a scanner that emits fine streams of X-rays, which detect increased blood flow and oxygen metabolism in areas of the brain as the person processes particular stimuli. As with fMRI, the result is a computerized image of “online” activity anywhere in the brain. Not appropriate for children younger than age 5 to 6.
Near-infrared spectroscopy (NIRS)	Using thin, flexible optical fibers attached to the scalp through a head cap, infrared (invisible) light is beamed at the brain; its absorption by areas of the cerebral cortex varies with changes in blood flow and oxygen metabolism as the individual processes particular stimuli. The result is a computerized moving picture of active areas in the cerebral cortex. Unlike fMRI and PET, NIRS is appropriate for infants and young children, who can move within limited range.

processes a particular stimulus, *event-related potentials (ERPs)* detect the general location of brain-wave activity—a technique often used to study preverbal infants' responsiveness to various stimuli, the impact of experience on specialization of specific brain regions, and atypical brain functioning in individuals with learning and emotional problems (DeBoer, Scott, & Nelson, 2007; deRegnier, 2005).

Neuroimaging techniques, which yield detailed, three-dimensional computerized pictures of the entire brain and its active areas, provide the most precise information about which

brain regions are specialized for certain capacities and about abnormalities in brain functioning. The most promising of these methods is *functional magnetic resonance imaging (fMRI)*. Unlike *positron emission tomography (PET)*, fMRI does not depend on X-ray photography, which requires injection of a radioactive substance. Rather, when an individual is exposed to a stimulus, fMRI detects changes in blood flow and oxygen metabolism throughout the brain magnetically, yielding a colorful, moving picture of parts of the brain used to perform a given activity (see Figure 4.4a, b, and c).

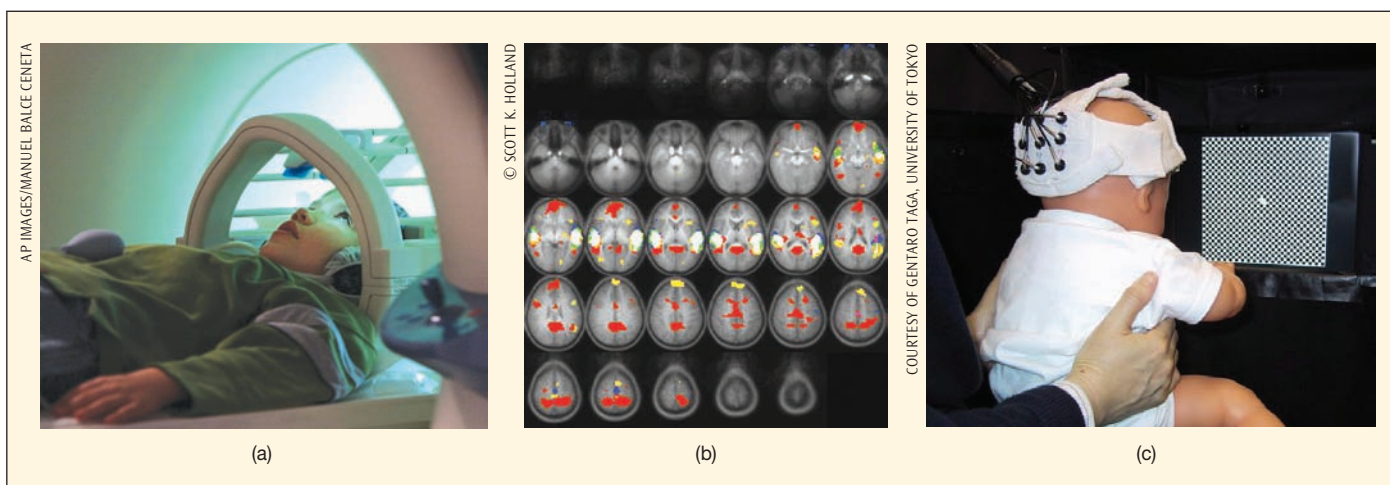

FIGURE 4.4 Functional magnetic resonance imaging (fMRI) and near-infrared spectroscopy (NIRS). (a) This 6-year-old is part of a study that uses fMRI to find out how his brain processes light and motion. (b) The fMRI image shows which areas of the child's brain are active while he views changing visual stimuli. (c) Here, NIRS is used to investigate a 2-month-old's response to a visual stimulus. During testing, the baby can move freely within a limited range. (Photo (c) from G. Taga, K. Asakawa, A. Maki, Y. Konishi, & H. Koisumi, 2003, "Brain Imaging in Awake Infants by Near-Infrared Optical Topography," *Proceedings of the National Academy of Sciences*, 100, p. 10723. Reprinted by permission.)

Because PET and fMRI require that the participant lie as motionless as possible for an extended time, they are not suitable for infants and young children (Nelson, Thomas, & de Haan, 2006). A neuroimaging technique that works well in infancy and early childhood is *near-infrared spectroscopy (NIRS)*, in which infrared (invisible) light is beamed at regions of the cerebral cortex to measure blood flow and oxygen metabolism while the child attends to a stimulus (refer again to Table 4.1). Because the apparatus consists only of thin, flexible optical fibers attached to the scalp using a head cap, a baby can sit on the parent's lap and move during testing—as Figure 4.4c illustrates (Hespos et al., 2010). But unlike PET and fMRI, which map activity changes throughout the brain, NIRS examines only the functioning of the cerebral cortex.

Development of the Cerebral Cortex

The **cerebral cortex** surrounds the rest of the brain, resembling half of a shelled walnut. It is the largest brain structure, accounting for 85 percent of the brain's weight and containing the greatest number of neurons and synapses. Because the cerebral cortex is the last part of the brain to stop growing, it is sensitive to environmental influences for a much longer period than any other part of the brain.

Regions of the Cerebral Cortex. Figure 4.5 shows specific functions of regions of the cerebral cortex, such as receiving information from the senses, instructing the body to move, and thinking. The order in which cortical regions develop corresponds to the order in which various capacities emerge in the infant and growing child. For example, a burst of activity

FIGURE 4.5 The left side of the human brain, showing the cerebral cortex. The cortex is divided into different lobes, each containing a variety of regions with specific functions. Some major regions are labeled here.

occurs in the auditory and visual cortexes and in areas responsible for body movement over the first year—a period of dramatic gains in auditory and visual perception and mastery of motor skills (Johnson, 2011). Language areas are especially active from late infancy through the preschool years, when language development flourishes (Pujol et al., 2006; Thompson, 2000).

The cortical regions with the most extended period of development are the *frontal lobes*. The **prefrontal cortex**, lying in front of areas controlling body movement, is responsible for thought—in particular, consciousness, inhibition of impulses, integration of information, and use of memory, reasoning, planning, and problem-solving strategies. From age 2 months on, the prefrontal cortex functions more effectively. But it undergoes especially rapid myelination and formation and pruning of synapses during the preschool and school years, followed by another period of accelerated growth in adolescence, when it reaches an adult level of synaptic connections (Nelson, 2002; Nelson, Thomas, & de Haan, 2006; Sowell et al., 2002).

Lateralization and Plasticity of the Cortex. The cerebral cortex has two *hemispheres*, or sides, that differ in their functions. Some tasks are done mostly by the left hemisphere, others by the right. For example, each hemisphere receives sensory information from the side of the body opposite to it and controls only that side.* For most of us, the left hemisphere is largely responsible for verbal abilities (such as spoken and written language) and positive emotion (such as joy). The right hemisphere handles spatial abilities (judging distances, reading maps, and recognizing geometric shapes) and negative emotion (such as distress) (Banish & Heller, 1998; Nelson & Bosquet, 2000). In left-handed people, this pattern may be reversed or, more commonly, the cerebral cortex may be less clearly specialized than in right-handers.

Why does this specialization of the two hemispheres, called **lateralization**, occur? Studies using fMRI reveal that the left hemisphere is better at processing information in a sequential, analytic (piece-by-piece) way, a good approach for dealing with communicative information—both verbal (language) and emotional (a joyful smile). In contrast, the right hemisphere is specialized for processing information in a holistic, integrative manner, ideal for making sense of spatial information and regulating negative emotion. A lateralized brain may have evolved because it enabled humans to cope more successfully with changing environmental demands (Falk, 2005). It permits a wider array of functions to be carried out effectively than if both sides processed information exactly the same way.

Researchers study the timing of brain lateralization to learn more about **brain plasticity**. A highly plastic cerebral cortex, in which many areas are not yet committed to specific functions, has a high capacity for learning. And if a part of the cortex is

*The eyes are an exception. Messages from the right half of each retina go to the right hemisphere; messages from the left half of each retina go to the left hemisphere. Thus, visual information from *both* eyes is received by *both* hemispheres.

damaged, other parts can take over tasks it would have handled. But once the hemispheres lateralize, damage to a specific region means that the abilities it controls cannot be recovered to the same extent or as easily as earlier.

At birth, the hemispheres have already begun to specialize. Most newborns show greater activation (detected with either ERP or NIRS) in the left hemisphere while listening to speech sounds or displaying a positive state of arousal. In contrast, the right hemisphere reacts more strongly to nonspeech sounds and to stimuli (such as a sour-tasting fluid) that evoke negative emotion (Davidson, 1994; Fox & Davidson, 1986; Hespos et al., 2010).

Nevertheless, research on brain-damaged children and adults offers dramatic evidence for substantial plasticity in the young brain, summarized in the Biology and Environment box on page 126. Furthermore, early experience greatly influences the organization of the cerebral cortex. For example, deaf adults who, as infants and children, learned sign language (a spatial skill) depend more than hearing individuals on the right hemisphere for language processing (Neville & Bavelier, 2002). And toddlers who are advanced in language development show greater left-hemispheric specialization for language than their more slowly developing agemates (Luna et al., 2001; Mills et al., 2005). Apparently, the very process of acquiring language and other skills promotes lateralization.

In sum, the brain is more plastic during the first few years than it will ever be again. An overabundance of synaptic connections supports brain plasticity, ensuring that young children will acquire certain capacities even if some areas are damaged. And although the cortex is programmed from the start for hemispheric specialization, experience greatly influences the rate and success of its advancing organization.

Sensitive Periods in Brain Development

Both animal and human studies reveal that early, extreme sensory deprivation results in permanent brain damage and loss of functions—findings that verify the existence of sensitive periods in brain development. For example, early, varied visual experiences must occur for the brain's visual centers to develop normally. If a 1-month-old kitten is deprived of light for just three or four days, these areas of the brain degenerate. If the kitten is kept in the dark during the fourth week of life and beyond, the damage is severe and permanent (Crair, Gillespie, & Stryker, 1998). And the general quality of the early environment affects overall brain growth. When animals reared from birth in physically and socially stimulating surroundings are compared with those reared under depleted conditions, the brains of the stimulated animals are larger and heavier and show much denser synaptic connections (Sale, Berardi, & Maffei, 2009).

Human Evidence: Victims of Deprived Early Environments.

For ethical reasons, we cannot deliberately deprive some infants of normal rearing experiences and observe the impact on their brains and competencies. Instead, we must turn to natural experiments, in which children were victims of

deprived early environments that were later rectified. Such studies have revealed some parallels with the animal evidence just described.

For example, when babies are born with cataracts (clouded lenses, preventing clear visual images) in both eyes, those who have corrective surgery within four to six months show rapid improvement in vision, except for subtle aspects of face perception, which require early visual input to the right hemisphere to develop (Le Grand et al., 2003; Maurer, Mondloch, & Lewis, 2007). The longer cataract surgery is postponed beyond infancy, the less complete the recovery in visual skills. And if surgery is delayed until adulthood, vision is severely and permanently impaired (Lewis & Maurer, 2005).

Studies of infants placed in orphanages who were later exposed to ordinary family rearing confirm the importance of a generally stimulating physical and social environment for psychological development. In one investigation, researchers followed the progress of a large sample of children transferred between birth and 3½ years from extremely deprived Romanian orphanages to adoptive families in Great Britain (Beckett et al., 2006; O'Connor et al., 2000; Rutter et al., 1998, 2004, 2010). On arrival, most were impaired in all domains of development. Cognitive catch-up was impressive for children adopted before 6 months, who attained average mental test scores in childhood and adolescence, performing as well as a comparison group of early-adopted British-born children.

But Romanian children who had been institutionalized for more than the first six months showed serious intellectual

These children in an orphanage in Romania receive little adult contact or stimulation. The longer they remain in this barren environment, the more likely they are to display profound impairments in all domains of development.

Biology and Environment

Brain Plasticity: Insights from Research on Brain-Damaged Children and Adults

In the first few years of life, the brain is highly plastic. It can reorganize areas committed to specific functions in ways that the mature brain cannot. Consistently, adults who suffered brain injuries in infancy and early childhood show fewer cognitive impairments than adults with later-occurring injuries (Holland, 2004; Huttenlocher, 2002). Nevertheless, the young brain is not totally plastic. When it is injured, its functioning is compromised. The extent of plasticity depends on several factors, including age at time of injury, site of damage, and skill area. Furthermore, plasticity is not restricted to childhood. Some reorganization after injury also occurs in the mature brain.

Brain Plasticity in Infancy and Early Childhood

In a large study of children with injuries to the cerebral cortex that occurred before birth or in the first six months of life, language and spatial skills were assessed repeatedly into adolescence (Akshoomoff et al., 2002; Stiles, 2001a; Stiles et al., 2005, 2008). All the children had experienced early brain seizures or hemorrhages. Brain-imaging techniques (fMRI and PET) revealed the precise site of damage.

Regardless of whether injury occurred in the left or right cerebral hemisphere, the children showed delays in language development that persisted until about 3½ years of age. That damage to either hemisphere affected early language competence indicates that at first, language functioning is broadly distributed in the brain. But by age 5, the children caught up in vocabulary and grammatical skills. Undamaged areas—in either the left or the right hemisphere—had taken over these language functions.

Compared with language, spatial skills were more impaired after early brain injury. When preschool through adolescent-age youngsters were asked to copy designs, those with early right-hemispheric damage had trouble with holistic processing—accurately representing the overall shape. In contrast, children with left-hemispheric damage captured the basic shape but omitted fine-grained

details. Nevertheless, the children improved in drawing skills with age—gains that do not occur in brain-injured adults (Akshoomoff et al., 2002; Stiles et al., 2003, 2008).

Clearly, recovery after early brain injury is greater for language than for spatial skills. Why is this so? Researchers speculate that spatial processing is the older of the two capacities in our evolutionary history and, therefore, more lateralized at birth (Stiles, 2001b; Stiles et al., 2002, 2008). But early brain injury has far less impact than later injury on *both* language and spatial skills. In sum, the young brain is remarkably plastic.

The Price of High Plasticity in the Young Brain

Despite impressive recovery of language and (to a lesser extent) spatial skills, children with early brain injuries show deficits in a wide range of complex mental abilities during the school years. For example, their reading and math progress is slow. And in telling stories, they produce simpler narratives than age-mates without early brain injuries (although many catch up in narrative skills by early adolescence) (Reilly, Bates, & Marchman, 1998; Reilly et al., 2004). Furthermore, the more brain tissue destroyed in infancy or early childhood, the poorer children score on intelligence tests (Anderson et al., 2006).

High brain plasticity, researchers explain, comes at a price. When healthy brain regions take over the functions of damaged areas, a “crowding effect” occurs: Multiple tasks must be done by a smaller-than-usual volume of brain tissue (Stiles, 2012). Consequently, the brain processes information less quickly and accurately than it would if it were intact. Complex mental abilities of all kinds suffer into middle childhood, and often longer, because performing them well requires considerable space in the cerebral cortex.

Brain Plasticity in Adulthood

Brain plasticity is not restricted to early childhood. Though far more limited, reorganization in the brain can occur later, even in adulthood. For example, adult stroke

© JIM WEST/THE IMAGE WORKS

This preschooler, who experienced brain damage in infancy, has been spared massive impairments because of early, high brain plasticity. A teacher guides his hand in drawing shapes to strengthen spatial skills, which are more impaired than language.

victims often display considerable recovery, especially in response to stimulation of language and motor skills. Brain-imaging techniques reveal that structures adjacent to the permanently damaged area or in the opposite cerebral hemisphere reorganize to support the impaired ability (Kalra & Ratan, 2007; Murphy & Corbett, 2009).

In infancy and childhood, the goal of brain growth is to form neural connections that ensure mastery of essential skills. Animal research reveals that plasticity is greatest while the brain is forming many new synapses; it declines during synaptic pruning (Murphy & Corbett, 2009). At older ages, specialized brain structures are in place, but after injury they can still reorganize to some degree. The adult brain can produce a small number of new neurons. And when an individual practices relevant tasks, the brain strengthens existing synapses and generates new ones (Nelson, Thomas, & de Haan, 2006).

Plasticity seems to be a basic property of the nervous system. Researchers hope to discover how experience and brain plasticity work together throughout life, so they can help people of all ages—with and without brain injuries—develop at their best.

FIGURE 4.6 Relationship of age at adoption to mental test scores at ages 6 and 11 among British and Romanian adoptees. Children transferred from Romanian orphanages to British adoptive homes in the first six months of life attained average scores and fared as well as British early-adopted children, suggesting that they had fully recovered from extreme early deprivation. Romanian children adopted after 6 months of age performed well below average. And although those adopted after age 2 improved between ages 6 and 11, they continued to show serious intellectual deficits. (Adapted from Beckett et al., 2006.)

deficits (see Figure 4.6). Although they improved in test scores during middle childhood and adolescence, they remained substantially below average. And most displayed at least three serious mental health problems, such as inattention, overactivity, unruly behavior, and autistic-like symptoms (social disinterest, stereotyped behavior) (Kreppner et al., 2007, 2010).

Neurobiological findings indicate that early, prolonged institutionalization leads to a generalized decrease in activity in the cerebral cortex, especially the prefrontal cortex, which governs complex cognition and impulse control. Neural fibers connecting the prefrontal cortex with other brain structures involved in control of emotion are also reduced (Eluvathingal et al., 2006; Nelson, 2007b). And activation of the left cerebral hemisphere, governing positive emotion, is diminished relative to right cerebral activation, governing negative emotion (McLaughlin et al., 2011).

Additional evidence confirms that the chronic stress of early, deprived orphanage rearing disrupts the brain's capacity to manage stress, with long-term physical and psychological consequences. In another investigation, researchers followed the development of children who had spent their first eight months or more in Romanian institutions and were then adopted into Canadian homes (Gunnar et al., 2001; Gunnar & Cheatham, 2003). Compared with agemates adopted shortly after birth, these children showed extreme stress reactivity, as indicated by high concentrations of the stress hormone *cortisol* in their saliva—a physiological response linked to persistent illness,

retarded physical growth, and learning and behavior problems, including deficits in attention and control of anger and other impulses. The longer the children spent in orphanage care, the higher their cortisol levels—even 6½ years after adoption. In other investigations, orphanage children displayed abnormally low cortisol—a blunted physiological stress response that may be the central nervous system's adaptation to earlier, frequent cortisol elevations (Loman & Gunnar, 2010).

Appropriate Stimulation. Unlike the orphanage children just described, Grace, whom Monica and Kevin had adopted in Cambodia at 16 months of age, showed favorable progress. Two years earlier, they had adopted Grace's older brother, Eli. When Eli was 2 years old, Monica and Kevin sent a letter and a photo of Eli to his biological mother, describing a bright, happy child. The next day, the Cambodian mother tearfully asked an adoption agency to send her baby daughter to join Eli and his American family. Although Grace's early environment was very depleted, her biological mother's loving care—holding gently, speaking softly, playfully stimulating, and breastfeeding—may have prevented irreversible damage to her brain.

In the Bucharest Early Intervention Project, about 200 institutionalized Romanian babies were randomized into conditions of either care as usual or transfer to high-quality foster families between ages 5 and 30 months. Specially trained social workers provided foster parents with counseling and support. Follow-ups between 2½ and 4 years revealed that the foster-care group exceeded the institutional-care group in intelligence test scores, language skills, emotional responsiveness, and EEG and ERP assessments of brain activity (Nelson et al., 2007; Smyke et al., 2009). On all measures, the earlier the foster placement, the better the outcome. But consistent with an early sensitive period, the foster-care group remained behind never-institutionalized agemates living with Bucharest families.

In addition to impoverished environments, ones that overwhelm children with expectations beyond their current capacities interfere with the brain's potential. In recent years, expensive early learning centers have sprung up, in which infants are trained with letter and number flash cards and slightly older toddlers are given a full curriculum of reading, math, science, art, gym, and more. There is no evidence that these programs yield smarter “superbabies” (Hirsh-Pasek & Golinkoff, 2003). To the contrary, trying to prime infants with stimulation for which they are not ready can cause them to withdraw, thereby threatening their interest in learning and creating conditions much like stimulus deprivation!

How, then, can we characterize appropriate stimulation during the early years? To answer this question, researchers distinguish between two types of brain development. The first, **experience-expectant brain growth**, refers to the young brain's rapidly developing organization, which depends on ordinary experiences—opportunities to explore the environment, interact with people, and hear language and other sounds. As a result of millions of years of evolution, the brains of all infants, toddlers, and young children *expect* to encounter these experiences

© ALAMY

Experience-expectant brain growth occurs naturally, through ordinary, stimulating experiences. This toddler exploring a mossy log enjoys the type of activity that best promotes brain development in the early years.

and, if they do, grow normally. The second type of brain development, **experience-dependent brain growth**, occurs throughout our lives. It consists of additional growth and refinement of established brain structures as a result of specific learning experiences that vary widely across individuals and cultures (Greenough & Black, 1992). Reading and writing, playing computer games, weaving an intricate rug, and practicing the violin are examples. The brain of a violinist differs in certain ways from the brain of a poet because each has exercised different brain regions for a long time.

Experience-expectant brain growth occurs early and naturally, as caregivers offer babies and preschoolers age-appropriate play materials and engage them in enjoyable daily routines—a shared meal, a game of peekaboo, a bath before bed, a picture book to talk about, or a song to sing. The resulting growth provides the foundation for later-occurring, experience-dependent development (Huttenlocher, 2002; Shonkoff & Phillips, 2001). No evidence exists for a sensitive period in the first five or six years for mastering skills that depend on extensive training, such as reading, musical performance, or gymnastics. To the contrary, rushing early learning harms the brain by overwhelming its neural circuits, thereby reducing the brain's sensitivity to the everyday experiences it needs for a healthy start in life.

Changing States of Arousal

Rapid brain growth means that the organization of sleep and wakefulness changes substantially between birth and 2 years, and fussiness and crying also decline. The newborn baby takes round-the-clock naps that total about 16 to 18 hours (Davis, Parker & Montgomery, 2004). Total sleep time declines slowly; the average 2-year-old still needs 12 to 13 hours. But periods of sleep and wakefulness become fewer and longer, and the sleep-wake pattern increasingly conforms to a night-day schedule. Most 6- to 9-month-olds take two daytime naps; by about 18 months, children generally need only one nap. Finally, between ages 3 and 5, napping subsides (Iglowstein et al., 2003).

These changing arousal patterns are due to brain development, but they are also affected by cultural beliefs and practices and individual parents' needs (Super & Harkness, 2002). Dutch parents, for example, view sleep regularity as far more important than the U.S. parents do. And whereas U.S. parents regard a predictable sleep schedule as emerging naturally from within the child, Dutch parents believe that a schedule must be imposed, or the baby's development might suffer (Super et al., 1996; Super & Harkness, 2010). At age 6 months, Dutch babies are put to bed earlier and sleep, on average, 2 hours more per day than their U.S. agemates.

Motivated by demanding work schedules and other needs, many Western parents try to get their babies to sleep through the night as early as 3 to 4 months by offering an evening feeding—a practice that may be at odds with young infants' neurological capacities. Not until the middle of the first year is the secretion of *melatonin*, a hormone within the brain that promotes drowsiness, much greater at night than during the day (Sadeh, 1997).

Furthermore, as the Cultural Influences box on the following page reveals, isolating infants to promote sleep is rare elsewhere in the world. When babies sleep with their parents, their average sleep period remains constant at three hours from 1 to 8 months of age. Only at the end of the first year, as REM sleep (the state that usually prompts waking) declines, do infants move in the direction of an adultlike sleep-waking schedule (Ficca et al., 1999).

Even after infants sleep through the night, they continue to wake occasionally. In studies carried out in Australia, Israel, and the United States, night wakings increased around 6 months and again between 1½ and 2 years and then declined (Armstrong, Quinn, & Dadds, 1994; Scher, Epstein, & Tirosh, 2004; Scher et al., 1995). As Chapter 6 will reveal, around the middle of the first year, infants are forming a clear-cut attachment to their familiar caregiver and begin protesting when he or she leaves. And the challenges of toddlerhood—the ability to range farther from the caregiver and increased awareness of the self as separate from others—often prompt anxiety, evident in disturbed sleep and clinginess. When parents offer comfort, these behaviors subside.

Cultural Influences

Cultural Variation in Infant Sleeping Arrangements

Western child-rearing advice from experts strongly encourages nighttime separation of baby from parent. For example, the most recent edition of Benjamin Spock's *Baby and Child Care* recommends that babies sleep in their own room by 3 months of age, explaining, "By 6 months, a child who regularly sleeps in her parents' room may feel uneasy sleeping anywhere else" (Spock & Needlman, 2012, p. 62). And the American Academy of Pediatrics (2012) has issued a controversial warning that parent–infant bedsharing may increase the risk of sudden infant death syndrome (SIDS).

Yet parent–infant "cosleeping" is the norm for approximately 90 percent of the world's population, in cultures as diverse as the Japanese, the rural Guatemalan Maya, the Inuit of northwestern Canada, and the !Kung of Botswana. Japanese and Korean children usually lie next to their mothers in infancy and early childhood, and many continue to sleep with a parent or other family member until adolescence (Takahashi, 1990; Yang & Hahn, 2002). Among the Maya, mother–infant bedsharing is interrupted only by the birth of a new baby, when the older child is moved next to the father or to another bed in the same room (Morelli et al., 1992). Bedsharing is also common in U.S. ethnic minority families (McKenna & Volpe, 2007). African-American children, for example, frequently fall asleep with their parents and remain with them for part or all of the night (Buswell & Spatz, 2007).

Cultural values—specifically, collectivism versus individualism (see Chapter 2)—strongly influence infant sleeping arrangements. In one study, researchers interviewed Guatemalan Mayan mothers and American middle-SES mothers about their sleeping practices. Mayan mothers stressed the importance of promoting an *interdependent self*, explaining that cosleeping builds a close parent–child bond, which is necessary for children to learn the ways of people around them. In contrast, American mothers emphasized an *independent self*, mentioning their desire to instill early autonomy, prevent bad habits, and protect their own privacy (Morelli et al., 1992).

Over the past two decades, cosleeping has increased in Western nations. An estimated 13 percent of U.S. infants routinely bedshare, and an additional 30 to 35 percent sometimes do (Buswell & Spatz, 2007; Willinger et al., 2003). Proponents of the practice say that it helps infants sleep, makes breastfeeding more convenient, and provides valuable bonding time (McKenna & Volpe, 2007).

During the night, cosleeping babies breastfeed three times longer than infants who sleep alone. Because infants arouse to nurse more often when sleeping next to their mothers, some researchers believe that cosleeping may actually help safeguard babies at risk for SIDS (see page 110 in Chapter 3). Consistent with this view, SIDS is rare in Asian cultures where cosleeping is widespread, including Cambodia, China, Japan, Korea, Thailand, and Vietnam (McKenna, 2002; McKenna & McDade, 2005). And contrary to popular belief, cosleeping does not reduce mothers' total sleep time, although they experience more brief awakenings, which permit them to check on their baby (Mao et al., 2004).

Infant sleeping practices affect other aspects of family life. For example, Mayan babies doze off in the midst of ongoing family activities and are carried to bed by their mothers. In contrast, for many American parents, bedtime often involves a lengthy, elaborate ritual. Perhaps bedtime struggles, so common in Western homes but rare elsewhere in the world, are related to the stress young children feel when they must fall asleep without assistance (Latz, Wolf, & Lozoff, 1999).

Critics warn that bedsharing will promote emotional problems, especially excessive dependency. Yet a study following children from the end of pregnancy through age 18 showed that young people who had bedshared in the early years were no different from others in any aspect of adjustment (Okami, Weisner, & Olmstead, 2002). Another

This Vietnamese mother and child sleep together—a practice common in their culture and around the globe. Hard wooden sleeping surfaces protect cosleeping children from entrapment in soft bedding.

concern is that infants might become trapped under the parent's body or in soft bedding and suffocate. Parents who are obese or who use alcohol, tobacco, or illegal drugs do pose a serious risk to their sleeping babies, as does the use of quilts and comforters or an overly soft mattress (American Academy of Pediatrics, 2012; Willinger et al., 2003).

But with appropriate precautions, parents and infants can cosleep safely (McKenna & Volpe, 2007). In cultures where cosleeping is widespread, parents and infants usually sleep with light covering on hard surfaces, such as firm mattresses, floor mats, and wooden planks, or infants sleep in a cradle or hammock next to the parents' bed (McKenna, 2001, 2002). And when sharing the same bed, infants typically lie on their back or side facing the mother—positions that promote frequent, easy communication between parent and baby and arousal if breathing is threatened.

Finally, breastfeeding mothers usually assume a distinctive sleeping posture: They face the infant, with knees drawn up under the baby's feet and arm above the baby's head. Besides facilitating feeding, the position prevents the infant from sliding down under covers or up under pillows (Ball, 2006). Because this posture is also seen in female great apes while sharing sleeping nests with their infants, researchers believe it may have evolved to enhance infant safety.

ASK YOURSELF

REVIEW How do overproduction of synapses and synaptic pruning support infants' and children's ability to learn?

CONNECT Explain how inappropriate stimulation—either too little or too much—can impair cognitive and emotional development in the early years.

APPLY Which infant enrichment program would you choose: one that emphasizes gentle talking and touching and social games, or one that includes reading and number drills and classical music lessons? Explain.

Influences on Early Physical Growth

Physical growth, like other aspects of development, results from a complex interplay between genetic and environmental factors. Heredity, nutrition, and emotional well-being all affect early physical growth.

Heredity

Because identical twins are much more alike in body size than fraternal twins, we know that heredity is important in physical growth (Estourgie-van Burk et al., 2006; Touwslager et al., 2011). When diet and health are adequate, height and rate of physical growth are largely influenced by heredity. In fact, as long as negative environmental influences such as poor nutrition and illness are not severe, children and adolescents typically show *catch-up growth*—a return to a genetically influenced growth path once conditions improve. Still, the brain, the heart, the digestive system, and many other internal organs may be permanently compromised (Hales & Ozanne, 2003). (Recall the consequences of inadequate prenatal nutrition for long-term health, discussed on page 92 in Chapter 3.)

Genetic makeup also affects body weight: The weights of adopted children correlate more strongly with those of their biological than of their adoptive parents (Kinnunen, Pietilainen, & Rissanen, 2006). At the same time, environment—in particular, nutrition—plays an especially important role.

Nutrition

Nutrition is especially crucial for development in the first two years because the baby's brain and body are growing so rapidly. Pound for pound, an infant's energy needs are twice those of an adult. Twenty-five percent of babies' total caloric intake is devoted to growth, and infants need extra calories to keep rapidly developing organs functioning properly (Meyer, 2009).

Breastfeeding versus Bottle-Feeding. Babies need not only enough food but also the right kind of food. In early infancy, breastfeeding is ideally suited to their needs, and bottled formulas try to imitate it. Applying What We Know on the following page summarizes major nutritional and health advantages of breastfeeding.

Because of these benefits, breastfed babies in poverty-stricken regions are much less likely to be malnourished and 6 to 14 times more likely to survive the first year of life. The World Health Organization recommends breastfeeding until age 2 years, with solid foods added at 6 months. These practices, if widely followed, would save the lives of more than a million infants annually (World Health Organization, 2012b). Even breastfeeding for just a few weeks offers some protection against respiratory and intestinal infections, which are devastating to young children in developing countries. Also, because a nursing mother is less likely to get pregnant, breastfeeding helps increase spacing between siblings, a major factor in reducing infant and childhood deaths in nations with widespread poverty. (Note, however, that breastfeeding is not a reliable method of birth control.)

Yet many mothers in the developing world do not know about these benefits. In Africa, the Middle East, and Latin America, most babies get some breastfeeding, but fewer than 40 percent are exclusively breastfed for the first six months, and one-third are fully weaned from the breast before 1 year (UNICEF, 2009). In place of breast milk, mothers give their babies commercial formula or low-grade nutrients, such as rice water or highly diluted cow or goat milk. Contamination of these foods as a result of poor sanitation is common and often leads to illness and infant death. The United Nations has encouraged all hospitals and maternity units in developing countries to promote breastfeeding as long as mothers do not have viral or bacterial infections (such as HIV or tuberculosis) that can be

Midwives in India support a mother as she learns to breastfeed her infant. Breastfeeding is especially important in developing countries, where it helps protect babies against life-threatening infections and early death.

Applying What We Know

Reasons to Breastfeed

Nutritional and Health Advantages	Explanation
Provides the correct balance of fat and protein	Compared with the milk of other mammals, human milk is higher in fat and lower in protein. This balance, as well as the unique proteins and fats contained in human milk, is ideal for a rapidly myelinating nervous system.
Ensures nutritional completeness	A mother who breastfeeds need not add other foods to her infant's diet until the baby is 6 months old. The milks of all mammals are low in iron, but the iron contained in breast milk is much more easily absorbed by the baby's system. Consequently, bottle-fed infants need iron-fortified formula.
Helps ensure healthy physical growth	One-year-old breastfed babies are leaner (have a higher percentage of muscle to fat), a growth pattern that persists through the preschool years and that may help prevent later overweight and obesity.
Protects against many diseases	Breastfeeding transfers antibodies and other infection-fighting agents from mother to child and enhances functioning of the immune system. Compared with bottle-fed infants, breastfed babies have far fewer allergic reactions and respiratory and intestinal illnesses. Breast milk also has anti-inflammatory effects, which reduce the severity of illness symptoms. Breastfeeding in the first four months is linked to lower blood cholesterol levels in adulthood and, thereby, may help prevent cardiovascular disease.
Protects against faulty jaw development and tooth decay	Sucking the mother's nipple instead of an artificial nipple helps avoid malocclusion, a condition in which the upper and lower jaws do not meet properly. It also protects against tooth decay due to sweet liquid remaining in the mouths of infants who fall asleep while sucking on a bottle.
Ensures digestibility	Because breastfed babies have a different kind of bacteria growing in their intestines than do bottle-fed infants, they rarely suffer from constipation or other gastrointestinal problems.
Smooths the transition to solid foods	Breastfed infants accept new solid foods more easily than bottle-fed infants, perhaps because of their greater experience with a variety of flavors, which pass from the maternal diet into the mother's milk.

transmitted to the baby. Today, most developing countries have banned the practice of giving free or subsidized formula to new mothers.

Partly as a result of the natural childbirth movement, breastfeeding has become more common in industrialized nations, especially among well-educated women. Today, 74 percent of American mothers breastfeed, but more than half stop by 6 months (Centers for Disease Control and Prevention, 2011a). Not surprisingly, mothers who return to work sooner wean their babies from the breast earlier (Kimbrow, 2006). But mothers who cannot be with their infants all the time can still combine breast- and bottle-feeding. The U.S. Department of Health and Human Services (2010a) advises exclusive breastfeeding for the first 6 months and inclusion of breast milk in the baby's diet until at least 1 year.

Women who do not breastfeed sometimes worry that they are depriving their baby of an experience essential for healthy psychological development. Yet breastfed and bottle-fed infants in industrialized nations do not differ in quality of the mother-infant relationship or in later emotional adjustment (Fergusson & Woodward, 1999; Jansen, de Weerth, & Riksen-Walraven, 2008). Some studies report a slight advantage in intelligence test performance for children and adolescents who were breastfed, after controlling for many factors. Most, however, find no cognitive benefits (Der, Batty, & Deary, 2006).

Are Chubby Babies at Risk for Later Overweight and Obesity? From early infancy, Timmy was an enthusiastic eater who nursed vigorously and gained weight quickly. By 5 months, he began reaching for food on his mother's plate. Vanessa wondered: Was she overfeeding Timmy and increasing his chances of becoming overweight?

Most chubby babies thin out during toddlerhood and early childhood, as weight gain slows and they become more active. Infants and toddlers can eat nutritious foods freely without risk of becoming overweight. But recent evidence does indicate a strengthening relationship between rapid weight gain in infancy and later obesity (Botton et al., 2008; Chomtho et al., 2008). The trend may be due to the rise in overweight and obesity among adults, who promote unhealthy eating habits in their young children. Interviews with 1,500 U.S. parents of 4- to 24-month-olds revealed that many routinely served older infants and toddlers french fries, pizza, candy, sugary fruit drinks, and soda. On average, infants consumed 20 percent and toddlers 30 percent more calories than they needed. At the same time, as many as one-fourth ate no fruits and one-third no vegetables (Siega-Riz et al., 2010).

How can concerned parents prevent their infants from becoming overweight children and adults? One way is to breastfeed for the first six months, which is associated with slower early weight gain (Gunnarsdottir et al., 2010). Another is to avoid giving them foods loaded with sugar, salt, and saturated

fats. Once toddlers learn to walk, climb, and run, parents can also provide plenty of opportunities for energetic play. Finally, because research shows a correlation between excessive television viewing and overweight in older children, parents should limit the time very young children spend in front of the TV.

Malnutrition

Osita is an Ethiopian 2-year-old whose mother has never had to worry about his gaining too much weight. When she weaned him at 1 year, there was little for him to eat besides starchy rice-flour cakes. Soon his belly enlarged, his feet swelled, his hair fell out, and a rash appeared on his skin. His bright-eyed curiosity vanished, and he became irritable and listless.

In developing countries and war-torn areas where food resources are limited, malnutrition is widespread. Recent evidence indicates that about 27 percent of the world's children suffer from malnutrition before age 5 (World Health Organization, 2010). The 10 percent who are severely affected suffer from two dietary diseases.

Marasmus is a wasted condition of the body caused by a diet low in all essential nutrients. It usually appears in the first year of life when a baby's mother is too malnourished to produce enough breast milk and bottle-feeding is also inadequate. Her starving baby becomes painfully thin and is in danger of dying.

Osita has **kwashiorkor**, caused by an unbalanced diet very low in protein. The disease usually strikes after weaning, between 1 and 3 years of age. It is common in regions where children get just enough calories from starchy foods but little protein. The child's body responds by breaking down its own protein reserves, which causes the swelling and other symptoms that Osita experienced.

Children who survive these extreme forms of malnutrition grow to be smaller in all body dimensions and suffer from lasting damage to the brain, heart, liver, or other organs (Müller & Krawinkel, 2005). When their diets do improve, they tend to gain excessive weight (Uauy et al., 2008). A malnourished body protects itself by establishing a low basal metabolism rate, which may endure after nutrition improves. Also, malnutrition may disrupt appetite control centers in the brain, causing the child to overeat when food becomes plentiful.

Learning and behavior are also seriously affected. In one long-term study of marasmic children, an improved diet led to some catch-up growth in height, but not in head size (Stoch et al., 1982). The malnutrition probably interfered with growth of neural fibers and myelination, causing a permanent loss in brain weight. And animal evidence reveals that a deficient diet alters the production of neurotransmitters in the brain—an effect that can disrupt all aspects of development (Haller, 2005). These children score low on intelligence tests, show poor fine-motor coordination, and have difficulty paying attention (Galler et al., 1990; Liu et al., 2003). They also display a more intense stress response to fear-arousing situations, perhaps caused by the constant, gnawing pain of hunger (Fernald & Grantham-McGregor, 1998).

Inadequate nutrition is not confined to developing countries. Because government-supported supplementary food programs do not reach all families in need, an estimated 21 percent of U.S. children suffer from *food insecurity*—uncertain access to enough food for a healthy, active life. Food insecurity is especially high among single-parent families (35 percent) and low-income ethnic minority families—for example, Hispanics and African Americans (25 and 27 percent, respectively) (U.S. Department of Agriculture, 2011a). Although few of these children have marasmus or kwashiorkor, their physical growth and ability to learn are still affected.

Left photo: This baby of Niger, Africa, has marasmus, a wasted condition caused by a diet low in all essential nutrients. *Right photo:* The swollen abdomen of this toddler, also of Niger, is a symptom of kwashiorkor, which results from a diet very low in protein. If these children survive, they are likely to be growth stunted and to suffer from lasting organ damage and serious cognitive and emotional impairments.

ASK YOURSELF

REVIEW Explain why breastfeeding can have lifelong consequences for the development of babies born in poverty-stricken regions of the world.

CONNECT How are bidirectional influences between parent and child involved in the impact of malnutrition on psychological development?

APPLY Eight-month-old Shaun is well below average in height and painfully thin. What serious growth disorder does he likely have, and what type of intervention, in addition to dietary enrichment, will help restore his development? (Hint: See page 92 in Chapter 3.)

REFLECT Imagine that you are the parent of a newborn baby. Describe feeding practices you would use, and ones you would avoid, to prevent overweight and obesity.

capable of two basic forms of learning, which were introduced in Chapter 1: classical and operant conditioning. They also learn through their natural preference for novel stimulation. Finally, shortly after birth, babies learn by observing others; they can imitate the facial expressions and gestures of adults.

Classical Conditioning

Newborn reflexes, discussed in Chapter 3, make **classical conditioning** possible in the young infant. In this form of learning, a neutral stimulus is paired with a stimulus that leads to a reflexive response. Once the baby's nervous system makes the connection between the two stimuli, the neutral stimulus produces the behavior by itself. Classical conditioning helps infants recognize which events usually occur together in the everyday world, so they can anticipate what is about to happen next. As a result, the environment becomes more orderly and predictable. Let's take a closer look at the steps of classical conditioning.

As Carolyn settled down in the rocking chair to nurse Caitlin, she often stroked Caitlin's forehead. Soon Carolyn noticed that each time she did this, Caitlin made sucking movements. Caitlin had been classically conditioned. Figure 4.7 shows how it happened:

1. Before learning takes place, an **unconditioned stimulus (UCS)** must consistently produce a reflexive, or **unconditioned, response (UCR)**. In Caitlin's case, sweet breast milk (UCS) resulted in sucking (UCR).

Learning Capacities

Learning refers to changes in behavior as the result of experience. Babies come into the world with built-in learning capacities that permit them to profit from experience immediately. Infants are

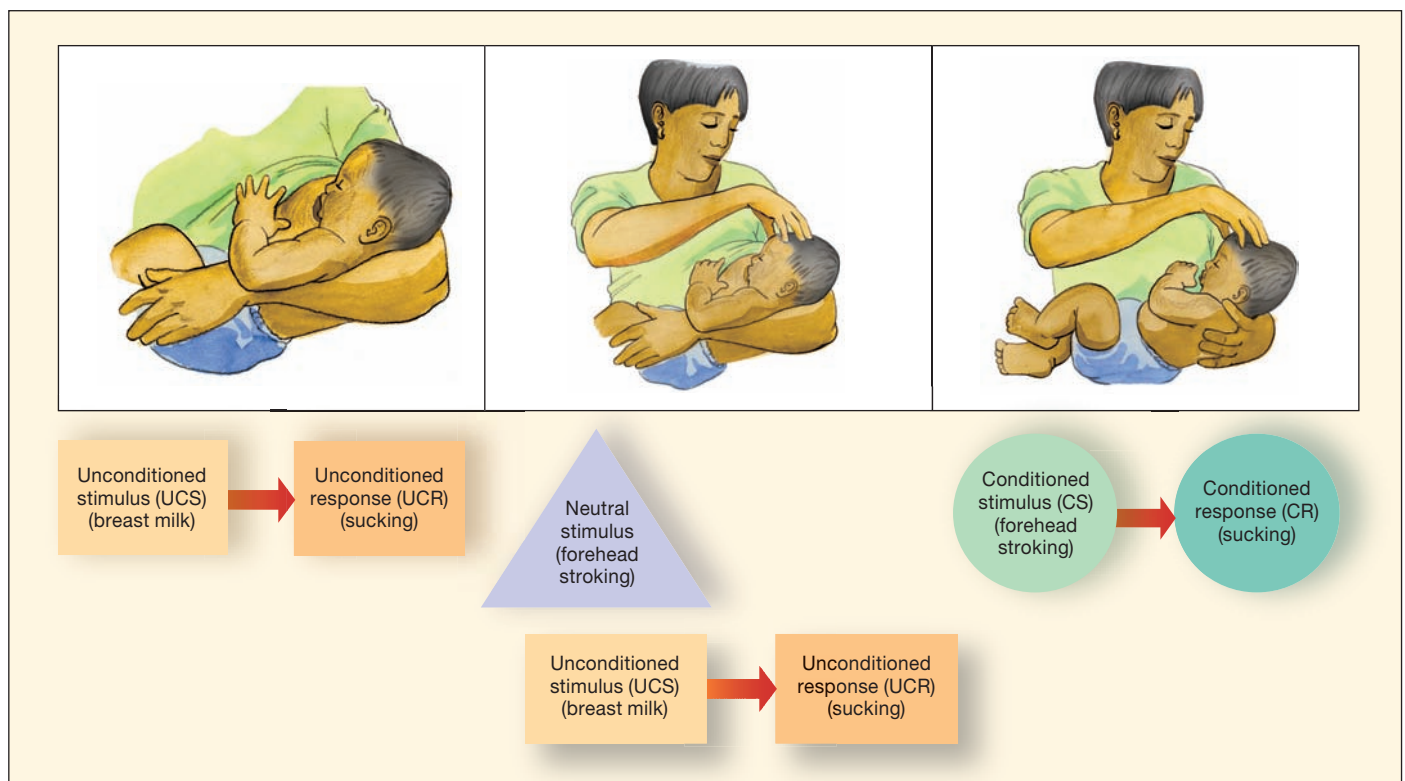

FIGURE 4.7 The steps of classical conditioning. This example shows how a mother classically conditioned her baby to make sucking movements by stroking the baby's forehead at the beginning of feedings.

2. To produce learning, a *neutral stimulus* that does not lead to the reflex is presented just before, or at about the same time as, the UCS. Carolyn stroked Caitlin's forehead as each nursing period began. The stroking (neutral stimulus) was paired with the taste of milk (UCS).
3. If learning has occurred, the neutral stimulus by itself produces a response similar to the reflexive response. The neutral stimulus is then called a **conditioned stimulus (CS)**, and the response it elicits is called a **conditioned response (CR)**. We know that Caitlin has been classically conditioned because stroking her forehead outside the feeding situation (CS) results in sucking (CR).

If the CS is presented alone enough times, without being paired with the UCS, the CR will no longer occur, an outcome called *extinction*. In other words, if Carolyn repeatedly strokes Caitlin's forehead without feeding her, Caitlin will gradually stop sucking in response to stroking.

Young infants can be classically conditioned most easily when the association between two stimuli has survival value. In the example just described, learning which stimuli regularly accompany feeding improves the infant's ability to get food and survive (Blass, Ganchrow, & Steiner, 1984).

In contrast, some responses, such as fear, are very difficult to classically condition in young babies. Until infants have the motor skills to escape unpleasant events, they have no biological need to form these associations. After age 6 months, however, fear is easy to condition. In Chapter 6, we will discuss the development of fear and other emotional reactions.

Operant Conditioning

In classical conditioning, babies build expectations about stimulus events in the environment, but their behavior does not influence the stimuli that occur. In **operant conditioning**, infants act, or *operate*, on the environment, and stimuli that follow their behavior change the probability that the behavior will occur again. A stimulus that increases the occurrence of a response is called a **reinforcer**. For example, sweet liquid *reinforces* the sucking response in newborns. Removing a desirable stimulus or presenting an unpleasant one to decrease the occurrence of a response is called **punishment**. A sour-tasting fluid *punishes* newborns' sucking response, causing them to purse their lips and stop sucking entirely.

Many stimuli besides food can serve as reinforcers of infant behavior. For example, newborns will suck faster on a nipple when their rate of sucking produces interesting sights and sounds, including visual designs, music, or human voices (Floccia, Christophe, & Bertoncini, 1997). As these findings suggest, operant conditioning is a powerful tool for finding out what stimuli babies can perceive and which ones they prefer.

As infants get older, operant conditioning includes a wider range of responses and stimuli. For example, researchers have hung mobiles over the cribs of 2- to 6-month-olds. When the baby's foot is attached to the mobile with a long cord, the infant

can, by kicking, make the mobile turn. Under these conditions, it takes only a few minutes for infants to start kicking vigorously (Rovee-Collier, 1999; Rovee-Collier & Barr, 2001). As you will see in Chapter 5, operant conditioning with mobiles is frequently used to study infants' memory and their ability to group similar stimuli into categories. Once babies learn the kicking response, researchers see how long and under what conditions they retain it when exposed again to the original mobile or to mobiles with varying features.

Operant conditioning also plays a vital role in the formation of social relationships. As the baby gazes into the adult's eyes, the adult looks and smiles back, and then the infant looks and smiles again. As the behavior of each partner reinforces the other, both continue their pleasurable interaction. In Chapter 6, we will see that this contingent responsiveness contributes to the development of infant–caregiver attachment.

Habituation

At birth, the human brain is set up to be attracted to novelty. Infants tend to respond more strongly to a new element that has entered their environment, an inclination that ensures that they will continually add to their knowledge base. **Habituation** refers to a gradual reduction in the strength of a response due to repetitive stimulation. Looking, heart rate, and respiration rate may all decline, indicating a loss of interest. Once this has occurred, a new stimulus—a change in the environment—causes responsiveness to return to a high level, an increase called **recovery**. For example, when you walk through a familiar space, you notice things that are new and different—a recently hung picture on the wall or a piece of furniture that has been moved. Habituation and recovery make learning more efficient by focusing our attention on those aspects of the environment we know least about.

Researchers investigating infants' understanding of the world rely on habituation and recovery more than any other learning capacity. For example, a baby who first *habituates* to a visual pattern (a photo of a baby) and then *recovers* to a new one (a photo of a bald man) appears to remember the first stimulus and perceive the second one as new and different from it. This method of studying infant perception and cognition, illustrated in Figure 4.8, can be used with newborns, including preterm infants (Kavšek & Bornstein, 2010). It has even been used to study the fetus's sensitivity to external stimuli—for example, by measuring changes in fetal heart rate when various repeated sounds are presented (see page 85 in Chapter 3).

Recovery to a new stimulus, or novelty preference, assesses infants' *recent memory*. **TAKE A MOMENT...** Think about what happens when you return to a place you have not seen for a long time. Instead of attending to novelty, you are likely to focus on aspects that are familiar: "I recognize that—I've been here before!" Like adults, infants shift from a novelty preference to a familiarity preference as more time intervenes between habituation and test phases in research. That is, babies recover to the familiar stimulus rather than to a novel stimulus (see Figure 4.8)

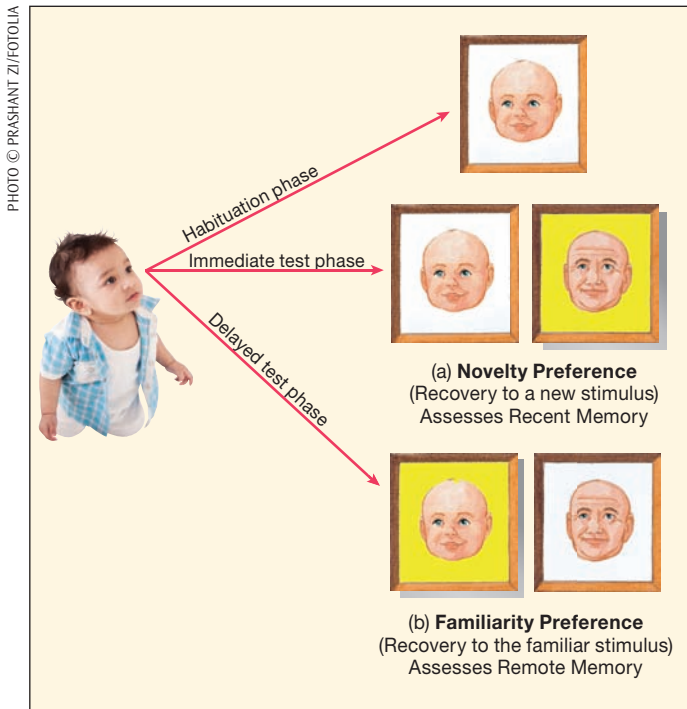

FIGURE 4.8 Using habituation to study infant perception and cognition. In the habituation phase, infants view a photo of a baby until their looking declines. In the test phase, infants are again shown the baby photo, but this time it appears alongside a photo of a bald-headed man. (a) When the test phase occurs soon after the habituation phase (within minutes, hours, or days, depending on the age of the infants), participants who remember the baby face and distinguish it from the man's face show a *novelty preference*; they recover to (spend more time looking at) the new stimulus. (b) When the test phase is delayed for weeks or months, infants who continue to remember the baby face shift to a *familiarity preference*; they recover to the familiar baby face rather than to the novel man's face.

(Bahrick, Hernandez-Reif, & Pickens, 1997; Courage & Howe, 1998; Flom & Bahrick, 2010; Richmond, Colombo, & Hayne, 2007). By focusing on that shift, researchers can also use habituation to assess *remote memory*, or memory for stimuli to which infants were exposed weeks or months earlier.

As Chapter 5 will reveal, habituation research has greatly enriched our understanding of how long babies remember a wide range of stimuli. And by varying stimulus features, researchers can use habituation and recovery to study babies' ability to categorize stimuli as well.

Imitation

Babies come into the world with a primitive ability to learn through **imitation**—by copying the behavior of another person. For example, Figure 4.9 shows a human newborn imitating two adult facial expressions (Meltzoff & Moore, 1977). The newborn's capacity to imitate extends to certain gestures, such as head and index-finger movements, and has been demonstrated in many ethnic groups and cultures (Meltzoff & Kuhl,

1994; Nagy et al., 2005). As the figure illustrates, even newborn primates, including chimpanzees (our closest evolutionary relatives), imitate some behaviors (Ferrari et al., 2006; Myowa-Yamakoshi et al., 2004).

Although newborns' capacity to imitate is widely accepted, a few studies have failed to reproduce the human findings (see, for example, Anisfeld et al., 2001). And because newborn mouth and tongue movements occur with increased frequency to almost any arousing change in stimulation (such as lively music or flashing lights), some researchers argue that certain newborn "imitative" responses are actually mouthing—a common early

FIGURE 4.9 Imitation by human and chimpanzee newborns. The human infants in the middle row imitating (left) tongue protrusion and (right) mouth opening are 2 to 3 weeks old. The chimpanzee imitating both facial expressions is 2 weeks old. (From A. N. Meltzoff & M. K. Moore, 1977, "Imitation of Facial and Manual Gestures by Human Neonates," *Science*, 198, p. 75. Copyright © 1977 by AAAS. Reprinted with permission of the AAAS and A. N. Meltzoff. And from M. Myowa-Yamakoshi et al., 2004, "Imitation in Neonatal Chimpanzees [*Pan Troglodytes*]." *Developmental Science*, 7, p. 440. Copyright 2004 by Blackwell Publishing. Reproduced with permission of John Wiley & Sons Ltd.)

exploratory response to interesting stimuli (Jones, 2009). Furthermore, imitation is harder to induce in babies 2 to 3 months old than just after birth. Therefore, skeptics believe that the newborn imitative capacity is little more than an automatic response that declines with age, much like a reflex (Heyes, 2005).

Others claim that newborns—both primates and humans—imitate a variety of facial expressions and head movements with effort and determination, even after short delays—when the adult is no longer demonstrating the behavior (Meltzoff & Moore, 1999; Paukner, Ferrari, & Suomi, 2011). Furthermore, these investigators argue that imitation—unlike reflexes—does not decline. Human babies several months old often do not imitate an adult's behavior right away because they first try to play familiar social games—mutual gazing, cooing, smiling, and waving their arms. But when an adult models a gesture repeatedly, older human infants soon get down to business and imitate (Meltzoff & Moore, 1994). Similarly, imitation declines in baby chimps around 9 weeks of age, when mother–baby mutual gazing and other face-to-face exchanges increase.

According to Andrew Meltzoff, newborns imitate much as older children and adults do—by actively trying to match body movements they *see* with ones they *feel* themselves make (Meltzoff, 2007). Later we will encounter evidence that young infants are remarkably adept at coordinating information across sensory systems.

Indeed, scientists have identified specialized cells in motor areas of the cerebral cortex in primates—called **mirror neurons**—that underlie these capacities (Ferrari & Coudé, 2011). Mirror neurons fire identically when a primate hears or sees an action and when it carries out that action on its own (Rizzolatti & Craighero, 2004). Human adults have especially elaborate systems of mirror neurons, which enable us to observe another's behavior (such as smiling or throwing a ball) while simulating the behavior in our own brain. Mirror neurons are believed to be the biological basis of a variety of interrelated, complex social abilities, including imitation, empathic sharing of emotions, and understanding others' intentions (Iacoboni, 2009; Schulte-Ruther et al., 2007).

Brain-imaging findings support a functioning mirror-neuron system as early as 6 months of age. Using NIRS, researchers found that the same motor areas of the cerebral cortex were activated in 6-month-olds and in adults when they observed a model engage in a behavior that could be imitated (tapping a box to make a toy pop out) as when they themselves engaged in the motor action (Shimada & Hiraki, 2006). In contrast, when infants and adults observed an object that appeared to move on its own, without human intervention (a ball hanging from the ceiling on a string, swinging like a pendulum), motor areas were not activated.

Still, Meltzoff's view of newborn imitation as a flexible, voluntary capacity remains controversial. Mirror neurons, though possibly functional at birth, undergo an extended period of development (Bertenthal & Longo, 2007; Lepage & Théoret, 2007). Similarly, as we will see in Chapter 5, the capacity to imitate expands greatly over the first two years. But however limited

it is at birth, imitation is a powerful means of learning. Using imitation, infants explore their social world, not only learning from other people but getting to know them by matching their behavioral states. As babies notice similarities between their own actions and those of others, they experience other people as “like me” and, thus, learn about themselves (Meltzoff, 2007). In this way, infant imitation may serve as the foundation for understanding others' thoughts and feelings, which we take up in Chapter 6. Finally, caregivers take great pleasure in a baby who imitates their facial gestures and actions, which helps get the infant's relationship with parents off to a good start.

ASK YOURSELF

REVIEW Provide an example of classical conditioning, of operant conditioning, and of habituation/recovery in young infants. Why is each type of learning useful?

CONNECT Which learning capacities contribute to an infant's first social relationships? Explain, providing examples.

APPLY Nine-month-old Byron has a toy with large, colored push buttons on it. Each time he pushes a button, he hears a nursery tune. Which learning capacity is the manufacturer of this toy taking advantage of? What can Byron's play with the toy reveal about his perception of sound patterns?

Motor Development

Carolyn, Monica, and Vanessa each kept a baby book, filled with proud notations about when their children first held up their heads, reached for objects, sat by themselves, and walked alone. Parents are understandably excited about these new motor skills, which allow babies to master their bodies and the environment in new ways. For example, sitting upright gives infants a new perspective on the world. Reaching permits babies to find out about objects by acting on them. And when infants can move on their own, their opportunities for exploration multiply.

Babies' motor achievements have a powerful effect on their social relationships. When Caitlin crawled at 7½ months, Carolyn and David began to restrict her movements by saying no and expressing mild impatience. When she walked three days after her first birthday, the first “testing of wills” occurred (Biringen et al., 1995). Despite her mother's warnings, she sometimes pulled items from shelves that were off limits. “I said, ‘Don't do that!’” Carolyn would say firmly, taking Caitlin's hand and redirecting her attention.

At the same time, newly walking babies more actively attend to and initiate social interaction (Clearfield, Osborn, & Mullen, 2008; Karasik et al., 2011). Caitlin frequently toddled over to her parents to express a greeting, give a hug, or show them objects of interest. Carolyn and David, in turn, increased

their expressions of affection and playful activities. And when Caitlin encountered risky situations, such as a sloping walkway or a dangerous object, Carolyn and David intervened, combining emotional warnings with rich verbal and gestural information that helped Caitlin notice critical features of her surroundings, regulate her motor actions, and acquire language (Campos et al., 2000; Karasik et al., 2008). Caitlin's delight as she worked on new motor skills triggered pleasurable reactions in others, which encouraged her efforts further. Motor, social, cognitive, and language competencies developed together and supported one another.

The Sequence of Motor Development

Gross-motor development refers to control over actions that help infants get around in the environment, such as crawling, standing, and walking. *Fine-motor development* has to do with smaller movements, such as reaching and grasping. Table 4.2 shows the average age at which U.S. infants and toddlers achieve a variety of gross- and fine-motor skills. It also presents the age ranges during which most babies accomplish each skill, indicating large individual differences in *rate* of motor progress. Also, a baby

who is a late reacher will not necessarily be a late crawler or walker. We would be concerned about a child's development only if many motor skills were seriously delayed.

Historically, researchers assumed that motor skills were separate, innate abilities that emerged in a fixed sequence governed by a built-in maturational timetable. This view has long been discredited. Rather, motor skills are interrelated. Each is a product of earlier motor attainments and a contributor to new ones. And children acquire motor skills in highly individual ways. For example, before her adoption, Grace spent most of her days lying in a hammock. Because she was rarely placed on her tummy and on firm surfaces that enabled her to move on her own, she did not try to crawl. As a result, she pulled to a stand and walked before she crawled! Babies display such skills as rolling, sitting, crawling, and walking in diverse orders rather than in the sequence implied by motor norms (Adolph, Karasik, & Tamis-LeMonda, 2010).

Motor Skills as Dynamic Systems

According to **dynamic systems theory of motor development**, mastery of motor skills involves acquiring increasingly complex

TABLE 4.2 Gross- and Fine-Motor Development in the First Two Years

MOTOR SKILL	AVERAGE AGE ACHIEVED	AGE RANGE IN WHICH 90 PERCENT OF INFANTS ACHIEVE THE SKILL
When held upright, holds head erect and steady	6 weeks	3 weeks–4 months
When prone, lifts self by arms	2 months	3 weeks–4 months
Rolls from side to back	2 months	3 weeks–5 months
Grasps cube	3 months, 3 weeks	2–7 months
Rolls from back to side	4½ months	2–7 months
Sits alone	7 months	5–9 months
Crawls	7 months	5–11 months
Pulls to stand	8 months	5–12 months
Plays pat-a-cake	9 months, 3 weeks	7–15 months
Stands alone	11 months	9–16 months
Walks alone	11 months, 3 weeks	9–17 months
Builds tower of two cubes	11 months, 3 weeks	10–19 months
Scribbles vigorously	14 months	10–21 months
Walks up stairs with help	16 months	12–23 months
Jumps in place	23 months, 2 weeks	17–30 months
Walks on tiptoe	25 months	16–30 months

Note: These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

systems of action. When motor skills work as a system, separate abilities blend together, each cooperating with others to produce more effective ways of exploring and controlling the environment. For example, control of the head and upper chest combine into sitting with support. Kicking, rocking on all fours, and reaching combine to become crawling. Then crawling, standing, and stepping are united into walking (Adolph & Berger, 2006; Thelen & Smith, 1998).

Each new skill is a joint product of four factors: (1) central nervous system development, (2) the body's movement capacities, (3) the goals the child has in mind, and (4) environmental supports for the skill. Change in any element makes the system less stable, and the child starts to explore and select new, more effective motor patterns.

The broader physical environment also profoundly influences motor skills. Infants with stairs in their home learn to crawl up stairs at an earlier age and also more readily master a back-descent strategy—the safest but also the most challenging position because the baby must turn around at the top, give up visual guidance of her goal, and crawl backward (Berger, Theuring, & Adolph, 2007). And if children were reared on the moon, with its reduced gravity, they would prefer jumping to walking or running!

LOOK AND LISTEN

Spend an hour observing a newly crawling or walking baby. Note the goals that motivate the baby to move, along with the baby's effort and motor experimentation. Describe parenting behaviors and features of the environment that promote mastery of the skill. ●

When a skill is first acquired, infants must refine it. For example, in trying to crawl, Caitlin often collapsed on her tummy and moved backward. Soon she figured out how to propel herself forward by alternately pulling with her arms and pushing with her feet, “belly-crawling” in various ways for several weeks (Vereijken & Adolph, 1999). As babies attempt a new skill, related, previously mastered skills often become less secure. As the novice walker experiments with balancing the body vertically over two small moving feet, balance during sitting may become temporarily less stable (Chen et al., 2007). In learning to walk, toddlers practice six or more hours a day, traveling the length of 29 football fields! Gradually their small, unsteady steps change to a longer stride, their feet move closer together, their toes point to the front, and their legs become symmetrically coordinated (Adolph, Vereijken, & Shrout, 2003). As movements are repeated thousands of times, they promote new synaptic connections in the brain that govern motor patterns.

Dynamic systems theory shows us why motor development cannot be genetically determined. Because it is motivated by exploration and the desire to master new tasks, heredity can map it out only at a general level. Rather than being *hardwired* into the nervous system, behaviors are *softly assembled*, allowing for different paths to the same motor skill (Adolph, 2008; Thelen & Smith, 2006).

© DEXTER GORMLEY/COURTESY OF COLE CALLOWAY, PH.D.

FIGURE 4.10 Reaching “feet first.” When sounding toys were held in front of babies’ hands and feet, they reached with their feet as early as 8 weeks of age, a month or more before they reached with their hands. This 2½-month-old skillfully explores an object with her foot.

Dynamic Motor Systems in Action. To find out how babies acquire motor capacities, some studies have tracked their first attempts at a skill until it became smooth and effortless. In one investigation, researchers held sounding toys alternately in front of infants’ hands and feet, from the time they showed interest until they engaged in well-coordinated reaching and grasping (Galloway & Thelen, 2004). As Figure 4.10 shows, the infants violated the normative sequence of arm and hand control preceding leg and foot control, shown in Table 4.2. They first reached for the toys with their feet—as early as 8 weeks of age, at least a month before reaching with their hands!

Why did babies reach “feet first”? Because the hip joint constrains the legs to move less freely than the shoulder constrains the arms, infants could more easily control their leg movements. When they first tried reaching with their hands, their arms actually moved *away* from the object! Consequently, foot reaching required far less practice than hand reaching. As these findings confirm, rather than following a strict, pre-determined pattern, the order in which motor skills develop depends on the anatomy of the body part being used, the surrounding environment, and the baby’s efforts.

Cultural Variations in Motor Development. Cross-cultural research further illustrates how early movement opportunities and a stimulating environment contribute to motor development. Over half a century ago, Wayne Dennis (1960) observed infants in Iranian orphanages who were deprived of the tantalizing surroundings that induce infants to acquire motor skills. These babies spent their days lying on their backs in cribs, without toys to play with. As a result, most did not move on their own until after 2 years of age. When they finally did

move, the constant experience of lying on their backs led them to scoot in a sitting position rather than crawl on their hands and knees. Because babies who scoot come up against furniture with their feet, not their hands, they are far less likely to pull themselves to a standing position in preparation for walking. Indeed, by 3 to 4 years of age, only 15 percent of the Iranian orphans were walking alone.

Cultural variations in infant-rearing practices affect motor development. **TAKE A MOMENT...** Take a quick survey of several parents you know: Should sitting, crawling, and walking be deliberately encouraged? Answers vary widely from culture to culture. Japanese mothers, for example, believe such efforts are unnecessary (Seymour, 1999). Among the Zinacanteco Indians of southern Mexico and the Gusii of Kenya, rapid motor progress is actively discouraged. Babies who walk before they know enough to keep away from cooking fires and weaving looms are viewed as dangerous to themselves and disruptive to others (Greenfield, 1992).

In contrast, among the Kipsigis of Kenya and the West Indians of Jamaica, babies hold their heads up, sit alone, and walk considerably earlier than North American infants. In both societies, parents emphasize early motor maturity, practicing formal exercises to stimulate particular skills (Adolph, Karasik, & Tamis-LeMonda, 2010). In the first few months, babies are seated in holes dug in the ground, with rolled blankets to keep them upright. Walking is promoted by frequently standing babies in adults' laps, bouncing them on their feet, and exercising the stepping reflex (Hopkins & Westra, 1988; Super, 1981). As parents in these cultures support babies in upright postures and rarely put them down on the floor, their infants usually skip crawling—a motor skill regarded as crucial in Western nations!

Finally, because it decreases exposure to “tummy time,” the current Western practice of having babies sleep on their backs to protect them from SIDS (see page 110 in Chapter 3) delays gross motor milestones of rolling, sitting, and crawling

This West Indian mother of Jamaica “walks” her baby up her body in a deliberate effort to promote early mastery of walking.

(Majnemer & Barr, 2005; Scrutton, 2005). Regularly exposing infants to the tummy-lying position during waking hours prevents these delays.

Fine-Motor Development: Reaching and Grasping

Of all motor skills, reaching may play the greatest role in infant cognitive development. By grasping things, turning them over, and seeing what happens when they are released, infants learn a great deal about the sights, sounds, and feel of objects.

Reaching and grasping, like many other motor skills, start out as gross, diffuse activity and move toward mastery of fine movements. Figure 4.11 illustrates some milestones of reaching

FIGURE 4.11 Some milestones of reaching and grasping. The average age at which each skill is attained is given. (Ages from Bayley, 1969; Rochat, 1989.)

over the first nine months. Newborns make poorly coordinated swipes or swings, called *prereaching*, toward an object in front of them, but because of poor arm and hand control they rarely contact the object. Like newborn reflexes, prereaching drops out around 7 weeks of age. Yet these early behaviors suggest that babies are biologically prepared to coordinate hand with eye in the act of exploring (Rosander & von Hofsten, 2002; von Hofsten, 2004).

At about 3 to 4 months, as infants develop the necessary eye, head, and shoulder control, reaching reappears as purposeful, forward arm movements in the presence of a nearby toy and gradually improves in accuracy (Bhat, Heathcock, & Galloway, 2005; Spencer et al., 2000). By 5 to 6 months, infants reach for an object in a room that has been darkened during the reach by switching off the lights—a skill that improves over the next few months (Clifton et al., 1994; McCarty & Ashmead, 1999). Early on, vision is freed from the basic act of reaching so it can focus on more complex adjustments. By 7 months, the arms become more independent; infants reach for an object by extending one arm rather than both (Fagard & Pezé, 1997). During the next few months, infants become more efficient at reaching for moving objects—ones that spin, change direction, and move sideways, closer, or farther away (Fagard, Spelke, & von Hofsten, 2009; Wentworth, Benson, & Haith, 2000).

Once infants can reach, they modify their grasp. The newborn's grasp reflex is replaced by the *ulnar grasp*, a clumsy motion in which the fingers close against the palm. Still, even 4-month-olds adjust their grasp to the size and shape of an object—a capacity that improves over the first year as infants orient the hand more precisely and do so in advance of contacting the object (Barrett, Traupman, & Needham, 2008; Witherington, 2005). Around 4 to 5 months, when infants begin to sit up, both hands become coordinated in exploring objects. Babies of this age can hold an object in one hand while the other scans it with the fingertips, and they frequently transfer objects from hand to hand (Rochat & Goubet, 1995). By the end of the first year, infants use the thumb and index finger opposably in a well-coordinated *pincer grasp*. Then the ability to manipulate objects greatly expands. The 1-year-old can pick up raisins and blades of grass, turn knobs, and open and close small boxes.

Between 8 and 11 months, reaching and grasping are well-practiced, so attention is released from the motor skill to events that occur before and after attaining the object. For example, 10-month-olds easily adjust their reach to anticipate their next action. They reach for a ball faster when they intend to throw it than when they intend to drop it carefully through a narrow tube (Claxton, Keen, & McCarty, 2003). Around this time, too, infants begin to solve simple problems that involve reaching, such as searching for and finding a hidden toy.

Finally, the capacity to reach for and manipulate an object increases infants' attention to the way an adult reaches for and plays with that same object (Hauf, Aschersleben, & Prinz, 2007). As babies watch what others do, they broaden their understanding of others' behaviors and of the range of actions that can be performed on various objects.

ASK YOURSELF

REVIEW Cite evidence that motor development is a joint product of biological, psychological, and environmental factors.

CONNECT Provide several examples of how motor development influences infants' attainment of cognitive and social competencies.

APPLY List everyday experiences that support mastery of reaching, grasping, sitting, and crawling. Why should caregivers place young infants in a variety of waking-time body positions?

REFLECT Do you favor early, systematic training of infants in motor skills such as crawling, walking, and stair climbing? Why or why not?

Perceptual Development

In Chapter 3, you learned that the senses of touch, taste, smell, and hearing—but not vision—are remarkably well-developed at birth. Now let's turn to a related question: How does perception change over the first year? Our discussion will address hearing and vision, the focus of almost all research. Recall that in Chapter 3, we used the word *sensation* to talk about these capacities. It suggests a fairly passive process—what the baby's receptors detect when exposed to stimulation. Now we use the word *perception*, which is active: When we perceive, we organize and interpret what we see.

As we review the perceptual achievements of infancy, you may find it hard to tell where perception leaves off and thinking begins. The research we are about to discuss provides an excellent bridge to the topic of Chapter 5—cognitive development during the first two years.

Hearing

On Timmy's first birthday, Vanessa bought several CDs of nursery songs, and she turned one on each afternoon at naptime. Soon Timmy let her know his favorite tune. If she put on "Twinkle, Twinkle," he stood up in his crib and whimpered until she replaced it with "Jack and Jill." Timmy's behavior illustrates the greatest change in hearing over the first year of life: Babies organize sounds into increasingly elaborate patterns.

Between 4 and 7 months, infants display a sense of musical phrasing: They prefer Mozart minuets with pauses between phrases to those with awkward breaks (Krumhansl & Jusczyk, 1990). Around 6 to 7 months, they can distinguish musical tunes on the basis of variations in rhythmic patterns, including beat structure (duple or triple) and accent structure (emphasis on the first note of every beat unit or at other positions) (Hannon & Johnson, 2004). And by the end of the first year, infants recognize the same melody when it is played in different keys (Trehub, 2001). As we will see shortly, 6- to 12-month-olds make comparable discriminations in human speech: They readily detect sound regularities that will facilitate later language learning.

Biology and Environment

“Tuning In” to Familiar Speech, Faces, and Music: A Sensitive Period for Culture-Specific Learning

To share experiences with members of their family and community, babies must become skilled at making perceptual discriminations that are meaningful in their culture. As we have seen, at first babies are sensitive to virtually all speech sounds, but around 6 months, they narrow their focus, limiting the distinctions they make to the language they hear and will soon learn.

The ability to perceive faces shows a similar **perceptual narrowing effect**—perceptual sensitivity that becomes increasingly attuned with age to information most often encountered. After habituating to one member of each pair of faces in Figure 4.12, 6-month-olds were shown the familiar and novel faces side-by-side. For both pairs, they recovered to (looked longer at) the novel face, indicating that they could discriminate individual faces of both humans and monkeys equally well (Pascalis, de Haan, & Nelson, 2002). But at 9 months, infants no longer showed a novelty preference when viewing the monkey pair. Like adults, they could distinguish only the human faces. Similar findings emerge with sheep faces: 4- to 6-month-olds easily distinguish them, but 9- to 11-month-olds no longer do (Simpson et al., 2011).

The perceptual narrowing effect appears again in musical rhythm perception. Western adults are accustomed to the even-beat pattern of Western music—repetition of the same rhythmic structure in every measure of a tune—and easily notice rhythmic changes that disrupt this familiar beat. But present them with music that does not follow this typical Western rhythmic

form—Baltic folk tunes, for example—and they fail to pick up on rhythmic-pattern deviations. Six-month-olds, however, can detect such disruptions in both Western and non-Western melodies. But by 12 months, after added exposure to Western music, babies are no longer aware of deviations in foreign musical rhythms, although their sensitivity to Western rhythmic structure remains unchanged (Hannon & Trehub, 2005b).

Several weeks of regular interaction with a foreign-language speaker and of daily opportunities to listen to non-Western music fully restore 12-month-olds’ sensitivity to wide-ranging speech sounds and music rhythms (Hannon & Trehub, 2005a; Kuhl, Tsao, & Liu, 2003). Similarly, 6-month-olds given three months of training in discriminating individual monkey faces, in which each image is labeled with a distinct name (“Carlos,” “Iona”) instead of the generic label “monkey,” retain their ability to discriminate monkey faces at 9 months (Scott & Monesson, 2009). Adults given similar extensive experiences, by contrast, show little improvement in perceptual sensitivity.

Taken together, these findings suggest a heightened capacity—or sensitive period—in the second half of the first year, when babies are biologically prepared to “zero in”

FIGURE 4.12 Discrimination of human and monkey faces. Which of these pairs is easiest for you to tell apart? After habituating to one of the photos in each pair, infants were shown the familiar and the novel face side-by-side. For both pairs, 6-month-olds recovered to (looked longer at) the novel face, indicating that they could discriminate human and monkey faces equally well. By 12 months, babies lost their ability to distinguish the monkey faces. Like adults, they showed a novelty preference only to human stimuli. (From O. Pascalis et al., 2002, “Is Face Processing Species-Specific During the First Year of Life?” *Science*, 296, p. 1322. Copyright © 2002 by AAAS. Reprinted by permission from AAAS.)

on socially meaningful perceptual distinctions. Notice how, between 6 and 12 months, learning is especially rapid across several domains (speech, faces, and music) and is easily modified by experience. This suggests a broad neurological change—perhaps a special time of experience-expectant brain growth (see page 127) in which babies analyze everyday stimulation of all kinds similarly, in ways that prepare them to participate in their cultural community.

Speech Perception. Recall from Chapter 3 that newborns can distinguish nearly all sounds in human languages and that they prefer listening to human speech over nonspeech sounds, and to their native tongue rather than a foreign language. As infants listen to people talking, they learn to focus on meaningful sound variations. ERP brain-wave recordings reveal that around

5 months, babies become sensitive to syllable stress patterns in their own language (Weber et al., 2004). Between 6 and 8 months, they start to “screen out” sounds not used in their native tongue (Anderson, Morgan, & White, 2003; Polka & Werker, 1994). As the Biology and Environment box above explains, this increased responsiveness to native-language sounds is part of a general

“tuning” process in the second half of the first year—a possible sensitive period in which infants acquire a range of perceptual skills for picking up socially important information.

Soon after, infants focus on larger speech segments that are critical to figuring out meaning. They recognize familiar words in spoken passages and listen longer to speech with clear clause and phrase boundaries (Johnson & Seidl, 2008; Jusczyk & Hohne, 1997; Soderstrom et al., 2003). Around 7 to 9 months, infants extend this sensitivity to speech structure to individual words: They begin to divide the speech stream into wordlike units (Jusczyk, 2002; Saffran, Werker, & Werner, 2006).

Analyzing the Speech Stream. How do infants make such rapid progress in perceiving the structure of language? Research shows that they have an impressive **statistical learning capacity**. By analyzing the speech stream for patterns—repeatedly occurring sequences of sounds—they acquire a stock of speech structures for which they will later learn meanings, long before they start to talk around age 12 months.

For example, when presented with controlled sequences of nonsense syllables, babies listen for statistical regularities: They locate words by distinguishing syllables that often occur together (indicating they belong to the same word) from syllables that seldom occur together (indicating a word boundary). Consider the English word sequence *pretty#baby*. After listening to the speech stream for just one minute (about 60 words), 8-month-olds discriminate a word-internal syllable pair (*pretty*) from a word-external syllable pair (*ty#ba*). They prefer to listen to new speech that preserves the word-internal pattern (Saffran, Aslin, & Newport, 1996; Saffran & Thiessen, 2003).

Once infants locate words, they focus on the words and, around 7 to 8 months, identify regular syllable-stress patterns—for example, in English and Dutch, that the onset of a strong syllable (*hap-py*, *rab-bit*) often signals a new word (Swingley, 2005; Thiessen & Saffran, 2007). By 10 months, babies can detect words that start with weak syllables, such as “*surprise*,” by listening for sound regularities before and after the words (Jusczyk, 2001; Kooijman, Hagoort, & Cutler, 2009).

Clearly, babies have a powerful ability to extract patterns from complex, continuous speech. Some researchers believe that infants are innately equipped with a general statistical learning capacity for detecting structure in the environment, which they also apply to nonspeech auditory information and to visual stimulation. Consistent with this idea, ERP recordings suggest that newborns perceive patterns in both sequences of speech syllables and sequences of tones (Kudo et al., 2011; Teinonen et al., 2009). And 2-month-olds detect regularities in sequences of visual stimuli (Kirkham, Slemmer, & Johnson, 2002).

Vision

For exploring the environment, humans depend on vision more than any other sense. Although at first a baby’s visual world is fragmented, it undergoes extraordinary changes during the first 7 to 8 months of life.

Visual development is supported by rapid maturation of the eye and visual centers in the cerebral cortex. Recall from Chapter 3 that the newborn baby focuses and perceives color poorly. Around 2 months, infants can focus on objects about as well as adults can, and their color vision is adultlike by 4 months (Kellman & Arterberry, 2006). *Visual acuity* (fineness of discrimination) improves steadily, reaching 20/80 by 6 months and an adult level of about 20/20 by 4 years (Slater et al., 2010). Scanning the environment and tracking moving objects improve over the first half-year as infants better control their eye movements and build an organized perceptual world (Johnson, Slemmer, & Amso, 2004; von Hofsten & Rosander, 1998).

As babies explore their visual field, they figure out the characteristics of objects and how they are arranged in space. To understand how they do so, let’s examine the development of two aspects of vision: depth and pattern perception.

Depth Perception. *Depth perception* is the ability to judge the distance of objects from one another and from ourselves. It is important for understanding the layout of the environment and for guiding motor activity.

Figure 4.13 shows the *visual cliff*, designed by Eleanor Gibson and Richard Walk (1960) and used in the earliest studies of depth perception. It consists of a Plexiglas-covered table with a platform at the center, a “shallow” side with a checkerboard pattern just under the glass, and a “deep” side with a checkerboard several feet below the glass. The researchers found that crawling babies readily crossed the shallow side, but most reacted with fear to the deep side. They concluded that around the time infants crawl, most distinguish deep from shallow surfaces and avoid drop-offs.

The visual cliff shows that crawling and avoidance of drop-offs are linked, but not how they are related or when depth perception first appears. Subsequent research has looked at babies’ ability to detect specific depth cues, using methods that do not require that they crawl.

Motion is the first depth cue to which infants are sensitive. Babies 3 to 4 weeks old blink their eyes defensively when an object moves toward their face as if it is going to hit (Náñez & Yonas, 1994). *Binocular depth cues* arise because our two eyes have slightly different views of the visual field. The brain blends these two images, resulting in perception of depth. Research in which two overlapping images are projected before the baby, who wears special goggles to ensure that each eye receives only one image, reveals that sensitivity to binocular cues emerges between 2 and 3 months and improves rapidly over the first year (Birch, 1993; Brown & Miracle, 2003). Finally, beginning at 3 to 4 months and strengthening between 5 and 7 months, babies display sensitivity to *pictorial depth cues*—the ones artists often use to make a painting look three-dimensional. Examples include receding lines that create the illusion of perspective, changes in texture (nearby textures are more detailed than faraway ones), overlapping objects (an object partially hidden by another object is perceived to be more distant), and shadows cast on surfaces (indicating a separation in space between

FIGURE 4.13 The visual cliff. Plexiglas covers the deep and shallow sides. By refusing to cross the deep side and showing a preference for the shallow side, this infant demonstrates the ability to perceive depth.

the object and the surface) (Kavšek, Yonas, & Granrud, 2012; Shuwairi, Albert, & Johnson, 2007).

Why does perception of depth cues emerge in the order just described? Researchers speculate that motor development is involved. For example, control of the head during the early weeks of life may help babies notice motion and binocular cues. Around the middle of the first year, the ability to turn, poke, and feel the surface of objects promotes sensitivity to pictorial cues as infants pick up information about size, texture, and three-dimensional shape (Bushnell & Boudreau, 1993; Soska, Adolph, & Johnson, 2010). And as we will see next, one aspect of motor progress—independent movement—plays a vital role in refinement of depth perception.

Independent Movement and Depth Perception.

At 6 months, Timmy started crawling. “He’s fearless!” exclaimed Vanessa. “If I put him down in the middle of my bed, he crawls right over the edge. The same thing happens by the stairs.” Will Timmy become wary of the side of the bed and the staircase as

he becomes a more experienced crawler? Research suggests that he will. Infants with more crawling experience (regardless of when they started to crawl) are far more likely to refuse to cross the deep side of the visual cliff (Campos et al., 2000).

From extensive everyday experience, babies gradually figure out how to use depth cues to detect the danger of falling. But because the loss of body control that leads to falling differs greatly for each body position, babies must undergo this learning separately for each posture. In one study, 9-month-olds who were experienced sitters but novice crawlers were placed on the edge of a shallow drop-off that could be widened (Adolph, 2002, 2008). While in the familiar sitting position, infants avoided leaning out for an attractive toy at distances likely to result in falling. But in the unfamiliar crawling posture, they headed over the edge, even when the distance was extremely wide! And newly walking babies, while avoiding sharp drop-offs, careen down slopes and over uneven surfaces without making the necessary postural adjustments, even when their mothers discourage them from proceeding! Thus, they fall frequently (Adolph et al., 2008; Joh & Adolph, 2006). As infants discover how to avoid falling in different postures and situations, their understanding of depth expands.

Crawling experience promotes other aspects of three-dimensional understanding. For example, seasoned crawlers are better than their inexperienced age mates at remembering object locations and finding hidden objects (Bai & Bertenthal, 1992; Campos et al., 2000). Why does crawling make such a difference?

Infants must learn to use depth cues to avoid falling in each new position—sitting, crawling, walking—and in various situations. As this 10-month-old takes her first steps, she uses vision to make postural adjustments, and her understanding of depth expands.

TAKE A MOMENT... Compare your own experience of the environment when you are driven from one place to another with what you experience when you walk or drive yourself. When you move on your own, you are much more aware of landmarks and routes of travel, and you take more careful note of what things look like from different points of view. The same is true for infants. In fact, crawling promotes a new level of brain organization, as indicated by more organized EEG brain-wave activity in the cerebral cortex (Bell & Fox, 1996). Perhaps crawling strengthens certain neural connections, especially those involved in vision and understanding of space.

Pattern Perception. Even newborns prefer to look at patterned rather than plain stimuli (Fantz, 1961). As they get older, infants prefer more complex patterns. For example, 3-week-old infants look longest at black-and-white checkerboards with a few large squares, whereas 8- and 14-week-olds prefer those with many squares (Brennan, Ames, & Moore, 1966).

A general principle, called **contrast sensitivity**, explains early pattern preferences (Banks & Ginsburg, 1985). *Contrast* refers to the difference in the amount of light between adjacent regions in a pattern. If babies are *sensitive to* (can detect) the contrast in two or more patterns, they prefer the one with more

FIGURE 4.14 The way two checkerboards differing in complexity look to infants in the first few weeks of life. Because of their poor vision, very young infants cannot resolve the fine detail in the *complex checkerboard*. It appears blurred, like a gray field. The large, *bold checkerboard* appears to have more contrast, so babies prefer to look at it. (Adapted from M. S. Banks & P. Salapatek, 1983, "Infant Visual Perception," in M. M. Haith & J. J. Campos [Eds.], *Handbook of Child Psychology: Vol. 2. Infancy and Developmental Psychobiology* [4th ed.], p. 504. Copyright © 1983 by John Wiley & Sons, Inc. Reproduced with permission of John Wiley & Sons, Inc.)

contrast. To understand this idea, look at the checkerboards in the top row of Figure 4.14. To us, the one with many small squares has more contrasting elements. Now look at the bottom row, which shows how these checkerboards appear to infants in the first few weeks of life. Because of their poor vision, very young babies cannot resolve the small features in more complex patterns, so they prefer to look at the large, bold checkerboard. Around 2 months, when detection of fine-grained detail has improved, infants become sensitive to the contrast in complex patterns and spend more time looking at them (Gwiazda & Birch, 2001). Contrast sensitivity continues to increase during infancy and childhood.

In the early weeks of life, infants respond to the separate parts of a pattern. They stare at single, high-contrast features and have difficulty shifting their gaze away toward other interesting stimuli (Hunnus & Geuze, 2004a, 2004b). At 2 to 3 months, when scanning ability and contrast sensitivity improve, infants thoroughly explore a pattern's features, pausing briefly to look at each part (Bronson, 1994).

Once babies take in all aspects of a pattern, they integrate the parts into a unified whole. Around 4 months, babies are so good at detecting pattern organization that they perceive subjective boundaries that are not really present. For example, they perceive a square in the center of Figure 4.15a, just as you do (Ghim, 1990). Older infants carry this sensitivity to subjective form further, applying it to complex, moving stimuli. For example, 9-month-olds look much longer at an organized series of blinking lights that resembles a human being walking than at an upside-down or scrambled version (Bertenthal, 1993). At 12 months, infants detect familiar objects represented by incomplete drawings, even when as much as two-thirds of the drawing is missing (see Figure 4.15b) (Rose, Jankowski, & Senior, 1997). As these findings reveal, infants' increasing knowledge of objects and actions supports pattern perception.

FIGURE 4.15 Subjective boundaries in visual patterns.

(a) Do you perceive a square in the middle of the figure? By 4 months of age, infants do, too. (b) What does the image, missing two-thirds of its outline, look like to you? By 12 months, infants detect a motorcycle. After habituating to the incomplete motorcycle image, they were shown an intact motorcycle figure paired with a novel form. Twelve-month-olds recovered to (looked longer at) the novel figure, indicating that they recognized the motorcycle pattern on the basis of very little visual information. (Adapted from Ghim, 1990; Rose, Jankowski, & Senior, 1997.)

FIGURE 4.16 Early face perception. Newborns prefer to look at the photo of a face (a) and the simple pattern resembling a face (b) over the upside-down versions. (c) When the complex drawing of a face on the left and the equally complex, scrambled version on the right are moved across newborns' visual field, they follow the face longer. But if the two stimuli are stationary, infants show no preference for the face until around 2 months of age. (From Cassia, Turati, & Simion, 2004; Johnson, 1999; Mondloch et al., 1999.)

Face Perception. Infants' tendency to search for structure in a patterned stimulus also applies to face perception. Newborns prefer to look at photos and simplified drawings of faces with features arranged naturally (upright) rather than unnaturally (upside-down or sideways) (see Figure 4.16a) (Cassia, Turati, & Simion, 2004; Mondloch et al., 1999). They also track a facelike pattern moving across their visual field farther than they track other stimuli (Johnson, 1999). And although they rely more on high-contrast, outer features (hairline and chin) than inner features to distinguish real faces, newborns prefer photos of faces with eyes open and a direct gaze (Farroni et al., 2002; Turati et al., 2006). Yet another amazing capacity is their tendency to look longer at both human and animal faces judged by adults as attractive—a preference that may be the origin of the widespread social bias favoring physically attractive people (Quinn et al., 2008; Slater et al., 2010).

Some researchers claim that these behaviors reflect a built-in capacity to orient toward members of one's own species, just as many newborn animals do (Johnson, 2001; Slater et al., 2011). Others assert that newborns prefer any stimulus in which the most salient elements are arranged horizontally in the upper part of a pattern—like the “eyes” in Figure 4.16b (Turati, 2004). Possibly, however, a bias favoring the facial pattern promotes such preferences. Still other researchers argue that newborns are exposed to faces more often than to other stimuli—early experiences that could quickly “wire” the brain to detect faces and prefer attractive ones (Nelson, 2001).

Although newborns respond to facelike structures, they cannot discriminate a complex facial pattern from other, equally complex patterns (see Figure 4.16c). But from repeated exposures to their mother's face, they quickly learn to prefer her face to that of an unfamiliar woman, although they mostly attend to its broad outlines. Around 2 months, when they can combine pattern elements into an organized whole, babies prefer a complex drawing of the human face to other equally complex stimulus arrangements (Dannemiller & Stephens, 1988). And they clearly prefer their mother's detailed facial features to those of another woman (Bartrip, Morton, & de Schonen, 2001).

Around 3 months, infants make fine distinctions among the features of different faces—for example, between photographs of two strangers, even when the faces are moderately similar (Farroni et al., 2007). At 5 months—and strengthening over the second half-year—infants perceive emotional expressions as meaningful wholes. They treat positive faces (happy and surprised) as different from negative ones (sad and fearful) (Bornstein & Arterberry, 2003; Ludemann, 1991).

Experience influences face processing, leading babies to form group biases at a tender age. As early as 3 months, infants prefer and more easily discriminate among female faces than among male faces (Quinn et al., 2002; Ramsey-Rennels & Langlois, 2006). The greater time infants spend with female adults explains this effect, since babies with a male primary caregiver prefer male faces. Furthermore, 3- to 6-month-olds exposed mostly to members of their own race prefer to look at the faces of members of that race and more easily detect differences among those faces (Bar-Haim et al., 2006; Kelly et al., 2007, 2009). This own-race face preference is absent in babies who have frequent contact with members of other races, and it can be reversed through exposure to racial diversity (Sangrigoli et al., 2005). **TAKE A MOMENT...** Notice how early experience promotes *perceptual narrowing* with respect to gender and racial information in faces, as occurs for species information, discussed in the Biology and Environment box on page 141.

Clearly, extensive face-to-face interaction with caregivers contributes to infants' refinement of face perception. And as babies recognize and respond to the expressive behavior of others, face perception supports their earliest social relationships.

Up to this point, we have considered the infant's sensory systems one by one. Now let's examine their coordination.

Intermodal Perception

Our world provides rich, continuous *intermodal stimulation*—simultaneous input from more than one modality, or sensory system. In **intermodal perception**, we make sense of these running streams of light, sound, tactile, odor, and taste information, perceiving them as integrated wholes. We know, for example,

This baby exploring the surface of a guitar readily picks up amodal information, such as common rate, rhythm, duration, and temporal synchrony, in the visual appearance and sounds of its moving strings.

that an object's shape is the same whether we see it or touch it, that lip movements are closely coordinated with the sound of a voice, and that dropping a rigid object on a hard surface will cause a sharp, banging sound.

Recall that newborns turn in the general direction of a sound and reach for objects in a primitive way. These behaviors suggest that infants expect sight, sound, and touch to go together. Research reveals that babies perceive input from different sensory systems in a unified way by detecting *amodal sensory properties*—information that overlaps two or more sensory systems, such as rate, rhythm, duration, intensity, temporal synchrony (for vision and hearing), and texture and shape (for vision and touch). Consider the sight and sound of a bouncing ball or the face and voice of a speaking person. In each event, visual and auditory information occur simultaneously and with the same rate, rhythm, duration, and intensity.

Even newborns are impressive perceivers of amodal properties. After touching an object (such as a cylinder) placed in their palms, they recognize it visually, distinguishing it from a different-shaped object (Sann & Streri, 2007). And they require just one exposure to learn the association between the sight and sound of a toy, such as a rhythmically jangling rattle (Morrongiello, Fenwick, & Chance, 1998).

Within the first half-year, infants master a remarkable range of intermodal relationships. Three- to 4-month-olds can match faces with voices on the basis of lip-voice synchrony, emotional expression, and even age and gender of the speaker (Bahrick, Netto, & Hernandez-Reif, 1998). Between 4 and 6 months, infants can perceive and remember the unique face-voice pairings of unfamiliar adults (Bahrick, Hernandez-Reif, & Flom, 2005).

How does intermodal perception develop so quickly? Young infants seem biologically primed to focus on amodal information. Their detection of amodal relations—for example,

the common tempo and rhythm in sights and sounds—precedes and seems to provide the basis for detecting more specific intermodal matches, such as the relation between a particular person's face and the sound of her voice or between an object and its verbal label (Bahrick, Hernandez-Reif, & Flom, 2005).

Intermodal sensitivity is crucial for perceptual development. In the first few months, when much stimulation is unfamiliar and confusing, it enables babies to notice meaningful correlations between sensory inputs and rapidly make sense of their surroundings (Bahrick, Lickliter, & Flom, 2004).

In addition to easing perception of the physical world, intermodal perception facilitates social and language processing. For example, as 3- to 4-month-olds gaze at an adult's face, they initially require both vocal and visual input to distinguish positive from negative emotional expressions (Walker-Andrews, 1997). Only later do infants discriminate positive from negative emotion in each sensory modality—first in voices (around 4 to 5 months), later (from 5 months on) in faces (Bahrick, Hernandez-Reif, & Flom, 2005). Furthermore, in speaking to infants, parents often provide temporal synchrony between words, object motions, and touch—for example, saying “doll” while moving a doll and having it touch the infant. This greatly increases the chances that babies will remember the association between the word and the object (Gogate & Bahrick, 1998, 2001).

LOOK AND LISTEN

While watching a parent and infant playing, list instances of parental intermodal stimulation and communication. What is the baby likely learning about people, objects, or language from each intermodal experience? ●

In sum, intermodal perception fosters all aspects of psychological development. When caregivers provide many concurrent sights, sounds, and touches, babies process more information and learn faster (Bahrick, 2010). Intermodal perception is yet another fundamental capacity that assists infants in their active efforts to build an orderly, predictable world.

Understanding Perceptual Development

Now that we have reviewed the development of infant perceptual capacities, how can we put together this diverse array of amazing achievements? Widely accepted answers come from the work of Eleanor and James Gibson. According to the Gibsons' **differentiation theory**, infants actively search for *invariant features* of the environment—those that remain stable—in a constantly changing perceptual world. In pattern perception, for example, young babies search for features that stand out and orient toward faces. Soon they thoroughly explore a stimulus, noticing *stable relationships* among its features. As a result, they detect patterns, such as complex designs and individual faces. Similarly, infants analyze the speech stream for regularities, detecting words, word-order sequences, and—within words—

FIGURE 4.17 Acting on the environment plays a major role in perceptual differentiation. Crawling and walking change the way babies perceive a sloping surface. The newly crawling infant on the left plunges headlong down the slope. He has not yet learned that it affords the possibility of falling. The toddler on the right, who has been walking for more than a month, approaches the slope cautiously. Experience in trying to remain upright but frequently tumbling over has made him more aware of the consequences of his movements. He perceives the incline differently than he did at a younger age.

DR. KAREN E. ADOLPH, INFANT ACTION LAB, NEW YORK UNIVERSITY

syllable-stress patterns. The development of intermodal perception also reflects this principle. Babies seek out invariant relationships—first, amodal properties, such as common rate and rhythm, in a voice and face, and later, more detailed associations, such as unique voice–face matches.

The Gibsons described their theory as *differentiation* (where *differentiate* means “analyze” or “break down”) because over time, the baby detects finer and finer invariant features among stimuli. In addition to pattern perception and intermodal perception, differentiation applies to depth perception. Recall how sensitivity to motion precedes detection of fine-grained pictorial features. So one way of understanding perceptual development is to think of it as a built-in tendency to seek order and consistency—a capacity that becomes increasingly fine-tuned with age (Gibson, 1970; Gibson, 1979).

Infants constantly look for ways in which the environment *affords possibilities for action* (Gibson, 2000, 2003). By exploring their surroundings, they figure out which things can be grasped, squeezed, bounced, or stroked and whether a surface is safe to cross or presents the possibility of falling (Adolph & Eppler, 1998, 1999). And from handling objects, babies become more aware of a variety of observable object properties (Perone et al., 2008). As a result, they differentiate the world in new ways and act more competently.

To illustrate, recall how infants’ changing capabilities for independent movement affect their perception. When babies crawl, and again when they walk, they gradually realize that a sloping surface *affords the possibility of falling* (see Figure 4.17). With added weeks of practicing each skill, they hesitate to crawl or walk down a risky incline. Experience in trying to keep their balance on various surfaces makes crawlers and walkers more aware of the consequences of their movements. Crawlers come to detect when surface slant places so much body weight on their arms that they will fall forward, and walkers come to sense when an incline shifts body weight so their legs and feet can no longer hold them upright. Learning is gradual and effortful because newly crawling and walking babies cross many types

of surfaces in their homes each day (Adolph, 2008; Adolph & Joh, 2009). As they experiment with balance and postural adjustments to accommodate each, they perceive surfaces in new ways that guide their movements. As a result, they act more competently.

As we conclude our discussion of infant perception, it is only fair to note that some researchers believe that babies do more than make sense of experience by searching for invariant features and action possibilities: They also *impose meaning* on what they perceive, constructing categories of objects and events in the surrounding environment. We have seen the glimmerings of this *cognitive* point of view in this chapter. For example, older babies *interpret* a familiar face as a source of pleasure and affection and a pattern of blinking lights as a moving human being. This cognitive perspective also has merit in understanding the achievements of infancy. In fact, many researchers combine these two positions, regarding infant development as proceeding from a perceptual to a cognitive emphasis over the first year of life.

ASK YOURSELF

REVIEW Using examples, explain why intermodal perception is vital for infants’ developing understanding of their physical and social worlds.

CONNECT According to differentiation theory, perceptual development reflects infants’ active search for invariant features. Provide examples from research on hearing, pattern perception, and intermodal perception.

APPLY After several weeks of crawling, Ben learned to avoid going headfirst down a steep incline. Now he has started to walk. Can his parents trust him not to try walking down a steep surface? Explain.

SUMMARY

Body Growth (p. 120)

Describe major changes in body growth over the first two years.

- Height and weight gains are greater during the first two years than at any other time after birth. Body fat is laid down quickly during the first nine months, whereas muscle development is slow and gradual. Body proportions change as growth follows the **cephalocaudal** and **proximodistal trends**.

Brain Development (p. 121)

Describe brain development during infancy and toddlerhood, including appropriate stimulation to support the brain's potential.

- Early in development, the brain grows faster than any other organ of the body. Once **neurons** are in place, they rapidly form **synapses**. To communicate, neurons release chemicals called **neurotransmitters**, which cross synapses. **Programmed cell death** makes space for neural fibers and synapses. Neurons that are seldom stimulated lose their synapses in a process called **synaptic pruning**. **Glial cells**, responsible for **myelination**, multiply rapidly through the second year, contributing to large gains in brain weight.
- The **cerebral cortex** is the largest, most complex brain structure and the last to stop growing. Its frontal lobes, which contain the **prefrontal cortex**, have the most extended period of development. Gradually, the hemispheres of the cerebral cortex specialize, a process called **lateralization**. But in the first few years of life, there is high **brain plasticity**, with many areas not yet committed to specific functions.
- Both heredity and early experience contribute to brain organization. Stimulation of the brain is essential during sensitive periods, when the brain is developing most rapidly. Prolonged early deprivation can impair functioning of the cerebral cortex, especially the prefrontal cortex, and interfere with the brain's capacity to manage stress, with long-term physical and psychological consequences.

- Appropriate early stimulation promotes **experience-expectant brain growth**, which depends on ordinary experiences. No evidence exists for a sensitive period in the first few years for **experience-dependent brain growth**, which relies on specific learning experiences. In fact, environments that overwhelm children with inappropriately advanced expectations can undermine the brain's potential.

How does the organization of sleep and wakefulness change over the first two years?

- Infants' changing arousal patterns are primarily affected by brain growth, but the social environment also plays a role. Periods of sleep and wakefulness become fewer but longer, increasingly conforming to a night-day schedule. Parents in Western nations try to get their babies to sleep through the night much earlier than parents throughout most of the world, who are more likely to sleep with their babies.

Influences on Early Physical Growth (p. 130)

Cite evidence that heredity and nutrition both contribute to early physical growth.

- Twin and adoption studies reveal that heredity contributes to body size and rate of physical growth.
- Breast milk is ideally suited to infants' growth needs. Breastfeeding protects against disease and prevents malnutrition and infant death in poverty-stricken areas of the world.

- Most infants and toddlers can eat nutritious foods freely without risk of becoming overweight. However, because of unhealthy parental feeding practices, the relationship between rapid weight gain in infancy and later obesity is strengthening.
- **Marasmus** and **kwashiorkor**, two dietary diseases caused by malnutrition, affect many children in developing countries. If prolonged, they can permanently stunt body growth and brain development.

Learning Capacities (p. 133)

Describe infant learning capacities, the conditions under which they occur, and the unique value of each.

- **Classical conditioning** is based on the infant's ability to associate events that usually occur together in the everyday world. Infants can be classically conditioned most easily when the pairing of an **unconditioned stimulus (UCS)** and a **conditioned stimulus (CS)** has survival value.
- In **operant conditioning**, infants act on the environment, and their behavior is followed by either **reinforcers**, which increase the occurrence of a preceding behavior, or **punishment**, which either removes a desirable stimulus or presents an unpleasant one to decrease the occurrence of a response. In young infants, interesting sights and sounds and pleasurable caregiver interaction serve as effective reinforcers.
- **Habituation** and **recovery** reveal that at birth, babies are attracted to novelty. Novelty preference (recovery to a novel stimulus) assesses recent memory, whereas familiarity preference (recovery to the familiar stimulus) assesses remote memory.
- Newborns have a primitive ability to imitate adults' facial expressions and gestures. **Imitation** is a powerful means of learning, which contributes to the parent-infant bond. Specialized cells called **mirror neurons** underlie infants' capacity to imitate, but whether imitation is a voluntary capacity in newborns remains controversial.

Motor Development (p. 136)

Describe dynamic systems theory of motor development, along with factors that influence motor progress in the first two years.

- According to **dynamic systems theory of motor development**, children acquire new motor skills by combining existing skills into increasingly complex systems of action. Each new skill is a joint product of central nervous system development, the body's movement possibilities, the child's goals, and environmental supports for the skill.

- Movement opportunities and a stimulating environment contribute to motor development, as shown by observations of infants learning to crawl and walk in varying contexts. Cultural values and child-rearing customs also contribute to the emergence and refinement of motor skills.
- During the first year, infants perfect reaching and grasping. Reaching gradually becomes more accurate and flexible, and the clumsy ulnar grasp is transformed into a refined pincer grasp.

Perceptual Development

(p. 140)

What changes in hearing, depth and pattern perception, and intermodal perception take place during infancy?

- Infants organize sounds into increasingly complex patterns and, as part of the **perceptual narrowing effect**, begin to “screen out” sounds not used in their native tongue by the middle of the first year. An impressive **statistical learning capacity** enables babies to detect regular sound patterns, for which they will later learn meanings.
- Rapid maturation of the eye and visual centers in the brain supports the development of focusing, color discrimination, and visual acuity during the first half-year. The ability to scan the environment and track moving objects also improves.
- Research on depth perception reveals that responsiveness to motion cues develops first, followed by sensitivity to binocular and then to pictorial cues. Experience in crawling enhances depth perception and other aspects of three-dimensional understanding, but babies must learn to avoid drop-offs for each body position.
- **Contrast sensitivity** explains infants' early pattern preferences. At first, babies stare at single, high-contrast features. At 2 to 3 months, they thoroughly explore a pattern's features and start to detect pattern organization. Over time, they discriminate increasingly complex, meaningful patterns.

- Newborns prefer to look at and track simple, facelike stimuli, but researchers disagree on whether they have a built-in tendency to orient toward human faces. Around 2 months, they recognize and prefer their mother's facial features, and at 3 months, they distinguish the features of different faces. Starting at 5 months, they perceive emotional expressions as meaningful wholes.
- From the start, infants are capable of **intermodal perception**—combining information across sensory modalities. Detection of amodal relations (such as common tempo or rhythm) may provide the basis for detecting other intermodal matches.

Explain differentiation theory of perceptual development.

- According to **differentiation theory**, perceptual development is a matter of detecting invariant features in a constantly changing perceptual world. Acting on the world plays a major role in perceptual differentiation. From a more cognitive perspective, infants also impose meaning on what they perceive. Many researchers combine these two ideas.

chapter 5

© KRISTIN DUVALL/GETTY IMAGES

A father encourages his child's curiosity and delight in discovery. With the sensitive support of caring adults, infants' and toddlers' cognition and language develop rapidly.

Cognitive Development in Infancy and Toddlerhood

When Caitlin, Grace, and Timmy gathered at Ginette’s child-care home, the playroom was alive with activity. The three spirited explorers, each nearly 18 months old, were bent on discovery. Grace dropped shapes through holes in a plastic box that Ginette held and adjusted so the harder ones would fall smoothly into place. Once a few shapes were inside, Grace grabbed the box and shook it, squealing with delight as the lid fell open and the shapes scattered around her. The clatter attracted Timmy, who picked up a shape, carried it to the railing at the top of the basement steps, and dropped it overboard, then followed with a teddy bear, a ball, his shoe, and a spoon. Meanwhile, Caitlin pulled open a drawer, unloaded a set of wooden bowls, stacked them in a pile, knocked it over, and then banged two bowls together.

As the toddlers experimented, I could see the beginnings of spoken language—a whole new way of influencing the world. “All gone baw!” Caitlin exclaimed as Timmy tossed the bright red ball down the basement steps. “Bye-bye,” Grace chimed in, waving as the ball disappeared from sight. Later that day, Grace revealed the beginnings of make-believe. “Night-night,” she said, putting her head down and closing her eyes, ever so pleased that she could decide for herself when and where to go to bed.

Over the first two years, the small, reflexive newborn baby becomes a self-assertive, purposeful being who solves simple problems and starts to master the most amazing human ability: language. Parents wonder, how does all this happen so quickly? This question has also captivated researchers, yielding a wealth of findings along with vigorous debate over how to explain the astonishing pace of infant and toddler cognition.

In this chapter, we take up three perspectives on early cognitive development: Piaget’s *cognitive-developmental theory*, *information processing*, and Vygotsky’s *sociocultural theory*. We also consider the usefulness of tests that measure infants’ and toddlers’ intellectual progress. Finally, we look at the beginnings of language. We will see how toddlers’ first words build on early cognitive achievements and how, very soon, new words and expressions greatly increase the speed and flexibility of their thinking. Throughout development, cognition and language mutually support each other. ●

Piaget's Cognitive-Developmental Theory

Swiss theorist Jean Piaget inspired a vision of children as busy, motivated explorers whose thinking develops as they act directly on the environment. Influenced by his background in biology, Piaget believed that the child's mind forms and modifies psychological structures so they achieve a better fit with external reality. Recall from Chapter 1 that in Piaget's theory, children move through four stages between infancy and adolescence. During these stages, all aspects of cognition develop in an integrated fashion, changing in a similar way at about the same time.

Piaget's first stage, the **sensorimotor stage**, spans the first two years of life. Piaget believed that infants and toddlers "think" with their eyes, ears, hands, and other sensorimotor equipment. They cannot yet carry out many activities inside their heads. But by the end of toddlerhood, children can solve practical, everyday problems and represent their experiences in speech, gesture, and play. To appreciate Piaget's view of how these vast changes take place, let's consider some important concepts.

Piaget's Ideas About Cognitive Change

According to Piaget, specific psychological structures—organized ways of making sense of experience called **schemes**—change with age. At first, schemes are sensorimotor action patterns. For example, at 6 months, Timmy dropped objects in a fairly rigid way, simply letting go of a rattle or teething ring and watching with interest. By 18 months, his "dropping scheme" had become deliberate and creative. In tossing objects down the basement stairs, he threw some in the air, bounced others off walls, released some gently and others forcefully. Soon, instead of just acting on objects, he will show evidence of thinking before he acts. For Piaget, this change marks the transition from sensorimotor to preoperational thought.

In Piaget's theory, two processes, *adaptation* and *organization*, account for changes in schemes.

Adaptation. TAKE A MOMENT... The next time you have a chance, notice how infants and toddlers tirelessly repeat actions that lead to interesting effects. **Adaptation** involves building schemes through direct interaction with the environment. It consists of two complementary activities, *assimilation* and *accommodation*. During **assimilation**, we use our current schemes to interpret the external world. For example, when Timmy dropped objects, he was assimilating them to his sensorimotor "dropping scheme." In **accommodation**, we create new schemes or adjust old ones after noticing that our current ways of thinking do not capture the environment completely. When Timmy dropped objects in different ways, he modified his dropping scheme to take account of the varied properties of objects.

According to Piaget, the balance between assimilation and accommodation varies over time. When children are not changing

© LAURA DWIGHT PHOTOGRAPHY

In Piaget's theory, first schemes are sensorimotor action patterns. As this 11-month-old repeatedly experiments with her dropping scheme, her dropping behavior becomes more deliberate and varied.

much, they assimilate more than they accommodate—a steady, comfortable state that Piaget called *cognitive equilibrium*. During rapid cognitive change, however, children are in a state of *disequilibrium*, or cognitive discomfort. Realizing that new information does not match their current schemes, they shift from assimilation toward accommodation. After modifying their schemes, they move back toward assimilation, exercising their newly changed structures until they are ready to be modified again.

Each time this back-and-forth movement between equilibrium and disequilibrium occurs, more effective schemes are produced. Because the times of greatest accommodation are the earliest ones, the sensorimotor stage is Piaget's most complex period of development.

Organization. Schemes also change through **organization**, a process that takes place internally, apart from direct contact with the environment. Once children form new schemes, they rearrange them, linking them with other schemes to create a strongly interconnected cognitive system. For example, eventually Timmy will relate "dropping" to "throwing" and to his developing understanding of "nearness" and "farness." According to Piaget, schemes truly reach equilibrium when they become

part of a broad network of structures that can be jointly applied to the surrounding world (Piaget, 1936/1952).

In the following sections, we will first describe infant development as Piaget saw it, noting research that supports his observations. Then we will consider evidence demonstrating that, in some ways, babies' cognitive competence is more advanced than Piaget believed.

The Sensorimotor Stage

The difference between the newborn baby and the 2-year-old child is so vast that Piaget divided the sensorimotor stage into six substages, summarized in Table 5.1. Piaget based this sequence on his own three children—a very small sample. He observed his son and two daughters carefully and also presented them with everyday problems (such as hidden objects) that helped reveal their understanding of the world.

According to Piaget, at birth infants know so little that they cannot explore purposefully. The **circular reaction** provides a special means of adapting their first schemes. It involves stumbling onto a new experience caused by the baby's own motor activity. The reaction is "circular" because, as the infant tries to repeat the event again and again, a sensorimotor response that first occurred by chance strengthens into a new scheme. Consider Caitlin, who at age 2 months accidentally made a smacking noise after a feeding. Finding the sound intriguing, she tried to repeat it until she became quite expert at smacking her lips.

The circular reaction initially centers on the infant's own body but later turns outward, toward manipulation of objects. In the second year, it becomes experimental and creative, aimed at producing novel outcomes. Infants' difficulty inhibiting new and interesting behaviors may underlie the circular reaction. This immaturity in inhibition seems to be adaptive, helping to ensure that new skills will not be interrupted before they strengthen (Carey & Markman, 1999). Piaget considered revisions in the circular reaction so important that, as Table 5.1 shows, he named the sensorimotor substages after them.

This 3-month-old tries to repeat a newly discovered action—sucking her toes—in a primary circular reaction that helps her gain voluntary control over her behavior.

Repeating Chance Behaviors. Piaget saw newborn reflexes as the building blocks of sensorimotor intelligence. In Substage 1, babies suck, grasp, and look in much the same way, no matter what experiences they encounter. In one amusing example, Carolyn described how 2-week-old Caitlin lay on the bed next to her sleeping father. Suddenly, he awoke with a start. Caitlin had latched on and begun to suck on his back!

Around 1 month, as babies enter Substage 2, they start to gain voluntary control over their actions through the *primary circular reaction*, by repeating chance behaviors largely motivated by basic needs. This leads to some simple motor habits, such as sucking their fist or thumb. Babies in this substage also begin to vary their behavior in response to environmental demands. For example, they open their mouths differently for a nipple than for a spoon. And they start to anticipate events. When hungry, 3-month-old Timmy would stop crying as soon as Vanessa entered the room—a signal that feeding time was near.

TABLE 5.1 Summary of Piaget's Sensorimotor Stage

SENSORIMOTOR SUBSTAGE	TYPICAL ADAPTIVE BEHAVIORS
1. Reflexive schemes (birth–1 month)	Newborn reflexes (see Chapter 3, page 107)
2. Primary circular reactions (1–4 months)	Simple motor habits centered around the infant's own body; limited anticipation of events
3. Secondary circular reactions (4–8 months)	Actions aimed at repeating interesting effects in the surrounding world; imitation of familiar behaviors
4. Coordination of secondary circular reactions (8–12 months)	Intentional, or goal-directed, behavior; ability to find a hidden object in the first location in which it is hidden (object permanence); improved anticipation of events; imitation of behaviors slightly different from those the infant usually performs
5. Tertiary circular reactions (12–18 months)	Exploration of the properties of objects by acting on them in novel ways; imitation of novel behaviors; ability to search in several locations for a hidden object (accurate A–B search)
6. Mental representation (18 months–2 years)	Internal depictions of objects and events, as indicated by sudden solutions to problems; ability to find an object that has been moved while out of sight (invisible displacement); deferred imitation; and make-believe play

During Substage 3, from 4 to 8 months, infants sit up and reach for and manipulate objects. These motor achievements strengthen the *secondary circular reaction*, through which babies try to repeat interesting events in the surrounding environment that are caused by their own actions. For example, 4-month-old Caitlin accidentally knocked a toy hung in front of her, producing a fascinating swinging motion. Over the next three days, Caitlin tried to repeat this effect, gradually forming a new “hitting” scheme. Improved control over their own behavior permits infants to imitate others’ behavior more effectively. However, they usually cannot adapt flexibly and quickly enough to imitate novel behaviors. Therefore, although they enjoy watching an adult demonstrate a game of pat-a-cake, they are not yet able to participate.

Intentional Behavior. In Substage 4, 8- to 12-month-olds combine schemes into new, more complex action sequences. As a result, actions that lead to new schemes no longer have a hit-or-miss quality—*accidentally* bringing the thumb to the mouth or *happening* to hit the toy. Instead, 8- to 12-month-olds can engage in **intentional, or goal-directed, behavior**, coordinating schemes deliberately to solve simple problems. Consider Piaget’s famous object-hiding task, in which he shows the baby an attractive toy and then hides it behind his hand or under a cover. Infants of this substage can find the object by coordinating two schemes—“pushing” aside the obstacle and “grasping” the toy. Piaget regarded these *means-end action sequences* as the foundation for all problem solving.

Retrieving hidden objects reveals that infants have begun to master **object permanence**, the understanding that objects continue to exist when out of sight. But this awareness is not yet complete. Babies still make the *A-not-B search error*: If they reach several times for an object at a first hiding place (A), then see it moved to a second (B), they still search for it in the first

© LAURA DWIGHT PHOTOGRAPHY

To find the toy hidden under the cloth, a 10-month-old engages in intentional, goal-directed behavior—the basis for all problem solving.

hiding place (A). Consequently, Piaget concluded, they do not have a clear image of the object as persisting when hidden from view.

Infants in Substage 4, who can better anticipate events, sometimes use their capacity for intentional behavior to try to change those events. At 10 months, Timmy crawled after Vanessa when she put on her coat, whimpering to keep her from leaving. Also, babies can now imitate behaviors slightly different from those they usually perform. After watching someone else, they try to stir with a spoon, push a toy car, or drop raisins into a cup (Piaget, 1945/1951).

In Substage 5, from 12 to 18 months, the *tertiary circular reaction*, in which toddlers repeat behaviors with variation, emerges. Recall how Timmy dropped objects over the basement steps, trying first this action, then that, then another. This deliberately exploratory approach makes 12- to 18-month-olds better problem solvers. For example, Grace figured out how to fit a shape through a hole in a container by turning and twisting it until it fell through and how to use a stick to get toys that were out of reach. According to Piaget, this capacity to experiment leads to a more advanced understanding of object permanence. Toddlers look for a hidden toy in several locations, displaying an accurate A–B search. Their more flexible action patterns also permit them to imitate many more behaviors—stacking blocks, scribbling on paper, and making funny faces.

Mental Representation. Substage 6 brings the ability to create **mental representations**—internal depictions of information that the mind can manipulate. Our most powerful mental representations are of two kinds: (1) *images*, or mental pictures of objects, people, and spaces; and (2) *concepts*, or categories in which similar objects or events are grouped together. We use a mental image to retrace our steps when we’ve misplaced something or to imitate another’s behavior long after observing it. By thinking in concepts and labeling them (for example, “ball” for all rounded, movable objects used in play), we become more efficient thinkers, organizing our diverse experiences into meaningful, manageable, and memorable units.

Piaget noted that 18- to 24-month-olds arrive at solutions suddenly rather than through trial-and-error behavior. In doing so, they seem to experiment with actions inside their heads—evidence that they can mentally represent their experiences. For example, at 19 months, Grace—after bumping her new push toy against a wall—paused for a moment as if to “think,” then immediately turned the toy in a new direction.

Representation also enables older toddlers to solve advanced object permanence problems involving *invisible displacement*—finding a toy moved while out of sight, such as into a small box while under a cover. It permits **deferred imitation**—the ability to remember and copy the behavior of models who are not present. And it makes possible **make-believe play**, in which children act out everyday and imaginary activities. As the sensorimotor stage draws to a close, mental symbols have become major instruments of thinking.

Follow-Up Research on Infant Cognitive Development

Many studies suggest that infants display a wide array of understandings earlier than Piaget believed. Recall the operant conditioning research reviewed in Chapter 4, in which newborns sucked vigorously on a nipple to gain access to interesting sights and sounds. This behavior, which closely resembles Piaget's secondary circular reaction, shows that infants explore and control the external world long before 4 to 8 months. In fact, they do so as soon as they are born.

To discover what infants know about hidden objects and other aspects of physical reality, researchers often use the **violation-of-expectation method**. They may *habituate* babies to a physical event (expose them to the event until their looking declines) to familiarize them with a situation in which their knowledge will be tested. Or they may simply show babies an *expected event* (one that follows physical laws) and an *unexpected event* (a variation of the first event that violates physical laws). Heightened attention to the unexpected event suggests that the infant is “surprised” by a deviation from physical reality and, therefore, is aware of that aspect of the physical world.

The violation-of-expectation method is controversial. Some researchers believe that it indicates limited awareness of physical events—not the full-blown, conscious understanding that was Piaget's focus in requiring infants to act on their surroundings, as in searching for hidden objects (Campos et al., 2008; Munakata, 2001). Others maintain that the method reveals only babies' perceptual preference for novelty, not their knowledge of the physical world (Bremner, 2010; Cohen, 2010; Kagan, 2008). Let's examine this debate in light of recent evidence.

Object Permanence. In a series of studies using the violation-of-expectation method, Renée Baillargeon and her collaborators claimed to have found evidence for object permanence in the first few months of life. Figure 5.1 illustrates one of these studies (Aguiar & Baillargeon, 2002; Baillargeon & DeVos, 1991). After habituating to a short and a tall carrot moving behind a screen, infants were given two test events: (1) an *expected event*, in which the short carrot moved behind a screen, could not be seen in its window, and reappeared on the other side; and (2) an *unexpected event*, in which the tall carrot moved behind a screen, could not be seen in its window (although it was taller than the window's lower edge), and reappeared. Infants as young as 2½ to 3½ months looked longer at the unexpected event, suggesting that they had some awareness that an object moved behind a screen would continue to exist.

Additional violation-of-expectation studies yielded similar results, suggesting that infants look longer at a wide variety of unexpected events involving hidden objects (Newcombe, Sluzenski, & Huttenlocher, 2005; Wang, Baillargeon, & Paterson, 2005). Still, several researchers using similar procedures failed to confirm Baillargeon's findings (Cohen & Marks, 2002; Schöner & Thelen, 2006; Sirois & Jackson, 2012). And, as previously

FIGURE 5.1 Testing young infants for understanding of object permanence using the violation-of-expectation method.

(a) First, infants were habituated to two events: a short carrot and a tall carrot moving behind a yellow screen, on alternate trials. Next, the researchers presented two test events. The color of the screen was changed to help infants notice its window. (b) In the *expected event*, the carrot shorter than the window's lower edge moved behind the blue screen and reappeared on the other side. (c) In the *unexpected event*, the carrot taller than the window's lower edge moved behind the screen and did not appear in the window, but then emerged intact on the other side. Infants as young as 2½ to 3½ months looked longer at the *unexpected event*, suggesting that they had some understanding of object permanence. (Adapted from R. Baillargeon & J. DeVos, 1991, “Object Permanence in Young Infants: Further Evidence,” *Child Development*, 62, p. 1230. © 1991, John Wiley and Sons. Reproduced with permission of John Wiley & Sons Ltd.)

noted, critics question what babies' looking preferences tell us about what they actually understand.

But another type of looking behavior suggests that young infants are aware that objects persist when out of view. Four- and 5-month-olds will track a ball's path of movement as it disappears and reappears from behind a barrier, even gazing ahead to where they expect it to emerge (Bertenthal, Longo, & Kenny, 2007; Rosander & von Hofsten, 2004). With age, babies are more likely to fixate on the predicted place of the ball's reappearance and wait for it—evidence of an increasingly secure grasp of object permanence.

In related research, 6-month-olds' ERP brain-wave activity was recorded as the babies watched two events on a computer screen. In one event, a black square moved until it covered an object, then moved away to reveal the object (object permanence). In the other, as a black square began to move across an object, the object disintegrated (object disappearance) (Kaufman, Csibra, & Johnson, 2005). Only while watching the first event did the infants show a particular brain-wave pattern in the right temporal lobe—the same pattern adults exhibit when told to sustain a mental image of an object.

If young infants do have some notion of object permanence, how do we explain Piaget's finding that even babies capable

of reaching do not try to search for hidden objects before 8 months of age? Consistent with Piaget's theory, searching for hidden objects is a true cognitive advance because infants solve some object-hiding tasks before others: Ten-month-olds search for an object placed on a table and covered by a cloth before they search for an object that a hand deposits under a cloth (Moore & Meltzoff, 1999). In the second, more difficult task, infants seem to expect the object to reappear in the hand from which it initially disappeared. When the hand emerges without the object, they conclude that there is no other place the object could be. Not until 14 months can most babies infer that the hand deposited the object under the cloth.

Once 8- to 12-month-olds search for hidden objects, they make the A-not-B search error. Some research suggests that they search at A (where they found the object previously) instead of B (its most recent location) because they have trouble inhibiting a previously rewarded response (Diamond, Cruttenden, & Neiderman, 1994). Another possibility is that after finding the object several times at A, they do not attend closely when it is hidden at B (Ruffman & Langman, 2002).

A more comprehensive explanation is that a complex, dynamic system of factors—having built a habit of reaching toward A, continuing to look at A, having the hiding place at B appear similar to the one at A, and maintaining a constant body posture—increases the chances that the baby will make the A-not-B search error. Disrupting any one of these factors increases 10-month-olds' accurate searching at B (Thelen et al., 2001). In addition, older infants are still perfecting reaching and grasping (see Chapter 3) (Berger, 2010). If these motor skills are challenging, babies have little attention left to focus on inhibiting their habitual reach toward A.

LOOK AND LISTEN

Using an attractive toy and cloth, try several object-hiding tasks with 8- to 14-month-olds. Is their searching behavior consistent with research findings? ●

In sum, mastery of object permanence is a gradual achievement. Babies' understanding becomes increasingly complex with age: They must distinguish the object from the barrier concealing it, keep track of the object's whereabouts, and use this knowledge to obtain the object (Cohen & Cashon, 2006; Moore & Meltzoff, 2008). Success at object search tasks coincides with rapid development of the frontal lobes of the cerebral cortex (Bell, 1998). Also crucial are a wide variety of experiences perceiving, acting on, and remembering objects.

Mental Representation. In Piaget's theory, before about 18 months of age, infants are unable to mentally represent experience. Yet 8- to 10-month-olds' ability to recall the location of hidden objects after delays of more than a minute, and 14-month-olds' recall after delays of a day or more, indicate that babies construct mental representations of objects and their whereabouts (McDonough, 1999; Moore & Meltzoff, 2004). And in studies of deferred imitation and problem solving, representational thought is evident even earlier.

Deferred and Inferred Imitation. Piaget studied imitation by noting when his three children demonstrated it in their everyday behavior. Under these conditions, a great deal must be known about the infant's daily life to be sure that deferred imitation—which requires infants to represent a model's past behavior—has occurred.

Laboratory research suggests that deferred imitation is present at 6 weeks of age! Infants who watched an unfamiliar adult's facial expression imitated it when exposed to the same adult the next day (Meltzoff & Moore, 1994). As motor capacities improve, infants copy actions with objects. In one study, an adult showed 6- and 9-month-olds a novel series of actions with a puppet: taking its glove off, shaking the glove to ring a bell inside, and replacing the glove. When tested a day later, infants who had seen the novel actions were far more likely to imitate them (see Figure 5.2). And when researchers paired a second, motionless puppet with the first puppet a day before the demonstration, 6-month-olds generalized the novel actions to this new, very different-looking puppet (Barr, Marrott, & Rovee-Collier, 2003).

Between 12 and 18 months, toddlers use deferred imitation skillfully to enrich their range of sensorimotor schemes. They retain modeled behaviors for at least several months, copy the actions of peers as well as adults, and imitate across a change in context—for example, enact at home a behavior seen at child care (Klein & Meltzoff, 1999; Meltzoff & Williamson, 2010). The ability to recall modeled behaviors in the order they occurred—evident as early as 6 months—also strengthens over the second year (Bauer, 2006; Rovee-Collier & Cuevas, 2009). And when toddlers imitate in correct sequence, they remember more behaviors (Knopf, Kraus, & Kressley-Mba, 2006).

Through deferred imitation, toddlers greatly expand their sensorimotor schemes. While imitating, this 2-year-old encounters a problem faced by all cookie bakers at one time or another.

FIGURE 5.2 Testing infants for deferred imitation. After researchers performed a novel series of actions with a puppet, this 6-month-old imitated the actions a day later—at left, removing the glove; at right, shaking the glove to ring a bell inside. With age, gains in recall are evident in deferred imitation of others' behaviors over longer delays.

Toddlers even imitate rationally, by *inferring* others' intentions! Fourteen-month-olds are more likely to imitate purposeful than accidental behaviors (Carpenter, Akhtar, & Tomasello, 1998). And they adapt their imitative acts to a model's goals. If 12-month-olds see an adult perform an unusual action for fun (make a toy dog enter a miniature house by jumping through the chimney, even though its door is wide open), they copy the behavior. But if the adult engages in the odd behavior because she *must* (she makes the dog go through the chimney only after first trying to use the door and finding it locked), 12-month-olds typically imitate the more efficient action (putting the dog through the door) (Schwier et al., 2006).

Between 14 and 18 months, toddlers become increasingly adept at imitating actions an adult *tries* to produce, even if these are not fully realized (Bellagamba, Camaioni, & Colonesi, 2006; Olineck & Poulin-Dubois, 2007, 2009). On one occasion, Ginette attempted to pour some raisins into a bag but missed, spilling them onto the counter. A moment later, Grace began dropping the raisins into the bag, indicating that she had inferred Ginette's goal.

Problem Solving. As Piaget indicated, around 7 to 8 months, infants develop intentional means–end action sequences, which they use to solve simple problems, such as pulling on a cloth to obtain a toy resting on its far end (Willatts, 1999). Soon after, infants' representational skills permit more effective problem solving than Piaget's theory suggests.

By 10 to 12 months, infants can *solve problems by analogy*—apply a solution strategy from one problem to other relevant problems. In one study, babies were given three similar problems, each requiring them to overcome a barrier, grasp a string, and pull it to get an attractive toy. The problems differed in many aspects of their superficial features—texture and color of the string, barrier, and floor mat and type of toy (horse, doll, or car). For the first problem, the parent demonstrated the solution and encouraged the infant to imitate. Babies obtained the toy more readily with each additional problem (Chen, Sanchez, & Campbell, 1997). Similarly, 12-month-olds who were repeatedly presented

with a spoon in the same orientation (handle to one side) readily adapted their motor actions when the spoon was presented with the handle to the other side, successfully transporting food to their mouths most of the time (McCarty & Keen, 2005).

These findings reveal that at the end of the first year, infants form flexible mental representations of how to use tools to get objects. They have some ability to move beyond trial-and-error experimentation, represent a solution mentally, and use it in new contexts.

Symbolic Understanding. One of the most momentous early attainments is the realization that words can be used to cue mental images of things not physically present—a symbolic capacity called **displaced reference** that emerges around the first birthday. It greatly expands toddlers' capacity to learn about the world through communicating with others. Observations of 12-month-olds reveal that they respond to the label of an absent toy by looking at and gesturing toward the spot where it usually rests (Saylor, 2004). As memory and vocabulary improve, skill at displaced reference expands.

But at first, toddlers have difficulty using language to acquire new information about an absent object—an ability that is essential to learn from symbols. In one study, an adult taught 19- and 22-month-olds a name for a stuffed animal—“Lucy” for a frog. Then, with the frog out of sight, the toddler was told that some water had spilled, so “Lucy's all wet!” Finally, the adult showed the toddler three stuffed animals—a wet frog, a dry frog, and a pig—and said, “Get Lucy!” (Ganea et al., 2007). Although all the children remembered that Lucy was a frog, only the 22-month-olds identified the wet frog as Lucy. This capacity to use language as a flexible symbolic tool—to modify and enrich existing mental representations—improves gradually into the preschool years.

Awareness of the symbolic function of pictures also emerges in the second year. Even newborns perceive a relation between a picture and its referent, as indicated by their preference for looking at a photo of their mother's face (see page 145 in Chapter 4). At the same time, infants do not treat pictures as symbols.

Rather, they touch, rub, and pat a color photo of an object, or pick it up and manipulate it. These behaviors, which reveal confusion about the picture's true nature, decline after 9 months, becoming rare around 18 months (DeLoache et al., 1988; DeLoache & Ganea, 2009).

As long as pictures strongly resemble real objects, by the middle of the second year toddlers treat them symbolically. After hearing a novel label (“blicket”) applied to a color photo of an unfamiliar object, most 15- to 24-month-olds—when presented with both the real object and its picture and asked to indicate the “blicket”—gave a symbolic response. They selected either the real object or both the object and its picture, not the picture alone (Ganea et al., 2009). Around this time, toddlers increasingly use pictures as vehicles for communicating with others and acquiring new knowledge (Ganea, Pickard, & DeLoache, 2008). They point to, name, and talk about pictures, and they can apply something learned from a book with realistic-looking pictures to real objects, and vice versa.

But even after coming to appreciate the symbolic nature of pictures, young children have difficulty grasping the distinction between some pictures (such as line drawings) and their referents, as we will see in Chapter 8. How do infants and toddlers interpret another ever-present, pictorial medium—video? Turn to the Social Issues: Education box on the following page to find out.

Evaluation of the Sensorimotor Stage

Table 5.2 summarizes the remarkable cognitive attainments we have just considered. **TAKE A MOMENT...** Compare this table with Piaget's description of the sensorimotor substages in Table 5.1 on page 153. You will see that infants anticipate events, actively search for hidden objects, master the A–B object search, flexibly vary their sensorimotor schemes, engage in make-believe play, and treat pictures and video images symbolically

within Piaget's time frame. Yet other capacities—including secondary circular reactions, understanding of object properties, first signs of object permanence, deferred imitation, problem solving by analogy, and displaced reference of words—emerge earlier than Piaget expected. These findings show that the cognitive attainments of infancy do not develop together in the neat, stepwise fashion that Piaget assumed.

Recent research raises questions about Piaget's view of how infant development takes place. Consistent with Piaget's ideas, sensorimotor action helps infants construct some forms of knowledge. For example, in Chapter 4, we saw that crawling enhances depth perception and ability to find hidden objects, and handling objects fosters awareness of object properties. Yet we have also seen that infants comprehend a great deal before they are capable of the motor behaviors that Piaget assumed led to those understandings. How can we account for babies' amazing cognitive accomplishments?

Alternative Explanations. Unlike Piaget, who thought young babies constructed all mental representations out of sensorimotor activity, most researchers now believe that infants have some built-in cognitive equipment for making sense of experience. But intense disagreement exists over the extent of this initial understanding. As we have seen, much evidence on young infants' cognition rests on the violation-of-expectation method. Researchers who lack confidence in this method argue that babies' cognitive starting point is limited (Campos et al., 2008; Cohen, 2010; Cohen & Cashon, 2006; Kagan, 2008). For example, some believe that newborns begin life with a set of biases for attending to certain information and with general-purpose learning procedures—such as powerful techniques for analyzing complex perceptual information. Together, these capacities enable infants to construct a wide variety of schemes (Bahrck, 2010; Huttenlocher, 2002; Quinn, 2008; Rakison, 2010).

TABLE 5.2 Some Cognitive Attainments of Infancy and Toddlerhood

AGE	COGNITIVE ATTAINMENTS
Birth–1 month	Secondary circular reactions using limited motor skills, such as sucking a nipple to gain access to interesting sights and sounds
1–4 months	Awareness of object permanence, object solidity, and gravity, as suggested by violation-of-expectation findings; deferred imitation of an adult's facial expression over a short delay (one day)
4–8 months	Improved knowledge of object properties and basic numerical knowledge, as suggested by violation-of-expectation findings; deferred imitation of an adult's novel actions on objects over a short delay (one to three days)
8–12 months	Ability to search for a hidden object when covered by a cloth; ability to solve simple problems by analogy to a previous problem
12–18 months	Ability to search in several locations for a hidden object, when a hand deposits it under a cloth, and when it is moved from one location to another (accurate A–B search); deferred imitation of an adult's novel actions on objects after long delays (at least several months) and across a change in situation (from child care to home); rational imitation, inferring the model's intentions; displaced reference of words
18 months–2 years	Ability to find an object moved while out of sight (invisible displacement); deferred imitation of actions an adult tries to produce, even if these are not fully realized; deferred imitation of everyday behaviors in make-believe play; beginning awareness of pictures and video as symbols of reality

TAKE A MOMENT... Which of the capacities listed in the table indicate that mental representation emerges earlier than Piaget believed?

Social Issues: Education

Baby Learning from TV and Video: The Video Deficit Effect

Children first become TV and video viewers in early infancy, as they are exposed to programs watched by parents and older siblings or to shows aimed at viewers not yet out of diapers, such as the Baby Einstein products. About 40 percent of U.S. 3-month-olds watch regularly, a figure that rises to 90 percent at age 2, a period during which average viewing time increases from just under an hour to 1½ hours a day (Zimmerman, Christakis, & Meltzoff, 2007). Although parents assume that babies learn from TV and videos, research indicates that they cannot take full advantage of them.

Initially, infants respond to videos of people as if viewing people directly—smiling, moving their arms and legs, and (by 6 months) imitating actions of a televised adult. But they confuse the images with the real thing (Barr, Muentener, & Garcia, 2007; Marian, Neisser, & Rochat, 1996). When shown videos of attractive toys, 9-month-olds manually explored the screen, as they do with pictures. By 19 months, touching and grabbing had declined in favor of pointing at the images (Pierroutsakos & Troseth, 2003). Nevertheless, toddlers continue to have difficulty applying what they see on video to real situations.

In a series of studies, some 2-year-olds watched through a window while a live adult hid an object in an adjoining room, while others watched the same event on a video screen. Children in the direct viewing condition retrieved the toy easily; those in the video condition had difficulty (Troseth, 2003; Troseth & DeLoache, 1998).

This **video deficit effect**—poorer performance after a video than a live demonstration—has also been found for 2-year-olds' deferred imitation, word learning, and means-end problem solving (Deocampo, 2003; Hayne, Herbert, & Simcock, 2003; Krcmar, Grela, & Linn, 2007).

One explanation is that 2-year-olds typically do not view a video character as offering socially relevant information. After an adult on video announced where she hid a toy, few 2-year-olds searched (Schmidt, Crawley-Davis, & Anderson, 2007). In contrast, when the adult uttered the same words while standing in front of the child, 2-year-olds promptly retrieved the object.

Toddlers seem to discount information on video as relevant to their everyday experiences because people do not look at and converse with them directly or establish a shared focus on objects, as their caregivers do. In one study, researchers gave some 2-year-olds an interactive video experience (using a two-way, closed-circuit video system). An adult on video interacted with the child for five minutes—calling the child by name, talking about the child's siblings and pets, waiting for the child to respond, and playing interactive games (Troseth, Saylor, & Archer, 2006). Compared with 2-year-olds who viewed the same adult in a noninteractive video, those in the interactive condition

© NIAH BALDOCK/ALAMY

This baby thinks the child she sees on the TV screen is real. Not until she is about 2½ will she understand how onscreen images relate to real people and objects.

were far more likely to use a verbal cue from a person on video to retrieve a toy.

Around age 2½, the video deficit effect declines. Before this age, the American Academy of Pediatrics (2001) recommends against mass media exposure. In support of this advice, amount of TV viewing is negatively related to 8- to 18-month-olds' language progress (Tanimura et al., 2004; Zimmerman, Christakis, & Meltzoff, 2007). And 1- to 3-year-old heavy viewers tend to have attention, memory, and reading difficulties in the early school years (Christakis et al., 2004; Zimmerman & Christakis, 2005).

When toddlers do watch TV and video, it is likely to work best as a teaching tool when it is rich in social cues—close-ups of characters who look directly at the camera, address questions to viewers, and pause to invite their response. Repetition of video programs also helps children over age 2 make sense of video content.

Others, convinced by violation-of-expectation findings, believe that infants start out with impressive understandings. According to this **core knowledge perspective**, babies are born with a set of innate knowledge systems, or *core domains of thought*. Each of these prewired understandings permits a ready grasp of new, related information and therefore supports early, rapid development (Carey & Markman, 1999; Leslie, 2004; Spelke, 2004; Spelke & Kinzler, 2007). Core knowledge theorists argue that infants could not make sense of the complex

stimulation around them without having been genetically “set up” in the course of evolution to comprehend its crucial aspects.

Researchers have conducted many studies of infants' *physical knowledge*, including object permanence, object solidity (that one object cannot move through another), and gravity (that an object will fall without support). Violation-of-expectation findings suggest that in the first few months, infants have some awareness of all these basic object properties and quickly build on this knowledge (Baillargeon, 2004; Hespos & Baillargeon,

2008; Luo & Baillargeon, 2005; Spelke, 2000). Core knowledge theorists also assume that an inherited foundation of *linguistic knowledge* enables swift language acquisition in early childhood—a possibility we will consider later in this chapter. Furthermore, these theorists argue, infants' early orientation toward people initiates rapid development of *psychological knowledge*—in particular, understanding of mental states, such as intentions, emotions, desires, and beliefs, which we will address further in Chapter 6.

Research even suggests that infants have basic *numerical knowledge*. In the best-known study, 5-month-olds saw a screen raised to hide a single toy animal and then watched a hand place a second toy behind the screen. Finally the screen was removed to reveal either one or two toys. If infants kept track of the two objects (requiring them to add one object to another), then they should look longer at the unexpected, one-toy display—which is what they did (see Figure 5.3) (Wynn, Bloom, & Chiang, 2002). These findings and those of similar investigations suggest that babies can discriminate quantities up to three and use that knowledge to perform simple arithmetic—both addition and subtraction (in which two objects are covered and one object is removed) (Kobayashi et al., 2004; Kobayashi, Hiraki, & Hasegawa, 2005; Wynn, Bloom, & Chiang, 2002).

Additional evidence suggests that 6-month-olds can distinguish among large sets of items, as long as the difference between those sets is very great—at least a factor of two. For example, they can tell the difference between 8 and 16 dots but not between

Did this toddler learn to build a block tower by repeatedly acting on objects, as Piaget assumed? Or did he begin life with innate knowledge that helps him understand objects and their relationships quickly, with little hands-on exploration?

6 and 12 (Lipton & Spelke, 2004; Xu, Spelke, & Goddard, 2005). As a result, some researchers believe that infants can represent approximate large-number values, in addition to the small-number discriminations evident in Figure 5.3.

But like other violation-of-expectation results, babies' numerical capacities are controversial. In experiments similar to those just described, looking preferences were inconsistent

FIGURE 5.3 Testing infants for basic number concepts. (a) First, infants saw a screen raised in front of a toy animal. Then an identical toy was added behind the screen. Next, the researchers presented two outcomes. (b) In the *expected outcome*, the screen dropped to reveal two toy animals. (c) In the *unexpected outcome*, the screen dropped to reveal one toy animal. Five-month-olds shown the unexpected outcome looked longer than did 5-month-olds shown the expected outcome. The researchers concluded that infants can discriminate the quantities “one” and “two” and use that knowledge to perform simple addition: $1 + 1 = 2$. A variation of this procedure suggested that 5-month-olds could also do simple subtraction: $2 - 1 = 1$. (From K. Wynn, 1992, “Addition and Subtraction by Human Infants.” *Nature*, 358, p. 749. © 1992 by Nature Publishing Group. Adapted with permission of Macmillan Publishers, Ltd.)

(Langer, Gillette, & Arriaga, 2003; Wakeley, Rivera, & Langer, 2000). These researchers point out that claims for infants' knowledge of number concepts are surprising, in view of other research indicating that before 14 to 16 months, toddlers have difficulty making less-than and greater-than comparisons between small sets. And not until the preschool years do children answer correctly when asked to add and subtract small sets.

The core knowledge perspective, while emphasizing native endowment, acknowledges that experience is essential for children to extend this initial knowledge. But so far, it has said little about which experiences are most important in each core domain of thought and how those experiences advance children's thinking. Despite ongoing challenges from critics, core knowledge research has sharpened the field's focus on specifying the starting point of human cognition and carefully tracking the changes that build on it.

Piaget's Legacy. Follow-up research on Piaget's sensorimotor stage yields broad agreement on two issues. First, many cognitive changes of infancy are gradual and continuous rather than abrupt and stagelike, as Piaget thought (Bjorklund, 2012; Courage & Howe, 2002). Second, rather than developing together, various aspects of infant cognition change unevenly because of the challenges posed by different types of tasks and infants' varying experience with them. These ideas serve as the basis for another major approach to cognitive development—*information processing*.

Before we turn to this alternative point of view, let's recognize Piaget's enormous contributions. Piaget's work inspired a wealth of research on infant cognition, including studies that challenged his theory. Today, researchers are far from consensus on how to modify or replace his account of infant cognitive development, and some believe that his general approach continues to make sense and fits most of the evidence (Cohen, 2010). Piaget's observations also have been of great practical value. Teachers and caregivers continue to look to the sensorimotor stage for guidelines on how to create developmentally appropriate environments for infants and toddlers.

ASK YOURSELF

REVIEW Using the text discussion on pages 155–158, construct your own summary table of infant and toddler cognitive development. Which entries in your table are consistent with Piaget's sensorimotor stage? Which ones develop earlier than Piaget anticipated?

REFLECT What advice would you give the typical U.S. parent about permitting an infant or toddler to watch as much as 1 to 1½ hours of TV or video per day? Explain.

Information Processing

Information-processing researchers agree with Piaget that children are active, inquiring beings. But instead of providing a single, unified theory of cognitive development, they focus on many aspects of thinking, from attention, memory, and categorization skills to complex problem solving.

Recall from Chapter 1 that the information-processing approach frequently relies on computer-like flowcharts to describe the human cognitive system. Information-processing theorists are not satisfied with general concepts, such as assimilation and accommodation, to describe how children think. Instead, they want to know exactly what individuals of different ages do when faced with a task or problem (Birney & Sternberg, 2011; Miller, 2009). The computer model of human thinking is attractive because it is explicit and precise.

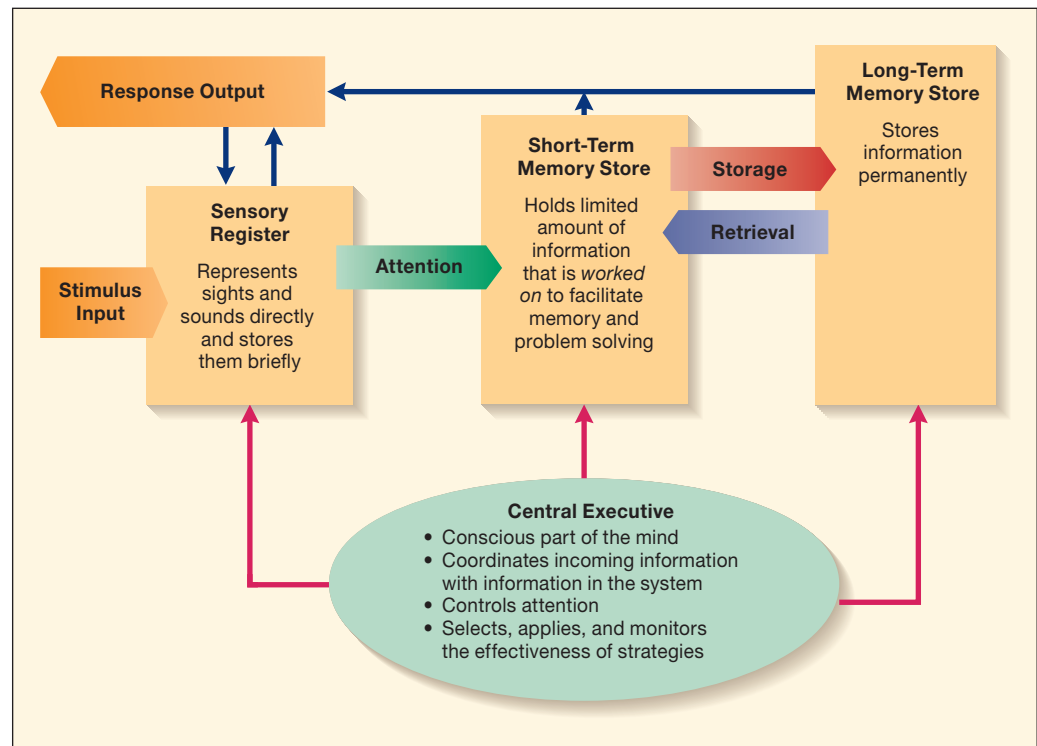

A General Model of Information Processing

Most information-processing researchers assume that we hold information in three parts of the mental system for processing: the *sensory register*, the *short-term memory store*, and the *long-term memory store* (see Figure 5.4 on page 162). As information flows through each, we can use *mental strategies* to operate on and transform it, increasing the chances that we will retain information, use it efficiently, and think flexibly, adapting the information to changing circumstances. To understand this more clearly, let's look at each component of the mental system.

First, information enters the **sensory register**, where sights and sounds are represented directly and stored briefly. **TAKE A MOMENT...** Look around you, and then close your eyes. An image of what you saw persists for a few seconds, but then it decays, or disappears, unless you use mental strategies to preserve it. For example, by *attending* to some information more carefully than to other information, you increase the chances that it will transfer to the next step of the information-processing system.

In the second part of the mind, the **short-term memory store**, we retain attended-to information briefly so we can actively “work” on it to reach our goals. One way of looking at the short-term store is in terms of its *basic capacity*, often referred to as *short-term memory*: how many pieces of information can be held at once for a few seconds. But most researchers endorse a contemporary view of the short-term store, which offers a more meaningful indicator of its capacity, called **working memory**—the number of items that can be briefly held in mind while also engaging in some effort to monitor or manipulate those items. Working memory can be thought of as a “mental workspace” that we use to accomplish many activities in daily life. From childhood on, researchers assess changes in working-memory capacity by presenting individuals with lists of items (such as numerical digits or short sentences), asking them to “work” on the items (for example, repeat the digits backward or remember the final word of each sentence in correct order), and seeing how well they do.

FIGURE 5.4 Model of the human information-processing system. Information flows through three parts of the mental system: the *sensory register*, the *short-term memory store*, and the *long-term memory store*. In each, mental strategies can be used to manipulate information, increasing the efficiency and flexibility of thinking and the chances that information will be retained. The *central executive* is the conscious, reflective part of the mental system. It coordinates incoming information with information already in the system, decides what to attend to, and oversees the use of strategies.

The sensory register can take in a wide panorama of information. Short-term and working memory are far more restricted, though their capacity increases steadily from early childhood to early adulthood—on a verbatim digit-span task tapping short-term memory, from about 2 to 7 items; and on working-memory tasks, from about 2 to 5 items (Cowan & Alloway, 2009). Still, individual differences are evident at all ages. By engaging in a variety of basic cognitive procedures, such as focusing attention on relevant items and repeating (rehearsing) them rapidly, we increase the chances that information will be retained and accessible to ongoing thinking.

To manage the cognitive system's activities, the **central executive** directs the flow of information, implementing the basic procedures just mentioned and also engaging in more sophisticated activities that enable complex, flexible thinking. For example, the central executive coordinates incoming information with information already in the system, and it selects, applies, and monitors strategies that facilitate memory storage, comprehension, reasoning, and problem solving (Pressley & Hilden, 2006). The central executive is the conscious, reflective part of our mental system. It ensures that we think purposefully, to attain our goals.

The more effectively the central executive joins with working memory to process information, the better learned cognitive activities will be and the more *automatically* we can apply them. Consider the richness of your thinking while you automatically drive a car. **Automatic processes** are so well-learned that they require no space in working memory and, therefore, permit us to focus on other information while performing them. Furthermore, the more effectively we process information in working memory,

the more likely it will transfer to the third, and largest, storage area—**long-term memory**, our permanent knowledge base, which is unlimited. In fact, we store so much in long-term memory that *retrieval*—getting information back from the system—can be problematic. To aid retrieval, we apply strategies, just as we do in working memory. Information in long-term memory is *categorized* by its contents, much like a library shelving system that enables us to retrieve items by following the same network of associations used to store them in the first place.

Information-processing research indicates that several aspects of the cognitive system improve during childhood and adolescence: (1) the *basic capacity* of its stores, especially working memory; (2) the *speed* with which information is worked on; and (3) the *functioning of the central executive*. Together, these changes make possible more complex forms of thinking with age (Case, 1998; Kail, 2003).

Gains in working-memory capacity are due in part to brain development, but greater processing speed also contributes. Fast, fluent thinking frees working-memory resources to support storage and manipulation of additional information. Furthermore, researchers have become increasingly interested in studying the development of **executive function**—the diverse cognitive operations and strategies that enable us to achieve our goals in cognitively challenging situations (Welsh, Friedman, & Spieker, 2008). These include controlling attention, suppressing impulses, coordinating information in working memory, and flexibly directing and monitoring thought and behavior. As we will see, gains in working memory capacity and aspects of executive function are under way in the first two years; dramatic strides will follow in childhood and adolescence.

Attention

Recall from Chapter 4 that around 2 to 3 months of age, infants shift from focusing on single, high-contrast features to exploring objects and patterns more thoroughly. Besides attending to more aspects of the environment, infants gradually become more efficient at managing their attention, taking in information more quickly. Habituation research reveals that preterm and newborn babies require a long time—about 3 to 4 minutes—to habituate and recover to novel visual stimuli. But by 4 or 5 months, they need as little as 5 to 10 seconds to take in a complex visual stimulus and recognize it as different from a previous one (Rose, Feldman, & Jankowski, 2001; Slater et al., 1996).

One reason that very young babies' habituation times are so much longer is their difficulty disengaging attention from a stimulus (Colombo, 2002). When Carolyn held up a colorful rattle, 2-month-old Caitlin stared intently until, unable to break her gaze, she burst into tears. The ability to shift attention from one stimulus to another improves by 4 months—a change believed to be due to development of structures in the cerebral cortex controlling eye movements (Bhaga & Colombo, 2006; Posner & Rothbart, 2007).

Over the first year, infants attend to novel and eye-catching events. In the second year, as toddlers become increasingly capable of intentional behavior (refer back to Piaget's Substage 4), attraction to novelty declines (but does not disappear) and *sustained attention* improves, especially when children play with toys. A toddler who engages even in simple goal-directed behavior, such as stacking blocks or putting them in a container, must sustain attention to reach the goal (Ruff & Capozzoli, 2003). As plans and activities gradually become more complex, the duration of attention increases.

Memory

Operant conditioning and habituation provide windows into early memory. Both methods show that retention of visual events increases dramatically over infancy and toddlerhood.

Using operant conditioning, researchers study infant memory by teaching 2- to 6-month-olds to move a mobile by kicking a foot tied to it with a long cord. Two-month-olds remember how to activate the mobile for 1 to 2 days after training, and 3-month-olds for one week. By 6 months, memory increases to two weeks (Rovee-Collier, 1999; Rovee-Collier & Bhatt, 1993). Around the middle of the first year, babies can manipulate switches or buttons to control stimulation. When 6- to 18-month-olds pressed a lever to make a toy train move around a track, duration of memory continued to increase with age; 13 weeks after training, 18-month-olds still remembered how to press the lever (see Figure 5.5) (Hartshorn et al., 1998).

Even after 2- to 6-month-olds forget an operant response, they need only a brief prompt—an adult who shakes the mobile—to reinstate the memory (Hildreth & Rovee-Collier, 2002). And when 6-month-olds are given a chance to reactivate the response themselves for just a couple of minutes, their memory not only returns but extends dramatically, to about

17 weeks (Hildreth, Sweeney, & Rovee-Collier, 2003). Perhaps permitting the baby to generate the previously learned behavior strengthens memory because it reexposes the child to more aspects of the original learning situation.

Habituation studies show that infants learn and retain a wide variety of information just by watching objects and events, without being physically active. Sometimes, they do so for much longer time spans than in operant conditioning studies. Babies are especially attentive to the movements of objects and people. In one investigation, 5½-month-olds remembered a woman's captivating action (such as blowing bubbles or brushing hair) seven weeks later, as indicated by a *familiarity preference* (see page 135 in Chapter 4) (Bahrick, Gogate, & Ruiz, 2002). The babies were so attentive to the woman's action that they did not remember her face, even when tested 1 minute later for a *novelty preference*.

In Chapter 4, we saw that 3- to 5-month-olds are excellent at discriminating faces. But their memory for the faces of unfamiliar people and for other visual patterns is short-lived—at 3 months, only about 24 hours, and at the end of the first year, several days to a few weeks (Fagan, 1973; Pascalis, de Haan, & Nelson, 1998). By contrast, 3-month-olds' memory for the unusual movements of objects (such as a metal nut swinging on the end of a string) persists for at least three months (Bahrick, Hernandez-Reif, & Pickens, 1997).

FIGURE 5.5 Increase in retention in two operant conditioning tasks from 2 to 18 months. Two- to 6-month-olds were trained to make a kicking response that turned a mobile. Six- to 18-month-olds were trained to press a lever that made a toy train move around a track. Six-month-olds learned both responses and retained them for an identical length of time, indicating that the tasks are comparable. Consequently, researchers could plot a single line tracking gains in retention of operant responses from 2 to 18 months of age. The line shows that memory improves dramatically. (From C. Rovee-Collier & R. Barr, 2001, "Infant Learning and Memory," in G. Bremner & A. Fogel, [Eds.], *Blackwell Handbook of Infant Development*, Oxford, U.K.: Blackwell, p. 150. © 2001, 2004 by Blackwell Publishing Ltd. Reproduced with permission of John Wiley & Sons Ltd.)

Biology and Environment

Infantile Amnesia

If infants and toddlers recall many aspects of their everyday lives, how do we explain **infantile amnesia**—that most of us cannot retrieve events that happened to us before age 3? The reason cannot be merely the passage of time because we can recall many personally meaningful one-time events from both the recent and the distant past: the day a sibling was born or a move to a new house—recollections known as **autobiographical memory**.

Several accounts of infantile amnesia exist. One theory credits brain development, suggesting that vital changes in the prefrontal cortex pave the way for an *explicit* memory system—one in which children remember deliberately rather than *implicitly*, without conscious awareness (Nelson, 1995). But mounting evidence indicates that even young infants engage in conscious recall (Bauer, 2006; Rovee-Collier & Cuevas, 2009). Their memory processing is not fundamentally different from that of children and adults.

Another conjecture is that older children and adults often use verbal means for storing information, whereas infants' and

toddlers' memory processing is largely nonverbal—an incompatibility that may prevent long-term retention of early experiences. To test this idea, researchers sent two adults to the homes of 2- to 4-year-olds with an unusual toy that the children were likely to remember: The Magic Shrinking Machine, shown in Figure 5.6. One adult showed the child how, after inserting an object in an opening on top of the machine and turning a crank that activated flashing lights and musical sounds, the child could retrieve a smaller, identical object (discretely dropped down a chute by the second adult) from behind a door on the front of the machine.

A day later, the researchers tested the children to see how well they recalled the event. Their nonverbal memory—based on acting out the “shrinking” event and recognizing the “shrunk” objects in photos—was excellent. But even when they had the vocabulary, children younger than age 3 had trouble describing features of the “shrinking” experience. Verbal recall increased sharply between ages 3 and 4—the period during which children “scramble over the

amnesia barrier” (Simcock & Hayne, 2003, p. 813). In a second study, preschoolers could not translate their nonverbal memory for the game into language 6 months to 1 year later, when their language had improved dramatically. Their verbal reports were “frozen in time,” reflecting their limited language skill at the age they played the game (Simcock & Hayne, 2002).

These findings help us reconcile infants' and toddlers' remarkable memory skills with infantile amnesia. During the first few years, children rely heavily on nonverbal memory techniques, such as visual images and motor actions. As language develops, preschoolers can use it to refer to preverbal memories. But their ability to do so is fragile, requiring strong contextual cues, such as direct exposure to the physical setting of the to-be-recalled experience (Morris & Baker-Ward, 2007). Only after age 3 do children often represent events verbally and participate in elaborate conversations with adults about them. As children encode autobiographical events in verbal form, they use language-based cues to retrieve them, increasing the accessibility of these memories at later ages (Peterson, Warren, & Short, 2011).

By 10 months, infants remember both novel actions and features of objects involved in those actions equally well (Horst, Oakes, & Madole, 2005). Thus, over the second half-year, sensitivity to object appearance increases. This change is fostered by infants' increasing ability to manipulate objects, which helps them learn about objects' observable properties.

So far, we have discussed only **recognition**—noticing when a stimulus is identical or similar to one previously experienced. It is the simplest form of memory: All babies have to do is indicate (by kicking, pressing a lever, or looking) that a new stimulus is identical or similar to a previous one. **Recall** is more challenging because it involves remembering something not present. But by the second half of the first year, infants are capable of recall, as indicated by their ability to find hidden objects and engage in deferred imitation. Recall, too, improves steadily with age. For example, 1-year-olds can retain short sequences of adult-modeled behaviors for up to 3 months, and 1½-year-olds can do so for as long as 12 months (Rovee-Collier & Cuevas, 2009).

Long-term recall depends on connections among multiple regions of the cerebral cortex, especially with the prefrontal cortex. During infancy and toddlerhood, these neural circuits develop rapidly (Nelson, Thomas, & de Haan, 2006). Yet a puzzling finding is that older children and adults no longer recall their earliest experiences! See the Biology and Environment box above for a discussion of *infantile amnesia*.

Categorization

Even young infants can *categorize*, grouping similar objects and events into a single representation. Categorization reduces the enormous amount of new information infants encounter every day, helping them learn and remember (Rakison, 2010).

Creative variations of operant conditioning research with mobiles have been used to investigate infant categorization. One such study, of 3-month-olds, is described and illustrated in

Other findings indicate that the advent of a clear self-image contributes to the end of infantile amnesia (Howe, Courage, & Rooksby, 2009). Toddlers who were advanced in development of a sense of self demonstrated better verbal memories a year later while conversing about past

events with their mothers (Harley & Reese, 1999).

Very likely, both neurobiological change and social experience contribute to the decline of infantile amnesia. Brain development and adult–child interaction may jointly foster self-awareness, language, and

improved memory, which enable children to talk with adults about significant past experiences (Bauer, 2007). As a result, preschoolers begin to construct a long-lasting autobiographical narrative of their lives and enter into the history of their family and community.

FIGURE 5.6 The Magic Shrinking Machine, used to test young children’s verbal and nonverbal memory of an unusual event. After being shown how the machine worked, the child participated in selecting objects from a polka-dot bag, dropping them into the top of the machine (a), and turning a crank, which produced a “shrunken” object (b). When tested the next day, 2- to 4-year-olds’ nonverbal memory for the event was excellent. But below 36 months, verbal recall was poor, based on the number of features recalled about the game during an open-ended interview (c). Recall improved between 36 and 48 months, the period during which infantile amnesia subsides. (From G. Simcock & H. Hayne, 2003, “Age-Related Changes in Verbal and Nonverbal Memory During Early Childhood,” *Developmental Psychology*, 39, pp. 807, 809. Copyright © 2003 by the American Psychological Association. Reprinted with permission of the American Psychological Association. Photos: Ross Coombes/Courtesy of Harlene Hayne.)

Figure 5.7 on page 166. Similar investigations reveal that in the first few months, babies categorize stimuli on the basis of shape, size, and other physical properties (Wasserman & Rovee-Collier, 2001). By 6 months of age, they can categorize on the basis of two correlated features—for example, the shape and color of an alphabet letter (Bhatt et al., 2004). This ability to categorize using clusters of features prepares babies for acquiring many complex everyday categories.

Habituation has also been used to study infant categorization. Researchers show babies a series of pictures belonging to one category and then see whether they recover to (look longer at) a picture that is not a member of the category. Findings reveal that in the second half of the first year, as long as they have sufficient familiarity with category members, infants group objects into an impressive array of categories—food items, furniture, birds, land animals, air animals, sea animals, plants, vehicles, kitchen utensils, and spatial location (“above” and “below,” “on” and “in”) (Bornstein, Arterberry, & Mash, 2010; Casasola,

Cohen, & Chiarello, 2003; Oakes, Coppage, & Dingel, 1997). Besides organizing the physical world, infants of this age categorize their emotional and social worlds. They sort people and their voices by gender and age, have begun to distinguish emotional expressions, separate people’s natural actions (walking) from other motions, and expect people (but not inanimate objects) to move spontaneously (Spelke, Phillips, & Woodward, 1995; see also Chapter 4, pages 144–145).

Babies’ earliest categories are based on similar overall appearance or prominent object part: legs for animals, wheels for vehicles. By the second half of the first year, more categories appear to be based on subtle sets of features (Cohen, 2003; Mandler, 2004; Quinn, 2008). Older infants can even make categorical distinctions when the perceptual contrast between two categories is minimal (birds versus airplanes).

As they gain experience in comparing to-be-categorized items in varied ways and as their store of verbal labels expands, toddlers start to categorize flexibly: When 14-month-olds are

COURTESY OF CAROLYN ROVEE-COLLIER

FIGURE 5.7 Investigating infant categorization using operant conditioning. Three-month-olds were taught to kick to move a mobile that was made of small blocks, all with the letter A on them. After a delay, kicking returned to a high level only if the babies were shown a mobile whose elements were labeled with the same form (the letter A). If the form was changed (from As to 2s), infants no longer kicked vigorously. While making the mobile move, the babies had grouped together its features. They associated the kicking response with the category A and, at later testing, distinguished it from the category 2. (Bhatt, Rovee-Collier, & Weiner, 1994; Hayne, Rovee-Collier, & Perris, 1987.)

given four balls and four blocks, some made of soft rubber and some of rigid plastic, their sequence of object touching reveals that after classifying by shape, they can switch to classifying by material (soft versus hard) if an adult calls their attention to the new basis for grouping (Ellis & Oakes, 2006).

In addition to touching and sorting, toddlers' categorization skills are evident in their play behaviors. After watching an adult give a toy dog a drink from a cup, most 14-month-olds shown a rabbit and a motorcycle offered the drink only to the rabbit (Mandler & McDonough, 1998). They clearly understood that certain actions are appropriate for some categories of items (animals) and not others (vehicles).

By the end of the second year, toddlers' grasp of the animate-inanimate distinction expands. Nonlinear motions are typical of animates (a person or a dog jumping), linear motions of inanimates (a car or a table pushed along a surface). At 18 months, toddlers more often imitate a nonlinear motion with a toy that has animate-like parts (legs), even if it represents an inanimate (a bed). At 22 months, displaying a fuller understanding, they imitate a nonlinear motion only with toys in the animate category (a cat but not a bed) (Rakison, 2005, 2006). They seem to realize that whereas animates are self-propelled and therefore

have varied paths of movement, inanimates move only when acted on, in highly restricted ways.

Researchers disagree on how toddlers gradually shift from categorizing on the basis of prominent perceptual features (things with flapping wings and feathers belong to one category; things with rigid wings and a smooth surface to another) to categorizing on a conceptual basis, grouping objects by their common function or behavior (birds versus airplanes, dogs versus cats) (Oakes et al., 2009; Rakison & Lupyan, 2008). But all acknowledge that exploration of objects and expanding knowledge of the world contribute. In addition, adult labeling of a set of objects with a consistently applied word ("Look at the car!" "Do you see the car?") calls babies' attention to commonalities among objects, fostering categorization as early as 3 to 4 months of age (Ferry, Hespos, & Waxman, 2010). Toddlers' vocabulary growth, in turn, fosters categorization (Cohen & Brunt, 2009; Waxman, 2003).

Variations among languages lead to cultural differences in development of categories. Korean toddlers, who learn a language in which object names are often omitted from sentences, develop object-sorting skills later than their English-speaking counterparts (Gopnik & Choi, 1990). At the same time, Korean contains a common word, *kkita*, with no English equivalent, referring to a tight fit between objects in contact (a ring on a finger, a cap on a pen), and Korean toddlers are advanced in forming the spatial category "tight fit" (Choi et al., 1999).

Evaluation of Information-Processing Findings

The information-processing perspective underscores the continuity of human thinking from infancy into adult life. In attending to the environment, remembering everyday events, and categorizing objects, Caitlin, Grace, and Timmy think in ways that are remarkably similar to our own, though their mental processing is far from proficient. Findings on memory and categorization join with other research in challenging Piaget's view of early cognitive development. Infants' capacity to recall events and to categorize stimuli attests, once again, to their ability to mentally represent their experiences.

Information-processing research has contributed greatly to our view of infants and toddlers as sophisticated cognitive beings. But its central strength—analyzing cognition into its components, such as perception, attention, memory, and categorization—is also its greatest drawback: Information processing has had difficulty putting these components back together into a broad, comprehensive theory.

One approach to overcoming this weakness has been to combine Piaget's theory with the information-processing approach, an effort we will explore in Chapter 9. A more recent trend has been the application of a *dynamic systems view* (see Chapter 4, pages 137–138) to early cognition. In this approach, researchers analyze each cognitive attainment to see how it results from a complex system of prior accomplishments and the child's current goals (Spencer & Perone, 2008; Thelen & Smith, 2006).

Once these ideas are fully tested, they may move the field closer to a more powerful view of how the minds of infants and children develop.

The Social Context of Early Cognitive Development

Recall the description at the beginning of this chapter of Grace dropping shapes into a container. Notice that she learns about the toy with Ginette's help. With adult support, Grace will gradually become better at matching shapes to openings and dropping them into the container. Then she will be able to perform this and similar activities on her own.

Vygotsky's sociocultural theory emphasizes that children live in rich social and cultural contexts that affect the way their cognitive world is structured (Bodrova & Leong, 2007; Rogoff, 2003). Vygotsky believed that complex mental activities have their origins in social interaction. Through joint activities with more mature members of their society, children master activities and think in ways that have meaning in their culture.

A special Vygotskian concept explains how this happens. The **zone of proximal** (or potential) **development** refers to a range of tasks too difficult for the child to do alone but possible with the help of more skilled partners. To understand this idea, think about how a sensitive adult (such as Ginette) introduces a child to a new activity. The adult picks a task that the child can master but that is challenging enough that the child cannot do it by herself. As the adult guides and supports, the child joins in the interaction and picks up mental strategies. As her competence increases, the adult steps back, permitting the child to take more responsibility for the task. This form of teaching—known as *scaffolding*—promotes learning at all ages, and we will consider it further in Chapter 7.

Vygotsky's ideas have been applied mostly to older children, who are more skilled in language and social communication. Recently, however, his theory has been extended to infancy and toddlerhood. Recall that babies are equipped with capacities that ensure that caregivers will interact with them. Then adults adjust the environment and their communication in ways that promote learning adapted to their cultural circumstances.

A study by Barbara Rogoff and her collaborators (1984) illustrates this process. Placing a jack-in-the-box nearby, the researchers watched how several adults played with Rogoff's son and daughter over the first two years. In the early months, the adults tried to focus the baby's attention by working the toy and, as the bunny popped out, saying something like "My, what happened?" By the end of the first year, when the baby's cognitive and motor skills had improved, interaction centered on how to use the toy. The adults guided the baby's hand in turning the crank and putting the bunny back in the box. During the second year, adults helped from a distance, using gestures and verbal prompts, such as making a turning motion with the hand near

the crank. Research indicates that this fine-tuned support is related to advanced play, language, and problem solving in toddlerhood and early childhood (Bornstein et al., 1992; Charman et al., 2001; Tamis-LeMonda & Bornstein, 1989).

As early as the first year, cultural variations in social experiences affect mental strategies. In the jack-in-the-box example, adults and children focused their attention on a single activity. This strategy, common in Western middle-SES homes, is well-suited to lessons in which children master skills apart from the everyday situations in which they will later use those skills. In contrast, Guatemalan Mayan adults and babies often attend to several events at once. For example, one 12-month-old skillfully put objects in a jar while watching a passing truck and blowing into a toy whistle (Chavajay & Rogoff, 1999). Processing several competing events simultaneously may be vital in cultures where children largely learn through keen observation of others' ongoing activities. Children of Guatemalan Mayan, Mexican, and Native-American parents without extensive education continue to display this style of attention well into middle childhood (Chavajay & Rogoff, 2002; Correa-Chavez, Rogoff, & Mejía-Arauz, 2005; Philips, 1983).

Earlier we saw how infants and toddlers create new schemes by acting on the physical world (Piaget) and how certain skills become better developed as children represent their experiences more efficiently and meaningfully (information processing). Vygotsky adds a third dimension to our understanding by emphasizing that many aspects of cognitive development are socially mediated. The Cultural Influences box on page 168 presents additional evidence for this idea, and we will see even more in the next section.

Using simple words and gestures, this mother brings a challenging task—rotating the plane's propeller—within her toddler's zone of proximal development. By adjusting her communication to suit the child's needs, she transfers mental strategies to him and promotes learning.

Cultural Influences

Social Origins of Make-Believe Play

One of the activities my husband, Ken, used to do with our two sons when they were young was to bake pineapple upside-down cake, a favorite treat. One Sunday afternoon when a cake was in the making, 21-month-old Peter stood on a chair at the kitchen sink, busily pouring water from one cup to another.

“He’s in the way, Dad!” complained 4-year-old David, trying to pull Peter away from the sink.

“Maybe if we let him help, he’ll give us room,” Ken suggested. As David stirred the batter, Ken poured some into a small bowl for Peter, moved his chair to the side of the sink, and handed him a spoon.

“Here’s how you do it, Petey,” instructed David, with a superior air. Peter watched as David stirred, then tried to copy his motion. When it was time to pour the batter, Ken helped Peter hold and tip the small bowl.

“Time to bake it,” said Ken.

“Bake it, bake it,” repeated Peter, watching Ken slip the pan into the oven.

Several hours later, we observed one of Peter’s earliest instances of make-believe play. He got his pail from the sandbox and, after filling it with a handful of sand, carried it into the kitchen and put it down on the floor in front of the oven. “Bake it, bake it,” Peter called to Ken. Together, father and son placed the pretend cake in the oven.

Piaget and his followers concluded that toddlers discover make-believe independently, once they are capable of representational schemes. Vygotsky challenged this view, pointing out that society provides children with opportunities to represent culturally meaningful activities in play. Make-believe, like other complex mental activities, is first learned under the guidance of experts (Berk, Mann, & Ogan, 2006). In the example just described, Peter extended his capacity to represent daily events when Ken drew him into the baking task and helped him act it out in play.

Current evidence supports the idea that early make-believe is the combined result of children’s readiness to engage in it and social experiences that promote it. In one observational study of U.S. middle-SES toddlers, 75 to 80 percent of make-believe involved mother-child interaction (Haight & Miller, 1993). At 12 months, almost all play episodes were initiated by mothers, but by the end of the second year, half of pretend episodes were initiated by each.

During make-believe, mothers offer toddlers a rich array of cues that they are pretending—looking and smiling at the child more, making more exaggerated movements, and using more “we” talk (acknowledging that pretending is a joint endeavor) than they do during the same real-life event (Lillard, 2007). These maternal cues encourage toddlers to join in and probably facilitate their ability to distinguish pretend from real acts, which strengthens over the second and third years (Lillard & Witherington, 2004; Ma & Lillard, 2006).

Also, when adults participate, toddlers’ make-believe is more elaborate (Keren et al., 2005). They are more likely to combine pretend acts into complex sequences, as Peter did when he put sand in the bucket (making the batter), carried it into the kitchen, and, with Ken’s help, put it in the oven (baking the cake). The more parents pretend with their toddlers, the more time their children devote to make-believe.

In some cultures, such as those of Indonesia and Mexico, where extended-family households and sibling caregiving are common, make-believe is more frequent and complex with older siblings than with mothers. As early as age 3 to 4, children provide rich, challenging stimulation to their younger brothers and sisters, take these teaching responsibilities seriously, and, with age, become better at them (Zukow-Goldring, 2002). In a study of Zinacanteco Indian children of southern Mexico, by

© CAROLINE PENN/PANOS PICTURES

A Kenyan child guides his younger brother in pretend play. In cultures where sibling caregiving is common, make-believe play is more frequent and complex with older siblings than with mothers.

age 8, sibling teachers were highly skilled at showing 2-year-olds how to play at everyday tasks, such as washing and cooking (Maynard, 2002). They often guided toddlers verbally and physically through the task and provided feedback.

In Western middle-SES families, older siblings less often teach deliberately but still serve as influential models of playful behavior. In a study of New Zealand families of Western European descent, when both a parent and an older sibling were available, toddlers more often imitated the actions of the sibling, especially when siblings engaged in make-believe (Barr & Hayne, 2003).

As we will see in Chapter 7, make-believe play is a major means through which children extend their cognitive skills and learn about important activities in their culture. Vygotsky’s theory, and the findings that support it, tell us that providing a stimulating physical environment is not enough to promote early cognitive development. In addition, toddlers must be invited and encouraged by more skilled members of their culture to participate in the social world around them. Parents and teachers can enhance early make-believe by playing often with toddlers, guiding and elaborating on their make-believe themes.

ASK YOURSELF

REVIEW What impact does toddlers' more advanced play with toys have on the development of attention?

CONNECT List techniques parents can use to *scaffold* the development of categorization in infancy and toddlerhood, and explain why each is effective.

APPLY When Timmy was 18 months old, his mother stood behind him, helping him throw a large ball into a box. As his skill improved, she stepped back, letting him try on his own. Using Vygotsky's ideas, explain how Timmy's mother is supporting his cognitive development.

REFLECT Describe your earliest autobiographical memory. How old were you when the event occurred? Do your responses fit with research on infantile amnesia?

Individual Differences in Early Mental Development

Because of Grace's deprived early environment, Kevin and Monica had a psychologist give her one of many tests available for assessing mental development in infants and toddlers. Worried about Timmy's progress, Vanessa also arranged for him to be tested. At age 22 months, he had only a handful of words in his vocabulary, played in a less mature way than Caitlin and Grace, and seemed restless and overactive.

The cognitive theories we have just discussed try to explain the *process* of development—how children's thinking changes. Mental tests, in contrast, focus on cognitive *products*. Their goal is to measure behaviors that reflect development and to arrive at scores that *predict* future performance, such as later intelligence, school achievement, and adult vocational success. This concern with prediction arose nearly a century ago, when French psychologist Alfred Binet designed the first successful intelligence test, which predicted school achievement (see Chapter 1). It inspired the design of many new tests, including ones that measure intelligence at very early ages.

Infant and Toddler Intelligence Tests

Accurately measuring infants' intelligence is a challenge because babies cannot answer questions or follow directions. All we can do is present them with stimuli, coax them to respond, and observe their behavior. As a result, most infant tests emphasize perceptual and motor responses. But new tests are being developed that also tap early language, cognition, and social behavior, especially with older infants and toddlers.

One commonly used test, the *Bayley Scales of Infant and Toddler Development*, is suitable for children between 1 month

and 3½ years. The most recent edition, the Bayley-III, has three main subtests: (1) the Cognitive Scale, which includes such items as attention to familiar and unfamiliar objects, looking for a fallen object, and pretend play; (2) the Language Scale, which assesses understanding and expression of language—for example, recognition of objects and people, following simple directions, and naming objects and pictures; and (3) the Motor Scale, which includes gross and fine motor skills, such as grasping, sitting, stacking blocks, and climbing stairs (Bayley, 2005).

Two additional Bayley-III scales depend on parental report: (4) the Social-Emotional Scale, which asks caregivers about such behaviors as ease of calming, social responsiveness, and imitation in play; and (5) the Adaptive Behavior Scale, which asks about adaptation to the demands of daily life, including communication, self-control, following rules, and getting along with others.

Computing Intelligence Test Scores. Intelligence tests for infants, children, and adults are scored in much the same way—by computing an **intelligence quotient (IQ)**, which indicates the extent to which the raw score (number of items passed) deviates from the typical performance of same-age individuals. To make this comparison possible, test designers engage in **standardization**—giving the test to a large, representative sample and using the results as the *standard* for interpreting scores. The standardization sample for the Bayley-III included 1,700 infants, toddlers, and young preschoolers, reflecting the U.S. population in SES and ethnic diversity.

Within the standardization sample, performances at each age level form a **normal distribution**, in which most scores cluster around the mean, or average, with progressively fewer falling toward the extremes (see Figure 5.8 on page 170). This *bell-shaped distribution* results whenever researchers measure individual differences in large samples. When intelligence tests are standardized, the mean IQ is set at 100. An individual's IQ is higher or lower than 100 by an amount that reflects how much

© PHOTO BY STEPHEN AUSMUS, USDAVARS

A trained examiner administers a test based on the Bayley Scales of Infant Development to a 1-year-old sitting in her mother's lap. Compared with earlier editions, the Bayley-III Cognitive and Language Scales better predict preschool mental test performance.

FIGURE 5.8 Normal distribution of intelligence test scores. To determine the percentage of same-age individuals in the population a person with a certain IQ outperformed, add the figures to the left of that IQ score. For example, an 8-year-old child with an IQ of 115 scored better than 84 percent of the population of 8-year-olds.

his or her test performance deviates from the standardization-sample mean.

The IQ offers a way of finding out whether an individual is ahead, behind, or on time (average) in mental development compared with others of the same age. For example, if Timmy's score is 100, then he did better than 50 percent of his agemates. A child with an IQ of 85 did better than only 16 percent, whereas a child with an IQ of 130 outperformed 98 percent. The IQs of 96 percent of individuals fall between 70 and 130; only a few achieve higher or lower scores.

Predicting Later Performance from Infant Tests.

Despite careful construction, most infant tests—including previous editions of the Bayley—predict later intelligence poorly. Infants and toddlers easily become distracted, fatigued, or bored during testing, so their scores often do not reflect their true abilities. And infant perceptual and motor items differ from the tasks given to older children, which increasingly emphasize verbal, conceptual, and problem-solving skills. In contrast, the Bayley-III Cognitive and Language Scales, which better dovetail with childhood tests, are good predictors of preschool mental test performance (Albers & Grieve, 2007). But because most infant test scores do not tap the same dimensions of intelligence assessed in older children, they are conservatively labeled **developmental quotients (DQs)** rather than IQs.

Infant tests are somewhat better at making long-term predictions for extremely low-scoring babies. Today, they are largely used for *screening*—helping to identify for further observation and intervention babies who are likely to have developmental problems.

As an alternative to infant tests, some researchers have turned to information-processing measures, such as habituation, to assess early mental progress. Their findings show that speed of habituation and recovery to novel visual stimuli are among the best available infant predictors of IQ from early childhood through early adulthood (Fagan, Holland, & Wheeler, 2007; Kavsek, 2004; McCall & Carriger, 1993). Habituation and recovery seem to be an especially effective early index of intelligence because they assess memory as well as quickness and

flexibility of thinking, which underlie intelligent behavior at all ages (Colombo, 2002; Colombo et al., 2004). The consistency of these findings has prompted designers of the Bayley-III to include items that tap such cognitive skills as habituation, object permanence, and categorization.

Early Environment and Mental Development

In Chapter 2, we indicated that intelligence is a complex blend of hereditary and environmental influences. Many studies have examined the relationship of environmental factors to infant and toddler mental test scores. As we consider this evidence, you will encounter findings that highlight the role of heredity as well.

Home Environment. The **Home Observation for Measurement of the Environment (HOME)** is a checklist for gathering information about the quality of children's home lives through observation and parental interview (Caldwell & Bradley, 1994). Applying What We Know on the following page lists factors measured by HOME during the first three years. Each is positively related to toddlers' mental test performance. Regardless of SES and ethnicity, an organized, stimulating physical setting and parental affection, involvement, and encouragement of new skills repeatedly predict better language and IQ scores in toddlerhood and early childhood (Fulgini, Han, & Brooks-Gunn, 2004; Linver, Martin, & Brooks-Gunn, 2004; Tamis-LeMonda et al., 2004; Tong et al., 2007). The extent to which parents talk to infants and toddlers is particularly important. It contributes strongly to early language progress, which, in turn, predicts intelligence and academic achievement in elementary school (Hart & Risley, 1995).

Yet we must interpret these correlational findings cautiously. In all the studies, children were reared by their biological parents, with whom they share not just a common environment but also a common heredity. Parents who are genetically more intelligent may provide better experiences while also giving birth to genetically brighter children, who evoke more stimulation from

A mother plays actively and affectionately with her baby. Parental warmth, attention, and verbal communication predict better language and IQ scores in toddlerhood and early childhood.

Applying What We Know

Features of a High-Quality Home Life: The HOME Infant–Toddler Subscales

Home Subscale	Sample Item
Emotional and verbal responsiveness of the parent	Parent caresses or kisses child at least once during observer's visit. Parent spontaneously speaks to child twice or more (excluding scolding) during observer's visit.
Parental acceptance of the child	Parent does not interfere with child's actions or restrict child's movements more than three times during observer's visit.
Organization of the physical environment	Child's play environment appears safe and free of hazards.
Provision of appropriate play materials	Parent provides toys or interesting activities for child during observer's visit.
Parental involvement with the child	Parent tends to keep child within visual range and to look at child often during observer's visit.
Opportunities for variety in daily stimulation	Child eats at least one meal per day with mother and/or father, according to parental report. Child frequently has a chance to get out of house (for example, accompanies parent on trips to grocery store).

Sources: Bradley, 1994; Bradley et al., 2001.

their parents. Research supports this hypothesis, which refers to *gene–environment correlation* (see Chapter 2, page 72) (Saudino & Plomin, 1997). But heredity does not account for the entire association between home environment and mental test scores. Family living conditions—both HOME scores and affluence of the surrounding neighborhood—continue to predict children's IQ beyond the contribution of parental IQ and education (Chase-Lansdale et al., 1997; Klebanov et al., 1998).

How can the research summarized so far help us understand Vanessa's concern about Timmy's development? Ben, the psychologist who tested Timmy, found that he scored only slightly below average. Ben talked with Vanessa about her child-rearing practices and watched her play with Timmy. A single parent who worked long hours, Vanessa had little energy for Timmy at the end of the day. Ben also noticed that Vanessa, anxious about Timmy's progress, tended to pressure him, dampening his active behavior and bombarding him with directions: "That's enough ball play. Stack these blocks."

Ben explained that when parents are intrusive in these ways, infants and toddlers are likely to be distractible, play immaturely, and do poorly on mental tests (Bono & Stifter, 2003; Stilson & Harding, 1997). He coached Vanessa in how to interact sensitively with Timmy, while also assuring her that Timmy's current performance need not forecast his future development. Warm, responsive parenting that builds on toddlers' current capacities is a much better indicator than an early mental test score of how children will do later.

Infant and Toddler Child Care. Today, more than 60 percent of U.S. mothers with a child under age 2 are employed (U.S. Census Bureau, 2012b). Child care for infants and toddlers has become common, and its quality—though not as influential as parenting—affects mental development. Research consistently

shows that infants and young children exposed to poor-quality child care—whether they come from middle-class or from low-SES homes—score lower on measures of cognitive and social skills (Belsky et al., 2007b; Hausfather et al., 1997; NICHD Early Child Care Research Network, 2000b, 2001, 2003b, 2006). In contrast, good child care can reduce the negative impact of a stressed, poverty-stricken home life, and it sustains the benefits of growing up in an economically advantaged family (Lamb & Ahnert, 2006; McCartney et al., 2007; NICHD Early Child Care Research Network, 2003b).

In contrast to most European countries and to Australia and New Zealand, where child care is nationally regulated and funded to ensure its quality, reports on U.S. child care raise serious concerns. Standards are set by the individual states and vary widely. In studies of quality, only 20 to 25 percent of U.S. child-care centers and family child-care settings (in which a caregiver cares for children in her home) provided infants and toddlers with sufficiently positive, stimulating experiences to promote healthy psychological development. Most settings offered substandard care (NICHD Early Childhood Research Network, 2000a, 2004).

LOOK AND LISTEN

Ask several employed parents of infants or toddlers to describe what they sought in a child-care setting, along with challenges they faced in finding child care. Are the parents knowledgeable about the ingredients of high-quality care? ●

Unfortunately, many U.S. children from low-income families experience inadequate child care (Brooks-Gunn, 2004). But U.S. settings providing the very worst care tend to serve middle-SES families. These parents are especially likely to place their

Applying What We Know

Signs of Developmentally Appropriate Infant and Toddler Child Care

Program Characteristics	Signs of Quality
Physical setting	Indoor environment is clean, in good repair, well-lighted, and well-ventilated. Fenced outdoor play space is available. Setting does not appear overcrowded when children are present.
Toys and equipment	Play materials are appropriate for infants and toddlers and are stored on low shelves within easy reach. Cribs, highchairs, infant seats, and child-sized tables and chairs are available. Outdoor equipment includes small riding toys, swings, slide, and sandbox.
Caregiver–child ratio	In child-care centers, caregiver–child ratio is no greater than 1 to 3 for infants and 1 to 6 for toddlers. Group size (number of children in one room) is no greater than 6 infants with 2 caregivers and 12 toddlers with 2 caregivers. In family child care, caregiver is responsible for no more than 6 children; within this group, no more than 2 are infants and toddlers. Staffing is consistent, so infants and toddlers can form relationships with particular caregivers.
Daily activities	Daily schedule includes times for active play, quiet play, naps, snacks, and meals. It is flexible rather than rigid, to meet the needs of individual children. Atmosphere is warm and supportive, and children are never left unsupervised.
Interactions among adults and children	Caregivers respond promptly to infants' and toddlers' distress; hold, talk to, sing to, and read to them; and interact with them in a manner that respects the individual child's interests and tolerance for stimulation.
Caregiver qualifications	Caregiver has some training in child development, first aid, and safety.
Relationships with parents	Parents are welcome anytime. Caregivers talk frequently with parents about children's behavior and development.
Licensing and accreditation	Child-care setting, whether a center or a home, is licensed by the state. In the United States, voluntary accreditation by the National Association for the Education of Young Children (www.naeyc.org/academy), or the National Association for Family Child Care (www.nafcc.org) is evidence of an especially high-quality program.

Sources: Copple & Bredekamp, 2009.

children in for-profit centers, where quality tends to be lowest. Low-SES children more often attend publicly subsidized, non-profit centers, which have smaller group sizes and better teacher–child ratios (Lamb & Ahnert, 2006). Still, child-care quality for low-SES children varies widely. And probably because of greater access to adult stimulation, infants and toddlers in high-quality family child care score higher than those in center care in cognitive and language development (NICHD Early Child Care Research Network, 2000b).

See Applying What We Know above for signs of high-quality care for infants and toddlers, based on standards for **developmentally appropriate practice**. These standards, devised by the U.S. National Association for the Education of Young Children, specify program characteristics that serve young children's developmental and individual needs, based on both current research and consensus among experts. Caitlin, Grace, and Timmy are fortunate to be in family child care that meets these standards.

Child care in the United States is affected by a macrosystem of individualistic values and weak government regulation and funding. Furthermore, many parents think that their children's child-care experiences are better than they really are. Unable to identify good care, they do not demand it (Helburn, 1995). In recent years, recognizing that child care is in a state of crisis, the U.S. federal government and some states have allocated

additional funds to subsidize its cost, primarily for low-income families. Though far from meeting the need, this increase in resources has had a positive impact on child-care quality and accessibility (Children's Defense Fund, 2009).

© ELLEN B. SENISI PHOTOGRAPHY

High-quality child care, with a generous caregiver–child ratio, well-trained caregivers, and developmentally appropriate activities, can be especially beneficial to children from low-SES homes.

Good child care is a cost-effective means of protecting children's well-being. And much like the programs we are about to consider, it can serve as effective early intervention for children whose development is at risk.

Early Intervention for At-Risk Infants and Toddlers

Children living in poverty are likely to show gradual declines in intelligence test scores and to achieve poorly when they reach school age (Bradley et al., 2001; Gutman, Sameroff, & Cole, 2003). These problems are largely due to stressful home environments that undermine children's ability to learn and increase the likelihood that they will remain poor as adults (McLoyd, Aikens, & Burton, 2006). A variety of intervention programs have been developed to break this tragic cycle of poverty. Although most begin during the preschool years (we will discuss these in Chapter 7), a few start during infancy and continue through early childhood.

In center-based interventions, children attend an organized child-care or preschool program where they receive educational, nutritional, and health services, and their parents receive child-rearing and other social service supports. In home-based interventions, a skilled adult visits the home and works with parents, teaching them how to stimulate a very young child's development. In most programs of either type, participating children score higher than untreated controls on mental tests by age 2. The earlier intervention begins, the longer it lasts, and the greater its scope and intensity, the better participants' cognitive and academic performance is throughout childhood and adolescence (Brooks-Gunn, 2004; Ramey, Ramey, & Lanzi, 2006; Sweet & Appelbaum, 2004).

The Carolina Abecedarian Project illustrates these favorable outcomes. In the 1970s, more than 100 infants from poverty-stricken families, ranging in age from 3 weeks to 3 months, were randomly assigned to either a treatment group or a control group. Treatment infants were enrolled in full-time, year-round child care through the preschool years. There they received stimulation aimed at promoting motor, cognitive, language, and social skills and, after age 3, literacy and math concepts. Special emphasis was placed on rich, responsive adult-child verbal communication. All children received nutrition and health services; the primary difference between treatment and controls was the intensive child-care experience.

As Figure 5.9 shows, by 12 months of age, the IQs of the two groups diverged. Treatment children sustained their advantage until last tested—at age 21. In addition, throughout their school years, treatment youths achieved considerably higher scores in reading and math. These gains translated into more years of schooling completed, higher rates of college enrollment and employment in skilled jobs, and lower rates of drug use and adolescent parenthood (Campbell et al., 2001, 2002; Campbell & Ramey, 2010).

Recognition of the power of intervening as early as possible led the U.S. Congress to provide limited funding for services

FIGURE 5.9 IQ scores of treatment and control children from infancy to 21 years in the Carolina Abecedarian Project.

At 1 year, treatment children outperformed controls, an advantage consistently maintained through age 21. The IQ scores of both groups declined gradually during childhood and adolescence—a trend probably due to the damaging impact of poverty on mental development. (Adapted from Campbell et al., 2001.)

directed at infants and toddlers who already have serious developmental problems or who are at risk for problems because of poverty. Early Head Start, begun in 1995, currently has 1,000 sites serving about 100,000 low-income children and their families (Early Head Start National Resource Center, 2011). A recent evaluation, conducted when children reached age 3, showed that intervention led to warmer, more stimulating parenting, a reduction in harsh discipline, gains in cognitive and language development, and lessening of child aggression (Love et al., 2005; Love, Chazan-Cohen, & Raikes, 2007; Raikes et al., 2010). The strongest effects occurred at sites mixing center- and home-based services. Though not yet plentiful enough to meet the need, such programs are a promising beginning.

ASK YOURSELF

REVIEW What probably accounts for the finding that speed of habituation and recovery to novel visual stimuli predicts later IQ better than most infant mental test scores?

CONNECT Using what you learned about brain development in Chapter 4, explain why it is best to initiate intervention for poverty-stricken children in the first two years rather than later.

APPLY Fifteen-month-old Joey's developmental quotient (DQ) is 115. His mother wants to know exactly what this means and what she should do to support his mental development. How would you respond?

REFLECT Suppose you were seeking a child-care setting for your baby. What would you want it to be like, and why?

Language Development

Improvements in perception and cognition during infancy pave the way for an extraordinary human achievement—language. In Chapter 4, we saw that by the second half of the first year, infants make dramatic progress in distinguishing the basic sounds of their language and in segmenting the flow of speech into word and phrase units. They also start to comprehend some word meanings and, around 12 months of age, say their first word. Sometime between 1½ and 2 years, toddlers combine two words (Gleason, 2009). By age 6, children understand the meaning of about 10,000 words, speak in elaborate sentences, and are skilled conversationalists.

To appreciate this awesome task, think about the many abilities involved in your own flexible use of language. When you speak, you must select words that match the underlying concepts you want to convey. To be understood, you must pronounce words correctly. Then you must combine them into phrases and sentences using a complex set of grammatical rules. Finally, you must follow the rules of everyday conversation—take turns, make comments relevant to what your partner just said, and use an appropriate tone of voice. How do infants and toddlers make such remarkable progress in launching these skills?

Theories of Language Development

In the 1950s, researchers did not take seriously the idea that very young children might be able to figure out important properties of language. Children's regular and rapid attainment of language milestones suggested a process largely governed by maturation, inspiring the nativist perspective on language development. In recent years, new evidence has spawned the interactionist perspective, which emphasizes the joint roles of children's inner capacities and communicative experiences.

The Nativist Perspective. According to linguist Noam Chomsky's (1957) *nativist* theory, language is a unique human accomplishment, etched into the structure of the brain. Focusing on grammar, Chomsky reasoned that the rules of sentence organization are too complex to be directly taught to or discovered by even a cognitively sophisticated young child. Rather, he proposed that all children have a **language acquisition device (LAD)**, an innate system that contains a *universal grammar*, or set of rules common to all languages. It enables children, no matter which language they hear, to understand and speak in a rule-oriented fashion as soon as they pick up enough words.

Are children biologically primed to acquire language? Recall from Chapter 4 that newborn babies are remarkably sensitive to speech sounds. And children everywhere reach major language milestones in a similar sequence. Also, the ability to master a grammatically complex language system seems unique to humans, as efforts to teach language to nonhuman primates—using either specially devised artificial symbol systems or sign language—have met with limited success. Even after extensive training, chimpanzees (who are closest to humans in terms of

evolution) master only a basic vocabulary and short word combinations, and they produce these far less consistently than human preschoolers (Tomasello, Call, & Hare, 2003).

Furthermore, evidence that childhood is a *sensitive period* for language acquisition is consistent with Chomsky's idea of a biologically based language program. Researchers have examined the language competence of deaf adults who acquired their first language—American Sign Language (ASL), a gestural system used by the deaf—at different ages. The later learners, whose parents chose to educate them through speech and lip-reading, did not acquire spoken language because of their profound deafness. Consistent with the sensitive-period notion, those who learned ASL in adolescence or adulthood never became as proficient as those who learned in childhood (Mayberry, 2010; Newport, 1991; Singleton & Newport, 2004).

But challenges to Chomsky's theory suggest that it, too, provides only a partial account of language development. First, researchers have had great difficulty specifying Chomsky's universal grammar. Chomsky's critics doubt that one set of rules can account for the extraordinary variation in grammatical forms among the world's 5,000 to 8,000 languages (Christiansen & Chater, 2008; Evans & Levinson, 2009; Tomasello, 2005). Second, children do not acquire language as quickly as nativist theory suggests. They refine and generalize many grammatical forms gradually, engaging in much piecemeal learning and making errors along the way. As we will see in Chapter 9, complete mastery of some grammatical forms, such as the passive voice, is not achieved until well into middle childhood (Tager-Flusberg & Zukowski, 2009; Tomasello, 2006). This suggests that more experimentation and learning are involved than Chomsky assumed.

Finally, recall from Chapter 4 that for most people, language is housed largely in the left hemisphere of the cerebral cortex, consistent with Chomsky's notion of a brain prepared to process language. But our discussion also revealed that language areas in the cortex *develop* as children acquire language. Although the left hemisphere is biased for language processing, if it is injured in the early years, other regions take over (see page 126 in Chapter 4). So localization of language in the left hemisphere is not necessary for effective language use. Furthermore, brain-imaging research shows that many regions of the cerebral cortex participate in language activities to differing degrees, depending on the language skill and the individual's mastery of that skill (Shafer & Garrido-Nag, 2007).

The Interactionist Perspective. Recent ideas about language development emphasize *interactions* between inner capacities and environmental influences. One type of interactionist theory applies the information-processing perspective to language development. A second type emphasizes social interaction.

Some information-processing theorists assume that children make sense of their complex language environments by applying powerful cognitive capacities of a general kind (Bates, 2004; Elman, 2001; Munakata, 2006; Saffran, 2009). These theorists note that brain regions housing language also govern similar perceptual and cognitive abilities, such as the capacity

© LAURA DWIGHT PHOTOGRAPHY

Infants communicate from the very beginning of life, as this interchange between a mother and her 1-month-old illustrates. How will this child become a fluent speaker of her native language within just a few years? Theorists disagree sharply on answers to this question.

to analyze musical and visual patterns (Saygin et al., 2004; Saygin, Leech, & Dick, 2010).

Other theorists blend this information-processing view with Chomsky's nativist perspective. They agree that infants are amazing analyzers of speech and other information. But, they argue, these capacities probably are not sufficient to account for mastery of higher-level aspects of language, such as intricate grammatical structures (Aslin & Newport, 2009). They also point out that grammatical competence may depend more on specific brain structures than the other components of language. When 2- to 2½-year-olds and adults listened to short sentences—some grammatically correct, others with phrase-structure violations—both groups showed similarly distinct ERP brain-wave patterns

for each sentence type in the left frontal and temporal lobes of the cerebral cortex (Oberecker & Friederici, 2006; Oberecker, Friedrich, & Friederici, 2005). This suggests that 2-year-olds process sentence structures using the same neural system as adults do. Furthermore, in studies of older children and adults with left-hemispheric brain damage, grammar is more impaired than other language functions (Stromswold, 2000).

Still other interactionists emphasize that children's social skills and language experiences are centrally involved in language development. In this *social-interactionist* view, an active child, well-endowed for making sense of language, strives to communicate. In doing so, she cues her caregivers to provide appropriate language experiences, which help her relate the content and structure of language to its social meanings (Bohannon & Bonvillian, 2009; Chapman, 2006).

Among social interactionists, disagreement continues over whether or not children are equipped with specialized language abilities (Lidz, 2007; Shatz, 2007; Tomasello, 2003, 2006). Nevertheless, as we chart the course of language development, we will encounter much support for their central premise—that children's social competencies and language experiences greatly affect their language progress. In reality, native endowment, cognitive-processing strategies, and social experience probably operate in different balances with respect to each aspect of language. Table 5.3 provides an overview of early language milestones that we will examine in the next few sections.

Getting Ready to Talk

Before babies say their first word, they make impressive progress toward understanding and speaking their native tongue. They listen attentively to human speech, and they make speechlike sounds. As adults, we can hardly help but respond.

TABLE 5.3 Milestones of Language Development During the First Two Years

APPROXIMATE AGE	MILESTONE
2 months	Infants coo, making pleasant vowel sounds.
4 months on	Infants observe with interest as the caregiver plays turn-taking games, such as pat-a-cake and peekaboo.
6 months on	Infants babble, adding consonants to their cooing sounds and repeating syllables. By 7 months, babbling starts to include many sounds of spoken languages. Infants begin to comprehend a few commonly heard words.
8–12 months	Infants become more accurate at establishing joint attention with the caregiver, who often verbally labels what the baby is looking at. Infants actively participate in turn-taking games, trading roles with the caregiver. Infants use preverbal gestures, such as showing and pointing, to influence others' goals and behavior and to convey information.
12 months	Babbling includes sound and intonation patterns of the child's language community. Speed and accuracy of word comprehension increase rapidly. Toddlers say their first recognizable word.
18–24 months	Spoken vocabulary expands from about 50 to 200 to 250 words. Toddlers combine two words.

Cooing and Babbling. Around 2 months, babies begin to make vowel-like noises, called **cooing** because of their pleasant “oo” quality. Gradually, consonants are added, and around 6 months, **babbling** appears, in which infants repeat consonant–vowel combinations in long strings, such as “bababababa” or “nanananana.”

Babies everywhere (even those who are deaf) start babbling at about the same age and produce a similar range of early sounds. But for babbling to develop further, infants must be able to hear human speech. In hearing-impaired babies, these speech-like sounds are greatly delayed. And a deaf infant not exposed to sign language will stop babbling entirely (Oller, 2000).

As infants listen to spoken language, babbling expands to include a broader range of sounds. Around 7 months, it starts to include many sounds common in spoken languages. As caregivers respond to infant babbles, babies modify their babbling to include sound patterns like those in the adult’s speech (Goldstein & Schwade, 2008). By 8 to 10 months, babbling reflects the sound and intonation patterns of children’s language community, some of which are transferred to their first words (Boysson-Bardies & Vihman, 1991).

Deaf infants exposed to sign language from birth babble with their hands much as hearing infants do through speech (Petitto & Marentette, 1991). Furthermore, hearing babies of deaf, signing parents produce babblelike hand motions with the rhythmic patterns of natural sign languages (Petitto et al., 2001, 2004). This sensitivity to language rhythm—evident in both spoken and signed babbling—supports both discovery and production of meaningful language units.

Becoming a Communicator. At birth, infants are prepared for some aspects of conversational behavior. For example, newborns initiate interaction through eye contact and terminate it by looking away. By 3 to 4 months, infants start to gaze in the same general direction adults are looking—a skill that becomes more accurate at 10 to 11 months, as babies realize that others’ focus offers information about their communicative intentions (to talk about an object) or other goals (to obtain an object) (Brooks & Meltzoff, 2005; Senju, Csibra, & Johnson, 2008). This **joint attention**, in which the child attends to the same object or event as the caregiver, who often labels it, contributes greatly to early language development. Infants and toddlers who frequently experience it sustain attention longer, comprehend more language, produce meaningful gestures and words earlier, and show faster vocabulary development (Brooks & Meltzoff, 2008; Carpenter, Nagell, & Tomasello, 1998; Flom & Pick, 2003; Silvén, 2001).

Between 4 and 6 months, interactions between caregivers and babies begin to include *give-and-take*, as in pat-a-cake and peekaboo games. At first, the parent starts the game and the baby is an amused observer. But even 4-month-olds are sensitive to the structure and timing of these interactions, smiling more to an organized than to a disorganized peekaboo exchange (Rochat, Querido, & Striano, 1999). By 12 months, babies participate

This baby uses a preverbal gesture to draw his caregiver’s attention to a picture. The caregiver’s verbal response promotes the baby’s transition to spoken language.

actively, trading roles with the caregiver. In this way, they practice the turn-taking pattern of conversation, a vital context for acquiring language and communication skills. Infants’ play maturity and vocalizations during games predict advanced language progress in the second year (Rome-Flanders & Cronk, 1995).

At the end of the first year, babies use *preverbal gestures* to direct adults’ attention, to influence their behavior, and to convey helpful information (Tomasello, Carpenter, & Liszkowski, 2007). For example, Caitlin held up a toy to show it, pointed to the cupboard when she wanted a cookie, and pointed at her mother’s car keys lying on the floor. Carolyn responded to these gestures and also labeled them (“That’s your bear!” “You want a cookie!” “Oh, there are my keys!”). In this way, toddlers learn that using language leads to desired results. Soon toddlers integrate words with gestures, using the gesture to expand their verbal message, as in pointing to a toy while saying “give” (Capirci et al., 2005). Gradually, gestures recede, and words become dominant. But the earlier toddlers form word–gesture combinations, the faster their vocabulary growth, the sooner they produce two-word utterances at the end of the second year, and the more complex their sentences at age 3½ (Özçaliskan & Goldin-Meadow, 2005; Rowe & Goldin-Meadow, 2009).

First Words

In the second half of the first year, infants begin to understand word meanings. When 6-month-olds listened to the word “Mommy” or “Daddy” while looking at side-by-side videos of their parents, they looked longer at the video of the named parent (Tincoff & Jusczyk, 1999). First spoken words, around 1 year, build on the sensorimotor foundations Piaget described and on categories children have formed. In a study tracking the first 10 words used by several hundred U.S. and Chinese

(both Mandarin- and Cantonese-speaking) babies, important people (“Mama,” “Dada”), common objects (“ball,” “bread”), and sound effects (“woof-woof,” “vroom”) were mentioned most often. Action words (“hit,” “grab,” “hug”) and social routines (“hi,” “bye”), though also appearing in all three groups, were more often produced by Chinese than U.S. babies, and the Chinese babies also named more important people—differences we will consider shortly (Tardif et al., 2008). In their first 50 words, toddlers rarely name things that just *sit there*, like “table” or “vase.”

When young children first learn words, they sometimes apply them too narrowly, an error called **underextension**. At 16 months, Caitlin used “bear” only to refer to the worn and tattered bear she carried nearly constantly. As vocabulary expands, a more common error is **overextension**—applying a word to a wider collection of objects and events than is appropriate. For example, Grace used “car” for buses, trains, trucks, and fire engines. Toddlers’ overextensions reflect their sensitivity to categories (MacWhinney, 2005). They apply a new word to a group of similar experiences: “car” to wheeled objects, “open” to opening a door, peeling fruit, and untying shoelaces. This suggests that children often overextend deliberately because they have difficulty recalling or have not acquired a suitable word. And when a word is hard to pronounce, toddlers are likely to substitute a related one they can say (Bloom, 2000). As vocabulary and pronunciation improve, overextensions disappear.

Overextensions illustrate another important feature of language development: the distinction between language *production* (the words children use) and language *comprehension* (the words they understand). At all ages, comprehension develops ahead of production. A 2-year-old who refers to trucks, trains, and bikes as “car” may look at or point to these objects correctly when given their names (Naigles & Gelman, 1995). Still, the two capacities are related. The speed and accuracy of toddlers’ comprehension of spoken language increase dramatically over the second year. And toddlers who are faster and more accurate in comprehension tend to show more rapid growth in words understood and produced as they approach age 2 (Fernald, Perfors, & Marchman, 2006). Quick comprehension frees space in working memory for picking up new words and for the more demanding task of using them to communicate.

The Two-Word Utterance Phase

Young toddlers add to their spoken vocabularies at a rate of one to three words per week. Gradually, the number of words learned accelerates. Because gains in word production between 18 and 24 months are so impressive (one or two words per day), many researchers concluded that toddlers undergo a *spurt in vocabulary*—a transition from a slower to a faster learning phase. But recent evidence indicates that most children show a steady increase in rate of word learning that continues through the preschool years (Ganger & Brent, 2004).

How do toddlers build their vocabularies so quickly? In the second year, they improve in ability to categorize experience, recall words, and grasp others’ social cues to meaning, such as eye gaze, pointing, and handling objects (Dapretto & Bjork, 2000; Golinkoff & Hirsh-Pasek, 2006; Liszkowski, Carpenter, & Tomasello, 2007). In Chapter 7, we will consider young children’s specific strategies for word learning.

Once toddlers produce 200 to 250 words, they start to combine two words: “Mommy shoe,” “go car,” “more cookie.” These two-word utterances are called **telegraphic speech** because, like a telegram, they focus on high-content words, omitting smaller, less important ones. Children the world over use them to express an impressive variety of meanings.

Two-word speech consists largely of simple formulas (“more + *X*,” “eat + *X*”), with different words inserted in the “*X*” position. Toddlers rarely make gross grammatical errors, such as saying “chair my” instead of “my chair.” But their word-order regularities are usually copies of adult word pairings, as when the parent says, “How about *more sandwich?*” or “Let’s see if you can *eat the berries*” (Tomasello, 2003; Tomasello & Brandt, 2009). These findings indicate that young children first acquire “concrete pieces of language” from frequent word pairings they hear. Only gradually do they generalize from those pieces to construct word-order and other grammatical rules (Tomasello, 2006). As we will see in Chapter 7, children master grammar steadily over the preschool years.

Individual and Cultural Differences

Although children typically produce their first word around their first birthday, the range is large, from 8 to 18 months—variation due to a complex blend of genetic and environmental influences. Earlier we saw that Timmy’s spoken language was delayed, in part because of Vanessa’s tense, directive communication with him. But Timmy is also a boy, and many studies show that girls are slightly ahead of boys in early vocabulary growth (Fenson et al., 1994; Van Hulle, Goldsmith, & Lemery, 2004). The most common explanation is girls’ faster rate of physical maturation, believed to promote earlier development of the left cerebral hemisphere.

Temperament matters, too. Shy toddlers often wait until they understand a great deal before trying to speak. Once they do speak, their vocabularies increase rapidly, although they remain slightly behind their age-mates (Spere et al., 2004). Temperamentally negative toddlers also acquire language more slowly because their high emotional reactivity diverts them from processing linguistic information (Salley & Dixon, 2007).

The quantity of caregiver–child conversation and richness of adults’ vocabularies also play a strong role (Zimmerman et al., 2009). Commonly used words for objects appear early in toddlers’ speech, and the more often their caregivers use a particular noun, the sooner young children produce it (Goodman, Dale, & Li, 2008). Mothers talk more to toddler-age girls than to boys, and parents converse less often with shy than with sociable

children (Leaper, Anderson, & Sanders, 1998; Patterson & Fisher, 2002).

Low-SES children, who receive less verbal stimulation in their homes than higher-SES children, usually have smaller vocabularies (Hoff, 2006). Limited parent–child book reading is a major factor. On average, a middle-SES child is read to for 1,000 hours between 1 and 5 years, a low-SES child for only 25 hours (Neuman, 2003). As a result, low-SES kindergartners have vocabularies only one-fourth as large as those of their higher SES agemates (Lee & Burkam, 2002). And low-income children are also behind in early literacy knowledge and later reading achievement, as we will see in Chapter 7.

Furthermore, 2-year-olds' spoken vocabularies vary substantially across languages—about 180 to 200 words for children acquiring Swedish, 250 to 300 words for children acquiring English, and 500 words for children acquiring Mandarin Chinese (Bleses et al., 2008; Tardif et al., 2009). In Swedish, a complicated system of speech sounds makes syllable and word boundaries challenging to discriminate and pronounce. In contrast, Mandarin Chinese has many short words with easy-to-pronounce initial consonants. Within Mandarin words, each syllable is given one of four distinct tones, aiding discrimination.

Young children have distinct styles of early language learning. Caitlin and Grace, like most toddlers, used a **referential style**; their vocabularies consisted mainly of words that refer to objects. A smaller number of toddlers use an **expressive style**; compared with referential children, they produce many more social formulas and pronouns (“thank you,” “done,” “I want it”). These styles reflect early ideas about the functions of language. Grace, for example, thought words were for naming things. In contrast, expressive-style children believe words are for talking about people’s feelings and needs (Bates et al., 1994). The vocabularies of referential-style toddlers grow faster because all languages contain many more object labels than social phrases.

What accounts for a toddler’s language style? Rapidly developing referential-style children often have an especially active interest in exploring objects. They also eagerly imitate their parents’ frequent naming of objects (Masur & Rodemaker, 1999). Expressive-style children tend to be highly sociable, and their parents more often use verbal routines (“How are you?” “It’s no trouble”) that support social relationships (Goldfield, 1987).

The two language styles are also linked to culture. Nouns are particularly common in the vocabularies of English-speaking toddlers, but Chinese, Japanese, and Korean toddlers have more words for social routines. Mothers’ speech in each culture reflects this difference (Choi & Gopnik, 1995; Fernald & Morikawa, 1993; Tardif, Gelman, & Xu, 1999). American mothers frequently label objects when interacting with their babies. Asian mothers, perhaps because of a cultural emphasis on the importance of group membership, teach social routines as soon as their children begin to speak.

At what point should parents be concerned if their child talks very little or not at all? If a toddler’s language is greatly delayed when compared with the norms in Table 5.3 (page 175),

then parents should consult the child’s doctor or a speech and language therapist. Late babbling may be a sign of slow language development that can be prevented with early intervention (Fasolo, Marjorano, & D’Odorico, 2008). Some toddlers who do not follow simple directions or who, after age 2, have difficulty putting their thoughts into words may suffer from a hearing impairment or a language disorder that requires immediate treatment.

Supporting Early Language Development

Consistent with the interactionist view, a rich social environment builds on young children’s natural readiness to acquire language. For a summary of how caregivers can consciously support early language development, see Applying What We Know on the following page. Caregivers also do so unconsciously—through a special style of speech.

Adults in many cultures speak to babies in **infant-directed speech (IDS)**, a form of communication made up of short sentences with high-pitched, exaggerated expression, clear pronunciation, distinct pauses between speech segments, and repetition of new words in a variety of contexts (“See the *ball*,” “The *ball* bounced!”) (Fernald et al., 1989; O’Neill et al., 2005). Deaf parents use a similar style of communication when signing to their deaf babies (Masataka, 1996).

© LAURA DWIGHT PHOTOGRAPHY

By using infant-directed speech, this father speaks in ways that are sensitive to his daughter’s language needs and encourages her to join in. Dialogues about picture books are especially powerful sources of early language learning.

Applying What We Know

Supporting Early Language Learning

Strategy	Consequence
Respond to coos and babbles with speech sounds and words.	Encourages experimentation with sounds that can later be blended into first words. Provides experience with turn-taking pattern of human conversation.
Establish joint attention, and comment on what child sees.	Predicts earlier onset of language and faster vocabulary development.
Play social games, such as pat-a-cake and peekaboo.	Provides experience with the turn-taking pattern of human conversation.
Engage toddlers in joint make-believe play.	Promotes all aspects of conversational dialogue.
Engage toddlers in frequent conversations.	Predicts faster early language development and academic success during the school years.
Read to toddlers often, engaging them in dialogues about picture books.	Provides exposure to many aspects of language, including vocabulary, grammar, communication skills, and information about written symbols and story structures.

IDS builds on several communicative strategies we have already considered: joint attention, turn-taking, and caregivers' sensitivity to toddlers' preverbal gestures. In this example, Carolyn uses IDS with 18-month-old Caitlin:

- Caitlin: "Go car."
 Carolyn: "Yes, time to go in the car. Where's your jacket?"
 Caitlin: [Looks around, walks to the closet.] "Dacket!"
 [Points to her jacket.]
 Carolyn: "There's that jacket! [She helps Caitlin into the jacket.] On it goes! Let's zip up. [Zips up the jacket.] Now, say bye-bye to Grace and Timmy."
 Caitlin: "Bye-bye, G-ace. Bye-bye, Te-te."
 Carolyn: "Where's your bear?"
 Caitlin: [Looks around.]
 Carolyn: [Pointing.] "See? By the sofa." [Caitlin gets the bear.]

From birth on, infants prefer IDS over other adult talk, and by 5 months they are more emotionally responsive to it (Aslin, Jusczyk, & Pisoni, 1998). Parents constantly fine-tune the length and content of their utterances to fit their children's needs—adjustments that foster word learning and enable toddlers to join in (Cameron-Faulkner, Lieven, & Tomasello, 2003; Rowe, 2008). As we saw earlier, parent–toddler conversation—especially, reading and talking about picture books—strongly predicts language development and reading success during the school years.

LOOK AND LISTEN

While observing a parent and toddler playing, describe how the parent adapts his or her language to the child's needs.

Did the parent use IDS? ●

Do social experiences that promote language development remind you of those that strengthen cognitive development in general? IDS and parent–child conversation create a *zone of proximal development* in which children's language expands. In contrast, impatience with and rejection of children's efforts to talk lead them to stop trying and result in immature language skills (Baumwell, Tamis-LeMonda, & Bornstein, 1997; Cabrera, Shannon, & Tamis-LeMonda, 2007). In the next chapter, we will see that sensitivity to children's needs and capacities supports their emotional and social development as well.

SUMMARY

Piaget's Cognitive-Developmental Theory (p. 152)

According to Piaget, how do schemes change over the course of development?

- By acting on the environment, children move through four stages in which psychological structures, or **schemes**, achieve a better fit with external reality.
- Schemes change in two ways: through **adaptation**, which is made up of two complementary activities—**assimilation** and **accommodation**—and through **organization**, the internal rearrangement of schemes into a strongly interconnected cognitive system.

Describe the major cognitive achievements of the sensorimotor stage.

- In the **sensorimotor stage**, the **circular reaction** provides a means of adapting first schemes, and the newborn's reflexes gradually transform into the flexible action patterns of the older infant. Eight- to 12-month-olds develop **intentional**, or **goal-directed**, **behavior** and begin to understand **object permanence**.
- Between 18 and 24 months, **mental representation** is evident in sudden solutions to sensorimotor problems, mastery of object permanence problems involving invisible displacement, **deferred imitation**, and **make-believe play**.

What does follow-up research reveal about the accuracy of Piaget's sensorimotor stage?

- Many studies suggest that infants display certain understandings earlier than Piaget believed. Some awareness of object permanence, as revealed by the **violation-of-expectation method** and object-tracking research, may be evident in the first few months.
- Around the first birthday, babies attain **displaced reference**, the realization that words may stand for things not physically present. By the middle of the second year, toddlers treat realistic-looking pictures symbolically; around 2½ years, they grasp the symbolic meaning of video.

- Today, researchers believe that newborns have more built-in equipment for making sense of their world than Piaget assumed, although they disagree on how much initial understanding infants have. According to the **core knowledge perspective**, infants are born with core domains of thought that support early, rapid cognitive development. Research suggests that infants have basic physical, linguistic, psychological, and numerical knowledge.

© EDITH HELD/CORBIS

- Broad agreement exists that many cognitive changes of infancy are continuous rather than stagelike and that various aspects of cognition develop unevenly rather than in an integrated fashion.

Information Processing

(p. 161)

Describe the information-processing view of cognitive development.

- Most information-processing researchers assume that we hold information in three parts of the mental system for processing: the **sensory register**, the **short-term memory store**, and **long-term memory**. The **central executive** joins with **working memory**—our “mental workspace”—to process information effectively, increasing the chances that it will transfer to our permanent knowledge base. Well-learned **automatic processes** require no space in working memory, permitting us to focus on other information while performing them.
- Gains in **executive function**—including attention, impulse control, and coordinating information in working memory—are under way in the first two years. Dramatic advances will follow in childhood and adolescence.

What changes in attention, memory, and categorization take place during the first two years?

- With age, infants attend to more aspects of the environment and take information in more quickly. In the second year, attention to novelty declines and sustained attention improves.
- Young infants are capable of **recognition memory**. By the second half of the first year, they also engage in **recall**. Both improve steadily with age.
- Infants group stimuli into increasingly complex categories, and toddlers' categorization gradually shifts from a perceptual to a conceptual basis. In the second half of the first year, infants have begun to grasp the animate-inanimate distinction, an understanding that expands during toddlerhood.

Describe contributions and limitations of the information-processing approach to our understanding of early cognitive development.

- Information-processing findings challenge Piaget's view of infants as purely sensorimotor beings who cannot mentally represent experiences. But information processing has not yet provided a broad, comprehensive theory of children's thinking.

The Social Context of Early Cognitive Development

(p. 167)

How does Vygotsky's concept of the zone of proximal development expand our understanding of early cognitive development?

- Vygotsky believed that infants master tasks within the **zone of proximal development**—ones just ahead of their current capacities—through the support and guidance of more skilled partners. As early as the first year, cultural variations in social experiences affect mental strategies.

Individual Differences in Early Mental Development (p. 169)

Describe the mental testing approach and the extent to which infant tests predict later performance.

- The mental testing approach measures intellectual development in an effort to predict future performance. Scores are arrived at by

computing an **intelligence quotient (IQ)**, which compares an individual's test performance with that of a **standardization** sample of same-age individuals, whose scores form a **normal distribution**.

- Infant tests consisting largely of perceptual and motor responses predict later intelligence poorly. As a result, scores on infant tests are called **developmental quotients (DQs)**, rather than IQs. Speed of habituation and recovery to visual stimuli are better predictors of future performance.

Discuss environmental influences on early mental development, including home, child care, and early intervention for at-risk infants and toddlers.

- Research with the **Home Observation for Measurement of the Environment (HOME)** shows that an organized, stimulating home environment and parental encouragement, involvement, and affection repeatedly predict early mental test scores. Although the HOME–IQ relationship is partly due to heredity, family living conditions also affect mental development.

- Infant and toddler child care is increasingly common, and its quality has a major impact on mental development. Standards for **developmentally appropriate practice** specify program characteristics that meet young children's developmental needs.

- Intensive intervention beginning in infancy and extending through early childhood can prevent the gradual declines in intelligence and the poor academic performance of many poverty-stricken children.

Language Development

(p. 174)

Describe theories of language development, and indicate how much emphasis each places on innate abilities and environmental influences.

- Chomsky's *nativist* theory regards children as naturally endowed with a **language acquisition device (LAD)**. Consistent with this perspective, mastery of a complex language system is unique to humans, and childhood is a sensitive period for language acquisition.
- Recent theories view language development as resulting from interactions between inner capacities and environmental influences. Some interactionists apply the information-processing perspective to language development. Others emphasize the importance of children's social skills and language experiences.

Describe major language milestones in the first two years, individual differences, and ways adults can support early language development.

- Infants begin **cooing** at 2 months and **babbling** at about 6 months. Around 10 to 11 months, their skill at establishing **joint attention** improves, and soon they use preverbal gestures. Adults can encourage language progress by responding to infants' coos and babbles, playing turn-taking games, establishing joint attention and labeling what babies see, and responding verbally to infants' preverbal gestures.

- Around 12 months, toddlers say their first word. Young children often make errors of **underextension** and **overextension**. Once vocabulary reaches 200 to 250 words, two-word utterances called **telegraphic speech** appear. At all ages, language comprehension is ahead of production.

- Girls show faster language progress than boys, and reserved, cautious toddlers may wait before trying to speak. Most toddlers use a **referential style** of language learning; their early words consist largely of names for objects. Some use an **expressive style**, in which social formulas and pronouns are common and vocabulary grows more slowly.
- Adults in many cultures speak to young children in **infant-directed speech (IDS)**, a simplified form of language that is well suited to their learning needs. Parent–toddler conversation is a good predictor of early language development and reading success during the school years.

chapter 6

© LAURA DWIGHT PHOTOGRAPHY

This father takes time to build a strong, affectionate bond with his infant daughter. His warmth and sensitivity engender a sense of security in the baby—a vital foundation for all aspects of early development.

Emotional and Social Development in Infancy and Toddlerhood

As Caitlin reached 8 months of age, her parents noticed that she had become more fearful. One evening, when Carolyn and David left her with a babysitter, she wailed as they headed for the door—an experience she had accepted easily a few weeks earlier. Caitlin and Timmy’s caregiver Ginette also observed an increasing wariness of strangers. When she turned to go to another room, both babies dropped their play to crawl after her. At the mail carrier’s knock at the door, they clung to Ginette’s legs, reaching out to be picked up.

At the same time, each baby seemed more willful. Removing an object from the hand produced little response at 5 months. But at 8 months, when Timmy’s mother, Vanessa, took away a table knife he had managed to reach, Timmy burst into angry screams and could not be consoled or distracted.

All Monica and Kevin knew about Grace’s first year was that she had been deeply loved by her destitute, homeless mother. Separation from her, followed by a long journey to an unfamiliar home, had left Grace in shock. At first she was extremely sad, turning away when Monica or Kevin picked her up. But as Grace’s new parents held her close, spoke gently, and satisfied her craving for food, Grace returned their affection. Two weeks after her arrival, her despondency gave way to a sunny, easy-going disposition. She burst into a wide grin, reached out at the sight of Monica and Kevin, and laughed at her brother Eli’s funny faces. As her second birthday approached, she pointed to herself, exclaiming “Gwace!” and laid claim to treasured possessions. “Gwace’s chicken!” she would announce at mealtimes, sucking the marrow from the drumstick, a practice she had brought with her from Cambodia.

Taken together, the children’s reactions reflect two related aspects of personality development during the first two years: close ties to others and a sense of self. We begin with Erikson’s psychosocial theory, which provides an overview of personality development during infancy and toddlerhood. Then, as we chart the course of emotional development, we will discover why fear and anger became more apparent in Caitlin’s and Timmy’s range of emotions by the end of the first year. Our attention then turns to individual

differences in temperament. We will examine genetic and environmental contributions to these differences and their consequences for future development.

Next, we take up attachment to the caregiver, the child's first affectionate tie. We will see how the feelings of security that grow out of this important bond support the child's sense of independence and expanding social relationships.

Finally, we focus on early self-development. By the end of toddlerhood, Grace recognized herself in mirrors and photographs, labeled herself as a girl, and showed the beginnings of self-control. "Don't touch!" she instructed herself one day as she resisted the desire to pull a lamp cord out of its socket. Cognitive advances combine with social experiences to produce these changes during the second year. ●

Erikson's Theory of Infant and Toddler Personality

Our discussion of major theories in Chapter 1 revealed that the psychoanalytic perspective is no longer in the mainstream of human development research. But one of its lasting contributions is its ability to capture the essence of personality during each period of development. Recall that Sigmund Freud believed that psychological health and maladjustment could be traced to the quality of the child's relationships with parents during the early years. Although Freud's preoccupation with the channeling of biological drives and his neglect of important experiences beyond infancy and early childhood came to be heavily criticized, the basic outlines of his theory were accepted and elaborated in several subsequent theories. The most influential is Erik Erikson's *psychosocial theory*, also introduced in Chapter 1.

Basic Trust versus Mistrust

Erikson accepted Freud's emphasis on the importance of the parent–infant relationship during feeding, but he expanded and enriched Freud's view. A healthy outcome during infancy, Erikson believed, does not depend on the *amount* of food or oral stimulation offered but rather on the *quality* of caregiving: relieving discomfort promptly and sensitively, holding the infant gently, waiting patiently until the baby has had enough milk, and weaning when the infant shows less interest in breast or bottle.

Erikson recognized that no parent can be perfectly in tune with the baby's needs. Many factors affect parental responsiveness—personal happiness, current life conditions (for example, additional young children in the family), and culturally valued child-rearing practices. But when the *balance of care* is sympathetic and loving, the psychological conflict of the first year—**basic trust versus mistrust**—is resolved on the positive side. The trusting infant expects the world to be good and gratifying, so he feels confident about venturing out and exploring it. The

mistrustful baby cannot count on the kindness and compassion of others, so she protects herself by withdrawing from people and things around her.

Autonomy versus Shame and Doubt

With the transition to toddlerhood, Freud viewed the parents' manner of toilet training as decisive for psychological health. In Erikson's view, toilet training is only one of many influential experiences. The familiar refrains of newly walking, talking toddlers—"No!" "Do it myself!"—reveal that they have entered a period of budding selfhood. They want to decide for themselves, not just in toileting but also in other situations. The conflict of toddlerhood, **autonomy versus shame and doubt**, is resolved favorably when parents provide young children with suitable guidance and reasonable choices. A self-confident, secure 2-year-old has parents who do not criticize or attack him when he fails at new skills—using the toilet, eating with a spoon, or putting away toys. And they meet his assertions of independence with tolerance and understanding—for example, by giving him an extra five minutes to finish his play before leaving for the grocery store. In contrast, when parents are over- or undercontrolling, the outcome is a child who feels forced and shamed and who doubts his ability to control his impulses and act competently on his own.

In sum, basic trust and autonomy grow out of warm, sensitive parenting and reasonable expectations for impulse control starting in the second year. If children emerge from the first few years without sufficient trust in caregivers and without a healthy sense of individuality, the seeds are sown for adjustment problems. Adults who have difficulty establishing intimate ties, who are overly dependent on a loved one, or who continually doubt their own ability to meet new challenges may not have fully mastered the tasks of trust and autonomy during infancy and toddlerhood.

© SYRACUSE NEWSPAPERS; CANIBELLI/THE IMAGE WORKS

On a visit to a science museum, a 2-year-old insists on exploring a flight simulator. As the mother supports her toddler's desire to "do it myself," she fosters a healthy sense of autonomy.

Emotional Development

TAKE A MOMENT... Observe several infants and toddlers, noting the emotions each displays, the cues you rely on to interpret the baby's emotional state, and how caregivers respond. Researchers have conducted many such observations to find out how babies convey their emotions and interpret those of others. They have discovered that emotions play powerful roles in organizing the attainments that Erikson regarded as so important: social relationships, exploration of the environment, and discovery of the self (Halle, 2003; Saarni et al., 2006).

Think back to the *dynamic systems perspective* introduced in Chapters 1 and 4. As you read about early emotional development in the sections that follow, notice how emotions are an integral part of young children's dynamic systems of action. Emotions energize development. At the same time, they are an aspect of the system that develops, becoming more varied and complex as children reorganize their behavior to attain new goals (Campos, Frankel, & Camras, 2004; Thompson, Winer, & Goodvin, 2011).

Because infants cannot describe their feelings, determining exactly which emotions they are experiencing is a challenge. Cross-cultural evidence reveals that people around the world associate photographs of different facial expressions with emotions in the same way (Ekman, 2003; Ekman & Friesen, 1972). These findings inspired researchers to analyze infants' facial patterns to determine the range of emotions they display at different ages. But to express a particular emotion, infants, children, and adults actually use diverse responses—not just facial expressions but also vocalizations and body movements—which vary with their developing capacities, goals, and contexts. Therefore, to infer babies' emotions as accurately as possible, researchers are best off attending to multiple interacting behavioral cues and seeing how they vary across situations believed to elicit different emotions (Lewis, 2000, 2008).

Development of Basic Emotions

Basic emotions—happiness, interest, surprise, fear, anger, sadness, and disgust—are universal in humans and other primates and have a long evolutionary history of promoting survival. Do infants come into the world with the ability to express basic emotions? Although signs of some emotions are present, babies' earliest emotional life consists of little more than two global arousal states: attraction to pleasant stimulation and withdrawal from unpleasant stimulation (Camras et al., 2003; Fox, 1991). Only gradually do emotions become clear, well-organized signals.

According to one view, sensitive, contingent caregiver communication, in which parents selectively mirror aspects of the baby's diffuse emotional behavior, helps infants construct emotional expressions that more closely resemble those of adults (Gergely & Watson, 1999). With age, face, voice, and posture start to form organized patterns that vary meaningfully with environmental events. For example, Caitlin typically responded to her parents' playful interaction with a joyful face, pleasant

babbling, and a relaxed posture, as if to say, "This is fun!" In contrast, an unresponsive parent often evokes a sad face, fussy sounds, and a drooping body (sending the message, "I'm despondent") or an angry face, crying, and "pick-me-up" gestures (as if to say, "Change this unpleasant event!") (Weinberg & Tronick, 1994; Yale et al., 1999). Gradually, emotional expressions become well-organized and specific—and therefore provide more precise information about the baby's internal state.

Four basic emotions—happiness, anger, sadness, and fear—have received the most research attention. Let's see how they develop.

Happiness. Happiness—expressed first in blissful smiles and later through exuberant laughter—contributes to many aspects of development. When infants achieve new skills, they smile and laugh, displaying delight in motor and cognitive mastery. As the smile encourages caregivers to be affectionate and stimulating, the baby smiles even more (Aksan & Kochanska, 2004). Happiness binds parent and baby into a warm, supportive relationship that fosters the infant's developing competencies.

During the early weeks, newborn babies smile when full, during REM sleep, and in response to gentle touches and sounds, such as stroking of the skin, rocking, and the mother's soft, high-pitched voice. By the end of the first month, infants smile at dynamic, eye-catching sights, such as a bright object jumping suddenly across their field of vision. Between 6 and 10 weeks, the parent's communication evokes a broad grin called the **social smile** (Lavelli & Fogel, 2005; Sroufe & Waters, 1976). These changes parallel the development of infant perceptual capacities—in particular, sensitivity to visual patterns, including the human face (see Chapter 4). And social smiling becomes better-organized and stable as babies learn to use it to evoke and sustain pleasurable face-to-face interaction.

Laughter, which appears around 3 to 4 months, reflects faster processing of information than smiling. But, as with smiling, the first laughs occur in response to very active stimuli, such as the parent saying playfully, "I'm gonna get you!" and kissing the baby's tummy. As infants understand more about their world, they laugh at events with subtler elements of surprise, such as a silent game of peekaboo (Sroufe & Wunsch, 1972).

Around the middle of the first year, infants smile and laugh more when interacting with familiar people, a preference that strengthens the parent-child bond. Between 8 and 10 months, infants more often interrupt their play with an interesting toy to relay their delight to an attentive adult (Venezia et al., 2004). And like adults, 10- to 12-month-olds have several smiles, which vary with context—a broad, "cheek-raised" smile in response to a parent's greeting; a reserved, muted smile for a friendly stranger; and a "mouth-open" smile during stimulating play (Bolzani et al., 2002; Messinger & Fogel, 2007). By the end of the first year, the smile has become a deliberate social signal.

Anger and Sadness. Newborn babies respond with generalized distress to a variety of unpleasant experiences, including hunger, painful medical procedures, changes in body temperature, and too much or too little stimulation. From 4 to 6 months

Biology and Environment

Parental Depression and Child Development

About 8 to 10 percent of women experience chronic depression—mild to severe feelings of sadness, distress, and withdrawal that continue for months or years. Often, the beginnings of this emotional state cannot be pinpointed. In other instances, depression emerges or strengthens after childbirth but fails to subside as the new mother adjusts to hormonal changes in her body and gains confidence in caring for her baby. This is called *postpartum depression*.

Although it is less recognized and studied, fathers, too, experience chronic depression. About 3 to 5 percent of fathers report symptoms after the birth of a child (Madsen & Juhl, 2007; Thombs, Roseman, & Arthurs, 2010). Parental depression can interfere with effective parenting and seriously impair children's development. Genetic makeup increases the risk of depressive illness, but social and cultural factors are also involved.

Maternal Depression

During Julia's pregnancy, her husband, Kyle, showed so little interest in the baby that Julia worried that having a child might be a mistake. Then, shortly after Lucy was born, Julia's mood plunged. She felt anxious and weepy, overwhelmed by Lucy's needs, and angry at loss of control over her own schedule. When Julia approached Kyle about her own fatigue and his unwillingness to help with the baby, he snapped that she was overreacting. Julia's childless friends stopped by just once to see Lucy but did not call again.

Julia's depressed mood quickly affected her baby. In the weeks after birth, infants of depressed mothers sleep poorly, are less attentive to their surroundings, and have elevated levels of the stress hormone cortisol (Field, 1998). The more extreme the depression and the greater the number of stressors in a mother's life (such as marital discord, little or no social support, and poverty), the more the parent-child relationship suffers (Simpson et al., 2003). Julia rarely smiled at,

comforted, or talked to Lucy, who responded to her mother's sad, vacant gaze by turning away, crying, and often looking sad or angry herself (Feldman et al., 2009; Field, 2011). Julia, in turn, felt guilty and inadequate, and her depression deepened. By age 6 months, Lucy showed symptoms common in babies of depressed mothers—delays in motor and mental development, an irritable mood, and attachment difficulties (Cornish et al., 2005; McMahon et al., 2006).

When maternal depression persists, the parent-child relationship worsens. Depressed mothers view their infants more negatively than independent observers do (Forman et al., 2007). And they use inconsistent discipline—sometimes lax, at other times too forceful. As we will see in later chapters, children who experience these maladaptive parenting practices often have serious adjustment problems. Some withdraw into a depressed mood themselves; others become impulsive and aggressive. In one study, infants born to mothers who were depressed during pregnancy were four times as likely as babies of nondepressed mothers to have engaged in violent antisocial behavior (such as fighting, bullying, assault with a weapon,

into the second year, angry expressions increase in frequency and intensity (Braungart-Rieker, Hill-Soderlund, & Karrass, 2010). Older infants also react with anger in a wider range of situations—when an interesting object or event is removed, an expected pleasant event does not occur, their arms are restrained, the caregiver leaves for a brief time, or they are put down for a nap (Camras et al., 1992; Stenberg & Campos, 1990; Sullivan & Lewis, 2003).

Why do angry reactions increase with age? As infants become capable of intentional behavior (see Chapter 5), they want to control their own actions and the effects they produce. They are also more persistent about obtaining desired objects (Mascolo & Fischer, 2007). Furthermore, older infants are better at identifying who caused them pain or removed a toy. The rise in anger is also adaptive. New motor capacities enable an angry infant to defend herself or overcome an obstacle (Izard & Ackerman, 2000). Finally, anger motivates caregivers to relieve the baby's distress and, in the case of separation, may discourage them from leaving again soon.

Although expressions of sadness also occur in response to pain, removal of an object, and brief separations, they are less frequent than anger (Alessandri, Sullivan, & Lewis, 1990).

But when caregiver-infant communication is seriously disrupted, infant sadness is common—a condition that impairs all aspects of development (see the Biology and Environment box above).

Fear. Like anger, fear rises from the second half of the first year into the second year (Braungart-Rieker, Hill-Soderland, & Karrass, 2010). Older infants hesitate before playing with a new toy, and newly crawling infants soon back away from heights (see Chapter 4). But the most frequent expression of fear is to unfamiliar adults, a response called **stranger anxiety**. Many infants and toddlers are quite wary of strangers, although the reaction does not always occur. It depends on several factors: temperament (some babies are generally more fearful), past experiences with strangers, and the current situation. When an unfamiliar adult picks up the infant in a new setting, stranger anxiety is likely. But if the adult sits still while the baby moves around and a parent is nearby, infants often show positive and curious behavior (Horner, 1980). The stranger's style of interaction—expressing warmth, holding out an attractive toy, playing a familiar game, and approaching slowly rather than abruptly—reduces the baby's fear.

and extreme bodily harm) by age 16, after other stressors in the mother's life that could contribute to youth antisocial conduct had been controlled (Hay et al., 2010).

Paternal Depression

Paternal depression is also linked to dissatisfaction with marriage and family life after childbirth and to other life stressors, including job loss and divorce (Bielawska-Batorowicz & Kossakowska-Petrycka, 2006). In a study of a large representative sample of British parents and babies, researchers assessed depressive symptoms of fathers shortly after birth and again the following year. Then they tracked the children's development into the preschool years. Persistent paternal depression was, like maternal depression, a strong predictor of child behavior problems—especially overactivity, defiance, and aggression in boys (Ramchandani et al., 2008).

Paternal depression is linked to frequent father–child conflict as children grow older (Kane & Garber, 2004). Over time, children subjected to parental negativity develop a pessimistic world view—one in which they lack self-confidence and perceive their parents and other people as threatening. Children who

constantly feel endangered are especially likely to become overly aroused in stressful situations, easily losing control in the face of cognitive and social challenges (Sturge-Apple et al., 2008). Although children of depressed parents may inherit a tendency toward emotional and behavior problems, quality of parenting is a major factor in their adjustment.

Interventions

Early treatment is vital to prevent parental depression from interfering with the parent–child relationship. Julia's doctor referred her to a therapist, who helped Julia and Kyle with their marital problems. At times, antidepressant medication is prescribed.

In addition to alleviating parental depression, therapy that encourages depressed mothers to revise their negative views of their babies and to engage in emotionally positive, responsive caregiving is vital for reducing young children's attachment and other developmental problems (Forman et al., 2007). When a depressed parent does not respond easily to treatment, a warm relationship with the other parent or another caregiver can safeguard children's development (Mezulis, Hyde, & Clark, 2004).

This father appears completely disengaged from his wife and toddler. If his depression continues, disruptions in the parent–child relationship will likely lead to serious child behavior problems.

Cross-cultural research reveals that infant-rearing practices can modify stranger anxiety. Among the Efe hunters and gatherers of the Republic of Congo, where the maternal death

rate is high, infant survival is safeguarded by a collective caregiving system in which, starting at birth, Efe babies are passed from one adult to another. Consequently, Efe infants show little stranger anxiety (Tronick, Morelli, & Ivey, 1992). In contrast, among infants in Israeli kibbutzim (cooperative agricultural settlements), who live in isolated communities vulnerable to terrorist attacks, wariness of strangers is widespread. By the end of the first year, when infants look to others for cues about how to respond emotionally, kibbutz babies display greater stranger anxiety than their city-reared counterparts (Saarni et al., 2006).

LOOK AND LISTEN

While observing an 8- to 18-month-old with his or her parent, gently approach the baby, offering a toy. Does the baby respond with stranger anxiety? To better understand the baby's behavior, ask the parent to describe his or her temperament and past experiences with strangers. ●

© ELLEN B. SENISI PHOTOGRAPHY

Stranger anxiety appears in many infants after 6 months of age. But this baby, safe in his mother's arms, also expresses curiosity, reaching out warily toward an unfamiliar adult who eases his fear by smiling and approaching slowly.

The rise in fear after age 6 months keeps newly mobile babies' enthusiasm for exploration in check. Once wariness develops, babies use the familiar caregiver as a **secure base**, or

point from which to explore, venturing into the environment and then returning for emotional support. As part of this adaptive system, encounters with strangers lead to two conflicting tendencies: approach (indicated by interest and friendliness) and avoidance (indicated by fear). The infant's behavior is a balance between the two.

Eventually, as cognitive development enables toddlers to discriminate more effectively between threatening and non-threatening people and situations, stranger anxiety and other fears of the first two years decline. Fear also wanes as toddlers acquire more strategies for coping with it, as you will see when we discuss emotional self-regulation.

Understanding and Responding to the Emotions of Others

Infants' emotional expressions are closely tied to their ability to interpret the emotional cues of others. We have seen that in the first few months, babies match the feeling tone of the caregiver in face-to-face communication. Some researchers claim that infants respond in kind to others' emotions through a built-in, automatic process of *emotional contagion* (Stern, 1985). Others, however, believe that infants acquire these emotional contingencies through operant conditioning—for example, learning that a smile generally triggers pleasurable feedback and that distress prompts a comforting response (Saarni et al., 2006).

Around 3 to 4 months, infants can match the emotion in a voice with the appropriate face of a speaking person, and they become sensitive to the structure and timing of face-to-face interactions. When they gaze, smile, or vocalize, they now expect their social partner to respond in kind, and they reply with positive vocal and emotional reactions (Markova & Legerstee, 2006; Rochat, Striano, & Blatt, 2002). Within these exchanges, babies become increasingly aware of the range of emotional expressions (Montague & Walker-Andrews, 2001). Recall from Chapter 4 (see page 136) that out of this early imitative communication, infants start to view others as “like me”—an awareness believed to lay the foundation for understanding others' thoughts and feelings (Meltzoff, 2007).

From 5 months on, infants perceive facial expressions as organized patterns (see Chapter 4). Responding to emotional expressions as organized wholes suggests that these signals are becoming meaningful to babies. As skill at establishing joint attention improves, infants realize that an emotional expression not only has meaning but is also a meaningful reaction to a specific object or event (Moses et al., 2001; Tomasello, 1999).

Once these understandings are in place, beginning at 8 to 10 months, infants engage in **social referencing**—actively seeking emotional information from a trusted person in an uncertain situation (Mumme et al., 2007). Many studies show that the caregiver's emotional expression (happy, angry, or fearful) influences whether a 1-year-old will be wary of strangers, play with an unfamiliar toy, or cross the deep side of the visual cliff (see page 143) (de Rosnay et al., 2006; Stenberg, 2003; Striano & Rochat, 2000). The caregiver's voice—either alone or combined with a facial expression—is more effective than a facial expression

alone (Kim, Walden, & Knieps, 2010; Vaish & Striano, 2004). The voice conveys both emotional and verbal information, and the baby need not turn toward the adult but, instead, can focus on evaluating the novel event.

Parents can take advantage of social referencing to teach their baby how to react to many everyday events. And around the middle of the second year, as toddlers begin to appreciate that others' emotional reactions may differ from their own, social referencing allows them to compare their own and others' assessments of events. In one study, an adult showed 14- and 18-month-olds broccoli and crackers and acted delighted with one food but disgusted with the other. When asked to share the food, 18-month-olds gave the adult whichever food she appeared to like, regardless of their own preferences (Repacholi & Gopnik, 1997).

In sum, in social referencing, toddlers move beyond simply reacting to others' emotional messages. They use those signals to evaluate the safety and security of their surroundings, to guide their own actions, and to gather information about others' intentions and preferences. These experiences, along with cognitive and language development, probably help toddlers refine the meanings of emotions—for example, happiness versus surprise, anger versus fear—during the second year (Gendler, Witherington, & Edwards, 2008; Saarni et al., 2006).

Emergence of Self-Conscious Emotions

Besides basic emotions, humans are capable of a second, higher-order set of feelings, including guilt, shame, embarrassment, envy, and pride. These are called **self-conscious emotions** because each involves injury to or enhancement of our sense of self. We feel guilt when we have harmed someone and want to correct the wrongdoing. When we are ashamed or embarrassed, we have negative feelings about our behavior, and we want to retreat so others will no longer notice our failings. In contrast, pride reflects delight in the self's achievements, and we are inclined to tell others what we have accomplished and to take on further challenges (Saarni et al., 2006).

Self-conscious emotions appear in the middle of the second year, as 18- to 24-month-olds become firmly aware of the self as a separate, unique individual. Toddlers show shame and embarrassment by lowering their eyes, hanging their heads, and hiding their faces with their hands. They show guiltlike reactions, too, like the 22-month-old who returned a toy she had grabbed and patted her upset playmate. Pride also emerges around this time, and envy by age 3 (Barrett, 2005; Garner, 2003; Lewis et al., 1989).

Besides self-awareness, self-conscious emotions require an additional ingredient: adult instruction in *when* to feel proud, ashamed, or guilty. Parents begin this tutoring early when they say, “Look how far you can throw that ball!” or “You should feel ashamed for grabbing that toy!” Self-conscious emotions play important roles in children's achievement-related and moral behaviors. The situations in which adults encourage these feelings vary from culture to culture. In Western individualistic nations, most children are taught to feel pride in personal

A mother praises her 2-year-old's success at tower-building. To experience self-conscious emotions, such as pride, young children need self-awareness as well as adult instruction.

achievement—throwing a ball the farthest, winning a game, and (later on) getting good grades. In collectivist cultures such as China and Japan, calling attention to individual success evokes embarrassment and self-effacement. And violating cultural standards by failing to show concern for others—a parent, a teacher, or an employer—sparks intense shame (Akimoto & Sanbonmatsu, 1999; Lewis, 1992).

Beginnings of Emotional Self-Regulation

Besides expressing a wider range of emotions, infants and toddlers begin to manage their emotional experiences. **Emotional self-regulation** refers to the strategies we use to adjust our emotional state to a comfortable level of intensity so we can accomplish our goals (Eisenberg & Spinrad, 2004; Thompson & Goodvin, 2007). When you remind yourself that an anxiety-provoking event will be over soon, suppress your anger at a friend's behavior, or decide not to see a scary horror film, you are engaging in emotional self-regulation.

Emotional self-regulation requires voluntary, effortful management of emotions. This capacity for *effortful control* improves gradually, as a result of development of the prefrontal cortex and the assistance of caregivers, who help children manage intense emotion and teach them strategies for doing so (Fox & Calkins, 2003; Rothbart, Posner, & Kieras, 2006). Individual differences in control of emotion are evident in infancy and, by early childhood, play such a vital role in children's adjustment that—as we will see later—effortful control is considered a major dimension of temperament. A good start in regulating emotion during the first two years contributes greatly to autonomy and mastery of cognitive and social skills (Eisenberg et al., 2004; Lawson & Ruff, 2004).

In the early months, infants have only a limited capacity to regulate their emotional states. When their feelings get too intense, they are easily overwhelmed. They depend on the soothing interventions of caregivers—being lifted to the shoulder, rocked, gently stroked, and talked to softly—for distraction and reorienting of attention.

More effective functioning of the prefrontal cortex increases the baby's tolerance for stimulation. Between 2 and 4 months, caregivers build on this capacity by initiating face-to-face play and attention to objects. In these interactions, parents arouse pleasure in the baby while adjusting the pace of their behavior so the infant does not become overwhelmed and distressed. As a result, the baby's tolerance for stimulation increases further (Kopp & Neufeld, 2003).

By 4 to 6 months, the ability to shift attention helps infants control emotion. Babies who more readily turn away from unpleasant events or engage in self-soothing are less prone to distress (Crockenberg & Leerkes, 2003). At the end of the first year, crawling and walking enable infants to regulate emotion more effectively by approaching or retreating from various situations.

Infants whose parents “read” and respond contingently and sympathetically to their emotional cues tend to be less fussy and fearful, to express more pleasurable emotion, to be more interested in exploration, and to be easier to soothe (Braungart-Rieker, Hill-Soderlund, & Karrass, 2010; Crockenberg & Leerkes, 2004; Volling et al., 2002). In contrast, parents who respond impatiently or angrily or who wait to intervene until the infant has become extremely agitated reinforce the baby's rapid rise to intense distress. When caregivers fail to regulate stressful experiences for babies, brain structures that buffer stress may not develop properly, resulting in an anxious, reactive child who has a reduced capacity for managing emotional problems (Blair & Raver, 2012; Feldman, 2007).

Caregivers also provide lessons in socially approved ways of expressing feelings. As early as the first few months, parents encourage infants to suppress negative emotion by imitating their expressions of interest, happiness, and surprise more often than their expressions of anger and sadness. Boys get more of this training than girls, in part because boys have a harder time regulating negative emotion (Else-Quest et al., 2006; Malatesta et al., 1986). As a result, the well-known sex difference—females as emotionally expressive and males as emotionally controlled—is promoted at a tender age. Collectivist cultures place particular emphasis on socially appropriate emotional behavior. Compared with Americans, Japanese and Chinese adults discourage the expression of strong emotion in babies (Fogel, 1993; Kuchner, 1989). By the end of the first year, Chinese and Japanese infants smile and cry less than American infants (Camras et al., 1998; Gartstein et al., 2010).

Toward the end of the second year, a vocabulary for talking about feelings—“happy,” “surprised,” “scary,” “yucky,” “mad”—develops rapidly, but toddlers are not yet good at using language to manage their emotions. Temper tantrums tend to occur when an adult rejects their demands, particularly when toddlers are fatigued or hungry (Mascolo & Fischer, 2007). Toddlers whose parents are emotionally sympathetic but set

limits (by not giving in to tantrums), who distract the child by offering acceptable alternatives, and who later suggest better ways to handle adult refusals display more effective anger-regulation strategies and social skills during the preschool years (Lecuyer & Houck, 2006).

Patient, sensitive parents also encourage toddlers to describe their internal states. Then, when 2-year-olds feel distressed, they can guide caregivers in helping them (Cole, Armstrong, & Pemberton, 2010). For example, while listening to a story about monsters, Grace whimpered, “Mommy, scary.” Monica put the book down and gave Grace a comforting hug.

ASK YOURSELF

REVIEW Why do many infants show stranger anxiety in the second half of the first year? What factors can increase or decrease wariness of strangers?

CONNECT Why do children of depressed parents have difficulty regulating emotion (see pages 186–187)? What implications do their weak self-regulatory skills have for their response to cognitive and social challenges?

APPLY At age 14 months, Reggie built a block tower and gleefully knocked it down. But at age 2, he called to his mother and pointed proudly to his tall block tower. What explains this change in Reggie’s emotional behavior?

REFLECT Describe several recent instances illustrating how you typically manage negative emotion. How might your early experiences, gender, and cultural background have influenced your style of emotional self-regulation?

Temperament and Development

From early infancy, Caitlin’s sociability was unmistakable. She smiled and laughed while interacting with adults and, in her second year, readily approached other children. Meanwhile, Monica marveled at Grace’s calm, relaxed disposition. At 19 months, she sat contented in a highchair through a two-hour family celebration at a restaurant. In contrast, Timmy was active and distractible. Vanessa found herself chasing him as he dropped one toy, moved on to the next, and climbed on chairs and tables.

When we describe one person as cheerful and “upbeat,” another as active and energetic, and still others as calm, cautious, persistent, or prone to angry outbursts, we are referring to **temperament**—early-appearing, stable individual differences in reactivity and self-regulation. *Reactivity* refers to quickness and intensity of emotional arousal, attention, and motor activity. *Self-regulation*, as we have seen, refers to strategies that modify that reactivity (Rothbart & Bates, 2006). The psychological traits that make up temperament are believed to form the cornerstone of the adult personality.

In 1956, Alexander Thomas and Stella Chess initiated the New York Longitudinal Study, a groundbreaking investigation of the development of temperament that followed 141 children from early infancy well into adulthood. Results showed that temperament can increase a child’s chances of experiencing psychological problems or, alternatively, protect a child from the negative effects of a highly stressful home life. At the same time, Thomas and Chess (1977) discovered that parenting practices can modify children’s temperaments considerably.

These findings stimulated a growing body of research on temperament, including its stability, biological roots, and interaction with child-rearing experiences. Let’s begin to explore these issues by looking at the structure, or makeup, of temperament and how it is measured.

The Structure of Temperament

Thomas and Chess’s model of temperament inspired all others that followed. When detailed descriptions of infants’ and children’s behavior obtained from parent interviews were rated on nine dimensions of temperament, certain characteristics clustered together, yielding three types of children:

- The **easy child** (40 percent of the sample) quickly establishes regular routines in infancy, is generally cheerful, and adapts easily to new experiences.
- The **difficult child** (10 percent of the sample) is irregular in daily routines, is slow to accept new experiences, and tends to react negatively and intensely.
- The **slow-to-warm-up child** (15 percent of the sample) is inactive, shows mild, low-key reactions to environmental stimuli, is negative in mood, and adjusts slowly to new experiences.

Note that 35 percent of the children did not fit any of these categories. Instead, they showed unique blends of temperamental characteristics.

The difficult pattern has sparked the most interest because it places children at high risk for adjustment problems—both anxious withdrawal and aggressive behavior in early and middle childhood (Bates, Wachs, & Emde, 1994; Ramos et al., 2005; Thomas, Chess, & Birch, 1968). Compared with difficult children, slow-to-warm-up children present fewer problems in the early years. However, they tend to show excessive fearfulness and slow, constricted behavior in the late preschool and school years, when they are expected to respond actively and quickly in classrooms and peer groups (Chess & Thomas, 1984; Schmitz et al., 1999).

Today, the most influential model of temperament is Mary Rothbart’s, described in Table 6.1. It combines related traits proposed by Thomas and Chess and other researchers, yielding a concise list of just six dimensions. For example, “distractibility” and “attention span and persistence” are considered opposite ends of the same dimension, which is labeled “attention span/persistence.” A unique feature of Rothbart’s model is inclusion of both “fearful distress” and “irritable distress,” which distinguish between reactivity triggered by fear and reactivity due to frustration. And the model deletes overly broad dimensions, such as

TABLE 6.1 Rothbart's Model of Temperament

DIMENSION	DESCRIPTION
REACTIVITY	
Activity level	Level of gross-motor activity
Attention span/persistence	Duration of orienting or interest
Fearful distress	Wariness and distress in response to intense or novel stimuli, including time to adjust to new situations
Irritable distress	Extent of fussing, crying, and distress when desires are frustrated
Positive affect	Frequency of expression of happiness and pleasure
SELF-REGULATION	
Effortful control	Capacity to voluntarily suppress a dominant, reactive response in order to plan and execute a more adaptive response

regularity of body functions and intensity of reaction (Rothbart, Ahadi, & Evans, 2000; Rothbart & Mauro, 1990). A child who is regular in sleeping is not necessarily regular in eating or bowel habits. And a child who smiles and laughs intensely is not necessarily intense in fear, irritability, or motor activity.

Rothbart's dimensions represent the three underlying components included in the definition of temperament: (1) *emotion* ("fearful distress," "irritable distress," "positive affect," and "soothability"), (2) *attention* ("attention span/persistence"), and (3) *action* ("activity level"). According to Rothbart, individuals differ not only in their reactivity on each dimension but also in the self-regulatory dimension of temperament, **effortful control**—the capacity to voluntarily suppress a dominant response in order to plan and execute a more adaptive response (Rothbart, 2003; Rothbart & Bates, 2006). Variations in effortful control are evident in how effectively a child can focus and shift attention, inhibit impulses, and manage negative emotion.

Beginning in early childhood, effortful control predicts favorable development and adjustment in cultures as diverse as China and the United States (Zhou, Lengua, & Wang, 2009). Positive outcomes include persistence, task mastery, academic achievement, cooperation, moral maturity (such as concern about wrongdoing and willingness to apologize), and positive social behaviors of sharing and helpfulness (Eisenberg, 2010; Harris et al., 2007; Kochanska & Aksan, 2006; Posner & Rothbart, 2007; Valiente et al., 2010). Effortful control is also associated with children's resistance to stress (David & Murphy, 2007). Perhaps children high in effortful control are better able to shift attention away from disturbing events and their own anxiety to more positive features of their social environments.

TAKE A MOMENT... Turn back to page 162 in Chapter 5 to review the concept of executive function, and note its resemblance to effortful control. These converging concepts,

which are associated with similar positive outcomes, reveal that the same mental activities lead to effective regulation in both the cognitive and emotional/social domains.

Measuring Temperament

Temperament is often assessed through interviews or questionnaires given to parents. Behavior ratings by pediatricians, teachers, and others familiar with the child and laboratory observations by researchers have also been used. Parental reports are convenient and take advantage of parents' depth of knowledge about their child across many situations (Gartstein & Rothbart, 2003). Although information from parents has been criticized as biased, parental reports are moderately related to researchers' observations of children's behavior (Majdandžić & van den Boom, 2007; Mangelsdorf, Schoppe, & Buur, 2000). And parent perceptions are useful for understanding how parents view and respond to their child.

Observations by researchers in the home or laboratory avoid the subjectivity of parental reports but can lead to other inaccuracies. In homes, observers find it hard to capture rare but important events, such as infants' response to frustration. And in the unfamiliar lab setting, fearful children who calmly avoid certain experiences at home may become too upset to complete the session (Wachs & Bates, 2001). Still, researchers can better control children's experiences in the lab. And they can conveniently combine observations of behavior with physiological measures to gain insight into the biological bases of temperament.

Most neurobiological research has focused on children who fall at opposite extremes of the positive-affect and fearful-distress dimensions of temperament: **inhibited, or shy, children**, who react negatively to and withdraw from novel stimuli, and **uninhibited, or sociable, children**, who display positive emotion to and approach novel stimuli. As the Biology and Environment box on page 192 reveals, biologically based reactivity—evident in heart rate, hormone levels, and measures of brain activity—differentiates children with inhibited and uninhibited temperaments.

Stability of Temperament

Young children who score low or high on attention span, irritability, sociability, shyness, or effortful control tend to respond similarly when assessed again several months to a few years later and, occasionally, even into the adult years (Caspi et al., 2003; Kochanska & Knaack, 2003; Majdandžić & van den Boom, 2007; Rothbart, Ahadi, & Evans, 2000; van den Akker et al., 2010). However, the overall stability of temperament is low in infancy and toddlerhood and only moderate from the preschool years on (Putnam, Samson, & Rothbart, 2000).

Why isn't temperament more stable? A major reason is that temperament itself develops with age. To illustrate, let's look at irritability and activity level. Recall from Chapter 3 that most babies fuss and cry in the early months. As infants better regulate their attention and emotions, many who initially seemed irritable become calm and content. In the case of activity level, the meaning of the behavior changes. At first, an active, wriggling

Biology and Environment

Development of Shyness and Sociability

Two 4-month-old babies, Larry and Mitch, visited the laboratory of Jerome Kagan, who observed their reactions to various unfamiliar experiences. When exposed to new sights and sounds, such as a moving mobile decorated with colorful toys, Larry tensed his muscles, moved his arms and legs with agitation, and began to cry. In contrast, Mitch remained relaxed and quiet, smiling and cooing.

As toddlers, Larry and Mitch returned to the laboratory, where they experienced several procedures designed to induce uncertainty. Electrodes were placed on their bodies and blood pressure cuffs on their arms to measure heart rate; toy robots, animals, and puppets moved before their eyes; and unfamiliar people behaved in unexpected ways or wore novel costumes. While Larry whimpered and quickly withdrew, Mitch watched with interest, laughed, and approached the toys and strangers.

On a third visit, at age 4½, Larry barely talked or smiled during an interview with an unfamiliar adult. In contrast, Mitch asked questions and communicated his pleasure at each new activity. In a playroom with two unfamiliar peers, Larry pulled back and watched, while Mitch quickly made friends.

In longitudinal research on several hundred children, Kagan found that about 20 percent of 4-month-old babies were, like Larry, easily upset by novelty; 40 percent, like Mitch, were comfortable, even delighted, with new experiences. About 20 to 30 percent of these groups retained their temperamental styles as they grew older (Kagan, 2003; Kagan & Saudino, 2001; Kagan et al., 2007). But most children's dispositions became less extreme over time. Biological makeup and child-rearing experiences jointly influenced stability and change in temperament.

Neurobiological Correlates of Shyness and Sociability

Individual differences in arousal of the *amygdala*, an inner brain structure devoted to processing emotional information, contribute to these contrasting temperaments. In shy,

inhibited children, novel stimuli easily excite the amygdala and its connections to the prefrontal cortex and the sympathetic nervous system, which prepares the body to act in the face of threat. In sociable, uninhibited children, the same level of stimulation evokes minimal neural excitation (Kagan & Fox, 2006). While viewing photos of unfamiliar faces, adults who had been classified as inhibited in the second year of life showed greater fMRI activity in the amygdala than adults who had been uninhibited as toddlers (Schwartz et al., 2003). And additional neurobiological responses known to be mediated by the amygdala distinguish these two emotional styles:

- **Heart rate.** From the first few weeks of life, the heart rates of shy children are consistently higher than those of sociable children, and they speed up further in response to unfamiliar events (Schmidt et al., 2007; Snidman et al., 1995).
- **Cortisol.** Saliva concentrations of the stress hormone cortisol tend to be higher, and to rise more in response to a stressful event, in shy than in sociable children (Schmidt et al., 1997, 1999; Zimmermann & Stansbury, 2004).
- **Pupil dilation, blood pressure, and skin surface temperature.** Compared with sociable children, shy children show greater pupil dilation, rise in blood pressure, and cooling of the fingertips when faced with novelty (Kagan et al., 1999, 2007).

Furthermore, shy infants and preschoolers show greater EEG activity in the right than in the left frontal lobe of the cerebral cortex, which is associated with negative emotional reactivity; sociable children show the opposite pattern (Fox et al., 2008; Kagan et al., 2007). Neural activity in the amygdala, which is transmitted to the frontal lobes, probably contributes to these differences.

Child-Rearing Practices

According to Kagan, extremely shy or sociable children inherit a physiology that biases them toward a particular temperamental style. Yet heritability research indicates that

A strong physiological response to uncertain situations prompts this toddler to cling to her father. With patient but insistent encouragement, her parents can help her overcome the urge to retreat.

genes contribute only modestly to shyness and sociability (Kagan & Fox, 2006).

Child-rearing practices affect the chances that an emotionally reactive baby will become a fearful child. Warm, supportive parenting reduces shy infants' and preschoolers' intense physiological reaction to novelty, whereas cold, intrusive parenting heightens anxiety (Coplan, Arbeau, & Armer, 2008; Hane et al., 2008). And if parents overprotect infants and young children who dislike novelty, they make it harder for their child to overcome an urge to retreat. Parents who make appropriate demands for their child to approach new experiences help shy youngsters develop strategies for regulating fear (Rubin & Burgess, 2002).

When inhibition persists, it leads to excessive cautiousness, low self-esteem, and loneliness. In adolescence, persistent shyness increases the risk of severe anxiety, especially social phobia—intense fear of being humiliated in social situations (Kagan & Fox, 2006). For inhibited children to acquire effective social skills, parenting must be tailored to their temperaments—a theme we will encounter again in this and later chapters.

infant tends to be highly aroused and uncomfortable, whereas an inactive baby is often alert and attentive. Once infants move on their own, the reverse is so! An active crawler is usually alert and interested in exploration, whereas an inactive baby may be fearful and withdrawn.

These discrepancies help us understand why long-term prediction from early temperament is best achieved after age 3, when styles of responding are better established (Roberts & DelVecchio, 2000). In line with this idea, between age 2½ and 3, children improve substantially and also perform more consistently across a wide range of tasks requiring effortful control, such as waiting for a reward, lowering their voice to a whisper, succeeding at games like “Simon Says,” and selectively attending to one stimulus while ignoring competing stimuli (Kochanska, Murray, & Harlan, 2000; Li-Grining, 2007). Researchers believe that around this time, areas in the prefrontal cortex involved in suppressing impulses develop rapidly (Gerardi-Caulton, 2000; Rothbart & Bates, 2006).

Nevertheless, the ease with which children manage their reactivity in early childhood depends on the type and strength of the reactive emotion involved. Preschoolers who were highly fearful as toddlers score slightly better than their agetates in effortful control. In contrast, angry, irritable toddlers tend to be less effective at effortful control at later ages (Bridgett et al., 2009; Kochanska & Knaack, 2003).

In sum, many factors affect the extent to which a child's temperament remains stable, including development of the biological systems on which temperament is based, the child's capacity for effortful control, and the success of her efforts, which depend on the quality and intensity of her emotional reactivity. When we consider the evidence as a whole, the low to moderate stability of temperament makes sense. It also confirms that experience can modify biologically based temperamental traits considerably, although children rarely change from one extreme to another—that is, shy toddlers practically never become highly sociable, and irritable toddlers seldom become easy-going. With these ideas in mind, let's turn to genetic and environmental contributions to temperament and personality.

Genetic and Environmental Influences

The word *temperament* implies a genetic foundation for individual differences in personality. Research indicates that identical twins are more similar than fraternal twins across a wide range of temperamental and personality traits (Bouchard, 2004; Bouchard & Loehlin, 2001; Caspi & Shiner, 2006; Goldsmith, Pollak, & Davidson, 2008). In Chapter 2, we noted that heritability estimates suggest a moderate role for heredity in temperament and personality: About half of individual differences have been attributed to differences in genetic makeup.

Nevertheless, genetic influences vary with the temperamental trait and with the age of individuals studied. For example, heritability estimates are higher for expressions of negative emotion than for positive emotion. And the role of heredity is considerably less in infancy than in childhood and later years, when temperament becomes more stable (Wachs & Bates, 2001).

Although genetic influences are clear, environment is also powerful. For example, persistent nutritional and emotional deprivation profoundly alters temperament, resulting in maladaptive emotional reactivity. Recall from Chapter 4 that even after dietary improvement, children exposed to severe malnutrition in infancy remain more distractible and fearful than their agetates. And infants reared in deprived orphanages are easily overwhelmed by stressful events. Their poor regulation of emotion results in inattention and weak impulse control, including frequent expressions of anger (see page 127).

Other evidence confirms that heredity and environment often jointly contribute to temperament, since a child's approach to the world affects the experiences to which she is exposed—an instance of gene–environment correlation (see page 72 in Chapter 2). To see how this works, let's look at ethnic and gender differences.

Ethnic and Gender Differences. Compared with American Caucasian infants, Chinese and Japanese babies tend to be less active, irritable, vocal, more easily soothed when upset, and better at quieting themselves (Kagan et al., 1994; Lewis, Ramsay, & Kawakami, 1993). Chinese and Japanese babies are also more fearful and inhibited, remaining closer to their mothers in an unfamiliar playroom and displaying more anxiety when interacting with a stranger (Chen, Wang, & DeSouza, 2006).

These variations may have genetic roots, but they are supported by cultural beliefs and practices. Japanese mothers usually say that babies come into the world as independent beings who must learn to rely on their mothers through close physical contact. American mothers typically believe just the opposite—that they must wean babies away from dependency toward autonomy. And while Asian cultures tend to view calmness as an ideal emotional state, Americans highly value the arousal and excitement generated by new places and activities (Kagan, 2010). Consistent with these beliefs, Asian mothers interact gently, soothingly, and gesturally with their babies, whereas Caucasian mothers use a more active, stimulating, verbal approach (Rothbaum et al., 2000a). Also, recall from our discussion of emotional self-regulation that Chinese and Japanese adults discourage babies from expressing strong emotion, which contributes further to their infants' tranquility.

Similarly, gender differences in temperament are evident as early as the first year, suggesting a genetic foundation. Boys are more active and daring, more irritable when frustrated, and slightly more impulsive—factors that contribute to their higher injury rates throughout childhood and adolescence. And girls' large advantage in effortful control undoubtedly contributes to their greater compliance, better school performance, and lower incidence of behavior problems (Eisenberg et al., 2004; Else-Quest et al., 2006). At the same time, parents more often encourage their young sons to be physically active and their daughters to seek help and physical closeness—through the toys they provide (trucks and footballs for boys, dolls and tea sets for girls) and through more positive reactions when the child exhibits temperamental traits consistent with gender stereotypes (Bryan & Dix, 2009; Ruble, Martin, & Berenbaum, 2006).

Children's Unique Experiences. In families with several children, an additional influence on temperament is at work. **TAKE A MOMENT...** Ask several parents to describe each of their children's personalities. You will see that they often look for differences between siblings: "She's a lot more active," "He's more sociable," "She's far more persistent." As a result, parents often regard siblings as more distinct than other observers do. In a large study of 1- to 3-year-old twin pairs, parents rated identical twins as resembling each other less in temperament than researchers' ratings indicated. And whereas researchers rated fraternal twins as moderately similar, parents viewed them as somewhat opposite in temperamental style (Saudino, 2003).

Parents' tendency to emphasize each child's unique qualities affects their child-rearing practices. In an investigation of identical-twin toddlers, mothers' differential treatment predicted differences in psychological adjustment. The twin who received more warmth and less harshness was more positive in mood and social behavior (Deater-Deckard et al., 2001). Each child, in turn, evokes responses from caregivers that are consistent with parental beliefs and the child's developing temperament.

Besides different experiences within the family, siblings have distinct experiences with teachers, peers, and others in their community that affect personality development. And in middle childhood and adolescence, they often seek ways to differ from one another. For all these reasons, both identical and fraternal twins tend to become increasingly dissimilar in personality with age (Loehlin & Martin, 2001; McCartney, Harris, & Bernieri, 1990). In sum, temperament and personality can be understood only in terms of complex interdependencies between genetic and environmental factors.

Temperament and Child Rearing: The Goodness-of-Fit Model

If a child's disposition interferes with learning or getting along with others, adults must gently but consistently counteract the child's maladaptive style. Thomas and Chess (1977) proposed a **goodness-of-fit model** to describe how temperament and environment together can produce favorable outcomes. Goodness of fit involves creating child-rearing environments that recognize each child's temperament while encouraging more adaptive functioning.

Difficult children (who withdraw from new experiences and react negatively and intensely) frequently experience parenting that fits poorly with their dispositions, putting them at high risk for later adjustment problems. By the second year, their parents tend to resort to angry, punitive discipline, which undermines the development of effortful control. As the child reacts with defiance and disobedience, parents become increasingly stressed (Bridgett et al., 2009; Paulussen-Hoogbeem et al., 2007). As a result, they continue their coercive tactics and also discipline inconsistently, at times rewarding the child's noncompliance by giving in to it. These practices sustain and even increase the child's irritable, conflict-ridden style (van Aken et al., 2007; Pesonen et al., 2008).

© CORBIS

A parent's firm but affectionate approach to discipline can help temperamentally difficult children gain in effortful control, managing negative emotion.

In contrast, when parents are positive and sensitive, which helps babies regulate emotion, difficultness declines by age 2 or 3 (Feldman, Greenbaum, & Yirmiya, 1999). In toddlerhood and childhood, parental sensitivity, support, clear expectations, and limits foster effortful control, also reducing the likelihood that difficultness will persist (Cipriano & Stifter, 2010; Raikes et al., 2007).

Recent evidence indicates that temperamentally difficult children function much worse than other children when exposed to inept parenting, yet benefit most from good parenting (Pluess & Belsky, 2011). Using molecular genetic analyses, researchers are investigating gene-environment interactions (see page 71 in Chapter 2) that explain this finding. In one study, 2-year-olds with a chromosome 17 gene that interferes with functioning of the neurotransmitter serotonin (involved in regulating negative mood) became increasingly irritable as their mothers' anxiety about parenting increased (Ivorra et al., 2010). Maternal anxiety had little impact on toddlers without this genetic marker. In another investigation, preschoolers with this gene benefited, especially, from positive parenting. With affection and support, their capacity for effortful control equaled that of age-mates with a low-risk genotype (Kochanska, Philibert, & Barry, 2009).

Cultural values also affect the fit between parenting and child temperament, as research in China illustrates. In the past, collectivist values, which discourage self-assertion, led Chinese adults to evaluate shy children positively (Chen, Rubin, & Li, 1995; Chen et al., 1998). But rapid expansion of a market economy in China, which requires assertiveness and sociability for success, may be responsible for a change in Chinese parents' and

teachers' attitudes toward childhood shyness (Chen, Wang, & DeSouza, 2006; Yu, 2002). In a study of Shanghai fourth graders, the association between shyness and adjustment changed over time. Whereas shyness was positively correlated with teacher-rated competence, peer acceptance, leadership, and academic achievement in 1990, these relationships weakened in 1998 and reversed in 2002, when they mirrored findings of Western research (see Figure 6.1) (Chen et al., 2005). But in rural areas of China, positive valuing of shyness persists, and shy children in rural communities continue to enjoy high social status and are well-adjusted (Chen, Wang, & Cao, 2011). Cultural context makes a difference in whether shy children fare well or poorly.

An effective match between rearing conditions and child temperament is best accomplished early, before unfavorable temperament–environment relationships produce maladjustment. Both difficult and shy children benefit from warm, accepting parenting that makes firm but reasonable demands for mastering new experiences. The goodness-of-fit model reminds us that children have unique dispositions that adults must accept. Parents can neither take full credit for their children's virtues nor be blamed for all their faults. But parents can turn an environment that exaggerates a child's problems into one that builds on the child's strengths.

As we will see next, goodness of fit is also at the heart of infant–caregiver attachment. This first intimate relationship grows out of interaction between parent and baby, to which the emotional styles of both partners contribute.

FIGURE 6.1 Changes over time in correlations between shyness and adjustment among Chinese fourth graders. In 1990, shy Chinese children appeared well-adjusted. But as China's market economy expanded and valuing of self-assertion and sociability increased, the direction of the correlations shifted. In 2002, shyness was negatively associated with adjustment. These findings are for teacher-rated competence and peer acceptance. Those for leadership (holding offices in student organizations) and academic achievement changed similarly. (Adapted from Chen et al., 2005.)

ASK YOURSELF

REFLECT How would you describe your temperament as a young child? Do you think your temperament has remained stable, or has it changed? What factors might be involved?

Development of Attachment

Attachment is the strong affectionate tie we have with special people in our lives that leads us to feel pleasure when we interact with them and to be comforted by their nearness in times of stress. By the second half of the first year, infants have become attached to familiar people who have responded to their needs.

TAKE A MOMENT... Watch how babies of this age single out their parents for special attention. When the parent enters the room, the baby breaks into a broad, friendly smile. When she picks him up, he pats her face, explores her hair, and snuggles against her. When he feels anxious or afraid, he crawls into her lap and clings closely.

Freud first suggested that the infant's emotional tie to the mother is the foundation for all later relationships. Contemporary research indicates that—although the parent–infant bond is vitally important—later development is influenced not just by early attachment experiences but also by the continuing quality of the parent–child relationship.

Attachment has also been the subject of intense theoretical debate. Recall that the *psychoanalytic perspective* regards feeding as the central context in which caregivers and babies build this close emotional bond. *Behaviorism*, too, emphasizes the importance of feeding, but for different reasons. According to a well-known behaviorist explanation, infants learn to prefer the mother's soft caresses, warm smiles, and tender words because these events are paired with tension relief as she satisfies the baby's hunger.

Although feeding is an important context for building a close relationship, attachment does not depend on hunger satisfaction. In the 1950s, a famous experiment showed that rhesus monkeys reared with terry-cloth and wire-mesh “surrogate

NINA LEEN/TIME LIFE PICTURES/GETTY IMAGES

Baby monkeys reared with “surrogate mothers” preferred to cling to a soft terry-cloth “mother” over a wire-mesh “mother” holding a bottle—evidence that parent–infant attachment is based on more than satisfaction of hunger.

mothers” cling to the soft terry-cloth substitute, even though the wire-mesh “mother” held the bottle and infants had to climb onto it to be fed (Harlow & Zimmerman, 1959). Human infants, too, become attached to family members who seldom feed them, including fathers, siblings, and grandparents. And toddlers in Western cultures who sleep alone and experience frequent daytime separations from their parents sometimes develop strong emotional ties to cuddly objects, such as blankets and teddy bears, that play no role in infant feeding!

Bowlby’s Ethological Theory

Today, **ethological theory of attachment**, which recognizes the infant’s emotional tie to the caregiver as an evolved response that promotes survival, is the most widely accepted view. John Bowlby (1969), who first applied this idea to the infant–caregiver bond, retained the psychoanalytic idea that quality of attachment to the caregiver has profound implications for the child’s feelings of security and capacity to form trusting relationships.

At the same time, Bowlby was inspired by Konrad Lorenz’s studies of imprinting (see Chapter 1). Bowlby believed that the human infant, like the young of other animal species, is endowed with a set of built-in behaviors that help keep the parent nearby to protect the infant from danger and to provide support for exploring and mastering the environment (Waters & Cummings, 2000). Contact with the parent also ensures that the baby will be fed, but Bowlby pointed out that feeding is not the basis for attachment. Rather, attachment can best be understood in an evolutionary context in which survival of the

species—through ensuring both safety and competence—is of utmost importance.

According to Bowlby, the infant’s relationship with the parent begins as a set of innate signals that call the adult to the baby’s side. Over time, a true affectionate bond forms, supported by new cognitive and emotional capacities as well as by a history of warm, sensitive care. Attachment develops in four phases:

1. **Preattachment phase** (birth to 6 weeks). Built-in signals—grasping, smiling, crying, and gazing into the adult’s eyes—help bring newborn babies into close contact with other humans, who comfort them. Babies of this age recognize their own mother’s smell, voice, and face (see Chapters 3 and 4). But they are not yet attached to her, since they do not mind being left with an unfamiliar adult.
2. **“Attachment-in-the-making” phase** (6 weeks to 6–8 months). During this phase, infants respond differently to a familiar caregiver than to a stranger. For example, at 4 months, Timmy smiled, laughed, and babbled more freely when interacting with his mother and quieted more quickly when she picked him up. As infants learn that their own actions affect the behavior of those around them, they begin to develop a *sense of trust*—the expectation that the caregiver will respond when signaled—but they still do not protest when separated from her.
3. **“Clear-cut” attachment phase** (6–8 months to 18 months–2 years). Now attachment to the familiar caregiver is evident. Babies display **separation anxiety**, becoming upset when their trusted caregiver leaves. Like stranger anxiety (see page 186), separation anxiety does not always occur; it depends on infant temperament and the current situation. But in many cultures, separation anxiety increases between 6 and 15 months. Besides protesting the parent’s departure, older infants and toddlers try hard to maintain her presence. They approach, follow, and climb on her in preference to others. And they use the familiar caregiver as a secure base from which to explore.

LOOK AND LISTEN

Watch an 8- to 18-month-old at play for 20 to 30 minutes.

Describe the baby’s use of the parent or other familiar caregiver as a secure base from which to explore. ●

4. **Formation of a reciprocal relationship** (18 months to 2 years and on). By the end of the second year, rapid growth in representation and language permits toddlers to understand some of the factors that influence the parent’s coming and going and to predict her return. As a result, separation protest declines. Now children negotiate with the caregiver, using requests and persuasion to alter her goals. For example, at age 2, Caitlin asked Carolyn and David to read a story before leaving her with a babysitter. The extra time with her parents, along with a better understanding of where they were going (“to have dinner with Uncle Charlie”) and when they would be back (“right after you go to sleep”), helped Caitlin withstand her parents’ absence.

© ELLEN B. SENISI PHOTOGRAPHY

Because this 2-year-old has the language and representational skills to predict his mother's return, separation anxiety declines. He accepts his mother's departure.

According to Bowlby (1980), out of their experiences during these four phases, children construct an enduring affectionate tie to the caregiver that they can use as a secure base in the parents' absence. This image serves as an **internal working model**, or set of expectations about the availability of attachment figures and their likelihood of providing support during times of stress. The internal working model becomes a vital part of personality, serving as a guide for all future close relationships (Bretherton & Munholland, 2008).

Consistent with these ideas, as early as the second year, toddlers form attachment-related expectations about parental comfort and support. In one study, securely attached 12- to 16-month-olds looked longer at a video of an unresponsive caregiver (inconsistent with their expectations) than a video of a responsive caregiver. Insecurely attached toddlers, in contrast, did not distinguish between the two (Johnson, Dweck, & Chen, 2007; Johnson et al., 2010). With age, children continually revise and expand their internal working model as their cognitive, emotional, and social capacities increase and as they interact with parents and form other bonds with adults, siblings, and friends.

Measuring the Security of Attachment

Although all family-reared babies become attached to a familiar caregiver by the second year, the quality of this relationship varies. Some infants appear relaxed and secure in the presence of the caregiver; they know they can count on her for protection and support. Others seem anxious and uncertain.

A widely used laboratory procedure for assessing the quality of attachment between 1 and 2 years of age is the **Strange Situation**. In designing it, Mary Ainsworth and her colleagues (1978) reasoned that securely attached infants and toddlers should use the parent as a secure base from which to explore an unfamiliar playroom. In addition, when the parent leaves, an unfamiliar adult should be less comforting than the parent. The Strange Situation takes the baby through eight short episodes

in which brief separations from and reunions with the parent occur (see Table 6.2).

Observing infants' responses to these episodes, researchers identified a secure attachment pattern and three patterns of insecurity; a few babies cannot be classified (Ainsworth et al., 1978; Barnett & Vondra, 1999; Main & Solomon, 1990; Thompson, 2006). Although separation anxiety varies among the groups, the baby's reunion responses define attachment quality. **TAKE A MOMENT...** From the description at the beginning of this chapter, which pattern do you think Grace displayed after adjusting to her adoptive family?

- **Secure attachment.** These infants use the parent as a secure base. When separated, they may or may not cry, but if they do, it is because the parent is absent and they prefer her to the stranger. When the parent returns, they actively seek contact, and their crying is reduced immediately. About 60 percent of North American infants in middle-SES families show this pattern. (In low-SES families, a smaller proportion of babies show the secure pattern, with higher proportions falling into the insecure patterns.)
- **Avoidant attachment.** These infants seem unresponsive to the parent when she is present. When she leaves, they usually are not distressed, and they react to the stranger in much the same way as to the parent. During reunion, they

TABLE 6.2 Episodes in the Strange Situation

EPISODE	EVENTS	ATTACHMENT BEHAVIOR OBSERVED
1	Researcher introduces parent and baby to playroom and then leaves.	
2	Parent is seated while baby plays with toys.	Parent as a secure base
3	Stranger enters, is seated, and talks to parent.	Reaction to unfamiliar adult
4	Parent leaves room. Stranger responds to baby and offers comfort if baby is upset.	Separation anxiety
5	Parent returns, greets baby, and offers comfort if necessary. Stranger leaves room.	Reaction to reunion
6	Parent leaves room.	Separation anxiety
7	Stranger enters room and offers comfort.	Ability to be soothed by stranger
8	Parent returns, greets baby, offers comfort if necessary, and tries to reinterest baby in toys.	Reaction to reunion

Note: Episode 1 lasts about 30 seconds; each of the remaining episodes lasts about 3 minutes. Separation episodes are cut short if the baby becomes very upset. Reunion episodes are extended if the baby needs more time to calm down and return to play. *Source:* Ainsworth et al., 1978.

avoid or are slow to greet the parent, and when picked up, they often fail to cling. About 15 percent of North American infants in middle-SES families show this pattern.

- **Resistant attachment.** Before separation, these infants seek closeness to the parent and often fail to explore. When the parent leaves, they are usually distressed, and on her return they combine clinginess with angry, resistive behavior, sometimes hitting and pushing. Many continue to cry after being picked up and cannot be comforted easily. About 10 percent of North American infants in middle-SES families show this pattern.
- **Disorganized/disoriented attachment.** This pattern reflects the greatest insecurity. At reunion, these infants show confused, contradictory behaviors—for example, looking away while the parent is holding them or approaching the parent with flat, depressed emotion. Most display a dazed facial expression, and a few cry out unexpectedly after having calmed down or display odd, frozen postures. About 15 percent of North American infants in middle-SES families show this pattern.

An alternative method, the **Attachment Q-Sort**, suitable for children between 1 and 4 years, depends on home observation (Waters et al., 1995). Either the parent or a highly trained observer sorts 90 behaviors (“Child greets mother with a big smile when she enters the room,” “If mother moves very far, child follows along”) into nine categories ranging from “highly descriptive” to “not at all descriptive” of the child. Then a score, ranging from high to low in security, is computed.

Because the Q-Sort taps a wider array of attachment-related behaviors than the Strange Situation, it may better reflect the parent–infant relationship in everyday life. However, the Q-Sort method is time-consuming, requiring a nonparent informant to spend several hours observing the child before sorting the descriptors, and it does not differentiate between types of insecurity. The Q-Sort responses of expert observers correspond well with babies’ secure-base behavior in the Strange Situation, but parents’ Q-Sorts do not (van IJzendoorn et al., 2004). Parents of insecure children, especially, may have difficulty accurately reporting their child’s attachment behaviors.

Stability of Attachment

Research on the stability of attachment patterns between 1 and 2 years of age yields a wide range of findings (Thompson, 2000, 2006). A close look at which babies stay the same and which ones change yields a more consistent picture. Quality of attachment is usually secure and stable for middle-SES babies experiencing favorable life conditions. And infants who move from insecurity to security typically have well-adjusted mothers with positive family and friendship ties. Perhaps many became parents before they were psychologically ready but, with social support, grew into the role.

In contrast, in low-SES families with many daily stresses and little social support, attachment generally moves away from

security or changes from one insecure pattern to another (Belsky et al., 1996; Fish, 2004; Levendosky et al., 2011; Vondra et al., 2001). In one long-term follow-up of a poverty-stricken sample, many securely attached infants ended up insecure when reassessed in early adulthood. Child maltreatment, maternal depression, and poor family functioning in adolescence distinguished these young people from the few who stayed securely attached (Weinfield, Sroufe, & Egeland, 2000; Weinfield, Whaley, & Egeland, 2004).

These findings indicate that securely attached babies more often maintain their attachment status than insecure babies. The exception is disorganized/disoriented attachment, an insecure pattern that is either highly stable or that consistently predicts insecurity of another type in adolescence and early adulthood (Aikens, Howes, & Hamilton, 2009; Hesse & Main, 2000; Sroufe et al., 2005; Weinfield, Whaley, & Egeland, 2004). As you will soon see, many disorganized/disoriented infants and children experience extremely negative caregiving, which may disrupt emotional self-regulation so severely that confused, ambivalent feelings toward parents often persist.

Cultural Variations

Cross-cultural evidence indicates that attachment patterns may have to be interpreted differently in certain cultures. For example, as Figure 6.2 reveals, German infants show considerably more avoidant attachment than American babies do.

FIGURE 6.2 A cross-cultural comparison of infants’ reactions in the Strange Situation. A high percentage of German babies seem avoidantly attached, whereas a substantial number of Japanese infants appear resistantly attached. Note that these responses may not reflect true insecurity. Instead, they are probably due to cultural differences in child-rearing practices. (Adapted from van IJzendoorn & Kroonenberg, 1988; van IJzendoorn & Sagi-Schwartz, 2008.)

Dogon mothers of Mali, West Africa, stay close to their babies and respond promptly and gently to infant hunger and distress. With their mothers consistently available, none of the Dogon babies show avoidant attachment.

But German parents value independence and encourage their infants to be nonclingy (Grossmann et al., 1985). In contrast, a study of infants of the Dogon people of Mali, Africa, revealed that none showed avoidant attachment to their mothers (True, Pisani, & Oumar, 2001). Even when grandmothers are primary caregivers (as they are with firstborn sons), Dogon mothers remain available, holding their babies close and nursing promptly in response to hunger and distress.

Japanese infants, as well, rarely show avoidant attachment (refer again to Figure 6.2). Rather, many are resistantly attached, but this reaction may not represent true insecurity. Japanese mothers rarely leave their babies in others' care, so the Strange Situation probably induces greater stress in them than in infants who experience frequent maternal separations (Takahashi, 1990). Also, Japanese parents view the attention seeking that is part of resistant attachment as a normal indicator of infants' efforts to satisfy dependency and security needs (Rothbaum et al., 2007). Despite such cultural variations, the secure pattern is still the most common attachment quality in all societies studied (van IJzendoorn & Sagi-Schwartz, 2008).

Factors That Affect Attachment Security

What factors might influence attachment security? Researchers have looked closely at four important influences: (1) early availability of a consistent caregiver, (2) quality of caregiving,

(3) the baby's characteristics, and (4) family context, including parents' internal working models.

Early Availability of a Consistent Caregiver. What happens when a baby does not have the opportunity to establish a close tie to a caregiver? To find out, researchers followed the development of infants in a British institution with a good caregiver-child ratio and a rich selection of books and toys. However, staff turnover was so rapid that the average child had 50 caregivers by age 4½! Many of these children became "late adoptees" who were placed in homes after age 4. Most developed deep ties with their adoptive parents, indicating that a first attachment can develop as late as 4 to 6 years of age (Hodges & Tizard, 1989; Tizard & Rees, 1975). But these children were more likely to display attachment difficulties, including an excessive desire for adult attention, "overfriendliness" to unfamiliar adults and peers, failure to check back with the parent in anxiety-arousing situations, and few friendships.

Children who spent their first year or more in deprived Eastern European orphanages—though also able to bond with their adoptive parents—show elevated rates of attachment insecurity (van den Dries et al., 2009; Smyke et al., 2010). And they, too, are at high risk for emotional and social difficulties. Whereas many are indiscriminately friendly, others are sad, anxious, and withdrawn. These symptoms typically persist and are associated with wide-ranging mental health problems in middle childhood and adolescence, including cognitive impairments, inattention and hyperactivity, depression, and either social avoidance or aggressive behavior (Kreppner et al., 2007, 2010; Rutter et al., 2007, 2010; Zeanah, 2000).

Furthermore, as early as 7 months, institutionalized children show reduced ERP brain waves in response to facial expressions of emotion and have trouble discriminating such expressions—outcomes that suggest disrupted formation of neural structures involved in "reading" emotions (Parker et al., 2005). Consistent with these findings, in adopted children with longer institutional stays, the volume of the *amygdala* (see page 192) is atypically large (Tottenham et al., 2011). The larger the amygdala, the worse adopted children perform on tasks assessing understanding of emotion and the poorer their emotional self-regulation. Overall, the evidence indicates that fully normal emotional development depends on establishing a close tie with a caregiver early in life.

Quality of Caregiving. Dozens of studies report that **sensitive caregiving**—responding promptly, consistently, and appropriately to infants and holding them tenderly and carefully—is moderately related to attachment security in diverse cultures and SES groups (Belsky & Fearon, 2008; De Wolff & van IJzendoorn, 1997; van IJzendoorn et al., 2004). In contrast, insecurely attached infants tend to have mothers who engage in less physical contact, handle them awkwardly or "routinely," and are sometimes resentful and rejecting, particularly in response to infant distress (Ainsworth et al., 1978; Isabella, 1993; McElwain & Booth-LaForce, 2006; Pederson & Moran, 1996).

VICKY KASALA PRODUCTIONS/DIGITAL VISION/GETTY IMAGES

This mother and baby engage in a sensitively tuned form of communication called **interactional synchrony**, in which they match emotional states, especially positive ones. Among Western infants, this style of communication predicts secure attachment.

Also, in studies of Western babies, a special form of communication called **interactional synchrony** separates the experiences of secure from insecure babies. It is best described as a sensitively tuned “emotional dance,” in which the caregiver responds to infant signals in a well-timed, rhythmic, appropriate fashion. In addition, both partners match emotional states, especially the positive ones (Bigelow et al., 2010; Isabella & Belsky, 1991; Nievar & Becker, 2008). Earlier we saw that sensitive face-to-face play, in which interactional synchrony occurs, also helps infants regulate emotion.

Cultures, however, vary in their view of sensitivity toward infants. Among the Gusii people of Kenya, for example, mothers rarely cuddle, hug, or interact playfully with their babies, although they are very responsive to their infants’ needs. Yet most Gusii infants appear securely attached (LeVine et al., 1994). This suggests that security depends on attentive caregiving, not necessarily on moment-by-moment contingent interaction. Puerto Rican mothers, who highly value obedience and socially appropriate behavior, often physically direct and limit their babies’ actions—a caregiving style linked to attachment security in Puerto Rican culture (Carlson & Harwood, 2003). Yet in many Western cultures, such physical control and restriction of exploration predict insecurity (Belsky & Fearon, 2008; Whipple, Bernier, & Mageau, 2011).

Compared with securely attached infants, avoidant babies tend to receive overstimulating, intrusive care. Their mothers might, for example, talk energetically to them while they are looking away or falling asleep. By avoiding the mother, these infants appear to be escaping from overwhelming interaction. Resistant infants often experience inconsistent care. Their mothers are unresponsive to infant signals. Yet when the baby begins to explore, these mothers interfere, shifting the infant’s

attention back to themselves. As a result, the baby is overly dependent as well as angry at the mother’s lack of involvement (Cassidy & Berlin, 1994; Isabella & Belsky, 1991).

Highly inadequate caregiving is a powerful predictor of disruptions in attachment. Child abuse and neglect (topics we will consider in Chapter 8) are associated with all three forms of attachment insecurity. Among maltreated infants, disorganized/disoriented attachment is especially high (van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999). Persistently depressed mothers, mothers with very low marital satisfaction, and parents suffering from a traumatic event, such as serious illness or loss of a loved one, also tend to promote the uncertain behaviors of this pattern (Campbell et al., 2004; Madigan et al., 2006; Moss et al., 2005). And some mothers of disorganized/disoriented infants engage in frightening, contradictory, and unpleasant behaviors, such as looking scared, teasing the baby, holding the baby stiffly at a

distance, roughly pulling the baby by the arm, or seeking reassurance from the upset child (Abrams, Rifkin, & Hesse, 2006; Lyons-Ruth, Bronfman, & Parsons, 1999; Moran et al., 2008).

Infant Characteristics. Because attachment is the result of a *relationship* that builds between two partners, infant characteristics should affect how easily it is established. In Chapter 3 we saw that prematurity, birth complications, and newborn illness make caregiving more taxing. In families under stress, these difficulties are linked to attachment insecurity (Poehlmann & Fiese, 2001). But at-risk newborns whose parents have the time and patience to care for them fare quite well in attachment security (Brisch et al., 2005; Cox, Hopkins, & Hans, 2000).

Babies whose temperament is emotionally reactive and difficult are more likely to develop later insecure attachments (van IJzendoorn et al., 2004; Vaughn, Bost, & van IJzendoorn, 2008). Again, however, caregiving is involved. In a study extending from birth to age 2, difficult infants more often had highly anxious mothers—a combination that, by the second year, often resulted in a “disharmonious relationship” characterized by both maternal insensitivity and attachment insecurity (Symons, 2001).

Other research focusing on disorganized/disoriented attachment has uncovered gene–environment interactions (Gervai, 2009). In one investigation, mothers’ experience of unresolved loss of a loved one or other trauma was associated with attachment disorganization only in infants with a chromosome-11 gene linked to deficient self-regulation (van IJzendoorn & Bakermans-Kranenburg, 2006). Babies with this genetic marker, who face special challenges in managing intense emotion, were more negatively affected by maternal adjustment problems.

If children’s temperaments determined attachment security, we would expect attachment, like temperament, to be at

least moderately heritable. Yet the heritability of attachment is virtually nil (Roisman & Fraley, 2008). In fact, about two-thirds of siblings establish similar attachment patterns with their parent, although the siblings often differ in temperament (Cole, 2006; Dozier et al., 2001). This suggests that most parents try to adjust their caregiving to each child's individual needs.

Why don't infant characteristics show strong relationships with attachment quality? Their influence probably depends on goodness of fit. From this perspective, *many* child attributes can lead to secure attachment as long as caregivers sensitively adjust their behavior to fit the baby's needs (Seifer & Schiller, 1995). Interventions that teach parents to interact with difficult-to-care-for infants are highly successful in enhancing both sensitive care and attachment security (Velderman et al., 2006). But when parents' capacity is strained—by their own personalities or by stressful living conditions—then infants with illnesses, disabilities, and difficult temperaments are at risk for attachment problems.

Family Circumstances. Shortly after Timmy's birth, his parents divorced and his father moved to a distant city. Anxious and distracted, Vanessa placed 1-month-old Timmy in Ginette's child-care home and began working 50-hour weeks to make ends meet. On days Vanessa stayed late at the office, a babysitter picked Timmy up, gave him dinner, and put him to bed. Once or twice a week, Vanessa went to get Timmy from child care. As he neared his first birthday, Vanessa noticed that unlike the other children, who reached out, crawled, or ran to their parents, Timmy ignored her.

Timmy's behavior reflects a repeated finding: Job loss, a failing marriage, and financial difficulties can undermine attachment by interfering with parental sensitivity. These stressors can also affect babies' sense of security directly, by altering the emotional climate of the family (for example, exposing them to angry adult interactions) or by disrupting familiar daily routines (Finger et al., 2009; Raikes & Thompson, 2005). (See the Social Issues: Health box on pages 202–203 to find out how child care affects early emotional development.) Social support fosters attachment security by reducing parental stress and improving the quality of parent–child communication (Belsky & Fearon, 2002b; Moss et al., 2005). Ginette's sensitivity was helpful, as was the parenting advice Vanessa received from Ben, a psychologist. As Timmy turned 2, his relationship with his mother seemed warmer.

Parents' Internal Working Models. Parents bring to the family context their own history of attachment experiences, from which they construct internal working models that they apply to the bonds they establish with their children. Monica, who recalled her mother as tense and preoccupied, expressed regret that they had not had a closer relationship. Is her image of parenthood likely to affect Grace's attachment security?

To assess parents' internal working models, researchers ask them to evaluate childhood memories of attachment experiences (Main & Goldwyn, 1998). Parents who discuss their

childhoods with objectivity and balance, regardless of whether their experiences were positive or negative, tend to have securely attached children. In contrast, parents who dismiss the importance of early relationships or describe them in angry, confused ways usually have insecurely attached children and are less warm, sensitive, and encouraging of learning and mastery (Behrens, Hesse, & Main, 2007; Coyl, Newland, & Freeman, 2010; Steele, Steele, & Fonagy, 1996; van IJzendoorn, 1995).

But we must not assume any direct transfer of parents' childhood experiences to quality of attachment with their own children. Internal working models are *reconstructed memories* affected by many factors, including relationship experiences over the life course, personality, and current life satisfaction. Longitudinal research reveals that negative life events can weaken the link between an individual's own attachment security in infancy and a secure internal working model in adulthood. And insecurely attached babies who become adults with insecure internal working models often have lives that, based on self-reports in adulthood, are filled with family crises (Waters et al., 2000; Weinfield, Sroufe, & Egeland, 2000).

In sum, our early rearing experiences do not destine us to become either sensitive or insensitive parents. Rather, the way we *view* our childhoods—our ability to come to terms with negative events, to integrate new information into our working models, and to look back on our own parents in an understanding, forgiving way—is far more influential in how we rear our children than the actual history of care we received (Bretherton & Munholland, 2008).

Multiple Attachments

Babies develop attachments to a variety of familiar people—not just mothers but also fathers, grandparents, siblings, and professional caregivers. Although Bowlby (1969) believed that infants are predisposed to direct their attachment behaviors to a single special person, especially when they are distressed, his theory allowed for these multiple attachments.

Fathers. When anxious or unhappy, most babies prefer to be comforted by their mother. But this preference typically declines over the second year. And when babies are not distressed, they approach, vocalize to, and smile equally often at both parents (Bornstein, 2006; Parke, 2002).

Fathers' sensitive caregiving and interactional synchrony with infants, like mothers', predict attachment security (Lundy, 2003; van IJzendoorn et al., 2004). But as infancy progresses, mothers and fathers in many cultures, including Australia, Canada, Germany, India, Israel, Italy, Japan, and the United States, tend to interact differently with their babies. Mothers devote more time to physical care and expressing affection, fathers to playful interaction (Freeman & Newland, 2010; Roopnarine et al., 1990).

Mothers and fathers also play differently. Mothers more often provide toys, talk to infants, and gently play conventional

Social Issues: Health

Does Child Care in Infancy Threaten Attachment Security and Later Adjustment?

Are infants who experience daily separation from their employed parents and early placement in child care at risk for attachment insecurity and development problems? Some researchers think so, but others disagree. Let's look closely at the evidence.

Attachment Quality

Some studies suggest that babies placed in full-time child care before 12 months of age are more likely to display insecure attachment in the Strange Situation (Belsky, 2001, 2005). But the best current evidence—from the National Institute of Child Health and Development (NICHD) Study of Early Child Care, the largest longitudinal investigation to date, including more than 1,300 infants and their families—confirms that nonparental care by itself does not affect attachment quality (NICHD Early Child Care Research Network, 1997, 2001). Rather, the relationship between child care and emotional well-being depends on both family and child-care experiences.

Family Circumstances

We have seen that family conditions affect children's attachment security and later

adjustment. Findings of the NICHD Study confirmed that parenting quality, assessed using a combination of maternal sensitivity and HOME scores (see page 171 in Chapter 5), exerted a more powerful impact on children's adjustment than did exposure to child care (NICHD Early Childhood Research Network, 1998; Watamura et al., 2011).

For employed parents, balancing work and caregiving can be stressful. Mothers who are fatigued and anxious because they feel overloaded by work and family pressures may respond less sensitively to their babies, thereby risking the infant's security. And as paternal involvement in caregiving has risen (see page 203), many more U.S. fathers in dual-earner families also report work–family life conflict (Galinsky, Aumann, & Bond, 2009).

Quality and Extent of Child Care

Nevertheless, poor-quality child care may contribute to a higher rate of insecure attachment. In the NICHD Study, when babies were exposed to combined home and child-care risk factors—insensitive caregiving at home along with insensitive caregiving in child care, long hours in child care, or more than one child-care arrangement—the rate

of attachment insecurity increased. Overall, mother–child interaction was more favorable when children attended higher-quality child care and also spent fewer hours in child care (NICHD Early Child Care Research Network, 1997, 1999).

Furthermore, when these children reached age 3, a history of higher-quality child care predicted better social skills (NICHD Early Child Care Research Network, 2002b). However, at age 4½ to 5, children averaging more than 30 child-care hours per week displayed more behavior problems, especially defiance, disobedience, and aggression. For those who had been in child-care centers as opposed to family child-care homes, this outcome persisted through elementary school (Belsky et al., 2007; NICHD Early Child Care Research Network, 2003a, 2006).

But these findings do not necessarily mean that child care causes behavior problems. Rather, heavy exposure to substandard care, which is widespread in the United States, may promote these difficulties, especially when combined with family risk factors. A closer look at the NICHD participants during the preschool years revealed that those in both poor-quality home and child-care environments fared worst in social skills and problem behaviors, whereas those in both high-quality home and child-care environments fared best. In between

games like pat-a-cake and peekaboo. In contrast, fathers—especially with their infant sons—tend to engage in highly stimulating physical play with bursts of excitement that increase as play progresses (Feldman, 2003). As long as fathers are also sensitive, this stimulating, startling play style helps babies regulate emotion in intensely arousing situations, including novel physical environments and play with peers (Cabrera et al., 2007; Hazen et al., 2010; Paquette, 2004). In a German study, fathers' sensitive, challenging play with preschoolers predicted favorable emotional and social adjustment from kindergarten to early adulthood (Grossmann et al., 2008).

Play is a vital context in which fathers build secure attachments (Newland, Coyl, & Freeman, 2008). It may be especially influential in cultures such as Japan, where long work hours prevent most fathers from sharing in infant caregiving (Hewlett, 2004). In many Western nations, however, a strict division of

parental roles—mother as caregiver, father as playmate—has changed over the past several decades in response to women's workforce participation and to cultural valuing of gender equality.

LOOK AND LISTEN

Observe parents at play with infants at home or a family gathering. Describe both similarities and differences in mothers' and fathers' behaviors. Are your observations consistent with research findings? ●

A recent U.S. national survey of several thousand employed workers indicated that U.S. fathers under age 29 devote about 85 percent as much time to children as mothers do—on average, just over 4 hours per workday, nearly double the hours young

were preschoolers in high-quality child care but poor-quality homes (Watamura et al., 2011). These children benefited from the *protective influence* of high-quality child care.

Evidence from other industrialized nations confirms that full-time child care need not harm children's development. In Australia, for example, infants who spend full days in government-funded, high-quality child-care centers have a higher rate of secure attachment than infants informally cared for by relatives, friends, or babysitters. And amount of time spent in child care is unrelated to Australian children's behavior problems (Love et al., 2003).

Still, some children may be particularly stressed by long child-care hours. Many infants, toddlers, and preschoolers attending child-care centers for full days show a mild increase in saliva concentrations of cortisol across the day—a pattern that does not occur on days they spend at home. In one study, children rated as highly fearful by their caregivers experienced an especially sharp increase in cortisol levels (Watamura et al., 2003). Inhibited children may find the constant company of large numbers of peers particularly stressful.

Conclusions

Taken together, research suggests that some infants may be at risk for attachment

insecurity and later adjustment problems due to inadequate child care, long hours in such care, and the joint pressures their parents experience from full-time employment and parenthood. But it is inappropriate to use these findings to justify a reduction in child-care services. When family incomes are limited or mothers who want to work are forced to stay at home, children's emotional security is not promoted.

Instead, it makes sense to increase the availability of high-quality child care and to relieve work–family-life conflict by providing parents with paid employment leave (see page 105 in Chapter 3) and opportunities for part-time work. In the NICHD study, part-time (as opposed to full-time) employment during the baby's first year was associated with greater maternal sensitivity and a higher-quality home environment, which yielded more favorable development in early childhood (Brooks-Gunn, Han, & Waldfogel, 2010).

Finally, for child care to foster attachment security, the professional caregiver's relationship with the baby is vital. When caregiver–child ratios are generous, group sizes are small, and caregivers are educated

© ELLEN B. SENISI PHOTOGRAPHY

High-quality child care, with generous caregiver–child ratios, small group sizes, and knowledgeable caregivers, can be part of a system that promotes all aspects of development, including attachment security.

about child development and child rearing, caregivers' interactions are more positive and children develop more favorably (McCartney et al., 2007; NICHD Early Child Care Research Network, 2000b, 2002a, 2006). Child care with these characteristics can become part of an ecological system that relieves parental and child stress, thereby promoting healthy attachment and development.

fathers reported three decades ago. Although fathers age 29 to 42 spend somewhat less time with children, their involvement has also increased substantially (see Figure 6.3). Today, nearly one-third of U.S. employed women say that their spouse or partner shares equally in or takes most responsibility for child-care tasks (Galinsky, Aumann, & Bond, 2009). Paternal availability to children is fairly similar across SES and ethnic groups, with one exception: Hispanic fathers spend more time engaged,

FIGURE 6.3 Average amount of time per workday U.S. employed mothers and fathers reported spending with their children (age 12 and younger) in 1977 and 2008. In national surveys of several thousand employed parents, mothers' time with children remained fairly stable from 1977 to 2008; fathers' time increased substantially. (Adapted from Galinsky, Aumann, & Bond, 2009.)

Cultural Influences

The Powerful Role of Paternal Warmth in Development

In studies of many societies and ethnic groups around the world, researchers coded paternal expressions of love and nurturance—evident in such behaviors as cuddling, hugging, comforting, playing, verbally expressing love, and praising the child's behavior. Fathers' affectionate involvement predicted later cognitive, emotional, and social competence as strongly as did mothers' warmth—and occasionally more strongly (Rohner & Veneziano, 2001; Veneziano, 2003). And in Western cultures, paternal warmth and secure attachment protected children against a wide range of difficulties, including childhood emotional and behavior problems and adolescent substance abuse and delinquency (Grant et al., 2000; Michiels et al., 2010; Nelson & Coyne, 2009; Tacon & Caldera, 2001).

Fathers who devote little time to physical caregiving express warmth through play. In a German study, fathers' play sensitivity—accepting toddlers' play initiatives, adapting play behaviors to toddlers' capacities, and responding appropriately to toddlers' expressions of emotion—predicted children's secure internal working models of attachment during middle childhood and adolescence (Grossmann et al., 2002). Through play, fathers seemed to transfer to young

children a sense of confidence about parental support, which may strengthen their capacity to master many later challenges.

What factors promote paternal warmth? Cross-cultural research reveals a consistent association between the amount of time fathers spend near infants and toddlers and their expressions of caring and affection (Rohner & Veneziano, 2001). Consider the Aka hunters and gatherers of Central Africa, where fathers spend more time in physical proximity to their babies than in any other known society. Aka fathers are within arm's reach of infants more than half the day, and they pick up, cuddle, and play with their babies at least five times as often as fathers in other hunting-and-gathering societies.

Why are Aka fathers so involved? The bond between Aka husband and wife is unusually cooperative and intimate. Throughout the day, couples share hunting, food preparation, and social and leisure activities. The more time Aka parents are together, the greater the father's loving interaction with his baby (Hewlett, 1992).

In Western cultures as well, happily married fathers whose partners cooperate with them in parenting spend more time with and interact more effectively with infants. In contrast, marital dissatisfaction

© JEFF GREENBERG/THE IMAGE WORKS

In diverse cultures, fathers' warmth predicts long-term favorable cognitive, emotional, and social development.

is associated with insensitive paternal care (Brown et al., 2010; Lundy, 2002; Seigny & Loutzenhiser, 2010). Clearly, fathers' warm relationships with their partners and their babies are closely linked. Evidence for the power of paternal affection, reported in virtually every culture and ethnic group studied, is reason to encourage and support fathers in nurturing care of young children.

probably because of the particularly high value that Hispanic cultures place on family involvement (Cabrera & García Coll, 2004; Parke et al., 2004).

Mothers in dual-earner families tend to engage in more playful stimulation of their babies than mothers who are at home full-time (Cox et al., 1992). But fathers who are primary caregivers retain their arousing play style (Lamb & Oppenheim, 1989). These highly involved fathers typically are less gender-stereotyped in their beliefs; have sympathetic, friendly personalities; often had fathers who were more involved in rearing them; and regard parenthood as an especially enriching experience (Cabrera et al., 2000; Levy-Shiff & Israelashvili, 1988).

Fathers' involvement with babies unfolds within a complex system of family attitudes and relationships. A warm

marital bond promotes both parents' sensitivity and involvement and children's attachment security, but it is particularly important for fathers (Brown et al., 2010; Lamb & Lewis, 2004). See the Cultural Influences box above for cross-cultural evidence documenting this conclusion—and also highlighting the powerful role of paternal warmth in children's development.

Siblings. Despite declines in family size, 80 percent of North American and European children grow up with at least one sibling (Dunn, 2004). The arrival of a new baby is a difficult experience for most preschoolers, who often become demanding, clingy, and deliberately naughty for a time. Attachment security also declines, especially for children over age 2 (old

Applying What We Know

Encouraging Affectionate Ties Between Infants and Their Preschool Siblings

Suggestion	Description
Spend extra time with the older child.	To minimize the older child's feelings of being deprived of affection and attention, set aside time to spend with her. Fathers can be especially helpful, planning special outings with the preschooler and taking over care of the baby so the mother can be with the older child.
Handle sibling misbehavior with patience.	Respond patiently to the older sibling's misbehavior and demands for attention, recognizing that these reactions are temporary. Give the preschooler opportunities to feel proud of being more grown-up than the baby. For example, encourage the older child to assist with feeding, bathing, dressing, and offering toys, and show appreciation for these efforts.
Discuss the baby's wants and needs.	By helping the older sibling understand the baby's point of view, parents can promote friendly, considerate behavior. Say, for example, "He's so little that he just can't wait to be fed," or "He's trying to reach his rattle, and he can't."
Express positive emotion toward your partner and engage in effective coparenting.	When parents mutually support each other's parenting behavior, their good communication helps the older sibling cope adaptively with jealousy and conflict.

enough to feel threatened and displaced) and for those with mothers under stress (Baydar, Greek, & Brooks-Gunn, 1997; Teti et al., 1996).

Yet resentment is only one feature of a rich emotional relationship that soon develops between siblings. Older children also show affection and concern—kissing and patting the baby and calling out, “Mom, he needs you,” when the infant cries. By the end of the first year, babies usually spend much time with older siblings and are comforted by the presence of a preschool-age brother or sister during short parental absences. Throughout childhood, children continue to treat older siblings as attachment figures, turning to them for comfort in stressful situations when parents are unavailable (Seibert & Kerns, 2009).

Nevertheless, individual differences in sibling relationships emerge soon after the new baby's arrival. Certain temperamental traits—high emotional reactivity or activity level—increase the chances of sibling conflict (Brody, Stoneman, & McCoy, 1994; Dunn, 1994). And maternal warmth toward both children is related to positive sibling interaction and to preschoolers' support of a distressed younger sibling (Volling, 2001; Volling & Belsky, 1992). In contrast, maternal harshness and lack of involvement are linked to antagonistic sibling relationships (Howe, Aquan-Assee, & Bukowski, 2001).

Finally, a good marriage and effective coparenting are linked to preschool siblings' capacity to cope adaptively with jealousy and conflict (Volling, McElwain, & Miller, 2002). Perhaps good communication between parents serves as a model of effective problem solving. It may also foster a generally happy family environment, giving children less reason to feel jealous.

Refer to Applying What We Know above for ways to promote positive sibling relationships between babies and

preschoolers. Siblings offer a rich social context in which young children learn and practice a wide range of skills, including affectionate caring, conflict resolution, and control of hostile and envious feelings.

© LAURA DWIGHT PHOTOGRAPHY

The arrival of a baby brother or sister is a difficult experience for most preschoolers. Maternal warmth toward both children assures the older sibling of continuing parental love and is related to positive sibling interaction.

Attachment and Later Development

According to psychoanalytic and ethological theories, the inner feelings of affection and security that result from a healthy attachment relationship support all aspects of psychological development. Consistent with this view, an extended longitudinal study found that preschoolers who had been securely attached as babies were rated by their teachers as higher in self-esteem, social skills, and empathy than were their insecurely attached counterparts, who displayed more behavior problems. When studied again at age 11 in summer camp, children who had been secure infants continued to be more socially competent, as judged by camp counselors. And as these well-functioning school-age children became adolescents and young adults, they continued to benefit from more supportive social networks, formed more stable and gratifying romantic relationships, and attained higher levels of education (Elicker, Englund, & Sroufe, 1992; Sroufe, 2002; Sroufe et al., 2005).

For some researchers, these findings indicate that secure attachment in infancy causes improved cognitive, emotional, and social competence in later years. Yet contrary evidence exists. In other longitudinal studies, secure infants generally fared better than insecure infants, but not always (Fearon et al., 2010; McCartney et al., 2004; Schneider, Atkinson, & Tardif, 2001; Stams, Juffer, & van IJzendoorn, 2002).

What accounts for this inconsistency? Mounting evidence indicates that *continuity of caregiving* determines whether attachment security is linked to later development (Lamb et al., 1985; Thompson, 2006). Children whose parents respond sensitively not just in infancy but also in later years are likely to develop favorably. In contrast, children of parents who react insensitively or who, over a long period, are exposed to a negative family climate tend to establish lasting patterns of avoidant, resistant, or disorganized behavior and are at greater risk for developmental difficulties.

A close look at the relationship between parenting and children's adjustment supports this interpretation. Disorganized/disoriented attachment, a pattern associated with serious parental psychological problems and highly maladaptive caregiving, is strongly linked to both internalizing and externalizing difficulties in childhood (Lyons-Ruth, Easterbrooks, & Cibelli, 1997; Moss et al., 2006). And when a large sample of children were tracked from ages 1 to 3 years, those experiencing secure attachment followed by sensitive parenting scored highest in cognitive, emotional, and social outcomes. Those experiencing insecure attachment followed by parental insensitivity scored lowest, while those with mixed histories of attachment and maternal sensitivity scored in between (Belsky & Fearon, 2002a).

Although a secure attachment in infancy does not guarantee good parenting, it does launch the parent-child relationship on a positive path. An early warm, positive parent-child tie, sustained over time, predicts a more confident and complex self-concept, more advanced emotional understanding, more effective social skills, a stronger sense of moral responsibility, and higher motivation to achieve in school (Thompson, 2006, 2008).

But the effects of early attachment security are *conditional*—dependent on the quality of the baby's future relationships. Finally, as we will see again in future chapters, attachment is just one of the complex influences on children's psychological development.

ASK YOURSELF

REVIEW What factors explain stability in attachment pattern for some children and change for others? Are these factors also involved in the link between attachment in infancy and later development? Explain.

CONNECT List the diverse factors that affect the parent-infant child bond, and discuss how research confirms the role of each level of ecological systems theory in attachment security.

APPLY What attachment pattern did Timmy display when Vanessa arrived home from work, and what factors probably contributed to it?

REFLECT How would you characterize your internal working model? What factors, in addition to your relationship with your parents, might have influenced it?

Self-Development

Infancy is a rich formative period for the development of both physical and social understanding. In Chapter 5, you learned that infants develop an appreciation of the permanence of objects. In this chapter, we have seen that over the first year, infants recognize and respond appropriately to others' emotions and distinguish familiar from unfamiliar people. That both objects and people achieve an independent, stable existence for the infant implies that knowledge of the self as a separate, permanent entity is also emerging.

Self-Awareness

When Carolyn held Caitlin in front of a mirror, as early as the first few months Caitlin smiled and returned friendly behaviors to her image. At what age did she realize that the charming baby gazing and smiling back was herself?

Beginnings of Self-Awareness. At birth, infants sense that they are distinct from their surroundings. For example, newborns display a stronger rooting reflex in response to external stimulation (an adult's finger touching their cheek) than to self-stimulation (their own hand contacting their cheek) (Rochat & Hespos, 1997). Newborns' remarkable capacity for *intermodal perception* (see page 145 in Chapter 4) supports the beginnings of self-awareness (Rochat, 2003). As they feel their own touch, feel and watch their limbs move, and feel and hear

themselves cry, babies experience intermodal matches that differentiate their own body from surrounding bodies and objects.

Over the first few months, infants distinguish their own visual image from other stimuli, but their self-awareness is limited—expressed only in perception and action. When shown two side-by-side video images of their kicking legs, one from their own perspective (camera behind the baby) and one from an observer's perspective (camera in front of the baby), 3-month-olds looked longer at the observer's view (Rochat, 1998). By 4 months, infants look and smile more at video images of others than at video images of themselves, indicating that they treat another person (as opposed to the self) as a social partner (Rochat & Striano, 2002).

Self-Recognition. During the second year, toddlers become consciously aware of the self's physical features. In several studies, 9- to 28-month-olds were placed in front of a mirror. Then, under the pretext of wiping the baby's face, each mother rubbed red dye on her child's nose or forehead. Younger babies typically touched the mirror as if the red mark had nothing to do with themselves. But those older than 20 months touched or rubbed their noses or foreheads, indicating awareness of their unique appearance (Bard et al., 2006; Lewis & Brooks-Gunn, 1979).

Around age 2, **self-recognition**—identification of the self as a physically unique being—is well under way. Children point to themselves in photos and refer to themselves by name or with a personal pronoun (“I” or “me”) (Lewis & Ramsay, 2004). Soon children identify themselves in images with less detail and fidelity than mirrors. Around age 2½, most reach for a sticker surreptitiously placed on top of their heads when shown themselves in a live video, and around age 3 most recognize their own shadow (Cameron & Gallup, 1988; Suddendorf, Simcock, & Nielsen, 2007).

Nevertheless, toddlers make **scale errors**, attempting to do things that their body size makes impossible. For example, they will try to put on dolls' clothes, sit in a doll-sized chair, or walk through a doorway too narrow for them to pass through (Brownell, Zerwas, & Ramani, 2007; DeLoache, Uttal, & Rosengren, 2004). Possibly, toddlers lack an accurate understanding of their own body dimensions. Alternatively, they may simply be exploring the consequences of squeezing into restricted spaces, as they are far less likely to try when the risk of harming themselves is high (the too-narrow doorway is next to a ledge where they could fall) (Franchak & Adolph, 2012). Scale errors decline around age 2, but many 2½-year-olds still make them.

What experiences contribute to gains in self-awareness? During the first year, as infants act on the environment, they probably notice effects that help them sort out self, other people, and objects (Nadel, Prepin, & Okanda, 2005; Rochat, 2001). For example, batting a mobile and seeing it swing in a pattern different from the infant's own actions informs the baby about the relation between self and physical world. Smiling and vocalizing at a caregiver who smiles and vocalizes back helps clarify the relation between self and social world. The contrast between

This 20-month-old's response to her mirror image indicates that she recognizes her unique physical features and is aware of herself as a separate being, distinct from other people and objects.

these experiences helps infants sense that they are separate from external reality.

Cultural variations exist in early self-development. Urban German and Greek toddlers attain mirror self-recognition earlier than toddlers of the Nso people of Cameroon, a collectivist farming society that highly values social harmony and responsibility to others (Keller et al., 2004, 2005). Compared to their German and Greek counterparts, Nso mothers engage in less face-to-face communication and object stimulation and more body contact and physical stimulation of their babies. German and Greek practices reflect a *distal parenting style* common in cultures that emphasize independence; the Nso practice a *proximal parenting style* typical in cultures that promote interdependence. In line with these differences, Nso proximal parenting is associated with later attainment of self-recognition but earlier emergence of toddlers' compliance with adult requests (see Figure 6.4 on page 208).

Self-Awareness and Early Emotional and Social Development. Self-awareness quickly becomes a central part of children's emotional and social lives. Recall that self-conscious emotions depend on a strengthening sense of self. Self-awareness also leads to first efforts to appreciate others' perspectives. Older toddlers who have experienced sensitive

FIGURE 6.4 Self-recognition and compliance among Nso and Greek toddlers. At 10 and 20 months, toddlers were tested for mirror self-recognition and for compliance (they were told not to open a transparent container with an attractive food). Among Greek toddlers, whose culture values independence, many more had attained self-recognition. But Nso toddlers, reared in an interdependent culture, were greatly advanced in compliance (following directions without prompting), whereas Greek toddlers either needed reminders or did not comply. (Adapted from Keller et al., 2004.)

caregiving draw on their advancing cognitive, language, and social skills to express first signs of **empathy**—the ability to understand another’s emotional state and *feel with* that person, or respond emotionally in a similar way. For example, they communicate concern when others are distressed and may offer what they themselves find comforting—a hug, a reassuring comment, or a favorite doll or blanket (Hoffman, 2000; Moreno, Klute, & Robinson, 2008).

At the same time, toddlers demonstrate clearer awareness of how to upset others. One 18-month-old heard her mother talking to another adult about an older sibling: “Anny is really frightened of spiders” (Dunn, 1989, p. 107). The innocent-looking toddler ran to the bedroom, returned with the toy spider, and pushed it in front of Anny’s face!

Categorizing the Self

By the end of the second year, language becomes a powerful tool in self-development. Between 18 and 30 months, children develop a **categorical self** as they classify themselves and others on the basis of age (“baby,” “boy,” or “man”), sex (“boy” or “girl”), physical characteristics (“big,” “strong”), and even goodness versus badness (“I a good girl.” “Tommy mean!”) and competencies (“Did it!” “I can’t”) (Stipek, Gralinski, & Kopp, 1990).

Toddlers use their limited understanding of these social categories to organize their own behavior. As early as 17 months, they select and play in a more involved way with toys that are

stereotyped for their own gender—dolls and tea sets for girls, trucks and cars for boys. Their ability to label their own gender predicts a sharp rise in these play preferences over the next few months (Zosuls et al., 2009). Then parents encourage gender-typed behavior by responding more positively when toddlers display it (Ruble, Martin, & Berenbaum, 2006). As we will see in Chapter 8, gender typing increases dramatically in early childhood.

Self-Control

Self-awareness also contributes to effortful control, evident in toddlers’ strengthening capacity to inhibit impulses, manage negative emotion, and behave in socially acceptable ways. Indeed, a firmer sense of self may underlie the increasing stability and organization of effortful control in the third year (see page 193). To behave in a self-controlled fashion, children must think of themselves as separate, autonomous beings who can direct their own actions. And they must have the representational and memory capacities to recall a caregiver’s directive (“Caitlin, don’t touch that light socket!”) and apply it to their own behavior.

As these capacities emerge between 12 and 18 months, toddlers first become capable of **compliance**. They show clear awareness of caregivers’ wishes and expectations and can obey simple requests and commands. And as every parent knows, they can also decide to do just the opposite! But for most, assertiveness and opposition occur alongside compliance with an eager, willing spirit, which suggests that the child is beginning to adopt the adult’s directives as his own (Dix et al., 2007; Kochanska, Murray, & Harlan, 2000). Compliance quickly leads to toddlers’ first consciencelike verbalizations—for example, correcting the self by saying “No!” before touching a delicate object or jumping on the sofa.

NATALIE KAUFFMAN/FIRST LIGHT/GETTY IMAGES

This toddler demonstrates compliance and the beginnings of self-control as she helps her father wash dishes. She eagerly joins in the task, suggesting that she is adopting the adult’s directives as her own.

Applying What We Know

Helping Toddlers Develop Compliance and Self-Control

Suggestion	Rationale
Respond to the toddler with sensitivity and encouragement.	Toddlers whose parents are sensitive and supportive actively resist at times, but they are also more compliant and self-controlled.
Provide advance notice when the toddler must stop an enjoyable activity.	Toddlers find it more difficult to stop a pleasant activity that is already under way than to wait before engaging in a desired action.
Offer many prompts and reminders.	Toddlers' ability to remember and comply with rules is limited; they need continuous adult oversight and patient assistance.
Respond to self-controlled behavior with verbal and physical approval.	Praise and hugs reinforce appropriate behavior, increasing the likelihood that it will occur again.
Encourage selective and sustained attention (see Chapter 5, page 163).	Development of attention is related to self-control. Children who can shift attention from a captivating stimulus and focus on a less attractive alternative are better at controlling their impulses.
Support language development (see Chapter 5, page 179).	In the second year, children begin to use language to remind themselves of adult expectations and to delay gratification.
Gradually increase rules in a manner consistent with the toddler's developing capacities.	As cognition and language improve, toddlers can follow more rules related to safety, respect for people and property, family routines, manners, and simple chores.

Researchers often study self-control by giving children tasks that, like the situations just mentioned, require **delay of gratification**—waiting for an appropriate time and place to engage in a tempting act. Between ages 1½ and 3, children show an increasing capacity to wait before eating a treat, opening a present, or playing with a toy (Vaughn, Kopp, & Krakow, 1984). Children who are advanced in development of attention and language tend to be better at delaying gratification (Else-Quest et al., 2006). These findings help explain why girls are typically more self-controlled than boys.

Like effortful control in general, young children's capacity to delay gratification is influenced by both biologically based temperament and quality of caregiving (Kochanska & Aksan, 2006; Kochanska & Knaack, 2003). Inhibited children find it easier to wait than angry, irritable children do. But toddlers who experience parental warmth and simple (as opposed to lengthy, detailed) statements that patiently redirect their behavior are more likely to be cooperative and resist temptation (Bandon & Volling, 2008; Hakman & Sullivan, 2009). Such parenting—which encourages and models patient, nonimpulsive behavior—is particularly important for temperamentally reactive children. In one study, anger-prone 7-month-olds with gentle, responsive mothers became eagerly compliant 15-month-olds (Kochanska, Aksan, & Carlson, 2005). Angry infants with insensitive mothers, by contrast, developed into strikingly uncooperative toddlers.

As self-control improves, parents gradually increase the range of rules they expect toddlers to follow, from safety and respect for property and people to family routines, manners, and simple chores (Gralinski & Kopp, 1993). Still, toddlers' control

over their own actions depends on constant parental oversight and reminders. Several prompts (“Remember, we’re going to go in just a minute”) and gentle insistence were usually necessary to get Caitlin to stop playing so that she and her parents could go on an errand. Applying What We Know above summarizes ways to help toddlers develop compliance and self-control.

As the second year of life drew to a close, Carolyn, Monica, and Vanessa were delighted at their children's readiness to learn the rules of social life. As we will see in Chapter 8, advances in cognition and language, along with parental warmth and reasonable demands for maturity, lead preschoolers to make tremendous strides in this area.

ASK YOURSELF

REVIEW What competencies are necessary for the emergence of compliance and self-control?

CONNECT What type of early parenting fosters the development of emotional self-regulation, secure attachment, and self-control? Why, in each instance, is it effective?

APPLY Len, a caregiver of 1- and 2-year-olds, wonders whether toddlers recognize themselves. List signs of self-recognition in the second year that Len can observe.

REFLECT Do you think that “the terrible twos,” a commonly used expression to characterize toddler behavior, is an apt description? Explain.

SUMMARY

Erikson's Theory of Infant and Toddler Personality (p. 184)

According to Erikson's psychosocial theory, how do infants and toddlers resolve the psychological conflicts of the first two years?

- Warm, responsive caregiving leads infants to resolve the psychological conflict of **basic trust versus mistrust** on the positive side. During toddlerhood, **autonomy versus shame and doubt** is resolved favorably when parents provide appropriate guidance and reasonable choices. If children emerge from the first few years without sufficient trust and autonomy, the seeds are sown for adjustment problems.

S. CANNIRELLI/THE IMAGE WORKS

Emotional Development

(p. 185)

Describe the development of basic emotions over the first year.

- During the first half-year, **basic emotions** gradually become clear, well-organized signals. The **social smile** appears between 6 and 10 weeks, laughter around 3 to 4 months. Happiness strengthens the parent-child bond and both reflects and supports physical and cognitive mastery.
- Anger and fear, especially in the form of **stranger anxiety**, increase in the second half of the first year as infants' cognitive and motor capacities improve. Newly mobile babies use the familiar caregiver as a **secure base** from which to explore.

Summarize changes during the first two years in understanding others' emotions, expression of self-conscious emotions, and emotional self-regulation.

- The ability to understand others' emotional expressions improves over the first year. At 8 to 10 months, infants engage in **social referencing**, actively seeking emotional

information from caregivers in uncertain situations. By the middle of the second year, toddlers appreciate that others' emotional reactions may differ from their own.

- During toddlerhood, self-awareness and adult instruction provide the foundation for **self-conscious emotions**, such as guilt, shame, embarrassment, envy, and pride. **Emotional self-regulation** emerges as the prefrontal cortex functions more effectively and as caregivers build on the infants' increasing tolerance for stimulation. When caregivers are emotionally sympathetic but set limits, children develop more effective anger-regulation strategies in the preschool years.

Temperament and Development (p. 190)

What is temperament, and how is it measured?

- **Temperament** refers to early-appearing, stable individual differences in reactivity and self-regulation. The New York Longitudinal Study identified three patterns: the **easy child**, the **difficult child**, and the **slow-to-warm-up child**. Mary Rothbart's model of temperament includes **effortful control**, the ability to regulate one's reactivity.
- Temperament is assessed through parental reports, behavior ratings by others familiar with the child, and laboratory observations. Most neurobiological research has focused on distinguishing **inhibited, or shy, children** from **uninhibited, or sociable, children**.

What roles do heredity and environment play in the stability of temperament?

- Temperament shows only low to moderate stability. Gene-environment correlation influences the experiences to which children are exposed, and experience modifies temperamental traits. Ethnic and gender differences may have a genetic foundation but are supported by cultural beliefs and practices.
- According to the **goodness-of-fit model**, parenting practices that fit well with the child's temperament help children achieve more adaptive functioning. Temperamentally difficult children are especially responsive to both positive and negative parenting.

Development of Attachment

(p. 195)

Describe the development of attachment during the first two years.

- **Ethological theory**, the most widely accepted perspective on **attachment**, recognizes the infant's emotional tie to the caregiver as an evolved response that promotes survival. In early infancy, a set of built-in behaviors encourages the parent to remain close to the baby.
- Around 6 to 8 months, **separation anxiety** and use of the caregiver as a secure base indicate that a true attachment bond has formed. As representation and language develop, separation protest declines. From early caregiving experiences, children construct an **internal working model** that guides future close relationships.

© ELLEN B. SENISI PHOTOGRAPHY

How do researchers measure attachment security, what factors affect it, and what are its implications for later development?

- Using the **Strange Situation**, a laboratory technique for assessing the quality of attachment between 1 and 2 years, researchers have identified four attachment patterns: **secure, avoidant, resistant, and disorganized/disoriented**. The **Attachment Q-Sort**, a home observation method suitable for 1- to 4-year-olds, yields a score ranging from high to low in security.
- Securely attached babies more often maintain their attachment pattern than insecure babies, although the disorganized/disoriented pattern is highly stable. Cultural conditions must be considered in interpreting attachment patterns.

- Attachment quality is influenced by early availability of a consistent caregiver, quality of caregiving, the fit between the baby's temperament and parenting practices, and family circumstances. **Sensitive caregiving** is moderately related to attachment security. In Western cultures, **interactional synchrony** characterizes the experiences of securely attached babies.

© JEFF GREENBERG/THE IMAGE WORKS

- Continuity of caregiving is the crucial factor determining whether attachment security is linked to later development. If caregiving improves, children can recover from an insecure attachment history.

Describe infants' capacity for multiple attachments.

- Infants develop strong affectionate ties to fathers, who tend to engage in more exciting, physical play with babies than mothers do. Early in the first year, infants begin to build rich emotional relationships with siblings that mix affection and caring with rivalry and resentment. Individual differences in the quality of sibling relationships are influenced by temperament and parenting.

Self-Development (p. 206)

Describe the development of self-awareness in infancy and toddlerhood, along with the emotional and social capacities it supports.

- At birth, infants sense that they are physically distinct from their surroundings, an awareness that is promoted by their capacity for intermodal perception. Around age 2, **self-recognition**—identification of the self as a physically unique being—is well under way. However, toddlers make **scale errors**, attempting to do things that their body size makes impossible.

- Self-awareness is associated with the beginnings of **empathy**, the ability to feel with another person. As language strengthens and toddlers compare themselves to others, they develop a **categorical self** based on age, sex, physical characteristics, goodness versus badness, and competencies.

NATALIE KAUFFMAN/
GETTY IMAGES/FIRST LIGHT

- Self-awareness provides the foundation for the emergence of **compliance** between 12 and 18 months and gains in **delay of gratification** between 1½ and 3 years. Children who are advanced in development of attention and language and who have warm, encouraging parents tend to be more self-controlled.

Important Terms and Concepts

attachment (p. 195)
Attachment Q-Sort (p. 198)
autonomy versus shame and doubt (p. 184)
avoidant attachment (p. 197)
basic emotions (p. 185)
basic trust versus mistrust (p. 184)
categorical self (p. 208)
compliance (p. 208)
delay of gratification (p. 209)
difficult child (p. 190)
disorganized/disoriented attachment (p. 198)
easy child (p. 190)

effortful control (p. 191)
emotional self-regulation (p. 189)
empathy (p. 208)
ethological theory of attachment (p. 196)
goodness-of-fit model (p. 194)
inhibited, or shy, child (p. 191)
interactional synchrony (p. 200)
internal working model (p. 197)
resistant attachment (p. 198)
scale errors (p. 207)
secure attachment (p. 197)
secure base (p. 187)

separation anxiety (p. 196)
slow-to-warm-up child (p. 190)
social referencing (p. 188)
social smile (p. 185)
stranger anxiety (p. 186)
Strange Situation (p. 197)
temperament (p. 190)
uninhibited, or sociable, child (p. 191)

milestones

Development in Infancy and Toddlerhood

ARIEL SKELLY/BLEND IMAGES/GETTY IMAGES

Birth–6 months

PHYSICAL

- Height and weight increase rapidly. (120)
- Newborn reflexes decline. (107–108)
- Distinguishes basic tastes and odors; shows preference for sweet-tasting foods. (112)
- Responses can be classically and operantly conditioned. (133–134)
- Habituates to unchanging stimuli; recovers to novel stimuli. (134–135)
- Sleep is increasingly organized into a night–day schedule. (128)
- Holds head up, rolls over, and grasps objects. (137, 139)
- Perceives auditory and visual stimuli as organized patterns. (140, 142, 144)
- Shows sensitivity to motion, then binocular, and finally pictorial depth cues. (142)
- Recognizes and prefers human facial pattern; recognizes features of mother’s face. (145)
- Masters a wide range of intermodal (visual, auditory, and tactile) relationships. (146)

COGNITIVE

- Engages in immediate and deferred imitation of adults’ facial expressions. (135–136, 156)
- Repeats chance behaviors that lead to pleasurable and interesting results. (153–154)

- Has some awareness of many physical properties (including object permanence) and basic numerical knowledge. (155, 160)
- Recognition memory for visual events improves. (163)
- Attention becomes more efficient and flexible. (163)
- Forms categories based on objects’ similar physical properties. (165–166)

LANGUAGE

- Coos and, by end of this period, babbles. (176)
- Begins to establish joint attention with caregiver, who labels objects and events. (176)

EMOTIONAL/SOCIAL

- Social smile and laughter emerge. (185)
- Matches feeling tone of caregiver in face-to-face communication; later, expects matched responses. (188)

© LAURA DWIGHT PHOTOGRAPHY

- Emotional expressions become well-organized and meaningfully related to environmental events. (185)

- Regulates emotion by shifting attention and self-soothing. (189)
- Awareness of self as physically distinct from surroundings increases. (206–207)

7–12 months

PHYSICAL

- Approaches adultlike sleep–wake schedule. (128)
- Sits alone, crawls, and walks. (137)

JIGI/BLEND IMAGES/GETTY IMAGES

- Reaching and grasping improve in flexibility and accuracy; shows refined pincer grasp. (140)
- Intermodal perception continues to improve. (146)

COGNITIVE

- Engages in intentional, or goal-directed, behavior. (154)
- Finds object hidden in an initial location. (154)
- Recall memory improves, as indicated by gains in deferred imitation of adults’ actions with objects. (156–157, 164)
- Solves simple problems by analogy to a previous problem. (157)
- Categorizes objects on the basis of subtle sets of features, even when the perceptual contrast between categories is minimal. (165)

LANGUAGE

- Babbling expands to include many sounds of spoken languages and patterns of the child's language community. (176)
- Joint attention with caregiver becomes more accurate. (176)
- Takes turns in games, such as pat-a-cake and peekaboo. (176)
- Comprehends some word meanings. (176)
- Uses preverbal gestures (showing, pointing) to influence others' behavior. (176)

© ELLEN B. SENISI PHOTOGRAPHY

- Around end of this period, understands displaced reference of words and says first words. (157, 176)

EMOTIONAL/SOCIAL

- Smiling and laughter increase in frequency and expressiveness. (185–186)
- Anger and fear increase in frequency and intensity. (185–186)
- Stranger anxiety and separation anxiety appear. (186, 196)
- Uses caregiver as a secure base for exploration. (187–188)
- Shows “clear-cut” attachment to familiar caregivers. (196)
- Increasingly detects the meaning of others' emotional expressions and engages in social referencing. (188)
- Regulates emotion by approaching and retreating from stimulation. (189)

13–18 months

PHYSICAL

- Height and weight gain are rapid, but not as great as in first year. (120)
- Walking is better coordinated. (138)
- Manipulates small objects with improved coordination. (140)

COGNITIVE

- Explores the properties of objects by acting on them in novel ways. (154)
- Searches in several locations for a hidden object. (154)
- Engages in deferred imitation of adults' actions with objects over longer delays and across a change in context—for example, from child care to home. (156)
- Sustained attention improves. (163)
- Recall memory improves further. (164)
- Sorts objects into categories. (166)
- Realizes that pictures can symbolize real objects. (158)

LANGUAGE

- Steadily adds to vocabulary. (175, 177)
- By end of this period, produces 50 words. (175)

EMOTIONAL/SOCIAL

- Joins in play with familiar adults and siblings. (201–202, 205)

© ELLEN B. SENISI PHOTOGRAPHY

- Realizes that others' emotional reactions may differ from one's own. (188)
- Complies with simple directives. (208)

19–24 months

PHYSICAL

- Jumps, walks on tiptoe, and runs. (137)
- Manipulates small objects with good coordination. (140)

COGNITIVE

- Solves simple problems suddenly, through representation. (154)
- Finds a hidden object that has been moved while out of sight. (154)
- Engages in make-believe play, using simple actions experienced in everyday life. (154, 168)

© LAURA DWIGHT PHOTOGRAPHY

- Engages in deferred imitation of actions an adult tries to produce, even if not fully realized. (157)
- Categorizes objects conceptually, on the basis of common function or behavior. (166)

LANGUAGE

- Produces 200 to 250 words. (175)
- Combines two words. (177)

EMOTIONAL/SOCIAL

- Self-conscious emotions (shame, embarrassment, guilt, envy, and pride) emerge. (188–189)
- Acquires a vocabulary for talking about feelings. (189)
- Begins to use language to assist with emotional self-regulation. (189–190)
- Begins to tolerate caregiver's absences more easily; separation anxiety declines. (197)
- Recognizes image of self and, by end of this period, uses own name or personal pronoun to refer to self. (207)
- Less often makes scale errors. (207)
- Shows signs of empathy. (207–208)
- Categorizes self and others on the basis of age, sex, physical characteristics, and goodness and badness. (208)
- Shows gender-stereotyped toy preferences. (208)
- Self-control, as indicated by delay of gratification, emerges. (209)

chapter 7

Rich opportunities for playful exploration and peer collaboration contribute vitally to preschoolers' rapidly advancing cognitive and language skills.

Physical and Cognitive Development in Early Childhood

For more than a decade, my fourth-floor office window overlooked the preschool and kindergarten play yard of our university laboratory school. On mild fall and spring mornings, the doors of the classrooms swung open, and sand table, easels, and large blocks spilled out into a small courtyard. Alongside the building was a grassy area with jungle gyms, swings, a playhouse, and a flower garden planted by the children. Beyond it lay a circular path lined with tricycles and wagons. Each day, the setting was alive with activity.

The years from 2 to 6 are often called “the play years,” since play blossoms during this time and supports every aspect of development. Our discussion opens with the physical attainments of early childhood—growth in body size and improvements in motor coordination. We look at genetic and environmental factors that support these changes and at their intimate connection with other domains of development.

Then we explore early childhood cognition, beginning with Piaget’s preoperational stage. Recent research, along with Vygotsky’s sociocultural theory and information processing, extends our understanding of preschoolers’ cognitive competencies. Next, we address factors that contribute to early childhood mental development—the home environment, the quality of preschool and child care, and the many hours young children spend watching television and using computers. We conclude with the dramatic expansion of language in early childhood. ●

PHYSICAL DEVELOPMENT

A Changing Body and Brain

In early childhood, body growth tapers off from the rapid rate of the first two years. On average, children add 2 to 3 inches in height and about 5 pounds in weight each year. Boys continue to be slightly larger than girls. As “baby fat” drops off further, children gradually become thinner, although girls retain somewhat more body fat than boys, who are slightly more muscular. As Figure 7.1 shows, by age 5 the top-heavy, bowlegged,

potbellied toddler has become a more streamlined, flat-tummied, longer-legged child with body proportions similar to those of adults. Consequently, posture and balance improve—changes that support gains in motor coordination.

Individual differences in body size are even more apparent during early childhood than in infancy and toddlerhood. Speeding around the bike path in the play yard, 5-year-old Darryl—at 48 inches tall and 55 pounds—towered over his kindergarten classmates. (The average North American 5-year-old boy is 43 inches tall and weighs 42 pounds.) Priti, an Asian-Indian child, was unusually small because of genetic factors linked to her cultural ancestry. Hal, a Caucasian child from a poverty-stricken home, was well below average for reasons we will discuss shortly.

FIGURE 7.1 Body growth during early childhood. During the preschool years, children grow more slowly than in infancy and toddlerhood. Chris and Mariel's bodies became more streamlined, flat-tummied, and longer-legged. Boys continue to be slightly taller, heavier, and more muscular than girls. But generally, the two sexes are similar in body proportions and physical capacities.

Skeletal Growth

The skeletal changes of infancy continue throughout early childhood. Between ages 2 and 6, approximately 45 new *epiphyses*, or growth centers in which cartilage hardens into bone, emerge in various parts of the skeleton. X-rays of these growth centers enable doctors to estimate children's *skeletal age*, or progress toward physical maturity (see page 121 in Chapter 4)—information helpful in diagnosing growth disorders.

By the end of the preschool years, children start to lose their primary, or “baby,” teeth. Genetic factors heavily influence the age at which they do so. For example, girls, who are ahead of boys in physical development, lose teeth earlier. Environmental influences also matter: Prolonged malnutrition delays the appearance of permanent teeth, whereas overweight and obesity accelerate it (Hilgers et al., 2006).

Diseased baby teeth can affect the health of permanent teeth, so preventing decay in primary teeth is essential—by brushing consistently, avoiding sugary foods, drinking fluoridated water, and getting topical fluoride treatments and sealants (plastic coatings that protect tooth surfaces). Another factor is exposure to tobacco smoke, which suppresses children's immune system, including the ability to fight bacteria responsible for tooth decay. Young children in homes with regular smokers are at increased risk for decayed teeth (Hanioka et al., 2011).

Unfortunately, an estimated 28 percent of U.S. preschoolers have tooth decay, a figure that rises to 50 percent in middle childhood and 60 percent by age 18. Causes include poor diet and inadequate health care—factors that are more likely to affect low-SES children. About 30 percent of U.S. children living in poverty have untreated dental caries (National Institutes of Health, 2011).

Brain Development

Between ages 2 and 6, the brain increases from 70 percent of its adult weight to 90 percent. At the same time, preschoolers improve in a wide variety of skills—physical coordination, perception, attention, memory, language, logical thinking, and imagination.

By age 4, many parts of the cerebral cortex have overproduced synapses. In some regions, such as the prefrontal cortex, the number of synapses is nearly double the adult value. Together, synaptic growth and myelination of neural fibers result in a high energy need. In fact, fMRI evidence reveals that energy metabolism in the cerebral cortex reaches a peak around this age (Huttenlocher, 2002; Nelson, Thomas, & de Haan, 2006). *Synaptic pruning* follows: Neurons that are seldom stimulated lose their connective fibers, and the number of synapses gradually declines. By age 8 to 10, energy consumption of most cortical regions diminishes to near-adult levels (Nelson, 2002). And cognitive capacities increasingly localize in distinct neural systems, reflecting a developmental shift toward a more fine-tuned, efficient neural organization (Tsujimoto, 2008).

EEG, NIRS, and fMRI measures of neural activity indicate especially rapid growth from early to middle childhood

© LAURA DWIGHT PHOTOGRAPHY

A 5-year-old illustrates gains in executive function, supported by rapid growth of the prefrontal cortex, as she engages in an activity that challenges her capacity to attend, remember, and plan.

in areas of the prefrontal cortex devoted to various aspects of executive function. These include inhibition of impulses, attention, memory, and planning and organizing behavior—capacities that advance markedly over the preschool years (Bunge & Wright, 2007; Durston & Casey, 2006). Furthermore, for most children, the left cerebral hemisphere is especially active between 3 and 6 years and then levels off. In contrast, activity in the right hemisphere increases steadily throughout early and middle childhood (Thatcher, Walker, & Giudice, 1987; Thompson et al., 2000). These findings fit nicely with what we know about several aspects of cognitive development. Language skills (typically housed in the left hemisphere) increase at an astonishing pace in early childhood, and they support children's improved executive function. In contrast, spatial skills (usually located in the right hemisphere), such as giving directions, drawing pictures, and recognizing geometric shapes, develop gradually over childhood and adolescence.

Differences in rate of development between the two hemispheres suggest that they are continuing to *lateralize* (specialize in cognitive functions). Let's take a closer look at brain lateralization in early childhood by focusing on handedness.

Handedness. Research on handedness, along with other evidence covered in Chapter 4, supports the joint contribution of nature and nurture to brain lateralization. By age 6 months, infants typically display a smoother, more efficient movement when reaching with their right than their left arm. This difference, believed to be biologically based, may contribute to the right-handed bias of most children by the end of the first year (Hinojosa, Sheu, & Michael, 2003; Rönqvist & Domellöf, 2006). Gradually, handedness extends to additional skills.

Handedness reflects the greater capacity of one side of the brain—the individual's **dominant cerebral hemisphere**—to carry out skilled motor action. Other important abilities are generally located on the dominant side as well. For right-handed people—in Western nations, 90 percent of the population—language is housed in the left hemisphere with hand control. For

the left-handed 10 percent, language is occasionally located in the right hemisphere or, more often, shared between the hemispheres (Szaflarski et al., 2012). This indicates that the brains of left-handers tend to be less strongly lateralized than those of right-handers.

Left-handed parents show only a weak tendency to have left-handed children (Vuoksimaa et al., 2009). One genetic theory proposes that most children inherit a gene that *biases* them for right-handedness and a left-dominant cerebral hemisphere. But that bias is not strong enough to overcome experiences that might sway children toward a left-hand preference (Annett, 2002). Even prenatal events may profoundly affect handedness. Both identical and fraternal twins are more likely than ordinary siblings to differ in hand preference, probably because twins usually lie in opposite orientations in the uterus (Derom et al., 1996). The orientation of most singleton fetuses—facing toward the left—is believed to promote greater control over movements on the body's right side (Previc, 1991).

Handedness also involves practice. It is strongest for complex skills requiring extensive training, such as eating with utensils, writing, and engaging in athletic activities. And wide cultural differences exist. For example, in tribal and village cultures, the rate of left-handedness is relatively high. But in a study of one such society in New Guinea, individuals who had attended school in childhood were far more likely to be extremely right-handed—findings that highlight the role of experience (Geuze et al., 2012).

Although rates of left-handedness are elevated among people with mental retardation and mental illness, atypical brain lateralization is probably not responsible for these individuals' problems. Rather, early damage to the left hemisphere may have caused their disabilities while also leading to a shift in handedness. In support of this idea, left-handedness is associated with prenatal and birth difficulties that can result in brain damage, including maternal stress, prolonged labor, prematurity, Rh incompatibility, and breech delivery (Kurganskaya, 2011; Rodriguez & Waldenström, 2008).

Most left-handers, however, have no developmental problems. In fact, left- and mixed-handed youngsters are slightly advantaged in speed and flexibility of thinking, and they are more likely than their right-handed agetates to develop outstanding verbal and mathematical talents (Flannery & Liederman, 1995; Gunstad et al., 2007). More even distribution of cognitive functions across both brain hemispheres may be responsible.

Other Advances in Brain Development. Besides the cerebral cortex, several other areas of the brain make strides during early childhood (see Figure 7.2). All of these changes involve establishing links between parts of the brain, increasing the coordinated functioning of the central nervous system.

At the rear and base of the brain is the **cerebellum**, a structure that aids in balance and control of body movement. Fibers linking the cerebellum to the cerebral cortex grow and myelinate from birth through the preschool years, contributing to dramatic gains in motor coordination: By the end of the preschool years, children can play hopscotch, throw and catch a

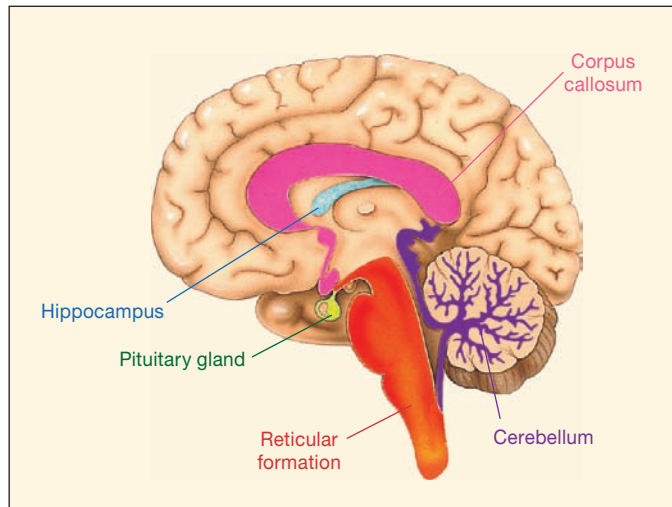

FIGURE 7.2 Cross-section of the human brain, showing the location of the cerebellum, the reticular formation, the hippocampus, and the corpus callosum. These structures undergo considerable development during early childhood. Also shown is the pituitary gland, which secretes hormones that control body growth (see page 219).

ball with well-coordinated movements, and print letters of the alphabet. Connections between the cerebellum and cerebral cortex also support thinking (Diamond, 2000): Children with damage to the cerebellum usually display both motor and cognitive deficits, including problems with memory, planning, and language (Noterdaeme et al., 2002; Riva & Giorgi, 2000).

The **reticular formation**, a structure in the brain stem that maintains alertness and consciousness, generates synapses and myelinates throughout childhood and into adolescence. Neurons in the reticular formation send out fibers to other brain regions. Many go to the prefrontal cortex, contributing to improvements in sustained, controlled attention.

An inner-brain structure called the **hippocampus**, which plays a vital role in memory and in images of space that help us find our way, undergoes rapid synapse formation and myelination in the second half of the first year, when recall memory and independent movement emerge. Over the preschool and elementary school years, the hippocampus and surrounding areas of the cerebral cortex continue to develop swiftly, establishing connections with one another and with the prefrontal cortex (Nelson, Thomas, & de Haan, 2006). These changes support the dramatic gains in memory and spatial understanding of early and middle childhood.

The **corpus callosum** is a large bundle of fibers connecting the two cerebral hemispheres. Production of synapses and myelination of the corpus callosum peak between 3 and 6 years, then continue more slowly through adolescence (Thompson et al., 2000). The corpus callosum supports smooth coordination of movements on both sides of the body and integration of many aspects of thinking, including perception, attention, memory, language, and problem solving. The more complex the task, the more essential is communication between the hemispheres.

Growth and myelination of fibers linking the cerebellum to the cerebral cortex contribute to improved motor coordination and thinking, enabling this child to master a game that requires him to play hopscotch while also throwing a ball.

ASK YOURSELF

REVIEW What aspects of brain development underlie the tremendous gains in language, thinking, and motor control of early childhood?

CONNECT What stand on the nature–nurture issue do findings on development of handedness support? Explain, using research findings.

APPLY Dental checkups reveal a high incidence of untreated tooth decay in a U.S. preschool program serving low-income children. Using findings presented in this and previous chapters, list possible contributing factors.

REFLECT How early, and to what extent, did you experience tooth decay in childhood? What factors might have been responsible?

Influences on Physical Growth and Health

As we consider factors affecting growth and health in early childhood, you will encounter some familiar themes. Heredity remains important, but environmental factors—good nutrition, relative freedom from disease, and physical safety—are also essential.

Heredity and Hormones

The impact of heredity on physical growth is evident throughout childhood. Children's physical size and rate of growth are related to those of their parents (Bogin, 2001). Genes influence growth by controlling the body's production of hormones. The **pituitary gland**, located at the base of the brain, plays a critical role by releasing two hormones that induce growth.

The first, **growth hormone (GH)**, is necessary for development of all body tissues except the central nervous system and the genitals. Children who lack GH reach an average mature height of only 4 to 4½ feet. When treated early with injections of GH, such children show catch-up growth and then grow at a normal rate, becoming much taller than they would have without treatment (Bright, Mendoza, & Rosenfeld, 2009).

A second pituitary hormone, **thyroid-stimulating hormone (TSH)**, prompts the thyroid gland in the neck to release *thyroxine*, which is necessary for brain development and for GH to have its full impact on body size. Infants born with a deficiency of thyroxine must receive it at once, or they will be mentally retarded. Once the most rapid period of brain development is complete, thyroxine deficiency no longer affects the central nervous system but still causes children to grow more slowly than average. With prompt treatment, however, such children catch up in body growth and eventually reach normal size (Salerno et al., 2001).

Nutrition

With the transition to early childhood, many children become unpredictable, picky eaters. One father I know wistfully recalled how his son, as a toddler, eagerly sampled Chinese food: “Now, at age 3, the only thing he'll try is the ice cream!”

Preschoolers' appetites decline because their growth has slowed. Their wariness of new foods is also adaptive. If they stick to familiar foods, they are less likely to swallow dangerous substances when adults are not around to protect them (Birch & Fisher, 1995). Parents need not worry about variations in amount eaten from meal to meal. Preschoolers compensate for eating little at one meal by eating more at a later one (Hursti, 1999).

Though they eat less, preschoolers require a high-quality diet, including the same foods adults need, but in smaller amounts. Fats, oils, and salt should be kept to a minimum because of their link to high blood pressure and heart disease in adulthood. Foods high in sugar should be eaten only in small amounts to prevent tooth decay and protect against overweight and obesity—a topic we will take up in Chapter 9.

Children tend to imitate the food choices of people they admire, both adults and peers. For example, in Mexico, where children often see family members enjoying peppery foods, preschoolers enthusiastically eat chili peppers, whereas most U.S. children reject them (Birch, Zimmerman, & Hind, 1980). Repeated, unpressured exposure to a new food also increases acceptance (Fuller et al., 2005). For example, serving broccoli or tofu increases children's liking for these healthy foods. In contrast, offering sweet fruit or soft drinks promotes “milk avoidance” (Black et al., 2002).

RED CHOPSTICKS/GETTY IMAGES

As this child's grandmother shows him how to eat with chopsticks, he also acquires a taste for foods commonly served in his culture.

Although children's healthy eating depends on a wholesome food environment, too much parental control limits children's opportunities to develop self-control. When parents offer bribes ("Finish your vegetables, and you can have an extra cookie") children tend to like the healthy food less and the treat more (Birch, Fisher, & Davison, 2003).

LOOK AND LISTEN

Arrange to join a family with at least one preschooler for a meal, and closely observe parental mealtime practices. Are they likely to promote healthy eating habits? Explain. ●

Finally, as indicated in earlier chapters, many children in the United States and in developing countries lack access to sufficient high-quality food to support healthy development. Five-year-old Hal rode a bus from a poor neighborhood to our laboratory preschool. His mother's welfare check barely covered her rent, let alone food. Hal's diet was deficient in protein and in essential vitamins and minerals—iron (to prevent anemia and support central nervous system processes), calcium (to support development of bones and teeth), vitamin A (to help maintain eyes, skin, and a variety of internal organs), and vitamin C (to facilitate iron absorption and wound healing). These are the most common deficiencies of the preschool years (Ganji, Hampl, & Betts, 2003).

Hal was small for his age, pale, inattentive, and unruly at preschool. By the school years, low-SES U.S. children are, on average, ½ to 1 inch shorter than their economically advantaged counterparts (Cecil et al., 2005; Yip, Scanlon, & Trowbridge, 1993). And throughout childhood and adolescence, a nutritionally deficient diet is associated with attention and memory difficulties, lower intelligence and achievement test scores, and behavior problems—especially hyperactivity and aggression—

even after family factors that might account for these relationships are controlled (Liu et al., 2004; Lukowski et al., 2010; Slack & Yoo, 2005).

Infectious Disease

One day, I noticed that Hal had been absent from the play yard for several weeks, so I asked Leslie, his preschool teacher, what was wrong. "Hal's been hospitalized with the measles," she explained. "He's had difficulty recovering—lost weight when there wasn't much to lose in the first place." In well-nourished children, ordinary childhood illnesses have no effect on physical growth. But when children are undernourished, disease interacts with malnutrition in a vicious spiral, with potentially severe consequences.

Infectious Disease and Malnutrition. Hal's reaction to the measles is commonplace in developing nations, where a large proportion of the population lives in poverty and many children do not receive routine immunizations. Illnesses such as measles and chicken pox, which typically do not appear until after age 3 in industrialized nations, occur much earlier. Poor diet depresses the body's immune system, making children far more susceptible to disease. Of the 7.5 million annual deaths of children under age 5 worldwide, 98 percent are in developing countries and 65 percent are due to infectious diseases (World Health Organization, 2012a).

Disease, in turn, is a major contributor to malnutrition, hindering both physical growth and cognitive development. Illness reduces appetite and limits the body's ability to absorb foods, especially in children with intestinal infections. In developing countries, widespread diarrhea, resulting from unsafe water and contaminated foods, leads to growth stunting and nearly 1 million childhood deaths each year (World Health Organization, 2012a). Studies carried out in the slums and shantytowns of Brazil and Peru reveal that the more persistent diarrhea is in early childhood, the shorter children are in height and the lower they score on mental tests during the school years (Checkley et al., 2003; Niehaus et al., 2002).

Most developmental impairments and deaths due to diarrhea can be prevented with nearly cost-free *oral rehydration therapy (ORT)*, in which sick children are given a solution of glucose, salt, and water that quickly replaces fluids the body loses. Since 1990, public health workers have taught nearly half the families in the developing world how to administer ORT. Also, supplements of zinc (essential for immune system functioning), which cost only 30 cents for a month's supply, substantially reduce the incidence of severe diarrhea (Aggarwal, Sentz, & Miller, 2007).

Immunization. In industrialized nations, childhood diseases have declined dramatically during the past half-century, largely as a result of widespread immunization of infants and young children. Hal got the measles because, unlike his classmates from more economically advantaged homes, he did not receive a full program of immunizations.

About 30 percent of U.S. preschoolers lack essential immunizations. The rate rises to 32 percent for poverty-stricken children, many of whom do not receive full protection until age 5 or 6, when it is required for school entry (U.S. Department of Health and Human Services, 2010e). In contrast, fewer than 10 percent of preschoolers lack immunizations in Denmark and Norway, and fewer than 7 percent in Canada, the Netherlands, Sweden, and the United Kingdom (World Health Organization, 2010).

Why does the United States lag behind these countries in immunization? As noted in earlier chapters, many U.S. children do not have access to the health care they need. In 1994, all medically uninsured children in the United States were guaranteed free immunizations, a program that has led to gains in immunization rates.

Inability to pay for vaccines is only one cause of inadequate immunization. Parents with stressful daily lives or without health benefits of their own often fail to schedule vaccination appointments, and those without a primary care physician do not want to endure long waits in crowded U.S. public health clinics (Falagas & Zarkadoulia, 2008). Some parents have been influenced by media reports suggesting a link between a mercury-based preservative used for decades in vaccines and a rise in the number of children diagnosed with autism. But large-scale studies show no association with autism and no consistent effects on cognitive performance (Richler et al., 2006; Stehr-Green et al., 2003; Thompson et al., 2007). Still, as a precautionary measure, mercury-free versions of childhood vaccines are now available.

In areas where many parents have refused to immunize their children, outbreaks of whooping cough and rubella have occurred, with life-threatening consequences (Kennedy & Gust, 2008; Tuyen & Bisgard, 2003). Public education programs directed at increasing parental knowledge about the importance and safety of timely immunizations are badly needed.

Childhood Injuries

More than any other child in the preschool classroom, 3-year-old Tommy had trouble sitting still and paying attention. Instead, he darted from one place and activity to another. One day, he narrowly escaped serious injury when he put his mother's car into gear while she was outside scraping ice from its windows. The vehicle rolled through a guardrail and over the side of a 10-foot concrete underpass, where it hung until rescue workers arrived. Police charged Tommy's mother with failure to use a restraint seat for a child younger than age 8.

Unintentional injuries are the leading cause of childhood mortality in industrialized nations. As Figure 7.3 reveals, the United States ranks poorly in these largely preventable events. About 20 percent of U.S. childhood deaths and 50 percent of adolescent deaths result from injuries (Centers for Disease Control and Prevention, 2012b). And among injured children and youths who survive, thousands suffer pain, brain damage, and permanent physical disabilities.

FIGURE 7.3 International death rates due to unintentional injury among 1- to 14-year-olds. Compared with other industrialized nations, the United States has a high injury rate, largely because of widespread childhood poverty and shortages of high-quality child care. Injury death rates are many times higher in developing nations, where poverty, rapid population growth, overcrowding in cities, and inadequate safety measures endanger children's lives. (Adapted from World Health Organization, 2008.)

Auto and traffic accidents, drownings, and burns are the most common injuries during early and middle childhood (Safe Kids USA, 2011b). Motor vehicle collisions are by far the most frequent source of injury across all ages, ranking as the leading cause of death among children more than 1 year old.

Factors Related to Childhood Injuries. The common view of childhood injuries as “accidental” suggests they are due to chance and cannot be prevented (Sleet & Mercy, 2003). In fact, these injuries occur within a complex *ecological system* of individual, family, community, and societal influences—and we can do something about them.

Because of their higher activity level and greater impulsivity and risk taking, boys are 1.5 times more likely to be injured than girls (Safe Kids USA, 2008). Children with certain temperamental and personality characteristics—inattentiveness, overactivity, irritability, defiance, and aggression—are also at greater risk (Ordonana, Caspi, & Moffitt, 2008; Schwebel & Gaines, 2007). As we saw in Chapter 6, these children present

Childhood injury rates are especially high in developing countries with weak public safety measures. These Cambodian children play unsupervised in a poverty-stricken, rundown neighborhood near a former dump site.

child-rearing challenges. They are likely to protest when placed in auto seat restraints, to refuse to take a companion's hand when crossing the street, and to disobey even after repeated instruction and discipline.

Poverty, single parenthood, and low parental education are also strongly associated with injury (Dudani, Macpherson, & Tamim, 2010; Schwebel & Brezausek, 2007). Parents who must cope with many daily stresses often have little energy to monitor the safety of their children. And their rundown homes and neighborhoods pose further risks (Dal Santo et al., 2004).

Broad societal conditions also affect childhood injury. In developing countries, the rate of death from injury before age 15 is five times as high as in developed nations and soon may exceed disease as the leading cause of childhood mortality (World Health Organization, 2008). Rapid population growth, overcrowding in cities, and heavy road traffic combined with weak safety measures are major causes. Safety devices, such as car safety seats and bicycle helmets, are neither readily available nor affordable.

Childhood injury rates are high in the United States because of extensive poverty, shortages of high-quality child care (to supervise children in their parents' absence), and a high rate of births to teenagers, who are not ready for parenthood. But U.S. children from advantaged families are also at considerably greater risk for injury than children in Western Europe (World Health Organization, 2008). This indicates that besides reducing poverty and teenage pregnancy and upgrading the status of child care, additional steps are needed to ensure children's safety.

Preventing Childhood Injuries. Childhood injuries have many causes, so a variety of approaches are needed to reduce them. Laws prevent many injuries by requiring car

safety seats, child-resistant caps on medicine bottles, flameproof clothing, and fencing around backyard swimming pools (the site of 50 percent of early childhood drownings) (Brenner & Committee on Injury, Violence, and Poison Protection, 2003). Communities can help by modifying their physical environments. Playgrounds, a common site of injury, can be covered with protective surfaces (Safe Kids USA, 2008). Free, easily installed window guards can be given to families in high-rise apartment buildings to prevent falls. And media campaigns can inform parents and children about safety issues.

But even though they know better, many parents and children behave in ways that compromise safety. About 27 percent of U.S. parents (like Tommy's mother) fail to place their preschoolers in car safety seats. And 84 percent of infant seats and 40 percent of child booster seats are improperly used (Safe Kids USA, 2011a). American parents, especially, seem willing to ignore familiar safety practices, perhaps because of the high value they place on individual rights and personal freedom (Damashek & Peterson, 2002).

Furthermore, many parents begin relying on children's knowledge of safety rules, rather than controlling access to hazards, as early as 2 or 3 years of age—a premature transition associated with a rise in home injuries (Morrongiello, Ondejko, & Littlejohn, 2004). But even older preschoolers spontaneously recall only about half the safety rules their parents teach them. And even with well-learned rules, they need supervision to ensure they comply (Morrongiello, Midgett, & Shields, 2001).

Parent interventions that highlight risk factors and that model and reinforce safety practices are effective in reducing home hazards and childhood injuries (Kendrick et al., 2008). But attention must also be paid to family conditions that can prevent childhood injury: relieving crowding in the home, providing social supports to ease parental stress, and teaching parents to use effective discipline—a topic we take up in Chapter 8.

ASK YOURSELF

REVIEW To effectively prevent childhood injury, why are diverse approaches essential? Cite examples at several levels of the *ecological system*.

CONNECT Using research on malnutrition, show how physical growth and health in early childhood result from a continuous, complex interplay between heredity and environment.

APPLY One day, Leslie prepared a new snack to serve at preschool: celery stuffed with ricotta cheese. The first time she served it, few children touched it. How can Leslie encourage her students to accept the snack? What tactics should she avoid?

REFLECT Ask a parent or other family member whether, as a preschooler, you were a picky eater, suffered from many infectious diseases, or sustained any serious injuries. In each instance, what factors might have been responsible?

Motor Development

TAKE A MOMENT... Observe several 2- to 6-year-olds at play in a neighborhood park, preschool, or child-care center. You will see that an explosion of new motor skills occurs in early childhood, each of which builds on the simpler movement patterns of toddlerhood.

During the preschool years, children continue to integrate previously acquired skills into more complex, *dynamic systems*. Then they revise each new skill as their bodies grow larger and stronger, their central nervous systems develop, their environments present new challenges, and they set new goals.

Gross-Motor Development

As children's bodies become more streamlined and less top-heavy, their center of gravity shifts downward, toward the trunk. As a result, balance improves greatly, paving the way for new motor skills involving large muscles of the body. By age 2, preschoolers' gaits become smooth and rhythmic—secure enough that soon they leave the ground, at first by running and later by jumping, hopping, galloping, and skipping.

As children become steadier on their feet, their arms and torsos are freed to experiment with new skills—throwing and catching balls, steering tricycles, and swinging on horizontal bars and rings. Then upper- and lower-body skills combine into more refined actions. Five- and 6-year-olds simultaneously steer and pedal a tricycle and flexibly move their whole body when

© ELLEN B. SENISI PHOTOGRAPHY

As balance improves, preschoolers can combine upper- and lower-body skills into more refined actions, such as walking on stilts.

throwing, catching, hopping, and jumping. By the end of the preschool years, all skills are performed with greater speed and endurance. Table 7.1 provides a closer look at gross-motor development in early childhood.

TABLE 7.1

Changes in Gross- and Fine-Motor Skills During Early Childhood

AGE	GROSS-MOTOR SKILLS	FINE-MOTOR SKILLS
2–3 years	Walks more rhythmically; hurried walk changes to run Jumps, hops, throws, and catches with rigid upper body Pushes riding toy with feet; little steering	Puts on and removes simple items of clothing Zips and unzips large zippers Uses spoon effectively
3–4 years	Walks up stairs, alternating feet, and down stairs, leading with one foot Jumps and hops, flexing upper body Throws and catches with slight involvement of upper body; still catches by trapping ball against chest Pedals and steers tricycle	Fastens and unfastens large buttons Serves self food without assistance Uses scissors Copies vertical line and circle Draws first picture of person, using tadpole image
4–5 years	Walks down stairs, alternating feet Runs more smoothly Gallops and skips with one foot Throws ball with increased body rotation and transfer of weight on feet; catches ball with hands Rides tricycle rapidly, steers smoothly	Uses fork effectively Cuts with scissors following line Copies triangle, cross, and some letters
5–6 years	Increases running speed Gallops more smoothly; engages in true skipping Displays mature, whole-body throwing and catching pattern; increases throwing speed Rides bicycle with training wheels	Uses knife to cut soft food Ties shoes Draws person with six parts Copies some numbers and simple words

Fine-Motor Development

Fine-motor skills, too, take a giant leap forward in the preschool years. As control of the hands and fingers improves, young children put puzzles together, build with small blocks, cut and paste, and string beads. To parents, fine-motor progress is most apparent in two areas: (1) children's care of their own bodies, and (2) the drawings and paintings that fill the walls at home, child care, and preschool.

Self-Help Skills. As Table 7.1 shows, young children gradually become self-sufficient at dressing and feeding. But parents must be patient about these abilities: When tired and in a hurry, young children often revert to eating with their fingers. And the 3-year-old who dresses himself may end up with his shirt on inside out, his pants on backward, and his left snow boot on his right foot! Perhaps the most complex self-help skill of early childhood is shoe tying, mastered around age 6. Success requires a longer attention span, memory for an intricate series of hand movements, and the dexterity to perform them. Shoe tying illustrates the close connection between motor and cognitive development, as do two other skills: drawing and writing.

Drawing. When given crayon and paper, even toddlers scribble in imitation of others. Gradually, marks on the page take on meaning. A variety of cognitive factors combine with fine-motor control to influence changes in children's artful representations (Golomb, 2004). These include the realization that pictures can serve as symbols, improved planning and spatial understanding, and the emphasis that the child's culture places on artistic expression.

Typically, drawing progresses through the following sequence:

1. *Scribbles.* At first, children's gestures rather than the resulting scribbles contain the intended representation. For

example, one 18-month-old made her crayon hop and, as it produced a series of dots, explained, "Rabbit goes hop-hop" (Winner, 1986).

2. *First representational forms.* Around age 3, children's scribbles start to become pictures. Often children make a gesture with the crayon, notice that they have drawn a recognizable shape, and then label it (Winner, 1986). Few 3-year-olds spontaneously draw so others can tell what their picture represents. But when adults draw with children and point out the resemblances between drawings and objects, preschoolers' pictures become more comprehensible and detailed (Braswell & Callanan, 2003).

A major milestone in drawing occurs when children use lines to represent the boundaries of objects, enabling 3- and 4-year-olds to draw their first picture of a person. Fine-motor and cognitive limitations lead the preschooler to reduce the figure to the simplest form that still looks human: the universal "tadpole" image, a circular shape with lines attached, shown on the left in Figure 7.4.

3. *More realistic drawings.* Five- and 6-year-olds create more complex drawings, like the one on the right in Figure 7.4, containing more conventional human and animal figures, with the head and body differentiated. Older preschoolers' drawings still contain perceptual distortions because they have just begun to represent depth (Cox & Littlejohn, 1995). This free depiction of reality makes their artwork look fanciful and inventive.

LOOK AND LISTEN

Visit a preschool or child-care center where artwork by 3- to 5-year-olds is plentiful. Note age differences in the complexity of children's drawings. ●

FIGURE 7.4 Examples of young children's drawings. The universal tadpole-like shape that children use to draw their first picture of a person is shown on the left. The tadpole soon becomes an anchor for greater details that sprout from the basic shape. By the end of the preschool years, children produce more complex, differentiated pictures like the one on the right, drawn by a 6-year-old child. Winner, "Where Pelicans Kiss Seals," *Psychology Today*, 20[8], August 1986, p. 35. Reprinted by permission from the collection of Ellen Winner.)

The complex drawings of these kindergartners in Suzhou, China, benefit from adult expectations that young children learn to draw well and from the rich artistic traditions of Chinese culture.

Cultural Variations in Development of Drawing.

In cultures with rich artistic traditions, children create elaborate drawings that reflect the conventions of their culture. Adults encourage young children by offering suggestions, modeling ways to draw, and asking them to label their pictures. Peers, as well, discuss one another's drawings and copy from one another's work (Braswell, 2006). All of these practices enhance young children's drawing progress.

But in cultures with little interest in art, even older children and adolescents produce simple forms. In the Jimi Valley, a remote region of Papua New Guinea with no indigenous pictorial art, many children do not go to school and therefore have little opportunity to develop drawing skills. When a Western researcher asked nonschooled Jimi 10- to 15-year-olds to draw a human figure for the first time, most produced nonrepresentational scribbles and shapes or simple "stick" images resembling preschoolers' tadpolelike shapes (Martlew & Connolly, 1996). These forms seem to be a universal beginning in drawing. Once children realize that lines must evoke human features, they find solutions to figure drawing that follow the general sequence described earlier.

Early Printing. When preschoolers first try to write, they scribble, making no distinction between writing and drawing. Around age 4, writing shows some distinctive features of print, such as separate forms arranged in a line on the page. But children often include picturelike devices—for example, a circular shape for "sun" (Ehri & Roberts, 2006). Only gradually, between ages 4 and 6, as they learn to name alphabet letters and link them

with language sounds, do children realize that writing stands for language.

Preschoolers' first attempts to print often involve their name, generally using a single letter. "How do you make a *D*?" my older son, David, asked at age 3½. When I printed a large uppercase *D*, he tried to copy. "*D* for David," he proclaimed, quite satisfied with his backward, imperfect creation. By age 5, David printed his name clearly enough for others to read but, like many children, continued to reverse some letters until well into second grade. Until children start to read, they do not find it useful to distinguish between mirror-image forms, such as *b* and *d* and *p* and *q* (Bornstein & Arterberry, 1999).

Individual Differences in Motor Skills

Wide individual differences exist in the ages at which children reach motor milestones. A tall, muscular child tends to move more quickly and to acquire certain skills earlier than a short, stocky youngster. And as in other domains, parents and teachers probably provide more encouragement to children with biologically based motor-skill advantages.

Sex differences in motor skills are evident in early childhood. Boys are ahead of girls in skills that emphasize force and power. By age 5, they can broad-jump slightly farther, run slightly faster, and throw a ball about 5 feet farther. Girls have an edge in fine-motor skills and in certain gross-motor skills that depend on balance and agility, such as hopping and skipping (Fischman, Moore, & Steele, 1992; Haywood & Getchell, 2009). Boys' greater muscle mass and, in the case of throwing, slightly longer forearms contribute to their skill advantages. And girls' greater overall physical maturity may be partly responsible for their better balance and precision of movement.

From an early age, boys and girls are usually encouraged into different physical activities. For example, fathers are more likely to play catch with their sons than with their daughters. Sex differences in motor skills increase with age, but they remain small throughout childhood (Greendorfer, Lewko, & Rosengren, 1996). This suggests that social pressures for boys, more than girls, to be active and physically skilled exaggerate small, genetically based sex differences.

Children master the motor skills of early childhood during everyday play. Aside from throwing (where direct instruction is helpful), preschoolers exposed to gymnastics, tumbling, and other formal lessons do not make faster progress. When children have access to play spaces appropriate for running, climbing, jumping, and throwing and are encouraged to use them, they respond eagerly to these challenges. Similarly, fine-motor skills can be supported through daily routines, such as pouring juice and dressing, and through play that involves puzzles, construction sets, drawing, painting, sculpting, cutting, and pasting.

Finally, the social climate created by adults can enhance or dampen preschoolers' motor development. When parents and

teachers criticize a child's performance, push specific motor skills, or promote a competitive attitude, they risk undermining children's self-confidence and, in turn, their motor progress (Berk, 2006). Adult involvement in young children's motor activities should focus on fun rather than on winning or perfecting the "correct" technique.

APPLY Mabel and Chad want to do everything they can to support their 3-year-old daughter's motor development. What advice would you give them?

COGNITIVE DEVELOPMENT

One rainy morning, as I observed in our laboratory preschool, Leslie, the children's teacher, joined me at the back of the room. "Preschoolers' minds are such a blend of logic, fantasy, and faulty reasoning," Leslie reflected. "Every day, I'm startled by the maturity and originality of what they say and do. Yet at other times, their thinking seems limited and inflexible."

Leslie's comments sum up the puzzling contradictions of early childhood cognition. Hearing a loud thunderclap outside, 3-year-old Sammy exclaimed, "A magic man turned on the thunder!" Even after Leslie explained that thunder is caused by lightning, not by a person turning it on, Sammy persisted: "Then a magic lady did it."

In other respects, Sammy's thinking was surprisingly advanced. At snack time, he accurately counted, "One, two, three, four!" and then got four cartons of milk, one for each child at his table. But when his snack group included more than four children, Sammy's counting broke down. And after Priti dumped out her raisins, scattering them in front of her on the table, Sammy asked, "How come you got lots, and I only got this little bit?" He didn't realize that he had just as many raisins; his were simply all bunched up in a tiny red box.

To understand Sammy's reasoning, we turn first to Piaget's and Vygotsky's theories and evidence highlighting the strengths and limitations of each. Then we consider additional research on young children's cognition inspired by the information-processing perspective, address factors that contribute to individual differences in mental development, and look at the dramatic expansion of language in early childhood.

Piaget's Theory: The Preoperational Stage

As children move from the sensorimotor to the **preoperational stage**, which spans the years 2 to 7, the most obvious change is an extraordinary increase in representational, or symbolic, activity. Infants and toddlers' mental representations are impressive, but in early childhood, representational capacities blossom.

Advances in Mental Representation

Piaget acknowledged that language is our most flexible means of mental representation. By detaching thought from action, language permits far more efficient thinking than was possible earlier. When we think in words, we overcome the limits of our momentary experiences. We can deal with past, present, and future at once and combine concepts in unique ways, as when we imagine a hungry caterpillar eating bananas or monsters flying through the forest at night.

But Piaget did not regard language as the primary ingredient in childhood cognitive change. Instead, he believed that sensorimotor activity leads to internal images of experience, which children then label with words (Piaget, 1936/1952). In support of Piaget's view, children's first words have a strong sensorimotor basis (see Chapter 5). In addition, infants and toddlers acquire an impressive range of categories long before they use words to label them (see page 127). But as we will see, Piaget underestimated the power of language to spur children's cognition.

Make-Believe Play

Make-believe play is another excellent example of the development of representation in early childhood. Piaget believed that through pretending, young children practice and strengthen newly acquired representational schemes. Drawing on his ideas, several investigators have traced the development of make-believe during the preschool years.

Development of Make-Believe. One day, Sammy's 20-month-old brother, Dwayne, visited the classroom. Dwayne wandered around, picked up a toy telephone receiver, said, "Hi, Mommy," and then dropped it. Next, he found a cup, pretended to drink, and then toddled off again. Meanwhile, Sammy joined Vance and Priti in the block area for a space shuttle launch.

"That can be our control tower," Sammy suggested, pointing to a corner by a bookshelf. "Countdown!" he announced, speaking into his "walkie-talkie"—a small wooden block. "Five, six, two, four, one, blastoff!" Priti made a doll push a pretend button, and the rocket was off!

Comparing Dwayne's pretend play with Sammy's, we see three important changes that reflect the preschool child's growing symbolic mastery:

- *Play detaches from the real-life conditions associated with it.* In early pretending, toddlers use only realistic objects—a

© LAURA DWIGHT PHOTOGRAPHY

Make-believe play increases in sophistication during the preschool years. Children pretend with less realistic toys and increasingly coordinate make-believe roles, such as bus driver and passengers.

toy telephone to talk into or a cup to drink from. Their earliest pretend acts usually imitate adults' actions and are not yet flexible. Children younger than age 2, for example, will pretend to drink from a cup but refuse to pretend a cup is a hat (Rakoczy, Tomasello, & Striano, 2005). They have trouble using an object (cup) that already has an obvious use as a symbol of another object (hat).

After age 2, children pretend with less realistic toys (a block for a telephone receiver). Gradually, they can imagine objects and events without any support from the real world, as Sammy's imaginary control tower illustrates (O'Reilly, 1995; Striano, Tomasello, & Rochat, 2001). And by age 3, they flexibly understand that an object (a yellow stick) may take on one fictional identity in one pretend game (a toothbrush) and another fictional identity (a carrot) in a different pretend game (Wyman, Rakoczy, & Tomasello, 2009).

- *Play becomes less self-centered.* At first, make-believe is directed toward the self—for example, Dwayne pretends to feed only himself. Soon, children direct pretend actions toward other objects, as when a child feeds a doll. Early in the third year, they become detached participants, making a doll feed itself or pushing a button to launch a rocket (McCune, 1993). Increasingly, preschoolers realize that agents and recipients of pretend actions can be independent of themselves.
- *Play includes more complex combinations of schemes.* Dwayne can pretend to drink from a cup, but he does not yet combine pouring and drinking. Later, children combine schemes with those of peers in **sociodramatic play**, the make-believe with others that is under way by the end of the second year and increases rapidly in complexity during early childhood (Kavanaugh, 2006). Already, Sammy and his classmates can create and coordinate several roles in an elaborate plot. By the end of early childhood, children have a sophisticated understanding of role relationships and story lines (Göncü, 1993).

LOOK AND LISTEN

Observe the make-believe play of several 2- to 4-year-olds. Describe pretend acts that exemplify important developmental changes. ●

In sociodramatic play, children display awareness that make-believe is a representational activity—an understanding that strengthens over early childhood (Lillard, 2003; Rakoczy, Tomasello, & Striano, 2004; Sobel, 2006). **TAKE A MOMENT...** Listen closely to a group of preschoolers as they assign roles and negotiate make-believe plans: “You *pretend to be* the astronaut, I’ll *act like* I’m operating the control tower!” In communicating about pretend, children think about their own and others’ fanciful representations—evidence that they have begun to reason about people’s mental activities.

Benefits of Make-Believe. Today, Piaget’s view of make-believe as mere practice of representational schemes is regarded as too limited. Play not only reflects but also contributes to children’s cognitive and social skills. Compared with social non-pretend activities (such as drawing or putting puzzles together), during sociodramatic play preschoolers’ interactions last longer, show more involvement, draw more children into the activity, and are more cooperative (Creasey, Jarvis, & Berk, 1998).

It is not surprising, then, that preschoolers who spend more time at sociodramatic play are seen as more socially competent by their teachers (Connolly & Doyle, 1984). And many studies reveal that make-believe strengthens a wide variety of mental abilities, including sustained attention, memory, logical reasoning, language and literacy, imagination, creativity, and the ability to reflect on one’s own thinking, regulate one’s own emotions and behavior, and take another’s perspective (Bergen & Mauer, 2000; Berk, Mann, & Ogan, 2006; Elias & Berk, 2002; Hirsh-Pasek et al., 2009; Lindsey & Colwell, 2003; Ogan & Berk, 2009; Ruff & Capozzoli, 2003). We will return to the topic of early childhood play in this and the next chapter.

Symbol–Real-World Relations

To make believe and draw—and to understand other forms of representation, such as photographs, models, and maps—preschoolers must realize that each symbol corresponds to something specific in everyday life. In Chapter 5, we saw that by the middle of the second year, children grasp the symbolic function of realistic-looking photos, and around age 2½, of TV and video. When do children comprehend other challenging symbols—for example, three-dimensional models of real-world spaces?

In one study, 2½- and 3-year-olds watched an adult hide a small toy (Little Snoopy) in a scale model of a room and then were asked to retrieve it. Next, they had to find a larger toy (Big Snoopy) hidden in the room that the model represented. Not until age 3 could most children use the model as a guide to finding Big Snoopy in the real room (DeLoache, 1987). The 2½-year-olds did not realize that the model could be both *a toy room* and *a symbol of another room*. They had trouble with **dual representation**—viewing a symbolic object as both an object

© ELLEN B. SENISI PHOTOGRAPHY

Preschoolers who experience a variety of symbols come to understand dual representation—for example, that this dollhouse is an object in its own right but can also stand for another, a full-sized house where people live.

in its own right and a symbol. In support of this interpretation, when researchers made the model room less prominent as an object, by placing it behind a window and preventing children from touching it, more 2½-year-olds succeeded at the search task (DeLoache, 2000, 2002). Recall, also, that in make-believe play, 1½- to 2-year-olds cannot use an object that has an obvious use (cup) to stand for another object (hat). Likewise, 2-year-olds do not yet grasp that a line drawing—an object in its own right—also represents real-world objects.

Similarly, when presented with objects disguised in various ways and asked what each “looks like” and what each “is really and truly,” preschoolers have difficulty. For example, when asked whether a stone painted to look like an egg “is really and truly” an egg, children younger than age 6 often responded “yes” (Flavell, Green, & Flavell, 1987). But simplify these appearance-reality tasks by permitting children to solve them nonverbally, by selecting from an array of objects the one that “really” has a particular identity, and most 3-year-olds perform well (Deák, Ray, & Brenneman, 2003). They realize that an object can be one thing (a stone) while symbolizing another (an egg).

How do children grasp the dual representation of symbolic objects? When adults point out similarities between models and real-world spaces, 2½-year-olds perform better on the find-Snoopy task (Peralta de Mendoza & Salsa, 2003). Also, insight into one type of symbol–real-world relation helps preschoolers master others. For example, children regard realistic-looking pictures as symbols early because a picture’s primary purpose is to stand for something; it is not an interesting object in its own right (Preissler & Carey, 2004; Simcock & DeLoache, 2006). And 3-year-olds who can use a model of a room to locate Big Snoopy readily transfer their understanding to a simple map (Marzolf & DeLoache, 1994). In sum, experiences with diverse symbols—photos, picture books, make-believe, and maps—help preschoolers appreciate that one object can stand for another.

Limitations of Preoperational Thought

Aside from gains in representation, Piaget described preschoolers in terms of what they *cannot* understand (Beilin, 1992). As the term *preoperational* suggests, he compared them to older, more competent children who have reached the concrete operational stage. According to Piaget, young children are not capable of *operations*—mental actions that obey logical rules. Rather, their thinking is rigid, limited to one aspect of a situation at a time, and strongly influenced by the way things appear at the moment.

Egocentrism. For Piaget, the most fundamental deficiency of preoperational thinking is **egocentrism**—failure to distinguish others’ symbolic viewpoints from one’s own. He believed that when children first mentally represent the world, they tend to focus on their own viewpoint and simply assume that others perceive, think, and feel the same way they do.

Piaget’s most convincing demonstration of egocentrism involves his *three-mountains problem*, described in Figure 7.5. He also regarded egocentrism as responsible for preoperational children’s *animistic thinking*—the belief that inanimate objects have lifelike qualities, such as thoughts, wishes, feelings, and intentions (Piaget, 1926/1930). Recall Sammy’s firm insistence that someone must have turned on the thunder. According to Piaget, because young children egocentrically assign human purposes to physical events, magical thinking is common during the preschool years.

Piaget argued that preschoolers’ egocentric bias prevents them from *accommodating*, or reflecting on and revising their faulty reasoning in response to their physical and social worlds. To understand this shortcoming, let’s consider some additional tasks that Piaget gave to children.

FIGURE 7.5 Piaget’s three-mountains problem. Each mountain is distinguished by its color and by its summit. One has a red cross, another a small house, and the third a snow-capped peak. Children at the preoperational stage respond egocentrically. They cannot select a picture that shows the mountains from the doll’s perspective. Instead, they simply choose the photo that reflects their own vantage point.

FIGURE 7.6 Some Piagetian conservation tasks. Children at the preoperational stage cannot yet conserve. These tasks are mastered gradually over the concrete operational stage. Children in Western nations typically acquire conservation of number, mass, and liquid sometime between 6 and 7 years and of weight between 8 and 10 years.

Inability to Conserve. Piaget's famous conservation tasks reveal a variety of deficiencies of preoperational thinking. **Conservation** refers to the idea that certain physical characteristics of objects remain the same, even when their outward appearance changes. At snack time, Priti and Sammy had identical boxes of raisins, but when Priti spread her raisins out on the table, Sammy was convinced that she had more.

In another conservation task involving liquid, the child is shown two identical tall glasses of water and asked if they contain equal amounts. Once the child agrees, the water in one glass is poured into a short, wide container, changing its appearance but not its amount. Then the child is asked whether the amount of water has changed. Preoperational children think the quantity has changed. They explain, "There is less now because the water is way down here" (that is, its level is so low) or, "There is more now because it is all spread out." Figure 7.6 illustrates other conservation tasks that you can try with children.

The inability to conserve highlights several related aspects of preoperational children's thinking. First, their understanding is *centered*, or characterized by **centration**. They focus on one aspect of a situation, neglecting other important features. In conservation of liquid, the child *centers* on the height of the water, failing to realize that changes in width compensate for changes in height. Second, children are easily distracted by the *perceptual appearance* of objects. Third, children treat the initial and final states of the water as unrelated events, ignoring the *dynamic transformation* (pouring of water) between them.

The most important illogical feature of preoperational thought is its **irreversibility**, an inability to mentally go through a series of steps in a problem and then reverse direction, returning to the starting point. **Reversibility** is part of every logical operation. After Priti spills her raisins, Sammy cannot reverse

by thinking, "I know that Priti doesn't have more raisins than I do. If we put them back in that little box, her raisins and my raisins would look just the same."

Lack of Hierarchical Classification. Preoperational children have difficulty with **hierarchical classification**—the organization of objects into classes and subclasses on the basis of similarities and differences. Piaget's famous *class inclusion problem*, illustrated in Figure 7.7, demonstrates this limitation. Preoperational children center on the overriding feature, red. They do not think reversibly by moving from the whole class (flowers) to the parts (red and blue) and back again.

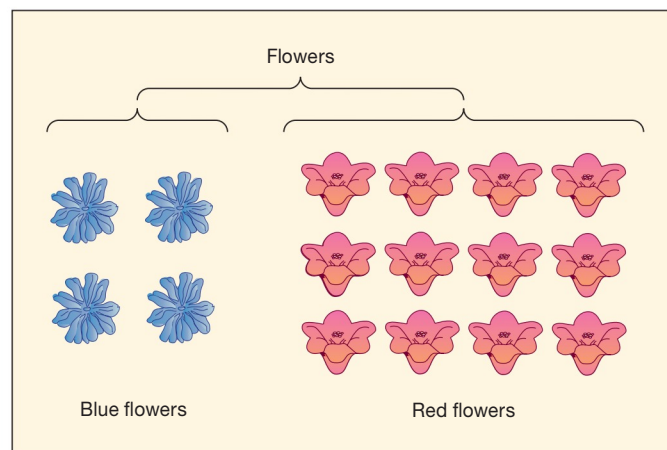

FIGURE 7.7 A Piagetian class inclusion problem. Children are shown 16 flowers, 4 of which are blue and 12 of which are red. Asked, "Are there more red flowers or flowers?" the preoperational child responds, "More red flowers," failing to realize that both red and blue flowers are included in the category "flowers."

Follow-Up Research on Preoperational Thought

Over the past three decades, researchers have challenged Piaget's view of preschoolers as cognitively deficient. Because many Piagetian problems contain unfamiliar elements or too many pieces of information for young children to handle at once, preschoolers' responses do not reflect their true abilities. Piaget also missed many naturally occurring instances of effective reasoning by preschoolers.

Egocentric, Animistic, and Magical Thinking. Do young children really believe that a person standing elsewhere in a room sees exactly what they see? When researchers use simplified tasks with familiar objects, 3-year-olds show clear awareness of others' vantage points, such as recognizing how something looks to another person who is looking at it through a color filter (Moll & Meltzoff, 2011). Even 2-year-olds realize that what they see sometimes differs from what another person sees. When asked to help an adult looking for a lost object, 24-month-olds—but not 18-month-olds—handed her a toy resting behind a bucket that was within the child's line of sight but not visible to the adult (Moll & Tomasello, 2006).

Nonegocentric responses also appear in young children's conversations. For example, preschoolers adapt their speech to fit the needs of their listeners. Four-year-olds use shorter, simpler expressions when talking to 2-year-olds than to age-mates or adults (Gelman & Shatz, 1978). And in describing objects, children do not use such words as "big" and "little" in a rigid, egocentric fashion. Instead, they *adjust* their descriptions to allow for context. By age 3, children judge a 2-inch shoe as small when seen by itself (because it is much smaller than most shoes) but as big for a tiny 5-inch-tall doll (Ebeling & Gelman, 1994).

In Chapter 5, we saw that toddlers have already begun to infer others' intentions (see page 157). And in his later writings, Piaget (1945/1951) did describe preschoolers' egocentrism as a *tendency* rather than an inability. As we revisit the topic of perspective taking, we will see that it develops gradually throughout childhood and adolescence.

Piaget also overestimated preschoolers' animistic beliefs. Even young infants have begun to distinguish animate from inanimate, as indicated by their developing categorical distinctions between living and nonliving things (see page 166). By age 2½, children give psychological explanations ("he likes to" or "she wants to") for people and occasionally for animals, but rarely for objects (Hickling & Wellman, 2001). In addition, preschoolers rarely attribute biological properties (like eating and growing) to robots, indicating that they are well aware that even a self-moving robot with life-like features is not alive. They often say that robots have perceptual and psychological capacities—for example, seeing, thinking, and remembering (Jipson & Gelman, 2007; Subrahmanyam, Gelman, & Lafosse, 2002). But these responses result from incomplete knowledge about certain objects, and they decline with age.

Similarly, preschoolers think that magic accounts for events they otherwise cannot explain, as in Sammy's magical explanation of thunder (Rosengren & Hickling, 2000). Consequently,

most 3- and 4-year-olds believe in the supernatural powers of fairies, goblins, and other enchanted creatures. Furthermore, older 3-year-olds and 4-year-olds think that violations of physical laws (walking through a wall) and mental laws (turning on the TV just by thinking about it) require magic more than violations of social conventions (taking a bath with shoes on) (Browne & Woolley, 2004). These responses indicate that preschoolers' notions of magic are flexible and appropriate.

Between ages 4 and 8, as children gain familiarity with physical events and principles, their magical beliefs decline. They figure out who is really behind Santa Claus and the Tooth Fairy, and they realize that the antics of magicians are due to trickery (Subbotsky, 2004). And increasingly, children say that characters and events in fantastical stories aren't real (Woolley & Cox, 2007). Still, because children entertain the possibility that something imaginary might materialize, they may react with anxiety to scary stories, TV shows, and nightmares.

Logical Thought. Many studies show that when preschoolers are given tasks that are simplified and relevant to their everyday lives, they do not display the illogical characteristics that Piaget saw in the preoperational stage. For example, when a conservation-of-number task is scaled down to include only three items instead of six or seven, 3-year-olds perform well (Gelman, 1972). And when asked carefully worded questions about what happens to a substance (such as sugar) after it is dissolved in water, most 3- to 5-year-olds know that the substance is conserved—that it continues to exist, can be tasted, and makes the liquid heavier, even though it is invisible in the water (Au, Sidle, & Rollins, 1993; Rosen & Rozin, 1993).

Preschoolers' ability to reason about transformations is evident on other problems. They can engage in impressive *reasoning by analogy* about physical changes. Presented with the picture-matching problem "Play dough is to cut-up play dough as apple is to . . . ?," even 3-year-olds choose the correct answer (a cut-up apple) from a set of alternatives, several of which (a bitten apple, a cut-up loaf of bread) share physical features with the right choice (Goswami, 1996). These findings indicate that in familiar contexts, preschoolers can overcome appearances and think logically about cause and effect.

Finally, even without detailed biological or mechanical knowledge, preschoolers understand that the insides of animals are responsible for certain cause–effect sequences (such as willing oneself to move) that are impossible for nonliving things, such as machines (Gelman, 2003; Keil & Lockhart, 1999). Preschoolers seem to use illogical reasoning only when grappling with unfamiliar topics, too much information, or contradictory facts that they cannot reconcile.

Categorization. Despite their difficulty with Piagetian class inclusion tasks, preschoolers organize their everyday knowledge into nested categories at an early age. By the beginning of early childhood, children's categories include objects that go together because of their common function, behavior, or natural kind (animate versus inanimate), despite varying widely in perceptual features.

© LAURA DWIGHT PHOTOGRAPHY

These 4-year-olds understand that a category (“dinosaurs”) can be based on underlying characteristics (“cold-blooded”), not just on perceptual features such as upright posture and scaly skin.

Indeed, 2- to 5-year-olds readily draw appropriate inferences about nonobservable characteristics shared by category members (Gopnik & Nazzi, 2003). For example, after being told that a bird has warm blood and that a stegosaurus (dinosaur) has cold blood, preschoolers infer that a pterodactyl (labeled a dinosaur) has cold blood, even though it closely resembles a bird.

During the second and third years, and perhaps earlier, children’s categories differentiate. They form many *basic-level categories*—ones that are at an intermediate level of generality, such as “chairs,” “tables,” and “beds.” By the third year, children

easily move back and forth between basic-level categories and *general categories*, such as “furniture.” And they break down basic-level categories into *subcategories*, such as “rocking chairs” and “desk chairs.”

Preschoolers’ rapidly expanding vocabularies and general knowledge support their impressive skill at categorizing. As they learn more about their world, they devise ideas about underlying characteristics that category members share—for example, that a combination of physical features, internal organs, and behaviors determines an animal’s identity (Gelman & Koenig, 2003). Also, adults label and explain categories to children, and picture-book reading is a rich context for doing so (Gelman & Kalish, 2006). In conversing about books, parents provide information (“Penguins live at the South Pole, swim, catch fish, and have thick layers of fat and feathers that help them stay warm”) that guides children’s inferences about the structure of categories. Furthermore, as the Social Issues: Education box on page 232 indicates, young children ask many questions about their world and usually get informative answers, which are well-suited to advancing their conceptual understanding.

In sum, although preschoolers’ category systems are less complex than those of older children and adults, they already have the capacity to classify hierarchically and on the basis of nonobvious properties. And they use logical, causal reasoning to identify the interrelated features that form the basis of a category and to classify new members.

Evaluation of the Preoperational Stage

Table 7.2 provides an overview of the cognitive attainments of early childhood. **TAKE A MOMENT...** Compare them with Piaget’s description of the preoperational child on pages 228–229.

Social Issues: Education

Children's Questions: Catalyst for Cognitive Development

Dad, what's that?" asked 4-year-old Emily as her father chopped vegetables for dinner.

"It's an onion," her father said.

"Is an onion a fruit?" Emily asked.

"It's a vegetable," her father replied.

"A root vegetable because it grows underground."

Emily wrinkled her nose. "Why does it smell yucky?"

"I don't know," her father admitted.

"But after dinner we can look it up online and find out."

When young children converse with adults, they ask, on average, more than one question per minute! Do inquisitive children like Emily really want answers to their many questions? Or are they—as their parents sometimes conclude—merely clamoring for attention?

An analysis of diaries that parents diverse in SES and ethnicity kept of their children's questions and of audio recordings of parent-child interactions revealed that at every age between 1 and 5 years, 70 to 90 percent of children's questions were information-seeking ("What's that [pointing to a crawfish]?") as opposed to non-information-seeking ("Can I have a cookie?") (Chouinard, 2007). And from age 2 on, children increasingly built on their fact-oriented questions

with follow-up questions that asked for causes and explanations ("What do crawfish eat?" "Why does it have claws?"). By age 3½, these sets of "building questions" made up about half of children's questions, confirming that preschoolers ask questions purposefully, to obtain clarifying information about things that puzzle them.

Unlike information obtained in other ways, answers to children's questions provide them with the precise knowledge they need at the precise moment they need it. And the content of children's questions is related to their cognitive development. At a time when vocabulary is advancing rapidly, about 60 percent of 1½- to 2-year-olds' questions ask for names of objects. With age, preschoolers increasingly ask about function ("What's it do?"), activity ("What's he doing?"), state ("Is she hungry?"), and theory of mind ("How does the pilot *know* where to fly?").

The usefulness of children's questions depends on adults' answers. Most of the time, parents respond informatively. If they do not, preschoolers are amazingly persistent: They ask again until they get the information they want. Parents adjust the complexity of their answers to fit their

CULTURA/MOOF/GETTY IMAGES

Preschoolers' questions are often purposeful efforts to understand things that puzzle them. Because adults' answers provide the precise knowledge children need at the precise moment they need it, question-asking is a powerful source of cognitive development.

children's maturity (Callanan & Oakes, 1992). To a question like "Why does the light come on?" 3-year-olds typically get simpler, "prior cause" explanations ("I turned on the switch"). Slightly older children frequently get "mechanism" explanations ("The switch allows electricity to reach the light bulb").

Clearly, asking questions is a major means through which children strive to attain adultlike understandings. Children's questions offer parents and teachers a fascinating window into their factual and conceptual knowledge, along with a wealth of opportunities to help them learn.

The evidence as a whole indicates that Piaget was partly wrong and partly right about young children's cognitive capacities. When given simplified tasks based on familiar experiences, preschoolers show the beginnings of logical thinking, which suggests that they attain logical operations gradually.

Evidence that preschoolers can be trained to perform well on Piagetian problems also supports the idea that operational thought is not absent at one point in time and present at another (Ping & Goldin-Meadow, 2008; Siegler & Svetina, 2006). Over time, children rely on increasingly effective mental (as opposed to perceptual) approaches to solving problems. For example, children who cannot use counting to compare two sets of items do not conserve number (Rouselle, Palmers, & Noël, 2004; Sophian, 1995). Once preschoolers can count, they apply this

skill to conservation-of-number tasks involving just a few items. As counting improves, they extend the strategy to problems with more items. By age 6, they understand that number remains the same after a transformation as long as nothing is added or taken away (Halford & Andrews, 2006). Consequently, they no longer need to count to verify their answer.

The gradual development of logical operations poses yet another challenge to Piaget's assumption of abrupt change toward logical reasoning around age 6 or 7. Does a preoperational stage really exist? Some no longer think so. Recall from Chapter 5 that according to the information-processing perspective, children work out their understanding of each type of task separately, and their thought processes are basically the same at all ages—just present to a greater or lesser extent.

Other experts think the stage concept is still valid, with modifications. For example, some *neo-Piagetian theorists* combine Piaget's stage approach with the information-processing emphasis on task-specific change (Case, 1998; Halford & Andrews, 2006). They believe that Piaget's strict stage definition must be transformed into a less tightly knit concept, one in which a related set of competencies develops over an extended period, depending on brain development and specific experiences. These investigators point to evidence that as long as the complexity of tasks and children's exposure to them are carefully controlled, children approach those tasks in similar, stage-consistent ways (Andrews & Halford, 2002; Case & Okamoto, 1996). For example, in drawing pictures, preschoolers depict objects separately, ignoring their spatial arrangement. In understanding stories, they grasp a single story line but have trouble with a main plot plus one or more subplots.

This flexible stage notion recognizes the unique qualities of early childhood thinking. At the same time, it provides a better account of why, as Leslie put it, "Preschoolers' minds are such a blend of logic, fantasy, and faulty reasoning."

Piaget and Education

Three educational principles derived from Piaget's theory continue to have a major impact on both teacher training and classroom practices, especially during early childhood:

- *Discovery learning.* In a Piagetian classroom, children are encouraged to discover for themselves through spontaneous interaction with the environment. Instead of presenting ready-made knowledge verbally, teachers provide a rich variety of activities designed to promote exploration, including art, puzzles, table games, dress-up clothing, building blocks, books, measuring tools, and musical instruments.
- *Sensitivity to children's readiness to learn.* In a Piagetian classroom, teachers introduce activities that build on children's current thinking, challenging their incorrect ways of viewing the world. But they do not try to hasten development by imposing new skills before children indicate interest or readiness.
- *Acceptance of individual differences.* Piaget's theory assumes that all children go through the same sequence of development, but at different rates. Therefore, teachers must plan activities for individual children and small groups, not just for the whole class. In addition, teachers evaluate educational progress in relation to the child's previous development, rather than on the basis of normative standards, or average performance of same-age peers.

Like his stages, educational applications of Piaget's theory have met with criticism. Perhaps the greatest challenge has to do with his insistence that young children learn mainly through acting on the environment (Brainerd, 2003). In the next section, we will see that young children also rely on language-based routes to knowledge.

ASK YOURSELF

REVIEW Select two of the following features of preoperational thought: egocentrism, a focus on perceptual appearances, difficulty reasoning about transformations, and lack of hierarchical classification. Present evidence indicating that preschoolers are more capable thinkers than Piaget assumed.

CONNECT Make-believe play promotes both cognitive and social development (see page 227). Explain why this is so.

APPLY Three-year-old Will understands that his tricycle isn't alive and can't feel or move on its own. But at the beach, while watching the sun dip below the horizon, Will exclaimed, "The sun is tired. It's going to sleep!" What explains this apparent contradiction in Will's reasoning?

REFLECT On the basis of what you have read, do you accept Piaget's claim for a preoperational stage of cognitive development? Explain.

Vygotsky's Sociocultural Theory

Piaget's deemphasis on language as a source of cognitive development brought on yet another challenge, this time from Vygotsky's sociocultural theory, which stresses the social context of cognitive development. During early childhood, rapid growth of language broadens preschoolers' participation in social dialogues with more knowledgeable individuals, who encourage them to master culturally important tasks. Soon children start to communicate with themselves in much the same way they converse with others. This greatly enhances their thinking and ability to control their own behavior. Let's see how this happens.

Private Speech

TAKE A MOMENT... Watch preschoolers as they play and explore the environment, and you will see that they frequently talk out loud to themselves. For example, as Sammy worked a puzzle, he said, "Where's the red piece? Now, a blue one. No, it doesn't fit. Try it here."

Piaget (1923/1926) called these utterances *egocentric speech*, reflecting his belief that young children have difficulty taking the perspectives of others. Their talk, he said, is often "talk for self" in which they express thoughts in whatever form they happen to occur, regardless of whether a listener can understand. Piaget believed that cognitive development and certain social experiences eventually bring an end to egocentric speech. Specifically, through disagreements with peers, children see that others hold viewpoints different from their own. As a result, egocentric speech declines.

A preschooler explores the possibilities of a handful of soap bubbles with the aid of private speech. Research supports Vygotsky's theory that children use private speech to guide their thinking and behavior.

Vygotsky (1934/1987) disagreed with Piaget's conclusions. Because language helps children think about their mental activities and behavior and select courses of action, Vygotsky saw it as the foundation for all higher cognitive processes, including controlled attention, deliberate memorization and recall, categorization, planning, problem solving, and self-reflection. In Vygotsky's view, children speak to themselves for self-guidance. As they get older and find tasks easier, their self-directed speech is internalized as silent, *inner speech*—the internal verbal dialogues we carry on while thinking and acting in everyday situations.

Over the past three decades, almost all studies have supported Vygotsky's perspective (Berk & Harris, 2003; Winsler, 2009). As a result, children's self-directed speech is now called **private speech** instead of egocentric speech. Research shows that children use more of it when tasks are appropriately challenging (neither too easy nor too hard), after they make errors, or when they are confused about how to proceed. With age, as Vygotsky predicted, private speech goes underground, changing into whispers and silent lip movements. Furthermore, children who freely use private speech during a challenging activity are more attentive and involved and show better task performance than their less talkative agemates (Al-Namlah, Fernyhough, & Meins, 2006; Lidstone, Meins, & Fernyhough, 2010; Winsler, Naglieri, & Manfra, 2006).

Social Origins of Early Childhood Cognition

Where does private speech come from? Recall from Chapter 5 that Vygotsky believed that children's learning takes place within the *zone of proximal development*—a range of tasks too difficult for the child to do alone but possible with the help of adults and

more skilled peers. Consider the joint activity of Sammy and his mother as she helps him put together a difficult puzzle:

Sammy: I can't get this one in. [*Tries to insert a piece in the wrong place.*]

Mother: Which piece might go down here? [*Points to the bottom of the puzzle.*]

Sammy: His shoes. [*Looks for a piece resembling the clown's shoes but tries the wrong one.*]

Mother: Well, what piece looks like this shape? [*Points again to the bottom of the puzzle.*]

Sammy: The brown one. [*Tries it, and it fits; then attempts another piece and looks at his mother.*]

Mother: Try turning it just a little. [*Gestures to show him.*]

Sammy: There! [*Puts in several more pieces while his mother watches.*]

Sammy's mother keeps the puzzle within his zone of proximal development, at a manageable level of difficulty. To do so, she engages in **scaffolding**—adjusting the support offered during a teaching session to fit the child's current level of performance. When the child has little notion of how to proceed, the adult uses direct instruction, breaking the task into manageable units, suggesting strategies, and offering rationales for using them. As the child's competence increases, effective scaffolders gradually and sensitively withdraw support, turning over responsibility to the child. Then children take the language of these dialogues, make it part of their private speech, and use this speech to organize their independent efforts.

What evidence supports Vygotsky's ideas on the social origins of cognitive development? In several studies, children whose parents were effective scaffolders used more private speech, were more successful when attempting difficult tasks on their own, and were advanced in overall cognitive development (Berk & Spuhl, 1995; Conner & Cross, 2003; Mulvaney et al., 2006). Adult cognitive support—teaching in small steps and offering strategies—predicts gains in children's thinking. And among Caucasian-American parent-child pairs, adult emotional support—offering encouragement and allowing the child to take over the task—predicts children's effort (Neitzel & Stright, 2003).

Nevertheless, effective scaffolding varies among cultures, as an investigation of Hmong families who had emigrated from Southeast Asia to the United States illustrates. Unlike Caucasian-American parents, who emphasize independence by encouraging their children to think of ways to approach a task, Hmong parents—who highly value interdependence and child obedience—frequently tell their children what to do (for example, "Put this piece here, then this piece on top of it") (Stright, Herr, & Neitzel, 2009). Among Caucasian-American children, such directive scaffolding is associated with kindergartners' lack of self-control and behavior problems. Among Hmong children, however, it predicts greater rule following, organization, and task completion.

Finally, although children benefit from working on tasks with same-age peers, their planning and problem solving improve more when their partner is either an "expert" peer (especially

capable at the task) or an adult. And peer disagreement (emphasized by Piaget) is less important in fostering cognitive development than the extent to which children resolve differences of opinion and cooperate (Kobayashi, 1994; Tudge, 1992).

Vygotsky and Education

Both Piagetian and Vygotskian classrooms accept individual differences and provide opportunities for children's active participation. But a Vygotskian classroom goes beyond independent discovery to promote *assisted discovery*. Teachers guide children's learning, tailoring their interventions to each child's zone of proximal development. Assisted discovery is aided by *peer collaboration*, as children of varying abilities work in groups, teaching and helping one another.

Vygotsky (1933/1978) saw make-believe play as the ideal social context for fostering cognitive development in early childhood. As children create imaginary situations, they learn to follow internal ideas and social rules rather than their immediate impulses. For example, a child pretending to go to sleep follows the rules of bedtime behavior. A child imagining himself as a father and a doll as a child conforms to the rules of parental behavior. According to Vygotsky, make-believe play is a unique, broadly influential zone of proximal development in which children try out a wide variety of challenging activities and acquire many new competencies.

Turn back to page 227 to review findings that make-believe play enhances a diverse array of cognitive and social skills. Pretending is also rich in private speech—a finding that supports its role in helping children bring action under the control of thought (Krafft & Berk, 1998). And preschoolers who spend more time engaged in sociodramatic play are better at taking personal responsibility for following classroom rules and at regulating emotion (Berk, Mann, & Ogan, 2006; Lemche et al., 2003). These findings support the role of make-believe in children's increasing self-control.

Evaluation of Vygotsky's Theory

In granting social experience a fundamental role in cognitive development, Vygotsky's theory underscores the vital role of teaching and helps us understand the wide cultural variation in children's cognitive skills. Nevertheless, it has not gone unchallenged. Verbal communication may not be the only means through which children's thinking develops—or even, in some cultures, the most important means. When Western parents scaffold their young children's mastery of challenging tasks, their verbal communication resembles the teaching that takes place in school, where their children will spend years preparing for adult life. In cultures that place less emphasis on schooling and literacy, parents often expect children to take greater responsibility for acquiring new skills through keen observation and participation in community activities (Paradise & Rogoff, 2009; Rogoff, 2003). (See the Cultural Influences box on page 236).

To account for children's diverse ways of learning through involvement with others, Barbara Rogoff (1998, 2003) suggests the term **guided participation**, a broader concept than scaffolding. It refers to shared endeavors between more expert and less expert participants, without specifying the precise features of communication. Consequently, it allows for variations across situations and cultures.

Finally, Vygotsky's theory says little about how basic motor, perceptual, attention, memory, and problem-solving skills, discussed in Chapters 4 and 5, contribute to socially transmitted higher cognitive processes. For example, his theory does not address how these elementary capacities spark changes in children's social experiences, from which more advanced cognition springs (Miller, 2009; Moll, 1994). Piaget paid far more attention than Vygotsky to the development of basic cognitive processes. It is intriguing to speculate about the broader theory that might exist today if Piaget and Vygotsky—the two twentieth-century giants of cognitive development—had had a chance to meet and weave together their extraordinary accomplishments.

In this Vygotsky-inspired classroom, 4- and 5-year-olds benefit from peer collaboration. As they jointly make music, their conductor ensures that each player stays on beat.

ASK YOURSELF

REVIEW Describe features of social interaction that support children's cognitive development. How does such interaction create a zone of proximal development?

CONNECT Explain how Piaget's and Vygotsky's theories complement each other. How would classroom practices inspired by these theories be similar? How would they be different?

APPLY Tanisha sees her 5-year-old son, Toby, talking aloud to himself as he plays. She wonders whether she should discourage this behavior. Use Vygotsky's theory to explain why Toby talks to himself. How would you advise Tanisha?

REFLECT When do you use private speech? Does it serve a self-guiding function for you, as it does for children? Explain.

Cultural Influences

Children in Village and Tribal Cultures Observe and Participate in Adult Work

In Western societies, the role of equipping children with the skills they need to become competent workers is assigned to school. In early childhood, middle-SES parents' interactions with children emphasize child-focused activities designed to prepare children to succeed in school—especially adult-child conversations and play that enhance language, literacy, and other academic knowledge. In village and tribal cultures, children receive little or no schooling, spend their days in contact with adult work, and start to assume mature responsibilities in early childhood (Rogoff et al., 2003). Consequently, parents have little need to rely on conversation and play to teach children.

A study comparing 2- and 3-year-olds' daily lives in four cultures—two U.S. middle-SES suburbs, the Efe hunters and gatherers of the Republic of Congo, and a Mayan agricultural town in Guatemala—documented these differences (Morelli, Rogoff, & Angelillo, 2003). In the U.S. communities, young children had little access to adult work and spent much time conversing and playing with adults. In contrast, the Efe and Mayan children rarely engaged in these child-focused activities. They spent their days close to—and frequently observing—adult work, which often took place in or near the Efe campsite or the Mayan family home.

An ethnography of a remote Mayan village in Yucatán, Mexico, shows that when young children are legitimate onlookers and participants in a daily life structured around adult work, their competencies differ from those of Western preschoolers (Gaskins, 1999; Gaskins, Haight, & Lancy, 2007). Yucatec Mayan adults are subsistence farmers. Men tend cornfields, aided by sons age 8 and older. Women prepare meals, wash clothes, and care for the livestock and garden, assisted by daughters and by sons too young to work in the fields. Children join in these activities from the second year on. When not participating, they are expected to be self-sufficient. Young children make many nonwork decisions for themselves—how much to sleep and eat, what to wear, and even when to start school. As a result, Yucatec Mayan preschoolers are highly competent at self-care. In contrast, their make-believe play is limited; when it occurs, they usually imitate adult work. Otherwise, they watch others—for hours each day.

Yucatec Mayan parents rarely converse or play with preschoolers or scaffold their learning. Rather, when children imitate adult tasks, parents conclude that they are ready for more responsibility. Then they assign chores, selecting tasks the child can

© PAUL W. LIEBHARDT/CORBIS

A Mayan 3-year-old imitates her mother in balancing a basket of laundry on her head. Children in Guatemalan Mayan culture observe and participate in the work of their community from an early age.

do with little help so that adult work is not disturbed. If a child cannot do a task, the adult takes over and the child observes, reengaging when able to contribute.

Expected to be autonomous and helpful, Yucatec Mayan children seldom ask others for something interesting to do. From an early age, they can sit quietly for long periods—through a lengthy religious service or a three-hour truck ride to town. And when an adult directs them to do a chore, they respond eagerly to the type of command that Western children frequently avoid or resent. By age 5, Yucatec Mayan children spontaneously take responsibility for tasks beyond those assigned.

Information Processing

Return to the model of information processing discussed on page 161 in Chapter 5. Recall that information processing focuses on cognitive operations and mental strategies that children use to transform stimuli flowing into their mental systems. As we have already seen, early childhood is a period of dramatic strides in mental representation. And the various components of *executive function* that enable children to succeed in cognitively challenging situations—including attention, impulse control, coordinating information in memory, and planning—show impressive gains (Welsh, Friedman, & Spieker, 2008). Preschoolers also become more aware of their own

mental life and begin to acquire academically relevant knowledge important for school success.

Attention

As parents and teachers know, preschoolers—compared with school-age children—spend shorter times involved in tasks and are easily distracted. But recall from Chapter 5 that sustained attention improves in toddlerhood, a trend that continues during early childhood.

Inhibition. A major reason is a steady gain in children's ability to inhibit impulses and keep their mind on a competing goal. Consider a task in which the child must tap once when the adult

FIGURE 7.8 Gains between ages 3 and 7 in performance on tasks requiring children to inhibit an impulse and focus on a competing goal. In the tapping task, children had to tap once when the adult tapped twice and tap twice when the adult tapped once. In the day–night task, children had to say “night” to a picture of the sun and “day” to a picture of the moon with stars. (From A. Diamond, 2004, “Normal Development of Prefrontal Cortex from Birth to Young Adulthood: Cognitive Functions, Anatomy, and Biochemistry,” as appeared in D. T. Stuss & R. T. Knight, [Eds.], *Principles of Frontal Lobe Function*, New York: Oxford University Press, p. 474. Reprinted by permission of Adele Diamond.)

taps twice and tap twice when the adult taps once or must say “night” to a picture of the sun and “day” to a picture of the moon with stars. As Figure 7.8 shows, 3- and 4-year-olds make many errors. But by age 6 to 7, children find such tasks easy (Johnson, Im-Bolter, & Pascual-Leone, 2003; Kirkham, Cruess, & Diamond, 2003). They can resist the “pull” of their attention toward a dominant stimulus—a skill that, as early as age 3 to 5, predicts social maturity as well as reading and math achievement from kindergarten through high school (Blair & Razza, 2007; Duncan et al., 2007; Rhoades, Greenberg, & Domitrovich, 2009).

Gains in inhibition are linked to development of the cerebral cortex, especially the prefrontal cortex (see page 217). But relevant experiences are also crucial. In *Tools of the Mind*—a preschool curriculum inspired by Vygotsky’s theory—scaffolding of attention skills is woven into virtually all classroom activities. For example, teachers provide external aids to support attention (a child might hold a drawing of an ear as a reminder to listen during story time); lead games requiring frequent inhibition and memory for instructions; and encourage make-believe play, which helps children follow rules and use thought to guide behavior (Bodrova & Leong, 2007). When preschoolers from low-income families were randomly assigned to either *Tools of the Mind* or comparison classrooms, *Tools* children performed substantially better on end-of-year tasks assessing inhibition and other attentional capacities (Diamond et al., 2007).

Planning. By the end of early childhood, children become better at *planning*—thinking out a sequence of acts ahead of time and allocating attention accordingly to reach a goal. As long as tasks are not too complex, 5-year-olds can generate and follow a plan, such as deciding in which of two locations to store

a camera so an agemate, who wants to take a photo of a kangaroo, can retrieve the camera before arriving at the kangaroo’s cage (McColgan & McCormack, 2008). Although younger children have trouble reasoning about a sequence of future events they have never before experienced, 4-year-olds can reason effectively about a short sequence of past events. For example, on a path with several landmarks they just traveled, they can identify the likely location of lost object (Friedman & Scholnick, 1997; Kaller et al., 2008).

Children learn much from cultural tools that support planning—directions for playing games, patterns for construction, recipes for cooking—especially when they collaborate with more expert planners. When 4- to 7-year-olds were observed jointly constructing a toy with their mothers, the mothers provided basic information about the usefulness of plans and how to implement specific steps: “Do you want to look at the picture and see what goes where? What piece do you need first?” After working with their mothers, younger children more often referred to the plan when building on their own (Gauvain, 2004; Gauvain, de la Ossa, & Hurtado-Ortiz, 2001). When parents encourage planning in everyday activities, from loading the dishwasher to packing for a vacation, they help children plan more effectively.

Memory

Unlike infants and toddlers, preschoolers have the language skills to describe what they remember, and they can follow directions on memory tasks. As a result, memory becomes easier to study in early childhood.

Recognition and Recall. TAKE A MOMENT... Show a young child a set of 10 pictures or toys. Then mix them up with some unfamiliar items, and ask the child to point to the ones in the original set. You will find that preschoolers’ *recognition* memory—ability to tell whether a stimulus is the same as or similar to one they have seen before—is remarkably good. In fact, 4- and 5-year-olds perform nearly perfectly.

Now keep the items out of view, and ask the child to name the ones she saw. This more challenging task requires *recall*—that the child generate a mental image of an absent stimulus. Young children’s recall is much poorer than their recognition. At age 2, they can recall no more than one or two of the items, at age 4 only about three or four (Perlmutter, 1984).

Improvement in recall in early childhood is strongly associated with language development, which greatly enhances long-lasting representations of past experiences (Melby-Lervag & Hulme, 2010; Ornstein, Haden, & Elishberger, 2006). But even preschoolers with good language skills recall poorly because they are not skilled at using **memory strategies**—deliberate mental activities that improve our chances of remembering. Preschoolers do not yet *rehearse*, or repeat items over and over to remember. Nor do they *organize*, grouping together items that are alike (all the animals together, all the vehicles together) so they can easily retrieve them by thinking of their similar characteristics—even when they are trained to do so (Gathercole, Adams, & Hitch, 1994).

Why do young children seldom use memory strategies? One reason is that strategies tax their limited working memories (see page 161 in Chapter 5). Preschoolers have difficulty holding on to pieces of information and applying a strategy at the same time.

Memory for Everyday Experiences. Think about the difference between your recall of listlike information and your memory for everyday experiences—what researchers call **episodic memory**. In remembering lists, you recall isolated bits, reproducing them exactly as you originally learned them. In remembering everyday experiences, you recall complex, meaningful information. Between 3 and 6 years, children improve sharply in memory for relations among stimuli—for example, in a set of photos, remembering not only the animals they saw but their contexts, such as a bear emerging from a tunnel or a zebra tied to a tree (Lloyd, Doydum, & Newcombe, 2009). The capacity to bind together stimuli supports an increasingly rich episodic memory in early childhood.

Memory for Familiar Events. Like adults, preschoolers remember familiar, repeated events—what you do when you go to preschool or have dinner—in terms of **scripts**, general descriptions of what occurs and when it occurs in a particular situation. Young children’s scripts begin as a structure of main acts. For example, when asked to tell what happens at a restaurant, a 3-year-old might say, “You go in, get the food, eat, and then pay.” Although first scripts contain only a few acts, they are almost always recalled in correct sequence (Bauer, 2002, 2006). With age, scripts become more elaborate, as in this 5-year-old’s account of going to a restaurant: “You go in. You can sit in a booth or at a table. Then you tell the waitress what you want. You eat. If you want dessert, you can have some. Then you pay and go home” (Hudson, Fivush, & Kuebli, 1992).

Scripts help children (and adults) organize and interpret everyday experiences. Once formed, they can be used to predict what will happen in the future. Children rely on scripts in make-believe play and when listening to and telling stories. Scripts also support children’s earliest efforts at planning as they represent sequences of actions that lead to desired goals (Hudson & Mayhew, 2009).

Memory for One-Time Events. In Chapter 5, we considered a second type of everyday memory—*autobiographical memory*, or representations of personally meaningful, one-time events. As preschoolers’ cognitive and conversational skills improve, their descriptions of special events become better organized in time, more detailed, and related to the larger context of their lives (Fivush, 2001).

Adults use two styles to elicit children’s autobiographical narratives. In the *elaborative style*, they follow the child’s lead, ask varied questions, add information to the child’s statements, and volunteer their own recollections and evaluations of events. For example, after a trip to the zoo, the parent might say, “What was the first thing we did? Why weren’t the parrots in their cages? I thought the lion was scary. What did you think?” In contrast, adults who use the *repetitive style* provide little information and

As this toddler talks with his mother about past experiences, she responds in an elaborative style, asking varied questions and contributing her own recollections. Through such conversations, she enriches his autobiographical memory.

keep repeating the same questions regardless of the child’s interest: “Do you remember the zoo? What did we do at the zoo?” Preschoolers who experience the elaborative style recall more information about past events, and they also produce more organized and detailed personal stories when followed up one to two years later (Cleveland & Reese, 2005; Farrant & Reese, 2000).

As children talk with adults about the past, they not only improve their autobiographical memory but also create a shared history that strengthens close relationships and self-understanding. Parents and preschoolers with secure attachment bonds engage in more elaborate reminiscing (Bost et al., 2006; Fivush & Reese, 2002). And 5- and 6-year-olds of elaborative-style parents describe themselves in clearer, more consistent ways (Bird & Reese, 2006).

Girls produce more organized and detailed narratives than boys. Compared with Asian children, Western children produce narratives with more talk about their own thoughts, emotions, and preferences. These differences fit with variations in parent-child conversations. Parents reminisce in greater detail and talk more about the emotional significance of events with daughters (Fivush, 2009). And collectivist cultural valuing of interdependence leads many Asian parents to discourage children from talking about themselves. Chinese parents, for example, engage in less detailed and evaluative past-event dialogues with their preschoolers (Fivush & Wang, 2005; Wang, 2006a).

Consistent with these early experiences, women report an earlier age of first memory and more vivid early memories than men. And Western children and adults’ autobiographical memories include earlier, more detailed events that focus more on their own roles than do the memories of Asians, who tend to highlight the roles of others (Wang, 2006b, 2008).

The Young Child’s Theory of Mind

As representation of the world, memory, and problem solving improve, children start to reflect on their own thought processes. They begin to construct a *theory of mind*, or coherent set of

ideas about mental activities. This understanding is also called **metacognition**, or “thinking about thought” (the prefix *meta-* means “beyond” or “higher”). As adults, we have a complex appreciation of our inner mental worlds, which we use to interpret our own and others’ behavior and to improve our performance on various tasks. How early are children aware of their mental lives, and how complete and accurate is their knowledge?

Awareness of Mental Life. At the end of the first year, babies view people as intentional beings who can share and influence one another’s mental states, a milestone that opens the door to new forms of communication—joint attention, social referencing, preverbal gestures, and spoken language. These early milestones serve as the foundation for later mental understandings. In longitudinal research, 10-month-olds’ ability to discern others’ intentions predicted theory-of-mind competence at age 4 (Wellman et al., 2008). As they approach age 2, children display a clearer grasp of others’ emotions and desires, evident in their realization that people often differ from one another and from themselves in likes, dislikes, wants, needs, and wishes (“Mommy like broccoli. Daddy like carrots. I no like carrots.”).

As 2-year-olds’ vocabularies expand, their first verbs include such words as *want*, *think*, *remember*, and *pretend* (Wellman, 2002). By age 3, children realize that thinking takes place inside their heads and that a person can think about something without seeing, touching, or talking about it (Flavell, Green, & Flavell, 1995). But 2- to 3-year-olds’ verbal responses indicate that they think that people always behave in ways consistent with their *desires* and do not understand that less obvious, more interpretive mental states, such as *beliefs*, also affect behavior.

Between ages 3 and 4, children increasingly refer to their own and others’ thoughts and beliefs (Wellman, 2011). And from age 4 on, they say that both *beliefs* and *desires* determine behavior. Dramatic evidence for this advance comes from games that test whether preschoolers realize that *false beliefs*—ones that do not represent reality accurately—can guide people’s actions.

TAKE A MOMENT... For example, show a child two small closed boxes—a familiar Band-Aid box and a plain, unmarked box (see Figure 7.9). Then say, “Pick the box you think has the Band-Aids in it.” Children usually pick the marked container. Next, open the boxes and show the child that, contrary to her own belief, the marked one is empty and the unmarked one contains the Band-Aids. Finally, introduce the child to a hand puppet and explain, “Here’s Pam. She has a cut, see? Where do you think she’ll look for Band-Aids? Why would she look in there? Before you looked inside, did you think that the plain box contained Band-Aids? Why?” (Bartsch & Wellman, 1995). Only a handful of 3-year-olds can explain Pam’s—and their own—false beliefs, but many 4-year-olds can.

Nevertheless, growing evidence indicates that toddlers may have an *implicit* grasp of false belief—revealed by their nonverbal behaviors. For example, most 18-month-olds—after witnessing an object moved from one box to another while an adult was not looking—helped the adult, when he tried to open the original box, locate the object in the new box (Buttelmann,

FIGURE 7.9 Example of a false-belief task. (a) An adult shows a child the contents of a Band-Aid box and of an unmarked box. The Band-Aids are in the unmarked container. (b) The adult introduces the child to a hand puppet named Pam and asks the child to predict where Pam would look for the Band-Aids and to explain Pam’s behavior. The task reveals whether children understand that without having seen that the Band-Aids are in the unmarked container, Pam will hold a false belief.

Carpenter, & Tomasello, 2009). And 15- to 18-month-olds’ looking behaviors—in violation-of-expectation studies and in investigations of their anticipatory glances toward the location they expect an adult to reach for an object—yield similar findings (Baillargeon, Scott, & He, 2010; Senju et al., 2011).

Performance on these implicit false-belief tasks predicts later *explicit* understanding, evident in the verbal explanations of older preschoolers (San Juan & Astington, 2012; Thoermer et al., 2012). Still, investigators disagree sharply on the depth of toddlers’ insights. Some argue that they have fully formed representations, others that their awareness is limited.

Among children of diverse cultural and SES backgrounds, explicit false-belief understanding strengthens after age 3½, becoming more secure between ages 4 and 6 (Amsterlaw & Wellman, 2006; Callaghan et al., 2005; Flynn, 2006). During that time, it becomes a powerful tool for understanding oneself and others and a good predictor of social skills (Harwood & Farrar, 2006; Hughes, Ensor, & Marks, 2010). It is also associated with early reading ability, probably because it helps children comprehend story narratives (Astington & Pelletier, 2005).

Factors Contributing to Preschoolers’ Theory of Mind. How do children develop a theory of mind at such a young age? Language, executive function, make-believe play, and social experiences all contribute.

Many studies indicate that language ability strongly predicts preschoolers’ false-belief understanding (Milligan, Astington, & Dack, 2007). Children who spontaneously use, or who are trained to use, mental-state words in conversation are especially likely to pass false-belief tasks (Hale & Tager-Flusberg, 2003; San Juan & Astington, 2012). Among the Quechua people of the Peruvian highlands, whose language lacks mental-state terms, children have difficulty with false-belief tasks for years after children in industrialized nations have mastered them (Vinden, 1996). In contrast, Chinese languages have verb markers that can label the word *believe* as decidedly false. When adults use those

markers in false-belief tasks, Chinese preschoolers perform better (Tardif, Wellman, & Cheung, 2004).

Several aspects of preschoolers' executive function—the ability to inhibit inappropriate responses, to reason about events inconsistent with immediate reality (for example, how to have avoided walking indoors with muddy shoes), and to plan—predict mastery of false belief (Drayton et al., 2011; Hughes & Ensor, 2007; Müller et al., 2012). Gains in inhibition are strongly related to mastery of false belief, perhaps because false-belief tasks require suppression of an irrelevant response—the tendency to assume that others share their own knowledge and beliefs (Birch & Bloom, 2003; Carlson, Moses, & Claxton, 2004).

Social experience also promotes understanding of the mind. In longitudinal research, mothers of securely attached babies were more likely to comment appropriately on their infants' mental states: “Do you *remember* Grandma?” “You really *like* that swing!” These mothers continued to describe their children, when they reached preschool age, in terms of mental characteristics: “She’s got a mind of her own!” This maternal “mind-mindedness” was positively associated with later performance on false-belief and other theory-of-mind tasks (Meins et al., 1998, 2003; Ruffman et al., 2006). Secure attachment is also related to more elaborative parent–child narratives, including discussions of mental states—conversations that expose preschoolers to concepts and language that help them think about their own and others' mental lives (Ontai & Thompson, 2008; Taumoepeau & Ruffman, 2006).

Also, preschoolers with siblings who are children (but not infants)—especially older siblings or two or more siblings—tend to be more aware of false belief because they are exposed to more family talk about others' perspectives (Jenkins et al., 2003; McAlister & Peterson, 2006, 2007). Similarly, preschool friends who often engage in mental-state talk—as children do during make-believe play—are ahead in false-belief understanding (de Rosnay & Hughes, 2006). Style of adult–child interaction contributes, too. Discourse involving well-connected exchanges in which each speaker's remark is related to the other's previous remark predicts preschoolers' theory-of-mind progress (Ontai & Thompson, 2010). In line with Vygotsky's theory, these exchanges offer children extra opportunities to talk about inner states, receive feedback, and become increasingly aware of their own and others' mental activities.

Core knowledge theorists (see Chapter 5, page 159) believe that to profit from the social experiences just described, children must be biologically prepared to develop a theory of mind. They claim that children with *autism*, for whom mastery of false belief is either greatly delayed or absent, are deficient in the brain mechanism that enables humans to detect mental states. See the Biology and Environment box on the following page to find out more about the biological basis of reasoning about the mind.

Limitations of Preschoolers' Understanding of Mental Life. Though surprisingly advanced, preschoolers' awareness of mental activities is far from complete. For example, 3- and 4-year-olds are unaware that people continue to think

while they wait, look at pictures, listen to stories, or read books—when there are no obvious cues that they are thinking (Flavell, Green, & Flavell, 1993, 1995, 2000). And children younger than age 5 pay little attention to the *process* of thinking. When asked about subtle distinctions between mental states, such as *know* and *forget*, they express confusion (Lyon & Flavell, 1994). And they believe that all events must be directly observed to be known. They do not understand that *mental inferences* can be a source of knowledge (Miller, Hardin, & Montgomery, 2003).

These findings suggest that preschoolers view the mind as a passive container of information. As they move into middle childhood, they will increasingly see it as an active, constructive agent—a change we will consider further in Chapter 9.

Early Childhood Literacy

One week, Leslie's students created a make-believe grocery store. They brought empty food boxes from home, placed them on shelves in the classroom, labeled items with prices, and made paper money for use at the cash register. A sign at the entrance announced the daily specials: “APLS BNS 5¢” (“apples bananas 5¢”).

As such play reveals, preschoolers understand a great deal about written language long before they learn to read or write in conventional ways. This is not surprising: Children in industrialized nations live in a world filled with written symbols. Each day, they observe and participate in activities involving storybooks, calendars, lists, and signs. Children's active efforts to construct literacy knowledge through informal experiences are called **emergent literacy**.

Young preschoolers search for units of written language as they “read” memorized versions of stories and recognize familiar signs, such as “PIZZA.” But they do not yet understand the symbolic function of the elements of print (Bialystok & Martin, 2003). Many preschoolers think that a single letter stands for a whole word or that each letter in a person's signature represents

Preschoolers acquire literacy knowledge informally through participating in everyday activities involving written symbols. Here a young chef “jots down” a phone order for a take-out meal.

Biology and Environment

“Mindblindness” and Autism

Michael stood at the water table in Leslie’s classroom, repeatedly filling a plastic cup and dumping out its contents—dip—splash, dip—splash—until Leslie came over and redirected his actions. Without looking at Leslie’s face, Michael moved to a new repetitive pursuit: pouring water from one cup into another and back again. As other children entered the play space and conversed, Michael hardly noticed.

Michael has *autism* (a term that means “absorbed in the self”), the most severe behavior disorder of childhood. Like other children with autism, by age 3 he displayed deficits in three core areas of functioning. First, he had only limited ability to engage in nonverbal behaviors required for successful social interaction, such as eye gaze, facial expressions, gestures, imitation, and give-and-take. Second, his language was delayed and stereotyped. He used words to echo what others said and to get things he wanted, not to exchange ideas. Third, he engaged in much less make-believe play than other children (Frith, 2003; Walenski, Tager-Flusberg, & Ullman, 2006). And Michael showed another typical feature of autism: His interests were narrow and overly intense. For example, one day he sat for more than an hour spinning a toy Ferris wheel.

Researchers agree that autism stems from abnormal brain functioning, usually due to genetic or prenatal environmental causes. Beginning in the first year, children with the disorder have larger-than-average brains, perhaps due to massive overgrowth of synapses and lack of synaptic pruning, which accompanies normal development of cognitive, language, and communication skills (Courchesne, Carper, & Akshoomoff, 2003).

Furthermore, the amygdala, devoted to emotion processing (see page 192 in Chapter 6), grows especially large in childhood, followed by a greater than average reduction in size in adolescence and adulthood. This deviant growth pattern is believed to contribute to the deficits in emotional responsiveness and social interaction involved in the disorder

(Schumann et al., 2009; Schumann & Amaral, 2010). fMRI studies reveal that autism is also associated with reduced activity in areas of the cerebral cortex involved in processing emotional and social responsiveness and with weaker connections between the amygdala and the temporal lobes (important for processing facial expressions) (Monk et al., 2010; Théoret et al., 2005).

Mounting evidence reveals that children with autism have a deficient theory of mind. Long after they reach the intellectual level of an average 4-year-old, they have great difficulty with false belief. Most find it hard to attribute mental states to themselves or others (Steele, Joseph, & Tager-Flusberg, 2003). They rarely use mental-state words, such as *believe*, *think*, *know*, *feel*, and *pretend*.

As early as the second year, children with autism show deficits in capacities believed to contribute to an understanding of mental life. Compared with other children, they have difficulty distinguishing facial expressions and less often establish joint attention, engage in social referencing, or imitate an adult’s novel behaviors (Chawarska & Shic, 2009; Mundy & Stella, 2000; Vivanti et al., 2008). Furthermore, they are relatively insensitive to eye gaze as a cue to what a speaker is talking about. Instead, they often assume that another person’s language refers to what they themselves are looking at—a possible reason for their frequent nonsensical expressions (Baron-Cohen, Baldwin, & Crowson, 1997).

Do these findings indicate that autism is due to impairment in an innate, core brain function, which leaves the child “mindblind” and therefore unable to engage in human sociability? Some researchers think so (Baron-Cohen & Belmonte, 2005; Scholl & Leslie, 2000). But others point out that individuals with mental retardation but not autism also do poorly on tasks assessing mental understanding (Yirmiya et al., 1998). This suggests that some kind of general intellectual impairment may be involved.

© BOB DAEMMIRICH/PHOTODISC

This child, who has autism, is barely aware of his teacher and classmates. His “mindblindness” might be due to a basic deficit in social awareness, a general impairment in executive function, or a deficit in holistic processing.

One conjecture is that children with autism are impaired in executive function. This leaves them deficient in skills involved in flexible, goal-oriented thinking, including shifting attention to relevant aspects of a situation, inhibiting irrelevant responses, applying strategies to hold information in working memory, and generating plans (Joseph & Tager-Flusberg, 2004; Robinson et al., 2009).

Another possibility is that children with autism display a peculiar style of information processing, preferring to process the parts of stimuli over patterns and coherent wholes (Happé & Frith, 2006). Deficits in thinking flexibly and in holistic processing of stimuli would each interfere with understanding the social world because social interaction requires quick integration of information from various sources and evaluation of alternative possibilities.

It is not clear which of these hypotheses is correct. Some research suggests that impairments in social awareness, flexible thinking, processing coherent wholes, and verbal ability contribute independently to autism (Morgan, Maybery, & Durkin, 2003; Pellicano et al., 2006). Perhaps several biologically based deficits underlie the tragic social isolation of children like Michael.

a separate name. Children revise these ideas as their cognitive capacities improve, as they encounter writing in many contexts, and as adults help them with written communication. Gradually, they notice more features of written language and depict writing that varies in function, as in the “story” and “grocery list” in Figure 7.10.

Eventually, children figure out that letters are parts of words and are linked to sounds in systematic ways, as seen in the invented spellings typical between ages 5 and 7. At first, children rely on sounds in the names of letters, as in “ADE LAFWTS KRMD NTU A LAVATR” (“eighty elephants crammed into a[n] elevator”). Soon they grasp sound–letter correspondences and learn that some letters have more than one common sound and that context affects their use (McGee & Richgels, 2012).

Literacy development builds on a broad foundation of spoken language and knowledge about the world (Dickinson, Golinkoff, & Hirsh-Pasek, 2010). Over time, children’s language and literacy progress facilitate each other. **Phonological awareness**—the ability to reflect on and manipulate the sound structure of spoken language, as indicated by sensitivity to changes in sounds within words, to rhyming, and to incorrect pronunciation—is a strong predictor of emergent literacy knowledge (Paris & Paris, 2006). When combined with sound–letter knowledge, it enables children to isolate speech segments and link them with their written symbols. Vocabulary and grammatical skills are also influential.

The more informal literacy-related experiences young children have, the better their language and emergent literacy development and their later reading skills (Dickinson & McCabe, 2001; Speece et al., 2004). Pointing out letter–sound correspondences and playing language–sound games enhance children’s awareness of the sound structure of language and how it is represented in print (Ehri & Roberts, 2006). *Interactive reading*, in which adults discuss storybook content with preschoolers, promotes many aspects of language and literacy development. And

FIGURE 7.10 A story (a) and a grocery list (b) written by a 4-year-old child. This child’s writing has many features of real print. It also reveals an awareness of different kinds of written expression. (From McGee, Lea M.; Richgels, Donald J., *Literacy’s Beginnings: Supporting Young Readers and Writers*, 4th Ed., © 2004, p. 76. Reprinted and electronically reproduced by permission of Pearson Education, Inc. Upper Saddle River, New Jersey.)

FIGURE 7.11 Some kindergarten reading readiness skills by family income. The gap in emergent literacy development between entering-kindergarten students from low-income and middle-income families is large. (Adapted from Lee & Burkam, 2002.)

adult-supported writing activities that focus on narrative, such as preparing a letter or a story, also have wide-ranging benefits. Each of these literacy experiences is linked to improved reading achievement in middle childhood (Hood, Conlon, & Andrews, 2008; Senechal & LeFevre, 2002; Storch & Whitehurst, 2001).

Compared to their economically advantaged agemates, preschoolers from low-income families have far fewer home and preschool language and literacy learning opportunities—a gap that translates into large differences in skills vital for reading readiness at kindergarten entry (see Figure 7.11) and into widening disparities in reading achievement during the school years (Hoff, 2013; Turnbull et al., 2009). When teachers of low-income preschoolers were given a tuition-free college course on effective early childhood literacy instruction, they readily offered many more literacy activities in their classrooms (Dickinson & Sprague, 2001). And providing parents with children’s books, along with guidance in how to stimulate literacy learning in preschoolers, greatly enhances literacy activities in the home (High et al., 2000; Huebner & Payne, 2010).

Early Childhood Mathematical Reasoning

Mathematical reasoning, like literacy, builds on informally acquired knowledge. Between 14 and 16 months, toddlers display a beginning grasp of **ordinality**, or order relationships between quantities—for example, that 3 is more than 2, and 2 is more than 1. And 2-year-olds often indicate without counting that a set of items has “lots,” “many,” or “little” in relation to others (Ginsburg, Lee, & Boyd, 2008). By the time children turn 3, most can count rows of about five objects, although they do not yet know exactly what the words mean. For example, when asked for *one*, they give one item, but when asked for *two*, *three*, *four*, or *five*, they usually give a larger, but incorrect, amount. Nevertheless, 2½- to 3½-year-olds understand that a number

word refers to a unique quantity—that when a number label changes (for example, from *five* to *six*), the number of items should also change (Sarnecka & Gelman, 2004).

By age 3½ to 4, most children have mastered the meaning of numbers up to 10, count correctly, and grasp the vital principle of **cardinality**—that the last number in a counting sequence indicates the quantity of items in a set (Geary, 2006a). Mastery of cardinality increases the efficiency of children’s counting.

Around age 4, children use counting to solve arithmetic problems. At first, their strategies are tied to the order of numbers as presented; to add $2 + 4$, they count on from 2 (Bryant & Nunes, 2002). But soon they experiment with other strategies and eventually arrive at the most efficient, accurate approach—in this example, beginning with the higher digit. Around this time, children realize that subtraction cancels out addition. Knowing, for example, that $4 + 3 = 7$, they can infer without counting that $7 - 3 = 4$ (Rasmussen, Ho, & Bisanz, 2003). Grasping basic arithmetic rules facilitates rapid computation, and with enough practice, children recall answers automatically.

When adults provide many occasions for counting, comparing quantities, and talking about number concepts, children acquire these understandings sooner (Ginsburg, Lee, & Boyd, 2008). Math proficiency at kindergarten entry predicts math achievement years later, in elementary and secondary school (Duncan et al., 2007; Romano et al., 2010).

As with emergent literacy, children from low-SES families begin kindergarten with considerably less math knowledge than their economically advantaged agemates—a gap due to differences in environmental supports. In an early childhood math curriculum called *Building Blocks*, materials that promote math concepts and skills enable teachers to weave math into many preschool daily activities, from building blocks to art and stories (Clements & Sarama, 2008). Compared with agemates randomly assigned to other preschool programs, low-SES preschoolers experiencing *Building Blocks* showed substantially greater year-end gains in math concepts and skills, including counting, sequencing, and arithmetic computation.

This board game helps preschoolers acquire basic math knowledge by affording many opportunities to count, compare quantities, and talk about number concepts.

ASK YOURSELF

REVIEW Describe a typical 4-year-old’s understanding of mental activities, noting both strengths and limitations.

CONNECT Cite evidence on the development of preschoolers’ memory, theory of mind, and literacy and mathematical understanding that is consistent with Vygotsky’s sociocultural theory.

APPLY Lena wonders why her son’s preschool teacher provides extensive playtime in learning centers instead of formal lessons in literacy and math skills. Explain to Lena why adult-supported play is the best way for preschoolers to develop academically.

REFLECT Describe informal experiences important for literacy and math development that you experienced while growing up. How do you think those experiences contributed to your academic progress in school?

Individual Differences in Mental Development

Five-year-old Hal sat in a testing room while Sarah gave him an intelligence test. Some of Sarah’s questions were *verbal*. For example, she showed him a picture of a shovel and said, “Tell me what this is”—an item measuring vocabulary. She tested his memory by asking him to repeat sentences and lists of numbers back to her. To assess Hal’s spatial reasoning, Sarah used *nonverbal* tasks: Hal copied designs with special blocks, figured out the pattern in a series of shapes, and indicated what a piece of paper folded and cut would look like when unfolded (Roid, 2003; Wechsler, 2002).

Sarah knew that Hal came from an economically disadvantaged family. When low-SES and certain ethnic minority preschoolers are bombarded with questions by an unfamiliar adult, they sometimes react with anxiety. Also, such children may not define the testing situation in achievement terms but, instead, may settle for lower performance than their abilities allow. Sarah spent time playing with Hal before she began testing and encouraged him while testing was in progress. Under these conditions, low-SES preschoolers improve in performance (Bracken, 2000).

The questions Sarah asked Hal tap knowledge and skills that not all children have equal opportunity to learn. In Chapter 9, we will take up the hotly debated issue of *cultural bias* in mental testing. For now, keep in mind that intelligence tests do not sample all human abilities, and performance is affected by cultural and situational factors (Sternberg, 2005). Nevertheless, test scores remain important: By age 6 to 7, they are good predictors of later IQ and academic achievement, which are related to vocational success in industrialized societies. Let’s see how the environments in which preschoolers spend their days—home, preschool, and child care—affect mental test performance.

Applying What We Know

Features of a High-Quality Home Life for Preschoolers: The HOME Early Childhood Subscales

Subscale	Sample Item
Cognitive stimulation through toys, games, and reading material	Home includes toys that teach colors, sizes, and shapes.
Language stimulation	Parent converses with child at least twice during observer's visit.
Organization of the physical environment	All visible rooms are reasonably clean and minimally cluttered.
Emotional support: parental pride, affection, and warmth	Parent spontaneously praises child's qualities or behavior twice during observer's visit. Parent caresses, kisses, or hugs child at least once during observer's visit.
Stimulation of academic behavior	Child is encouraged to learn colors.
Parental modeling and encouragement of social maturity	Parent introduces interviewer to child.
Opportunities for variety in daily stimulation	Family member takes child on one outing (picnic, shopping) at least every other week.
Avoidance of physical punishment	Parent neither slaps nor spansks child during observer's visit.

Sources: Bradley, 1994; Bradley et al., 2001.

Home Environment and Mental Development

A special version of the *Home Observation for Measurement of the Environment (HOME)*, covered in Chapter 5, assesses aspects of 3- to 6-year-olds' home lives that support mental development (see Applying What We Know above). Preschoolers who develop well intellectually have homes rich in educational toys and books. Their parents are warm and affectionate, stimulate language and academic knowledge, and arrange interesting outings. They also make reasonable demands for socially mature behavior—for example, that the child perform simple chores and behave courteously toward others. And these parents resolve conflicts with reason instead of physical force and punishment (Bradley & Caldwell, 1982; Espy, Molfese, & DiLalla, 2001; Roberts, Burchinal, & Durham, 1999).

As we saw in Chapter 2, these characteristics are less often seen in low-SES families. When parents manage, despite low education and income, to obtain high HOME scores, their preschoolers do substantially better on tests of intelligence and measures of language and emergent literacy skills (Berger, Paxson, & Waldfogel, 2009; Foster et al., 2005; Mistry et al., 2008). And in a study of low-SES African-American 3- and 4-year-olds, HOME cognitive stimulation and emotional support subscales predicted reading achievement four years later (Zaslow et al., 2006). These findings highlight the vital role of home environmental quality in children's mental development.

Preschool, Kindergarten, and Child Care

Children between ages 2 and 6 spend even more time away from their homes and parents than infants and toddlers do. Largely

because of the rise in maternal employment, over the past several decades the number of young children enrolled in preschool or child care has steadily increased to more than 60 percent in the United States (U.S. Census Bureau, 2012b).

A *preschool* is a program with planned educational experiences aimed at enhancing the development of 2- to 5-year-olds. In contrast, *child care* refers to a variety of arrangements for supervising children. With age, children tend to shift from home-based to center-based programs. Many children, however, experience several types of arrangements at once (Federal Interagency Forum on Child and Family Statistics, 2011).

The line between preschool and child care is fuzzy. In response to the needs of employed parents, many U.S. preschools, as well as most public school kindergartens, have increased their hours from half to full days (U.S. Department of Education, 2012b). At the same time, good child care should provide the same high-quality educational experiences that an effective preschool does.

Types of Preschool and Kindergarten. Preschool and kindergarten programs range along a continuum from child-centered to teacher-directed. In **child-centered programs**, teachers provide a variety of activities from which children select, and much learning takes place through play. In contrast, in **academic programs**, teachers structure children's learning, teaching letters, numbers, colors, shapes, and other academic skills through formal lessons, often using repetition and drill.

Despite evidence that formal academic training in early childhood undermines motivation and emotional well-being, preschool and kindergarten teachers have felt increased pressure to take this approach. Young children who spend much time passively sitting and completing worksheets display more stress behaviors (such as wiggling and rocking), have less confidence

in their abilities, prefer less challenging tasks, and are less advanced in motor, academic, language, and social skills at the end of the school year (Marcon, 1999a; Stipek et al., 1995). Follow-ups reveal lasting effects through elementary school in poorer study habits and achievement (Burts et al., 1992; Hart et al., 1998, 2003). These outcomes are strongest for low-SES children.

A special type of child-centered approach is *Montessori education*, devised a century ago by Italian physician Maria Montessori, who originally applied her method to poverty-stricken children. Features of Montessori schooling include materials specially designed to promote exploration and discovery, child-chosen activities, and equal emphasis on academic and social development (Lillard, 2007). In an evaluation of public preschools serving mostly urban minority children in Milwaukee, researchers compared students randomly assigned to either Montessori or other classrooms (Lillard & Else-Quest, 2006). Five-year-olds who had completed two years of Montessori education outperformed controls in literacy and math skills, false-belief understanding, concern with fairness in solving conflicts with peers, and cooperative play with classmates.

Early Intervention for At-Risk Preschoolers. In the 1960s, as part of the “War on Poverty” in the United States, many intervention programs for economically disadvantaged preschoolers were initiated in an effort to address learning problems before formal schooling begins. The most extensive of these federal programs, **Project Head Start**, began in 1965. A typical Head Start center provides children with a year or two of preschool, along with nutritional and health services. Parent involvement is central to the Head Start philosophy. Parents serve on policy councils, contribute to program planning, work directly with children in classrooms, attend special programs on parenting and child development, and receive services directed at their own emotional, social, and vocational needs. Currently, Head Start serves about 904,000 children and their families across the nation (Head Start Bureau, 2010).

More than two decades of research have established the long-term benefits of preschool intervention. The most extensive of these studies combined data from seven interventions implemented by universities or research foundations. Results showed that poverty-stricken children who attended programs scored higher in IQ and achievement than controls during the first two to three years of elementary school. After that, differences declined (Lazar & Darlington, 1982). But on real-life measures of school adjustment, children and adolescents who had received intervention remained ahead. They were less likely to be placed in special education or retained in grade, and a greater number graduated from high school.

A separate report on one program—the High/Scope Perry Preschool Project—revealed benefits lasting well into adulthood. Two years’ exposure to cognitively enriching preschool was associated with increased employment and reduced pregnancy and delinquency rates in adolescence. At age 27, those who had attended preschool were more likely than no-preschool controls to have graduated from high school and college, have higher earnings, be married, and own their own home—and

Project Head Start provides children from poverty-stricken families with preschool education and nutritional and health services. High-quality early educational intervention has benefits lasting into adulthood.

less likely to have been involved with the criminal justice system (see Figure 7.12). In the most recent follow-up, at age 40, the intervention group sustained its advantage on all measures of life success, including education, income, family life, and law-abiding behavior (Schweinhart, 2010; Schweinhart et al., 2005).

Do effects on school adjustment of these well-designed and well-delivered programs generalize to Head Start and other community-based preschool interventions? Findings are similar, though not as strong. Head Start preschoolers, who are more economically disadvantaged than children in other programs,

FIGURE 7.12 Some outcomes of the High/Scope Perry Preschool Project on follow-up at age 27. Although two years of a cognitively enriching preschool program did not eradicate the effects of growing up in poverty, children who received intervention were advantaged over no-intervention controls on all measures of life success when they reached adulthood. (Adapted from Schweinhart, 2010; Schweinhart et al., 2005.)

have more severe learning and behavior problems. And quality of services often does not equal that of model university-based programs (Barnett, 2011). But interventions of high quality are associated with diverse, long-lasting favorable outcomes, including higher rates of high school graduation and college enrollment and lower rates of adolescent drug use and delinquency (Garces, Thomas, & Currie, 2002; Love et al., 2006; Mashburn, 2008).

A consistent finding is that gains in IQ and achievement test scores from attending Head Start and other interventions quickly dissolve. In the Head Start Impact Study, a nationally representative sample of 5,000 Head Start 3- and 4-year-olds was randomly assigned to one year of Head Start or to a control group that could attend other types of preschool programs (U.S. Department of Health and Human Services, 2010d). By year's end, Head Start 3-year-olds exceeded controls in vocabulary, emergent literacy, and math skills; 4-year-olds in vocabulary, emergent literacy, and color identification. But except for language skills, academic advantages were no longer evident by end of first grade.

What explains these disappointing results? Head Start children typically enter inferior public schools in poverty-stricken neighborhoods, which undermine the benefits of preschool education (Brooks-Gunn, 2003; Ramey, Ramey, & Lanzi, 2006). An exception is the Chicago Child-Parent Centers—a program emphasizing literacy intervention and parent involvement that began at age 3 and continued through third grade—in which gains in academic achievement were still evident in junior high school (Reynolds & Temple, 1998).

Still, the improved school adjustment that results from attending a one- or two-year Head Start program is impressive. Program effects on parents may contribute: The more involved parents are in Head Start, the better their child-rearing practices and the more stimulating their home learning environments—factors positively related to preschoolers' task persistence and year-end academic, language, and social skills (Marcon, 1999b; McLoyd, Aikens, & Burton, 2006; Parker et al., 1999).

Head Start is highly cost-effective when compared with the cost of providing special education, treating criminal behavior, and supporting unemployed adults. Economists estimate a lifetime return to society of \$300,000 to \$500,000 on an investment of about \$17,000 per preschool child—a potential total savings of many billions of dollars if every poverty-stricken preschooler in the United States were enrolled (Heckman et al., 2010). Because of limited funding, however, only 60 percent of poverty-stricken 3- and 4-year-olds attend some type of preschool program, with Head Start serving just half of these children (Magnuson & Shager, 2010).

Child Care. We have seen that high-quality early intervention can enhance the development of economically disadvantaged children. As noted in Chapter 5, however, much U.S. child care lacks quality. Preschoolers exposed to substandard child care, especially for long hours, score lower in cognitive and social skills and higher in behavior problems (Belsky, 2006; Lamb & Ahnert, 2006; NICHD Early Child Care Research Network, 2003b, 2006). Externalizing difficulties are especially likely to

endure through middle childhood and into adolescence after extensive exposure to mediocre care (Belsky et al., 2007b; Vandell et al., 2010).

In contrast, good child care enhances cognitive, language, and social development, especially for low-SES children—effects that persist into elementary school and, for academic achievement, adolescence (Belsky et al., 2007b; Burchinal, Vandergrift, & Pianta, 2010; NICHD Early Child Care Research Network, 2006; Vandell et al., 2010). And in a study that followed very-low-income children over the preschool years, center-based care was more strongly associated with cognitive gains than were other child-care arrangements, probably because centers are more likely to provide a systematic educational program (Loeb et al., 2004).

Applying What We Know on the following page summarizes characteristics of high-quality early childhood programs, based on standards for developmentally appropriate practice devised by the U.S. National Association for the Education of Young Children. These standards offer a set of worthy goals as the United States strives to upgrade child-care and educational services for young children.

Educational Media

Besides home and preschool, young children spend much time in another learning environment: electronic media, including both television and computers. In the industrialized world, nearly all homes have at least one television set, and most have two or more. And more than 90 percent of U.S. children live in homes with one or more computers, 80 percent of which have an Internet connection, usually a high-speed link (Rideout, Foehr, & Roberts, 2010; U.S. Census Bureau, 2012b).

Educational Television. Sammy's favorite TV program, *Sesame Street*, uses lively visual and sound effects to stress basic literacy and number concepts and puppet and human characters to teach general knowledge, emotional and social understanding, and social skills. Today, *Sesame Street* is broadcast in more than 140 countries, making it the most widely viewed children's program in the world (Sesame Workshop, 2009).

Time devoted to watching children's educational programs is associated with gains in early literacy and math skills and academic progress in elementary school (Ennemoser & Schneider, 2007; Linebarger et al., 2004; Wright et al., 2001). Consistent with these findings, one study reported a link between preschool viewing of *Sesame Street* and other similar educational programs and getting higher grades, reading more books, and placing more value on achievement in high school (Anderson et al., 2001).

Sesame Street has modified its previous rapid-paced format in favor of more leisurely episodes with a clear story line. Children's programs with slow-paced action and easy-to-follow narratives, such as *Arthur & Friends*, *The Magic School Bus*, and *Wishbone*, lead to more elaborate make-believe play in early childhood and to greater recall of program content and gains in vocabulary and reading skills in the early school grades than programs that simply provide information (Linebarger &

Applying What We Know

Signs of Developmentally Appropriate Early Childhood Programs

Program Characteristics	Signs of Quality
Physical setting	Indoor environment is clean, in good repair, and well-ventilated. Classroom space is divided into richly equipped activity areas, including make-believe play, blocks, science, math, games and puzzles, books, art, and music. Fenced outdoor play space is equipped with swings, climbing equipment, tricycles, and sandbox.
Group size	In preschools and child-care centers, group size is no greater than 18 to 20 children with two teachers.
Caregiver–child ratio	In preschools and child-care centers, teacher is responsible for no more than 8 to 10 children. In child-care homes, caregiver is responsible for no more than 6 children.
Daily activities	Children select many of their own activities and learn through experiences relevant to their own lives, mainly in small groups or individually. Teachers facilitate children's involvement, accept individual differences, and adjust expectations to children's developing capacities.
Interactions between adults and children	Teachers move among groups and individuals, asking questions, offering suggestions, and adding more complex ideas. Teachers use positive guidance techniques, such as modeling and encouraging expected behavior and redirecting children to more acceptable activities.
Teacher qualifications	Teachers have college-level specialized preparation in early childhood development, early childhood education, or a related field.
Relationships with parents	Parents are encouraged to observe and participate. Teachers talk frequently with parents about children's behavior and development.
Licensing and accreditation	Child-care setting, whether a center or a home, is licensed by the state. Voluntary accreditation by the National Association for the Education of Young Children (www.naeyc.org/academy) or the National Association for Family Child Care (www.nafcc.org) is evidence of an especially high-quality program.

Source: Copple & Bredekamp, 2009.

Piotrowski, 2010; Singer & Singer, 2005). Narratively structured educational TV eases processing demands, freeing up space in working memory for applying program content to real-life situations.

Despite the spread of computers, television remains the dominant form of youth media. The average U.S. 2- to 6-year-old watches TV programs and videos from 1½ to 2⅓ hours a day. In middle childhood, viewing time increases to an average of 3½ hours a day, before declining slightly in adolescence (Rideout, Foehr, & Roberts, 2010; Rideout & Hamel, 2006).

Low-SES, African-American, and Hispanic children are more frequent viewers, perhaps because few alternative forms of entertainment are available in their neighborhoods or affordable for their parents. Also, parents with limited education are more likely to engage in practices that heighten TV viewing, including leaving the TV on all day and eating family meals in front of it (Rideout, Foehr, & Roberts, 2010). About one-third of U.S. preschoolers and 70 percent of school-age children and adolescents have a TV set in their bedroom; these children spend from 40 to 90 more minutes per day watching than age-mates without one (Rideout & Hamel, 2006).

Does extensive TV viewing take children away from worthwhile activities? Persistent background TV distracts infants and preschoolers from their play, diminishing time spent in focused attention and involvement with a set of toys (Courage & Howe, 2010). The more preschool and school-age children watch

prime-time shows and cartoons, the less time they spend reading and interacting with others and the poorer their academic skills (Ennemoser & Schneider, 2007; Huston et al., 1999; Wright et al., 2001). Whereas educational programs can be beneficial, watching entertainment TV—especially heavy viewing—detracts from children's school success and social experiences.

Learning with Computers. More than one-fourth of 4- to 6-year-olds use a computer regularly, with preschoolers of higher-SES parents having greater computer access (Calvert et al., 2005). And because computers can have rich educational benefits, many early childhood classrooms include computer learning centers. Kindergartners who use computers to draw or write produce more elaborate pictures and text, make fewer writing errors, and edit their work much as older children do. And combining everyday and computer experiences with math manipulatives is especially effective in promoting math concepts and skills (Clements & Sarama, 2003).

Simplified computer languages that children can use to make designs or build structures introduce them to programming skills. As long as adults support children's efforts, computer programming promotes improved problem solving and metacognition because children must plan and reflect on their thinking to get their programs to work. Furthermore, while programming, children are especially likely to help one another and to persist in the face of challenge (Nastasi & Clements, 1994; Resnick & Silverman, 2005).

As with television, children spend much time using computers for entertainment purposes, especially game playing. Both media are rife with gender stereotypes and violence. We will consider their impact on emotional and social development in the next chapter.

Language Development

Language is intimately related to virtually all cognitive changes discussed in this chapter. Between ages 2 and 6, children make momentous advances in language. Their remarkable achievements, as well as their mistakes along the way, reveal their active, rule-oriented approach to language learning.

Vocabulary

At age 2, Sammy had a spoken vocabulary of about 250 words. By age 6 he will have acquired around 10,000 words (Bloom, 1998). To accomplish this feat, Sammy acquired about five new words each day. How do children build their vocabularies so quickly? Research shows that they can connect new words with their underlying concepts after only a brief encounter, a process called **fast-mapping**. Preschoolers can even fast-map two or more new words encountered in the same situation (Wilkinson, Ross, & Diamond, 2003).

Types of Words. Children in many Western and non-Western language communities fast-map labels for objects especially rapidly because these refer to concepts that are easy to perceive. When adults point to, label, and talk about an object, they help the child figure out the word's meaning (Gershoff-Stowe & Hahn, 2007). Soon children add verbs (*go, run, broke*), which require more complex understandings of relationships between objects and actions. Children learning Chinese, Japanese, and Korean—languages in which nouns are often omitted from adult sentences, while verbs are stressed—

acquire verbs more readily than their English-speaking agemates (Kim, McGregor, & Thompson, 2000; Tardif, 2006). Gradually, preschoolers add modifiers (*red, round, sad*). Among those that are related in meaning, first they make general distinctions (*big–small*), then more specific ones (*tall–short, high–low, wide–narrow*) (Stevenson & Pollitt, 1987).

To fill in for words they have not yet learned, children as young as age 3 coin new words using ones they already know—for example, “plant-man,” for a gardener, “crayoner” for a child using crayons. Preschoolers also extend language meanings through metaphor—like the 3-year-old who described a stomachache as a “fire engine in my tummy” (Winner, 1988). Young preschoolers’ metaphors involve concrete sensory comparisons: “Clouds are pillows,” “Leaves are dancers.” Once vocabulary and general knowledge expand, children also appreciate nonsensory comparisons: “Friends are like magnets,” “Time flies by” (Keil, 1986; Özçaliskan, 2005). As a result, young children sometimes communicate in amazingly vivid and memorable ways.

Strategies for Word Learning. Preschoolers figure out the meanings of new words by contrasting them with words they already know. How do they discover which concept each word picks out? One speculation is that early in vocabulary growth, children adopt a *mutual exclusivity bias*—the assumption that words refer to entirely separate (nonoverlapping) categories (Markman, 1992). Consistent with this idea, when 2-year-olds hear the labels for two distinct novel objects (for example, *clip* and *horn*), they assign each word correctly, to the whole object and not just a part of it (Waxman & Senghas, 1992).

Indeed, children’s first several hundred nouns refer mostly to objects well-organized by shape. And learning of nouns based on the perceptual property of shape heightens young children’s attention to the distinctive shapes of other objects (Smith et al., 2002; Yoshida & Smith, 2003). This *shape bias* helps preschoolers master additional names of objects, and vocabulary accelerates.

Once the name of a whole object is familiar, on hearing a new name for the object, 2- and 3-year-olds set aside the mutual exclusivity bias. For example, if the object (bottle) has a distinctively shaped part (spout), children readily apply the new label to it (Hansen & Markman, 2009). Still, mutual exclusivity and object shape cannot account for preschoolers’ remarkably flexible responses when objects have more than one name. Children often call on other components of language in these instances.

According to one proposal, preschoolers figure out many word meanings by observing how words are used in the structure of sentences (Gleitman et al., 2005; Naigles & Swenson, 2007). Consider an adult who says, “This is a *citron* one,” while showing the child a yellow car. Two- and 3-year-olds conclude that a new word used as an adjective for a familiar object (car) refers to a property of that object (Hall & Graham, 1999; Imai & Haryu, 2004). As preschoolers hear the word in various sentence structures (“That lemon is bright *citron*”), they refine its meaning.

Young children also take advantage of rich social information that adults frequently provide, while drawing on their own expanding ability to infer others’ intentions, desires, and perspectives (Akhtar & Tomasello, 2000). In one study, an adult

© ELLEN B. SENISI PHOTOGRAPHY

Young children rely on any useful information available to add to their vocabularies. As he makes a bird feeder, this preschooler attends to a variety of perceptual, social, and linguistic cues to grasp the meanings of unfamiliar words, such as *pine cone*, *spread*, *dip*, *bird seed*, and *munching sparrow*.

performed an action on an object and then used a new label while looking back and forth between the child and the object, as if inviting the child to play. Two-year-olds concluded that the label referred to the action, not the object (Tomasello & Akhtar, 1995). By age 3, children can even use a speaker's recently expressed desire ("I really want to play with the *riff*") to figure out the label belonging to one of two novel objects (Saylor & Troseth, 2006).

Adults also inform children directly about which of two or more words to use—by saying, for example, "You can call it a sea creature, but it's better to say *dolphin*." Preschoolers' vocabularies grow more quickly when they have parents who provide such clarifying information (Callanan & Sabbagh, 2004).

Explaining Vocabulary Development. Children acquire vocabulary so efficiently and accurately that some theorists believe that they are innately biased to induce word meanings using certain principles, such as mutual exclusivity (Lidz, Gleitman, & Gleitman, 2004; Woodward & Markman, 1998). But critics point out that a small set of built-in, fixed principles cannot account for the flexible manner in which children master vocabulary (Deák, 2000). And many word-learning strategies cannot be innate because children acquiring different languages use different approaches to mastering the same meanings.

An alternative view is that vocabulary growth is governed by the same cognitive strategies that children apply to non-linguistic information. According to one account, children draw on a *coalition* of cues—perceptual, social, and linguistic—which shift in importance with age (Golinkoff & Hirsh-Pasek, 2006, 2008). Infants rely solely on perceptual features. Toddlers and young preschoolers, while still sensitive to perceptual features (such as object shape), increasingly attend to social cues—the speaker's direction of gaze, gestures, and expressions of desire and intention (Hollich, Hirsh-Pasek, & Golinkoff, 2000; Pruden et al., 2006). And as language develops further, linguistic cues—

sentence structure and intonation (stress, pitch, and loudness)—play larger roles.

Preschoolers are most successful at figuring out new word meanings when several kinds of information are available (Saylor, Baldwin, & Sabbagh, 2005). Researchers have just begun to study the multiple cues that children use for different kinds of words and how their combined strategies change with development.

Grammar

Between ages 2 and 3, English-speaking children use simple sentences that follow a subject–verb–object word order. Children learning other languages adopt the word orders of the adult speech to which they are exposed.

Basic Rules. Studies of children acquiring diverse languages reveal that their first use of grammatical rules is piecemeal—limited to just a few verbs. As children listen for familiar verbs in adults' speech, they expand their own utterances containing those verbs, relying on adult speech as their model (Gathercole, Sebastián, & Soto, 1999; Lieven, Pine, & Baldwin, 1997). Sammy, for example, added the preposition *with* to the verb *open* ("You open with scissors") but not to the word *hit* ("He hit me stick").

To test preschoolers' ability to generate novel sentences that conform to basic English grammar, researchers had them use a new verb in the subject–verb–object form after hearing it in a different construction, such as passive: "Ernie is getting *gorped* by the dog." The percentage of children who, when asked what the dog was doing, could respond, "He's *gorping* Ernie," rose steadily with age. But not until age 3½ to 4 could the majority of children apply the subject–verb–object structure broadly, to newly acquired verbs (Chan et al., 2010; Tomasello, 2003, 2006).

Once children form three-word sentences, they make small additions and changes to words that enable them to express meanings flexibly and efficiently. For example, they add *-s* for plural (*cats*), use prepositions (*in* and *on*), and form various tenses of the verb *to be* (*is*, *are*, *were*, *has been*, *will*). English-speaking children master these grammatical markers in a regular sequence, starting with those that involve the simplest meanings and structures (Brown, 1973; de Villiers & de Villiers, 1973).

When preschoolers acquire these markers, they sometimes overextend the rules to words that are exceptions—a type of error called **overregularization**. "My toy car *broken*" and "We each have two *foots*" are expressions that appear between ages 2 and 3 (Maratsos, 2000; Marcus, 1995).

Complex Structures. Gradually, preschoolers master more complex grammatical structures, although they do make mistakes. In first creating questions, 2- to 3-year-olds use many formulas: "Where's *X*?" "Can I *X*?" (Dabrowska, 2000; Tomasello, 1992, 2003). Question asking remains variable for the next couple of years. An analysis of one child's questions revealed that he inverted the subject and verb when asking certain questions but not others ("What she will do?" "Why he can go?") The correct expressions were the ones he heard most often in his mother's speech (Rowland & Pine, 2000). And sometimes children produce

errors in subject–verb agreement (“Where does the dogs play?”) and in subject case (“Where can me sit?”) (Rowland, 2007).

Similarly, children have trouble with some passive sentences. When told, “The car was pushed by the truck,” young preschoolers often make a toy car push a truck. By age 5, they understand such expressions, but full mastery of the passive form is not complete until the end of middle childhood (Lempert, 1990; Tomasello, 2006).

Nevertheless, preschoolers’ grasp of grammar is remarkable. By age 4 to 5, they form embedded sentences (“I think *he will come*”), tag questions (“Dad’s going to be home soon, *isn’t he?*”), and indirect objects (“He showed *his friend* the present”). As the preschool years draw to a close, children use most of the grammatical constructions of their language competently (Tager-Flusberg & Zukowski, 2009).

Explaining Grammatical Development. Evidence that grammatical development is an extended process has raised questions about Chomsky’s nativist theory (to review, see page 174 in Chapter 5). Some experts believe that grammar is a product of general cognitive development—children’s tendency to search for consistencies and patterns of all sorts. These *information-processing theorists* believe that children notice which words appear in the same positions in sentences and are similarly combined with other words (Chang, Dell, & Bock, 2006; Tomasello, 2003, 2011). Over time, they group words into grammatical categories and use them appropriately in sentences.

Still other theorists, while also focusing on how children process language, agree with the essence of Chomsky’s theory. One idea proposes that the grammatical categories into which children group word meanings are innate—present at the outset (Pinker, 1999). Critics, however, point out that children’s early word combinations do not show a grasp of grammar. Still another theory holds that children do not start with innate knowledge but, rather, have a *special language-making capacity*—a set of procedures for analyzing the language they hear, which supports the discovery of grammatical regularities (Slobin, 1985, 1997). Controversy persists over whether a universal language-processing device exists or whether children who hear different languages devise unique strategies (Lidz, 2007; Marchman & Thal, 2005).

Conversation

Besides acquiring vocabulary and grammar, children must learn to engage in effective and appropriate communication. This practical, social side of language is called **pragmatics**, and preschoolers make considerable headway in mastering it.

As early as age 2, children are skilled conversationalists. In face-to-face interaction, they take turns and respond appropriately to their partners’ remarks (Pan & Snow, 1999). With age, the number of turns over which children can sustain interaction and their ability to maintain a topic over time increase. By age 4, children adjust their speech to fit the age, sex, and social status of their listeners. For example, in acting out roles with hand puppets, they use more commands when playing socially dominant and male roles (teacher, doctor, father) but speak more politely

and use more indirect requests when playing less dominant and female roles (student, patient, mother) (Anderson, 2000).

Preschoolers’ conversational skills occasionally do break down—for example, when talking on the phone. Here is an excerpt from one 4-year-old’s phone conversation with his grandfather:

Grandfather: How old will you be?

John: Dis many. [*Holding up four fingers.*]

Grandfather: Huh?

John: Dis many. [*Again holding up four fingers.*]
(Warren & Tate, 1992, pp. 259–260)

Young children’s conversations appear less mature in highly demanding situations in which they cannot see their listeners’ reactions or rely on typical conversational aids, such as gestures and objects to talk about. But when asked to tell a listener how to solve a simple puzzle, 3- to 6-year-olds give more specific directions over the phone than in person, indicating that they realize the need for more verbal description on the phone (Cameron & Lee, 1997). Between ages 4 and 8, both conversing and giving directions over the phone improve greatly. Telephone talk provides yet another example of how preschoolers’ competencies depend on the demands of the situation.

Supporting Language Development in Early Childhood

How can adults foster preschoolers’ language development? As in toddlerhood, conversational give-and-take with adults, either at home or in preschool, is consistently related to language progress (Hart & Risley, 1995; NICHD Early Child Care Research Network, 2000b).

Sensitive, caring adults use additional techniques that promote early language skills. When children use words incorrectly or communicate unclearly, they give helpful, explicit feedback, such as, “I can’t tell which ball you want. Do you mean the large red one?” But they do not overcorrect, especially when children make grammatical mistakes. Criticism discourages children from freely using language in ways that lead to new skills.

© WAVE ROYALTY FREE/ALAMY

Responding to his 3-year-old child, this father expands her brief sentences and recasts them into accurate form—techniques that inform children about correct grammar.

Instead, adults often provide indirect feedback about grammar by using two strategies, often in combination: **recasts**—restructuring inaccurate speech into correct form, and **expansions**—elaborating on children’s speech, increasing its complexity (Bohannon & Stanowicz, 1988; Chouinard & Clark, 2003). For example, if a child says, “I gotted new red shoes,” the parent might respond, “Yes, you got a pair of new red shoes.” After such corrective input, 2- to 4-year-olds often shift to correct forms—improvements still evident several months later (Saxton, Bäckley, & Gallaway, 2005). However, the impact of such feedback has been challenged. The techniques are not used in all cultures and, in a few investigations, did not affect children’s grammar (Strapp & Federico, 2000; Valian, 1999). Rather than eliminating errors, perhaps expansions and recasts model grammatical alternatives and encourage children to experiment with them.

LOOK AND LISTEN

In a 30- to 60-minute observation of a 2- to 4-year-old and his or her parent, note grammatical errors the child makes and adult feedback. How often does the parent reformulate child errors or ask clarifying questions? How does the child respond? ●

Do the findings just described remind you once again of Vygotsky’s theory? In language, as in other aspects of intellectual growth, parents and teachers gently prompt children to take the

next step forward. Children strive to master language because they want to connect with other people. Adults, in turn, respond to children’s desire to become competent speakers by listening attentively, elaborating on what children say, modeling correct usage, and stimulating children to talk further. In the next chapter, we will see that this combination of warmth and encouragement of mature behavior is at the heart of early childhood emotional and social development as well.

ASK YOURSELF

REVIEW Provide a list of recommendations for supporting language development in early childhood, noting research that supports each.

CONNECT Explain how children’s strategies for word learning support the interactionist perspective on language development, described on pages 174–175 in Chapter 5.

APPLY Sammy’s mother explained to him that the family would take a vacation in Miami. The next morning, Sammy announced, “I gotted my bags packed. When are we going to Your-ami?” What explains Sammy’s errors?

SUMMARY

PHYSICAL DEVELOPMENT

A Changing Body and Brain (p. 216)

Describe body growth and brain development during early childhood.

- Children grow more slowly in early childhood than they did in the first two years, and they become longer and leaner. New growth centers emerge in the skeleton, and by the end of early childhood, children start to lose their primary teeth.
- Areas of the prefrontal cortex devoted to various aspects of executive function develop rapidly. The left cerebral hemisphere is especially active, supporting preschoolers’ expanding language skills and improved executive function.
- Hand preference, reflecting an individual’s **dominant cerebral hemisphere**, strengthens during early childhood. Research on handedness supports the joint contribution of nature and nurture to brain lateralization.
- In early childhood, fibers linking the **cerebellum** to the cerebral cortex grow and myelinate, enhancing motor coordination and thinking. The **reticular formation**, responsible for alertness and consciousness; the **hippocampus**, which plays a vital role in memory and spatial orientation; and the **corpus callosum**, connecting the two cerebral hemispheres, also develop rapidly.

Influences on Physical Growth and Health (p. 219)

Describe the effects of heredity, nutrition, and infectious disease on physical growth in early childhood.

- Heredity controls production and release of two hormones from the **pituitary gland**: **growth hormone (GH)**, which is necessary for development of almost all body tissues, and **thyroid-stimulating hormone (TSH)**, which affects brain development and body size.
- As growth rate slows, preschoolers’ appetites decline, and many become picky eaters. Repeated, unpressured exposure to new foods promotes healthy, varied eating.
- Dietary deficiencies, especially in protein, vitamins, and minerals, can affect growth and are associated with attention and memory difficulties, academic and behavior problems, and greater susceptibility to infectious diseases. Disease also contributes to malnutrition, especially when intestinal infections cause persistent diarrhea.

GETTY IMAGES/RED CHOPSTICKS

- Immunization rates are lower in the United States than in other industrialized nations because many children lack access to health care. Parental stress and misconceptions about vaccine safety also contribute.

What factors increase the risk of unintentional injuries, and how can childhood injuries be prevented?

- Unintentional injuries are the leading cause of childhood mortality in industrialized nations. Victims are more likely to be boys; to be temperamentally inattentive, overactive, irritable, defiant, and aggressive; and to be growing up in stressed, poverty-stricken families.
- Effective injury prevention includes passing laws that promote child safety; creating safer home, travel, and play environments; improving public education; changing parent and child behaviors; and providing social supports to ease parental stress.

Motor Development (p. 223)

Cite major milestones of gross- and fine-motor development in early childhood, and describe individual differences.

- As the child's center of gravity shifts toward the trunk, balance improves, paving the way for new gross-motor achievements. Preschoolers run, jump, hop, gallop and eventually skip, throw, and catch, and generally become better coordinated.
- Improved control of the hands and fingers leads to dramatic gains in fine-motor skills. Preschoolers gradually become self-sufficient at dressing and feeding.
- By age 3, children's scribbles become pictures. With age, their drawings increase in complexity and realism, influenced by their culture's artistic traditions. Preschoolers also try to print alphabet letters and, later, words.

HANG XINGWEI/XINHUA /LANDOO

- Body build and opportunity for physical play affect motor development. Sex differences that favor boys in force and power and girls in balance and fine movements are partly genetic, but environmental pressures exaggerate them. Children master the motor skills of early childhood through informal play experiences.

COGNITIVE DEVELOPMENT

Piaget's Theory: The Preoperational Stage (p. 226)

Describe cognitive advances and limitations during the preoperational stage.

- Rapid advances in mental representation mark the beginning of Piaget's **preoperational stage**. Make-believe, which supports many aspects of development, becomes increasingly complex, evolving into **sociodramatic play** with peers. Gradually, children become capable of **dual representation**—viewing a symbolic object as both an object in its own right and a symbol.
- Preoperational children's **egocentrism**—their inability to imagine others' perspectives—contributes to **centration**, a focus on perceptual appearances, and **irreversibility**. As a result, preschoolers fail **conservation** and **hierarchical classification** tasks.

What does follow-up research reveal about the accuracy of Piaget's preoperational stage?

- When young children are given simplified tasks relevant to their everyday lives, their performance appears more mature than Piaget assumed. Preschoolers recognize others' perspectives, distinguish animate from inanimate objects, reason by analogy about physical transformations, understand cause-and-effect relationships, and organize knowledge into hierarchical categories.
- Evidence that operational thinking develops gradually over the preschool years challenges Piaget's stage concept. Some theorists propose a more flexible view of stages.

What educational principles can be derived from Piaget's theory?

- A Piagetian classroom promotes discovery learning, sensitivity to children's readiness to learn, and acceptance of individual differences.

Vygotsky's Sociocultural Theory (p. 233)

Explain Vygotsky's perspective on the social origins and significance of children's private speech.

- Unlike Piaget, Vygotsky regarded language as the foundation for all higher cognitive processes. According to Vygotsky, **private speech**, or language used for self-guidance, emerges out of social communication as adults and more skilled peers help children master appropriately challenging tasks. Private speech is eventually internalized as silent, inner speech.

- **Scaffolding**—adjusting teaching support to fit children's current needs and suggesting strategies—promotes gains in children's thinking.

Describe applications of Vygotsky's theory to education, and evaluate his major ideas.

- A Vygotskian classroom emphasizes assisted discovery—verbal guidance from teachers and peer collaboration. Make-believe play is a vital zone of proximal development that promotes many competencies.
- **Guided participation**, a broader concept than scaffolding, recognizes cultural and situational variations in shared endeavors between more expert and less expert participants.

© PAUL W. LIEBHARDT/CORBIS

Information Processing (p. 236)

How do attention and memory change during early childhood?

- Preschoolers' attention gradually becomes more sustained, and planning improves. But compared with older children, they spend less time involved in tasks and are less systematic in planning.
- Preschoolers' recognition memory is remarkably good, but their recall for listlike information is poor because they use **memory strategies** less effectively than older children.
- **Episodic memory**—memory for everyday experiences—improves greatly in early childhood. Like adults, preschoolers remember recurring events as **scripts**, which become increasingly elaborate with age. When adults use an elaborative style of conversing with children about the past, children's autobiographical memory becomes more organized and detailed.

Describe the young child's theory of mind.

- Preschoolers begin to construct a theory of mind, evidence of their capacity for **metacognition**. Language, executive function, and social experiences all contribute. Toddlers' nonverbal behaviors suggest an implicit awareness that people can hold false beliefs; around age 4, children's understanding becomes explicit.

- Preschoolers regard the mind as a passive container of information rather than as an active, constructive agent.

Summarize children's literacy and mathematical knowledge during early childhood.

- Children's active efforts to figure out how written symbols convey meaning are known as **emergent literacy**. Preschoolers revise these ideas as their cognitive capacities improve, as they encounter writing in many contexts, and as adults help them with written communication. **Phonological awareness** is a strong predictor of emergent literacy knowledge.
- Toddlers display a beginning grasp of **ordinality**. By age 4, preschoolers understand **cardinality** and use counting to solve arithmetic problems, eventually arriving at the most efficient, accurate approach. Adults promote children's mathematical knowledge by providing many occasions for counting, comparing quantities, and talking about number concepts.

Individual Differences in Mental Development (p. 243)

Discuss the impact of home, educational programs, child care, and media on preschoolers' mental development.

- By age 6 to 7, intelligence test scores are good predictors of later IQ and academic achievement. Children growing up in warm, stimulating homes with parents who make reasonable demands for mature behavior develop well intellectually.

- Preschool and kindergarten programs include both **child-centered programs**, in which much learning takes place through play, and **academic programs**, in which teachers train children in academic skills, often using repetition and drill. Emphasizing formal academic instruction undermines young children's motivation and negatively influences later achievement.
- **Project Head Start** is the most extensive U.S. federally funded preschool program for low-income children. High-quality preschool intervention results in immediate IQ and achievement gains and long-term improvements in school adjustment. Parent involvement in Head Start is positively related to more stimulating home environments, with benefits for children's academic, language, and social skills. Good child care enhances cognitive, language, and social development, especially for low-SES children.
- Children pick up many cognitive skills from educational television programs. Programs with slow-paced action and easy-to-follow story lines foster more elaborate make-believe play and gains in vocabulary and reading skills. But heavy exposure to entertainment TV is associated with poorer academic skills.
- Computers can have rich educational benefits when young children use them to draw or write, combine computer experiences with math manipulatives, or learn programming skills.

Language Development

(p. 248)

Trace the development of vocabulary, grammar, and conversational skills in early childhood.

- Supported by **fast-mapping**, preschoolers' vocabularies increase dramatically. Initially, they rely heavily on the perceptual cue of object shape to expand their vocabulary. With age, they increasingly draw on social and linguistic cues.
- Between ages 2 and 3, children adopt the basic word order of their language. As preschoolers gradually master grammatical rules, they sometimes overextend them in a type of error called **overregularization**. By the end of early childhood, children have acquired complex grammatical forms.
- **Pragmatics** is the practical, social side of language. Two-year-olds are already skilled conversationalists in face-to-face interaction. By age 4, children adapt their speech to their listener's age, sex, and social status.

© WAVE ROYALTY FREE/ALAMY

Cite factors that support language learning in early childhood.

- Conversational give-and-take with more skilled speakers fosters language progress. Adults provide explicit feedback on the clarity of children's language and indirect feedback about grammar through **recasts** and **expansions**.

chapter 8

© ELLEN B. SENISI PHOTOGRAPHY

During the preschool years, children make great strides in understanding the thoughts and feelings of others, and they build on these skills as they form first friendships—special relationships marked by attachment and common interests.

Emotional and Social Development in Early Childhood

As the children in Leslie's classroom moved through the preschool years, their personalities took on clearer definition. By age 3, they voiced firm likes and dislikes as well as new ideas about themselves.

"Stop bothering me," Sammy said to Mark, who had reached for Sammy's beanbag as Sammy aimed it toward the mouth of a large clown face. "See, I'm great at this game," Sammy announced with confidence, an attitude that kept him trying, even though he missed most of the throws.

The children's conversations also revealed early notions about morality. Often they combined adults' statements about right and wrong with forceful attempts to defend their own desires. "You're 'posed to share," stated Mark, grabbing the beanbag out of Sammy's hand.

"I was here first! Gimme it back," demanded Sammy, pushing Mark. The two boys struggled until Leslie intervened, provided an extra set of beanbags, and showed them how they could both play.

As the interaction between Sammy and Mark reveals, preschoolers quickly become complex social beings. Young children argue, grab, and push, but cooperative exchanges are far more frequent. Between ages 2 and 6, first friendships form, in which children converse, act out complementary roles, and learn that their own desires for companionship and toys are best met when they consider others' needs and interests.

The children's developing understanding of their social world was especially apparent in their growing attention to the dividing line between male and female. While Priti and Karen cared for a sick baby doll in the housekeeping area, Sammy, Vance, and Mark transformed the block corner into a busy intersection. "Green light, go!" shouted police officer Sammy as Vance and Mark pushed large wooden cars and trucks across the floor. Already, the children preferred peers of their own gender, and their play themes mirrored their culture's gender stereotypes.

This chapter is devoted to the many facets of early childhood emotional and social development. We begin with Erik Erikson's theory, which provides an overview of personality change in the preschool years. Then we consider children's concepts of themselves, their insights into their social and moral worlds, their gender typing, and their increasing ability to manage their emotional and social behaviors. Finally, we ask, What is effective child rearing? And we discuss the complex conditions that support good parenting or lead it to break down. ●

Erikson's Theory: Initiative versus Guilt

Erikson (1950) described early childhood as a period of “vigorous unfolding.” Once children have a sense of autonomy, they become less contrary than they were as toddlers. Their energies are freed for tackling the psychological conflict of the preschool years: **initiative versus guilt**. As the word *initiative* suggests, young children have a new sense of purposefulness. They are eager to tackle new tasks, join in activities with peers, and discover what they can do with the help of adults. They also make strides in conscience development.

Erikson regarded play as a means through which young children learn about themselves and their social world. Play permits preschoolers to try new skills with little risk of criticism and failure. It also creates a small social organization of children who must cooperate to achieve common goals. Around the world, children act out family scenes and highly visible occupations—police officer, doctor, and nurse in Western societies, rabbit hunter and potter among the Hopi Indians, hut builder and spear maker among the Baka of West Africa (Göncü, Patt, & Kouba, 2004).

Recall that Erikson's theory builds on Freud's psychosexual stages (see Chapter 1, page 16). In Freud's Oedipus and Electra conflicts, to avoid punishment and maintain parents' affection, children form a *superego*, or conscience, by *identifying* with the same-sex parent. As a result, they adopt the moral and gender-role standards of their society. For Erikson, the negative

outcome of early childhood is an overly strict superego that causes children to feel too much guilt because they have been threatened, criticized, and punished excessively by adults. When this happens, preschoolers' exuberant play and bold efforts to master new tasks break down.

Although Freud's ideas are no longer accepted as satisfactory explanations of conscience development, Erikson's image of initiative captures the diverse changes in young children's emotional and social lives. Early childhood is, indeed, a time when children develop a confident self-image, more effective control over their emotions, new social skills, the foundations of morality, and a clear sense of themselves as boy or girl.

Self-Understanding

The development of language enables young children to talk about their own subjective experience of being. In Chapter 7, we noted that young children acquire a vocabulary for talking about their inner mental lives and gain in understanding of mental states. As self-awareness strengthens, preschoolers focus more intently on qualities that make the self unique. They begin to develop a **self-concept**, the set of attributes, abilities, attitudes, and values that an individual believes defines who he or she is.

Foundations of Self-Concept

Ask a 3- to 5-year-old to tell you about himself, and you are likely to hear something like this: “I'm Tommy. See, I got this new red T-shirt. I'm 4 years old. I can wash my hair all by myself. I have a new Tinkertoy set, and I made this big, big tower.” Preschoolers' self-concepts consist largely of observable characteristics, such as their name, physical appearance, possessions, and everyday behaviors (Harter, 2006; Watson, 1990).

By age 3½, children also describe themselves in terms of typical emotions and attitudes—“I'm happy when I play with my friends”; “I don't like scary TV programs”; “I usually do what Mommy says”—suggesting a beginning understanding of their unique psychological characteristics (Eder & Mangelsdorf, 1997). And by age 5, children's degree of agreement with such statements coincides with maternal reports of their personality traits, indicating that older preschoolers have a sense of their own timidity, agreeableness, and positive or negative affect (Brown et al., 2008). But preschoolers do not yet say, “I'm helpful” or “I'm shy.” Direct references to personality traits must wait for greater cognitive maturity.

A warm, sensitive parent-child relationship seems to foster a more positive, coherent early self-concept. In one study, 4-year-olds with a secure attachment to their mothers were more likely than their insecurely attached agemates to describe themselves in favorable terms at age 5—with statements that reflect agreeableness and positive affect (Goodvin et al., 2008). Also recall from Chapter 7 that securely attached preschoolers participate in more elaborative parent-child conversations about personally experienced events, which help them understand themselves (see page 240).

A Guatemalan 3-year-old pretends to shell corn. By acting out family scenes and highly visible occupations, young children around the world develop a sense of initiative, gaining insight into what they can do and become in their culture.

Cultural Influences

Cultural Variations in Personal Storytelling: Implications for Early Self-Concept

Preschoolers of many cultural backgrounds participate in personal storytelling with their parents. Striking cultural differences exist in parents' selection and interpretation of events in these narratives, affecting the way children view themselves.

In one study, researchers spent thousands of hours studying the storytelling practices of six middle-SES Irish-American families in Chicago and six middle-SES Chinese families in Taiwan. From extensive videotapes of adults' conversations with the children from age 2½ to 4, the investigators identified personal stories and coded them for content (Miller, Fung, & Mintz, 1996; Miller et al., 1997, 2012).

Parents in both cultures discussed pleasurable holidays and family excursions in similar ways and with similar frequency. But five times more often than the Irish-American parents, the Chinese parents told long stories about their preschooler's previous misdeeds—using impolite language, writing on the wall, or playing in an overly rowdy way. These narratives, often sparked by a current misdeed, were used as opportunities to educate: Parents conveyed stories with warmth and

caring, stressed the impact of misbehavior on others (“You made Mama lose face”), and often ended with direct teaching of proper behavior and a moral lesson (“Saying dirty words is not good”). By contrast, in the few instances in which Irish-American stories referred to transgressions, parents downplayed their seriousness, attributing them to the child's spunk and assertiveness.

Early narratives about the child launch preschoolers' self-concepts on culturally distinct paths (Miller, Fung, & Koven, 2007). Influenced by Confucian traditions of strict discipline and social obligations, Chinese parents integrated these values into their stories, affirming the importance of not disgracing the family and explicitly conveying expectations for improvement in the story's conclusion. Although Irish-American parents disciplined their children, they rarely dwelt on misdeeds in storytelling. Rather, they cast the child's shortcomings in a positive light, perhaps to promote self-esteem.

Whereas most Americans believe that favorable self-esteem is crucial for healthy development, Chinese adults generally see it as unimportant or even negative—as impeding the child's willingness to listen

RONNIE KAUFMAN/LARRY HIRSHOWITZ/
GETTY IMAGES/BLEND IMAGES

A Chinese mother speaks gently to her child about proper behavior. Chinese parents often tell preschoolers stories that point out the negative impact on others of the child's misdeeds. The Chinese child's self-concept, in turn, emphasizes social obligations.

and be corrected (Miller et al., 2002). Consistent with this view, the Chinese parents did little to cultivate their child's individuality. Instead, they used storytelling to guide the child toward responsible behavior. Hence, the Chinese child's self-image emphasizes obligations to others, whereas the American child's is more autonomous.

As early as age 2, parents use narratives of past events to impart rules, standards for behavior, and evaluative information about the child: “You added the milk when we made the mashed potatoes. That's a very important job!” (Nelson, 2003). As the Cultural Influences box above reveals, these self-evaluative narratives are a major means through which caregivers imbue the young child's self-concept with cultural values.

As they talk about personally significant events and as their cognitive skills advance, preschoolers gradually come to view themselves as persisting over time. Around age 4, children first become certain that a video image of themselves replayed a few minutes after it was filmed is still “me” (Povinelli, 2001). Similarly, when researchers asked 3- to 5-year-olds to imagine a future event (walking next to a waterfall) and to envision a future personal state by choosing from three items (a raincoat, money, a blanket) the one they would need to bring with them, performance—along with future-state justifications (“I'm gonna get wet”)—increased sharply from age 3 to 4 (Atance & Meltzoff, 2005).

Emergence of Self-Esteem

Another aspect of self-concept emerges in early childhood: **self-esteem**, the judgments we make about our own worth and the feelings associated with those judgments. **TAKE A MOMENT...** Make a list of your own self-judgments. Notice that, besides a global appraisal of your worth as a person, you have a variety of separate self-evaluations concerning how well you perform at different activities. These evaluations are among the most important aspects of self-development because they affect our emotional experiences, future behavior, and long-term psychological adjustment.

By age 4, preschoolers have several self-judgments—for example, about learning things in school, making friends, getting along with parents, and treating others kindly (Marsh, Ellis, & Craven, 2002). But because they have difficulty distinguishing between their desired and their actual competence, they usually rate their own ability as extremely high and underestimate task

After creating a “camera” and “flash,” this preschooler pretends to take pictures. Her high self-esteem contributes greatly to her initiative in mastering many new skills.

difficulty, as when Sammy asserted, despite his many misses, that he was great at beanbag throwing (Harter, 2003, 2006).

High self-esteem contributes greatly to preschoolers’ initiative during a period in which they must master many new skills. By age 3, children whose parents patiently encourage while offering information about how to succeed are enthusiastic and highly motivated. In contrast, children whose parents criticize their worth and performance give up easily when faced with a challenge and express shame and despondency after failing (Kelley, Brownell, & Campbell, 2000). Adults can avoid promoting these self-defeating reactions by adjusting their expectations to children’s capacities, scaffolding children’s attempts at difficult tasks (see Chapter 7, page 234), and pointing out effort and improvement in children’s behavior.

Emotional Development

Gains in representation, language, and self-concept support emotional development in early childhood. Between ages 2 and 6, children make strides in emotional abilities that, collectively, researchers refer to as *emotional competence* (Halberstadt, Denham, & Dunsmore, 2001; Saarni et al., 2006). First, preschoolers gain in emotional understanding, becoming better able to talk about feelings and to respond appropriately to others’ emotional signals. Second, they become better at emotional self-regulation—in particular, at coping with intense negative emotion. Finally, preschoolers more often experience *self-conscious emotions* and *empathy*, which contribute to their developing sense of morality.

Parenting strongly influences preschoolers’ emotional competence. Emotional competence, in turn, is vital for successful peer relationships and overall mental health.

Understanding Emotion

Early in the preschool years, children refer to causes, consequences, and behavioral signs of emotion, and over time their understanding becomes more accurate and complex (Stein & Levine, 1999). By age 4 to 5, children correctly judge the causes of many basic emotions (“He’s happy because he’s swinging very high”; “He’s sad because he misses his mother”). Preschoolers’ explanations tend to emphasize external factors over internal states, a balance that changes with age (Levine, 1995). After age 4, children appreciate that both desires and beliefs motivate behavior (Chapter 7). Then their grasp of how internal factors can trigger emotion expands.

Preschoolers can also predict what a playmate expressing a certain emotion might do next. Four-year-olds know that an angry child might hit someone and that a happy child is more likely to share (Russell, 1990). And they realize that thinking and feeling are interconnected—that a person reminded of a previous sad experience is likely to feel sad (Lagattuta, Wellman, & Flavell, 1997). Furthermore, they come up with effective ways to relieve others’ negative feelings, such as hugging to reduce sadness (Fabes et al., 1988).

At the same time, preschoolers have difficulty interpreting situations that offer conflicting cues about how a person is feeling. When asked what might be happening in a picture of a happy-faced child with a broken bicycle, 4- and 5-year-olds tended to rely only on the emotional expression: “He’s happy because he likes to ride his bike.” Older children more often reconciled the two cues: “He’s happy because his father promised to help fix his broken bike” (Gnepp, 1983; Hoffner & Badzinski, 1989). As in their approach to Piagetian tasks, preschoolers focus on the most obvious aspect of an emotional situation to the neglect of other relevant information.

The more parents label emotions, explain them, and express warmth and enthusiasm when conversing with preschoolers, the more “emotion words” children use and the better developed their emotional understanding (Fivush & Haden, 2005; Laible & Song, 2006). In one study, mothers who explained feelings and who negotiated and compromised during conflicts with their 2½-year-olds had children who, at age 3, were advanced in emotional understanding and used similar strategies to resolve disagreements (Laible & Thompson, 2002). Furthermore, 3- to 5-year-olds who are securely attached to their mothers better understand emotion. Attachment security is related to warmer and more elaborative parent–child narratives, including discussions of feelings that highlight the emotional significance of events (Laible, 2004; Laible & Song, 2006; Raikes & Thompson, 2006).

As preschoolers learn about emotion from interacting with adults, they engage in more emotion talk with siblings and friends, especially during make-believe play (Hughes & Dunn, 1998). Make-believe, in turn, contributes to emotional understanding, especially when children play with siblings (Youngblade & Dunn, 1995). The intense nature of the sibling relationship, combined with frequent acting out of feelings, makes pretending an excellent context for learning about emotions.

Applying What We Know

Helping Children Manage Common Fears of Early Childhood

Fear	Suggestion
Monsters, ghosts, and darkness	Reduce exposure to frightening stories in books and on TV until the child is better able to sort out appearance from reality. Make a thorough “search” of the child’s room for monsters, showing him that none are there. Leave a night-light burning, sit by the child’s bed until he falls asleep, and tuck in a favorite toy for protection.
Preschool or child care	If the child resists going to preschool but seems content once there, the fear is probably separation. Provide a sense of warmth and caring while gently encouraging independence. If the child fears being at preschool, find out what is frightening—the teacher, the children, or a crowded, noisy environment. Provide extra support by accompanying the child and gradually lessening the amount of time you are present.
Animals	Do not force the child to approach a dog, cat, or other animal that arouses fear. Let the child move at her own pace. Demonstrate how to hold and pet the animal, showing the child that when treated gently, the animal is friendly. If the child is larger than the animal, emphasize this: “You’re so big. That kitty is probably afraid of you!”
Intense fears	If a child’s fear is intense, persists for a long time, interferes with daily activities, and cannot be reduced in any of the ways just suggested, it has reached the level of a <i>phobia</i> . Sometimes phobias are linked to family problems, and counseling is needed to reduce them. At other times, phobias diminish without treatment as the child’s capacity for emotional self-regulation improves.

As early as 3 to 5 years of age, knowledge about emotions is related to children’s friendly, considerate behavior, willingness to make amends after harming another, and constructive responses to disputes with agemates (Dunn, Brown, & Maguire, 1995; Garner & Estep, 2001; Hughes & Ensor, 2010). Also, the more preschoolers refer to feelings when interacting with playmates, the better liked they are by their peers (Fabes et al., 2001). Children seem to recognize that acknowledging others’ emotions and explaining their own enhance the quality of relationships.

Emotional Self-Regulation

Language also contributes to preschoolers’ improved *emotional self-regulation* (Cole, Armstrong, & Pemberton, 2010). By age 3 to 4, children verbalize a variety of strategies for adjusting their emotional arousal to a more comfortable level. For example, they know they can blunt emotions by restricting sensory input (covering their eyes or ears to block out an unpleasant sight or sound), talking to themselves (“Mommy said she’ll be back soon”), or changing their goals (deciding that they don’t want to play anyway after being excluded from a game) (Thompson & Goodvin, 2007). As children use these strategies, emotional outbursts decline. *Effortful control*—in particular, inhibiting impulses and shifting attention—also continues to be vital in managing emotion during early childhood. Three-year-olds who can distract themselves when frustrated tend to become cooperative school-age children with few problem behaviors (Gilliom et al., 2002).

Warm, patient parents who use verbal guidance, including suggesting and explaining strategies and prompting children to generate their own, strengthen children’s capacity to handle stress (Colman et al., 2006; Morris et al., 2011). In contrast, when parents rarely express positive emotion, dismiss children’s

feelings as unimportant, and have difficulty controlling their own anger, children have continuing problems in managing emotion (Hill et al., 2006; Katz & Windecker-Nelson, 2004; Thompson & Meyer, 2007).

As with infants and toddlers, preschoolers who experience negative emotion intensely find it harder to shift attention away from disturbing events and inhibit their feelings. They are more likely to be anxious and fearful, respond with irritation to others’ distress, react angrily or aggressively when frustrated, and get along poorly with teachers and peers (Chang et al., 2003; Eisenberg et al., 2005; Raikes et al., 2007). Because these emotionally reactive children become increasingly difficult to rear, they are often targets of ineffective parenting, which compounds their poor self-regulation.

Adult–child conversations that prepare children for difficult experiences also foster emotional self-regulation (Thompson & Goodman, 2010). Parents who discuss what to expect and ways to handle anxiety offer strategies that children can apply. Nevertheless, preschoolers’ vivid imaginations and incomplete grasp of the distinction between appearance and reality make fears common in early childhood. See Applying What We Know above for ways adults can help young children manage fears.

Self-Conscious Emotions

One morning in Leslie’s classroom, a group of children crowded around for a bread-baking activity. Leslie asked them to wait patiently while she got a baking pan. But Sammy reached over to feel the dough, and the bowl tumbled off the table. When Leslie returned, Sammy looked at her, then covered his eyes with his hands and said, “I did something bad.” He felt ashamed and guilty.

As their self-concepts develop, preschoolers become increasingly sensitive to praise and blame or to the possibility of such feedback. They more often experience *self-conscious emotions*—feelings that involve injury to or enhancement of their sense of self (see Chapter 6). By age 3, self-conscious emotions are clearly linked to self-evaluation (Lewis, 1995; Thompson, Meyer, & McGinley, 2006). But because preschoolers are still developing standards of excellence and conduct, they depend on the messages of parents, teachers, and others who matter to them to know *when* to feel proud, ashamed, or guilty, often viewing adult expectations as obligatory rules (“Dad said you’re ‘posed to take turns”) (Thompson, Meyer, & McGinley, 2006).

When parents repeatedly comment on the worth of the child and her performance (“That’s a bad job! I thought you were a good girl!”), children experience self-conscious emotions intensely—more shame after failure, more pride after success. In contrast, parents who focus on how to improve performance (“You did it this way; now try doing it that way”) induce moderate, more adaptive levels of shame and pride and greater persistence on difficult tasks (Kelley, Brownell, & Campbell, 2000; Lewis, 1998).

Among Western children, intense shame is associated with feelings of personal inadequacy (“I’m stupid”; “I’m a terrible person”) and with maladjustment—withdrawal and depression as well as intense anger and aggression toward those who participated in the shame-evoking situation (Lindsay-Hartz, de Rivera, & Mascolo, 1995; Mills, 2005). In contrast, guilt—when it occurs in appropriate circumstances and is neither excessive nor accompanied by shame—is related to good adjustment. Guilt helps children resist harmful impulses, and it motivates a misbehaving child to repair the damage and behave more considerately (Mascolo & Fischer, 2007; Tangney, Stuewig, & Mashek, 2007). But overwhelming guilt—involving such high emotional distress that the child cannot make amends—is linked to depressive symptoms as early as age 3 (Luby et al., 2009).

Finally, the consequences of shame for children’s adjustment may vary across cultures. As illustrated in the Cultural Influences box on page 267 and on page 189 in Chapter 6, people in Asian collectivist societies, who define themselves in relation to their social group, view shame as an adaptive reminder of an interdependent self and of the importance of others’ judgments (Bedford, 2004).

Empathy and Sympathy

Another emotional capacity that becomes more common in early childhood is *empathy*, which serves as an important motivator of **prosocial, or altruistic, behavior**—actions that benefit another person without any expected reward for the self (Spinrad & Eisenberg, 2009). Compared with toddlers, preschoolers rely more on words to communicate empathic feelings, a change that indicates a more reflective level of empathy. When a 4-year-old received a Christmas gift that she hadn’t included on her list for Santa, she assumed it belonged to another little girl and pleaded with her parents, “We’ve got to give it back—

© LAURA DWIGHT PHOTOGRAPHY

As children’s language skills and capacity to take the perspective of others improve, empathy also increases, motivating prosocial, or altruistic, behavior.

Santa’s made a big mistake. I think the girl’s crying ‘cause she didn’t get her present!”

Yet in some children, empathizing—*feeling with* an upset adult or peer and responding emotionally in a similar way—does not yield acts of kindness and helpfulness but, instead, escalates into personal distress. In trying to reduce these feelings, the child focuses on his own anxiety rather than the person in need. As a result, empathy does not lead to **sympathy**—feelings of concern or sorrow for another’s plight.

Temperament plays a role in whether empathy occurs and whether it prompts sympathetic, prosocial behavior or self-focused personal distress. Children who are sociable, assertive, and good at regulating emotion are more likely to empathize with others’ distress, display sympathetic concern, and engage in prosocial behavior, helping, sharing, and comforting others in distress (Bengtsson, 2005; Eisenberg et al., 1998; Valiente et al., 2004). In contrast, when poor emotion regulators are faced with someone in need, they react with facial and physiological indicators of distress—frowning, lip biting, a rise in heart rate, and a sharp increase in EEG brain-wave activity in the right cerebral hemisphere (which houses negative emotion)—indications that they are overwhelmed by their feelings (Jones, Field, & Davalos, 2000; Pickens, Field, & Nawrocki, 2001).

As with other aspects of emotional development, parenting affects empathy and sympathy. When parents are warm, encourage emotional expressiveness, and show sensitive, empathic concern for their preschoolers’ feelings, children are likely to react in a concerned way to the distress of others—relationships that persist into adolescence and early adulthood (Koestner, Franz, & Weinberger, 1990; Michalik et al., 2007; Strayer & Roberts, 2004). Besides modeling sympathy, parents can help shy children manage excessive anxiety and aggressive children regulate intense anger. They can also teach children the importance of kindness and can intervene when they display

inappropriate emotion—strategies that predict high levels of sympathetic responding (Eisenberg, 2003).

In contrast, punitive parenting disrupts empathy at an early age (Valiente et al., 2004). In one study, physically abused preschoolers at a child-care center rarely expressed concern at a peer's unhappiness but, rather, reacted with fear, anger, and physical attacks (Klimes-Dougan & Kistner, 1990). The children's behavior resembled their parents' insensitive responses to others' suffering.

Peer Relations

As children become increasingly self-aware and better at communicating and understanding others' thoughts and feelings, their skill at interacting with peers improves rapidly. Peers provide young children with learning experiences they can get in no other way. Because peers interact on an equal footing, children must keep a conversation going, cooperate, and set goals in play. With peers, children form friendships—special relationships marked by attachment and common interests. Let's look at how peer interaction changes over the preschool years.

Advances in Peer Sociability

Mildred Parten (1932), one of the first to study peer sociability among 2- to 5-year-olds, noticed a dramatic rise with age in joint, interactive play. She concluded that social development proceeds in a three-step sequence. It begins with **nonsocial activity**—unoccupied, onlooker behavior and solitary play. Then it shifts to **parallel play**, in which a child plays near other children with similar materials but does not try to influence their behavior. At the highest level are two forms of true social interaction. In **associative play**, children engage in separate activities but exchange toys and comment on one another's behavior. Finally, in **cooperative play**, a more advanced type of interaction, children orient toward a common goal, such as acting out a make-believe theme.

Follow-Up Research on Peer Sociability. Longitudinal evidence indicates that these play forms emerge in the order suggested by Parten but that later-appearing ones do not replace earlier ones in a developmental sequence (Rubin, Bukowski, & Parker, 2006). Rather, all types coexist in early childhood.

TAKE A MOMENT... Watch children move from one type of play to another in a play group or preschool classroom, and you will see that they often transition from onlooker to parallel to cooperative play and back again (Robinson et al., 2003). Preschoolers seem to use parallel play as a way station—a respite from the demands of complex social interaction and a crossroad to new activities. And although nonsocial activity declines with age, it is still the most frequent form among 3- to 4-year-olds and accounts for a third of kindergartners' free-play time. Also, both solitary and parallel play remain fairly stable from 3 to 6 years, accounting for as much of the child's play as cooperative interaction (Rubin, Fein, & Vandenberg, 1983).

We now understand that the *type*, not the amount, of solitary and parallel play changes in early childhood. In studies of preschoolers' play in Taiwan and the United States, researchers rated the *cognitive maturity* of nonsocial, parallel, and cooperative play, using the categories shown in Table 8.1 on page 262. Within each play type, older children displayed more cognitively mature behavior than younger children (Pan, 1994; Rubin, Watson, & Jambor, 1978).

Often parents wonder whether a preschooler who spends much time playing alone is developing normally. But only *certain types* of nonsocial activity—aimless wandering, hovering near peers, and functional play involving repetitive motor action—are cause for concern. Children who watch peers without playing are usually temperamentally inhibited—high in social fearfulness (Coplan et al., 2004; Rubin, Bukowski, & Parker, 2006). And preschoolers who engage in solitary, repetitive behavior (banging blocks, making a doll jump up and down) tend to be immature, impulsive children who find it difficult to regulate anger and aggression (Coplan et al., 2001). In the classroom, both reticent and impulsive children tend to experience peer ostracism (Coplan & Arbeau, 2008).

These 4-year-olds (left) engage in parallel play. Cooperative play (right) develops later than parallel play, but preschool children continue to move back and forth between the two types of sociability, using parallel play as a respite from the complex demands of cooperation.

TABLE 8.1 Developmental Sequence of Cognitive Play Categories

PLAY CATEGORY	DESCRIPTION	EXAMPLES
Functional play	Simple, repetitive motor movements with or without objects, especially common during the first two years	Running around a room, rolling a car back and forth, kneading clay with no intent to make something
Constructive play	Creating or constructing something, especially common between 3 and 6 years	Making a house out of toy blocks, drawing a picture, putting together a puzzle
Make-believe play	Acting out everyday and imaginary roles, especially common between 2 and 6 years	Playing house, school, or police officer; acting out storybook or television characters

Source: Rubin, Fein, & Vandenberg, 1983.

But most preschoolers with low rates of peer interaction simply like to play alone, and their solitary activities are positive and constructive. Children who prefer solitary play with art materials, puzzles, and building toys are typically well-adjusted youngsters who, when they do play with peers, show socially skilled behavior (Coplan & Armer, 2007). Still, a few preschoolers who engage in such age-appropriate solitary play—again, more often boys—are rebuffed by peers. Perhaps because quiet play is inconsistent with the “masculine” gender role, boys who engage in it are at risk for negative reactions from both parents and peers and, eventually, for adjustment problems (Coplan et al., 2001, 2004).

Cultural Variations. Peer sociability in collectivist societies, which stress group harmony, takes different forms than in individualistic cultures (Chen & French, 2008). For example, children in India generally play in large groups, which require high levels of cooperation. Much of their behavior is imitative, occurs in unison, and involves close physical contact. In a game called *Bhatto Bhatto*, children act out a script about a trip to the market, touching one another’s elbows and hands as they pretend to cut and share a tasty vegetable (Roopnarine et al., 1994).

© JACOB MAENTZ/CORBIS

Agta village children in the Philippines play a tug-of-war game. Large-group, highly cooperative play is typical of peer sociability in collectivist societies.

As another example, Chinese preschoolers—unlike American preschoolers, who tend to reject reticent classmates—are typically willing to include a quiet, reserved child in play (Chen et al., 2006). In Chapter 6, we saw that until recently collectivist values, which discourage self-assertion, led to positive evaluations of shyness in China (see pages 194–195). Apparently, this benevolent attitude persists in the play behaviors of Chinese young children.

Cultural beliefs about the importance of play also affect early peer associations. Caregivers who view play as mere entertainment are less likely to provide props or to encourage pretend than those who value its cognitive and social benefits (Farver & Wimbarti, 1995). Preschoolers of Korean-American parents, who emphasize task persistence as vital for learning, spend less time than Caucasian-American children in joint make-believe and more time unoccupied and in parallel play (Farver, Kim, & Lee, 1995).

Recall the description of children’s daily lives in a Mayan village culture on page 236 in Chapter 7. Mayan parents do not promote children’s play—yet Mayan children are socially competent (Gaskins, 2000). Perhaps Western-style sociodramatic play, with its elaborate materials and wide-ranging themes, is particularly important for social development in societies where the worlds of children and adults are distinct. It may be less crucial in village cultures where children participate in adult activities from an early age.

First Friendships

As preschoolers interact, first friendships form that serve as important contexts for emotional and social development. To adults, friendship is a mutual relationship involving companionship, sharing, understanding of thoughts and feelings, and caring for and comforting each other in times of need. In addition, mature friendships endure over time and survive occasional conflicts.

Preschoolers understand something about the uniqueness of friendship. They say that a friend is someone “who likes you,” with whom you spend a lot of time playing, and with whom you share toys. But friendship does not yet have a long-term, enduring quality based on mutual trust (Damon, 1988a; Hartup, 2006). “Mark’s my best friend,” Sammy would declare on days when the boys got along well. But when a dispute arose, he would reverse himself: “Mark, you’re not my friend!”

Nevertheless, interactions between young friends are unique. Preschoolers give far more reinforcement—greetings, praise, and compliance—to children they identify as friends, and they also receive more from them. Friends are more cooperative and emotionally expressive—talking, laughing, and looking at each other more often than nonfriends do (Hartup, 2006; Vaughn et al., 2001). Furthermore, children who begin kindergarten with friends in their class or readily make new friends adjust to school more favorably (Ladd, Birch, & Buhs, 1999; Ladd & Price, 1987). Perhaps the company of friends serves as a secure base from which to develop new relationships, enhancing children's feelings of comfort in the new classroom.

Peer Relations and School Readiness

The ease with which kindergartners make new friends and are accepted by their classmates predicts cooperative participation in classroom activities and self-directed completion of learning tasks—behaviors linked to gains in achievement (Ladd, Birch, & Buhs, 1999; Ladd, Buhs, & Seid, 2000). The capacity to form friendships enables kindergartners to integrate themselves into classroom environments in ways that foster both academic and social competence. In a longitudinal follow-up of a large sample of 4-year-olds, children of average intelligence but with above-average social skills fared better in academic achievement in first grade than children of equal mental ability who were socially below average (Konold & Pianta, 2005).

Because social maturity in early childhood contributes to later academic performance, a growing number of experts propose that kindergarten readiness be assessed in terms of not just academic skills but also social skills (Ladd, Herald, & Kochel, 2006; Thompson & Raikes, 2007). Preschool programs, too, should attend to these vital social prerequisites. Warm, responsive teacher–child interaction is vital, especially for shy, impulsive, and emotionally negative children, who are at risk for social difficulties. In studies involving several thousand 4-year-olds in public preschools in six states, teacher sensitivity and emotional support were strong predictors of children's social competence, both during preschool and after kindergarten entry (Curby et al., 2009; Mashburn et al., 2008).

Parental Influences on Early Peer Relations

Children first acquire skills for interacting with peers within the family. Parents influence children's peer sociability both *directly*, through attempts to influence children's peer relations, and *indirectly*, through their child-rearing practices and play behaviors (Ladd & Pettit, 2002; Rubin et al., 2005).

Direct Parental Influences. Preschoolers whose parents frequently arrange informal peer play activities tend to have larger peer networks and to be more socially skilled (Ladd, LeSieur, & Proffitt, 1993). In providing play opportunities, parents show children how to initiate peer contacts. And parents' skillful suggestions for managing conflict, discouraging teasing,

© CULTURA/CORBIS

Parents' play with children, especially same-sex children, contributes to social competence. By playing with his father as he would with a peer, this child acquires social skills that facilitate peer interaction.

and entering a play group are associated with preschoolers' social competence and peer acceptance (Mize & Pettit, 2010; Parke et al., 2004b).

Indirect Parental Influences. Many parenting behaviors not directly aimed at promoting peer sociability nevertheless influence it. For example, secure attachments to parents are linked to more responsive, harmonious peer interaction, larger peer networks, and warmer, more supportive friendships during the preschool and school years (Laible, 2007; Lucas-Thompson & Clarke-Stewart, 2007; Wood, Emmerson, & Cowan, 2004). The sensitive, emotionally expressive communication that contributes to attachment security may be responsible.

Parent–child play seems particularly effective for promoting peer interaction skills. During play, parents interact with their child on a “level playing field,” much as peers do. And perhaps because parents play more with children of their own sex, mothers' play is more strongly linked to daughters' competence, fathers' play to sons' competence (Lindsey & Mize, 2000; Pettit et al., 1998).

As we have seen, some preschoolers already have great difficulty with peer relations. In Leslie's classroom, Robbie was one of them. Wherever he happened to be, comments like “Robbie ruined our block tower” and “Robbie hit me for no reason” could be heard. As we take up moral development in the next section, you will learn more about how parenting contributed to Robbie's peer problems.

ASK YOURSELF

REVIEW Among children who spend much time playing alone, what factors distinguish those who are likely to have adjustment difficulties from those who are well-adjusted and socially skilled?

CONNECT How does emotional self-regulation affect the development of empathy and sympathy? Why are these emotional capacities vital for positive peer relations?

APPLY Three-year-old Ben lives in the country, with no other preschoolers nearby. His parents wonder whether it is worth driving Ben into town once a week to participate in a peer play group. What advice would you give Ben's parents, and why?

REFLECT What did your parents do, directly and indirectly, that might have influenced your earliest peer relationships?

Foundations of Morality

Children's conversations and behavior provide many examples of their developing moral sense. By age 2, they use words to evaluate behavior as "good" or "bad" and react with distress to aggressive or potentially harmful behaviors (Kochanska, Casey, & Fukumoto, 1995). And we have seen that children of this age share toys, help others, and cooperate in games—early indicators of considerate, responsible prosocial attitudes.

Adults everywhere take note of this budding capacity to distinguish right from wrong. Some cultures have special terms for it. The Utku Indians of Hudson Bay say the child develops *ihuma* (reason). The Fijians believe that *vakayalo* (sense) appears. In response, parents hold children more responsible for their behavior (Dunn, 2005). By the end of early childhood, children can state many moral rules: "Don't take someone's things without asking!" "Tell the truth!" In addition, they argue over matters of justice: "You sat there last time, so it's my turn." "It's not fair. He got more!"

All theories of moral development recognize that conscience begins to take shape in early childhood. And most agree that at first, the child's morality is *externally controlled* by adults. Gradually, it becomes regulated by *inner standards*. Truly moral individuals do not do the right thing just to conform to others' expectations. Rather, they have developed compassionate concerns and principles of good conduct, which they follow in many situations.

Each major theory emphasizes a different aspect of morality. Psychoanalytic theory stresses the *emotional side* of conscience development—in particular, identification and guilt as motivators of good conduct. Social learning theory focuses on how *moral behavior* is learned through reinforcement and modeling. Finally, the cognitive-developmental perspective emphasizes *thinking*—children's ability to reason about justice and fairness.

The Psychoanalytic Perspective

Recall that according to Freud, young children form a *superego*, or conscience, by *identifying* with the same-sex parent, whose moral standards they adopt. Children obey the superego to avoid *guilt*, a painful emotion that arises each time they are tempted to misbehave. Moral development, Freud believed, is largely complete by 5 to 6 years of age.

Today, most researchers disagree with Freud's view of conscience development. In his theory (see page 256), fear of punishment and loss of parental love motivate conscience formation and moral behavior. Yet children whose parents frequently use threats, commands, or physical force tend to violate standards often and feel little guilt, whereas parental warmth and responsiveness predict greater guilt following transgressions (Kochanska et al., 2002, 2005, 2008). And if a parent withdraws love after misbehavior—for example, refuses to speak to or states a dislike for the child—children often respond with high levels of self-blame, thinking "I'm no good," or "Nobody loves me." Eventually, to protect themselves from overwhelming guilt, these children may deny the emotion and, as a result, also develop a weak conscience (Kochanska, 1991; Zahn-Waxler et al., 1990).

Inductive Discipline. In contrast, conscience formation is promoted by a type of discipline called **induction**, in which an adult helps the child notice feelings by pointing out the effects of the child's misbehavior on others. For example, a parent might say, "She's crying because you won't give back her doll" (Hoffman, 2000). When generally warm parents provide explanations that match the child's capacity to understand, while firmly insisting that the child listen and comply, induction is effective as early as age 2. Preschoolers whose parents use it are more likely to refrain from wrongdoing, confess and repair damage after misdeeds, and display prosocial behavior (Kerr et al., 2004; Volling, Mahoney, & Rauer, 2009; Zahn-Waxler, Radke-Yarrow, & King, 1979).

© LAURA DWIGHT PHOTOGRAPHY

A teacher uses inductive discipline to explain to a child the impact of her transgression on others, pointing out classmates' feelings. Induction encourages empathy, sympathy, and commitment to moral standards.

The success of induction may lie in its power to motivate children's active commitment to moral standards. Induction gives children information about how to behave that they can use in future situations. By emphasizing the impact of the child's actions on others, it encourages empathy and sympathy (Krevans & Gibbs, 1996). And giving children reasons for changing their behavior encourages them to adopt moral standards because they make sense.

In contrast, discipline that relies too heavily on threats of punishment or withdrawal of love makes children so anxious and frightened that they cannot think clearly enough to figure out what they should do. As a result, these practices do not get children to internalize moral rules (Eisenberg, Fabes, & Spinrad, 2006).

The Child's Contribution. Although good discipline is crucial, children's characteristics also affect the success of parenting techniques. Twin studies suggest a modest genetic contribution to empathy (Knafo et al., 2009). More empathic children require less power assertion and are more responsive to induction.

Temperament is also influential. Mild, patient tactics—requests, suggestions, and explanations—are sufficient to prompt guilt reactions in anxious, fearful preschoolers (Kochanska et al., 2002). But with fearless, impulsive children, gentle discipline has little impact. Power assertion also works poorly. It undermines the child's capacity for effortful control, which strongly predicts good conduct, empathy, sympathy, and prosocial behavior (Kochanska & Aksan, 2006; Kochanska & Knaack, 2003). Parents of impulsive children can foster conscience development by ensuring a secure attachment relationship and combining firm correction with induction (Kochanska, Aksan, & Joy, 2007). When children are so low in anxiety that parental disapproval causes them little discomfort, a close parent-child bond motivates them to listen to parents as a means of preserving an affectionate, supportive relationship.

The Role of Guilt. Although little support exists for Freudian ideas about conscience development, Freud was correct that guilt is an important motivator of moral action. Inducing *empathy-based guilt* (expressions of personal responsibility and regret, such as "I'm sorry I hurt him") by explaining that the child is harming someone and has disappointed the parent is a means of influencing children without using coercion. Empathy-based guilt reactions are associated with stopping harmful actions, repairing damage caused by misdeeds, and engaging in future prosocial behavior (Baumeister, 1998; Eisenberg, Eggum, & Edwards, 2010). At the same time, parents must help children deal with guilt feelings constructively—by guiding them to make up for immoral behavior rather than minimizing or excusing it.

But contrary to what Freud believed, guilt is not the only force that compels us to act morally. Nor is moral development complete by the end of early childhood. Rather, it is a gradual process, extending into adulthood.

Social Learning Theory

According to social learning theory, morality does not have a unique course of development. Rather, moral behavior is acquired just like any other set of responses: through reinforcement and modeling.

Importance of Modeling. *Operant conditioning*—reinforcement for good behavior with approval, affection, and other rewards—is not enough for children to acquire moral responses. For a behavior to be reinforced, it must first occur spontaneously. Yet many prosocial acts, such as sharing, helping, or comforting an unhappy playmate, occur so rarely at first that reinforcement cannot explain their rapid development in early childhood. Rather, social learning theorists believe that children learn to behave morally largely through *modeling*—observing and imitating people who demonstrate appropriate behavior (Bandura, 1977; Grusec, 1988). Once children acquire a moral response, reinforcement in the form of praise increases its frequency (Mills & Grusec, 1989).

Many studies show that having helpful or generous models increases young children's prosocial responses. And certain characteristics of models affect children's willingness to imitate:

- **Warmth and responsiveness.** Preschoolers are more likely to copy the prosocial actions of a warm, responsive adult than those of a cold, distant adult (Yarrow, Scott, & Waxler, 1973). Warmth seems to make children more attentive and receptive to the model and is itself an example of a prosocial response.
- **Competence and power.** Children admire and therefore tend to imitate competent, powerful models—especially older peers and adults (Bandura, 1977).
- **Consistency between assertions and behavior.** When models say one thing and do another—for example, announce that "it's important to help others" but rarely engage in helpful acts—children generally choose the most lenient standard of behavior that adults demonstrate (Mischel & Liebert, 1966).

Models are most influential in the early years. In one study, toddlers' eager, willing imitation of their mothers' behavior predicted moral conduct (not cheating in a game) and guilt following transgressions at age 3 (Forman, Aksan, & Kochanska, 2004). At the end of early childhood, children who have had consistent exposure to caring adults have internalized prosocial rules and follow them whether or not a model is present (Mussen & Eisenberg-Berg, 1977).

Effects of Punishment. Many parents know that yelling at, slapping, and spanking children for misbehavior are ineffective disciplinary tactics. A sharp reprimand or physical force to restrain or move a child is justified when immediate obedience is necessary—for example, when a 3-year-old is about to run into the street. In fact, parents are most likely to use forceful methods under these conditions. But to foster long-term goals,

such as acting kindly toward others, they tend to rely on warmth and reasoning (Kuczynski, 1984). And in response to very serious transgressions, such as lying and stealing, they often combine power assertion with reasoning (Grusec, 2006; Grusec & Goodnow, 1994).

Frequent punishment, however, promotes only immediate compliance, not lasting changes in behavior. For example, Robbie's parents often punished by hitting, criticizing, and shouting at him. But as soon as they were out of sight, Robbie usually engaged in the unacceptable behavior again. The more harsh threats, angry physical control, and physical punishment children experience, the more likely they are to develop serious, lasting mental health problems. These include weak internalization of moral rules; depression, aggression, antisocial behavior, and poor academic performance in childhood and adolescence; and depression, alcohol abuse, criminality, and partner and child abuse in adulthood (Afifi et al., 2006; Bender et al., 2007; Gershoff, 2002a; Kochanska, Aksan, & Nichols, 2003; Lynch et al., 2006).

Repeated harsh punishment has wide-ranging, undesirable side effects:

- Parents often spank in response to children's aggression (Holden, Coleman, & Schmidt, 1995). Yet the punishment itself models aggression!
- Harshly treated children develop a chronic sense of being personally threatened, which prompts a focus on their own distress rather than a sympathetic orientation to others' needs.
- Children who are frequently punished learn to avoid the punishing adult, who, as a result, has little opportunity to teach desirable behaviors.
- By stopping children's misbehavior temporarily, harsh punishment gives adults immediate relief. For this reason, a punitive adult is likely to punish with greater frequency over time, a course of action that can spiral into serious abuse.
- Children, adolescents, and adults whose parents used *corporal punishment*—the use of physical force to inflict pain but not injury—are more accepting of such discipline (Deater-Deckard et al., 2003; Vitrup & Holden, 2010). In this way, use of physical punishment may transfer to the next generation.

Although corporal punishment spans the SES spectrum, its frequency and harshness are elevated among less educated, economically disadvantaged parents (Lansford et al., 2004, 2009). And consistently, parents with conflict-ridden marriages and with mental health problems (who are emotionally reactive, depressed, or aggressive) are more likely to be punitive and also to have hard-to-manage children, whose disobedience evokes more parental harshness (Berlin et al., 2009; Erath et al., 2006; Taylor et al., 2010). These parent-child similarities suggest that heredity contributes to the link between punitive discipline and children's adjustment difficulties.

But heredity is not a complete explanation. Return to page 73 in Chapter 2 to review findings indicating that good parenting can shield children who are genetically at risk for aggression

FIGURE 8.1 Prevalence of corporal punishment by children's age. Estimates are based on the percentage of parents in a nationally representative U.S. sample of nearly 1,000 reporting one or more instances of spanking, slapping, pinching, shaking, or hitting with a hard object in the past year. Physical punishment increases sharply during early childhood and then declines, but it is high at all ages. (From M. A. Straus & J. H. Stewart, 1999, "Corporal Punishment by American Parents: National Data on Prevalence, Chronicity, Severity, and Duration, in Relation to Child and Family Characteristics," *Clinical Child and Family Psychology Review*, 2, p. 59. Adapted with kind permission from Springer Science+Business Media and Murray A. Straus.)

and antisocial activity from developing those behaviors. Furthermore, longitudinal studies reveal that parental harshness and corporal punishment predict child and adolescent emotional and behavior problems, even after child, parenting, and family characteristics that might otherwise account for the relationship were controlled (Berlin et al., 2009; Lansford et al., 2009, 2011; Taylor et al., 2010).

In view of these findings, the widespread use of corporal punishment by American parents is cause for concern. Surveys of nationally representative samples of U.S. families reveal that although corporal punishment increases from infancy to age 5 and then declines, it is high at all ages (see Figure 8.1) (Gershoff et al., 2012; Straus & Stewart, 1999). Repeated use of physical punishment is more common with toddlers and preschoolers. And more than one-fourth of physically punishing parents report having used a hard object, such as a brush or a belt (Gershoff, 2002b).

A prevailing American belief is that corporal punishment, if implemented by caring parents, is harmless, perhaps even beneficial. But as the Cultural Influences box on the following page reveals, this assumption is valid only under conditions of limited use in certain social contexts.

Alternatives to Harsh Punishment. Alternatives to criticism, slaps, and spankings can reduce the side effects of punishment. A technique called **time out** involves removing children from the immediate setting—for example, by sending them to their rooms—until they are ready to act appropriately. When a child is out of control, a few minutes in time out can be

Cultural Influences

Ethnic Differences in the Consequences of Physical Punishment

In an African-American community, six elders, who had volunteered to serve as mentors for parents facing child-rearing challenges, met to discuss parenting issues at a social service agency. Their attitudes toward discipline were strikingly different from those of the white social workers who had brought them together. Each elder argued that successful child rearing required appropriate physical tactics. At the same time, they voiced strong disapproval of screaming or cursing at children, calling such out-of-control parental behavior “abusive.” Ruth, the oldest and most respected member of the group, characterized good parenting as a complex combination of warmth, teaching, talking nicely, and disciplining physically. She related how an older neighbor advised her to handle her own children when she was a young parent:

She said to me says, don’t scream . . . you talk to them real nice and sweet and when they do something ugly . . . she say you get a nice little switch and you won’t have any trouble with them and from that day that’s the way I raised ’em. (Mosby et al., 1999, pp. 511–512)

In several studies, corporal punishment predicted externalizing problems similarly among white, black, Hispanic, and Asian children (Gershoff et al., 2012; Pardini, Fite, & Burke, 2008). But other investigations point to ethnic variations.

In one, researchers followed several hundred families for 12 years, collecting

information from mothers on disciplinary strategies in early and middle childhood and from both mothers and their children on youth problem behaviors in adolescence (Lansford et al., 2004). Even after many child and family characteristics were controlled, the findings were striking: In Caucasian-American families, physical punishment was positively associated with adolescent aggression and antisocial behavior. In African-American families, by contrast, the more mothers had disciplined physically in childhood, the less their teenagers displayed angry, acting-out behavior and got in trouble at school and with the police.

According to the researchers, African-American and Caucasian-American parents tend to mete out physical punishment differently. In black families, such discipline is typically culturally approved and often mild, delivered in a context of parental warmth, and aimed at helping children become responsible adults. White parents, in contrast, consider physical punishment to be wrong, so when they resort to it, they are usually highly agitated and rejecting of the child (Dodge, McLoyd, & Lansford, 2006). As a result, many black children may view spanking as a practice carried out with their best interests in mind, whereas white children may regard it as an “act of personal aggression” (Gunnoe & Mariner, 1997, p. 768).

In support of this view, when several thousand ethnically diverse children were followed from the preschool through the early school years, spanking was associated

© ELLEN B. SENISI PHOTOGRAPHY

In African-American families, discipline often includes mild physical punishment. Because the practice is culturally approved and delivered in a context of parental warmth, children may view it as an effort to encourage maturity, not as an act of aggression.

with a rise in behavior problems if parents were cold and rejecting, but not if they were warm and supportive (McLoyd & Smith, 2002). And in another study, spanking predicted depressive symptoms only among African-American children whose mothers disapproved of the practice and, as a result, tended to use it when they were highly angry and frustrated (McLoyd et al., 2007).

These findings are not an endorsement of physical punishment. Other forms of discipline, including time out, withdrawal of privileges, and the positive strategies listed on page 268, are far more effective. But it is noteworthy that the meaning and impact of physical discipline vary sharply with its intensity level, context of warmth and support, and cultural approval.

enough to change behavior while also giving angry parents time to cool off (Morawska & Sanders, 2011). Another approach is *withdrawal of privileges*, such as watching a favorite TV program. Like time out, removing privileges allows parents to avoid using harsh techniques that can easily intensify into violence.

When parents do decide to use punishment, they can increase its effectiveness in three ways:

- *Consistency.* Permitting children to act inappropriately on some occasions but scolding them on others confuses them, and the unacceptable act persists (Acker & O’Leary, 1996).
- *A warm parent–child relationship.* Children of involved, caring parents find the interruption in parental affection that accompanies punishment especially unpleasant. They want to regain parental warmth and approval as quickly as possible.
- *Explanations.* Providing reasons for mild punishment helps children relate the misdeed to expectations for future behavior. This approach leads to a far greater reduction in misbehavior than using punishment alone (Larzelere et al., 1996).

Applying What We Know

Positive Parenting

Strategy	Explanation
Use transgressions as opportunities to teach.	When a child engages in harmful or unsafe behavior, intervene firmly, and then use induction, which motivates children to make amends and behave prosocially.
Reduce opportunities for misbehavior.	On a long car trip, bring back-seat activities that relieve children's restlessness. At the supermarket, converse with children and let them help with shopping. As a result, children learn to occupy themselves constructively when options are limited.
Provide reasons for rules.	When children appreciate that rules are rational, not arbitrary, they are more likely to strive to follow the rules.
Arrange for children to participate in family routines and duties.	By joining with adults in preparing a meal, washing dishes, or raking leaves, children develop a sense of responsible participation in family and community life and acquire many practical skills.
When children are obstinate, try compromising and problem solving.	When a child refuses to obey, express understanding of the child's feelings ("I know it's not fun to clean up"), suggest a compromise ("You put those away, I'll take care of these"), and help the child think of ways to avoid the problem in the future. Responding firmly but kindly and respectfully increases the likelihood of willing cooperation.
Encourage mature behavior.	Express confidence in children's capacity to learn and appreciation for effort and cooperation: "You gave that your best!" "Thanks for helping!" Adult encouragement fosters pride and satisfaction in succeeding, thereby inspiring children to improve further.

Sources: Berk, 2001; Grusec, 2006.

Positive Relationships, Positive Parenting. The most effective forms of discipline encourage good conduct—by building a mutually respectful bond with the child, letting the child know ahead of time how to act, and praising mature behavior. When sensitivity, cooperation, and shared positive emotion are evident in joint activities between parents and

preschoolers, children show firmer conscience development—expressing empathy after transgressions, playing fairly in games, and considering others' welfare (Kochanska et al., 2005, 2008). Parent-child closeness leads children to heed parental demands because the child feels a sense of commitment to the relationship.

See Applying What We Know above for ways to parent positively. Parents who use these strategies focus on long-term social and life skills—cooperation, problem solving, and consideration for others. As a result, they greatly reduce the need for punishment.

© MAURITIUS IMAGES GMBH/ALAMY

With parental encouragement, these sisters follow their route on a map during a long car trip. This positive parenting strategy keeps them constructively involved and reduces the likelihood of misbehavior.

The Cognitive-Developmental Perspective

The psychoanalytic and behaviorist approaches to morality focus on how children acquire ready-made standards of good conduct from adults. In contrast, the cognitive-developmental perspective regards children as *active thinkers* about social rules. As early as the preschool years, children make moral judgments, deciding what is right or wrong on the basis of concepts they construct about justice and fairness (Gibbs, 2010a; Turiel, 2006).

Young children have some well-developed ideas about morality. As long as researchers emphasize people's intentions, 3-year-olds say that a person with bad intentions—someone who deliberately frightens, embarrasses, or otherwise hurts another—is more deserving of punishment than a well-intentioned person

(Helwig, Zelazo, & Wilson, 2001; Jones & Thompson, 2001). Around age 4, children know that a person who expresses an insincere intention—saying, “I’ll come over and help you rake leaves,” while not intending to do so—is lying (Maas, 2008). And 4-year-olds approve of telling the truth and disapprove of lying, even when a lie remains undetected (Bussey, 1992).

Furthermore, preschoolers distinguish **moral imperatives**, which protect people’s rights and welfare, from two other types of rules and expectations: **social conventions**, customs determined solely by consensus, such as table manners and politeness rituals (saying “hello,” “please,” “thank you”); and **matters of personal choice**, such as friends, hairstyle, and leisure activities, which do not violate rights and are up to the individual (Killen, Margie, & Sinno, 2006; Nucci, 1996; Smetana, 2006). Interviews with 3- and 4-year-olds reveal that they judge moral violations (stealing an apple) as more wrong than violations of social conventions (eating ice cream with your fingers). And preschoolers’ concern with personal choice, conveyed through statements like “I’m gonna wear *this* shirt,” serves as the springboard for moral concepts of individual rights, which will expand greatly in middle childhood and adolescence (Nucci, 2005).

Within the moral domain, however, preschool and young school-age children tend to reason *rigidly*, making judgments based on salient features and consequences while neglecting other important information. For example, they are more likely than older children to claim that stealing and lying are always wrong, even when a person has a morally sound reason for doing so (Lourenco, 2003). Their explanations for why hitting others is wrong, even in the absence of rules against hitting, are simplistic and centered on physical harm: “When you get hit, it hurts, and you start to cry” (Nucci, 2008). And their focus on outcomes means that they fail to realize that a promise is still a promise, even if it is unfulfilled (Maas, 2008; Maas & Abbeduto, 2001).

Still, preschoolers’ ability to distinguish moral imperatives from social conventions is impressive. How do they do so? According to cognitive-developmental theorists, they *actively make sense* of their experiences (Turiel, 2006). They observe that after a moral offense, peers respond with strong negative emotion, describe their own injury or loss, tell another child to stop, or retaliate. And an adult who intervenes is likely to call attention to the victim’s rights and feelings. In contrast, violations of social convention elicit less intense peer reactions. And in these situations, adults usually demand obedience without explanation or point to the importance of keeping order.

Cognition and language support preschoolers’ moral understanding, but social experiences are vital. Disputes with siblings and peers over rights, possessions, and property allow preschoolers to negotiate, compromise, and work out their first ideas about justice and fairness. Children also learn from warm, sensitive parental communication and from observing the way adults handle rule violations to protect the welfare of others (Turiel & Killen, 2010). Children who are advanced in moral thinking tend to have parents who adapt their communications about fighting, honesty, and ownership to what their children can understand, tell stories with moral implications, encourage

prosocial behavior, and gently stimulate the child to think further, without being hostile or critical (Janssens & Deković, 1997; Walker & Taylor, 1991a).

Preschoolers who verbally and physically assault others, often with little or no provocation, are already delayed in moral reasoning (Helwig & Turiel, 2004; Sanderson & Siegal, 1988). Without special help, such children show long-term disruptions in moral development, deficits in self-control, and ultimately an antisocial lifestyle.

The Other Side of Morality: Development of Aggression

Beginning in late infancy, all children display aggression at times. As interactions with siblings and peers increase, so do aggressive outbursts. By the second year, aggressive acts with two distinct purposes emerge. Initially, the most common is **proactive** (or *instrumental*) **aggression**, in which children act to fulfill a need or desire—obtain an object, privilege, space, or social reward, such as adult or peer attention—and unemotionally attack a person to achieve their goal. The other type, **reactive** (or *hostile*) **aggression**, is an angry, defensive response to provocation or a blocked goal and is meant to hurt another person (Dodge, Coie, & Lynam, 2006; Little et al., 2003).

Proactive and reactive aggression come in three forms, which are the focus of most research:

- **Physical aggression** harms others through physical injury—pushing, hitting, kicking, or punching others or destroying another’s property.
- **Verbal aggression** harms others through threats of physical aggression, name-calling, or hostile teasing.
- **Relational aggression** damages another’s peer relationships through social exclusion, malicious gossip, or friendship manipulation.

Although verbal aggression is always direct, physical and relational aggression can be either *direct* or *indirect*. For example, hitting injures a person directly, whereas destroying property inflicts physical harm indirectly. Similarly, saying, “Do what I say, or I won’t be your friend,” conveys relational aggression directly, while spreading rumors, refusing to talk to a peer, or manipulating friendships by saying behind someone’s back, “Don’t play with her; she’s a nerd,” do so indirectly.

In early childhood, verbal aggression gradually replaces physical aggression (Alink et al., 2006; Tremblay et al., 1999). And proactive aggression declines as preschoolers’ improved capacity to delay gratification enables them to avoid grabbing others’ possessions. But reactive aggression in verbal and relational forms tends to rise over early and middle childhood (Côté et al., 2007; Tremblay, 2000). Older children are better able to recognize malicious intentions and, as a result, more often respond in hostile ways.

By age 17 months, boys are more physically aggressive than girls—a difference found throughout childhood in many cultures

© BOB EBBERSEN/ALAMY

These preschoolers display proactive aggression, pushing and grabbing as they argue over a game. As children learn to compromise and share, and as their capacity to delay gratification improves, proactive aggression declines.

(Baillargeon et al., 2007; Card et al., 2008). The sex difference is due in part to biology—in particular, to male sex hormones (androgens) and temperamental traits (activity level, irritability, impulsivity) on which boys exceed girls. Gender-role conformity is also important. As soon as preschoolers are aware of gender stereotypes—that males and females are expected to behave differently—physical aggression drops off more sharply for girls than for boys (Fagot & Leinbach, 1989).

Although girls have a reputation for being both more verbally and relationally aggressive than boys, the sex difference is small (Crick et al., 2004, 2006; Crick, Ostrov, & Werner, 2006). Beginning in the preschool years, girls concentrate most of their aggressive acts in the relational category. Boys inflict harm in more variable ways and, therefore, display overall rates of aggression that are much higher than girls'.

At the same time, girls more often use indirect relational tactics that—in disrupting intimate bonds especially important to girls—can be particularly mean. Whereas physical attacks are usually brief, acts of indirect relational aggression may extend for hours, weeks, or even months (Nelson, Robinson, & Hart, 2005; Underwood, 2003). In one instance, a 6-year-old girl formed a “pretty-girls club” and—for nearly an entire school year—convinced its members to exclude several classmates by saying they were “ugly and smelly.”

An occasional aggressive exchange between preschoolers is normal. But children who are emotionally negative, impulsive, and disobedient are prone to early, high rates of physical or relational aggression (or both) that often persist, placing them at risk for internalizing and externalizing difficulties, social skills deficits, and antisocial activity in middle childhood and adolescence (Campbell et al., 2006; Côté et al., 2007; Vaillancourt et al., 2003). These negative outcomes, however, depend on child-rearing conditions.

The Family as Training Ground for Aggressive Behavior.

“I can’t control him, he’s impossible,” Robbie’s mother, Nadine, complained to Leslie one day. When Leslie asked if Robbie might be troubled by something happening at home, she discovered that his parents fought constantly and resorted to harsh, inconsistent discipline. The same child-rearing practices that undermine moral internalization—love withdrawal, power assertion, critical remarks, physical punishment, and inconsistent discipline—are linked to aggression from early childhood through adolescence in diverse cultures, with most of these practices predicting both physical and relational forms (Bradford et al., 2003; Casas et al., 2006; Côté et al., 2007; Gershoff et al., 2010; Kuppens et al., 2009; Nelson et al., 2006a).

In families like Robbie’s, anger and punitiveness quickly create a conflict-ridden family atmosphere and an “out-of-control” child. The pattern begins with forceful discipline, which occurs more often with stressful life experiences, a parent with an unstable personality, or a difficult child (Dodge, Coie, & Lynam, 2006). Typically, the parent threatens, criticizes, and punishes, and the child angrily resists until the parent “gives in.” As these cycles become more frequent, they generate anxiety and irritability among other family members, who soon join in the hostile interactions. Compared with siblings in typical families, preschool siblings who have critical, punitive parents are more aggressive toward one another. Destructive sibling conflict, in turn, quickly spreads to peer relationships, contributing to poor impulse control and antisocial behavior by the early school years (Garcia et al., 2000; Ostrov, Crick, & Stauffacher, 2006).

Boys are more likely than girls to be targets of harsh, inconsistent discipline because they are more active and impulsive and therefore harder to control. When children who are extreme in these characteristics are exposed to emotionally negative, inept parenting, their capacity for emotional self-regulation, empathic responding, and guilt after transgressions is disrupted (Eisenberg, Eggum, & Edwards, 2010). Consequently, they lash out when disappointed, frustrated, or faced with a sad or fearful victim.

Children subjected to these family processes acquire a distorted view of the social world, often seeing hostile intent where it does not exist and, as a result, making many unprovoked attacks (Lochman & Dodge, 1998; Orbio de Castro et al., 2002). And some, who conclude that aggression “works” to access rewards and control others, callously use it to advance their own goals and are unconcerned about causing suffering in others—an aggressive style associated with later more severe conduct problems, violent behavior, and delinquency (Marsee & Frick, 2010).

Highly aggressive children tend to be rejected by peers, to fail in school, and (by adolescence) to seek out deviant peer groups that lead them toward violent delinquency and adult criminality. We will consider this life-course path of antisocial activity in Chapter 12.

Violent Media and Aggression. In the United States, 57 percent of TV programs between 6 A.M. and 11 P.M. contain violent scenes, often portraying repeated aggressive acts that

go unpunished. Victims of TV violence are rarely shown experiencing serious harm, and few programs condemn violence or depict other ways of solving problems (Center for Communication and Social Policy, 1998). Verbally and relationally aggressive acts are particularly frequent in reality TV shows (Coyne, Robinson, & Nelson, 2010). And violent content is 9 percent above average in children's programming, with cartoons being the most violent.

LOOK AND LISTEN

Watch a half-hour of Saturday morning cartoons and a prime-time movie on TV, and tally the number of violent acts, including those that go unpunished. How often did violence occur in each type of program? What do young viewers learn about the consequences of violence? ●

Reviewers of thousands of studies have concluded that TV violence increases the likelihood of hostile thoughts and emotions and of verbally, physically, and relationally aggressive behavior (Comstock & Scharrer, 2006; Ostrov, Gentile, & Crick, 2006). And a growing number of studies confirm that playing violent video games has similar effects (Anderson et al., 2008; Hoffferth, 2010). Although young people of all ages are susceptible, preschool and young school-age children are especially likely to imitate TV violence because they believe that much TV fiction is real and accept what they see uncritically.

Violent programming not only creates short-term difficulties in parent and peer relations but also has lasting negative consequences. In several longitudinal studies, time spent watching TV in childhood and adolescence predicted aggressive behavior in adulthood, after other factors linked to TV viewing (such as prior child and parent aggression, IQ, parent education, family income, and neighborhood crime) were controlled (see

FIGURE 8.2 Relationship of television viewing in childhood and early adolescence to aggressive acts in adolescence and early adulthood. Interviews with more than 700 parents and youths revealed that the more TV watched in childhood and early adolescence, the greater the annual number of aggressive acts committed by the young person, as reported in follow-up interviews at ages 16 and 22. (Adapted from Johnson et al., 2002.)

Figure 8.2) (Graber et al., 2006; Huesmann, 1986; Huesmann et al., 2003; Johnson et al., 2002). Aggressive children and adolescents have a greater appetite for violent TV and computer games. And boys devote more time to violent media than girls, in part because of male-oriented themes of conquest and adventure. But even in nonaggressive children, violent TV sparks hostile thoughts and behavior; its impact is simply less intense (Bushman & Huesmann, 2001).

The ease with which television and video games can manipulate children's attitudes and behavior has led to strong public pressure to improve media content. In the United States, the First Amendment right to free speech has hampered efforts to regulate TV broadcasting. Instead, all programs must be rated for violent and sexual content, and all new TV sets are required to contain the V-chip, which allows parents to block undesired material. In general, parents bear most responsibility for regulating their children's exposure to media violence and other inappropriate content. As with the V-chip for TV, parents can control children's Internet access by using filters or programs that monitor website visits. Yet surveys of U.S. parents indicate that 20 to 30 percent of preschoolers and about half of school-age children experience no limits on TV or computer use at home. Some children begin visiting websites without parental supervision as early as age 4 (Rideout, Foehr, & Roberts, 2010; Rideout & Hamel, 2006; Varnhagen, 2007). Applying What We Know on page 272 lists strategies parents can use to protect their children from undesirable TV and computer fare.

Watching TV violence increases the likelihood of hostile thoughts and emotions and aggressive behavior. Playing violent video games has similar effects.

Applying What We Know

Regulating TV and Computer Use

Strategy	Description
Limit TV viewing and computer use.	Parents should provide clear rules limiting children's TV and computer use and stick to them. The TV or computer should not be used as a babysitter for young children. Placing a TV or a computer in a child's bedroom substantially increases use and makes the child's activity hard to monitor.
Avoid using TV or computer time as a reward.	When TV or computer access is used as a reward or withheld as a punishment, children become increasingly attracted to it.
When possible, watch TV with children.	By raising questions about realism in TV depictions, expressing disapproval of on-screen behavior, and encouraging discussion, adults help children understand and evaluate TV content.
Link TV content to everyday learning experiences.	Parents can extend TV learning in ways that encourage children to engage actively with their surroundings. For example, a program on animals might spark a trip to the zoo, a visit to the library for a book about animals, or new ways of observing and caring for the family pet.
Model good TV and computer practices.	Parents' media behavior—avoiding excessive TV and computer use and limiting exposure to harmful content—influences their children's media behavior.

Helping Children and Parents Control Aggression.

Treatment for aggressive children is best begun early, before their antisocial behavior becomes well-practiced and difficult to change. Breaking the cycle of hostilities between family members and promoting effective ways of relating to others are crucial.

Leslie suggested that Robbie's parents enroll in a parent training program aimed at improving the parenting of children with conduct problems. In one approach, called *Incredible Years*, parents complete 18 weekly group sessions facilitated by two professionals, who teach positive parenting techniques for promoting preschool and school-age children's academic, emotional, and social skills and for managing disruptive behaviors (Webster-Stratton & Reid, 2010b). A complementary six-day training program for teachers, aimed at improving classroom management strategies and strengthening children's social skills, is also available. And a 22-week program intervenes directly with children, teaching appropriate classroom behavior, self-control, and social skills.

Evaluations in which families with aggressive children were randomly assigned to either *Incredible Years* or control groups reveal that the program is highly effective at improving parenting and reducing child behavior problems. Combining parent training with teacher and/or child intervention strengthens child outcomes (Webster-Stratton & Herman, 2010). And effects of parent training endure. In one long-term follow-up, 75 percent of young children with serious conduct problems whose parents participated in *Incredible Years* were well-adjusted as teenagers (Webster-Stratton & Reid, 2010a; Webster-Stratton, Rinaldi, & Reid, 2011).

Other interventions focus on modifying aggressive children's distorted social perspectives, by encouraging them to attend to nonhostile social cues, seek additional information

before acting, and take the perspective of others, which promotes empathy and sympathetic concern for others. Another approach is to teach effective conflict-resolution skills. At preschool, Robbie participated in a social problem-solving intervention. Over several months, he met with Leslie and a small group of classmates to act out common conflicts using puppets, discuss alternatives for settling disputes, and practice successful strategies. Children who receive such training show gains in social competence still present several months later (Bierman & Powers, 2009; Shure & Abersson, 2005).

Finally, Robbie's parents sought counseling for their marital problems. When parents receive help in coping with stressors in their own lives, interventions aimed at reducing children's aggression are even more effective (Kazdin & Whitley, 2003).

ASK YOURSELF

APPLY Alice and Wayne want their two children to become morally mature, caring individuals. List some parenting practices they should use and some they should avoid.

REFLECT Which types of punishment for a misbehaving preschooler do you endorse, and which types do you reject? Why?

Gender Typing

Gender typing refers to any association of objects, activities, roles, or traits with one sex or the other in ways that conform to cultural stereotypes (Liben & Bigler, 2002). In Leslie's classroom, girls spent more time in the housekeeping, art, and reading corners, while boys gathered more often in spaces devoted to blocks, woodworking, and active play. Already, the children had acquired many gender-linked beliefs and preferences and tended to play with peers of their own sex.

The same theories that provide accounts of morality have been used to explain children's gender typing: *social learning theory*, with its emphasis on modeling and reinforcement, and *cognitive-developmental theory*, with its focus on children as active thinkers about their social world. As we will see, neither is adequate by itself. *Gender schema theory*, a third perspective that combines elements of both, has gained favor. In the following sections, we consider the early development of gender typing.

Gender-Stereotyped Beliefs and Behavior

Even before children can label their own sex consistently, they have begun to acquire common associations with gender—men as rough and sharp, women as soft and round. In one study, 18-month-olds linked such items as fir trees and hammers with males, although they had not yet learned comparable feminine associations (Eichstedt et al., 2002). Recall from Chapter 6 that around age 2, children use such words as *boy*, *girl*, *lady*, and *man* appropriately. As soon as gender categories are established, children sort out what they mean in terms of activities and behavior.

Preschoolers associate toys, articles of clothing, tools, household items, games, occupations, colors (blue and pink), and behaviors (physical and relational aggression) with one sex or the other (Banse et al., 2010; Giles & Heyman, 2005; Poulin-Dubois et al., 2002). And their actions reflect their beliefs, not only in play preferences but in personality traits as well. As we have seen, boys tend to be more active, impulsive, assertive, and physically aggressive. Girls tend to be more fearful, dependent, emotionally sensitive, compliant, advanced in effortful control, and skilled at understanding self-conscious emotions and at inflicting indirect relational aggression (Bosacki & Moore, 2004; Else-Quest et al., 2006; Underwood, 2003).

During early childhood, gender-stereotyped beliefs strengthen—so much so that many children apply them as blanket rules rather than as flexible guidelines. When children were asked whether gender stereotypes could be violated, half or more of 3- and 4-year-olds answered “no” to clothing, hairstyle, and play with certain toys (Barbie dolls and G.I. Joes) (Blakemore, 2003). Furthermore, most 3- to 6-year-olds are firm about not wanting to be friends with a child who violates a gender stereotype (a boy who wears nail polish, a girl who plays with trucks) or to attend a school where such violations are allowed (Ruble et al., 2007).

© LAURA DWIGHT PHOTOGRAPHY

Early in the preschool years, gender typing is well under way. Girls tend to play with girls and are drawn to toys and activities that emphasize nurturance and cooperation.

The rigidity of preschoolers' gender stereotypes helps us understand some commonly observed everyday behaviors. When Leslie showed her class a picture of a Scottish bagpiper wearing a kilt, the children insisted, “Men don't wear skirts!” During free play, they often exclaimed that girls can't be police officers and boys don't take care of babies. These one-sided judgments are a joint product of gender stereotyping in the environment and young children's cognitive limitations (Trautner et al., 2005). Most preschoolers do not yet realize that characteristics *associated with* being male or female—activities, toys, occupations, hairstyle, and clothing—do not *determine* a person's sex.

Biological Influences on Gender Typing

The sex differences just described appear in many cultures around the world (Munroe & Romney, 2006; Whiting & Edwards, 1988). Certain ones—male activity level and physical aggression, female emotional sensitivity, and preference for same-sex playmates—are widespread among mammalian species (de Waal, 1993, 2001). According to an evolutionary perspective, the adult life of our male ancestors was largely oriented toward competing for mates, that of our female ancestors toward rearing children. Therefore, males became genetically primed for dominance and females for intimacy, responsiveness, and cooperativeness. Evolutionary theorists claim that family and cultural forces can influence the intensity of biologically based sex differences. But experience cannot eradicate aspects of gender typing that served adaptive functions in human history (Konner, 2010; Maccoby, 2002).

Experiments with animals reveal that prenatally administered androgens increase active play and aggression and suppress maternal caregiving in both male and female mammals

(Sato et al., 2004). Eleanor Maccoby (1998) argues that sex hormones also affect human play styles, leading to rough, noisy movements among boys and calm, gentle actions among girls. Then, as children interact with peers, they choose partners whose interests and behaviors are compatible with their own. Preschool girls increasingly seek out other girls and like to play in pairs because they share a preference for quieter activities involving cooperative roles. Boys come to prefer larger-group play with other boys, who share a desire to run, climb, play-fight, compete, and build up and knock down (Fabes, Martin, & Hanish, 2003). At age 4, children spend three times as much time with same-sex as with other-sex playmates. By age 6, this ratio has climbed to 11 to 1 (Martin & Fabes, 2001).

Even stronger support for the role of biology in human gender typing comes from research on girls exposed prenatally to high levels of androgens, due either to normal variation in hormone levels or to a genetic defect. In both instances, these girls showed more “masculine” behavior—a preference for trucks and blocks over dolls, for active over quiet play, and for boys as playmates—even when parents encouraged them to engage in gender-typical play (Cohen-Bendahan, van de Beek, & Berenbaum, 2005; Pasterski et al., 2005).

Research on boys with low early androgen exposure, either because production by the testes is reduced or because body cells are androgen-insensitive, also yields consistent findings (Jürgensen et al., 2007). The greater the degree of impairment, the more these boys display “feminine” behaviors, including toy choices and preference for girl playmates.

Environmental Influences on Gender Typing

A wealth of evidence reveals that environmental forces—at home, at school, and in the community—build on genetic influences to promote vigorous gender typing in early childhood.

Parents. Beginning at birth, parents have different expectations of sons than of daughters. Many parents prefer that their children play with “gender-appropriate” toys. And they tend to describe achievement, competition, and control of emotion as important for sons and warmth, “ladylike” behavior, and closely supervised activities as important for daughters (Brody, 1999; Turner & Gervai, 1995).

Actual parenting practices reflect these beliefs. Parents give their sons toys that stress action and competition (cars, tools, footballs) and their daughters toys that emphasize nurturance, cooperation, and physical attractiveness (dolls, tea sets, jewelry) (Leaper, 1994; Leaper & Friedman, 2007). Parents also actively reinforce independence in boys and closeness and dependency in girls. For example, parents react more positively when a son plays with cars and trucks, demands attention, runs and climbs, or tries to take toys from others. When interacting with daughters, they more often direct play activities, provide help, encourage participation in household tasks, make supportive statements (approval, praise, and agreement), and refer to emotions (Clearfield & Nelson, 2006; Fagot & Hagan, 1991; Kuebli, Butler,

CAVAN IMAGES/GETTY IMAGES

Of the two sexes, boys are more gender-typed. Fathers, especially, promote “masculine” behavior in their preschool sons through activities that stress action and competition.

& Fivush, 1995). Gender-typed play contexts amplify these communication differences. For example, when playing housekeeping, mothers engage in high rates of supportive emotion talk with girls (Leaper, 2000).

As these findings suggest, language is a powerful indirect means for teaching children about gender stereotypes. Earlier we saw that most young children hold rigid beliefs about gender. Although their strict views are due in part to cognitive limitations, they also draw on relevant social experiences to construct these beliefs. Even parents who believe strongly in gender equality unconsciously use language that highlights gender distinctions and informs children about traditional gender roles (see the Social Issues: Education box on the following page).

LOOK AND LISTEN

Observe a parent discussing a picture book with a 3- to 6-year-old. How many times did the parent make generic statements about gender? How about the child? Did the parent accept or correct the child’s generic utterances? ●

Of the two sexes, boys are more gender-typed. Fathers, especially, are more insistent that boys conform to gender roles. They place more pressure to achieve on sons than on daughters and are less tolerant of “cross-gender” behavior in sons—more concerned when a boy acts like a “sissy” than when a girl acts like a “tomboy” (Sandnabba & Ahlberg, 1999; Wood, Desmarais, & Gugula, 2002). Parents who hold nonstereotyped values and consciously avoid behaving in these ways have children who are less gender-typed (Brody, 1997; Tenenbaum & Leaper, 2002).

Teachers. Teachers often act in ways that extend gender-role learning. Several times, Leslie caught herself emphasizing gender distinctions when she called out, “Will the girls line up on one side and the boys on the other?” or pleaded, “Boys, I wish you’d quiet down like the girls!”

Social Issues: Education

Young Children Learn About Gender Through Mother–Child Conversations

In an investigation of the power of language to shape preschoolers' beliefs about gender, mothers were asked to converse with their 2- to 6-year-olds about picture books containing images both consistent and inconsistent with gender stereotypes (Gelman, Taylor, & Nguyen, 2004). Each picture was accompanied by the question, "Who can X?" where X was the activity on the page.

A detailed analysis of picture-book conversations revealed that mothers' directly expressed gender attitudes were neutral, largely because they mostly posed questions to their children, such as, "Who's driving that boat?" "Who can be a sailor? Boys and girls?" But by age 4, children often voiced stereotypes ("No, only boys can do that!"), and nearly one-third of the time, mothers affirmed them ("OK, only boys"). In other instances mothers either moved on or repeated the question. But rarely—just 2 percent of the time—did they explicitly counter a child's stereotype, and usually only when the book itself included stereotype-inconsistent pictures.

Although the mothers were not asked to discuss gender, they called attention to it even when they did not need to do so. In English, many nouns referring to people

convey age-related information (*kid, baby, 2-year-old, preschooler, teenager, grownup, senior*), whereas only a few encode gender (*male, female, sister, brother, aunt, uncle*). Yet when referring to persons, mothers called attention to gender more than half the time, even though the people shown in the books varied as much in age as in gender. Referring often to gender encourages young children to sort the social world into gender categories.

Furthermore, both mothers and children frequently expressed *generic utterances*—ones that were broad in scope, referring to many, or nearly all, males and females: "Boys can be sailors." "Most girls don't like trucks." Even generics that were gender-neutral ("Lots of girls in this book") or that denied a stereotype ("Boys can be ballet dancers") prompted children to view individuals of the same gender as alike and to ignore exceptions.

Mothers' and children's use of generics increased with age (see Figure 8.3). At age 2, mothers introduced these generalizations nearly three times as often as children. But by age 6 children were producing generics more often than mothers. Generics were

especially common in speech to and from boys, likely contributing to boys' stronger gender typing.

Even though these mothers over-

While reading, this mother may unconsciously teach her child to see the world in gender-linked terms—by referring to gender unnecessarily or by making generic gender statements ("Most girls prefer X"; "Boys usually don't like X").

whelmingly believed in gender equality, in conversing with their children, they provided a wealth of implicit cues that foster gender-stereotyping. Adults can combat children's gender stereotyped beliefs by refraining from labeling gender unnecessarily (substituting *friend* for *boy* or *girl*), using references to individuals ("That person wants to be firefighter") or qualifiers ("Some boys and some girls want to be firefighters"), countering children's stereotypical claims, and discussing gender biases in language with children and asking them to avoid using gender labels and generics.

FIGURE 8.3 Mothers' and children's use of generic reference to gender during storybook conversations. Mothers' and children's use of generics increased dramatically with age. At age 2, mothers produced more generics than children. By age 6, children produced more generics than mothers. (From S. A. Gelman, M. G. Taylor, & S. P. Nguyen, "Mother–Child Conversations About Gender," *Monographs of the Society for Research in Child Development*, 69[1, Serial No. 275], p. 46. © 2004 The Society for Research in Child Development, Inc. Reproduced with permission of John Wiley & Sons Ltd)

Like parents, preschool teachers give girls more encouragement to participate in adult-structured activities. Girls frequently cluster around the teacher, following directions, whereas boys are attracted to play areas where teachers are minimally involved (Campbell, Shirley, & Candy, 2004; Powlishta, Serbin, & Moller, 1993). As a result, boys and girls practice different social behaviors. Compliance and bids for help occur more often in adult-structured contexts; assertiveness, leadership, and creative use of materials in unstructured pursuits.

Furthermore, as early as kindergarten, teachers give more overall attention (both positive and negative) to boys than to girls—a difference evident in diverse countries, including China, England, and the United States. They tend to praise boys more for their academic knowledge, perhaps as a means of motivating them because boys' school performance is behind that of girls. Teachers also use more disapproval and controlling discipline with boys (Chen & Rao, 2011; Davies, 2008; Swinson & Harrop, 2009). They seem to expect boys to misbehave more often—a belief based partly on boys' actual behavior and partly on gender stereotypes.

Peers. The more preschoolers play with same-sex partners, the more their behavior becomes gender-typed—in toy choices, activity level, aggression, and adult involvement (Martin & Fabes, 2001). By age 3, same-sex peers positively reinforce one another for gender-typed play by praising, imitating, or joining in. In contrast, when preschoolers engage in “cross-gender” activities—for example, when boys play with dolls or girls with cars and trucks—peers criticize them. Boys are especially intolerant of cross-gender play in other boys (Thorne, 1993). A boy who frequently crosses gender lines is likely to be ostracized by other boys, even when he does engage in “masculine” activities!

Children also develop different styles of social influence in gender-segregated peer groups. To get their way in large-group play, boys often rely on commands, threats, and physical force. Girls' preference for playing in pairs leads to greater concern with a partner's needs, evident in girls' use of polite requests, persuasion, and acceptance. Girls soon find that these tactics succeed with other girls but not with boys, who ignore their courteous overtures (Leaper, 1994; Leaper, Tenenbaum, & Shaffer, 1999). Boys' unresponsiveness gives girls another reason to stop interacting with them.

Over time, children come to believe in the “correctness” of gender-segregated play, which further strengthens gender segregation and gender-stereotyped activities (Martin et al., 1999). As boys and girls separate, *in-group favoritism*—more positive evaluations of members of one's own gender—becomes another factor that sustains the separate social worlds of boys and girls, resulting in “two distinct subcultures” of knowledge, beliefs, interests, and behaviors (Maccoby, 2002).

Although gender segregation is pervasive, cultural variations exist in the extent of gender-typed communication within such groups. African-American and Hispanic girls from low-SES families tend to be more assertive and independent when interacting with one another and with boys than are Caucasian-

American girls (Goodwin, 1998). Similarly, in a comparison of Chinese and U.S. preschoolers' play, Chinese girls used more direct commands and criticism when interacting with same- and other-sex peers (Kyratzis & Guo, 2001). In cultures where interdependence is highly valued, perhaps children do not feel a need to work as hard at maintaining same-sex peer relations through traditional interaction.

The Broader Social Environment. Finally, although children's everyday environments have changed to some degree, they continue to present many examples of gender-typed behavior—in occupations, leisure activities, media portrayals, and achievements of men and women. As we will see next, children soon come to view not just their social surroundings but also themselves through a “gender-biased lens”—a perspective that can seriously restrict their interests and learning opportunities.

Gender Identity

As adults, each of us has a **gender identity**—an image of oneself as relatively masculine or feminine in characteristics. By middle childhood, researchers can measure gender identity by asking children to rate themselves on personality traits. A child or adult with a “masculine” identity scores high on traditionally masculine items (such as *ambitious*, *competitive*, and *self-sufficient*) and low on traditionally feminine items (such as *affectionate*, *cheerful*, and *soft-spoken*). Someone with a “feminine” identity does the reverse. And a substantial minority (especially females) have a gender identity called **androgyny**, scoring high on both masculine and feminine personality characteristics.

Gender identity is a good predictor of psychological adjustment. “Masculine” and androgynous children and adults have higher self-esteem than “feminine” individuals (Boldizar, 1991; DiDonato & Berenbaum, 2011; Harter, 2006). In line with their flexible self-definitions, androgynous individuals are more adaptable—able to show masculine independence or feminine sensitivity, depending on the situation (Huyck, 1996; Taylor & Hall, 1982). The existence of an androgynous identity demonstrates that children can acquire a mixture of positive qualities traditionally associated with each gender—an orientation that may best help them realize their potential.

Emergence of Gender Identity. How do children develop a gender identity? According to *social learning theory*, behavior comes before self-perceptions. Preschoolers first acquire gender-typed responses through modeling and reinforcement and only later organize these behaviors into gender-linked ideas about themselves. In contrast, *cognitive-developmental theory* maintains that self-perceptions come before behavior. Over the preschool years, children acquire a cognitive appreciation of the permanence of their sex. They develop **gender constancy**—a full understanding of the biologically based permanence of their gender, including the realization that sex remains the same even if clothing, hairstyle, and play activities change. Then children use this knowledge to guide their behavior.

Children younger than age 6 who watch an adult dress a doll in “other-gender” clothing typically insist that the doll’s sex has also changed (Chauhan, Shastri, & Mohite, 2005; Fagot, 1985). Attainment of gender constancy is strongly related to ability to pass verbal appearance–reality tasks (see page 228 in Chapter 7) (Trautner, Gervai, & Nemeth, 2003). Indeed, gender constancy tasks can be considered a type of appearance–reality problem, in that children must distinguish what a person looks like from who he or she really is.

In many cultures, young children do not have access to basic biological knowledge about gender because they rarely see members of the other sex naked. But giving preschoolers information about genital differences does not result in gender constancy. Those who have such knowledge usually say changing a doll’s clothing will not change its sex, but when asked to justify their responses, they do not refer to sex as an innate, unchanging quality of people (Szkrybalo & Ruble, 1999). This suggests that cognitive immaturity, not social experience, is responsible for preschoolers’ difficulty grasping the permanence of sex.

Is cognitive-developmental theory correct that gender constancy is responsible for children’s gender-typed behavior? Evidence for this assumption is weak. “Gender-appropriate” behavior appears so early in the preschool years that its initial appearance must result from modeling and reinforcement, as social learning theory suggests. Although outcomes are not entirely consistent, some evidence suggests that gender constancy actually contributes to the emergence of more flexible gender-role attitudes during the school years (Ruble et al., 2007). But overall, the impact of gender constancy on gender typing is not great. As research in the following section reveals,

gender-role adoption is more powerfully affected by children’s beliefs about how close the connection must be between their own gender and their behavior.

Gender Schema Theory. Gender schema theory is an information-processing approach that combines social learning and cognitive-developmental features. It explains how environmental pressures and children’s cognitions work together to shape gender-role development (Martin & Halverson, 1987; Martin, Ruble, & Szkrybalo, 2002). At an early age, children pick up gender-typed preferences and behaviors from others. At the same time, they organize their experiences into *gender schemas*, or masculine and feminine categories, that they use to interpret their world. As soon as preschoolers can label their own gender, they select gender schemas consistent with it (“Only boys can be doctors” or “Cooking is a girl’s job”) and apply those categories to themselves. Their self-perceptions then become gender-typed and serve as additional schemas that children use to process information and guide their own behavior.

We have seen that individual differences exist in the extent to which children endorse gender-typed views. Figure 8.4 shows different cognitive pathways for children who often apply gender schemas to their experiences and those who rarely do (Liben & Bigler, 2002). Consider Billy, who encounters a doll. If Billy is a *gender-schematic child*, his *gender-salience filter* immediately makes gender highly relevant. Drawing on his prior learning, he asks himself, “Should boys play with dolls?” If he answers “yes” and the toy interests him, he will explore it and learn more about it. If he answers “no,” he will avoid the “gender-inappropriate” toy. But if Billy is a *gender-aschematic child*—one

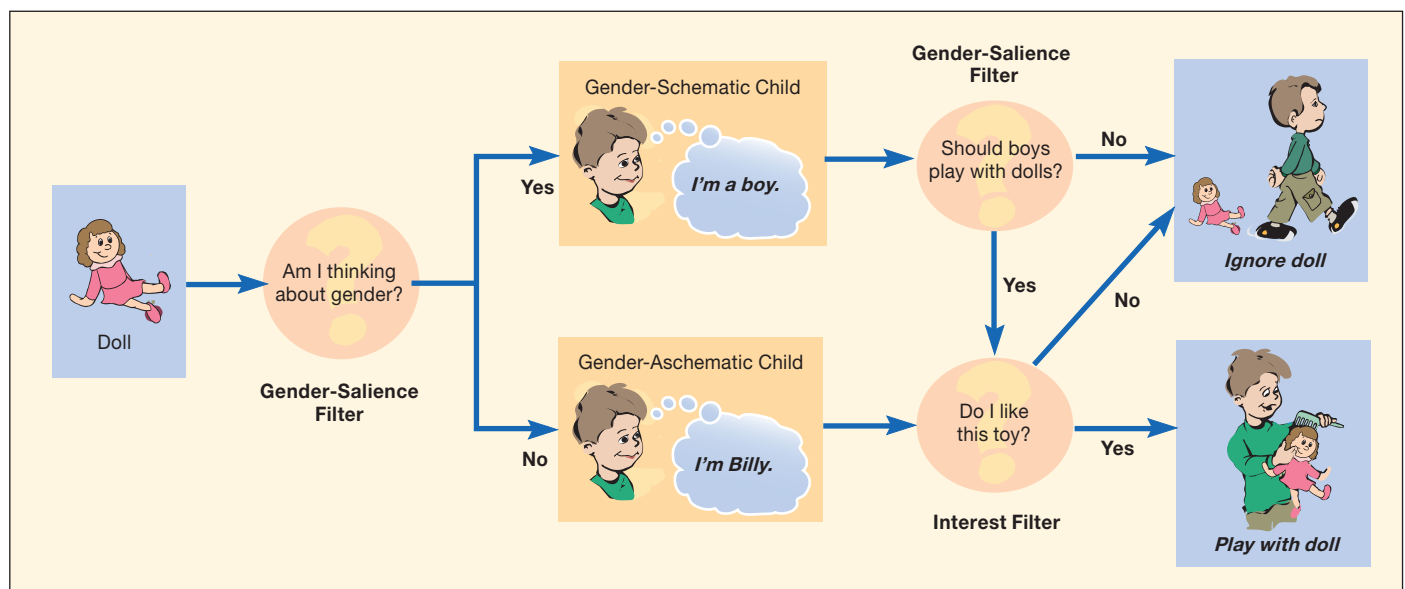

FIGURE 8.4 Cognitive pathways for gender-schematic and gender-aschematic children. In *gender-schematic children*, the gender-salience filter immediately makes gender highly relevant: Billy sees a doll and thinks, “I’m a boy. Should boys play with dolls?” Drawing on his experiences, he answers “yes” or “no.” If he answers “yes” and the doll interests him, he plays with the doll. If he answers “no,” he avoids the “gender-inappropriate” toy. *Gender-aschematic children* rarely view the world in gender-linked terms: Billy simply asks, “Do I like this toy?” and responds on the basis of his interests. (Reprinted by permission of Rebecca Bigler.)

who seldom views the world in gender-linked terms—he simply asks himself, “Do I like this toy?” and responds on the basis of his interests.

Gender-schematic thinking is so powerful that when children see others behaving in “gender-inconsistent” ways, they often cannot remember the information or distort it to make it “gender-consistent.” For example, when shown a picture of a male nurse, they may remember him as a doctor (Martin & Ruble, 2004). And because gender-schematic preschoolers typically conclude, “What I like, children of my own sex will also like,” they often use their own preferences to add to their gender biases (Liben & Bigler, 2002). For example, a girl who dislikes oysters may conclude that only boys like oysters even though she has never actually been given information promoting such a stereotype. At least partly for this reason, young children’s gender schemas contain both culturally standard and nonstandard ideas (Tennenbaum et al., 2010). Not until well into the school years do children’s gender schemas fully resemble those of adults.

Reducing Gender Stereotyping in Young Children

How can we help young children avoid rigid gender schemas that restrict their behavior and learning opportunities? No easy recipe exists. Biology clearly affects children’s gender typing, channeling boys toward active, competitive play and girls toward quieter, more intimate interaction. But most aspects of gender typing are not built into human nature (Ruble, Martin, & Berenbaum, 2006).

Because young children’s cognitive limitations lead them to assume that cultural practices determine gender, parents and teachers are wise to try to delay preschoolers’ exposure to gender-stereotyped messages. Adults can begin by limiting traditional gender roles in their own behavior and by providing children with nontraditional alternatives. For example, parents can take turns making dinner, bathing children, and driving the family car, and they can give their sons and daughters both trucks and dolls and both pink and blue clothing. Teachers can ensure that all children spend time in both adult-structured and unstructured activities. Adults can also avoid using language that conveys gender stereotypes and can shield children from media presentations that do so.

Once children notice the vast array of gender stereotypes in their society, parents and teachers can point out exceptions. For example, they can arrange for children to see men and women pursuing nontraditional careers and can explain that interests and skills, not sex, should determine a person’s occupation. Research shows that such reasoning is highly effective in reducing children’s tendency to view the world in a gender-biased fashion. By middle childhood, children who hold flexible beliefs about what boys and girls can do are more likely to notice instances of gender discrimination (Brown & Bigler, 2004). And as we will see next, a rational approach to child rearing promotes healthy, adaptable functioning in many other areas as well.

ASK YOURSELF

REVIEW Explain how the social environment and young children’s cognitive limitations jointly contribute to rigid gender stereotyping in early childhood.

CONNECT What other aspects of young children’s social understanding, in addition to gender-stereotyped beliefs, tend to be rigid and one-sided in early childhood?

APPLY List findings indicating that language and communication—between parents and children, between teachers and children, and between peers—powerfully affect children’s gender typing. What recommendations would you make to counteract these influences?

REFLECT Would you describe your own gender identity as “masculine,” “feminine,” or androgynous? What biological and social factors might have influenced your gender identity?

Child Rearing and Emotional and Social Development

In this and previous chapters, we have seen how parents can foster children’s competence—by building a parent–child relationship based on affection and cooperation, by serving as models and reinforcers of mature behavior, by using reasoning and inductive discipline, and by guiding and encouraging children’s mastery of new skills. Now let’s put these practices together into an overall view of effective parenting.

Styles of Child Rearing

Child-rearing styles are combinations of parenting behaviors that occur over a wide range of situations, creating an enduring child-rearing climate. In a landmark series of studies, Diana Baumrind (1971) gathered information on child rearing by watching parents interact with their preschoolers. Her findings, and those of others who have extended her work, reveal three features that consistently differentiate an effective style from less effective ones: (1) acceptance and involvement, (2) control, and (3) autonomy granting (Gray & Steinberg, 1999; Hart, Newell, & Olsen, 2003). Table 8.2 shows how child-rearing styles differ in these features.

Authoritative Child Rearing. The authoritative child-rearing style—the most successful approach—involves high acceptance and involvement, adaptive control techniques, and appropriate autonomy granting. Authoritative parents are warm, attentive, and sensitive to their child’s needs. They establish an enjoyable, emotionally fulfilling parent–child relationship that

TABLE 8.2 Features of Child-Rearing Styles

CHILD-REARING STYLE	ACCEPTANCE AND INVOLVEMENT	CONTROL	AUTONOMY GRANTING
Authoritative	Is warm, responsive, attentive, patient, and sensitive to the child's needs	Makes reasonable demands for maturity and consistently enforces and explains them	Permits the child to make decisions in accord with readiness Encourages the child to express thoughts, feelings, and desires When parent and child disagree, engages in joint decision making when possible
Authoritarian	Is cold and rejecting and frequently degrades the child	Makes many demands coercively, using force and punishment Often uses psychological control, withdrawing love and intruding on the child's individuality	Makes decisions for the child Rarely listens to the child's point of view
Permissive	Is warm but overindulgent or inattentive	Makes few or no demands for maturity	Permits the child to make many decisions before the child is ready
Uninvolved	Is emotionally detached and withdrawn	Makes few or no demands for maturity	Is indifferent to the child's decision making and point of view

draws the child into close connection. At the same time, authoritative parents exercise firm, reasonable control. They insist on appropriate maturity, give reasons for their expectations, and use disciplinary encounters as “teaching moments” to promote the child's self-regulation. Finally, authoritative parents engage in gradual, appropriate autonomy granting, allowing the child to make decisions in areas where he is ready to do so (Kuczynski & Lollis, 2002; Russell, Mize, & Bissaker, 2004).

Throughout childhood and adolescence, authoritative parenting is linked to many aspects of competence—an upbeat mood, self-control, task persistence, cooperativeness, high self-esteem, social and moral maturity, and favorable school performance (Amato & Fowler, 2002; Aunola, Stattin, & Nurmi, 2000; Gonzalez & Wolters, 2006; Mackey, Arnold, & Pratt, 2001; Milevsky et al., 2007; Steinberg, Darling, & Fletcher, 1995).

Authoritarian Child Rearing. The authoritarian child-rearing style is low in acceptance and involvement, high in coercive control, and low in autonomy granting. Authoritarian parents appear cold and rejecting. To exert control, they yell, command, criticize, and threaten. “Do it because I said so!” is their attitude. They make decisions for their child and expect the child to accept their word unquestioningly. If the child resists, authoritarian parents resort to force and punishment.

Children of authoritarian parents are more likely to be anxious, unhappy, and low in self-esteem and self-reliance. When frustrated, they tend to react with hostility and, like their parents, resort to force when they do not get their way. Boys, especially, show high rates of anger and defiance. Although girls also engage in acting-out behavior, they are more likely to be dependent, lacking interest in exploration, and overwhelmed by challenging tasks (Hart, Newell, & Olsen, 2003; Kakihara et al., 2010; Thompson, Hollis, & Richards, 2003). Children and adolescents exposed to the authoritarian style typically do poorly

in school, but because of their parents' concern with control, they tend to achieve better and to commit fewer antisocial acts than peers with undemanding parents—that is, whose parents use one of the styles we will consider next (Steinberg, Blatt-Eisengart, & Cauffman, 2006).

In addition to unwarranted direct control, authoritarian parents engage in a more subtle type called **psychological control**—behaviors that intrude on and manipulate children's verbal expression, individuality, and attachments to parents. In an attempt to decide virtually everything for the child, these parents frequently interrupt or put down the child's ideas, decisions, and choice of friends. When they are dissatisfied, they withdraw love, making their affection or attention contingent on the child's compliance. They also hold excessively high expectations that do not fit the child's developing capacities. Children subjected to psychological control exhibit adjustment problems involving both anxious, withdrawn behavior and defiance and aggression—especially the relational form, which (like parental psychological control) damages relationships through manipulation and exclusion (Barber et al., 2005; Kuppens et al., 2009; Nelson et al., 2006; Silk et al., 2003).

Permissive Child Rearing. The permissive child-rearing style is warm and accepting but uninvolved. Permissive parents are either overindulgent or inattentive and, thus, engage in little control. Instead of gradually granting autonomy, they allow children to make many of their own decisions at an age when they are not yet capable of doing so. Their children can eat meals and go to bed whenever they wish and can watch as much television as they want. They do not have to learn good manners or do any household chores. Although some permissive parents truly believe in this approach, many others simply lack confidence in their ability to influence their child's behavior (Oyserman et al., 2005).

Children of permissive parents tend to be impulsive, disobedient, and rebellious. Compared with children whose parents exert more control, they are also overly demanding and dependent on adults, and they show less persistence on tasks, poorer school achievement, and more antisocial behavior. The link between permissive parenting and dependent, nonachieving, rebellious behavior is especially strong for boys (Barber & Olsen, 1997; Baumrind, 1971; Steinberg, Blatt-Eisengart, & Cauffman, 2006).

Uninvolved Child Rearing. The uninvolved child-rearing style combines low acceptance and involvement with little control and general indifference to issues of autonomy. Often these parents are emotionally detached and depressed and so overwhelmed by life stress that they have little time and energy for children. At its extreme, uninvolved parenting is a form of child maltreatment called *neglect*. Especially when it begins early, it disrupts virtually all aspects of development (see Chapter 6, page 200). Even with less extreme parental disengagement, children and adolescents display many problems—poor emotional self-regulation, school achievement difficulties, depression, anger, and antisocial behavior (Aunola, Stattin, & Nurmi, 2000; Kurdek & Fine, 1994; Schroeder et al., 2010).

What Makes Authoritative Child Rearing Effective?

Like all correlational findings, the relationship between the authoritative style and children's competence is open to interpretation. Perhaps parents of well-adjusted children are authoritative because their youngsters have especially cooperative dispositions. But although temperamentally fearless, impulsive children and emotionally negative, difficult children are more likely to evoke coercive, inconsistent discipline, extra warmth and firm control succeed in modifying these children's maladaptive styles (Cipriano & Stifter, 2010; Kochanska, Philibert, & Barry, 2009; Pettit et al., 2007).

Longitudinal research indicates that authoritative child rearing promotes maturity and adjustment in children of diverse temperaments (Hart, Newell, & Olsen, 2003; Rubin, Burgess, & Coplan, 2002). And a variant of authoritativeness in which parents exert strong control over the child's behavior—becoming directive but not coercive—yields just as favorable long-term outcomes as a more democratic approach (Baumrind, Larzelere, & Owens, 2010). Indeed, as the findings on temperament and parenting just mentioned illustrate, some children, because of their dispositions, require “heavier doses” of certain authoritative features.

In sum, authoritative child rearing seems to create a positive emotional context for parental influence in the following ways:

- Warm, involved parents who are secure in the standards they hold for their children provide models of caring concern as well as confident, self-controlled behavior.

- Children are far more likely to comply with and internalize control that appears fair and reasonable, not arbitrary.
- By making demands and engaging in autonomy granting that match children's ability to take responsibility for their own behavior, authoritative parents convey a sense of competence to their children, which fosters favorable self-esteem and cognitive and social maturity.
- Supportive aspects of the authoritative style, including parental acceptance, involvement, and rational control, are a powerful source of *resilience*, protecting children from the negative effects of family stress and poverty (Beyers et al., 2003).

LOOK AND LISTEN

Ask several parents to explain their style of child rearing, inquiring about acceptance and involvement, control, and autonomy granting. Look, especially, for variations in authoritativeness—more or less control over the child's behavior—along with parents' rationales. ●

Cultural Variations

Although authoritative parenting is broadly advantageous, parents of different ethnicities often have distinct child-rearing beliefs and practices that reflect cultural values. Let's take some examples.

Compared with Western parents, Chinese parents describe their parenting as more controlling. They are more directive in

© JANINE WIEDEL PHOTOLIBRARY/ALAMY

In Caribbean families of African origins, respect for parental authority is paired with high parental warmth—a combination that promotes competence and family loyalty.

teaching and scheduling their children's time, as a way of fostering self-control and high achievement. Chinese parents may appear less warm than Western parents because they withhold praise, which they believe results in self-satisfied, poorly motivated children (Chao, 1994; Chen et al., 2001). Chinese parents report expressing affection and using induction and other reasoning-oriented discipline as much as American parents do, but they more often shame a misbehaving child (see page 257), withdraw love, and use physical punishment (Cheah et al., 2009; Shwalb et al., 2004; Wu et al., 2002). When these practices become excessive, resulting in an authoritarian style high in psychological or coercive control, Chinese children display the same negative outcomes as Western children: poor academic achievement, anxiety, depression, and aggressive behavior (Chan, 2010; Nelson et al., 2006; Pong, Johnston, & Chen, 2010).

In Hispanic families, Asian Pacific Island families, and Caribbean families of African and East Indian origins, firm insistence on respect for parental authority is paired with high parental warmth—a combination suited to promoting cognitive and social competence and family loyalty (Halgunseth, Ispa, & Rudy, 2006; Roopnarine & Evans, 2007). Hispanic fathers often spend much time with their children and are warm and sensitive (Cabrera & Bradley, 2012). In Caribbean families that have immigrated to the United States, fathers' authoritativeness—but not mothers—predicted preschoolers' literacy and math skills, probably because Caribbean fathers take a larger role in guiding their children's academic progress (Roopnarine et al., 2006).

Although wide variation exists, low-SES African-American parents tend to expect immediate obedience, regarding strictness as fostering self-control and a watchful attitude in risky surroundings. Consistent with these beliefs, African-American parents who use more controlling strategies tend to have more cognitively and socially competent children (Brody & Flor, 1998). Recall, also, that a history of physical punishment is associated with a reduction in antisocial behavior among African-American youths but with an increase among Caucasian Americans (see page 267). Most African-American parents who use strict, “no-nonsense” discipline use physical punishment sparingly and combine it with warmth and reasoning.

These cultural variations remind us that child-rearing styles must be viewed in their larger context. As we have seen, many factors contribute to good parenting: personal characteristics of child and parent, SES, access to extended family and community supports, cultural values and practices, and public policies.

As we turn to the topic of child maltreatment, our discussion will underscore, once again, that effective child rearing is sustained not just by the desire of mothers and fathers to be good parents. Almost all want to be. Unfortunately, when vital supports for parenting break down, children—as well as parents—can suffer terribly.

Child Maltreatment

Child maltreatment is as old as human history, but only recently has the problem been widely acknowledged and research aimed

at understanding it. Perhaps public concern has increased because child maltreatment is especially common in large industrialized nations. In the most recently reported year, about 700,000 U.S. children (9 out of every 1,000) were identified as victims (U.S. Department of Health and Human Services, 2011b). Most cases go unreported, so the true figures are much higher.

Child maltreatment takes the following forms:

- *Physical abuse:* Assaults, such as kicking, biting, shaking, punching, or stabbing, that inflict physical injury
- *Sexual abuse:* Fondling, intercourse, exhibitionism, commercial exploitation through prostitution or production of pornography, and other forms of exploitation
- *Neglect:* Failure to meet a child's basic needs for food, clothing, medical attention, education, or supervision
- *Emotional abuse:* Acts that could cause serious mental or behavioral disorders, including social isolation, repeated unreasonable demands, ridicule, humiliation, intimidation, or terrorizing

Parents commit more than 80 percent of abusive incidents. Other relatives account for about 7 percent. The remainder are perpetrated by parents' unmarried partners, school officials, camp counselors, and other adults. Mothers engage in neglect more often than fathers, whereas fathers engage in sexual abuse more often than mothers. Maternal and paternal rates of physical and emotional abuse are fairly similar. Infants and young preschoolers are at greatest risk for neglect; preschool and school-age children for physical, emotional, and sexual abuse (Trocomé & Wolfe, 2002; U.S. Department of Health and Human Services, 2011b). Because most sexual abuse victims are identified in middle childhood, we will pay special attention to this form of maltreatment in Chapter 10.

Each year, fourth to sixth graders across Los Angeles County enter a poster contest to celebrate National Child Abuse Prevention Month. This 2012 winner expresses a heartfelt appeal: “Don’t Let Our Children Live in Fear.” (Gillian Lih Bautista, 6th Grade, St. Genevieve Elementary, Panorama City, CA. Courtesy ICAN Associates, Los Angeles County Inter-Agency Council on Child Abuse and Neglect, ican4kids.org.)

Origins of Child Maltreatment. Early findings suggested that child maltreatment was rooted in adult psychological disturbance (Kempe et al., 1962). But although child maltreatment is more common among disturbed parents, no single “abusive personality type” exists. Parents who were abused as children do not necessarily become abusers (Buchanan, 1996; Simons et al., 1991). And sometimes even “normal” parents harm their children!

For help in understanding child maltreatment, researchers turned to *ecological systems theory* (see Chapters 1 and 2). They discovered that many interacting variables—at the family, community, and cultural levels—contribute. The more risks present, the greater the likelihood of abuse or neglect (see Table 8.3).

The Family. Within the family, children whose characteristics make them more challenging to rear are more likely to become targets of abuse. These include premature or very sick babies and children who are temperamentally difficult, are inattentive and overactive, or have other developmental problems. Child factors, however, only slightly increase the risk (Jaudes & Mackey-Bilaver, 2008; Sidebotham et al., 2003). Whether such children are maltreated largely depends on parents’ characteristics.

Maltreating parents are less skillful than other parents in handling discipline confrontations. They also suffer from biased thinking about their child. For example, they often attribute their baby’s crying or their child’s misdeeds to a stubborn or bad disposition, evaluate child transgressions as worse than they are, and feel powerless in parenting—perspectives that lead them to move quickly toward physical force (Bugental & Happaney, 2004; Crouch et al., 2008).

Once abuse begins, it quickly becomes part of a self-sustaining relationship. The small irritations to which abusive parents react—a fussy baby, a preschooler who will not mind immediately—soon become bigger ones. Then the harshness increases. By the preschool years, abusive and neglectful parents

seldom interact with their children. When they do, the communication is almost always negative (Wolfe, 2005).

Most parents have enough self-control not to respond with abuse to their child’s misbehavior or developmental problems. Other factors combine with these conditions to prompt an extreme response. Abusive parents react to stressful situations with high emotional arousal. And low income, low education (less than a high school diploma), unemployment, alcohol and drug use, marital conflict, overcrowded living conditions, frequent moves, and extreme household disorganization are common in abusive homes (Wekerle et al., 2007; Wulczyn, 2009). These conditions increase the chances that parents will be too overwhelmed to meet basic child-rearing responsibilities or will vent their frustrations by lashing out at their children.

The Community. The majority of abusive and neglectful parents are isolated from both formal and informal social supports. Because of their life histories, many have learned to mistrust and avoid others and are poorly skilled at establishing and maintaining positive relationships. Also, maltreating parents are more likely to live in unstable, rundown neighborhoods that provide few links between family and community, such as preschool programs, recreation centers, and religious institutions (Coulton et al., 2007; Guterman et al., 2009). They lack “lifelines” to others and have no one to turn to for help during stressful times.

The Larger Culture. Cultural values, laws, and customs profoundly affect the chances that child maltreatment will occur when parents feel overburdened. Societies that view violence as an appropriate way to solve problems set the stage for child abuse.

Although the United States has laws to protect children from maltreatment, widespread support exists for use of physical force with children (refer back to page 266). Many countries—including Austria, Croatia, Cyprus, Denmark, Finland,

TABLE 8.3 Factors Related to Child Maltreatment

FACTOR	DESCRIPTION
Parent characteristics	Psychological disturbance; alcohol and drug abuse; history of abuse as a child; belief in harsh physical discipline; desire to satisfy unmet emotional needs through the child; unreasonable expectations for child behavior; young age (most under 30); low educational level
Child characteristics	Premature or very sick baby; difficult temperament; inattentiveness and overactivity; other developmental problems
Family characteristics	Low income; poverty; homelessness; marital instability; social isolation; physical abuse of mother by husband or boyfriend; frequent moves; large families with closely spaced children; overcrowded living conditions; disorganized household; lack of steady employment; other signs of high life stress
Community	Characterized by violence and social isolation; few parks, child-care centers, preschool programs, recreation centers, or religious institutions to serve as family supports
Culture	Approval of physical force and violence as ways to solve problems

Sources: U.S. Department of Health and Human Services, 2011b; Wekerle & Wolfe, 2003; Whipple, 2006.

Germany, Israel, Italy, Latvia, Norway, Sweden, and Uruguay—have outlawed corporal punishment, a measure that dampens both physical discipline and abuse (Zolotor & Puzia, 2010). Furthermore, all industrialized nations except the United States and France now prohibit corporal punishment in schools. The U.S. Supreme Court has twice upheld the right of school officials to use corporal punishment. Fortunately, 31 U.S. states and the District of Columbia have passed laws that ban it.

Consequences of Child Maltreatment. The family circumstances of maltreated children impair the development of emotional self-regulation, empathy and sympathy, self-concept, social skills, and academic motivation. Over time, these youngsters show serious adjustment problems—cognitive deficits (including impaired working memory and executive function), severe depression, aggressive behavior, peer difficulties, substance abuse, and violent crime—that persist into adulthood (Gould et al., 2010; Kaplow & Widom, 2007; Sanchez & Pollak, 2009).

How do these damaging consequences occur? Think back to our earlier discussion of hostile cycles of parent–child interaction. For abused children, these are especially severe. Also, a family characteristic strongly associated with child abuse is partner abuse (Graham-Bermann & Howell, 2011). Clearly, the home lives of abused children overflow with experiences that evoke profound distress and with opportunities to learn to use aggression to solve problems.

Furthermore, demeaning parental messages, in which children are ridiculed, humiliated, rejected, or terrorized, result in low self-esteem, high anxiety, self-blame, and efforts to escape from extreme psychological pain—at times severe enough to lead to attempted suicide in adolescence. At school, maltreated children present serious discipline problems (Wolfe, 2005). Their noncompliance, poor motivation, and cognitive immaturity interfere with academic achievement, further undermining their chances for life success.

Finally, repeated abuse is associated with central nervous system damage, including abnormal EEG brain-wave activity; fMRI-detected reduced size and impaired functioning of the cerebral cortex, corpus callosum, and cerebellum; and atypical production of the stress hormone cortisol—initially too high but, after months of abuse, often too low. Over time, the massive trauma of persistent abuse seems to blunt children’s normal physiological response to stress (Cicchetti, 2007; Hart & Rubia, 2012). These effects increase the chances that cognitive and emotional problems will endure.

Preventing Child Maltreatment. Because child maltreatment is embedded in families, communities, and society as a whole, efforts to prevent it must be directed at each of these levels. Many approaches have been suggested, from teaching high-risk parents effective child-rearing strategies to developing broad social programs aimed at improving community services and economic conditions.

We have seen that providing social supports to families is effective in easing parental stress. This approach sharply reduces child maltreatment. Parents Anonymous, a U.S. organization with affiliate programs around the world, helps child-abusing parents learn constructive parenting practices, largely through social supports. Its local chapters offer self-help group meetings, daily phone calls, and regular home visits to relieve social isolation and teach child-rearing skills.

Early intervention aimed at strengthening both child and parent competencies can reduce child maltreatment. Healthy Families America, a program that began in Hawaii and has spread to 440 sites across the United States and Canada, identifies at-risk families during pregnancy or at birth. Each receives three years of home visitation, in which a trained worker helps parents manage crises, encourages effective child rearing, and puts parents in touch with community services (Healthy Families America, 2011). In an evaluation of its effectiveness, Healthy Families home visitation alone reduced only neglect, not abuse (Duggan et al., 2004). But adding a *cognitive component* dramatically increased its impact. When home visitors helped parents change negative appraisals of their children—by countering inaccurate interpretations (for example, that the baby is behaving with malicious intent) and by working on solving child-rearing problems—physical punishment and abuse dropped sharply after one year of intervention (Bugental et al., 2002).

Even with intensive treatment, some adults persist in their abusive acts. An estimated 1,500 U.S. children, most of them infants and preschoolers, die from maltreatment each year (U.S. Department of Health and Human Services, 2011b). When parents are unlikely to change their behavior, the drastic step of separating parent from child and legally terminating parental rights is the only justifiable course of action.

Child maltreatment is a sad note on which to end our discussion of a period of childhood that is so full of excitement, awakening, and discovery. But there is reason to be optimistic. Great strides have been made over the past several decades in understanding and preventing child maltreatment.

ASK YOURSELF

REVIEW Is the concept of authoritative parenting useful for understanding effective parenting across cultures? Explain.

CONNECT Which child-rearing style is most likely to be associated with inductive discipline, and why?

APPLY Chandra heard a news report about 10 severely neglected children, living in squalor in an inner-city tenement. She wondered, “Why would parents so mistreat their children?” How would you answer Chandra?

REFLECT How would you classify your parents’ child-rearing styles? What factors might have influenced their approach to parenting?

SUMMARY

Erikson's Theory: Initiative versus Guilt (p. 256)

What personality changes take place during Erikson's stage of initiative versus guilt?

- Preschoolers develop a new sense of purposefulness as they grapple with Erikson's psychological conflict of **initiative versus guilt**. A healthy sense of initiative depends on exploring the social world through play, cooperating with peers to achieve common goals, and forming a conscience through identification with the same-sex parent.

© AGE FOTOSTOCK/ROBERT HARDING

Self-Understanding (p. 256)

Describe preschoolers' self-concepts and the development of self-esteem.

- As preschoolers think more intently about themselves, they construct a **self-concept** consisting largely of observable characteristics and typical emotions and attitudes. A warm, sensitive parent-child relationship seems to foster a more positive, coherent early self-concept.
- During early childhood, high **self-esteem** contributes to a mastery-oriented approach to the environment. But even a little adult disapproval can undermine a young child's self-esteem and enthusiasm for learning.

Emotional Development

(p. 258)

Identify changes in understanding and expressing emotion during early childhood, citing factors that influence those changes.

- Preschoolers' impressive understanding of the causes, consequences, and behavioral signs of basic emotions is supported by cognitive and language development, secure attachment, and conversations about feelings. By age 3

to 4, children are aware of various strategies for emotional self-regulation. Temperament and parental communication about coping strategies influence preschoolers' capacity to handle stress and negative emotion.

- As their self-concepts develop, preschoolers more often experience self-conscious emotions. They depend on feedback from parents and other adults to know when to feel each of these emotions.
- Empathy also becomes more common. Temperament and parenting influence the extent to which empathy leads to **sympathy** and results in **prosocial**, or **altruistic, behavior**.

Peer Relations (p. 261)

Describe peer sociability and friendship in early childhood, citing cultural and parental influences on early peer relations.

- During early childhood, peer interaction increases as children move from **nonsocial activity** to **parallel play**, then to **associative** and **cooperative play**. Nevertheless, both solitary and parallel play remain common.
- Sociodramatic play seems especially important in societies where child and adult worlds are distinct. In collectivist cultures, play generally occurs in large groups and is highly cooperative.
- Preschoolers understand something about the uniqueness of friendship, but their friendships do not yet have an enduring quality. Children's social maturity contributes to later academic performance. Parents affect peer sociability both directly, through attempts to influence their child's peer relations, and indirectly, through their child-rearing practices.

Foundations of Morality

(p. 264)

What are the central features of psychoanalytic, social learning, and cognitive-developmental approaches to moral development?

- Psychoanalytic theory emphasizes the emotional side of moral development, especially identification and guilt as motivators of good conduct. Contrary to Freud's theory, conscience formation is promoted not by fear of punishment and loss of parental love but by **induction**, in which an adult points out the effects of the child's misbehavior on others.

- Social learning theory focuses on how moral behavior is learned through reinforcement and modeling. Effective adult models of pro-social responses are warm and powerful, and they practice what they preach.
- Alternatives to harsh punishment such as **time out** and withdrawal of privileges can help parents avoid undesirable side effects of punishment. Parents can increase the effectiveness of punishment by being consistent, maintaining a warm parent-child relationship, and offering explanations.
- The cognitive-developmental perspective views children as active thinkers about social rules. By age 4, children consider intentions in making moral judgments and distinguish truthfulness from lying. Preschoolers also distinguish **moral imperatives** from **social conventions** and **matters of personal choice**. However, they tend to reason rigidly about morality, focusing on outcomes and on physical harm.

Describe the development of aggression in early childhood, including family and media influences and effective approaches to reducing aggressive behavior.

- During early childhood, **proactive aggression** declines while **reactive aggression** increases. Proactive and reactive aggression come in three forms: **physical aggression** (more common in boys), **verbal aggression**, and **relational aggression**.

© BOB EBBERSEN/LAMY

- Ineffective discipline and a conflict-ridden family atmosphere promote children's aggression, as does media violence. Effective approaches to reducing aggressive behavior include training parents in effective child-rearing practices, teaching children conflict-resolution skills, helping parents cope with stressors in their own lives, and shielding children from violent media.

Gender Typing (p. 273)

Discuss genetic and environmental influences on preschoolers' gender-stereotyped beliefs and behavior.

- **Gender typing** is well under way in the preschool years. Preschoolers acquire a wide range of gender-stereotyped beliefs, often applying them rigidly.
- Prenatal sex hormones contribute to boys' higher activity level and rougher play and to children's preference for same-sex playmates. But parents, teachers, peers, and the broader social environment also encourage many gender-typed responses.

CAVAN IMAGES/GETTY IMAGES

Describe and evaluate theories that explain the emergence of gender identity.

- Although most people have a traditional **gender identity**, some are **androgynous**, combining both masculine and feminine characteristics. Masculine and androgynous identities are linked to better psychological adjustment.

- According to social learning theory, preschoolers first acquire gender-typed responses through modeling and reinforcement and then organize these behaviors into gender-linked ideas about themselves. Cognitive-developmental theory maintains that children must master **gender constancy** before they develop gender-typed behavior, though evidence for this assumption is weak.
- **Gender schema theory** combines features of social learning and cognitive-developmental perspectives. As children acquire gender-typed preferences and behaviors, they form masculine and feminine categories, or gender schemas, that they apply to themselves and their world.

Child Rearing and Emotional and Social Development (p. 278)

Describe the impact of child-rearing styles on children's development, and note cultural variations in child rearing.

- Three features distinguish major **child-rearing styles**: (1) acceptance and involvement, (2) control, and (3) autonomy granting. In contrast to the **authoritarian**, **permissive**, and **uninvolved** styles, the **authoritative style** promotes cognitive, emotional, and social competence. Warmth, explanations, and reasonable demands for mature behavior account for the effectiveness of this style. **Psychological control**, associated with authoritarian parenting, contributes to adjustment problems.

- Certain ethnic groups, including Chinese, Hispanic, Asian Pacific Island, and African-American, combine parental warmth with high levels of control. But when control becomes harsh and excessive, it impairs academic and social competence.

© JANINE WIEDEL PHOTOLIBRARY/ALAMY

Discuss the multiple origins of child maltreatment, its consequences for development, and effective prevention.

- Maltreating parents use ineffective discipline, hold a negatively biased view of their child, and feel powerless in parenting. Unmanageable parental stress and social isolation greatly increase the likelihood of abuse and neglect. Societal approval of physical force as a means of solving problems promotes child abuse.
- Maltreated children are impaired in emotional self-regulation, empathy and sympathy, self-concept, social skills, and academic motivation. The trauma of repeated abuse is associated with central nervous system damage and serious, lasting adjustment problems. Successful prevention requires efforts at the family, community, and societal levels.

Important Terms and Concepts

androgyny (p. 276)
 associative play (p. 261)
 authoritarian child-rearing style (p. 279)
 authoritative child-rearing style (p. 278)
 child-rearing styles (p. 278)
 cooperative play (p. 261)
 gender constancy (p. 276)
 gender identity (p. 276)
 gender schema theory (p. 277)

milestones

Development in Early Childhood

© ELLEN B. SENISI PHOTOGRAPHY

2 years

PHYSICAL

- Throughout early childhood, height and weight increase more slowly than in toddlerhood. (216)
- Balance improves; walks more rhythmically; hurried walk changes to run. (223)
- Jumps, hops, throws, and catches with rigid upper body. (223)
- Puts on and removes simple items of clothing. (223)
- Uses spoon effectively. (223)
- First drawings are gestural scribbles. (224)

COGNITIVE

- Make-believe becomes less dependent on realistic objects, less self-centered, and more complex; sociodramatic play increases. (226–227)
- Understands the symbolic function of photos and realistic-looking pictures. (228)

- Takes the perspective of others in simplified, familiar situations and in face-to-face communication. (230)
- Recognition memory is well-developed. (237)
- Shows awareness of the distinction between inner mental and outer physical events. (239)
- Begins to count. (242)

LANGUAGE

- Vocabulary increases rapidly. (248)
- Uses a coalition of cues—perceptual and, increasingly, social and linguistic—to figure out word meanings. (249)
- Speaks in simple sentences that follow basic word order of native language, gradually adding grammatical markers. (249)
- Displays effective conversational skills. (250)

EMOTIONAL/SOCIAL

- Understands causes, consequences, and behavioral signs of basic emotions. (258)
- Begins to develop self-concept and self-esteem. (256–258)
- Shows early signs of developing moral sense—verbal evaluations of own and others' actions and distress at harmful behaviors. (264)
- May display proactive (instrumental) aggression. (269)
- Gender-stereotyped beliefs and behavior increase. (273)

© ELLEN B. SENISI PHOTOGRAPHY

3–4 years

PHYSICAL

- Running, jumping, hopping, throwing, and catching become better coordinated. (223)
- Pedals and steers tricycle. (223)

© LAURA DWIGHT PHOTOGRAPHY

- Galloping and one-foot skipping appear. (223)
- Fastens and unfastens large buttons. (223)
- Uses scissors. (223)
- Uses fork effectively. (223)
- Draws first picture of a person, using tadpole image. (224)

COGNITIVE

- Understands the symbolic function of drawings and of models of real-world spaces. (224, 227–228)
- Distinguishes appearance from reality. (228)
- Grasps conservation, reasons about transformations, reverses thinking, and understands cause-effect sequences in familiar contexts. (230)
- Sorts familiar objects into hierarchically organized categories. (231)
- Uses private speech to guide behavior during challenging tasks. (234)
- Improves in sustained attention. (236–237)
- Uses scripts to recall familiar events. (238)
- Understands that both beliefs and desires determine behavior. (239)
- Knows the meaning of numbers up to 10, counts correctly, and grasps cardinality. (243)

LANGUAGE

- Aware of some meaningful features of written language. (242)
- Coins new words based on known words; extends language meanings through metaphor. (248)
- Masters increasingly complex grammatical structures, occasionally overextending grammatical rules to exceptions. (249–250)
- Adjusts speech to fit the age, sex, and social status of listeners. (250)

EMOTIONAL/SOCIAL

- Describes self in terms of observable characteristics and typical emotions and attitudes. (256)
- Has several self-esteems, such as learning things in school, making friends, getting along with parents, and treating others kindly. (257)
- Emotional self-regulation improves. (259)
- Experiences self-conscious emotions more often. (260)
- Relies more on language to express empathy. (260)

- Engages in associative and cooperative play with peers, in addition to parallel play. (261)
- Forms first friendships, based on pleasurable play and sharing of toys. (262)
- Distinguishes truthfulness from lying. (269)
- Distinguishes moral imperatives from social conventions and matters of personal choice. (269)
- Proactive aggression declines, while reactive aggression (verbal and relational) increases. (269)
- Preference for same-sex playmates strengthens. (274)

5–6 years

PHYSICAL

- Starts to lose primary teeth. (217)
- Increases running speed, gallops more smoothly, and engages in true skipping. (223)
- Displays mature, flexible throwing and catching patterns. (223)
- Uses knife to cut soft foods. (223)
- Ties shoes. (223, 224)

- Draws more complex pictures. (224)
- Copies some numbers and simple words; prints name. (223, 225)

COGNITIVE

- Magical beliefs decline. (230)
- Improves in ability to distinguish appearance from reality. (228)

- Improves in sustained attention and planning. (237)
- Recognition, recall, scripted memory, and autobiographical memory improve. (237–238)

- Understanding of false belief strengthens. (239)

LANGUAGE

- Understands that letters and sounds are linked in systematic ways. (242)
- Uses invented spellings. (242)
- By age 6, vocabulary reaches about 10,000 words. (248)
- Uses most grammatical constructions competently. (250)

EMOTIONAL/SOCIAL

- Improves in emotional understanding (ability to interpret, predict, and influence others' emotional reactions). (258)

- Has acquired many morally relevant rules and behaviors. (265)
- Gender-stereotyped beliefs and behavior and preference for same-sex playmates continue to strengthen. (274)
- Understands gender constancy. (276–277)

chapter 9

© ELLEN B. SENISI PHOTOGRAPHY

During a science lesson, sixth graders use a map to chart catastrophic weather events around the world. An improved capacity to remember, reason, and reflect on one's own thinking makes middle childhood a time of dramatic advances in academic learning and problem solving.

Physical and Cognitive Development in Middle Childhood

“I’m on my way, Mom!” hollered 10-year-old Joey as he stuffed the last bite of toast into his mouth, slung his book bag over his shoulder, dashed out the door, jumped on his bike, and headed down the street for school. Joey’s 8-year-old sister Lizzie followed, pedaling furiously until she caught up with Joey. Rena, the children’s mother and one of my colleagues at the university, watched from the front porch as her son and daughter disappeared in the distance.

“They’re branching out,” Rena told me over lunch that day as she described the children’s expanding activities and relationships. Homework, household chores, soccer teams, music lessons, scouting, friends at school and in the neighborhood, and Joey’s new paper route were all part of the children’s routine. “It seems the basics are all there. I don’t have to monitor Joey and Lizzie constantly anymore. Being a parent is still challenging, but it’s more a matter of refinements—helping them become independent, competent, and productive individuals.”

Joey and Lizzie have entered middle childhood—the years from 6 to 11. Around the world, children of this age are assigned new responsibilities. For children in industrialized nations, middle childhood is often called the “school years” because its onset is marked by the start of formal schooling. In village and tribal cultures, the school may be a field or a jungle. But universally in this period, children are guided by mature members of society toward real-world tasks that increasingly resemble those they will perform as adults.

This chapter focuses on physical and cognitive development in middle childhood. By age 6, the brain has reached 90 percent of its adult weight, and the body continues to grow slowly. In this way, nature gives school-age children the mental powers to master challenging tasks as well as added time to acquire the knowledge and skills essential for life in a complex social world.

We begin by reviewing typical growth trends, gains in motor skills, and special health concerns. Then we return to Piaget’s theory and the information-processing approach for an overview of cognitive changes. Next, we examine genetic and environmental contributions to IQ scores, which often enter into educational decisions. Our discussion continues with the further blossoming of language. Finally, we turn to the importance of schools in children’s learning and development. ●

Class Size • Educational Philosophies • Teacher–Student Interaction • Grouping Practices • Teaching Children with Special Needs • How Well-Educated Are American Children?

■ **SOCIAL ISSUES: EDUCATION** Magnet Schools: Equal Access to High-Quality Education

PHYSICAL DEVELOPMENT

Body Growth

Physical growth during the school years continues at the slow, regular pace of early childhood. At age 6, the average North American child weighs about 45 pounds and is 3½ feet tall. Over the next few years, children add about 2 to 3 inches in height and 5 pounds in weight each year (see Figure 9.1). Between ages 6 and 8, girls are slightly shorter and lighter than boys. By age 9, this trend reverses as girls approach the dramatic adolescent growth spurt, which occurs two years earlier in girls than in boys.

Because the lower portion of the body is growing fastest, Joey and Lizzie appeared longer-legged than they had in early childhood. They grew out of their jeans more quickly than their jackets and frequently needed larger shoes. As in early childhood, girls have slightly more body fat and boys more muscle. After age 8, girls begin accumulating fat at a faster rate, and they will add even more during adolescence (Siervogel et al., 2000).

During middle childhood, the bones of the body lengthen and broaden. But ligaments are not yet firmly attached to bones, and this, combined with increasing muscle strength, gives chil-

dren the unusual flexibility needed to perform cartwheels and handstands. As their bodies become stronger, many children experience a greater desire for physical exercise. Nighttime “growing pains”—stiffness and aches in the legs—are common as muscles adapt to an enlarging skeleton (Evans, 2008).

Between ages 6 and 12, all 20 primary teeth are lost and replaced by permanent ones, with girls losing their teeth slightly earlier than boys. For a while, the permanent teeth seem much too large. Gradually, growth of facial bones, especially the jaw and chin, causes the child’s face to lengthen and mouth to widen, accommodating the newly erupting teeth.

Common Health Problems

Children from economically advantaged homes, like Joey and Lizzie, are at their healthiest in middle childhood, full of energy and play. The cumulative effects of good nutrition, combined with rapid development of the body’s immune system, offer greater protection against disease. At the same time, growth in lung size permits more air to be exchanged with each breath, so children are better able to exercise vigorously without tiring.

PHOTOS COURTESY OF PATRICIA SELEFE

FIGURE 9.1 Body growth during middle childhood. School-age children continue the slow, regular pattern of growth they showed in early childhood. But around age 9, girls begin to grow at a faster rate than boys. At age 10½, Amy was taller, heavier, and more mature-looking than Andy.

Not surprisingly, poverty continues to be a powerful predictor of ill health during the school years. Because economically disadvantaged U.S. families often lack health insurance (see Chapter 7), many children do not have regular access to a doctor. A substantial number also lack such basic necessities as a comfortable home and regular meals.

Nutrition

School-age children need a well-balanced, plentiful diet to provide energy for successful learning in school and increased physical activity. With their increasing focus on friendships and new activities, many children spend little time at the table, and the percentage who eat dinner with their families drops sharply between ages 9 and 14. Family dinnertimes have waned in general over the past two decades. Yet eating an evening meal with parents leads to a diet higher in fruits, vegetables, grains, and milk products and lower in soft drinks and fast foods (Burgess-Champoux et al., 2009; Fiese & Schwartz, 2008).

School-age children say that they “feel better” and “focus better” after eating healthy foods and that they feel sluggish, “like a blob,” after eating junk foods (O’Dea, 2003). Consistent with these informal reports, even mild nutritional deficits can affect cognitive functioning. Among school-age children from middle- to high-SES families, insufficient dietary iron and folate predicted slightly lower mental test performance (Arija et al., 2006).

As we saw in earlier chapters, many poverty-stricken children in developing countries and in the United States suffer from serious and prolonged malnutrition. Unfortunately, malnutrition that persists from infancy or early childhood into the school years usually leads to permanent physical and mental damage (Grantham-McGregor, Walker, & Chang, 2000; Liu et al., 2003). Government-sponsored supplementary food programs from the early years through adolescence can prevent these effects.

Overweight and Obesity

Mona, a very heavy child in Lizzie’s class, often watched from the sidelines during recess. When she did join in games, she was slow and clumsy, the target of unkind comments: “Move it, Tubs!” Most afternoons, she walked home from school alone while the other children gathered in groups, talking, laughing, and chasing. At home, Mona sought comfort in high-calorie snacks.

Mona suffers from **obesity**, a greater-than-20-percent increase over healthy weight, based on *body mass index (BMI)*—a ratio of weight to height associated with body fat. (A BMI above the 85th percentile for a child’s age and sex is considered *overweight*, a BMI above the 95th percentile *obese*.) During the past several decades, a rise in overweight and obesity has occurred in many Western nations, with large increases in Canada, Germany, Israel, Greece, Ireland, New Zealand, the United Kingdom, and especially the United States. Today, 32 percent of U.S. children and adolescents are overweight, more than half of them extremely so: 17 percent are obese—trends that are worsening (Ogden et al., 2010; World Health Organization, 2012c, 2013a).

Obesity rates are also increasing rapidly in developing countries, as urbanization shifts the population toward sedentary lifestyles and diets high in meats and energy-dense refined foods (World Health Organization, 2012c, 2013a). In China, for example, where obesity was nearly nonexistent a generation ago, today 20 percent of children are overweight and 7 percent obese—a nearly fivefold increase over the past 25 years, with boys affected more than girls (Ding, 2008). In addition to lifestyle changes, a prevailing belief in Chinese culture that excess body fat signifies prosperity and health—carried over from a half-century ago, when famine caused millions of deaths—has contributed to this alarming upsurge. High valuing of sons may induce Chinese parents to offer boys especially generous portions of energy-dense foods that are now widely available.

Overweight rises with age, from 21 percent among U.S. preschoolers to 35 percent among school-age children and adolescents. An estimated 70 percent of affected teenagers become overweight adults (U.S. Department of Health and Human Services, 2011f). Besides serious emotional and social difficulties, obese children are at risk for lifelong health problems. Symptoms that begin to appear in the early school years—high blood pressure, high cholesterol levels, respiratory abnormalities, and insulin resistance—are powerful predictors of heart disease, circulatory difficulties, type 2 diabetes, gallbladder disease, sleep and digestive disorders, many forms of cancer, and early death (Krishnamoorthy, Hart, & Jelalian, 2006; World Cancer Research Fund, 2007). Furthermore, obesity has caused a dramatic rise in cases of diabetes in children, sometimes leading to early, severe complications, including stroke, kidney failure, and circulatory problems that heighten the risk of eventual blindness and leg amputation (Hannon, Rao, & Arslanian, 2005).

Causes of Obesity. Not all children are equally at risk for excessive weight gain. Overweight children tend to have overweight parents, and identical twins are more likely to share the disorder than fraternal twins. But heredity accounts for only a *tendency* to gain weight (Kral & Faith, 2009). The importance of environment is apparent in the consistent relationship of low SES to overweight and obesity in industrialized nations, especially among ethnic minorities—in the United States, African-American, Hispanic, and Native-American children and adults (Anand et al., 2001; Ogden et al., 2010). Factors responsible include lack of knowledge about healthy diet; a tendency to buy high-fat, low-cost foods; and family stress, which can prompt overeating. Recall, also, that children who were undernourished in their early years are at risk for later excessive weight gain (see page 132 in Chapter 4).

Parental feeding practices also contribute to childhood obesity. Some parents anxiously overfeed, interpreting almost all their child’s discomforts as a desire for food. Others pressure their children to eat, a practice common among immigrant parents and grandparents who, as children themselves, survived periods of food deprivation. Still other parents are overly controlling, restricting when, what, and how much their child eats and constantly worrying about weight gain (Moens, Braet,

& Soetens, 2007). In each case, parents fail to help children learn to regulate their own food intake. Also, parents of overweight children often use high-fat, sugary foods to reinforce other behaviors, leading children to attach great value to treats (Sherry et al., 2004).

Because of these experiences, obese children soon develop maladaptive eating habits. They are more responsive than normal-weight individuals to external stimuli associated with food—taste, sight, smell, time of day, and food-related words—and less responsive to internal hunger cues (Jansen et al., 2003; Temple et al., 2007). They also eat faster, a behavior that appears as early as 18 months of age (Drabman et al., 1979).

Another factor consistently associated with weight gain is insufficient sleep (Nielsen, Danielsen, & Sørensen, 2011). Reduced sleep may increase time available for eating, leave children too fatigued for physical activity, or disrupt the brain's regulation of hunger and metabolism.

Overweight children are less physically active than their normal-weight peers. Inactivity is both cause and consequence of excessive weight gain. Research reveals that the rise in childhood obesity is due in part to the many hours U.S. children spend watching television. In a study that tracked children's TV viewing from ages 4 to 11, the more TV children watched, the more body fat they added: Children who devoted more than 3 hours per day to TV accumulated 40 percent more fat than those devoting less than 1¼ hours (see Figure 9.2) (Proctor et al., 2003). Watching TV reduces time spent in physical exercise, and TV ads encourage children to eat fattening, unhealthy snacks. Children permitted to have a TV in their bedroom—a practice linked to especially high TV viewing—are at even further risk for overweight (Adachi-Mejia et al., 2007).

© OCEAN/CORBIS

Parental unhealthy feeding practices—frequent take-out meals consisting of foods high in calories and fat—and a physically inactive lifestyle play major roles in these siblings' excessive weight gain.

FIGURE 9.2 Relationship of television viewing to gains in body fat from ages 4 to 11. Researchers followed more than 100 children longitudinally, collecting information on hours per day of television viewing and on body fat, measured in millimeters of skinfold thickness at five body sites (upper arms, shoulders, abdomen, trunk, and thighs). The more TV children watched, the greater the gain in body fat. At ages 10 to 11, the difference between children watching fewer than 1¼ hours and those watching more than 3 hours had become large. (Adapted from M. H. Proctor et al., 2003, “Television Viewing and Change in Body Fat from Preschool to Early Adolescence: The Framingham Children’s Study,” *International Journal of Obesity*, 27, p. 831. Reprinted by permission from Macmillan Publishers Ltd.)

Finally, the broader food environment affects the incidence of obesity. Over the past three decades, the number of families who frequently eat meals outside the home has risen dramatically. Eating in restaurants or at relatives’, neighbors’, or friends’ homes, as opposed to at home, substantially increases children’s overall food consumption, including high-calorie drinks, fast foods, and snacks, and their risk of weight gain (Ayala et al., 2008; Poti & Popkin, 2011).

Consequences of Obesity. Unfortunately, physical attractiveness is a powerful predictor of social acceptance. In Western societies, both children and adults rate obese youngsters as less likable than other children, stereotyping them as lazy, sloppy, ugly, stupid, self-doubting, and deceitful (Kilpatrick & Sanders, 1978; Penny & Haddock, 2007; Tiggemann & Anesbury, 2000). In school, obese children and adolescents are often socially isolated. They report more emotional, social, and school difficulties, including peer teasing and consequent low self-esteem, depression, and (among obese teenagers) suicidal thoughts and suicide attempts. Persistent obesity from childhood into adolescence predicts serious disorders, including defiance, aggression, and severe depression (Puhl & Latner, 2007; Young-Hyman et al., 2006). As we will see in Chapter 13, these psychological consequences combine with continuing discrimination to result in reduced life chances in close relationships and employment.

Treating Obesity. In Mona’s case, the school nurse suggested that Mona and her obese mother enter a weight-loss pro-

gram together. But Mona's mother, unhappily married for many years, had her own reasons for overeating and rejected this idea. In one study, only one-fourth of overweight parents judged their overweight children to have a weight problem (Jeffrey, 2004). Consistent with these findings, most obese children do not get any treatment.

The most effective interventions are family-based and focus on changing behaviors (Oude et al., 2009). In one program, both parent and child revised eating patterns, exercised daily, and reinforced each other with praise and points for progress, which they exchanged for special activities and times together. The more weight parents lost, the more their children lost (Wrotniak et al., 2004). Follow-ups after five and ten years showed that children maintained their weight loss more effectively than adults—a finding that underscores the importance of early intervention (Epstein, Roemmich, & Raynor, 2001). Treatment programs that focus on both diet and lifestyle can yield substantial, long-lasting weight reduction among children and adolescents (Eliakim et al., 2004; Nemet et al., 2005). But these interventions work best when parents' and children's weight problems are not severe.

Children consume one-third of their daily caloric intake at school. Therefore, schools can also help reduce obesity by serving healthier meals, ensuring regular physical activity, and offering weight reduction programs. Because obesity is expected to rise further without broad prevention strategies, many U.S. states and cities have passed obesity-reduction legislation (Levi et al., 2009). Among measures taken are weight-related school screenings for all children, improved school nutrition standards, additional school recess time and physical education, school-based obesity awareness and weight-reduction programs, and menu nutrition labeling (including calorie counts) in chain and fast-food restaurants.

Vision and Hearing

The most common vision problem in middle childhood is *myopia*, or nearsightedness. By the end of the school years, it affects nearly 25 percent of children—a rate that rises to 60 percent by early adulthood. Heredity plays a role: Identical twins are more likely than fraternal twins to share the condition (Pacella et al., 1999). And worldwide, it occurs far more frequently in Asian than in Caucasian populations (Feldkämper & Schaeffel, 2003). Early biological trauma also can induce myopia. School-age children with low birth weights show an especially high rate, believed to result from immaturity of visual structures, slower eye growth, and a greater incidence of eye disease (O'Connor et al., 2002).

When parents warn their children not to read in dim light or sit too close to the TV or computer screen, their concern

(“You’ll ruin your eyes!”) is well-founded. In diverse cultures, the more time children spend reading, writing, using the computer, and doing other close work, the more likely they are to be myopic (Pan, Ramamurthy, & Saw, 2012; Rahi, Cumberland, & Peckham, 2011). Consequently, myopia is one of the few health conditions to increase with SES. Fortunately, it can be overcome easily with corrective lenses.

During middle childhood, the Eustachian tube (canal that runs from the inner ear to the throat) becomes longer, narrower, and more slanted, preventing fluid and bacteria from traveling so easily from the mouth to the ear. As a result, middle-ear infections, common in infancy and early childhood, become less frequent. Still, about 3 to 4 percent of the school-age population, and as many as 20 percent of low-SES children, develop permanent hearing loss as a result of repeated untreated infections (Ryding et al., 2002). With regular screening for both vision and hearing, defects can be corrected before they lead to serious learning difficulties.

Illnesses

Children experience a somewhat higher rate of illness during the first two years of elementary school than later because of exposure to sick children and an immune system that is still developing. About 15 to 20 percent of U.S. children have chronic diseases and conditions (including physical disabilities) (Van Cleave, Gortmaker, & Perrin, 2010). By far the most common—accounting for about one-third of childhood chronic illness and the most frequent cause of school absence and childhood hospitalization—is *asthma*, in which the bronchial tubes (passages that connect the throat and lungs) are highly sensitive (Bonilla et al., 2005). In response to a variety of stimuli, such as cold weather, infection, exercise, allergies, and emotional stress, they fill with mucus and contract, leading to coughing, wheezing, and serious breathing difficulties.

From 1980 to 1997, the prevalence of asthma among U.S. children more than doubled and then stabilized at 9 percent (Akinbami et al., 2009). Although heredity contributes to asthma, researchers believe that environmental factors are necessary to spark the illness. Boys, African-American children, and children who were born underweight, whose parents smoke, or who live in poverty are at greatest risk (Federico & Liu, 2003; Pearlman et al., 2006). The higher rate and greater severity of asthma among African-American and poverty-stricken children may be the result of pollution in inner-city areas (which triggers allergic reactions), stressful home lives, and lack of access to good health care. Childhood obesity is also related to asthma in middle childhood, perhaps due to high levels of blood-circulating inflammatory substances associated with body fat (Story, 2007).

About 2 percent of U.S. children have more severe chronic illnesses, such as sickle cell anemia, cystic fibrosis, diabetes, arthritis, cancer, and AIDS. Painful medical treatments, physical discomfort, and changes in appearance often disrupt the sick child's daily life, making it difficult to concentrate in school and separating the child from peers. As the illness worsens, family

stress increases (LeBlanc, Goldsmith, & Patel, 2003). For these reasons, chronically ill children are at risk for academic, emotional, and social difficulties.

A strong link exists between good family functioning and child well-being for chronically ill children, just as it does for physically healthy children (Drotar et al., 2006). Interventions that foster positive family relationships help parent and child cope with the disease and improve children's adjustment. These include health education, counseling, parent and peer support groups, and disease-specific summer camps, which teach children self-help skills and give parents time off from the demands of caring for an ill youngster.

Unintentional Injuries

As we conclude our discussion of threats to school-age children's health, let's return to the topic of unintentional injuries (discussed in detail in Chapter 7). As Figure 9.3 shows, injury fatalities increase from middle childhood into adolescence, with rates for boys rising considerably above those for girls.

Motor vehicle accidents, involving children as passengers or pedestrians, continue to be the leading cause of injury, followed by bicycle accidents (Bailar-Heath & Valley-Gray, 2010). Pedestrian injuries most often result from midblock dart-outs, bicycle accidents from disobeying traffic signals and rules. When many stimuli impinge on them at once, young school-age children often fail to think before they act. They need frequent reminders, supervision, and prohibitions against venturing into busy traffic on their own.

FIGURE 9.3 U.S. rates of injury mortality from middle childhood to adolescence. Injury fatalities increase with age, and the gap between boys and girls expands. Motor vehicle (passenger and pedestrian) accidents are the leading cause, with bicycle injuries next in line. (From National Center for Injury Prevention and Control, 2012.)

Effective school-based prevention programs use extensive modeling and rehearsal of safety practices, give children feedback about their performance along with praise and tangible rewards for acquiring safety skills, and provide occasional booster sessions (Zins et al., 1994). Parents, who often overestimate their child's safety knowledge and physical abilities, must be educated about children's age-related safety capacities (Schwebel & Bounds, 2003). One vital safety measure is insisting that children wear protective helmets while bicycling, in-line skating, skateboarding, or using scooters. This simple precaution leads to a 25 percent reduction in risk of head injury, a leading cause of permanent disability and death in school-age children (Macpherson & Spinks, 2007; Wesson et al., 2008).

Highly active, impulsive, risk-taking children, many of whom are boys, remain especially susceptible to injury in middle childhood. Although they have just as much safety knowledge as their peers, they are far less likely to implement it. Parents tend to be particularly lax in intervening in the dangerous behaviors of such children, especially under conditions of persistent marital conflict or other forms of mental distress (Schwebel et al., 2011, 2012). The greatest challenge for prevention programs is reaching these children and reducing their exposure to hazardous situations.

Motor Development and Play

TAKE A MOMENT... Visit a park on a pleasant weekend afternoon, and watch several preschool and school-age children at play. You will see that gains in body size and muscle strength support improved motor coordination in middle childhood. And greater cognitive and social maturity enables older children to use their new motor skills in more complex ways. A major change in children's play takes place at this time.

Gross-Motor Development

During the school years, running, jumping, hopping, and ball skills become more refined. Third to sixth graders burst into sprints as they race across the playground, jump quickly over rotating ropes, engage in intricate hopscotch patterns, kick and dribble soccer balls, bat at balls pitched by their classmates, and balance adeptly as they walk heel-to-toe across narrow ledges. These diverse skills reflect gains in four basic motor capacities:

- **Flexibility.** Compared with preschoolers, school-age children are physically more pliable and elastic, a difference that can be seen as they swing bats, kick balls, jump over hurdles, and execute tumbling routines.
- **Balance.** Improved balance supports many athletic skills, including running, hopping, skipping, throwing, kicking, and the rapid changes of direction required in many team sports.

© STEVE SKOLD/ALAMY

Improved physical flexibility, balance, agility, and force, along with more efficient information processing, are evident in these 8-year-olds' soccer skills.

- **Agility.** Quicker and more accurate movements are evident in the fancy footwork of dance and cheerleading and in the forward, backward, and sideways motions used to dodge opponents in tag and soccer.
- **Force.** Older youngsters can throw and kick a ball harder and propel themselves farther off the ground when running and jumping than they could at earlier ages (Haywood & Getchell, 2009).

Along with body growth, more efficient information processing plays a vital role in improved motor performance. During middle childhood, the capacity to react only to relevant information increases. And steady gains in reaction time occur, with 11-year-olds responding twice as quickly as 5-year-olds (Kail, 2003; Largo et al., 2001). Because 6- and 7-year-olds are seldom successful at batting a thrown ball, T-ball is more appropriate for them than baseball. Similarly, handball, four-square, and kickball should precede instruction in tennis, basketball, and football.

Fine-Motor Development

Fine-motor development also improves over the school years. On rainy afternoons, Joey and Lizzie experimented with yo-yos, built model airplanes, and wove potholders on small looms. Like many children, they took up musical instruments, which demand considerable fine-motor control.

Gains in fine-motor skill are especially evident in children's writing and drawing. By age 6, most children can print the alphabet, their first and last names, and the numbers from 1 to 10 with reasonable clarity. Their writing is large, however, because they make strokes with the entire arm rather than just the wrist and fingers. Children usually master uppercase letters first because their horizontal and vertical motions are easier to control than the small curves of the lowercase alphabet. Legibility

of writing gradually increases as children produce more accurate letters with uniform height and spacing. These improvements prepare children for mastering cursive writing by third grade.

Children's drawings show dramatic gains in middle childhood. By the end of the preschool years, children can accurately copy many two-dimensional shapes, and they integrate these into their drawings. Some depth cues have also begun to appear, such as making distant objects smaller than near ones (Braine et al., 1993). Around 9 to 10 years, the third dimension is clearly evident through overlapping objects, diagonal placement, and converging lines. Furthermore, as Figure 9.4 below shows, school-age children not only depict objects in considerable detail but also relate them to one another as part of an organized whole (Case, 1998; Case & Okamoto, 1996).

© INTERNATIONAL COLLECTION OF CHILD ART, MILNER LIBRARY, ILLINOIS STATE UNIVERSITY, NORMAL, IL

FIGURE 9.4 Increase in organization, detail, and depth cues in school-age children's drawings. **TAKE A MOMENT...**

Compare both drawings to the one by a 6-year-old on page 224 in Chapter 7. In the drawing by an 8-year-old on the top, notice how all parts are depicted in relation to one another and with greater detail. Integration of depth cues increases dramatically over the school years, as shown in the drawing on the bottom, by an 11-year-old. Here, the third dimension is indicated by overlapping objects and diagonal lines, as well as by making distant objects appear smaller than near ones.

Sex Differences

Sex differences in motor skills extend into middle childhood and, in some instances, become more pronounced. Girls have an edge in fine-motor skills of handwriting and drawing and in gross-motor capacities that depend on balance and agility, such as hopping and skipping. But boys outperform girls on all other gross-motor skills, especially throwing and kicking (Cratty, 1986; Haywood & Getchell, 2009).

School-age boys' genetic advantage in muscle mass is not large enough to account for their gross-motor superiority. Rather, the social environment plays a larger role. Research confirms that parents hold higher expectations for boys' athletic performance, and children readily absorb these messages. From first through twelfth grades, girls are less positive than boys about the value of sports and their own sports ability—differences explained in part by parental beliefs (Fredricks & Eccles, 2002). The more strongly girls believe that females are incompetent at sports (such as hockey or soccer), the lower they judge their own ability and the poorer they actually perform (Belcher et al., 2003; Chalabaev, Sarrazin & Fontayne, 2009).

Educating parents about the minimal differences between school-age boys' and girls' physical capacities and sensitizing them to unfair biases against promotion of girls' athletic ability may help increase girls' self-confidence and participation in athletics. And greater emphasis on skill training for girls, along with increased attention to their athletic achievements, is also likely to help. As a positive sign, compared with a generation ago, many more girls now participate in individual and team sports such as gymnastics and soccer (National Council of Youth Sports, 2008; Sabo & Veliz, 2011). Middle childhood is a crucial time to encourage girls' sports participation because during this period, children start to discover what they are good at and make some definite skill commitments.

Games with Rules

The physical activities of school-age children reflect an important advance in quality of play: Games with rules become common. Children around the world engage in an enormous variety of informally organized games, including variants on popular sports such as soccer, baseball, and basketball. In addition to the best-known childhood games, such as tag, jacks, and hopscotch, children have invented hundreds of other games, including red rover, statues, leapfrog, kick the can, and prisoner's base (Kirchner, 2000).

Gains in perspective taking—in particular, the ability to understand the roles of several players in a game—permit this transition to rule-oriented games. These play experiences, in turn, contribute greatly to emotional and social development. Child-invented games usually rely on simple physical skills and a sizable element of luck. As a result, they rarely become contests of individual ability. Instead, they permit children to try out different styles of cooperating, competing, winning, and losing with little personal risk. Also, in their efforts to organize a game, children discover why rules are necessary and

© DENNIS MACDONALD/LAMY

With their coach's encouragement, these young softball players are likely to view themselves as good at sports and to continue playing. In contrast, coaches who criticize and overemphasize competition promote early athletic dropout.

which ones work well. As we will see in Chapter 10, these experiences help children form more mature concepts of fairness and justice.

School-age children today spend less time engaged in informal outdoor play—a change that reflects parental concerns about neighborhood safety as well as competition for children's time from TV, video games, and the Internet. Another factor is the rise in adult-organized sports, such as Little League baseball and soccer and hockey leagues, which fill many hours that children used to devote to spontaneous play. About half of U.S. children—60 percent of boys and 37 percent of girls—participate in organized sports at some time between ages 5 and 18 (National Council of Youth Sports, 2008).

For most children, joining community athletic teams is associated with increased self-esteem and social skills (Daniels & Leaper, 2006; Fletcher, Nickerson, & Wright, 2003). Among shy children, sports participation seems to foster self-confidence and a decline in social anxiety, perhaps because it provides a sense of group belonging and a basis for communicating with peers (Findlay & Coplan, 2008). And children who view themselves as good at sports are more likely to continue playing on teams in adolescence, which predicts greater participation in sports and other physical fitness activities in early adulthood (Kjønniksen, Anderssen, & Wold, 2009; Marsh et al., 2007).

In some cases, though, the arguments of critics—that youth sports overemphasize competition and substitute adult control for children's natural experimentation with rules and strategies—are valid. Coaches and parents who criticize rather than encourage can prompt intense anxiety in some children, setting the stage for emotional difficulties and early athletic dropout, not elite performance (Tofler, Knapp, & Drell, 1998; Wall &

Applying What We Know

Providing Developmentally Appropriate Organized Sports in Middle Childhood

Suggestion	Description
Build on children's interests.	Permit children to select from among appropriate activities the ones that suit them best. Do not push children into sports they do not enjoy.
Teach age-appropriate skills.	For children younger than age 9, emphasize basic skills, such as kicking, throwing, and batting, and simplified games that grant all participants adequate playing time.
Emphasize enjoyment.	Permit children to progress at their own pace and to play for the fun of it, whether or not they become expert athletes.
Limit the frequency and length of practices.	Adjust practice time to children's attention spans and need for unstructured time with peers, with family, and for homework. Two practices a week, each no longer than 30 minutes for younger school-age children and 60 minutes for older school-age children, are sufficient.
Focus on personal and team improvement.	Emphasize effort, skill gains, and teamwork rather than winning. Avoid criticism for errors and defeat, which promotes anxiety and avoidance of athletics.
Discourage unhealthy competition.	Avoid all-star games and championship ceremonies that recognize individuals. Instead, acknowledge all participants.
Permit children to contribute to rules and strategies.	Involve children in decisions aimed at ensuring fair play and teamwork. To strengthen desirable responses, reinforce compliance rather than punishing noncompliance.

Côté, 2007). See Applying What We Know above for ways to ensure that athletic leagues provide children with positive learning experiences.

Shadows of Our Evolutionary Past

TAKE A MOMENT... While watching children in your neighborhood park, notice how they sometimes wrestle, roll, hit, and run after one another, alternating roles while smiling and laughing. This friendly chasing and play-fighting is called **rough-and-tumble play**. It emerges in the preschool years and peaks in middle childhood, and children in many cultures engage in it with peers whom they like especially well (Pellegrini, 2004).

Children's rough-and-tumble play resembles the social behavior of many other young mammals. It seems to originate in parents' physical play with babies, especially fathers' with sons (see page 202 in Chapter 6). And it is more common among boys, probably because prenatal exposure to androgens (male sex hormones) predisposes boys toward active play (see Chapter 8).

In our evolutionary past, rough-and-tumble play may have been important for developing fighting skill (Power, 2000). It also helps children form a **dominance hierarchy**—a stable ordering of group members that predicts who will win when conflict arises. Observations of arguments, threats, and physical

attacks between children reveal a consistent lineup of winners and losers that becomes increasingly stable in middle childhood, especially among boys. Once school-age children establish a dominance hierarchy, hostility is rare (Pellegrini & Smith,

© CLEVE BRANT/PHOTODISC

In our evolutionary past, rough-and-tumble play—which can be distinguished from aggression by its friendly quality—may have been important for developing fighting skill and establishing dominance hierarchies.

Social Issues: Education

School Recess—A Time to Play, a Time to Learn

When 7-year-old Whitney's family moved to a new city, she left a school with three daily recess periods for one with just a single 15-minute break per day, which her second-grade teacher cancelled if any child misbehaved. Whitney, who had previously enjoyed school, complained daily of headaches and an upset stomach. Her mother, Jill, thought, "My child is stressing out because she can't move all day!" After Jill and other parents successfully appealed to the school board to add a second recess period, Whitney's symptoms vanished (Rauber, 2006).

In recent years, recess—with its rich opportunities for child-organized play and peer interaction—has diminished or disappeared in many U.S. elementary schools (Ginsburg, 2007; Pellegrini & Holmes, 2006). Under the assumption that extra time for academics will translate into achievement gains, 7 percent of U.S. schools no longer provide recess to students as young as second grade. And over half of schools that do have recess now schedule it just once a day (U.S. Department of Education, 2012b).

Yet rather than subtracting from classroom learning, recess periods boost it! Research dating back more than 100 years confirms that distributing cognitively demanding tasks over a longer time by introducing regular breaks enhances attention and performance at all ages. Such breaks are particularly important for children. In a series of studies, elementary school students were more attentive in the classroom after recess than before it—an effect that was greater for second than fourth graders (Pellegrini, Huberty, & Jones, 1995). Teacher ratings of classroom disruptive behavior also decline for children who have more than 15 minutes of recess a day (Barros, Silver, & Stein, 2009).

In other research, kindergartners' and first graders' engagement in peer conversation and games during recess positively predicted academic achievement, even

TORONTO STAR/FIRSTLIGHT

Recess offers rich opportunities for child-organized play and games that provide practice in social skills while also promoting physical and academic competence.

after other factors that might explain the relationship (such as previous achievement) were controlled (Pellegrini, 1992; Pellegrini et al., 2002). Recall from Chapter 8 that children's social maturity contributes substantially to academic competence. Recess is one of the few remaining contexts devoted to child-organized games that provide practice in vital social skills—cooperation, leadership, followership, and inhibition of aggression—under adult supervision rather than adult direction. As children transfer these skills to the classroom, they may participate in discussions, collaborate, follow rules, and enjoy academic pursuits more—factors that enhance motivation and achievement.

1998; Roseth et al., 2007). Children seem to use play-fighting as a safe context to assess the strength of a peer before challenging that peer's dominance.

As children reach puberty, individual differences in strength become apparent, and rough-and-tumble play declines. When it does occur, its meaning changes: Adolescent boys' rough-and-tumble is linked to aggression (Pellegrini, 2003). Unlike children, teenage rough-and-tumble players "cheat," hurting their opponent. In explanation, boys often say that they are retaliating, apparently to reestablish dominance. Thus, a play behavior that limits aggression in childhood becomes a context for hostility in adolescence.

Physical Education

Physical activity supports many aspects of children's development—health, sense of self-worth, and the cognitive and social skills necessary for getting along with others. Yet to devote more time to academic instruction, U.S. elementary schools have cut

back on recess, despite its contribution to all domains of development (see the Social Issues: Education box above). Similarly, although most U.S. states require some physical education, only six require it in every grade, and only one mandates at least 30 minutes per school day in elementary school and 45 minutes in middle and high school. Not surprisingly, physical inactivity among school-age children is pervasive: Fewer than one-third of 6- to 17-year-olds engage in at least moderate-intensity activity for 60 minutes per day and vigorous activity (involving breathing hard and sweating) for 20 minutes, recommended for good health (National Association for Sport and Physical Education, 2010).

Many experts believe that schools should not only offer more physical education classes but also change the content of these programs. Training in competitive sports, often a high priority, is unlikely to reach the least physically fit youngsters, who avoid activities demanding a high level of skill. Instead, programs should emphasize enjoyable, informal games and individual exercise—pursuits most likely to endure.

Physically fit children tend to become active adults who reap many benefits (Kjønniksen, Torsheim, & Wold, 2008; Tammelin et al., 2003). These include greater physical strength, resistance to many illnesses (from colds and flu to cancer, diabetes, and heart disease), enhanced psychological well-being, and a longer life.

ASK YOURSELF

COGNITIVE DEVELOPMENT

"Finally!" 6-year-old Lizzie exclaimed the day she entered first grade. "Now I get to go to real school, just like Joey!" Lizzie walked into her classroom confidently, pencils, crayons, and writing pad in hand, ready for a more disciplined approach to learning. In a single morning, she and her classmates wrote in journals, met in reading groups, worked on addition and subtraction, and sorted leaves gathered for a science project. As Lizzie and Joey moved through the elementary school grades, they tackled increasingly complex tasks and became more accomplished at reading, writing, math skills, and general knowledge of the world.

To understand the cognitive attainments of middle childhood, we turn to research inspired by Piaget's theory and the information-processing perspective. And we look at expanding definitions of intelligence that help us appreciate individual differences. Our discussion continues with language, which blossoms further in these years. Finally, we consider the role of schools in children's development.

Piaget's Theory: The Concrete Operational Stage

When Lizzie visited my child development class as a 4-year-old, Piaget's conservation problems confused her (see Chapter 7, page 229). For example, when water was poured from a tall,

narrow container into a short, wide one, she insisted that the amount of water had changed. But when Lizzie returned at age 8, she found these tasks easy. "Of course it's the same!" she exclaimed. "The water's shorter, but it's also wider. Pour it back," she instructed the college student who was interviewing her. "You'll see, it's the same amount!"

Concrete Operational Thought

Lizzie has entered Piaget's **concrete operational stage**, which extends from about 7 to 11 years. Compared with early childhood, thought is far more logical, flexible, and organized.

Conservation. The ability to pass *conservation tasks* provides clear evidence of *operations*—mental actions that obey logical rules. Notice how Lizzie is capable of *decentration*, focusing on several aspects of a problem and relating them, rather than centering on just one. She also demonstrates **reversibility**, the capacity to think through a series of steps and then mentally reverse direction, returning to the starting point. Recall from Chapter 7 that reversibility is part of every logical operation. It is solidly achieved in middle childhood.

Classification. Between ages 7 and 10, children pass Piaget's *class inclusion problem* (see page 229). This indicates that they are more aware of classification hierarchies and can focus on relations between a general category and two specific categories at the same time—that is, on three relations at once (Hodges & French, 1988; Ni, 1998). Collections—stamps, coins, baseball cards, rocks, bottle caps—become common in middle childhood. At age 10, Joey spent hours sorting and resorting his baseball cards, grouping them first by league and team, then by playing position and batting average. He could separate the players into a variety of classes and subclasses and easily rearrange them.

© LAURA DWIGHT PHOTOGRAPHY

An improved ability to categorize underlies children's interest in collecting objects during middle childhood. This 9-year-old sorts and organizes her extensive shell collection.

Seriation. The ability to order items along a quantitative dimension, such as length or weight, is called **seriation**. To test for it, Piaget asked children to arrange sticks of different lengths from shortest to longest. Older preschoolers can put the sticks in a row, but they do so haphazardly, making many errors. In contrast, 6- to 7-year-olds create the series efficiently, moving in an orderly sequence from the smallest stick, to the next largest, and so on.

The concrete operational child can also seriate mentally, an ability called **transitive inference**. In a well-known transitive inference problem, Piaget showed children pairings of sticks of different colors. From observing that Stick A is longer than Stick B and Stick B is longer than Stick C, children must infer that A is longer than C. Like Piaget's class inclusion task, transitive inference requires children to integrate three relations at once—in this instance, A–B, B–C, and A–C. When researchers take steps to ensure that children remember the premises (A–B and B–C), 7-year-olds can grasp transitive inference (Andrews & Halford, 1998; Wright, 2006).

Spatial Reasoning. Piaget found that school-age children's understanding of space is more accurate than that of preschoolers. Let's consider children's **cognitive maps**—mental representations of familiar large-scale spaces, such as their neighborhood or school. Drawing a map of a large-scale space requires considerable perspective-taking skill. Because the entire space cannot be seen at once, children must infer its overall layout by relating its separate parts.

Preschoolers and young school-age children include **landmarks** on the maps they draw, but their arrangement is not always accurate. They do better when asked to place stickers showing the location of desks and people on a map of their classroom. But if the map is rotated to a position other than the orientation of the classroom, they have difficulty (Liben & Downs, 1993).

Around age 8 to 10, children's maps become better organized, showing landmarks along an **organized route of travel**. At the same time, children are able to give clear, well-organized

instructions for getting from one place to another by using a “mental walk” strategy—imagining another person's movements along a route (Gauvain & Rogoff, 1989). By the end of middle childhood, children combine landmarks and routes into an **overall view of a large-scale space**. And they readily draw and read maps of extended outdoor environments, even when the orientation of the map and the space it represents do not match (Liben, 2009). Ten- to 12-year-olds also grasp the notion of **scale**—the proportional relation between a space and its representation on a map (Liben, 2006).

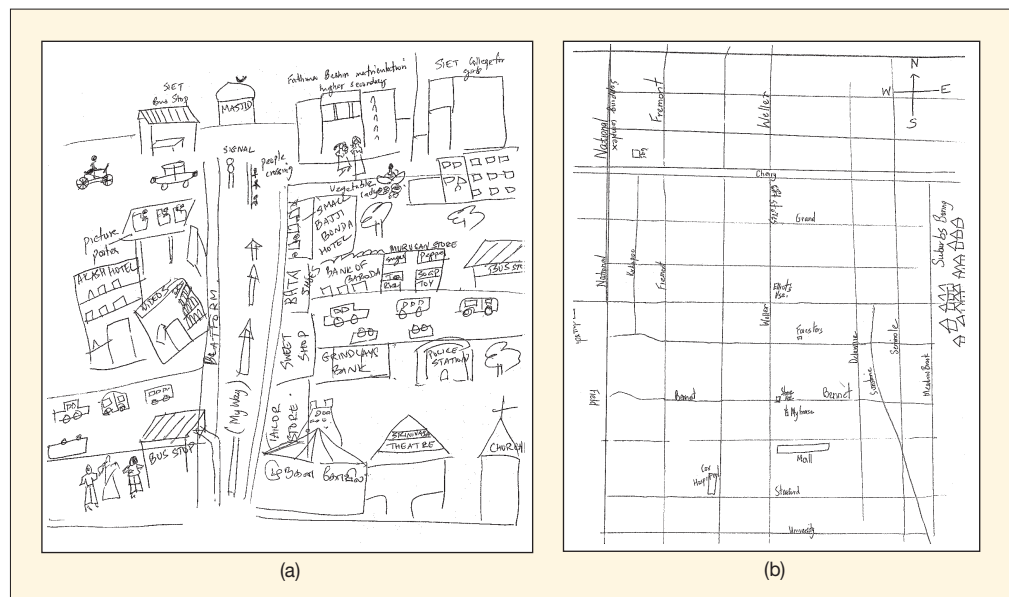

LOOK AND LISTEN

Ask a 6- to 8-year-old and a 9- to 12-year-old to draw a neighborhood map showing important landmarks, such as the school, a friend's house, or a shopping area. In what ways do the children's maps differ? ●

Cultural frameworks influence children's map making. In many non-Western communities, people rarely use maps for way-finding but rely on information from neighbors, street vendors, and shopkeepers. Also, compared to their Western agemates, non-Western children less often ride in cars and more often walk, which results in intimate neighborhood knowledge. When older school-age children in small cities in India and in the United States drew maps of their neighborhoods, the Indian children represented a rich array of landmarks and aspects of social life, such as people and vehicles, in a small area surrounding their home. The U.S. children, in contrast, drew a more formal, extended space, highlighting main streets and key directions (north–south, east–west) but including few landmarks (see Figure 9.5) (Parameswaran, 2003). Although the U.S. children's maps scored higher in cognitive maturity, this difference reflected cultural interpretations of the task. When asked to create a map to “help people find their way,” the Indian children drew spaces as far-reaching and organized as the U.S. children's.

Limitations of Concrete Operational Thought

As the name of this stage suggests, concrete operational thinking suffers from one important limitation: Children think in an organized, logical fashion only when dealing with concrete information they can perceive directly. Their mental operations work poorly with abstract ideas—ones not apparent in the real world. Consider children's solutions to transitive inference problems. When shown pairs of sticks of unequal length, Lizzie easily engaged in transitive inference. But she had difficulty with a hypothetical version of this task: "Susan is taller than Sally, and Sally is taller than Mary. Who is the tallest?" Not until age 11 or 12 can children solve this problem.

That logical thought is at first tied to immediate situations helps account for a special feature of concrete operational reasoning: Children master concrete operational tasks step by step. For example, they usually grasp conservation of number first, followed by conservation of length, liquid, and mass, and then weight. This *continuum of acquisition* (or gradual mastery) of logical concepts is another indication of the limitations of concrete operational thinking (Fischer & Bidell, 1991). Rather than coming up with general logical principles that they apply to all relevant situations, school-age children seem to work out the logic of each problem separately.

Follow-Up Research on Concrete Operational Thought

According to Piaget, brain development combined with experience in a rich and varied external world should lead children everywhere to reach the concrete operational stage at about the same time. Yet recent evidence indicates that specific cultural and school practices have much to do with mastery of Piagetian tasks (Rogoff, 2003). And information-processing research helps explain the gradual mastery of logical concepts in middle childhood.

The Impact of Culture and Schooling. In tribal and village societies, conservation is often delayed. Among the Hausa of Nigeria, who live in small agricultural settlements and rarely send their children to school, even basic conservation tasks—number, length, and liquid—are not understood until age 11 or later (Fahrmeier, 1978). This suggests that participating in relevant everyday activities helps children master conservation and other Piagetian problems. Joey and Lizzie, for example, think of fairness in terms of equal distribution—a value emphasized in their culture. They frequently divide materials, such as crayons or treats, equally among their friends. Because they often see the same quantity arranged in different ways, they grasp conservation early.

The very experience of going to school seems to promote mastery of Piagetian tasks. When children of the same age are tested, those who have been in school longer do better on transitive inference problems (Artman & Cahan, 1993). Opportunities

to seriate objects, to learn about order relations, and to remember the parts of complex problems are probably responsible. Yet certain informal nonschool experiences can also foster operational thought. Around age 7 to 8, Zinacanteco Indian girls of southern Mexico, who learn to weave elaborately designed fabrics as an alternative to schooling, engage in mental transformations to figure out how a warp strung on a loom will turn out as woven cloth—reasoning expected at the concrete operational stage. American children of the same age, who do much better than Zinacanteco children on Piagetian tasks, have great difficulty with these weaving problems (Maynard & Greenfield, 2003).

On the basis of such findings, some investigators have concluded that the forms of logic required by Piagetian tasks do not emerge spontaneously but, rather, are heavily influenced by training, context, and cultural conditions. Does this view remind you of Vygotsky's sociocultural theory, discussed in earlier chapters?

An Information-Processing View of Concrete Operational Thought. The gradual mastery of logical concepts in middle childhood raises a familiar question about Piaget's theory: Is an abrupt stagewise transition to logical thought the best way to describe cognitive development in middle childhood?

Some *neo-Piagetian theorists* argue that the development of operational thinking can best be understood in terms of gains in information-processing speed rather than a sudden shift to a new stage (Halford & Andrews, 2006). For example, Robbie Case (1996, 1998) proposed that, with practice, cognitive schemes demand less attention and become more automatic. This frees up space in *working memory* so children can focus on combining old schemes and generating new ones. For instance, the child who sees water poured from one container to another recognizes that the height of the liquid changes. As this understanding

becomes routine, the child notices that the width of the water changes as well. Soon children coordinate these observations, and they grasp conservation of liquid. Then, as this logical idea becomes well-practiced, the child transfers it to more demanding situations, such as weight.

Once the schemes of a Piagetian stage are sufficiently automatic, enough working memory is available to integrate them into an improved representation. As a result, children acquire *central conceptual structures*—networks of concepts and relations that permit them to think more effectively about a wide range of situations (Case, 1996, 1998). The central conceptual structures that emerge from integrating concrete operational schemes are broadly applicable principles that result in increasingly complex, systematic reasoning, which we will discuss in Chapter 11 in the context of formal operational thought.

Case and his colleagues—along with other information-processing researchers—have examined children’s performance on a wide variety of tasks: solving arithmetic word problems, understanding stories, drawing pictures, and interpreting social situations. In each task, preschoolers typically focus on only one dimension. In understanding stories, for example, they grasp only a single story line. By the early school years, they combine two story lines into a single plot. Around 9 to 11 years, children integrate multiple dimensions (Case, 1998; Halford & Andrews, 2006). They tell coherent stories with a main plot and several subplots.

Case’s theory helps explain why many understandings appear in specific situations at different times rather than being mastered all at once. First, different forms of the same logical insight, such as the various conservation tasks, vary in their processing demands, with those acquired later requiring more space in working memory. Second, children’s experiences vary widely. A child who often listens to and tells stories but rarely draws pictures displays more advanced central conceptual structures in storytelling. Compared with Piaget’s, Case’s theory better accounts for unevenness in cognitive development.

Evaluation of the Concrete Operational Stage

Piaget was correct that school-age children approach many problems in more organized, rational ways than preschoolers. But disagreement continues over whether this difference occurs because of *continuous* improvement in logical skills or *discontinuous* restructuring of children’s thinking (as Piaget’s stage idea assumes). Many researchers think that both types of change may be involved (Case, 1998; Demetriou et al., 2002; Fischer & Bidell, 2006; Halford & Andrews, 2006).

During the school years, children apply logical schemes to many more tasks. In the process, their thought seems to change qualitatively—toward a more comprehensive grasp of the underlying principles of logical thought. Piaget himself recognized this possibility in evidence for gradual mastery of conservation and other tasks. So perhaps some blend of Piagetian and information-processing ideas holds the greatest promise for explaining cognitive development in middle childhood.

Information Processing

In contrast to Piaget’s focus on overall cognitive change, the information-processing perspective examines separate aspects of thinking. Working-memory capacity, as noted in our discussion of Case’s theory, continues to increase in middle childhood. And school-age children make great strides in executive function, yielding significant advances in attention, planning, memory, and self-regulation. Each contributes vitally to academic learning.

Working-Memory Capacity

Improved performance on working-memory tasks (see page 161 in Chapter 5) is supported by brain development. And working memory—as we have seen in our discussion of Case’s theory—benefits from enhanced speed of thinking. Time needed to process information on a wide variety of cognitive tasks declines rapidly between ages 6 and 12, likely due to myelination and synaptic pruning in the cerebral cortex (Kail, 1993, 1997). A faster thinker can hold on to and operate on more information in working memory (Luna et al., 2004; Nettelbeck & Burns, 2010). Still, individual differences in working-memory capacity exist, and they are of particular concern because they predict intelligence test scores and academic achievement in diverse subjects (Colom et al., 2007; Gathercole et al., 2005).

Indeed, children with persistent learning difficulties in reading and math are often deficient in working-memory capacity (Alloway, 2009; Gathercole et al., 2006). Reduced working memory creates a bottleneck for learning. Observations of elementary school children with limited working memories revealed that they often failed at school assignments that made heavy memory demands (Gathercole, Lamont, & Alloway, 2006). They could not follow complex instructions, lost their place in

tasks with multiple steps, and frequently gave up before finishing their work. The children struggled because they could not hold in mind sufficient information to complete assignments.

Compared to their economically advantaged age mates, children from poverty-stricken families are more likely to score low on working-memory tasks—a strong contributor to their generally poorer academic achievement (Farah et al., 2006; Noble, McCandliss, & Farah, 2007). In one study, years of childhood spent in poverty predicted reduced working-memory capacity in early adulthood (Evans & Schamberg, 2009). Childhood neurobiological measures of stress—elevated blood pressure and stress hormone levels, including cortisol—largely explained this poverty–working-memory association. Chronic stress, as we saw in Chapter 4, can impair brain structure and function, especially in the prefrontal cortex and its connections with the hippocampus, which govern working-memory capacity.

Interventions are needed that reduce memory loads so children with limited working memories can learn. Effective approaches include communicating in short sentences with familiar vocabulary, repeating task instructions, breaking complex tasks into manageable parts, and encouraging children to use external memory aids (such as lists of useful spellings when writing or number lines when doing math) (Gathercole & Alloway, 2008). Do these techniques remind you of *scaffolding*, a style of teaching introduced in Chapter 7 known to promote cognitive development?

Executive Function

Our discussion in Chapter 7 revealed that early childhood is a vital time for laying the foundations of executive function. During the school years, a time of continued development of the prefrontal cortex, executive function undergoes its most energetic period of development (Welsh, 2002). Children handle increasingly difficult tasks that require the integration of working memory, inhibition, planning, flexible use of strategies, and self-monitoring and self-correction of behavior (Luciana, 2003; Welsh, Pennington, & Groisser, 1991).

Heritability evidence suggests substantial genetic influence on various aspects of executive function, including combining information in working memory, controlling attention, and inhibiting inappropriate responses (Hansell et al., 2001; Polderman et al., 2009; Young et al., 2009). And molecular genetic analyses are identifying specific genes related to severely deficient functioning of executive components, such as attention and inhibition, which (as we will soon see) contributes to learning and behavior disorders, such as attention-deficit hyperactivity disorder (ADHD).

But in both typically and atypically developing children, heredity combines with environmental contexts to influence executive function. In Chapter 3, we reviewed evidence indicating that prenatal teratogens can impair impulse control, attention, planning, and other executive processes. And as with working memory, poverty and stressful living conditions can undermine executive function, with powerfully negative consequences for academic achievement and social adjustment (Blair

© LAURA DWIGHT PHOTOGRAPHY

Middle childhood is a period of dramatic gains in executive function. This complex map-making project requires fourth graders to coordinate relevant information in working memory, inhibit inappropriate responses, flexibly implement strategies, and monitor their progress, redirecting unsuccessful efforts.

& Raver, 2012). As we turn now to the development of an array of executive processes, our discussion will confirm that supportive home and school experiences are essential for their optimal development.

Attention

In middle childhood, attention becomes more selective, adaptable, and planful. First, children become better at deliberately attending to just those aspects of a situation that are relevant to their goals. Researchers study this increasing selectivity of attention by introducing irrelevant stimuli into a task and seeing how well children attend to its central elements. Selective attention improves sharply between ages 6 and 10, with gains continuing throughout adolescence (Gomez-Perez & Ostrosky-Solis, 2006; Tabibi & Pfeffer, 2007; Vakil et al., 2009).

Second, older children are better at flexibly adapting their attention to task requirements. When asked to sort cards with pictures that vary in both color and shape, children age 5 and older readily switch their basis of sorting from color to shape when asked to do so. Younger children typically persist in sorting in just one way (Brooks et al., 2003; Zelazo, Carlson, & Kesek, 2008). And when studying for a spelling test, 10-year-old Joey was much more likely than Lizzie to devote most attention to the words he knew least well (Masur, McIntyre, & Flavell, 1973).

Finally, planning, which requires children to coordinate attention skills with other cognitive processes, improves greatly in middle childhood (Gauvain, 2004; Scholnick, 1995). On tasks with many parts, school-age children make decisions about what to do first and what to do next in an orderly fashion. Having many opportunities to practice planning helps them imagine future possibilities, postpone action in favor of evaluating alternatives, organize task materials (such as items on a

Biology and Environment

Children with Attention-Deficit Hyperactivity Disorder

While the other fifth graders worked quietly at their desks, Calvin squirmed, dropped his pencil, looked out the window, and fiddled with his shoelaces. “Hey Joey,” he yelled across the room, “wanna play ball after school?” But the other children weren’t eager to play with Calvin, who was physically awkward and failed to follow the rules of the game. He had trouble taking turns at bat and, in the outfield, looked elsewhere when the ball came his way. Calvin’s desk was a chaotic mess. He often lost pencils, books, and other school materials, and he had difficulty remembering assignments and due dates.

Symptoms of ADHD

Calvin is one of 3 to 7 percent of U.S. school-age children with **attention-deficit hyperactivity disorder (ADHD)**, which involves inattention, impulsivity, and excessive motor activity resulting in academic and social problems (American Psychiatric

Association, 2000). Boys are diagnosed about four times as often as girls. However, many girls with ADHD seem to be overlooked, either because their symptoms are less flagrant or because of a gender bias: A difficult, disruptive boy is more likely to be referred for treatment (Biederman et al., 2005).

Children with ADHD cannot stay focused on a task that requires mental effort for more than a few minutes. They often act impulsively, ignoring social rules and lashing out with hostility when frustrated. Many, though not all, are *hyperactive*, exhausting parents and teachers and irritating other children with their excessive motor activity. For a child to be diagnosed with ADHD, these symptoms must have appeared before age 7 as a persistent problem.

Because of their difficulty concentrating, children with ADHD score 7 to 15 points lower than other children on intelligence tests (Barkley, 2002). Researchers agree that executive function deficiencies underlie ADHD symptoms. According to one view,

children with ADHD are impaired in capacity to inhibit action in favor of thought—a basic difficulty resulting in wide-ranging inadequacies in executive processing and, therefore, in impulsive, disorganized behavior (Barkley, 2003a). Another hypothesis is that ADHD is the direct result of a cluster of executive processing problems that interfere with ability to guide one’s own actions (Brown, 2006). Research confirms that children with ADHD do poorly on tasks requiring sustained attention; find it hard to ignore irrelevant information; have difficulty with memory, planning, reasoning, and problem solving in academic and social situations; and often fail to manage frustration and intense emotion (Barkley, 2003b, 2006).

Origins of ADHD

ADHD runs in families and is highly heritable: Identical twins share it more often than fraternal twins (Freitag et al., 2010; Rasmussen et al., 2004). Children with ADHD show abnormal brain functioning, including reduced electrical and blood-flow activity and structural abnormalities in the

grocery list), and remember the steps of their plan so they can attend to each one in sequence. Parents can foster planning by encouraging it in everyday activities, from loading the dishwasher to preparing for a vacation. In one study, discussions involving planning with school-age children predicted planning in adolescence (Gauvain & Huard, 1999). The demands of school tasks—and teachers’ explanations of how to plan—also contribute to gains in planning.

The attentional strategies just considered are crucial for success in school. Unfortunately, some children have grave difficulties paying attention. See the Biology and Environment box above for a discussion of the serious learning and behavior problems of children with attention-deficit hyperactivity disorder.

Memory Strategies

As attention improves, so do *memory strategies*, deliberate mental activities we use to store and retain information. When Lizzie had a list of things to learn—for example, the state capitals of the United States—she immediately used **rehearsal**—repeating

the information to herself. This memory strategy first appears in the early grade school years. Soon after, a second strategy becomes common: **organization**—grouping related items together (for example, all state capitals in the same part of the country) (Schneider, 2002).

Perfecting memory strategies requires time and effort. Eight-year-old Lizzie rehearsed in a piecemeal fashion. After being given the word *cat* in a list of items, she said, “Cat, cat, cat.” But 10-year-old Joey used a more effective approach: He combined previous words with each new item, saying, “Desk, man, yard, cat, cat.” This more active rehearsal approach, in which neighboring words create contexts for one another that trigger recall, yields much better memory (Lehman & Hasselhorn, 2007, 2010). Furthermore, whereas Lizzie organized by everyday association (hat–head, carrot–rabbit), Joey grouped items *taxonomically*, based on common properties (clothing, food, animals) and, thus, into fewer categories—an efficient procedure yielding dramatic memory gains (Bjorklund et al., 1994). And Joey used organization in a wide range of memory tasks, whereas Lizzie used it only when categorical relations among items were obvious.

prefrontal cortex and in other areas involved in attention, inhibition of behavior, and other aspects of motor control (Mackie et al., 2007; Sowell et al., 2003). Also, the brains of children with ADHD grow more slowly and are about 3 percent smaller in overall volume, with a thinner cerebral cortex, than those of unaffected age mates (Narr et al., 2009; Shaw et al., 2007). Several genes that disrupt functioning of neurotransmitters involved in inhibition and cognitive processing have been implicated in the disorder (Bobb et al., 2006; Faraone & Mick, 2010).

At the same time, ADHD is associated with environmental factors. Prenatal teratogens—such as tobacco, alcohol, and environmental pollutants—are linked to inattention and hyperactivity. And they can combine with certain genotypes to greatly increase risk of the disorder (see page 74 in Chapter 2). Furthermore, children with ADHD are more likely to come from homes in which marriages are unhappy and family stress is high (Bernier & Siegel, 1994). But a stressful home life rarely causes ADHD. Rather, these children's behaviors can contribute to family problems, which intensify the child's preexisting difficulties.

Furthermore, Joey often combined several strategies—for example, organizing items, then stating the category names, and finally rehearsing. The more strategies children apply simultaneously and consistently, the better they remember (Hock, Park, & Bjorklund, 1998; Schwenck, Bjorklund, & Schneider, 2007). Younger school-age children often try out various memory strategies but use them less systematically and successfully than older children. Still, their tendency to experiment allows them to discover which strategies work best and how to combine them effectively. Indeed, children experiment with strategies when faced with many cognitive challenges—an approach that enables them to gradually “home in” on the most effective techniques (Siegler, 1996, 2007).

By the end of middle childhood, children start to use **elaboration**—creating a relationship, or shared meaning, between two or more pieces of information that do not belong to the same category. For example, to learn the words *fish* and *pipe*, you might generate the verbal statement or mental image, “The fish is smoking a pipe.” This highly effective memory technique, which requires considerable effort and space in working memory, becomes increasingly common in adolescence and early adulthood (Schneider & Pressley, 1997).

Treating ADHD

Calvin's doctor eventually prescribed stimulant medication, the most common treatment for ADHD. As long as dosage is carefully regulated, these drugs reduce activity level and improve attention, academic performance, and peer relations for about 70 percent of children who take them (Greenhill, Halperin, & Abikoff, 1999). Stimulant medication seems to increase activity in the prefrontal cortex, thereby improving the child's capacity to sustain attention and to inhibit off-task behavior.

Nevertheless, drug treatment cannot teach children to compensate for inattention and impulsivity. The most effective treatment approach combines medication with interventions that model and reinforce appropriate academic and social behavior (Smith, Barkley, & Shapiro, 2006).

Family intervention is also important. Inattentive, overactive children strain the patience of parents, who are likely to react punitively and inconsistently—a child-

This child frequently engages in disruptive behavior at school. Children with ADHD have great difficulty staying on task and often act impulsively, ignoring social rules.

rearing style that strengthens defiant, aggressive behavior. In fact, in 50 to 75 percent of cases, these two sets of behavior problems occur together (Goldstein, 2011).

ADHD is usually a lifelong disorder. Adults with ADHD continue to need help in structuring their environments, regulating negative emotion, selecting appropriate careers, and understanding their condition as a biological deficit rather than a character flaw.

Because organization and elaboration combine items into *meaningful chunks*, they permit children to hold onto much more information and, as a result, further expand working memory. In addition, when children link a new item to information they already know, they can *retrieve* the new item easily by thinking of other items associated with it. As we will see, this also contributes to improved memory during the school years.

Knowledge and Memory

During middle childhood, the long-term knowledge base grows larger and becomes organized into increasingly elaborate, hierarchically structured networks. This rapid growth of knowledge helps children use strategies and remember (Schneider, 2002). In other words, knowing more about a topic makes new information more meaningful and familiar so it is easier to store and retrieve.

In a test of this idea, researchers classified fourth graders as either experts or novices in knowledge of soccer and then gave both groups lists of soccer and nonsoccer items to learn. Experts remembered far more items on the soccer list (but not on the

nonsoccer list) than novices. And during recall, experts' listing of items was better organized, as indicated by clustering of items into categories (Schneider & Bjorklund, 1992). This superior organization at retrieval suggests that highly knowledgeable children organize information in their area of expertise with little or no effort. Consequently, experts can devote more working-memory resources to using recalled information for reasoning and problem solving.

But knowledge is not the only important factor in children's strategic memory processing. Children who are expert in an area are usually highly motivated. As a result, they not only acquire knowledge more quickly but also *actively use what they know* to add more. In contrast, academically unsuccessful children fail to ask how previously stored information can clarify new material. This, in turn, interferes with the development of a broad knowledge base (Schneider & Bjorklund, 1998). So extensive knowledge and use of memory strategies support one another.

Culture, Schooling, and Memory Strategies

Children and adults usually use memory strategies when they need to remember information for its own sake. On many other occasions, memory occurs as a natural byproduct of participation in daily activities (Rogoff, 2003).

A repeated finding is that people in non-Western cultures who lack formal schooling rarely use or benefit from instruction in memory strategies because they see no practical reason to use these techniques (Rogoff & Chavajay, 1995). Tasks that require children to recall isolated bits of information, which are common in school, strongly motivate use of memory strategies. In fact, Western children get so much practice with this type of learning that they do not refine techniques that rely on cues available in everyday life, such as spatial location and arrangement

An 8-year-old of the Dorze people of Ethiopia winds cotton onto a bobbin for his father, a skilled weaver. Despite his keen memory for the complex steps involved in preparing the bobbin, this child might have difficulty recalling the isolated bits of information that school tasks often require.

of objects. For example, Guatemalan Mayan 9-year-olds do slightly better than their U.S. age-mates when told to remember the placement of 40 familiar objects in a play scene. U.S. children often rehearse object names when it would be more effective to keep track of spatial relations (Rogoff & Wadell, 1982). The development of memory strategies, then, is not just a product of a more competent information-processing system. It also depends on task demands and cultural circumstances.

The School-Age Child's Theory of Mind

During middle childhood, children's *theory of mind*, or set of ideas about mental activities, becomes more elaborate and refined. Recall from Chapter 7 that this awareness of thought is often called *metacognition*. School-age children's improved ability to reflect on their own mental life is another reason that their thinking advances.

Unlike preschoolers, who view the mind as a passive container of information, older children regard it as an active, constructive agent that selects and transforms information (Kuhn, 2000). Consequently, they have a much better understanding of cognitive processes and the impact of psychological factors on performance. For example, with age, school-age children become increasingly aware of effective memory strategies and why they work (Alexander et al., 2003). They also grasp relationships between mental activities—for example, that remembering is crucial for understanding and that understanding strengthens memory (Schwanenflugel, Henderson, & Fabricius, 1998).

Furthermore, school-age children's understanding of sources of knowledge expands. They realize that people can extend their knowledge not just by directly observing events and talking to others but also by making *mental inferences* (Miller, Hardin, & Montgomery, 2003). This grasp of inference enables knowledge of *false belief* to expand. In several studies, researchers told children complex stories involving one character's belief about a second character's belief. Then the children answered questions about what the first character thought the second character would do (see Figure 9.6). By age 6 to 7, children were aware that people form beliefs about other people's beliefs and that these second-order beliefs can be wrong! Appreciation of *second-order false belief* enables children to pinpoint the reasons that another person arrived at a certain belief (Astington, Pelletier, & Homer, 2002; Miller, 2009; Naito & Seki, 2009). This assists them greatly in understanding others' perspectives.

Indeed, shortly thereafter, around age 7 to 8, children grasp that two people are likely to interpret the same event—such as an ambiguous fragment removed from a larger drawing they have never seen—differently, no matter what beliefs or other biases they bring to the situation (Lalonde & Chandler, 2002). They realize that the same reality can be construed in many ways.

Besides more complex thinking and language, experiences that foster awareness of mental activities contribute to school-age children's more reflective, process-oriented view of the mind. In a study of rural children of Cameroon, Africa, those who attended school performed much better on theory-of-mind tasks (Vinden, 2002). In school, teachers often call attention to the

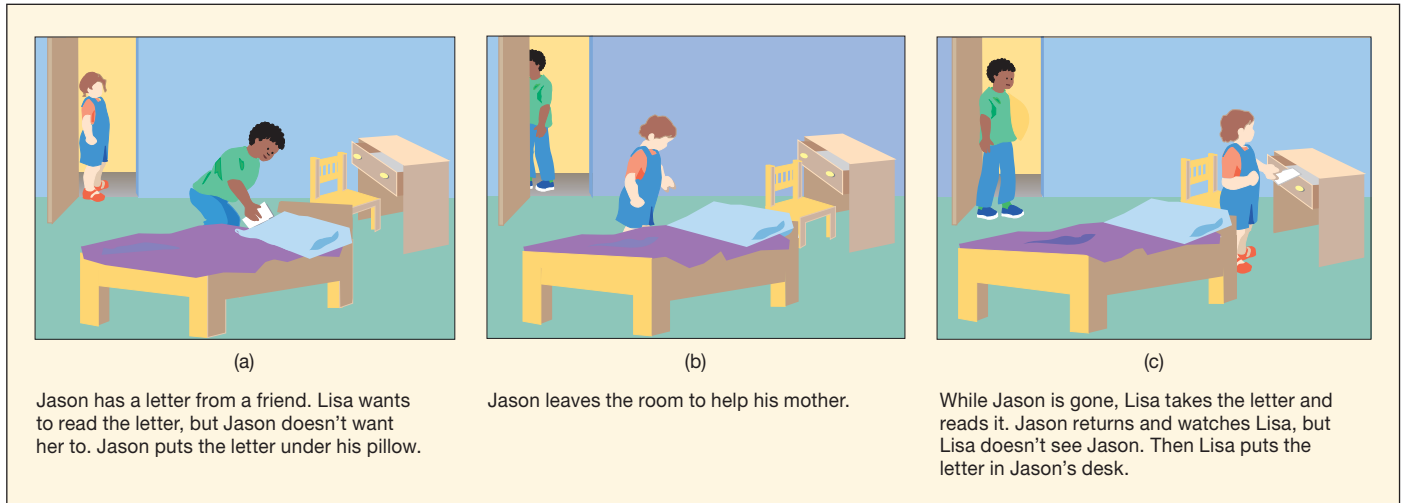

FIGURE 9.6 A second-order false-belief task. After relating the story in the sequence of pictures, the researcher asks a second-order false-belief question: “Where does Lisa think Jason will look for the letter? Why?” Around age 7, children answer correctly—that Lisa thinks Jason will look under his pillow because Lisa doesn't know that Jason saw her put the letter in the desk. (Adapted from Astington, Pelletier, & Homer, 2002.)

workings of the mind by asking children to remember mental steps, share points of view with peers, and evaluate their own and others' reasoning.

Cognitive Self-Regulation

Although metacognition expands, school-age children often have difficulty putting what they know about thinking into action. They are not yet good at **cognitive self-regulation**, the process of continuously monitoring progress toward a goal, checking outcomes, and redirecting unsuccessful efforts. For example, Lizzie is aware that she should group items when memorizing, reread a complicated paragraph to make sure she understands it, and relate new information to what she already knows. But she does not always engage in these activities.

To study cognitive self-regulation, researchers sometimes look at the impact of children's awareness of memory strategies on how well they remember. By second grade, the more children know about memory strategies, the more they recall—a relationship that strengthens over middle childhood (Pierce & Lange, 2000). And when children apply a strategy consistently, their knowledge of strategies strengthens, resulting in a bidirectional association between metacognition and strategy use that enhances self-regulation (Schlagmüller & Schneider, 2002).

Why does cognitive self-regulation develop gradually? Monitoring and controlling task outcomes is cognitively demanding, requiring constant evaluation of effort and progress. Throughout elementary and secondary school, self-regulation predicts academic success (Valiente et al., 2008; Zimmerman & Cleary, 2009). Students who do well in school know whether their learning is going well. If they encounter obstacles, they take steps to address them—for example, organize the learning environment, review confusing material, or seek support from more expert adults or peers. This active, purposeful approach contrasts sharply with the passive orientation of students who achieve poorly.

Parents and teachers play vital roles in promoting children's self-regulation (Larkin, 2010). In one study, researchers observed parents helping their children with problem solving during the summer before third grade. Parents who patiently pointed out important features of the task and suggested strategies had children who, in the classroom, more often discussed ways to approach problems and monitored their own performance (Stright et al., 2002). Explaining the effectiveness of strategies is particularly helpful because it provides a rationale for future action.

Children who acquire effective self-regulatory skills develop a sense of *academic self-efficacy*—confidence in their own ability, which supports future self-regulation (Zimmerman & Moylan, 2009). Unfortunately, some children receive messages from parents and teachers that seriously undermine their academic self-esteem and self-regulatory skills. We will consider these *learned-helpless* children, along with ways to help them, in Chapter 10.

Applications of Information Processing to Academic Learning

Fundamental discoveries about the development of information processing have been applied to children's learning of reading and mathematics. Researchers are identifying the cognitive ingredients of skilled performance, tracing their development, and pinpointing differences in cognitive skills between good and poor learners. They hope, as a result, to design teaching methods that will improve children's learning.

Reading. Reading makes use of many skills at once, taxing all aspects of our information-processing system. Joey and Lizzie must perceive single letters and letter combinations, translate them into speech sounds, recognize the visual appearance of many common words, hold chunks of text in working memory

while interpreting their meaning, and combine the meanings of various parts of a text passage into an understandable whole. Because reading is so demanding, most or all of these skills must be done automatically. If one or more are poorly developed, they will compete for space in our limited working memories, and reading performance will decline.

As children make the transition from emergent literacy to conventional reading, *phonological awareness* (see page 242 in Chapter 7) continues to predict reading (and spelling) progress. Other information-processing skills also contribute. Gains in processing speed foster children's rapid conversion of visual symbols into sounds (McBride-Chang & Kail, 2002). Visual scanning and discrimination play important roles and improve with reading experience (Rayner, Pollatsek, & Starr, 2003). Performing all these skills efficiently releases working memory for higher-level activities involved in comprehending the text's meaning.

Until recently, researchers were involved in an intense debate over how to teach beginning reading. Those who took a **whole-language approach** argued that from the beginning, children should be exposed to text in its complete form—stories, poems, letters, posters, and lists—so that they can appreciate the communicative function of written language. According to this view, as long as reading is kept whole and meaningful, children will be motivated to discover the specific skills they need. Other experts advocated a **phonics approach**, believing that children should first be coached on *phonics*—the basic rules for translating written symbols into sounds. Only after mastering these skills should they get complex reading material.

Many studies show that children learn best with a mixture of both approaches. In kindergarten and first and second grades, teaching that includes phonics boosts reading scores, especially for children who lag behind in reading progress (Stahl & Miller, 2006; Xue & Meisels, 2004). And when teachers combine real reading and writing with teaching of phonics and engage in other excellent teaching practices—encouraging children to tackle reading challenges and integrating reading into all school subjects—first graders show far greater literacy progress (Pressley et al., 2002).

Why might combining phonics with whole language work best? Learning relationships between letters and sounds enables children to *decode*, or decipher, words they have never seen before. Children who enter school low in phonological awareness make far better reading progress when given training in phonics (Casalis & Cole, 2009). Yet too much emphasis on basic skills may cause children to lose sight of the goal of reading: understanding. Children who read aloud fluently without registering meaning know little about effective metacognitive reading strategies—for example, that they must read more carefully if they will be tested than if they are reading for pleasure, or that explaining a passage in their own words is a good way to assess comprehension. Providing instruction aimed at increasing knowledge and use of reading strategies enhances reading performance from third grade on (McKeown & Beck, 2009; Paris & Paris, 2006).

Mathematics. Mathematics teaching in elementary school builds on and greatly enriches children's informal knowledge of number concepts and counting. Written notation systems and formal computational procedures enhance children's ability to represent numbers and compute. Over the early elementary school years, children acquire basic math facts through a combination of frequent practice, experimentation with diverse computational procedures (through which they discover faster, more accurate techniques), reasoning about number concepts, and teaching that conveys effective strategies. Eventually children retrieve answers automatically and apply this knowledge to more complex problems.

Arguments about how to teach mathematics resemble those in reading, pitting drill in computing against “number sense,” or understanding. Again, a blend of both approaches is most beneficial (Fuson, 2009). In learning basic math, poorly performing students use cumbersome techniques or try to retrieve answers from memory too soon. They have not sufficiently experimented with strategies to see which are most effective and to reorganize their observations in logical, efficient ways—for example, noticing that multiplication problems involving 2 (2×8) are equivalent to addition doubles ($8 + 8$). On tasks that assess their understanding of math concepts, their performance is weak (Canobi, 2004; Canobi, Reeve, & Pattison, 2003). This suggests that encouraging students to apply strategies and making sure they understand why certain strategies work well are essential for solid mastery of basic math.

A similar picture emerges for more complex skills, such as carrying in addition, borrowing in subtraction, and operating with decimals and fractions. Children taught by rote cannot apply the procedure to new problems. Instead, they persistently make mistakes, following a “math rule” that they recall incor-

By using manipulative materials to understand number and place value, these first graders gain conceptual knowledge that helps them become more effective math problem solvers.

rectly because they do not understand it (Carpenter et al., 1999). Consider the following subtraction errors:

$$\begin{array}{r} 427 \\ - 138 \\ \hline 311 \end{array} \qquad \begin{array}{r} 7,002 \\ - 5,445 \\ \hline 1,447 \end{array}$$

In the first problem, the child subtracts a smaller from a larger digit, regardless of which is on top. In the second, the child skips columns with zeros in a borrowing operation, and the bottom digit is written as the answer.

Children who are given rich opportunities to experiment with problem solving, to grasp the reasons behind strategies, and to evaluate solution techniques seldom make such errors. In one study, second graders taught in these ways not only mastered correct procedures but even invented their own successful strategies, some of which were superior to standard, school-taught methods (Fuson & Burghard, 2003).

In Asian countries, students receive a variety of supports for acquiring mathematical knowledge and often excel at both math reasoning and computation. Use of the metric system helps Asian children grasp place value. The consistent structure of number words in Asian languages (*ten-two* for 12, *ten-three* for 13) also makes this idea clear (Miura & Okamoto, 2003). And because Asian number words are shorter and more quickly pronounced, more digits can be held in working memory at once, increasing the speed of thinking. Furthermore, Chinese parents provide their preschoolers with extensive practice in counting and adding—experiences that contribute to the superiority of Chinese over U.S. children’s math knowledge even before school entry (Siegler & Mu, 2008; Zhou et al., 2006). Finally, as we will see later in this chapter, compared with lessons in the United States, those in Asian classrooms devote more time to exploring math concepts and strategies and less to drill and repetition.

ASK YOURSELF

REVIEW Cite evidence that school-age children view the mind as an active, constructive agent.

CONNECT Explain why gains in working-memory capacity and executive-function skills are vital for mastery of reading and math in middle childhood.

APPLY Lizzie knows that if you have difficulty learning part of a task, you should devote extra attention to that part. But she plays each of her piano pieces from beginning to end instead of practicing the hard parts. What explains Lizzie’s failure to engage in cognitive self-regulation?

REFLECT In your own elementary school math education, how much emphasis was placed on computational drill and how much on understanding of concepts? How do you think that balance affected your interest and performance in math?

Individual Differences in Mental Development

Around age 6, IQ becomes more stable than it was at earlier ages, and it correlates moderately well with academic achievement, typically around .50 to .60. And children with higher IQs are more likely when they grow up to attain higher levels of education and enter more prestigious occupations (Brody, 1997; Deary et al., 2007). Because IQ predicts school performance and educational attainment, it often enters into educational decisions. Do intelligence tests accurately assess the school-age child’s ability to profit from academic instruction? Let’s look closely at this controversial issue.

Defining and Measuring Intelligence

Virtually all intelligence tests provide an overall score (the IQ), which represents *general intelligence*, or reasoning ability, along with an array of separate scores measuring specific mental abilities. But intelligence is a collection of many capacities, not all of which are included on currently available tests (Carroll, 2005; Sternberg, 2005). Test designers use a complicated statistical technique called *factor analysis* to identify the various abilities that intelligence tests measure. It identifies which sets of test items cluster together, meaning that test-takers who do well on one item in a cluster tend to do well on the others. Distinct clusters are called *factors*, each of which represents an ability. See Figure 9.7 on page 310 for items typically included in intelligence tests for children.

The intelligence tests given from time to time in classrooms are *group-administered tests*. They permit large numbers of students to be tested at once and are useful for instructional planning and for identifying children who require more extensive evaluation with *individually administered tests*. Unlike group tests, which teachers can give with minimal training, individually administered tests demand considerable training and experience to give well. The examiner not only considers the child’s answers but also observes the child’s behavior, noting such reactions as attention to and interest in the tasks and wariness of the adult. These observations provide insight into whether the test results accurately reflect the child’s abilities. Two individual tests—the Stanford-Binet and the Wechsler—are often used to identify highly intelligent children and to diagnose children with learning problems.

The contemporary descendant of Alfred Binet’s first successful intelligence test is the *Stanford-Binet Intelligence Scales*, Fifth Edition, for individuals from age 2 to adulthood. In addition to general intelligence, it assesses five intellectual factors: general knowledge, quantitative reasoning, visual–spatial processing, working memory, and basic information processing (such as speed of analyzing information). Each factor includes both a verbal mode and a nonverbal mode of testing, yielding 10 subtests in all (Roid, 2003). The nonverbal subtests, which do not require spoken language, are especially useful when

TYPICAL VERBAL ITEMS

Vocabulary Tell me what *carpet* means.

General Information What day of the week comes right after Thursday?

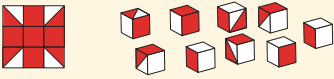

Verbal Comprehension Why do we need police officers?

Similarities How are a ship and a train alike?

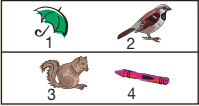

Arithmetic If a \$60 jacket is 25% off, how much does it cost?

TYPICAL PERCEPTUAL- AND SPATIAL-REASONING ITEMS

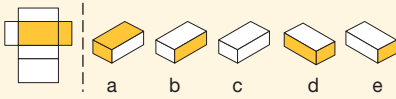

Block Design Make these blocks look just like the picture.

Picture Concepts Choose one object from each row to make a group of objects that goes together.

Spatial Visualization Which of the boxes on the right can be made from the pattern on the left?

TYPICAL WORKING-MEMORY ITEMS

Digit Span Repeat these digits in the same order. Now repeat these digits (a similar series) backward.
2, 6, 4, 7, 1, 8

Letter-Number Sequencing Repeat these numbers and letters, first giving the numbers, then the letters, each in correct sequence.
8 G 4 B 5 N 2

TYPICAL PROCESSING-SPEED ITEM

Symbol Search If the shape on the left is the same as any of those on the right, mark YES. If the shape is not the same, mark NO. Work as quickly as you can without making mistakes.

FIGURE 9.7 Test items like those on commonly used intelligence tests for children. The verbal items emphasize culturally loaded, fact-oriented information. The perceptual- and spatial-reasoning, working-memory, and processing-speed items emphasize aspects of information processing and are assumed to assess more biologically based skills.

assessing individuals with limited English, hearing impairments, or communication disorders. The knowledge and quantitative reasoning factors emphasize culturally loaded, fact-oriented information, such as vocabulary and arithmetic problems. In contrast, the visual-spatial processing, working-memory, and basic information-processing factors are assumed to be less culturally biased (see the spatial visualization item in Figure 9.7).

The *Wechsler Intelligence Scale for Children (WISC-IV)* is the fourth edition of a widely used test for 6- through 16-year-olds (Wechsler, 2003). It measures general intelligence and four

broad factors: verbal reasoning, perceptual (or visual-spatial) reasoning, working memory, and processing speed. Each factor is made up of two or three subtests, yielding 10 separate scores in all. The WISC-IV was designed to downplay culturally dependent knowledge, which is emphasized on only one factor (verbal reasoning). According to the test designers, the result is the most “culture-fair” intelligence test available (Williams, Weis, & Rolfhus, 2003). The WISC was also the first test to be standardized on children representing the total population of the United States, including ethnic minorities.

Recent Efforts to Define Intelligence

As we have seen, mental tests now tap important aspects of information processing. In line with this trend, some researchers combine the mental testing approach to defining intelligence with the information-processing approach. They believe that once we identify the processing skills that separate individuals who test well from those who test poorly, we will know more about how to intervene to improve performance. These investigators conduct *componential analyses* of children’s test scores. This means that they look for relationships between aspects (or components) of information processing and children’s intelligence test scores.

Processing speed, assessed in terms of reaction time on diverse cognitive tasks, is moderately related to IQ (Deary, 2001; Li et al., 2004). Individuals whose nervous systems function more efficiently, permitting them to take in information and manipulate it quickly, appear to have an edge in intellectual skills.

But flexible attention, memory, and reasoning strategies are as important as efficient thinking in predicting IQ, and they explain some of the association between response speed and good test performance (Lohman, 2000; Miller & Vernon, 1992). Children who apply strategies effectively acquire more knowledge and can retrieve it rapidly—advantages that carry over to mental test performance. Similarly, available space in working memory depends in part on effective inhibition (the ability to keep one’s mind from straying to irrelevant thoughts). Inhibition and sustained and selective attention are among a wide array of attentional skills that are good predictors of IQ (Schweizer, Moosbrugger, & Goldhammer, 2006).

The componential approach has one major shortcoming: It regards intelligence as entirely due to causes within the child. Throughout this book, we have seen how cultural and situational factors affect children’s thinking. Robert Sternberg has expanded componential approach into a comprehensive theory that regards intelligence as a product of inner and outer forces.

Sternberg’s Triarchic Theory. As Figure 9.8 shows, Sternberg’s (2001, 2005, 2008) **triarchic theory of successful intelligence** identifies three broad, interacting intelligences: (1) *analytical intelligence*, or information-processing skills; (2) *creative intelligence*, the capacity to solve novel problems; and (3) *practical intelligence*, application of intellectual skills in everyday situations. Intelligent behavior involves balancing all

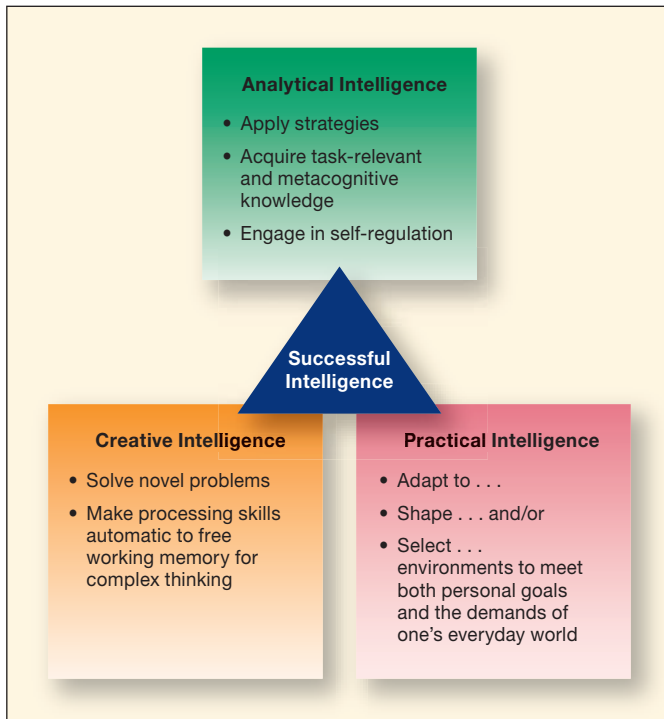

FIGURE 9.8 Sternberg's triarchic theory of successful intelligence. People who behave intelligently balance three interrelated intelligences—analytical, creative, and practical—to achieve success in life, defined by their personal goals and the requirements of their cultural communities.

three to succeed in life according to one's personal goals and the requirements of one's cultural community.

Analytical Intelligence. *Analytical intelligence* consists of the information-processing components that underlie all intelligent acts: applying strategies, acquiring task-relevant and metacognitive knowledge, and engaging in self-regulation. But on mental tests, processing skills are used in only a few of their potential ways, resulting in far too narrow a view of intelligent behavior.

Creative Intelligence. In any context, success depends not only on processing familiar information but also on generating useful solutions to new problems. People who are *creative* think more skillfully than others when faced with novelty. Given a new task, they apply their information-processing skills in exceptionally effective ways, rapidly making these skills automatic so that working memory is freed for more complex aspects of the situation. Consequently, they quickly move to high-level performance. Although all of us are capable of some creativity, only a few individuals excel at generating novel solutions.

Practical Intelligence. Finally, intelligence is a *practical*, goal-oriented activity aimed at *adapting to*, *shaping*, or *selecting environments*. Intelligent people skillfully *adapt* their thinking to fit with both their desires and the demands of their everyday worlds. When they cannot adapt to a situation, they try to *shape*,

or change, it to meet their needs. If they cannot shape it, they *select* new contexts that better match their skills, values, or goals. Practical intelligence reminds us that intelligent behavior is never culture-free. Children with certain life histories do well at the behaviors required for success on intelligence tests and adapt easily to the testing conditions. Others, with different backgrounds, may misinterpret or reject the testing context. Yet such children often display sophisticated abilities in daily life—for example, telling stories, engaging in complex artistic activities, or interacting skillfully with other people.

The triarchic theory highlights the complexity of intelligent behavior and the limitations of current intelligence tests in assessing that complexity. For example, out-of-school, practical forms of intelligence are vital for life success and help explain why cultures vary widely in the behaviors they regard as intelligent (Sternberg et al., 2000). When researchers asked ethnically diverse parents to describe an intelligent first grader, Caucasian Americans mentioned cognitive traits. In contrast, ethnic minorities (Cambodian, Filipino, Vietnamese, and Mexican immigrants) identified noncognitive capacities—motivation, self-management, and social skills (Okagaki & Sternberg, 1993). According to Sternberg, mental tests can easily underestimate, and even overlook, the intellectual strengths of some children, especially ethnic minorities.

Gardner's Theory of Multiple Intelligences. In yet another view of how information-processing skills underlie intelligent behavior, Howard Gardner's (1983, 1993, 2000) **theory of multiple intelligences** defines intelligence in terms of distinct sets of processing operations that permit individuals to engage in a wide range of culturally valued activities. Dismissing the idea of general intelligence, Gardner proposes at least eight independent intelligences (see Table 9.1 on page 312).

© AGE FOTOSTOCK/ROBERT HARDING

According to Gardner, people are capable of at least eight distinct intelligences. Through a project aimed at improving sea turtle nesting habitats, these children expand and enrich their naturalist intelligence.

TABLE 9.1 Gardner's Multiple Intelligences

INTELLIGENCE	PROCESSING OPERATIONS	END-STATE PERFORMANCE POSSIBILITIES
Linguistic	Sensitivity to the sounds, rhythms, and meaning of words and the functions of language	Poet, journalist
Logico-mathematical	Sensitivity to, and capacity to detect, logical or numerical patterns; ability to handle long chains of logical reasoning	Mathematician
Musical	Ability to produce and appreciate pitch, rhythm (or melody), and aesthetic quality of the forms of musical expressiveness	Instrumentalist, composer
Spatial	Ability to perceive the visual–spatial world accurately, to perform transformations on those perceptions, and to re-create aspects of visual experience in the absence of relevant stimuli	Sculptor, navigator
Bodily-kinesthetic	Ability to use the body skillfully for expressive as well as goal-directed purposes; ability to handle objects skillfully	Dancer, athlete
Naturalist	Ability to recognize and classify all varieties of animals, minerals, and plants	Biologist
Interpersonal	Ability to detect and respond appropriately to the moods, temperaments, motivations, and intentions of others	Therapist, salesperson
Intrapersonal	Ability to discriminate complex inner feelings and to use them to guide one's own behavior; knowledge of one's own strengths, weaknesses, desires, and intelligences	Person with detailed, accurate self-knowledge

Sources: Gardner, 1993, 1998, 2000.

Gardner believes that each intelligence has a unique biological basis, a distinct course of development, and different expert, or “end-state,” performances. At the same time, he emphasizes that a lengthy process of education is required to transform any raw potential into a mature social role (Connell, Sheridan, & Gardner, 2003). Cultural values and learning opportunities affect the extent to which a child's intellectual strengths are realized and the ways they are expressed.

Gardner's list of abilities has yet to be firmly grounded in research. Neurological evidence for the independence of his abilities is weak. Some exceptionally gifted individuals have abilities that are broad rather than limited to a particular domain (Piiro, 2007). And research with mental tests suggests that several of Gardner's intelligences (linguistic, logico-mathematical, and spatial) have common features. Nevertheless, Gardner calls attention to several intelligences not tapped by IQ scores. For example, his interpersonal and intrapersonal intelligences include a set of capacities for dealing with people and understanding oneself. As the Social Issues: Health box on the following page indicates, researchers are attempting to define, measure, and foster these vital abilities.

Explaining Individual and Group Differences in IQ

When we compare individuals in terms of academic achievement, years of education, and occupational status, it quickly becomes clear that certain sectors of the population are advantaged over others. In trying to explain these differences, researchers have compared the IQ scores of ethnic and SES groups. American black children and adolescents score, on average, 10 to 12 IQ

points below American white children. Although the difference has been shrinking over the past several decades, a substantial gap remains (Edwards & Oakland, 2006; Flynn, 2007; Nisbett, 2009). Hispanic children fall midway between black and white children, and Asian Americans score slightly higher than their white counterparts—about 3 points (Ceci, Rosenblum, & Kumpf, 1998).

The gap between middle- and low-SES children—about 9 points—accounts for some of the ethnic differences in IQ, but not all. Matching black and white children on parental education and income reduces the black–white IQ gap by a third to a half (Brooks-Gunn et al., 2003). Of course, IQ varies greatly *within* each ethnic and SES group. Still, these group differences are large enough and of serious enough consequence that they cannot be ignored.

In the 1970s, the IQ nature–nurture controversy escalated after psychologist Arthur Jensen (1969) published a controversial monograph entitled, “How Much Can We Boost IQ and Scholastic Achievement?” Jensen claimed—and still maintains—that heredity is largely responsible for individual, ethnic, and SES variations in intelligence (Jensen, 1998, 2001; Rushton & Jensen, 2006, 2010). His work sparked an outpouring of research and responses, including ethical challenges reflecting deep concern that his conclusions would fuel social prejudices. Richard Herrnstein and Charles Murray rekindled the controversy with *The Bell Curve* (1994). Like Jensen, they argued that heredity contributes substantially to individual and SES differences in IQ, and they implied that heredity plays a sizable role in the black–white IQ gap. Let's look closely at some important evidence.

Nature versus Nurture. In Chapter 2, we introduced the *heritability estimate*. The most powerful evidence on the

Social Issues: Health

Emotional Intelligence

During recess, Emily handed a birthday party invitation to every fifth-grade girl except Claire, who looked on sadly as her classmates chattered about the party. But one of Emily's friends, Jessica, looked troubled. Pulling Emily aside, she exclaimed, "Why'd you do that? You hurt Claire's feelings—you embarrassed her! If you bring invitations to school, you've got to give everybody one!" After school, Jessica comforted Claire, saying, "If you aren't invited, I'm not going, either!"

Jessica's IQ is only slightly above average, but she excels at *emotional intelligence*—a term that has captured public attention because of popular books suggesting that it is an overlooked set of skills that can greatly improve life success (Goleman, 1995, 1998). According to one influential definition, **emotional intelligence** refers to a set of emotional abilities that enable individuals to process and adapt to emotional information (Salovey & Pizarro, 2003). To measure it, researchers have devised items tapping emotional skills that enable people to manage their own emotions and interact competently with others. One test requires individuals to identify and rate the strength of emotions expressed in photographs of faces (emotional perception), to reason about emotions in social situations (emotion understanding), to identify which emotions promote

certain thoughts and activities (emotional facilitation), and to evaluate the effectiveness of strategies for controlling negative emotions (emotion regulation). Factor analyses of the scores of hundreds of test-takers identified several emotional capacities as well as a higher-order general factor (Mayer, Salovey, & Caruso, 2003).

Emotional intelligence is no more than modestly related to IQ. And among school-age children, adolescents, and adults, it is positively associated with self-esteem, empathy, prosocial behavior, cooperation, leadership skills, and life satisfaction and negatively related to drug and alcohol use, dependency, depression, and aggressive behavior (Brackett, Mayer, & Warner, 2004; Mavroveli et al., 2009; Petrides et al., 2006). In adulthood, emotional intelligence predicts many aspects of workplace success, including managerial effectiveness, productive co-worker relationships, and job performance (Mayer, Salovey, & Caruso, 2008).

Only a few assessments of emotional intelligence are available for children. These require careful training of teachers in observing and recording children's emotional skills during everyday activities, gathering information from parents, and taking ethnic backgrounds into account (Denham,

© ELLEN B. SENISI PHOTOGRAPHY

The 9-year-old on the right displays high emotional intelligence, accurately identifying his friend's emotion as anger and calmly talking over their disagreement.

2005). As more and better measures are devised, they may help identify children with weak social and emotional competencies who would profit from intervention (Stewart-Brown & Edmunds, 2007).

The concept of emotional intelligence has increased teachers' awareness of providing experiences that meet students' social and emotional needs can improve their adjustment. Lessons that teach emotional understanding, respect and caring for others, strategies for regulating emotion, and resistance to unfavorable peer pressure—using active learning techniques that provide skill practice both in and out of the classroom—are becoming more common (Bowkett & Percival 2011).

heritability of IQ involves twin comparisons. The IQ scores of identical twins (who share all their genes) are more similar than those of fraternal twins (who are genetically no more alike than ordinary siblings). On the basis of this and other kinship evidence, researchers estimate that about half the differences in IQ among children can be traced to their genetic makeup.

Recall, however, that heritabilities risk overestimating genetic influences and underestimating environmental influences (Grigorenko, 2000; Plomin, 2003). And heritability estimates do not reveal the complex processes through which genes and experiences influence intelligence as children develop.

Adoption studies offer a wider range of information. When young children are adopted into caring, stimulating homes, their IQs rise substantially compared with the IQs of nonadopted

children who remain in economically deprived families (van IJzendoorn, Juffer, & Poelhuis, 2005). But adopted children benefit to varying degrees. In one investigation, children of two extreme groups of biological mothers—those with IQs below 95 and those with IQs above 120—were adopted at birth by parents who were well above average in income and education. During the school years, the children of the low-IQ biological mothers scored above average in IQ. But they did not do as well as children of high-IQ biological mothers placed in similar adoptive families (Loehlin, Horn, & Willerman, 1997). Adoption research confirms that heredity and environment contribute jointly to IQ.

Adoption research also sheds light on the black-white IQ gap. In two studies, African-American children adopted into

economically well-off white homes during the first year of life scored high on intelligence tests, attaining mean IQs of 110 and 117 by middle childhood (Moore, 1986; Scarr & Weinberg, 1983). The IQ gains of black children “reared in the culture of the tests and schools” are consistent with a wealth of evidence that poverty severely depresses the intelligence of ethnic minority children (Nisbett, 2009).

Furthermore, a dramatic *secular trend* in mental test performance—a generational rise in average IQ in both industrialized nations and the developing world—supports the role of environmental factors. The greatest gains have occurred on tests of spatial reasoning—tasks often assumed to be “culture fair” and, therefore, more genetically based (Flynn, 2007). The existence of a large, environmentally induced secular trend that exceeds the black–white IQ gap presents another major challenge to the assumption that ethnic variations in IQ are mostly genetic.

Cultural Influences. A controversial question raised about ethnic differences in IQ has to do with whether they result from *test bias*. If a test samples knowledge and skills that not all groups of children have had equal opportunity to learn, or if the testing situation impairs the performance of some groups but not others, then the resulting score is a biased, or unfair, measure.

Some experts claim that because IQ predicts academic achievement equally well for majority and minority children, intelligence tests are fair to both groups. The tests, they say, represent success in the common culture (Edwards & Oakland, 2006; Jensen, 2002). Others believe that lack of exposure to certain communication styles and knowledge, along with negative stereotypes about the test-taker’s ethnic group, can undermine children’s performance (Ceci & Williams, 1997; Sternberg, 2005). Let’s look at the evidence.

Communication Styles. Ethnic minority families often foster unique language skills that do not match the expectations of most classrooms and testing situations. An observational study carried out in low-SES African-American homes in a southeastern U.S. city revealed that the black parents rarely asked their children knowledge-training questions (“What color is it?” “What’s this story about?”), which are typical of middle-SES white parents and of tests and classrooms. Instead, the black parents asked analogy questions (“What’s that like?”) or story-starter questions (“Did you hear Sally this morning?”) that called for elaborate responses about everyday events and had no “right” answer. These experiences led the black children to develop complex verbal skills at home. But their language emphasized storytelling and emotional and social concerns rather than factual knowledge. When the black children started school, many were unfamiliar with and confused by the “objective” questions they encountered on tests and in classrooms.

Furthermore, many ethnic minority parents without extensive schooling prefer a *collaborative style of communication* when completing tasks with children. They work together in a coordinated, fluid way, each focused on the same aspect of the problem. This pattern of adult–child engagement has been observed in Native-American, Canadian Inuit, Hispanic, and Guatemalan

Mayan cultures (Chavajay & Rogoff, 2002; Crago, Annahatak, & Ningiuruvik, 1993; Paradise & Rogoff, 2009). With increasing education, parents establish a *hierarchical style of communication*, like that of classrooms and tests. The parent directs each child to carry out an aspect of the task, and children work independently. This sharp discontinuity between home and school practices may contribute to low-SES minority children’s lower IQs and school performance.

Knowledge. Many researchers argue that IQ scores are affected by specific information acquired as part of majority-culture upbringing. Consistent with this view, low-SES African-American children often miss vocabulary words on mental tests that have alternative meanings in their cultural community—for example, interpreting the word *frame* as “physique” and *wrapping* as “rapping,” referring to the style of music (Champion, 2003a).

Even nonverbal test items, such as spatial reasoning, depend on learning opportunities. For example, using small blocks to duplicate designs and playing video games requiring mental rotation of visual images increase success on spatial tasks (Dirks, 1982; Maynard, Subrahmanyam, & Greenfield, 2005). Low-income minority children, who often grow up in more “people-oriented” than “object-oriented” homes, may lack toys and games that promote certain intellectual skills.

Furthermore, the sheer amount of time a child spends in school predicts IQ. When children of the same age enrolled in different grades are compared, those who have been in school longer score higher on intelligence tests (Ceci, 1991, 1999). Taken together, these findings indicate that children’s exposure to the knowledge and ways of thinking valued in classrooms has a sizable impact on their intelligence test performance.

Stereotypes. Imagine trying to succeed at an activity when the prevailing attitude is that members of your group are incompetent. **Stereotype threat**—the fear of being judged on the basis of a negative stereotype—can trigger anxiety that interferes

© ELLEN B. SENISI PHOTOGRAPHY

School-age children, especially those from stigmatized groups, become increasingly conscious of ethnic stereotypes. Fear of being judged on the basis of a negative stereotype may be behind this child’s reluctance to try a new task in school.

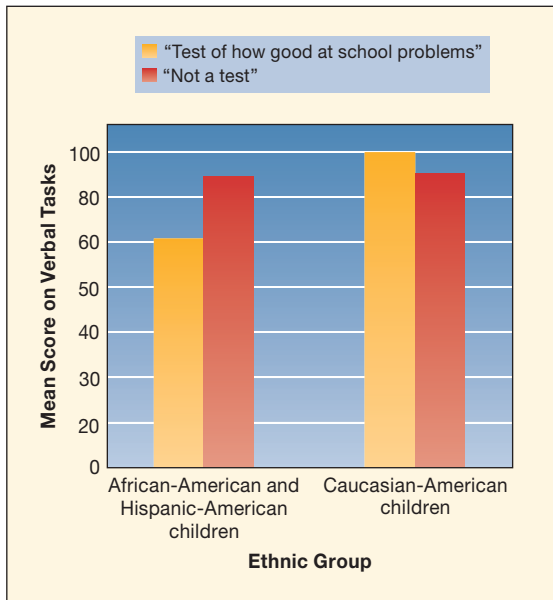

FIGURE 9.9 Effect of stereotype threat on test performance.

Among African-American and Hispanic-American children who were aware of ethnic stereotypes, being told that verbal tasks were a “test of how good children are at school problems” led to far worse performance than being told the tasks were “not a test.” These statements had little impact on the performance of Caucasian-American children. (Adapted from McKown & Weinstein, 2003.)

with performance. Mounting evidence confirms that stereotype threat undermines test taking in children and adults (McKown & Strambler, 2009; Steele, 1997). For example, researchers gave African-American, Hispanic, and Caucasian 6- to 10-year-olds verbal tasks. Some children were told that the tasks were “not a test.” Others were told they were “a test of how good children are at school problems”—a statement designed to induce stereotype threat in the ethnic minority children (McKown & Weinstein, 2003). Among children who were aware of ethnic stereotypes (such as “black people aren’t smart”), African Americans and Hispanics performed far worse in the “test” condition than in the “not a test” condition. Caucasian children, in contrast, performed similarly in both conditions (see Figure 9.9).

Over middle childhood, children become increasingly conscious of ethnic stereotypes, and those from stigmatized groups are especially mindful of them. By early adolescence, many low-SES minority students start to devalue doing well in school, saying it is not important to them (Cooper & Huh, 2008). Self-protective disengagement, sparked by stereotype threat, may be responsible. This weakening of motivation can have serious, long-term consequences. Research shows that self-discipline—effort and delay of gratification—predicts school performance at least as well as, and sometimes better than, IQ does (Duckworth & Seligman, 2005).

Reducing Cultural Bias in Testing. Although not all experts agree, many acknowledge that IQ scores can underestimate the intelligence of children from ethnic minority groups. A special concern exists about incorrectly labeling minority

children as slow learners and assigning them to remedial classes, which are far less stimulating than regular school experiences. To avoid this danger, test scores need to be combined with assessments of children’s adaptive behavior—their ability to cope with the demands of their everyday environments. The child who does poorly on an intelligence test yet plays a complex game on the playground or figures out how to rewire a broken TV is unlikely to be mentally deficient.

In addition, culturally relevant testing procedures enhance minority children’s test performance. In an approach called **dynamic assessment**, an innovation consistent with Vygotsky’s zone of proximal development, an adult introduces purposeful teaching into the testing situation to find out what the child can attain with social support. Research shows that children’s receptivity to teaching and their capacity to transfer what they have learned to novel problems contribute substantially to gains in test performance (Haywood & Lidz, 2007; Sternberg & Grigorenko, 2002). In one study, Ethiopian 6- and 7-year-olds who had recently immigrated to Israel scored well below their Israeli-born agetates on spatial reasoning tasks. The Ethiopian children had little experience with this type of thinking. After several dynamic assessment sessions in which the adult suggested effective strategies, the Ethiopian children’s scores rose sharply, nearly equaling those of the Israeli-born children (Tzuriel & Kaufman, 1999). They also transferred their learning to new test items.

In view of its many problems, should intelligence testing in schools be suspended? Most experts reject this solution. Without testing, important educational decisions would be based only on subjective impressions, perhaps increasing discriminatory placement of minority children. Intelligence tests are useful when interpreted carefully by psychologists and educators who are sensitive to cultural influences on test performance. And despite their limitations, IQ scores continue to be fairly accurate measures of school learning potential for the majority of Western children.

This teacher uses dynamic assessment, tailoring instruction to students’ individual needs—an approach that reveals what each child can learn with social support.

CONNECT Explain how dynamic assessment is consistent with Vygotsky’s zone of proximal development and with scaffolding. (See Chapter 7, page 234.)

APPLY Josefina, a Hispanic fourth grader, does well on homework assignments. But when her teacher announces, “It’s time for a test to see how much you’ve learned,” Josefina usually does poorly. How might stereotype threat explain this inconsistency?

REFLECT Do you think that intelligence tests are culturally biased? What observations and evidence influenced your conclusions?

Language Development

Vocabulary, grammar, and pragmatics continue to develop in middle childhood, though less obviously than at earlier ages. In addition, children’s attitude toward language undergoes a fundamental shift: They develop language awareness.

Schooling contributes greatly to these language competencies. Reflecting on language is extremely common during reading instruction. And fluent reading is a major new source of language learning (Ravid & Tolchinsky, 2002). As we will see, an improved ability to reflect on language grows out of literacy and supports many complex language skills.

Vocabulary

During the elementary school years, vocabulary increases fourfold, eventually exceeding comprehension of 40,000 words. On average, children learn about 20 new words each day, a rate of growth greater than in early childhood. In addition to the word-learning strategies discussed in Chapter 7, school-age children add to their vocabularies by analyzing the structure of complex words. From *happy* and *decide*, they quickly derive the meanings of *happiness* and *decision* (Larsen & Nippold, 2007). They also figure out many more word meanings from context (Nagy & Scott, 2000).

As at earlier ages, children benefit from conversation with more expert speakers, especially when their partners use and explain complex words (Weizman & Snow, 2001). But because written language contains a far more diverse and complex vocabulary than spoken language, reading contributes enormously to vocabulary growth. Children who engage in as little as 21 minutes of independent reading per day are exposed to nearly 2 million words per year (Cunningham & Stanovich, 1998).

As their knowledge expands and becomes better organized, older school-age children think about and use words more precisely: In addition to the verb *fall*, for example, they also use *topple*, *tumble*, and *plummet* (Berman, 2007). Word definitions also illustrate this change. Five- and 6-year-olds offer concrete descriptions referring to functions or appearance—*knife*: “when you’re cutting carrots”; *bicycle*: “it’s got wheels, a chain, and handlebars.” By the end of elementary school, synonyms and explanations of categorical relationships appear—for example, *knife*: “something you could cut with. A saw is like a knife. It could also be a weapon” (Wehren, De Lisi, & Arnold, 1981). This advance reflects older children’s ability to deal with word meanings on an entirely verbal plane. They can add new words to their vocabulary simply by being given a definition.

School-age children’s more reflective, analytical approach to language permits them to appreciate the multiple meanings of words—to recognize, for example, that many words, such as *cool* or *neat*, have psychological as well as physical meanings: “What a cool shirt!” or “That movie was really neat!” This grasp of double meanings permits 8- to 10-year-olds to comprehend subtle metaphors, such as “sharp as a tack” and “spilling the beans” (Nippold, Taylor, & Baker, 1996; Wellman & Hickling, 1994). It also leads to a change in children’s humor. Riddles and puns that alternate between different meanings of a key word are common: “Hey, did you take a bath?” “Why, is one missing?”

LOOK AND LISTEN

Record examples of 8- to 10-year-olds’ humor, or examine storybooks for humor aimed at second through fourth graders. Does it require a grasp of the multiple meanings of words? ●

Grammar

During the school years, mastery of complex grammatical constructions improves. For example, English-speaking children use the passive voice more frequently, and they more often extend it from an abbreviated form (“It broke”) into full statements (“The glass was broken by Mary”) (Israel, Johnson, & Brooks, 2000; Tomasello, 2006). Although the passive form is challenging, language input makes a difference. When adults speak a language that emphasizes full passives, such as Inuktitut (spoken by the Inuit people of Arctic Canada), children produce them earlier (Allen & Crago, 1996).

Another grammatical achievement of middle childhood is advanced understanding of infinitive phrases—the difference between “John is eager to please” and “John is easy to please” (Berman, 2007; Chomsky, 1969). Like gains in vocabulary, appreciation of these subtle grammatical distinctions is supported by an improved ability to analyze and reflect on language.

Pragmatics

Improvements in *pragmatics*, the communicative side of language, also occur. Conversational strategies become more refined.

For example, school-age children are better at phrasing things to get their way. When an adult refuses to hand over a desired object, 9-year-olds, but not 5-year-olds, state their second requests more politely (Axia & Baroni, 1985).

Furthermore, as a result of improved memory, ability to take the perspective of listeners, and conversations with adults about past experiences, children's narratives increase in organization, detail, and expressiveness. A typical 4- or 5-year-old's narrative states what happened: "We went to the lake. We fished and waited. Paul caught a huge catfish." Six- and 7-year-olds add orienting information (time, place, participants) and connectives ("next," "then," "so," "finally") that lend coherence to the story. Gradually, narratives lengthen into a *classic form* in which events not only build to a high point but resolve: "After Paul reeled in the catfish, Dad cleaned and cooked it. Then we ate it all up!" And evaluative comments rise dramatically, becoming common by age 8 to 9: "The catfish tasted great. Paul was so proud!" (Melzi & Ely, 2009; Ukrainetz et al., 2005).

Because children pick up the narrative styles of significant adults in their lives, their narrative forms vary widely across cultures. For example, instead of the *topic-focused style* of most Caucasian-American school-age children, who describe an experience from beginning to end, African-American children often use a *topic-associating style* in which they blend several similar anecdotes. One 9-year-old related having a tooth pulled, then described seeing her sister's tooth pulled, next told how she had removed one of her baby teeth, and concluded, "I'm a pullin-teeth expert . . . call me, and I'll be over" (McCabe, 1997, p. 164). As a result, African-American children's narratives are usually longer and more complex than those of white children (Champion, 2003b).

The ability to generate clear oral narratives enhances reading comprehension and prepares children for producing longer, more explicit written narratives. In families who regularly eat meals together, children are advanced in language and literacy development (Snow & Beals, 2006). Mealtimes offer many opportunities to relate personal stories.

In families who regularly eat meals together, children are advanced in language and literacy development. Mealtimes offer many opportunities to relate complex, extended personal stories.

Learning Two Languages

Joey and Lizzie speak only one language—English, their native tongue. Yet throughout the world, many children grow up *bilingual*, learning two languages and sometimes more than two. An estimated 20 percent of U.S. children—10 million in all—speak a language other than English at home (U.S. Census Bureau, 2012b).

Bilingual Development. Children can become bilingual in two ways: (1) by acquiring both languages at the same time in early childhood or (2) by learning a second language after mastering the first. Children of bilingual parents who teach them both languages in infancy and early childhood separate the language systems early on and attain early language milestones according to a typical timetable (Conboy & Thal, 2006; Genesee & Nicoladis, 2007; Weikum et al., 2007). When school-age children acquire a second language after they already speak a first language, they generally take five to seven years to attain speaking and writing skills on a par with those of native-speaking agemates (Paradis, 2007).

As with first-language development, a *sensitive period* for second-language development exists. Mastery must begin sometime in childhood for most second-language learners to attain full proficiency (Hakuta, Bialystok, & Wiley, 2003). But a precise age cutoff for a decline in second-language learning has not been established. Rather, a continuous age-related decrease from childhood to adulthood occurs.

A large body of research shows that bilingualism has positive consequences for development. Children who are fluent in two languages outperform others on tests of selective attention, inhibition of irrelevant information, analytical reasoning, concept formation, and cognitive flexibility (Bialystok et al., 2009; Carlson & Meltzoff, 2008). They are also advanced in certain aspects of language awareness, such as detection of errors in grammar and meaning. And children readily transfer their phonological awareness skills in one language to the other, especially if the two languages share phonological features, as Spanish and English do (Siegal, Iozzi, & Surian, 2009; Snow & Kang, 2006). These capacities, as noted earlier, enhance reading achievement.

Bilingual Education. The advantages of bilingualism provide strong justification for bilingual education programs in schools. In Canada, about 7 percent of elementary school students are enrolled in *language immersion programs*, in which English-speaking children are taught entirely in French for several years. This strategy succeeds in developing children who are proficient in both languages and who, by grade 6, achieve as well in reading, writing, and math as their counterparts in the regular English program (Harley & Jean, 1999; Holobow, Genesee, & Lambert, 1991; Turnbull, Hart, & Lapkin, 2003).

In the United States, fierce disagreement exists over the question of how best to educate ethnic minority children with limited English proficiency. Some believe that time spent communicating in the child's native tongue detracts from English-language

achievement, which is crucial for success in school and at work. Other educators, committed to developing minority children's native language while fostering mastery of English, note that providing instruction in the native tongue lets minority children know that their heritage is respected. It also prevents inadequate proficiency in both languages. Minority children who gradually lose the first language as a result of being taught the second end up limited in both languages for a time (Ovando & Collier, 1998). This circumstance leads to serious academic difficulties and is believed to contribute to high rates of school failure and dropout among low-SES Hispanic young people, who make up nearly 50 percent of the U.S. language-minority population.

At present, public opinion and educational practice favor English-only instruction. Many U.S. states have passed laws declaring English to be their official language, creating conditions in which schools have no obligation to teach minority students in languages other than English. Yet in classrooms where both languages are integrated into the curriculum, minority children are more involved in learning and acquire the second language more easily—gains that predict better academic achievement (Guglielmi, 2008). In contrast, when teachers speak only in a language children can barely understand, minority children display frustration, boredom, and escalating academic difficulties (Kieffer, 2008). This downward spiral in achievement is greatest in high-poverty schools, where resources to support the needs of language-minority children are scarce.

Supporters of U.S. English-only education often point to the success of Canadian language immersion programs, in which classroom lessons are conducted in the second language. But Canadian parents enroll their children in immersion classrooms voluntarily, and both French and English are majority languages that are equally valued in Canada. For U.S. non-English-speaking minority children, whose native languages are not valued by the larger society, a different strategy seems necessary: one that promotes children's native-language skills while they learn English.

The child on the left, a native Spanish speaker, benefits from an English–Spanish bilingual classroom, which sustains her native language while she masters English. And her native-English-speaking classmate has the opportunity to begin learning Spanish!

Learning in School

Evidence cited throughout this chapter indicates that schools are vital forces in children's cognitive development. How do schools exert such a powerful influence? Research looking at schools as complex social systems—class size, educational philosophies, teacher–student relationships, and larger cultural context—provides important insights. As you read about these topics, refer to Applying What We Know on the following page, which summarizes characteristics of high-quality education in elementary school.

Class Size

As each school year began, Rena telephoned the principal's office to ask, "How large will Joey's and Lizzie's classes be?" Her concern is well-founded. In a large field experiment, more than 6,000 Tennessee kindergartners were randomly assigned to three class types: "small" (13 to 17 students), "regular" (22 to 25 students) with only a teacher, and regular with a teacher plus a full-time teacher's aide. These arrangements continued into third grade. Compared with students in regular-size classes, small-class students—especially ethnic minority children—scored higher in reading and math achievement each year (Mosteller, 1995). These gains persist from fourth through ninth grades, after children return to regular-size classes (Finn, Gerber, & Boyd-Zaharias, 2005; Nye, Hedges, & Konstantopoulos, 2001). And small-class size predicts academic progress even after diverse measures of teacher quality have been controlled (Brühwiler & Blatchford, 2011).

Why is small class size beneficial? With fewer children, teachers spend less time disciplining and more time teaching and giving individual attention. Also, children who learn in smaller groups show better concentration, higher-quality class participation, and more favorable attitudes toward school (Blatchford et al., 2003, 2007; Blatchford, Bassett, & Brown, 2005).

Applying What We Know

Signs of High-Quality Education in Elementary School

Classroom Characteristics	Signs of Quality
Class size	Optimum class size is no larger than 18 children.
Physical setting	Space is divided into richly equipped activity centers—for reading, writing, playing math or language games, exploring science, working on construction projects, using computers, and engaging in other academic pursuits. Spaces are used flexibly for individual and small-group activities and whole-class gatherings.
Curriculum	The curriculum helps children both achieve academic standards and make sense of their learning. Subjects are integrated so that children apply knowledge in one area to others. The curriculum is implemented through activities responsive to children's interests, ideas, and everyday lives, including their cultural backgrounds.
Daily activities	Teachers provide challenging activities that include opportunities for small-group and independent work. Groupings vary in size and makeup of children, depending on the activity and on children's learning needs. Teachers encourage cooperative learning and guide children in attaining it.
Interactions between teachers and children	Teachers foster each child's progress and use intellectually engaging strategies, including posing problems, asking thought-provoking questions, discussing ideas, and adding complexity to tasks. They also demonstrate, explain, coach, and assist in other ways, depending on each child's learning needs.
Evaluations of progress	Teachers regularly evaluate children's progress through written observations and work samples, which they use to enhance and individualize teaching. They help children reflect on their work and decide how to improve it. They also seek information and perspectives from parents on how well children are learning and include parents' views in evaluations.
Relationship with parents	Teachers forge partnerships with parents. They hold periodic conferences and encourage parents to visit the classroom anytime, to observe and volunteer.

Educational Philosophies

Teachers' educational philosophies play a major role in children's learning. Two philosophical approaches have received most research attention. They differ in what children are taught, the way they are believed to learn, and how their progress is evaluated.

Traditional versus Constructivist Classrooms. In a **traditional classroom**, the teacher is the sole authority for knowledge, rules, and decision making. Students are relatively passive—listening, responding when called on, and completing teacher-assigned tasks. Their progress is evaluated by how well they keep pace with a uniform set of standards for their grade.

A **constructivist classroom**, in contrast, encourages students to *construct* their own knowledge. Although constructivist approaches vary, many are grounded in Piaget's theory, which views children as active agents who reflect on and coordinate their own thoughts rather than absorbing those of others. A glance inside a constructivist classroom reveals richly equipped learning centers, small groups and individuals solving self-chosen problems, and a teacher who guides and supports in response to children's needs. Students are evaluated by considering their progress in relation to their own prior development.

In the United States, the pendulum has swung back and forth between these two views. In the 1960s and early 1970s,

constructivist classrooms gained in popularity. Then, as concern arose over the academic progress of children and youths, a "back-to-basics" movement arose, and classrooms returned to traditional instruction. This style, still prevalent today, has become increasingly pronounced as a result of the U.S. No Child Left Behind Act, signed into law in 2001 (Darling-Hammond, 2010; Ravitch, 2010). Because it places heavy pressure on teachers and school administrators to improve achievement test scores, it has narrowed the curricular focus in many schools to preparing students to take such tests.

Although older elementary school children in traditional classrooms have a slight edge in achievement test scores, constructivist settings are associated with many other benefits—gains in critical thinking, greater social and moral maturity, and more positive attitudes toward school (DeVries, 2001; Rathunde & Csikszentmihalyi, 2005; Walberg, 1986). And as noted in Chapter 7, when teacher-directed instruction is emphasized in preschool and kindergarten, it actually undermines academic motivation and achievement, especially in low-SES children.

New Philosophical Directions. New approaches to education, grounded in Vygotsky's sociocultural theory, capitalize on the rich social context of the classroom to spur children's learning. In these **social-constructivist classrooms**, children

participate in a wide range of challenging activities with teachers and peers, with whom they jointly construct understandings. As children acquire knowledge and strategies through working together, they become competent, contributing members of their classroom community and advance in cognitive and social development (Bodrova & Leong, 2007; Palincsar, 2003). Vygotsky's emphasis on the social origins of higher cognitive processes has inspired the following educational themes:

- *Teachers and children as partners in learning.* A classroom rich in both teacher–child and child–child collaboration transfers culturally valued ways of thinking to children.
- *Experiences with many types of symbolic communication in meaningful activities.* As children master reading, writing, and mathematics, they become aware of their culture's communication systems, reflect on their own thinking, and bring it under voluntary control. **TAKE A MOMENT...** Can you identify research presented earlier in this chapter that supports this theme?
- *Teaching adapted to each child's zone of proximal development.* Assistance that both responds to current understandings and encourages children to take the next step helps ensure that each child makes the best progress possible.

According to Vygotsky, besides teachers, more expert peers can spur children's learning, as long as they adjust the help they provide to fit the less mature child's zone of proximal development. Consistent with this idea, mounting evidence confirms that peer collaboration promotes development only under certain conditions. A crucial factor is **cooperative learning**, in which small groups of classmates work toward common goals—by resolving differences of opinion, sharing responsibilities, and providing one another with sufficient explanations to correct misunderstandings. And when more expert students cooperate with less expert students, both benefit in achievement and self-esteem (Ginsburg-Block, Rohrbeck, & Fantuzzo, 2006; Renninger, 1998).

© AGE FOTOSTOCK/ROBERT HARDING

These children attending a rural school in Laos cooperate easily while completing a writing assignment. Their Western cultural-majority agemates, in contrast, typically require extensive guidance to succeed at cooperative learning.

LOOK AND LISTEN

Ask an elementary school teacher to sum up his or her educational philosophy. Is it closest to a traditional, constructivist, or social-constructivist view? Has the teacher encountered any obstacles to implementing that philosophy? Explain. ●

Because Western cultural-majority children regard competition and independent work as natural, they typically require extensive guidance to succeed at cooperative learning. In several studies, groups of students trained in collaborative processes displayed more cooperative behavior, gave clearer explanations, enjoyed learning more, and made greater academic progress in diverse school subjects than did untrained groups (Gillies, 2000, 2003; Terwel et al., 2001; Webb et al., 2008). Teaching through cooperative learning broadens Vygotsky's concept of the zone of proximal development, from a child in collaboration with a more expert partner (adult or peer) to multiple partners with diverse expertises, stimulating and encouraging one another.

Teacher–Student Interaction

Elementary school students describe good teachers as caring, helpful, and stimulating—behaviors associated with gains in motivation, achievement, and positive peer relations (Hughes & Kwok, 2006, 2007; Hughes, Zhang, & Hill, 2006; O'Connor & McCartney, 2007). But too many U.S. teachers emphasize repetitive drill over higher-level thinking, such as grappling with ideas and applying knowledge to new situations (Sacks, 2005).

Of course, teachers do not interact in the same way with all children. Well-behaved, high-achieving students typically get more encouragement and praise, whereas unruly students have more conflicts with teachers and receive more criticism from them (Henricsson & Rydell, 2004). Caring teacher–student relationships have an especially strong impact on the achievement and social behavior of low-SES minority students (Baker, 2006; Crosno, Kirkpatrick, & Elder, 2004). But overall, higher-SES students—who tend to be higher-achieving and to have fewer discipline problems—have more supportive relationships with teachers (Jerome, Hamre, & Pianta, 2009; Pianta, Hamre, & Stuhlman, 2003).

Unfortunately, once teachers' attitudes toward students are established, they can become more extreme than is warranted by students' behavior. Of special concern are **educational self-fulfilling prophecies**: Children may adopt teachers' positive or negative views and start to live up to them. This effect is especially strong when teachers emphasize competition and publicly compare children, regularly favoring the best students (Kuklinski & Weinstein, 2001; Weinstein, 2002).

Teacher expectations have a greater impact on low-achieving than high-achieving students (Madon, Jussim, & Eccles, 1997). When a teacher is critical, high achievers can fall back on their history of success. Low-achieving students' sensitivity to self-fulfilling prophecies can be beneficial when teachers believe in them. But biased teacher judgments are usually slanted in a negative direction. In one study, African-American and Hispanic elementary school students taught by high-bias teachers (who

Social Issues: Education

Magnet Schools: Equal Access to High-Quality Education

Each school-day morning, Emma leaves her affluent suburban neighborhood, riding a school bus to a magnet school in an impoverished, mostly Hispanic inner-city community. In her sixth-grade class, she settles into a science project with her friend, Maricela, who lives in the local neighborhood. The girls use a thermometer, ice water, and a stopwatch to determine which of several materials is the best insulator, recording and graphing their data. Throughout the school, which specializes in innovative math and science teaching, students diverse in SES and ethnicity learn side-by-side.

Despite the 1954 U.S. Supreme Court *Brown v. Board of Education* decision ordering schools to desegregate, school integration has receded since the late 1980s, as federal courts canceled their integration orders and returned this authority to states and cities. Today, the racial divide in American education is deepening (Frankenburg & Orfield, 2007). African-American children are just as likely to attend a school that serves a mostly black population as they were in the 1960s; Hispanic children are even more segregated. And when minority students attend ethnically mixed schools, they typically do so with other minorities.

U.S. schools in low-income neighborhoods are vastly disadvantaged in funding and therefore in educational opportunities, largely because public education is primarily supported by local property

taxes. Federal and state grants-in-aid are not sufficient to close this funding gap between rich and poor districts (Darling-Hammond, 2010). Consequently, dilapidated school buildings, inexperienced teachers, and poor-quality educational resources are widespread in inner-city neighborhoods (Kozol, 2005). The negative impact on student achievement is severe.

Magnet schools offer a solution. In addition to the usual curriculum, they emphasize a specific area of interest—such as performing arts, math and science, or technology. Families outside the school neighborhood are attracted to magnet schools (hence the name) by their rich academic offerings. Often magnets are located in low-income minority areas, where they serve the neighborhood student population. Other students, who apply and are admitted by lottery, are bussed in—many from well-to-do city and suburban neighborhoods. In another model, all students—including those in the surrounding neighborhood—must apply. In either case, magnet schools are voluntarily desegregated.

Research confirms that less segregated education enhances minority student

© ELLEN B. SENISI PHOTOGRAPHY

Third graders at a fine-arts magnet school jointly create a painting. The ethnically diverse learning environments of many magnet schools enhance academic achievement, especially among low-SES minority students.

achievement (Linn & Welner, 2007). Is this so for magnet schools? A Connecticut study comparing seventh to tenth graders enrolled in magnet schools with those whose lottery numbers were not drawn and who therefore attended other city schools confirmed that magnet students showed greater gains in reading and math achievement over a two-year period (Bifulco, Cobb, & Bell, 2009). These outcomes were strongest for low-SES, ethnic minority students.

By high school, the higher-achieving peer environments of ethnically diverse schools encourage more students to pursue higher education (Franklin, 2012). In sum, magnet schools are a promising approach to overcoming the negative forces of SES and ethnic isolation in American schools.

expected them to do poorly) showed substantially lower end-of-year achievement than their counterparts taught by low-bias teachers (McKown & Weinstein, 2008). Recall our discussion of *stereotype threat*. A child in the position of confirming a negative stereotype may respond with anxiety and reduced motivation, amplifying a negative self-fulfilling prophecy.

Grouping Practices

In many schools, students are assigned to *homogeneous* groups or classes in which children of similar ability levels are taught together. Homogeneous grouping can be a potent source of self-

fulfilling prophecies. Low-group students—who as early as first grade are more likely to be low-SES, minority, and male—get more drill on basic facts and skills, engage in less discussion, and progress at a slower pace. Gradually, they decline in self-esteem and motivation and fall further behind in achievement (Lleras & Rangel, 2009; Worthy, Hungerford-Kresser, & Hampton, 2009). Unfortunately, widespread SES and ethnic segregation in U.S. schools consigns large numbers of low-SES minority students to a form of schoolwide homogeneous grouping. Refer to the Social Issues: Education box above to find out how magnet schools foster heterogeneous learning contexts, thereby reducing achievement differences between SES and ethnic minority groups.

Another way schools can increase the *heterogeneity* of student groups is to combine two or three adjacent grades. In *multigrade classrooms*, academic achievement, self-esteem, and attitudes toward school are usually more favorable than in the single-grade arrangement (Lloyd, 1999; Ong, Allison, & Haladyna, 2000). Perhaps multigrade grouping decreases competition and promotes *cooperative learning*, which also fosters these positive outcomes (see page 320).

Teaching Children with Special Needs

We have seen that effective teachers flexibly adjust their teaching strategies to accommodate students with a wide range of characteristics. These adjustments are especially challenging at the very low and high ends of the ability distribution. How do schools serve children with special learning needs?

Children with Learning Difficulties. U.S. legislation mandates that schools place children who require special supports for learning in the “least restrictive” (as close to normal as possible) environments that meet their educational needs. In **inclusive classrooms**, students with learning difficulties learn alongside typical students in the regular educational setting for all or part of the school day—a practice designed to prepare them for participation in society and to combat prejudices against individuals with disabilities (Kugelmass & Ainscow, 2004). Largely as the result of parental pressures, an increasing number of students experience *full inclusion*—full-time placement in regular classrooms.

Some students in inclusive classrooms have *mild mental retardation*: Their IQs fall between 55 and 70, and they also show problems in adaptive behavior, or skills of everyday living (American Psychiatric Association, 2000). But the largest number—5 to 10 percent of school-age children—have **learning disabilities**, great difficulty with one or more aspects of learning, usually reading. As a result, their achievement is considerably behind what would be expected on the basis of their IQ. Sometimes deficits express themselves in other ways—for example, as severe inattention, which depresses both IQ and achievement (recall our discussion of ADHD on pages 304–305). The problems of students with learning disabilities cannot be traced to any obvious physical or emotional difficulty or to environmental disadvantage. Instead, deficits in brain functioning are involved (Waber, 2010). In many instances, the cause is unknown.

Although some students benefit academically from inclusion, many do not. Achievement gains depend on both the severity of the disability and the support services available (Downing, 2010). Furthermore, children with disabilities are often rejected by regular-classroom peers. Students with mental retardation are overwhelmed by the social skills of their classmates; they cannot interact adeptly in a conversation or game. And the processing deficits of some students with learning disabilities lead to problems in social awareness and responsiveness (Kelly & Norwich, 2004; Lohrmann & Bambara, 2006).

Does this mean that students with special needs cannot be served in regular classrooms? Not necessarily. Often these

© ELLEN B. SENISI PHOTOGRAPHY

In this inclusive first-grade classroom, a teacher encourages special-needs students' active participation. They are likely to do well if they receive support from a special education teacher and if their regular classroom teacher minimizes comparisons and promotes positive peer relations.

children do best when they receive instruction in a resource room for part of the day and in the regular classroom for the remainder (Weiner & Tardif, 2004). In the resource room, a special education teacher works with students on an individual and small-group basis. Then, depending on their progress, children join regular classrooms for different subjects and amounts of time.

Special steps must be taken to promote peer relations in inclusive classrooms. Cooperative learning and peer-tutoring experiences in which teachers guide children with learning difficulties and their classmates in working together lead to friendly interaction, improved peer acceptance, and achievement gains (Fuchs et al., 2002a, 2002b). Teachers can also prepare their class for the arrival of a student with special needs. Under these conditions, inclusion may foster emotional sensitivity and prosocial behavior among regular classmates.

Gifted Children. In Joey and Lizzie's school, some children are **gifted**, displaying exceptional intellectual strengths. One or two students in every grade have IQ scores above 130, the standard definition of giftedness based on intelligence test performance. High-IQ children, as we have seen, have keen memories and an exceptional capacity to solve challenging academic problems. Yet recognition that intelligence tests do not sample the entire range of human mental skills has led to an expanded conception of giftedness.

Creativity and Talent. Creativity is the ability to produce work that is original yet appropriate—something others have not thought of that is useful in some way (Kaufman & Sternberg, 2007; Sternberg, 2003). A child with high potential for creativity can be designated as gifted. Tests of creative capacity tap **divergent thinking**—the generation of multiple and unusual possibilities when faced with a task or problem. Divergent thinking contrasts with **convergent thinking**, which involves arriving at a single correct answer and is emphasized on intelligence tests (Guilford, 1985).

FIGURE 9.10 Responses of an 8-year-old who scored high on a figural measure of divergent thinking. This child was asked to make as many pictures as she could from the circles on the page. The titles she gave her drawings, from left to right, are as follows: “Dracula,” “one-eyed monster,” “pumpkin,” “Hula-Hoop,” “poster,” “wheelchair,” “earth,” “stop-light,” “planet,” “movie camera,” “sad face,” “picture,” “beach ball,” “the letter O,” “car,” “glasses.” Tests of divergent thinking tap only one of the complex cognitive contributions to creativity. (Reprinted by permission of Laura E. Berk.)

Because highly creative children (like high-IQ children) are often better at some tasks than others, a variety of tests of divergent thinking are available (Runco, 1992; Torrance, 1988). A verbal measure might ask children to name uses for common objects (such as a newspaper). A figural measure might ask them to create drawings based on a circular motif (see Figure 9.10). A “real-world problem” measure requires students to suggest solutions to everyday problems. Responses can be scored for the number of ideas generated and their originality.

Yet critics point out that these measures are poor predictors of creative accomplishment in everyday life because they tap only one of the complex cognitive contributions to creativity (Plucker & Makel, 2010). Also involved are defining new and important problems, evaluating divergent ideas, choosing the most promising, and calling on relevant knowledge to understand and solve problems (Sternberg, 2003; Lubart, Georgsdottir, & Besançon, 2009).

Consider these ingredients, and you will see why people usually demonstrate creativity in only one or a few related areas. Partly for this reason, definitions of giftedness have been extended to include **talent**—outstanding performance in a specific field. Case studies reveal that excellence in creative writing, mathematics, science, music, visual arts, athletics, or leadership has roots in specialized interests and skills that first appear in childhood (Moran & Gardner, 2006). Highly talented children are biologically prepared to master their domain of interest, and they display a passion for doing so.

But talent must be nurtured. Studies of the backgrounds of talented children and highly accomplished adults often reveal

warm, sensitive parents who provide a stimulating home life, are devoted to developing their child’s abilities, and provide models of hard work. These parents are reasonably demanding but not driving or overambitious (Winner, 2000, 2003). They arrange for caring teachers while the child is young and for more rigorous master teachers as the talent develops.

Many gifted children and adolescents are socially isolated, partly because their highly driven, nonconforming, and independent styles leave them out of step with peers and partly because they enjoy solitude, which is necessary to develop their talents. Still, gifted children desire gratifying peer relationships, and some—more often girls than boys—try to become better-liked by hiding their abilities. Compared with their typical agetates, gifted youths, especially girls, report more emotional and social difficulties, including low self-esteem and depression (Reis, 2004; Winner, 2000).

Finally, whereas many talented youths become experts in their fields, few become highly creative. Rapidly mastering an existing field requires different skills than innovating in that field (Moran & Gardner, 2006). The world, however, needs both experts and creators.

Educating the Gifted. Debate about the effectiveness of school programs for the gifted typically focuses on factors irrelevant to giftedness—whether to provide enrichment in regular classrooms, pull children out for special instruction (the most common practice), or advance brighter students to a higher grade. Overall, gifted children fare well academically and socially within each of these models, as long as the special activities provided do not reinforce academic convergent thinking to the detriment of problem solving, critical thinking, and creativity (Guignard & Lubart, 2007).

Gardner’s theory of multiple intelligences has inspired several model programs that provide enrichment to all students in diverse disciplines. Meaningful activities, each tapping a specific intelligence or set of intelligences, serve as contexts for assessing strengths and weaknesses and, on that basis, teaching new knowledge and original thinking (Gardner, 2000; Hoerr, 2004). For example, linguistic intelligence might be fostered through storytelling or playwriting; spatial intelligence through drawing, sculpting, or taking apart and reassembling objects; and kinesthetic intelligence through dance or pantomime.

Evidence is still needed on how well these programs nurture children’s talents and creativity. But they have already succeeded in one way—by highlighting the strengths of some students who previously had been considered unexceptional or even at risk for school failure (Kornhaber, 2004). Consequently, they may be especially useful in identifying talented low-SES, ethnic minority children, who are underrepresented in school programs for the gifted (McBee, 2006).

How Well-Educated Are U.S. Children?

Our discussion of schooling has largely focused on how teachers can support the education of children. Yet many factors—both within and outside schools—affect children’s learning. Societal

values, school resources, quality of teaching, and parental encouragement all play important roles. These multiple influences are especially apparent than when schooling is examined in cross-cultural perspective.

In international studies of reading, mathematics, and science achievement, young people in China, Korea, and Japan are consistently top performers. Among Western nations, Australia, Canada, Finland, the Netherlands, and Switzerland are also in the top tier. But U.S. students typically perform at or below the international averages (see Figure 9.11) (Programme for International Student Assessment, 2009).

Why do U.S. students fall behind in academic accomplishment? According to international comparisons, instruction in the United States is less challenging, more focused on absorbing facts, and less focused on high-level reasoning and critical

FIGURE 9.11 Average mathematics scores of 15-year-olds by country. The Programme for International Student Assessment measured achievement in many nations around the world. In its most recent comparison of countries' performance, the United States performed below the international average in math; in reading and science, its performance was about average. (Adapted from Programme for International Student Assessment, 2009.)

Finnish students explain the results of a static electricity experiment. Their country's education system—designed to cultivate initiative, problem solving, and creativity in all students—has nearly eliminated SES variations in achievement.

thinking than in other countries. According to a growing number of experts, the U.S. No Child Left Behind Act has contributed to these trends because it mandates severe sanctions for schools whose students do not meet targeted goals on achievement tests—initially, student transfers to higher-performing schools; and ultimately, staff firing, closure, state takeover, or other restructuring (Darling-Hammond, 2010; Noguera, 2010; Ravitch, 2010). Furthermore, compared with top-achieving countries, the United States is far less equitable in the quality of education it provides to its low-income and ethnic minority students. And U.S. teachers vary much more in training, salaries, and teaching conditions.

Finland is a case in point. Its nationally mandated curricula, teaching practices, and assessments are aimed at cultivating initiative, problem solving, and creativity—vital abilities needed for success in the twenty-first century. Finnish teachers are highly trained: They must complete several years of graduate-level education at government expense (Sahlberg, 2010). And Finnish education is grounded in equal opportunity for all—a policy that has nearly eliminated SES variations in achievement.

In-depth research on learning environments in Asian nations, such as Japan, Korea, and Taiwan, also highlights social forces that foster strong student learning. Among these is cultural valuing of effort. Whereas American parents and teachers tend to regard native ability as the key to academic success, Japanese, Korean, and Taiwanese parents and teachers believe that all children can succeed academically with enough effort. Asian parents devote many more hours to helping their children with homework (Stevenson, Lee, & Mu, 2000). And Asian children, influenced by collectivist values, typically view striving to achieve as a moral obligation—part of their responsibility to family and community (Hau & Ho, 2010).

As in Finland, all students in Japan, Korea, and Taiwan receive the same nationally mandated, high-quality curriculum that encourages high-level thinking, delivered by teachers who are well-prepared, highly respected in their society, and far

better paid than U.S. teachers (Kang & Hong, 2008; U.S. Department of Education, 2012a).

The Finnish and Asian examples underscore the need for American families, schools, and the larger society to work together to upgrade education. Recommended strategies, verified by research, include:

- providing intellectually challenging, relevant instruction with real-world applications
- strengthening teacher education
- supporting parents in creating stimulating home learning environments and monitoring their children's academic progress
- investing in high-quality preschool education, so every child arrives at school ready to learn
- vigorously pursuing school improvements that reduce the large inequities in quality of education between SES and ethnic groups (Economic Policy Institute, 2010).

ASK YOURSELF

REVIEW List some teaching practices that foster children's achievement and some that undermine it. Provide a brief explanation of each practice.

CONNECT Review research on child-rearing styles on pages 278–280 in Chapter 8. What style do gifted children who realize their potential typically experience? Explain.

APPLY Sandy wonders why her daughter Mira's teacher often has students work on assignments in small, cooperative groups. Explain the benefits of this approach to Sandy.

REFLECT What grouping practices were used in your elementary education—homogeneous, heterogeneous, or a combination? What impact do you think those practices had on your motivation and achievement?

SUMMARY

PHYSICAL DEVELOPMENT

Body Growth (p. 290)

Describe major trends in body growth during middle childhood.

- During middle childhood, physical growth continues at a slow, regular pace. Bones lengthen and broaden, and permanent teeth replace the primary teeth. By age 9, girls overtake boys in physical size.

Common Health Problems

(p. 290)

Describe the causes and consequences of serious nutritional problems in middle childhood, giving special attention to obesity.

- Many poverty-stricken children in developing countries and in the United States continue to suffer from serious and prolonged malnutrition, which can permanently impair physical and mental development.
- Overweight and **obesity** have increased dramatically in both industrialized and developing nations, especially in the United States. Although heredity contributes to obesity, parental feeding practices, maladaptive eating habits, reduced sleep, lack of exercise, and diets high in meats and energy-dense refined foods are more powerful influences.

- Obese children are rated as less likable by peers and adults and have serious adjustment problems. The most effective interventions are family-based and focus on changing parents' and children's eating patterns and lifestyles. Schools can help by serving healthier meals and ensuring regular physical activity.

© OCEAN/CORBIS

What vision and hearing problems are common in middle childhood?

- The most common vision problem, myopia, is influenced by heredity, early biological trauma, and time spent doing close work. It is one of the few health conditions that increases with SES.
- Although ear infections decline during the school years, many low-SES children experience some hearing loss because of repeated untreated middle-ear infections.

What factors contribute to illness during the school years, and how can these health problems be reduced?

- Children experience more illnesses during the first two years of elementary school than later because of exposure to sick children and an immature immune system.
- The most common cause of school absence and childhood hospitalization is asthma. Although heredity contributes to asthma, environmental factors—pollution, stressful home lives, lack of access to good health care, and the rise in childhood obesity—have led to an increase in the disease, especially among African-American and poverty-stricken children.
- Children with severe chronic illnesses are at risk for academic, emotional, and social difficulties, but positive family relationships improve adjustment.

Describe changes in the occurrence of unintentional injuries in middle childhood, and cite effective interventions.

- Unintentional injuries increase from middle childhood into adolescence, especially for boys. Auto and bicycle accidents account for most of the rise. Effective school-based prevention programs use modeling, rehearsal, and rewards for acquiring safety skills.

Motor Development and Play (p. 294)

Cite major changes in motor development and play during middle childhood.

- Gains in flexibility, balance, agility, and force, along with more efficient information processing, contribute to school-age children's improved gross-motor performance.

© STEVE SKJOLD/ALAMY

- Fine-motor development also improves. Children's writing becomes more legible, and their drawings increase in organization, detail, and depth cues.
- Although girls outperform boys in fine-motor skills, boys outperform girls in all gross-motor skills except those requiring balance and agility. Parents' higher expectations for boys' athletic performance play a large role.
- Games with rules become common during the school years, contributing to emotional and social development. Children, especially boys, also engage in **rough-and-tumble play**, friendly play-fighting that helps establish a **dominance hierarchy** among group members.
- Most U.S. school-age children are not active enough for good health, in part because of cutbacks in recess and physical education.

COGNITIVE DEVELOPMENT

Piaget's Theory: The Concrete Operational Stage (p. 299)

What are the major characteristics of concrete operational thought?

- In the **concrete operational stage**, children's thought becomes more logical, flexible, and organized. Mastery of conservation demonstrates decentration and **reversibility** in thinking.
- School-age children are also better at hierarchical classification and **seriation**, including **transitive inference**. Their spatial reasoning improves, evident in their ability to create **cognitive maps** representing familiar large-scale spaces.

- Concrete operational thought is limited in that children do not come up with general logical principles. They master concrete operational tasks step by step.

Discuss follow-up research on concrete operational thought.

- Specific cultural practices, especially those associated with schooling, promote children's mastery of Piagetian tasks.
- Some researchers attribute the gradual development of operational thought to gains in information-processing speed. Case's neo-Piagetian theory proposes that with practice, cognitive schemes become more automatic, freeing up space in working memory for combining old schemes and generating new ones. Eventually, children consolidate schemes into central conceptual structures, which enable them to coordinate and integrate multiple dimensions.

Information Processing (p. 302)

Describe gains in working-memory capacity and executive function, along with the development of attention and memory in middle childhood.

- Brain development contributes to increases in processing speed and expansion of working memory, which predicts intelligence test scores and academic achievement. As the prefrontal cortex continues to develop, children make great strides in executive function.
- Attention becomes more selective, adaptable, and planful, and memory strategies also improve. **Rehearsal** appears first, followed by **organization** and then **elaboration**. With age, children combine memory strategies.
- Development of the long-term knowledge base makes new information easier to store and retrieve. Children's motivation to use what they know also contributes to memory development. Memory strategies are promoted by learning activities in school.

Describe the school-age child's theory of mind and capacity to engage in self-regulation.

- School-age children regard the mind as an active, constructive agent, yielding a better understanding of cognitive processes, including effective memory strategies, mental inference, and second-order false belief. **Cognitive self-regulation** develops gradually, improving with adult instruction in strategy use.

Discuss current controversies in teaching reading and mathematics to elementary school children.

- Skilled reading draws on all aspects of the information-processing system. A combination of **whole language** and **phonics** is most effective for teaching beginning reading. Teaching that blends practice in basic skills with conceptual understanding also is best in mathematics.

Individual Differences in Mental Development (p. 309)

Describe major approaches to defining and measuring intelligence.

- Most intelligence tests yield an overall score as well as scores for separate intellectual factors. During the school years, IQ becomes more stable and correlates moderately with academic achievement.
- Componential analyses identify information-processing skills that contribute to mental test performance. Processing speed and flexible attention, memory, and reasoning strategies are positively related to IQ.
- Sternberg's **triarchic theory of successful intelligence** identifies three broad, interacting intelligences: analytical intelligence (information-processing skills), creative intelligence (capacity to solve novel problems), and practical intelligence (application of intellectual skills in everyday situations).
- Gardner's **theory of multiple intelligences** identifies at least eight distinct mental abilities. It has stimulated efforts to define, measure, and foster **emotional intelligence**.

© AGE FOTOSTOCK/ROBERT HARDING

Describe evidence indicating that both heredity and environment contribute to intelligence.

- Heritability estimates and adoption research indicate that intelligence is a product of both heredity and environment. Adoption studies indicate that environmental factors underlie the black-white IQ gap.

- IQ scores are affected by culturally influenced communication styles and knowledge. **Stereotype threat** triggers anxiety that interferes with test performance. **Dynamic assessment** helps many minority children perform more competently on mental tests.

Language Development

(p. 316)

Describe changes in school-age children's vocabulary, grammar, and pragmatics, and cite the advantages of bilingualism for development.

- Language awareness contributes to school-age children's language progress. They have a more precise and flexible understanding of word meanings and use more complex grammatical constructions and conversational strategies. Their narratives increase in organization, detail, and expressiveness.
- Mastery of a second language must begin in childhood for full proficiency to occur. Bilingualism has positive consequences for cognitive development and aspects of language awareness. In Canada, language immersion programs succeed in developing children who are proficient in both English and French. In the United States, bilingual education that combines instruction in the native tongue and in English supports ethnic minority children's academic learning.

© CHRISTINA KENNEDY/PHOTOFEST

Learning in School (p. 318)

Describe the impact of class size and educational philosophies on children's motivation and academic achievement.

- Smaller classes in the early elementary grades promote lasting gains in academic achievement. Older elementary school students in **traditional classrooms** have a slight edge in achievement test scores over those in **constructivist classrooms**, who gain in critical thinking, social and moral maturity, and positive attitudes toward school.
- Students in **social-constructivist classrooms** benefit from working collaboratively in meaningful activities and from teaching adapted to each child's zone of proximal development. **Cooperative learning** promotes achievement and self-esteem.

Discuss the role of teacher–student interaction and grouping practices in academic achievement.

- Caring, helpful, and stimulating teaching fosters children's motivation, achievement, and peer relations. **Educational self-fulfilling prophecies** have a greater impact on low than high achievers and are especially likely to occur in classrooms that emphasize competition and public evaluation. Heterogeneous grouping in multigrade classrooms promotes favorable self-esteem and school attitudes and higher achievement.

Under what conditions is placement of children with learning difficulties in regular classrooms successful?

- The success of **inclusive classrooms** for students with mild mental retardation and **learning disabilities** depends on meeting individual learning needs and promoting positive peer relations.

© ELLEN B. SENISI PHOTOGRAPHY

Describe the characteristics of gifted children and current efforts to meet their educational needs.

- **Giftedness** includes high IQ, **creativity**, and **talent**. Tests of creativity that tap **divergent** rather than **convergent thinking** focus on only one of the ingredients of creativity. Highly talented children generally have parents and teachers who nurture their exceptional abilities. Gifted children benefit from educational programs that build on their special strengths.

How well-educated are U.S. children compared with children in other industrialized nations?

- In international studies, young people in Asian nations are consistently top performers, whereas U.S. students typically perform at or below international averages. Compared with top-achieving countries, education in the United States is more focused on absorbing facts, less focused on high-level reasoning and critical thinking, and less equitable across SES groups.

Social understanding expands greatly in middle childhood. Like others their age around the world, these third graders choose friends based on personal qualities, and they count on those friends for understanding and emotional support.

Emotional and Social Development in Middle Childhood

Late one afternoon, Rena heard her son Joey burst through the front door, run upstairs, and phone his best friend Terry. “Terry, gotta talk to you,” Joey pleaded breathlessly. “Everything was going great until I got that word—*porcupine*,” Joey went on, referring to the fifth-grade spelling bee at school that day. “Just my luck! *P-o-r-k*, that’s how I spelled it! I can’t believe it. Maybe I’m not so good at social studies,” Joey confided, “but I *know* I’m better at spelling than that stuck-up Belinda Brown. I knocked myself out studying those spelling lists. Then *she* got all the easy words. If I *had* to lose, why couldn’t it be to a nice person?”

Joey’s conversation reflects new emotional and social capacities. By entering the spelling bee, he shows *industriousness*, the energetic pursuit of meaningful achievement in his culture—a major change of middle childhood. Joey’s social understanding has also expanded: He can size up strengths, weaknesses, and personality characteristics. Furthermore, friendship means something different to Joey than it did earlier—he counts on his best friend, Terry, for understanding and emotional support.

For an overview of the personality changes of middle childhood, we return to Erikson’s theory. Then we look at children’s views of themselves and of others, their moral understanding, and their peer relationships. Each increases in complexity as children reason more effectively and spend more time in school and with agemates.

Despite changing parent–child relationships, the family remains powerfully influential in middle childhood. Today, family lifestyles are more diverse than ever before. Through Joey and his younger sister Lizzie’s experiences with parental divorce, we will see that family functioning is far more important than family structure in ensuring children’s well-being. Finally, we look at some common emotional problems of middle childhood. ●

chapter outline

Erikson’s Theory: Industry versus Inferiority

Self-Understanding

Self-Concept • Self-Esteem • Influences on Self-Esteem

Emotional Development

Self-Conscious Emotions • Emotional Understanding • Emotional Self-Regulation

Moral Development

Moral and Social-Conventional Understanding • Understanding Individual Rights • Understanding Diversity and Inequality

Peer Relations

Peer Groups • Friendships • Peer Acceptance

■ BIOLOGY AND ENVIRONMENT

Bullies and Their Victims

Gender Typing

Gender-Stereotyped Beliefs • Gender Identity and Behavior

Family Influences

Parent–Child Relationships • Siblings • Only Children • Divorce • Blended Families • Maternal Employment and Dual-Earner Families

Some Common Problems of Development

Fears and Anxieties • Child Sexual Abuse • Fostering Resilience in Middle Childhood

■ CULTURAL INFLUENCES

Impact of Ethnic and Political Violence on Children

■ SOCIAL ISSUES: HEALTH

Children’s Eyewitness Testimony

Erikson's Theory: Industry versus Inferiority

According to Erikson (1950), children whose previous experiences have been positive enter middle childhood prepared to redirect their energies from the make-believe of early childhood into realistic accomplishment. Erikson believed that the combination of adult expectations and children's drive toward mastery sets the stage for the psychological conflict of middle childhood, **industry versus inferiority**, which is resolved positively when children develop a sense of competence at useful skills and tasks. In cultures everywhere, adults respond to children's improved physical and cognitive capacities by making new demands, and children are ready to benefit from those challenges.

In industrialized nations, the beginning of formal schooling marks the transition to middle childhood. With it comes literacy training, which prepares children for a vast array of specialized careers. In school, children discover their own and others' unique capacities, learn the value of division of labor, and develop a sense of moral commitment and responsibility. The danger at this stage is *inferiority*, reflected in the pessimism of children who lack confidence in their ability to do things well. This sense of inadequacy can develop when family life has not prepared children for school life or when teachers and peers destroy children's self-confidence with negative responses.

Erikson's sense of industry combines several developments of middle childhood: a positive but realistic self-concept, pride in accomplishment, moral responsibility, and cooperative participation with age-mates. How do these aspects of self and social relationships change over the school years?

The industriousness of middle childhood involves responding to new expectations for realistic accomplishment. In the informal, encouraging atmosphere of this classroom in India, children come to view themselves as responsible, capable, and cooperative.

Self-Understanding

In middle childhood, children begin to describe themselves in terms of psychological traits, compare their own characteristics with those of their peers, and speculate about the causes of their strengths and weaknesses. These transformations in self-understanding have a major impact on self-esteem.

Self-Concept

During the school years, children refine their self-concept, organizing their observations of behaviors and internal states into general dispositions. A major change takes place between ages 8 and 11, as the following self-description by an 11-year-old illustrates:

My name is A. I'm a human being. I'm a girl. I'm a truthful person. I'm not pretty. I do so-so in my studies. I'm a very good cellist. I'm a very good pianist. I'm a little bit tall for my age. I like several boys. I like several girls. I'm old-fashioned. I play tennis. I am a very good swimmer. I try to be helpful. I'm always ready to be friends with anybody. Mostly I'm good, but I lose my temper. I'm not well-liked by some girls and boys. I don't know if I'm liked by boys or not. (Montemayor & Eisen, 1977, pp. 317–318)

Instead of specific behaviors, this child emphasizes competencies: "I'm a very good cellist" (Damon & Hart, 1988). She also describes her personality, mentioning both positive and negative traits: "truthful" but short-tempered. Older school-age children are far less likely than younger children to describe themselves in extreme, all-or-none ways.

These evaluative self-descriptions result from school-age children's frequent **social comparisons**—judgments of their appearance, abilities, and behavior in relation to those of others. For example, Joey observed that he was "better at spelling" than his peers but "not so good at social studies." Whereas 4- to 6-year-olds can compare their own performance to that of one peer, older children can compare multiple individuals, including themselves (Butler, 1998; Harter, 2006).

What factors account for these revisions in self-concept? Cognitive development affects the changing *structure* of the self. School-age children, as we saw in Chapter 9, can better coordinate several aspects of a situation in reasoning about their physical world. Similarly, in the social realm, they combine typical experiences and behaviors into stable psychological dispositions, blend positive and negative characteristics, and compare their own characteristics with those of many peers (Harter, 2003, 2006).

The changing *content* of self-concept is a product of both cognitive capacities and feedback from others. Sociologist George Herbert Mead (1934) proposed that a well-organized psychological self emerges when children adopt a view of the self that resembles others' attitudes toward the child. Mead's ideas indicate that *perspective-taking skills*—in particular, an improved ability to infer what other people are thinking—are crucial for developing a self-concept based on personality traits. School-age children become better at "reading" others' messages and internalizing

their expectations. As they do so, they form an *ideal self* that they use to evaluate their real self. A large discrepancy between the two, as we will see shortly, can undermine self-esteem.

In middle childhood, children look to more people beyond the family for information about themselves as they enter a wider range of settings in school and community. And self-descriptions now include frequent reference to social groups: “I’m a Boy Scout, a paper boy, and a Prairie City soccer player,” said Joey. As children move into adolescence, although parents and other adults remain influential, self-concept is increasingly vested in feedback from close friends (Oosterwegel & Oppenheimer, 1993).

LOOK AND LISTEN

Ask several 8- to 11-year-old children to tell you about themselves. Do their self-descriptions include personality traits (both positive and negative), social comparisons, and references to social groups? ●

But recall that the content of self-concept varies from culture to culture. In earlier chapters, we noted that Asian parents stress harmonious interdependence, whereas Western parents stress independence and self-assertion. When asked to recall personally significant past experiences (their last birthday, a time their parent scolded them), U.S. school-age children gave longer accounts including more personal preferences, interests, skills, and opinions. Chinese children, in contrast, more often referred to social interactions and to others. Similarly, in their self-descriptions, U.S. children listed more personal attributes (“I’m smart,” “I like hockey”), Chinese children more attributes involving group membership and relationships (“I’m in second grade,” “My friends are crazy about me”) (Wang, 2006b; Wang, Shao, & Li, 2010).

Finally, although school-age children from diverse cultures view themselves as more knowledgeable about their own inner attributes than significant adults, Japanese children credit their parents and teachers with considerably more knowledge than Western children do (Mitchell et al., 2010, p. 249). Perhaps because of their more interdependent self, Japanese children assume that their inner states are more transparent to others.

Self-Esteem

Recall that most preschoolers have extremely high self-esteem. But as children enter school and receive much more feedback about how well they perform compared with their peers, self-esteem differentiates and also adjusts to a more realistic level.

A Hierarchically Structured Self-Esteem. Researchers have asked children to indicate the extent to which statements such as “I am good at reading” or “I’m usually the one chosen for games” are true of themselves. By age 6 to 7, children in diverse Western cultures have formed at least four broad self-evaluations: academic competence, social competence, physical/athletic competence, and physical appearance. Within these are more refined categories that become increasingly distinct

with age (Marsh, 1990; Marsh & Ayotte, 2003; Van den Bergh & De Rycke, 2003). Furthermore, the capacity to view the self in terms of stable dispositions permits school-age children to combine their separate self-evaluations into a general psychological image of themselves—an overall sense of self-esteem (Harter, 2003, 2006). As a result, self-esteem takes on the hierarchical structure shown in Figure 10.1 on page 332.

Children attach greater importance to certain self-evaluations than to others. Although individual differences exist, during childhood and adolescence, perceived physical appearance correlates more strongly with overall self-worth than any other self-esteem factor (Klomsten, Skaalvik, & Espnes, 2004; Shapka & Keating, 2005). Emphasis on appearance—in the media, by parents and peers, and in society—has major implications for young people’s overall satisfaction with themselves.

Changes in Level of Self-Esteem. Self-esteem declines during the first few years of elementary school as children evaluate themselves in various areas (Marsh, Craven, & Debus, 1998; Wigfield et al., 1997). Typically, the drop is not great enough to be harmful. Most (but not all) children appraise their characteristics and competencies realistically while maintaining an attitude of self-respect. Then, from fourth grade on, self-esteem rises for the majority of young people, who feel especially good about their peer relationships and athletic capabilities (Impett et al., 2008; Twenge & Campbell, 2001).

Influences on Self-Esteem

From middle childhood on, individual differences in self-esteem become increasingly stable (Trzesniewski, Donnellan, & Robins, 2003). And positive relationships among self-esteem, valuing of various activities, and success at those activities emerge and strengthen. Academic self-esteem predicts how important, useful, and enjoyable children judge school subjects to be, willingness to try hard, achievement, and eventual career choice (Denissen, Zarrett, & Eccles, 2007; Valentine, DuBois, & Cooper, 2004; Whitesell et al., 2009). Children with high social self-esteem are consistently better-liked by classmates (Jacobs et al., 2002). And as we saw in Chapter 9, sense of athletic competence is positively associated with investment in and performance at sports.

A profile of low self-esteem in all areas is linked to anxiety, depression, and increasing antisocial behavior (DuBois et al., 1999; Kim & Cicchetti, 2006; Robins et al., 2001). What social influences might lead self-esteem to be high for some children and low for others?

Culture. Cultural forces profoundly affect self-esteem. An especially strong emphasis on social comparison in school may explain why Chinese and Japanese children, despite their higher academic achievement, score lower than U.S. children in self-esteem—a difference that widens with age (Harter, 2006; Hawkins, 1994; Twenge & Crocker, 2002). In Asian classrooms, competition is tough and achievement pressure is high. At the same time, because their culture values social harmony, Asian children tend to be reserved about judging themselves positively but generous in their praise of others (Falbo et al., 1997).

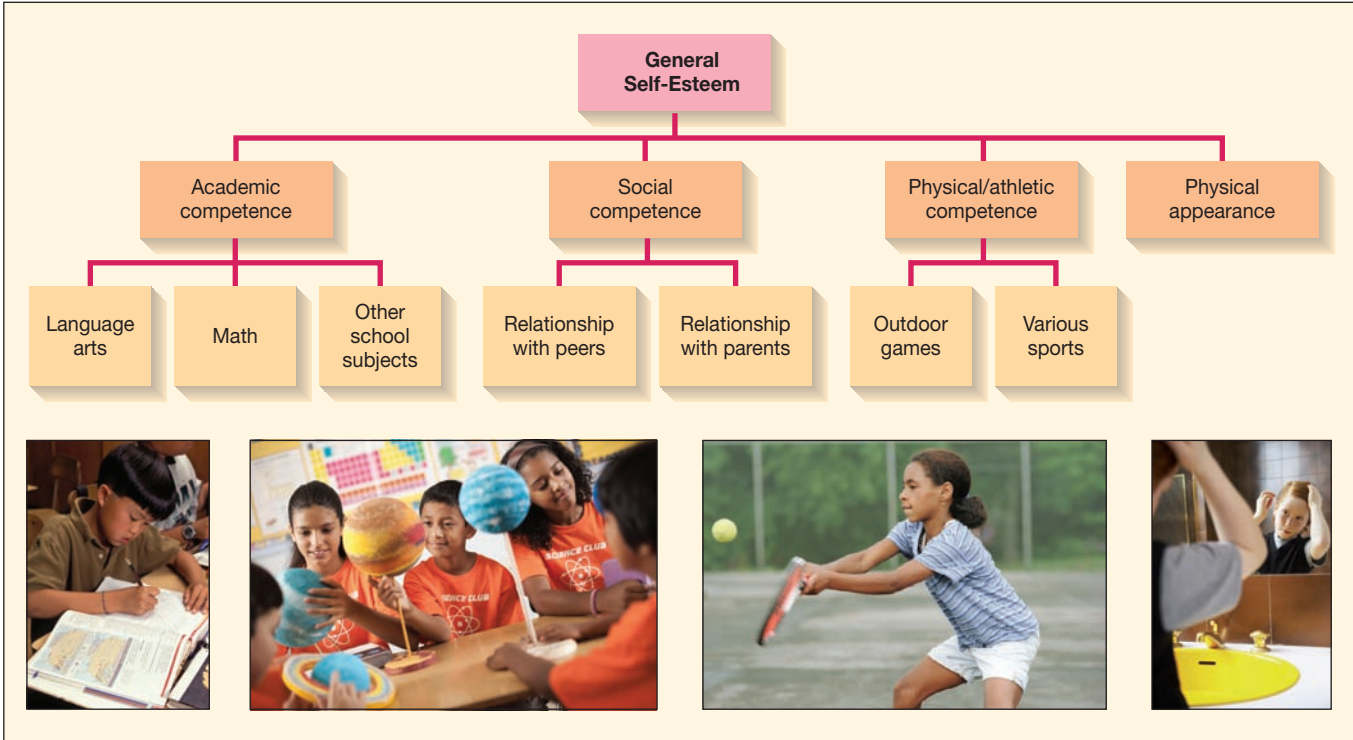

FIGURE 10.1 Hierarchical structure of self-esteem in the mid-elementary school years. From their experiences in different settings, children form at least four separate self-esteems: academic competence, social competence, physical/athletic competence, and physical appearance. These differentiate into additional self-evaluations and combine to form a general sense of self-esteem.

Gender-stereotyped expectations also affect self-esteem. In one study, the more 5- to 8-year-old girls talked with friends about the way people look, watched TV shows focusing on physical appearance, and perceived their friends as valuing thinness, the greater their dissatisfaction with their physical self and the lower their overall self-esteem a year later (Dohnt & Tiggemann, 2006). In academic self-judgments, girls score higher in language arts self-esteem, whereas boys have higher

math, science, and physical/athletic self-esteem—even when children of equal skill levels are compared (Fredricks & Eccles, 2002; Jacobs et al., 2002; Kurtz-Costes et al., 2008). At the same time, girls exceed boys in self-esteem dimensions of close friendship and social acceptance. And despite a widely held assumption that boys’ overall self-worth is much higher than girls’, the difference is slight (Marsh & Ayotte, 2003; Young & Mroczek, 2003). Girls may think less well of themselves because they internalize this negative cultural message.

Compared with their Caucasian agemates, African-American children tend to have slightly higher self-esteem, possibly because of warm extended families and a stronger sense of ethnic pride (Gray-Little & Hafdahl, 2000). Finally, children and adolescents who attend schools or live in neighborhoods where their SES and ethnic groups are well-represented feel a stronger sense of belonging and have fewer self-esteem problems (Gray-Little & Carels, 1997).

Child-Rearing Practices. Children whose parents use an *authoritative* child-rearing style (see Chapter 8) feel especially good about themselves (Lindsey et al., 2008; Wilkinson, 2004). Warm, positive parenting lets children know that they are accepted as competent and worthwhile. And firm but appropriate expectations, backed up with explanations, help them evaluate their own behavior against reasonable standards.

Controlling parents—those who too often help or make decisions for their child—communicate a sense of inadequacy to children. Having parents who are repeatedly disapproving

and insulting is also linked to low self-esteem (Kernis, 2002; Pomerantz & Eaton, 2000). Children subjected to such parenting need constant reassurance, and many rely heavily on peers to affirm their self-worth—a risk factor for adjustment difficulties, including aggression and antisocial behavior (Donnellan et al., 2005). In contrast, indulgent parenting is correlated with unrealistically high self-esteem. These children tend to lash out at challenges to their overblown self-images and, thus, are also likely to be hostile and aggressive (Hughes, Cavell, & Grossman, 1997; Thomaes et al., 2008).

American cultural values have increasingly emphasized a focus on the self that may lead parents to indulge children and boost their self-esteem too much. The self-esteem of U.S. youths rose sharply from the 1970s to the 1990s—a period in which much popular parenting literature advised promoting children's self-esteem (Twenge & Campbell, 2001). Yet compared with previous generations, American youths are achieving less well and displaying more antisocial behavior and other adjustment problems (Berk, 2005). Research confirms that children do not benefit from compliments (“You’re terrific”) that have no basis in real accomplishment (Damon, 1995). Rather, the best way to foster a positive, secure self-image is to encourage children to strive for worthwhile goals. Over time, a bidirectional relationship emerges: Achievement fosters self-esteem, which contributes to further effort and gains in performance (Gest, Domitrovich, & Welsh, 2005; Marsh et al., 2005).

What can adults do to promote, and to avoid undermining, this mutually supportive relationship between motivation and self-esteem? Some answers come from research on the precise content of adults’ messages to children in achievement situations.

Achievement-Related Attributions. *Attributions* are our common, everyday explanations for the causes of behavior—our answers to the question, “Why did I or another person do that?” Notice how Joey, in talking about the spelling bee at the beginning of this chapter, attributes his disappointing performance to *luck* (Belinda got all the easy words) and his usual success to *ability* (he *knows* he’s a better speller than Belinda). Joey also appreciates that *effort* matters: “I knocked myself out studying those spelling lists.”

Cognitive development permits school-age children to separate all these variables in explaining performance (Dweck, 2002). Those who are high in academic self-esteem and motivation make **mastery-oriented attributions**, crediting their successes to ability—a characteristic they can improve through trying hard and can count on when facing new challenges. And they attribute failure to factors that can be changed or controlled, such as insufficient effort or a very difficult task (Heyman & Dweck, 1998). Whether these children succeed or fail, they take an industrious, persistent approach to learning.

In contrast, children who develop **learned helplessness** attribute their failures, not their successes, to ability. When they succeed, they conclude that external factors, such as luck, are responsible. Unlike their mastery-oriented counterparts, they believe that ability is fixed and cannot be improved by trying hard (Cain & Dweck, 1995). When a task is difficult, these

children experience an anxious loss of control—in Erikson’s terms, a pervasive sense of inferiority. They give up without really trying.

Children’s attributions affect their goals. Mastery-oriented children seek information on how best to increase their ability through effort. Hence, their performance improves over time (Blackwell, Trzesniewski, & Dweck, 2007). In contrast, learned-helpless children focus on obtaining positive and avoiding negative evaluations of their fragile sense of ability. Over time, their ability no longer predicts how well they do (Pomerantz & Saxon, 2001). Because they fail to connect effort with success, learned-helpless children do not develop the metacognitive and self-regulatory skills necessary for high achievement (see Chapter 9). Lack of effective learning strategies, reduced persistence, and a sense of loss of control sustain one another in a vicious cycle (Chan & Moore, 2006).

Influences on Achievement-Related Attributions.

What accounts for the different attributions of mastery-oriented and learned-helpless children? Adult communication plays a key role (Pomerantz & Dong, 2006.) Children with a learned-helpless style often have parents who believe that their child is not very capable and must work harder than others to succeed. When the child fails, the parent might say, “You can’t do that, can you? It’s OK if you quit.” When the child succeeds, the parent might offer feedback that evaluates the child’s traits (“You’re so smart”). Such trait statements—even when positive—encourage children to adopt a fixed view of ability, which leads them to question their competence in the face of challenges (Mueller & Dweck, 1998).

Teachers’ messages also affect children’s attributions. Teachers who attribute children’s failures to insufficient effort, who are caring and helpful, and who emphasize learning over getting good grades tend to have mastery-oriented students (Anderman et al., 2001; Natale et al., 2009). In contrast, students with unsupportive teachers often regard their performance as

externally controlled (by teachers or by luck), withdraw from learning activities, and decline in achievement—outcomes that lead children to doubt their ability (Skinner, Zimmer-Gembeck, & Connell, 1998).

For some children, performance is especially likely to be undermined by adult feedback. Despite their higher achievement, girls more often than boys blame poor performance on lack of ability. When girls do not do well, they tend to receive messages from teachers and parents that their ability is at fault, and negative stereotypes (for example, that girls are weak at math) undermine their interest and effort (Bleeker & Jacobs, 2004; Cole et al., 1999). And as Chapter 9 revealed, low-SES ethnic minority students often receive less favorable feedback from teachers, especially when assigned to homogeneous groups of poorly achieving students—conditions that result in a drop in academic self-esteem and achievement (Harris & Graham, 2007).

LOOK AND LISTEN

Observe a school-age child working on a challenging homework assignment under the guidance of a parent or other adult. What features of the adult's communication likely foster mastery-oriented attributions? How about learned helplessness? Explain. ●

Finally, cultural values affect the likelihood that children will develop learned helplessness. Asian parents and teachers are more likely than their American counterparts to view effort as key to success and as a moral responsibility—messages they transmit to children (Mok, Kennedy, & Moore, 2011; Pomerantz, Ng, & Wang, 2008). Asians also attend more to failure than to success because failure indicates where corrective action is needed. Americans, in contrast, focus more on success because it enhances self-esteem. Observations of U.S. and Chinese mothers' responses to their fourth and fifth graders' puzzle solutions revealed that the U.S. mothers offered more praise after success, whereas the Chinese mothers more often pointed out the child's inadequate performance. And Chinese mothers made more task-relevant statements aimed at ensuring that children exerted sufficient effort ("You concentrated on it": "You got only 6 out of 12") (see Figure 10.2) (Ng, Pomerantz, & Lam, 2007). When children continued with the task after mothers left the room, the Chinese children showed greater gains in performance.

Fostering a Mastery-Oriented Approach. Attribution research suggests that well-intended messages from adults sometimes undermine children's competence. An intervention called *attribution retraining* encourages learned-helpless children to believe that they can overcome failure by exerting more effort. Children are given tasks difficult enough that they will experience some failure, followed by repeated feedback that helps them revise their attributions: "You can do it if you try harder." After they succeed, children receive additional feedback—"You're really good at this" or "You really tried hard on that one"—so that they attribute their success to both ability and effort, not chance. Another approach is to encourage low-effort students to focus less on grades and more on mastering a task

FIGURE 10.2 Chinese and U.S. mothers' task-relevant statements in response to their fourth-grade child's success or failure on puzzle tasks. Observations revealed that regardless of whether their child had just succeeded or failed, Chinese mothers were more likely than U.S. mothers to make task-relevant statements aimed at ensuring that the child exerted high effort. (Adapted from Ng, Pomerantz, & Lam, 2007.)

for individual improvement (Hilt, 2004; Yeh, 2010). Instruction in effective strategies and self-regulation is also vital, to compensate for development lost in this area and to ensure that renewed effort pays off (Wigfield et al., 2006).

Attribution retraining is best begun early, before children's views of themselves become hard to change. An even better approach is to prevent learned helplessness, using the strategies summarized in Applying What We Know on the following page.

ASK YOURSELF

REVIEW How does level of self-esteem change in middle childhood, and what accounts for these changes?

CONNECT What cognitive changes, described in Chapter 9, support the transition to a self-concept emphasizing competencies, personality traits, and social comparisons?

APPLY Should parents promote children's self-esteem by telling them they're "smart" or "wonderful"? Are children harmed if they do not feel good about everything they do? Why or why not?

REFLECT Recall your own attributions for academic successes and failures when you were in elementary school. What are those attributions like now? What messages from others may have contributed to your attributions?

Applying What We Know

Fostering a Mastery-Oriented Approach to Learning

Strategy	Description
Provision of tasks	Select tasks that are meaningful, responsive to a diversity of student interests, and appropriately matched to current competence so that the child is challenged but not overwhelmed.
Parent and teacher encouragement	Communicate warmth, confidence in the child's abilities, the value of achievement, and the importance of effort in success. Model high effort in overcoming failure. (For teachers) Communicate often with parents, suggesting ways to foster children's effort and progress. (For parents) Monitor schoolwork; provide scaffolded assistance that promotes knowledge of effective strategies and self-regulation.
Performance evaluations	Make evaluations private; avoid publicizing success or failure through wall posters, stars, privileges for "smart" children, or prizes for "best" performance. Emphasize individual progress and self-improvement.
School environment	Offer small classes, which permit teachers to provide individualized support for mastery. Provide for cooperative learning and peer tutoring, in which children assist one another; avoid ability grouping, which makes evaluations of children's progress public. Accommodate individual and cultural differences in learning styles. Create an atmosphere that sends a clear message that all students can learn.

Emotional Development

Greater self-awareness and social sensitivity support gains in emotional competence in middle childhood. Changes take place in experience of self-conscious emotions, emotional understanding, and emotional self-regulation.

Self-Conscious Emotions

In middle childhood, the self-conscious emotions of pride and guilt become clearly governed by personal responsibility. Children experience pride in a new accomplishment and guilt over a transgression, even when no adult is present (Harter & Whitesell, 1989). Also, children no longer report guilt for any mishap, as they did earlier, but only for intentional wrongdoing, such as ignoring responsibilities, cheating, or lying (Ferguson, Stegge, & Damhuis, 1991).

Pride motivates children to take on further challenges, whereas guilt prompts them to make amends and to strive for self-improvement. But in Chapter 8 we noted that excessive guilt is linked to depressive symptoms. And harsh, insensitive reprimands from adults ("Everyone else can do it! Why can't you?") can lead to intense shame, which is particularly destructive, yielding both internalizing and externalizing problems (see page 260).

Emotional Understanding

School-age children's understanding of mental activity means that, unlike preschoolers, they are likely to explain emotion by

referring to internal states, such as happy or sad thoughts, rather than to external events (Flavell, Flavell, & Green, 2001). Also, between ages 6 and 12, children become more aware of circumstances likely to spark mixed emotions, each of which may be positive or negative and may differ in intensity (Larsen, To, & Fireman, 2007; Pons et al., 2003). For example, recalling the birthday present he received from his grandmother, Joey reflected, "I was very happy that I got something but a little sad that I didn't get just what I wanted."

Appreciating mixed emotions helps children realize that people's expressions may not reflect their true feelings (Misailidi, 2006; Saarni, 1999). It also fosters awareness of self-conscious emotions. For example, between ages 6 and 7, children improve sharply in ability to distinguish pride from happiness and surprise (Tracy, Robins, & Lagattuta, 2005). And 8- and 9-year-olds understand that pride combines two sources of happiness—joy in accomplishment and joy that a significant person recognized that accomplishment (Harter, 1999). Furthermore, children of this age can reconcile contradictory facial and situational cues in figuring out another's feelings (see page 258 in Chapter 8).

As with self-understanding, gains in emotional understanding are supported by cognitive development and social experiences, especially adults' sensitivity to children's feelings and willingness to discuss emotions. Together, these factors lead to a rise in empathy as well. As children move closer to adolescence, advances in perspective taking permit an empathic response not just to people's immediate distress but also to their general life condition (Hoffman, 2000). As Joey and Lizzie imagined how people who are chronically ill or hungry feel and

evoked those emotions in themselves, they gave part of their allowance to charity and joined in fundraising projects through school, community center, and scouting.

Emotional Self-Regulation

Rapid gains in emotional self-regulation occur in middle childhood. As children engage in social comparison and care more about peer approval, they must learn to manage negative emotion that threatens their self-esteem.

By age 10, most children shift adaptively between two general strategies for managing emotion. In **problem-centered coping**, they appraise the situation as changeable, identify the difficulty, and decide what to do about it. If problem solving does not work, they engage in **emotion-centered coping**, which is internal, private, and aimed at controlling distress when little can be done about an outcome (Kliewer, Fearnow, & Miller, 1996; Lazarus & Lazarus, 1994). For example, when faced with an anxiety-provoking test or an angry friend, older school-age children view problem solving and seeking social support as the best strategies. But when outcomes are beyond their control—for example, after receiving a bad grade—they opt for distraction or try to redefine the situation: “Things could be worse. There’ll be another test.” School-age children’s improved ability to appraise situations and reflect on thoughts and feelings means that, compared with preschoolers, they more often use these internal strategies to manage emotion (Brenner & Salovey, 1997).

Furthermore, through interacting with parents, teachers, and peers, school-age children become more knowledgeable about socially approved ways to display negative emotion. They increasingly prefer verbal strategies (“Please stop pushing and wait your turn”) to crying, sulking, or aggression (Shipman et al., 2003). Young school-age children justify these more mature displays of emotion by mentioning avoidance of punishment or adult approval but, by third grade, they begin to emphasize concern for others’ feelings. Children with this awareness are rated as especially helpful, cooperative, and socially responsive

by teachers and as better-liked by peers (Garner, 1996; McDowell & Parke, 2000).

When emotional self-regulation has developed well, school-age children acquire a sense of *emotional self-efficacy*—a feeling of being in control of their emotional experience (Saarni, 2000; Thompson & Goodman, 2010). This fosters a favorable self-image and an optimistic outlook, which further help children face emotional challenges. As at younger ages, school-age children whose parents respond sensitively and helpfully when the child is distressed are emotionally well-regulated—generally upbeat in mood and also empathic and prosocial. In contrast, poorly regulated children often experience hostile, dismissive parental reactions to distress (Davidov & Grusec, 2006; Zeman, Shipman, & Suveg, 2002). These children are overwhelmed by negative emotion, a response that interferes with empathy and prosocial behavior.

Moral Development

Recall from Chapter 8 that preschoolers pick up many morally relevant behaviors through modeling and reinforcement. By middle childhood, they have had time to internalize rules for good conduct: “It’s good to help others in trouble” or “It’s wrong to take something that doesn’t belong to you.” This change leads children to become considerably more independent and trustworthy.

In Chapter 8, we also saw that children do not just copy their morality from others. As the cognitive-developmental approach emphasizes, they actively think about right and wrong. An expanding social world, the capacity to consider more information when reasoning, and perspective taking lead moral understanding to advance greatly in middle childhood.

Moral and Social-Conventional Understanding

During the school years, children construct a flexible appreciation of moral rules. By age 7 to 8, they no longer say truth telling is always good and lying is always bad but also consider prosocial and antisocial intentions. They evaluate certain types of truthfulness very negatively—for example, blunt statements, particularly when made in public contexts where they are especially likely to have negative social consequences (telling a classmate that you don’t like her drawing) (Bussey, 1999; Ma et al., 2011). And although both Chinese and Canadian schoolchildren consider lying about antisocial acts “very naughty,” Chinese children—influenced by collectivist values—more often rate lying favorably when the intention is modesty, as when a student who has thoughtfully picked up litter from the playground says, “I didn’t do it” (Lee et al., 1997, 2001). Similarly, Chinese children are more likely to favor lying to support the group at the expense of the individual (saying you’re sick so, as a poor singer, you won’t harm your class’s chances of winning a singing competition). In contrast, Canadian children more often favor lying to support the individual at the expense of the group (claiming that a friend who is a poor speller is actually a

good speller because he wants to participate in a spelling competition) (Fu et al., 2007).

As children's ideas about justice take into account an increasing number of variables, they clarify and link moral imperatives and social conventions. School-age children, for example, distinguish social conventions with a clear *purpose* (not running in school hallways to prevent injuries) from ones with no obvious justification (crossing a “forbidden” line on the playground). They regard violations of purposeful social conventions as closer to moral transgressions (Buchanan-Barrow & Barrett, 1998). With age, they also realize that people's *intentions* and the *contexts* of their actions affect the moral implications of violating a social convention. In one study, 8- to 10-year-olds stated that because of a flag's symbolic value, burning it to express disapproval of a country or to start a cooking fire is worse than burning it accidentally. But they recognized that flag burning is a form of freedom of expression, and most agreed that it would be acceptable in a country that treated its citizens unfairly (Helwig & Prencipe, 1999).

Children in Western and non-Western cultures reason similarly about moral and social-conventional concerns (Neff & Helwig, 2002; Nucci, 2002, 2005, 2008). When a directive is fair and caring, such as telling children to stop fighting or to share candy, school-age children view it as right, regardless of who states it—a principal, a teacher, or a child with no authority. In contrast, even in Korean culture, which places a high value on deference to authority, 7- to 11-year-olds evaluate negatively a teacher's or principal's order to engage in immoral acts, such as stealing or refusing to share—a response that strengthens with age (Kim, 1998; Kim & Turiel, 1996). In sum, children everywhere seem to realize that higher principles, independent of rule and authority, must prevail when people's personal rights and welfare are at stake.

Understanding Individual Rights

When children challenge adult authority, they typically do so within the personal domain. As their grasp of moral imperatives

and social conventions strengthens, so does their conviction that certain choices, such as hairstyle, friends, and leisure activities, are up to the individual. A Colombian child illustrated this passionate defense of personal control when asked if a teacher had the right to tell a student where to sit during circle time. In the absence of a moral reason from the teacher, the child declared, “She should be able to sit wherever she wants” (Ardila-Rey & Killen, 2001, p. 249).

Notions of personal choice, in turn, enhance children's moral understanding. As early as age 6, children view freedom of speech and religion as individual rights, even if laws exist that deny those rights (Helwig, 2006). And they regard laws that discriminate against individuals—for example, denying certain people access to medical care or education—as wrong and worthy of violating (Helwig & Jasiobedzka, 2001). In justifying their responses, children appeal to personal privileges and, by the end of middle childhood, to the importance of individual rights for maintaining a fair society.

At the same time, older school-age children place limits on individual choice, depending on circumstances. While they believe that nonacademic matters (such as where to go on field trips) are best decided democratically, they regard the academic curriculum as the province of teachers, based on teachers' superior ability to make such choices (Helwig & Kim, 1999). And fourth graders faced with conflicting moral and personal concerns—such as whether or not to befriend a classmate of a different race or gender—typically decide in favor of kindness and fairness (Killen et al., 2002). Partly for this reason, as we will see next, prejudice usually declines during middle childhood.

Understanding Diversity and Inequality

By the early school years, children associate power and privilege with white people and poverty and inferior status with people of color. They do not necessarily acquire these views directly from parents or friends, whose attitudes are often different from their own (Aboud & Doyle, 1996). Rather, children seem to pick up prevailing societal attitudes from implicit messages in the media and elsewhere in their environments. Powerful sources include social contexts that present a world sorted into groups, such as racial and ethnic segregation in schools and communities.

In-Group and Out-Group Biases: Development of Prejudice.

Studies in diverse Western nations confirm that by age 5 to 6, white children generally evaluate their own racial group favorably and other racial groups less favorably or negatively. *In-group favoritism* emerges first; children simply prefer their own group, generalizing from self to similar others (Bennett et al., 2004; Nesdale et al., 2004). And the ease with which a trivial group label supplied by an adult can induce in-group favoritism is striking. In one study, Caucasian-American 5-year-olds were told that they were members of a group based on T-shirt color. Although no information was provided about group status and the children never met any group members, they still displayed vigorous in-group favoritism

(Dunham, Baron, & Carey, 2011). When shown photos of unfamiliar agemates wearing either an in-group or an out-group shirt, the children claimed to like members of their own group better, gave them more resources, and engaged in positively biased recall of group members' behavior.

Out-group prejudice requires a more challenging social comparison between in-group and out-group. But it does not take long for white children to acquire negative attitudes toward ethnic minority out-groups when such attitudes are encouraged by circumstances in their environments. When white Canadian 4- to 7-year-olds living in a white community and attending nearly all-white schools sorted positive and negative adjectives into boxes labeled as belonging to a white child and a black child, out-group prejudice emerged at age 5. Unfortunately, many minority children show a reverse pattern: *out-group favoritism*, in which they assign positive characteristics to the privileged white majority and negative characteristics to their own group (Averhart & Bigler, 1997; Corenblum, 2003).

But recall that with age, children pay more attention to inner traits. The capacity to classify the social world in multiple ways enables school-age children to understand that people who look different need not think, feel, or act differently (Aboud, 2008). Consequently, voicing of negative attitudes toward minorities declines. After age 7 to 8, both majority and minority children express in-group favoritism, and white children's prejudice against out-group members often weakens (Nesdale et al., 2005; Ruble et al., 2004).

Yet even in children aware of the injustice of discrimination, prejudice can operate unintentionally and without awareness—as it does in many white adults (Dunham, Baron, & Banaji, 2006). Consider a study in which German and Dutch 9- to 15-year-olds were presented with pictures of Turkish and Moroccan immigrants, the largest ethnic minority groups in the two countries. Each was followed by a target picture with either emotionally positive or negative content, which the participants were asked to categorize quickly as either positive or negative by pressing a key (Degner & Wentura, 2010). With age, the participants responded more rapidly when negative rather than positive target pictures followed the immigrant images. Negative affect toward the ethnic minorities “spilled over” to the target pictures—evidence for automatic prejudice.

Findings like these raise the question of whether the decline in overt racial bias during middle childhood is a true decrease or whether it reflects older children's growing awareness of widely held standards that deem prejudice to be inappropriate—or both. Around age 10, white children start to avoid talking about race to appear unbiased, just as many adults do (Apfelbaum et al., 2008). At least to some degree, then, older school-age children's desire to present themselves in a socially acceptable light may contribute to reduced expressions of out-group prejudice.

Nevertheless, the extent to which children hold racial and ethnic biases varies, depending on the following personal and situational factors:

- *A fixed view of personality traits.* Children who believe that people's personality traits are fixed rather than change-

able often judge others as either “good” or “bad.” Ignoring motives and circumstances, they readily form prejudices on the basis of limited information. For example, they might infer that “a new child at school who tells a lie to get other kids to like her” is simply a bad kid (Levy & Dweck, 1999).

- *Overly high self-esteem.* Children (and adults) with very high self-esteem are more likely to hold racial and ethnic prejudices (Baumeister et al., 2003; Bigler, Brown, & Markell, 2001). These individuals seem to belittle disadvantaged people or groups to justify their own extremely favorable, yet insecure, self-evaluations. Furthermore, children who say their own ethnicity makes them feel especially “good”—and thus perhaps socially superior—are more likely to display in-group favoritism and out-group prejudice (Pfeifer et al., 2007).
- *A social world in which people are sorted into groups.* The more adults highlight group distinctions and the less interracial contact children experience in their families, schools, and communities, the more likely white children will express in-group favoritism and out-group prejudice (Killen et al., 2010).

Reducing Prejudice. Research confirms that an effective way to reduce prejudice is through intergroup contact, in which racially and ethnically different children have equal status, work toward common goals, and become personally acquainted, and in which parents and teachers expect them to engage in such interaction. Children assigned to cooperative learning groups with peers of diverse backgrounds show low levels of prejudice in their expressions of likability and in their behavior. For example, they form more cross-race friendships (Pettigrew & Tropp, 2006). Sharing thoughts and feelings with close, cross-race friends, in turn, reduces even subtle, unintentional prejudices (Turner, Hewstone, & Voci, 2007). But these positive effects seem not to generalize to out-group members who are not part of these learning teams.

THE STAR-LEADER/STEVE HOCKSTEIN/THE IMAGE WORKS

Third graders perform a traditional Chinese dance at their culturally diverse school. Long-term contact and collaboration with members of other ethnic groups reduces prejudice.

Long-term contact and collaboration among neighborhood, school, and community groups may be the best way to reduce prejudice (Rutland, Killen, & Abrams, 2010). Classrooms that expose children to ethnic diversity, teach them to value those differences, directly address the damage caused by prejudice, and encourage perspective taking and empathy both prevent children from forming negative biases and reduce already acquired biases (Dweck, 2009).

Finally, inducing children to view others' traits as changeable, by discussing with them the many possible influences on those traits, is helpful. The more children believe that people can change their personalities, the more they report liking and perceiving themselves as similar to members of disadvantaged out-groups. Furthermore, children who believe in the changeability of human attributes spend more time volunteering to help the needy (Karafantis & Levy, 2004). Volunteering may, in turn, promote a changeable view of others by helping children take the perspective of the underprivileged and appreciate the social conditions that lead to disadvantage.

ASK YOURSELF

Peer Relations

In middle childhood, the society of peers becomes an increasingly important context for development. Peer contact, as we have seen, contributes to perspective taking and understanding of self and others. These developments, in turn, enhance peer interaction. Compared with preschoolers, school-age children resolve conflicts more effectively, using persuasion and compromise (Mayeux & Cillessen, 2003). Sharing, helping, and other prosocial acts also increase. In line with these changes, aggression declines. But the drop is greatest for physical attacks (Côté et al., 2007). As we will see, verbal and relational aggression continue as children form peer groups.

Peer Groups

TAKE A MOMENT... Watch children in the schoolyard or neighborhood, and notice how often they gather in groups of three to a dozen or more. In what ways are members of the same group noticeably alike?

By the end of middle childhood, children display a strong desire for group belonging. They form **peer groups**, collectives that generate unique values and standards for behavior and a social structure of leaders and followers. Peer groups organize on the basis of proximity (being in the same classroom) and similarity in sex, ethnicity, academic achievement, popularity, and aggression (Rubin, Bukowski, & Parker, 2006).

The practices of these informal groups lead to a "peer culture" that typically involves a specialized vocabulary, dress code, and place to "hang out." As children develop these exclusive associations, the codes of dress and behavior that grow out of them become more broadly influential. Schoolmates who deviate—by "kissing up" to teachers, wearing the wrong kind of shirt or shoes, or tattling on classmates—are often rebuffed, becoming targets of critical glances and comments. These customs bind peers together, creating a sense of group identity. Within the group, children acquire many social skills—cooperation, leadership, followership, and loyalty to collective goals.

Most school-age children believe a group is wrong to exclude a peer (Killen, Crystal, & Watanabe, 2002). Nevertheless, children do exclude, often using relationally aggressive tactics. Peer groups—at the instigation of their leaders, who can be skillfully aggressive—frequently oust no longer "respected" children. Some of these castouts, whose own previous behavior toward outsiders reduces their chances of being included elsewhere, turn to other low-status peers with poor social skills (Farmer et al., 2010; Werner & Crick, 2004). Socially anxious

children, when ousted, often become increasingly peer-avoidant and thus more isolated (Buhs, Ladd, & Herald-Brown, 2010). In either case, opportunities to acquire socially competent behavior diminish. As excluded children's class participation declines, their academic achievement suffers.

School-age children's desire for group membership can also be satisfied through formal group ties such as scouting, 4-H, and religious youth groups. Adult involvement holds in check the negative behaviors associated with children's informal peer groups. And through working on joint projects and helping in their communities, children gain in social and moral maturity (Vandell & Shumow, 1999).

Friendships

Whereas peer groups provide children with insight into larger social structures, friendships contribute to the development of trust and sensitivity. During the school years, friendship becomes more complex and psychologically based. Consider the following 8-year-old's ideas:

Why is Shelly your best friend? Because she helps me when I'm sad, and she shares. . . . *What makes Shelly so special?* I've known her longer, I sit next to her and got to know her better. . . . *How come you like Shelly better than anyone else?* She's done the most for me. She never disagrees, she never eats in front of me, she never walks away when I'm crying, and she helps me with my homework. . . . *How do you get someone to like you?* . . . If you're nice to [your friends], they'll be nice to you. (Damon, 1988b, pp. 80–81)

As these responses show, friendship has become a mutually agreed-on relationship in which children like each other's personal qualities and respond to one another's needs and desires. And once a friendship forms, *trust* becomes its defining feature. School-age children state that a good friendship is based on acts of kindness that signify that each person can be counted on to support the other (Hartup & Abecassis, 2004). Consequently, older children regard violations of trust, such as not helping when others need help, breaking promises, and gossiping behind the other's back, as serious breaches of friendship.

LOOK AND LISTEN

Ask an 8- to 11-year-old to tell you what he or she looks for in a best friend. Is *trust* centrally important? Does the child mention personality traits, just as school-age children do in describing themselves? ●

Because of these features, school-age children's friendships are more selective. Whereas preschoolers say they have lots of friends, by age 8 or 9, children name only a handful of good friends. Girls, who demand greater closeness than boys, are more exclusive in their friendships (Markovits, Benenson, & Dolensky, 2001).

In addition, children tend to select friends similar to themselves in age, sex, ethnicity, and SES. Friends also resemble one another in personality (sociability, inattention/hyperactivity, aggression, depression), popularity, academic achievement,

School-age children tend to select friends who are similar to themselves in personality and academic achievement. And friendships are fairly stable: These fourth graders are likely to remain friends for at least a full school year.

prosocial behavior, and judgments (including biased perceptions) of other people (Hartup, 2006; Mariano & Harton, 2005). But friendship opportunities offered by children's environments also affect their choices. As noted earlier, in integrated classrooms with mixed-race collaborative learning groups, students form more cross-race friendships.

Over middle childhood, high-quality friendships remain fairly stable, with about 50 to 70 percent enduring over a school year, and some for several years (Berndt, 2004). But context is influential, with friendships spanning several situations—such as school, religious institution, and children of parents' friends—more likely to persist (Troutman & Fletcher, 2010). At the same time, stability increases with age as friendships become psychologically based and, therefore, higher in sharing thoughts and feelings, social support, and prosocial behavior.

School-age friends not only behave more prosocially but also disagree with each other more than nonfriends. At the same time, they use negotiation to resolve conflicts more often than nonfriends do. Friends seem to realize that close relationships can survive disagreements if friends are secure in their liking for each other (Hartup, 2006). Clearly, friendship serves as an important context in which children learn to tolerate criticism and resolve disputes.

Yet the impact of friendships on children's development depends on the nature of those friends. Children who bring kindness and compassion to their friendships strengthen each other's prosocial tendencies and form more lasting ties. When aggressive children make friends, the relationship is often riddled with hostile interaction and is at risk for breakup, especially when just one member of the pair is aggressive (Ellis & Zabatany, 2007). Aggressive girls' friendships are high in exchange of private feelings but full of jealousy, conflict, and betrayal. Aggressive boys' friendships involve frequent expressions of anger, coercive statements, physical attacks, and enticements to rule-breaking behavior (Bagwell & Coie, 2004; Crick & Nelson, 2002; Werner & Crick, 2004). These findings indicate that the social problems of aggressive children operate within their closest peer ties.

Peer Acceptance

Peer acceptance refers to likability—the extent to which a child is viewed by a group of age mates, such as classmates, as a worthy social partner. Unlike friendship, likability is not a mutual relationship but a one-sided perspective, involving the group’s view of an individual. Nevertheless, certain social skills that contribute to friendship also enhance peer acceptance. Better-accepted children tend to have more friends and more positive relationships with them (Lansford et al., 2006).

To assess peer acceptance, researchers usually use self-reports that measure *social preferences*—for example, asking children to identify classmates whom they “like very much” or “like very little” (Hymel et al., 2004). Another approach assesses *social prominence*—children’s judgments of the peers most of their classmates admire. Only moderate correspondence exists between the classmates children identify as prominent (looked up to by many others) and those they say they personally prefer (Prinstein & Cillessen, 2003).

Children’s self-reports yield four general categories of peer acceptance:

- **Popular children**, who get many positive votes (are well-liked)
- **Rejected children**, who get many negative votes (are disliked)
- **Controversial children**, who get a large number of positive and negative votes (are both liked and disliked)
- **Neglected children**, who are seldom mentioned, either positively or negatively

About two-thirds of students in a typical elementary school classroom fit one of these categories (Coie, Dodge, & Coppotelli, 1982). The remaining one-third, who do not receive extreme scores, are *average* in peer acceptance.

Peer acceptance is a powerful predictor of psychological adjustment. Rejected children, especially, are anxious, unhappy, disruptive, and low in self-esteem. Both teachers and parents rate them as having a wide range of emotional and social problems. Peer rejection in middle childhood is also strongly associated with poor school performance, absenteeism, dropping out, substance use, depression, antisocial behavior, and delinquency in adolescence and with criminality in early adulthood (Ladd, 2005; Laird et al., 2001; Rubin, Bukowski, & Parker, 2006).

However, earlier influences—children’s characteristics combined with parenting practices—may largely explain the link between peer acceptance and adjustment. School-age children with peer-relationship problems are more likely to have weak emotion regulation skills and to have experienced family stress due to low income, insensitive child rearing, and coercive discipline (Cowan & Cowan, 2004; Trentacosta & Shaw, 2009). Nevertheless, peer rejection adds to the risk of maladjustment, beyond rejected children’s maladaptive behavioral styles (Sturaro et al., 2011).

Determinants of Peer Acceptance. Why is one child liked while another is rejected? A wealth of research reveals that social behavior plays a powerful role.

Popular Children. Two subtypes of popular children exist.

The majority are **popular-prosocial children**, who combine academic and social competence, performing well in school and communicating with peers in sensitive, friendly, and cooperative ways (Cillessen & Bellmore, 2004). A smaller number are admired for their socially adept yet belligerent behavior. These **popular-antisocial children** include “tough” boys—athletically skilled but poor students who cause trouble and defy adult authority—and relationally aggressive boys and girls who enhance their own status by ignoring, excluding, and spreading rumors about other children (Rodkin et al., 2000; Rose, Swenson, & Waller, 2004; Vaillancourt & Hymel, 2006).

Although peer admiration gives popular-antisocial children some protection against lasting adjustment difficulties, their antisocial acts require intervention (Prinstein & La Greca, 2004; Rodkin et al., 2006). With age, peers like these high-status, aggressive youths less and less, eventually condemning their nasty tactics and rejecting them.

Rejected Children. Rejected children display a wide range of negative social behaviors. The largest subtype, **rejected-aggressive children**, show high rates of conflict, physical and relational aggression, and hyperactive, inattentive, and impulsive behavior. They are usually deficient in perspective taking, misinterpreting the innocent behaviors of peers as hostile and to blaming others for their social difficulties (Crick, Casas, & Nelson, 2002; Dodge, Coie, & Lynam, 2006; Hoza et al., 2005). Compared with popular-aggressive children, they are more extremely antagonistic. In contrast, **rejected-withdrawn children** are passive and socially awkward. These timid children are overwhelmed by social anxiety, hold negative expectations for treatment by peers, and worry about being scorned and attacked (Hart et al., 2000; Rubin, Bowker, & Gazelle, 2010; Troop-Gordon & Asher, 2005).

Rejected children are excluded by peers as early as kindergarten. Soon their classroom participation declines, their feelings of loneliness rise, their academic achievement falters, and they want to avoid school (Buhs, Ladd, & Herald-Brown, 2010; Gooren et al., 2011). Most have few friends, and some have none—a circumstance that predicts severe adjustment difficulties (Ladd et al., 2011; Pedersen et al., 2007).

Both types of rejected children are at risk for peer harassment. But as the Biology and Environment box on page 342 reveals, rejected-aggressive children also act as bullies, and rejected-withdrawn children are especially likely to be victimized.

LOOK AND LISTEN

Controversial and Neglected Children. Consistent with the mixed peer opinion they engender, controversial children display a blend of positive and negative social behaviors. They are hostile and disruptive, but they also engage in positive, prosocial acts. Even though some peers dislike them, they have

Biology and Environment

Bullies and Their Victims

Follow the activities of aggressive children over a school day, and you will see that they reserve their hostilities for certain peers. A particularly destructive form of interaction is **peer victimization**, in which certain children become targets of verbal and physical attacks or other forms of abuse. What sustains these repeated assault–retreat cycles between pairs of children?

About 20 percent of children are bullies, while 25 percent are repeatedly victimized. Most bullies are boys who use both physically, verbally, and relationally aggressive tactics, but a considerable number of girls bombard vulnerable classmates with verbal and relational hostility (Cook et al., 2010). As bullies move into adolescence, gender harassment increases—powerful youths (more often boys) delivering insults of a sexual nature against weaker agemates, and heterosexual youths targeting sexual minority peers (Pepler et al., 2006). Furthermore, many youths amplify their attacks through electronic means. About 20 to 40 percent of youths have experienced “cyberbullying” through text messages, e-mail, chat rooms, or other electronic tools (Tokunaga, 2010). They often do not report it to parents or adults at school.

Many bullies are disliked because of their cruelty. But a substantial number are socially prominent youngsters, who are broadly admired for their physical attractiveness, leadership, or athletic abilities (Vaillancourt et al., 2010c). To preserve their high social status, bullies often target already peer-rejected children, whom classmates are unlikely to defend (Veenstra et al., 2010). This helps explain why peers rarely intervene to help victims, and why 20 to 30 percent of onlookers actually encourage bullies, even joining in (Salmivalli & Voeten, 2004).

Chronic victims tend to be passive when active behavior is expected. On the playground, they hang around chatting or

wander on their own. When bullied, they give in, cry, and assume defensive postures (Boulton, 1999). Biologically based traits—an inhibited temperament and a frail physical appearance—contribute to victimization. But victims also have histories of resistant attachment, overly controlling child rearing, and maternal overprotection—parenting that prompts anxiety, low self-esteem, and dependency, resulting in a fearful demeanor that marks these children as vulnerable (Snyder et al., 2003). Victims’ adjustment problems include depression, loneliness, poor school performance, unruly behavior, and school avoidance (Paul & Cillessen, 2003). And like persistent child abuse, victimization is linked to impaired production of cortisol, suggesting a disrupted physiological response to stress (Vaillancourt et al., 2010b).

Aggression and victimization are not polar opposites. One-third to one-half of victims are also aggressive. Occasionally, they retaliate against powerful bullies, who respond by abusing them again—a cycle that sustains their victim status (Kochenderfer-Ladd, 2003). Among rejected children, these bully/victims are the most despised. They often have histories of extremely maladaptive parenting, including child abuse. This combination of highly negative home and peer experiences places them at severe risk for maladjustment (Kowalski, Limber, & Agatston, 2008).

Interventions that change victimized children’s negative opinions of themselves and that teach them to respond in non-reinforcing ways to their attackers are helpful. Another way to assist victimized children is to help them form and maintain a gratifying friendship. When children have a close friend to whom they can turn for

© ELLEN B. SENISI PHOTOGRAPHY

Some bullies are high-status youngsters, but many are disliked, or become so, because of their cruelty. And chronic victims are often easy targets—physically weak, passive, and inhibited.

help, bullying episodes usually end quickly. Anxious, withdrawn children with a close friend have fewer adjustment problems than those with no friends (Fox & Boulton, 2006; Laursen et al., 2007).

Although modifying victimized children’s behavior can help, this does not mean they are to blame. The best way to reduce bullying is to change youth environments (including school, sports programs, recreation centers, and neighborhoods), promoting prosocial attitudes and behaviors. Effective approaches include developing school and community codes against bullying; teaching child bystanders to intervene; strengthening adult supervision of high-bullying areas in schools, such as hallways and schoolyard; enlisting parents’ assistance in changing bullies’ behaviors; and (if necessary) moving socially prominent bullies to another class or school (Kiriakidis & Kavoura, 2010; Vaillancourt et al., 2010a).

qualities that protect them from social exclusion. They have as many friends as popular children and are happy with their peer relationships (de Bruyn & Cillessen, 2006; Newcomb, Bukowski, & Pattee, 1993). But like their popular-antisocial and rejected-aggressive counterparts, they often bully others and engage in calculated relational aggression to sustain their dominance (DeRosier & Thomas, 2003; Putallaz et al., 2007).

Perhaps the most surprising finding is that neglected children, once thought to be in need of treatment, are usually well-adjusted. Although they engage in low rates of interaction, most are just as socially skilled as average children. They do not report feeling lonely or unhappy, and when they want to, they can break away from their usual pattern of playing alone, cooperating well with peers and forming positive, stable friendships (Ladd & Burgess, 1999; Ladd et al., 2011). Neglected, socially competent children remind us that an outgoing, gregarious personality style is not the only path to emotional well-being.

Helping Rejected Children. A variety of interventions exist to improve the peer relations and psychological adjustment of rejected children. Most involve coaching, modeling, and reinforcing positive social skills, such as how to initiate interaction with a peer, cooperate in play, and respond to another child with friendly emotion and approval. Several of these programs have produced lasting gains in social competence and peer acceptance (Asher & Rose, 1997; DeRosier, 2007). Combining social-skills training with other treatments increases their effectiveness. Rejected children are often poor students, whose low academic self-esteem magnifies negative reactions to teachers and classmates. Intensive academic tutoring improves both school achievement and social acceptance (O'Neill et al., 1997).

Still another approach focuses on training in perspective taking and in solving social problems. But many rejected-aggressive children are unaware of their poor social skills and do not take responsibility for their social failures (Mrug, Hoza, & Gerdes, 2001). Rejected-withdrawn children, in contrast, are likely to develop a *learned-helpless* approach to peer difficulties—concluding, after repeated rebuffs, that they will never be liked (Wichmann, Coplan, & Daniels, 2004). Both types of children need help attributing their peer difficulties to internal, changeable causes.

As rejected children gain in social skills, teachers must encourage peers to alter their negative opinions. Accepted children often selectively recall their negative acts while overlooking their positive ones (Mikami, Lerner, & Lun, 2010; Peets et al., 2007). Consequently, even in the face of contrary evidence, rejected children's negative reputations tend to persist. Teachers' praise and expressions of liking can modify peer judgments.

Finally, because rejected children's socially incompetent behaviors often originate in a poor fit between the child's temperament and parenting practices, interventions focusing on the child alone may not be sufficient (Bierman & Powers, 2009). Without interventions directed at improving the quality of parent-child interaction, rejected children may soon return to their old behavior patterns.

Gender Typing

Children's understanding of gender roles broadens in middle childhood, and their gender identities (views of themselves as relatively masculine or feminine) change as well. We will see that development differs for boys and girls, and it can vary considerably across cultures.

Gender-Stereotyped Beliefs

Research in many countries reveals that stereotyping of personality traits increases steadily in middle childhood, becoming adultlike around age 11 (Best, 2001; Heyman & Legare, 2004). For example, children regard "tough," "aggressive," "rational," and "dominant" as masculine and "gentle," "sympathetic," and "dependent" as feminine (Serbin, Powlishta, & Gulko, 1993).

Children derive these distinctions from observing sex differences in behavior as well as from adult treatment. When helping a child with a task, for example, parents (especially fathers) behave in a more mastery-oriented fashion with sons, setting higher standards, explaining concepts, and pointing out important features of tasks—particularly during gender-typed pursuits, such as science activities (Tenenbaum & Leaper, 2003; Tenenbaum et al., 2005). Furthermore, parents less often encourage girls to make their own decisions. And both parents and teachers more often praise boys for knowledge and accomplishment, girls for obedience (Good & Brophy, 2003; Leaper, Anderson, & Sanders, 1998; Pomerantz & Ruble, 1998).

Also in line with adult stereotypes, school-age children quickly figure out which academic subjects and skill areas are "masculine" and which are "feminine." They often regard reading, spelling, art, and music as more for girls and mathematics, athletics, and mechanical skills as more for boys (Cvencek, Meltzoff, & Greenwald, 2011; Eccles, Jacobs, & Harold, 1990). These attitudes influence children's preferences for and sense of competence at certain subjects. As we saw earlier (page 332), boys tend to feel more competent at math, science, and athletics, whereas girls feel more competent at language arts—gender differences still evident after controlling for actual performance.

An encouraging sign is that some gender-stereotyped beliefs about achievement may be changing. In several recent investigations carried out in Canada, France, and the United States, a majority of elementary and secondary students disagreed with the idea that math is a "masculine" subject (Martinot & Désert, 2007; Plante, Théoret, & Favreau, 2009; Rowley et al. 2007). And when Canadian students were given the option of rating math as a "feminine" subject (not offered in previous studies), an impressive number expressed the view that it is predominantly feminine. The overwhelming majority of these young people, however, continued to view language arts traditionally—as largely "feminine." And they still perceived girls to do better in language arts than in math.

Although school-age children are aware of many stereotypes, they also develop a more open-minded view of what

males and females *can do* (Trautner et al., 2005). As with racial stereotypes (see page 338), the ability to classify flexibly contributes to this change. School-age children realize that a person's sex is not a certain predictor of his or her personality traits, activities, and behavior. Similarly, by the end of middle childhood, most children regard gender typing as socially rather than biologically influenced (Taylor, Rhoades, & Gelman, 2009).

Nevertheless, acknowledging that people *can* cross gender lines does not mean that children always *approve* of doing so. In one longitudinal study, between ages 7 and 13, children of both genders became more open-minded about girls being offered the same opportunities as boys. This increasing flexibility, however, was less pronounced among boys (Crouter et al., 2007). Furthermore, many school-age children take a harsh view of certain violations—boys playing with dolls and wearing girls' clothing, girls acting noisily and roughly. They are especially intolerant when boys engage in these “cross-gender” acts, which children regard as nearly as bad as moral transgressions (Blakemore, 2003; Levy, Taylor, & Gelman, 1995).

Gender Identity and Behavior

From third to sixth grade, boys tend to strengthen their identification with “masculine” personality traits, whereas girls' identification with “feminine” traits declines. While still leaning toward the “feminine” side, girls are more *androgynous* than boys—more likely to describe themselves as having some “other-gender” characteristics (Serbin, Powlishta, & Gulko, 1993). And whereas boys usually stick to “masculine” pursuits, many girls experiment with a wider range of options—from cooking and sewing to sports and science fairs—and more often consider traditionally male future work roles, such as firefighter or astronomer (Liben & Bigler, 2002).

These changes are due to a mixture of cognitive and social forces. School-age children of both sexes are aware that society attaches greater prestige to “masculine” characteristics. For example, they rate “masculine” occupations as having higher status than “feminine” occupations (Liben, Bigler, & Krogh, 2001). And they more often regard a novel job (such as *clipster*, “a person who tests batteries”) as higher in status and as appropriate “for both men and woman” when it is portrayed with a male worker than with a female worker (Liben, Bigler, & Krogh, 2001; Weisgram, Bigler, & Liben, 2010). Messages from adults and peers are also influential. In Chapter 8, we saw that parents (especially fathers) are far less tolerant when sons, as opposed to daughters, cross gender lines. Similarly, a tomboyish girl can make her way into boys' activities without losing the approval of her female peers, but a boy who engages in “feminine” pursuits is likely to be ridiculed and rejected.

As school-age children make social comparisons and characterize themselves in terms of stable dispositions, their gender identity expands to include the following self-evaluations, which greatly affect their adjustment:

- *Gender typicality*—the degree to which the child feels similar to others of the same gender. Although children need not be highly gender-typed to view themselves as

An 8-year-old launches the rocket she made in her school's Young Astronaut Club. Whereas school-age boys usually stick to “masculine” pursuits, girls experiment with a wider range of options.

gender-typical, their psychological well-being depends, to some degree, on feeling that they “fit in” with their same-sex peers (Egan & Perry, 2001).

- *Gender contentedness*—the degree to which the child feels comfortable with his or her gender assignment, which also promotes happiness.
- *Felt pressure to conform to gender roles*—the degree to which the child feels parents and peers disapprove of his or her gender-related traits. Because such pressure reduces the likelihood that children will explore options related to their interests and talents, children who feel strong gender-typed pressure are often distressed.

In a longitudinal study of third through seventh graders, *gender-typical* and *gender-contented* children gained in self-esteem over the following year. In contrast, children who were *gender-atypical* and *gender-discontented* declined in self-worth. Furthermore, gender-atypical children who reported *intense pressure to conform to gender roles* experienced serious difficulties—withdrawal, sadness, disappointment, and anxiety (Yunger, Carver, & Perry, 2004).

Clearly, how children feel about themselves in relation to their gender group becomes vitally important in middle childhood, and those who experience rejection because of their gender-atypical traits suffer profoundly. Researchers and therapists are debating how best to help children who feel gender-atypical. Some favor providing these children with therapy that reinforces them for engaging in traditional gender-role activities so they will feel more compatible with same-sex peers (Zucker, 2006). Others oppose this approach on grounds that it promotes a pathological view of gender atypicality, is likely to heighten felt pressure to conform (which predicts maladjustment), and—for children who fail to change—may result in parental rejection. These experts advocate intervening with parents and peers to help them become more accepting of children's gender-atypical interests and behaviors (Bigler, 2007; Conway, 2007; Crawford,

2003). **TAKE A MOMENT...** In view of what you have learned about the development of children's gender typing, which approach do you think would be more successful, and why?

REFLECT As a school-age child, did you have classmates you would classify as popular-aggressive? What were they like, and why do you think peers admired them?

Family Influences

As children move into school, peer, and community contexts, the parent-child relationship changes. At the same time, children's well-being continues to depend on the quality of family interaction. In the following sections, we will see that contemporary diversity in family life—divorce, remarriage, maternal employment, and dual-earner families—can have positive as well as negative effects on children. In later chapters, we take up other family structures, including gay and lesbian families, never-married single-parent families, and the increasing numbers of grandparents rearing grandchildren.

Parent-Child Relationships

In middle childhood, the amount of time children spend with parents declines dramatically. Children's growing independence means that parents must deal with new issues. "I've struggled with how many chores to assign, how much allowance to give, whether their friends are good influences, and what to do about problems at school," Rena remarked. "And then there's the challenge of keeping track of them when they're out—or even when they're home and I'm not there to see what's going on."

Despite these new concerns, child rearing becomes easier for those parents who established an authoritative style during the early years. Reasoning is more effective with school-age children because of their greater capacity for logical thinking and their increased respect for parents' expert knowledge (Collins, Madsen, & Susman-Stillman, 2002). And children of parents who engage in joint decision making where possible are more likely to listen to parents' perspectives in situations where compliance is vital (Russell, Mize, & Bissaker, 2004).

As children demonstrate that they can manage daily activities and responsibilities, effective parents gradually shift control from adult to child. They do not let go entirely but, rather, engage

in **coregulation**, a form of supervision in which parents exercise general oversight while letting children take charge of moment-by-moment decision making. Coregulation grows out of a warm, cooperative relationship between parent and child based on give-and-take. Parents must guide and monitor from a distance and effectively communicate expectations when they are with their children. And children must inform parents of their whereabouts, activities, and problems so parents can intervene when necessary (Maccoby, 1984). Coregulation supports and protects children while preparing them for adolescence, when they will make many important decisions themselves.

As at younger ages, mothers tend to spend more time than fathers with school-age children. Mothers also are more knowledgeable about children's everyday activities. Still, many fathers are highly involved (Galinsky, Aumann, & Bond, 2009). Each parent, however, tends to devote more time to children of their own sex (Lamb & Lewis, 2004; Tucker, McHale, & Crouter, 2003). And parents are more vigilant about monitoring the activities of same-sex children while their children are away from home.

Although school-age children often press for greater independence, they know how much they need their parents' support. In one study, fifth and sixth graders described parents as the most influential people in their lives (Furman & Buhrmester, 1992). They often turned to mothers and fathers for affection, advice, enhancement of self-worth, and assistance with everyday problems.

Siblings

In addition to parents and friends, siblings continue to be important sources of support. Yet sibling rivalry tends to increase in middle childhood. As children participate in a wider range of activities, parents often compare siblings' traits and accomplishments (Dunn, 2004; Tamrouti-Makkink et al., 2004). The child who gets less parental affection, more disapproval, or fewer material resources is likely to be resentful and show poorer adjustment.

BRUCE LAURANCE/BLEND IMAGES/GETTY IMAGES

Although sibling rivalry tends to increase in middle childhood, siblings also provide each other with emotional support and help with difficult tasks.

For same-sex siblings who are close in age, parental comparisons are more frequent, resulting in more quarreling and antagonism. This effect is particularly strong when parents are under stress as a result of financial worries, marital conflict, single parenthood, or child negativity (Jenkins, Rasbash, & O'Connor, 2003). Parents whose energies are drained become less careful about being fair.

To reduce this rivalry, siblings often strive to be different from one another. For example, two brothers I know deliberately selected different athletic pursuits and musical instruments. If the older one did especially well at an activity, the younger one did not want to try it. Parents can limit these effects by making an effort not to compare children, but some feedback about their competencies is inevitable. As siblings strive to win recognition for their own uniqueness, they shape important aspects of each other's development.

Although conflict rises, school-age siblings continue to rely on each other for companionship, assistance, and emotional support (Seibert & Kerns, 2009). When researchers asked siblings about shared daily activities, children mentioned that older siblings often helped younger siblings with academic and peer challenges. And both offered each other help with family issues (Tucker, McHale, & Crouter, 2001). But for siblings to reap these benefits, parental encouragement of warm, considerate sibling ties is vital. The more positive their relationship, the more siblings resolve disagreements constructively, provide emotional support and concrete forms of assistance, and contribute to resilience in the face of major stressors, such as parental divorce (Conger, Stocker, & McGuire, 2009; Soli, McHale, & Feinberg, 2009).

When siblings get along well, the older sibling's academic and social competence tends to "rub off on" the younger sibling, fostering more favorable achievement and peer relations (Brody & Murry, 2001; Lamarche et al., 2006). But destructive sibling conflict in middle childhood is associated with negative outcomes, including conflict-ridden peer relationships, anxiety, depressed mood, and later substance use and delinquency, even after other family relationship factors are controlled (Criss & Shaw, 2005; Kim et al., 2007; Stocker, Burwell, & Briggs, 2002).

Only Children

Although sibling relationships bring many benefits, they are not essential for healthy development. Contrary to popular belief, only children are not spoiled, and in some respects, they are advantaged. U.S. children growing up in one-child and multi-child families do not differ in self-rated personality traits (Mottus, Indus, & Allik, 2008). And compared to children with siblings, only children are higher in self-esteem and achievement motivation, do better in school, and attain higher levels of education. One reason may be that only children have somewhat closer relationships with parents, who may exert more pressure for mastery and accomplishment (Falbo, 1992). However, only children tend to be less well-accepted in the peer group, perhaps because they have not had opportunities to learn effective conflict-resolution strategies through sibling interactions (Kitzmann, Cohen, & Lockwood, 2002).

WANG ZHAO/AFP/GETTY IMAGES

Limiting family size has been a national policy in China for more than three decades. In urban areas, the majority of couples have no more than one child.

Favorable development also characterizes only children in China, where a one-child family policy has been strictly enforced in urban areas for more than three decades to control population growth (Yang, 2008). Compared with agetates who have siblings, Chinese only children are advanced in cognitive development and academic achievement. They also feel more emotionally secure, perhaps because government disapproval promotes tension in families with more than one child (Falbo & Poston, 1993; Jiao, Ji, & Jing, 1996; Yang et al., 1995). Chinese mothers usually ensure that their children have regular contact with first cousins (who are considered siblings). Perhaps as a result, Chinese only children do not differ from agetates with siblings in social skills and peer acceptance (Hart, Newell, & Olsen, 2003). The next generation of Chinese only children, however, will have no first cousins.

China's birth rate, at 1.5 overall and 0.7 in its largest cities, is now lower than that of many developed nations. As a result, its elderly population is rapidly increasing while its working-age population has leveled off—an imbalance that threatens the country's economic progress. And because sons are more highly valued than daughters, the policy has resulted in an epidemic of abortions of female fetuses and abandonment of girl babies, yielding a vastly skewed population sex ratio (130 male births for every 100 female births) that jeopardizes social stability (Zhu & Hesketh, 2009). Consequently, China is considering relaxing the one-child policy, but it is now so culturally ingrained that couples typically say they would not have a second child, even if offered the opportunity (LaFraniere, 2011).

Divorce

Children's interactions with parents and siblings are affected by other aspects of family life. Joey and Lizzie's relationship, Rena told me, had been particularly negative only a few years before.

Joey pushed, hit, and taunted Lizzie and called her names. Although she tried to retaliate, she was no match for Joey's larger size. The arguments usually ended with Lizzie running in tears to her mother. Joey and Lizzie's fighting coincided with their parents' growing marital unhappiness. When Joey was 8 and Lizzie 5, their father, Drake, moved out.

Between 1960 and 1985, divorce rates in Western nations rose dramatically before stabilizing in most countries. The United States has experienced a decline in divorces over the past decade, largely due to a rise in age at first marriage (Amato & Dorius, 2010). Nevertheless, the United States continues to have the highest divorce rate in the world (see Figure 10.3). Of the 45 percent of American marriages that end in divorce, half involve children. At any given time, one-fourth of U.S. children live in single-parent households. Although most reside with their mothers, the percentage in father-headed households has increased steadily, to about 12 percent (Federal Interagency Forum on Child and Family Statistics, 2011).

Children of divorce spend an average of five years in a single-parent home—almost a third of childhood. For many, divorce leads to new family relationships. About two-thirds of divorced parents marry again. Half their children eventually experience a third major change—the end of a parent's second marriage (Hetherington & Kelly, 2002).

FIGURE 10.3 Divorce rates in 12 industrialized nations. The U.S. divorce rate is the highest in the industrialized world, far exceeding divorce rates in other countries. (Adapted from U.S. Census Bureau, 2012b.)

These figures reveal that divorce is not a single event in the lives of parents and children. Instead, it is a transition that leads to a variety of new living arrangements, accompanied by changes in housing, income, and family roles and responsibilities. Since the 1960s, many studies have reported that marital breakup is stressful for children. But the research also reveals great individual differences (Fine, Ganong, & Demo, 2010). How well children fare depends on many factors: the custodial parent's psychological health, the child's characteristics, and social supports within the family and surrounding community.

Immediate Consequences. “Things were worst during the period Drake and I decided to separate,” Rena reflected. “We fought over division of our belongings and custody of the children, and the kids suffered. Sobbing, Lizzie told me she was ‘sorry she made Daddy go away.’ Joey kicked and threw things at home and didn’t do his work at school. In the midst of everything, I could hardly deal with their problems. We had to sell the house, and I needed a better-paying job.”

Family conflict often rises around the time of divorce as parents try to settle disputes over children and possessions. Once one parent moves out, additional events threaten supportive interactions between parents and children. Many mother-headed households experience a sharp drop in income. In the United States, 27 percent of divorced mothers with young children live in poverty, and more are low-income, getting less than the full amount of child support from the absent father or none at all (Grall, 2011). They usually must move to lower-cost housing, reducing supportive ties to neighbors and friends.

The transition from marriage to divorce typically leads to high maternal stress, depression, and anxiety and to a disorganized family situation. Declines in well-being are greatest for mothers of young children (Williams & Dunne-Bryant, 2006). “Meals and bedtimes were at all hours, the house didn’t get cleaned, and I stopped taking Joey and Lizzie on weekend outings,” said Rena. As children react with distress and anger to their less secure home lives, discipline may become harsh and inconsistent. Contact with noncustodial fathers often decreases over time (Hetherington & Kelly, 2002). Fathers who see their children only occasionally are inclined to be permissive and indulgent, making the mother’s task of managing the child even more difficult.

The more parents argue and fail to provide children with warmth, involvement, and consistent guidance, the poorer children’s adjustment. About 20 to 25 percent of children in divorced families display severe problems, compared with about 10 percent in nondivorced families (Lansford, 2009; Noller et al., 2008). At the same time, reactions vary with children’s age, temperament, and sex.

Children’s Age. Five-year-old Lizzie’s fear that she had caused her father to leave is not unusual. Preschool and young school-age children often blame themselves for a marital breakup and fear that both parents may abandon them. And although older children have the cognitive maturity to understand that they are not responsible for their parents’ divorce, many react strongly, declining in school performance, becoming unruly,

and escaping into undesirable peer activities, especially when family conflict is high and parental supervision is low (D'Onofrio et al., 2006; Lansford et al., 2006). Some older children—especially the oldest child in the family—display more mature behavior, willingly taking on extra family and household tasks as well as emotional support of a depressed, anxious mother. But if these demands are too great, these children may eventually become resentful, withdraw from the family, and engage in angry, acting-out behavior (Hetherington, 1999).

Children's Temperament and Sex. Exposure to stressful life events and inadequate parenting magnifies the problems of temperamentally difficult children (Lengua et al., 2000). In contrast, easy children are less often targets of parental anger and also cope more effectively with adversity.

These findings help explain sex differences in response to divorce. Girls sometimes respond as Lizzie did, with internalizing reactions such as crying, self-criticism, and withdrawal. More often, children of both sexes show demanding, attention-getting behavior. But in mother-custody families, boys are at slightly greater risk for serious adjustment problems (Amato, 2010). Recall from Chapter 8 that boys are more active and noncompliant—behaviors that increase with exposure to parental conflict and inconsistent discipline. Coercive maternal behavior and defiance by sons are common in divorcing households.

Perhaps because their behavior is so unruly, boys receive less emotional support from mothers, teachers, and peers. And as Joey's behavior toward Lizzie illustrates, the coercive cycles of interaction between boys and their divorced mothers soon spread to sibling relationships, compounding adjustment difficulties (Hetherington & Kelly, 2002; Sheehan et al., 2004). After divorce, children who are challenging to rear generally get worse.

Long-Term Consequences. Rena eventually found better-paying work and gained control over the daily operation of the household. And after several meetings with a counselor, Rena and Drake realized the harmful impact of their quarreling on Joey and Lizzie. Drake visited regularly and handled Joey's unruliness with firmness and consistency. Soon Joey's school performance improved, his behavior problems subsided, and both children seemed calmer and happier.

Most children show improved adjustment by two years after divorce. Yet overall, children and adolescents of divorced parents continue to score slightly lower than children of continuously married parents in academic achievement, self-esteem, social competence, and emotional and behavior problems (Lansford, 2009). And divorce is linked to problems with adolescent sexuality and development of intimate ties. Young people who experienced parental divorce—especially more than once—display higher rates of early sexual activity and adolescent parenthood (Wolfinger, 2000). Some experience other lasting difficulties—reduced educational attainment, troubled romantic relationships and marriages, divorce in adulthood, and unsatisfying parent-child relationships (Amato, 2006, 2010).

The overriding factor in positive adjustment following divorce is effective parenting—shielding the child from family

conflict and using authoritative child rearing (Leon, 2003; Wolchik et al., 2000). Where the custodial parent is the mother, contact with fathers is important. In the United States, paternal contact has risen over the past three decades, with about one-third of children today experiencing at least weekly visits (Amato & Dorius, 2010).

The more paternal contact and the warmer the father-child relationship, the less children react with defiance and aggression (Dunn et al., 2004). For girls, a good father-child relationship protects against early sexual activity and unhappy romantic involvements. For boys, it seems to affect overall psychological well-being. In fact, several studies indicate that outcomes for sons are better when the father is the custodial parent (Clarke-Stewart & Hayward, 1996; McLanahan, 1999). Fathers' greater economic security and image of authority seem to help them engage in effective parenting with sons. And boys in father-custody families may benefit from greater involvement of both parents because noncustodial mothers participate more in their children's lives than do noncustodial fathers.

Although divorce is painful for children, remaining in an intact but high-conflict family is much worse than making the transition to a low-conflict, single-parent household (Greene et al., 2003; Strohschein, 2005). However, more parents today are divorcing because they are moderately (rather than extremely) dissatisfied with their relationship. Research suggests that children in these low-discord homes are especially puzzled and upset. Perhaps these youngsters' inability to understand the marital breakup and grief over the loss of a seemingly happy home life explain why the adjustment problems of children of divorce have intensified over time (Amato, 2001; Lansford, 2009).

Regardless of the extent of their friction, divorcing parents who manage to engage in *coparenting* (see page 60 in Chapter 2), supporting each other in their child-rearing roles, greatly improve their children's chances of growing up competent, stable, and happy. Caring extended-family members, teachers, siblings, and friends also reduce the likelihood that divorce will result in long-term difficulties (Hetherington, 2003).

Divorce Mediation, Joint Custody, and Child Support.

Awareness that divorce is highly stressful for children and families has led to community-based services aimed at helping them through this difficult time. One such service is *divorce mediation*, a series of meetings between divorcing adults and a trained professional aimed at reducing family conflict, including legal battles over property division and child custody. Research reveals that mediation increases out-of-court settlements, cooperation and involvement of both parents in child rearing, and parents' and children's feelings of well-being (Emery, Sbarra, & Grover, 2005).

Joint custody, which grants parents equal say in important decisions about the child's upbringing, is becoming increasingly common. Children usually reside with one parent and see the other on a fixed schedule, similar to the typical sole-custody situation. In other cases, parents share physical custody, and children move between homes and sometimes schools and peer groups. These transitions can be especially hard on some

Applying What We Know

Helping Children Adjust to Their Parents' Divorce

Suggestion	Explanation
Shield children from conflict.	Witnessing intense parental conflict is very damaging to children. If one parent insists on expressing hostility, children fare better if the other parent does not respond in kind.
Provide children with as much continuity, familiarity, and predictability as possible.	Children adjust better during the period surrounding divorce when their lives have some stability—for example, the same school, bedroom, babysitter, playmates, and daily schedule.
Explain the divorce, and tell children what to expect.	Children are more likely to develop fears of abandonment if they are not prepared for their parents' separation. They should be told that their parents will not be living together anymore, which parent will be moving out, and when they will be able to see that parent. If possible, parents should explain the divorce together, providing a reason that each child can understand and assuring children that they are not to blame.
Emphasize the permanence of the divorce.	Fantasies of parents getting back together can prevent children from accepting the reality of their current life. Children should be told that the divorce is final and that they cannot change this fact.
Respond sympathetically to children's feelings.	Children need a supportive and understanding response to their feelings of sadness, fear, and anger. For children to adjust well, their painful emotions must be acknowledged, not denied or avoided.
Engage in authoritative parenting.	Parents who engage in authoritative parenting—providing affection and acceptance, reasonable demands for mature behavior, and consistent, rational discipline—greatly reduce their children's risk of maladjustment following divorce.
Promote a continuing relationship with both parents.	When parents disentangle their lingering hostility toward the former spouse from the child's need for a continuing relationship with the other parent, children adjust well. Grandparents and other extended-family members can help by not taking sides.

Source: Teyber, 2001.

children. Joint-custody parents report little conflict—fortunately so, since the success of the arrangement depends on coparenting. And their children—regardless of living arrangements—tend to be better-adjusted than children in sole-maternal-custody homes (Bauserman, 2002).

Finally, many single-parent families depend on child support from the noncustodial parent to relieve financial strain. All U.S. states have procedures for withholding wages from parents who fail to make these payments. Although child support is usually not enough to lift a single-parent family out of poverty, it can ease its burdens substantially. Noncustodial fathers who have generous visitation schedules and who often see their children are more likely to pay child support regularly (Amato & Sobolewski, 2004). Applying What We Know above summarizes ways to help children adjust to their parents' divorce.

Blended Families

“If you get married to Wendell, and Daddy gets married to Carol,” Lizzie wondered aloud to Rena, “then I’ll have two sisters and one more brother. And let’s see, how many grandmothers and grandfathers? A lot!” exclaimed Lizzie.

About 60 percent of divorced parents remarry within a few years. Others *cohabit*, or share a sexual relationship and a residence with a partner outside of marriage. Parent, stepparent, and children form a new family structure called the **blended**, or **reconstituted**, family. For some children, this expanded

family network is positive, bringing greater adult attention. But children in blended families usually have more adjustment problems than children in stable, first-marriage families (Jeynes, 2007; Nicholson et al., 2008). Switching to stepparents' new rules and expectations can be stressful, and children often view steprelatives as intruders. How well they adapt is, again, related to the quality of family functioning (Hetherington & Kelly, 2002). This depends on which parent forms a new relationship, the child's age and sex, and the complexity of blended-family relationships. As we will see, older children and girls seem to have the hardest time.

Mother-Stepfather Families. Because mothers generally retain custody of children, the most common form of blended family is a mother-stepfather arrangement. Boys tend to adjust quickly, welcoming a stepfather who is warm, who refrains from exerting his authority too quickly, and who offers relief from coercive cycles of mother-son interaction. Mothers' friction with sons also declines as a result of greater economic security, another adult to share household tasks, and an end to loneliness (Visher, Visher, & Pasley, 2003). Stepfathers who marry rather than cohabit are more involved in parenting, perhaps because men who choose to marry a mother with children are more interested in and skilled at child rearing (Hofferth & Anderson, 2003). Girls, however, often have difficulty with their custodial mother's remarriage. Stepfathers disrupt the close

ties many girls have established with their mothers, and girls often react with sulky, resistant behavior (Bray, 1999; Ganong, Coleman, & Jamison, 2011).

But age affects these findings. Older school-age children and adolescents of both sexes display more irresponsible, acting-out behavior than their peers not in stepfamilies (Hetherington & Stanley-Hagan, 2000; Robertson, 2008). If parents are warmer and more involved with their biological children than with their stepchildren, older children are more likely to notice and challenge unfair treatment. And adolescents often view the new stepparent as a threat to their freedom, especially if they experienced little parental monitoring in the single-parent family. But when teenagers have affectionate, cooperative relationships with their mothers, many eventually develop good relations with their stepfathers—a circumstance linked to better adjustment (King, 2009; Yuan & Hamilton, 2006).

Father–Stepmother Families. Remarriage of noncustodial fathers often leads to reduced contact with their biological children, especially when fathers remarry quickly, before they have established post-divorce parent–child routines (Dunn, 2002; Juby et al., 2007). When fathers have custody, children typically react negatively to remarriage. One reason is that children living with fathers often start out with more problems. Perhaps the biological mother could no longer handle the difficult child (usually a boy), so the father and his new partner are faced with a youngster who has behavior problems. In other instances, the father has custody because of a very close relationship with the child, and his remarriage disrupts this bond (Buchanan, Maccoby, & Dornbusch, 1996).

Girls, especially, have a hard time getting along with their stepmothers, either because the remarriage threatens the girl's bond with her father or because she becomes entangled in loyalty conflicts between the two mother figures. But the longer girls live in father–stepmother households, the more positive their interaction with stepmothers becomes (King, 2007). With time and patience, most girls benefit from the support of a second mother figure.

Support for Blended Families. Parenting education and couples counseling can help parents and children adapt to the complexities of blended families. Effective approaches encourage stepparents to move into their new roles gradually by first building a warm relationship with the child (Nicholson et al., 2008). Counselors can offer couples guidance in coparenting to limit loyalty conflicts and provide consistency in child rearing. This allows children to benefit from the increased diversity that stepparent relationships bring to their lives.

Unfortunately, the divorce rate for second marriages is even higher than for first marriages. Parents with antisocial tendencies and poor child-rearing skills are particularly likely to have several divorces and remarriages. The more marital transitions children experience, the greater their adjustment difficulties (Amato, 2010). These families usually require prolonged, intensive therapy.

© KAYTE DEIOMAPHOTOEDIT

To help these teenagers adapt to life in a complex blended family, both father and stepmother must avoid favoring their much younger children, born after remarriage.

Maternal Employment and Dual-Earner Families

Today, U.S. single and married mothers are in the labor market in nearly equal proportions, and more than three-fourths of those with school-age children are employed (U.S. Census Bureau, 2012b). In previous chapters, we saw that the impact of maternal employment on early development depends on the quality of child care and the continuing parent–child relationship. The same is true in middle childhood.

Maternal Employment and Child Development.

When mothers enjoy their work and remain committed to parenting, children show favorable adjustment—higher self-esteem, more positive family and peer relations, less gender-stereotyped beliefs, and better grades in school. Girls, especially, profit from the image of female competence. Regardless of SES, daughters of employed mothers perceive women's roles as involving more freedom of choice and satisfaction and are more achievement- and career-oriented (Hoffman, 2000).

Parenting practices contribute to these benefits. Employed mothers who value their parenting role are more likely to use authoritative child rearing and coregulation. Also, children in dual-earner households devote more daily hours to doing homework under parental guidance and participate more in household chores. And maternal employment leads fathers—especially those who believe in the importance of the paternal role and who feel successful at parenting—to take on greater child-care responsibilities (Gottfried, Gottfried, & Bathurst, 2002; Jacobs & Kelley, 2006). Paternal involvement is associated in childhood and adolescence with higher intelligence and achievement, more mature social behavior, and a flexible view of gender roles; and in adulthood with generally better mental health (Pleck & Masciadrelli, 2004).

But when employment places heavy demands on a mother's or a father's schedule or is stressful for other reasons, children are at risk for ineffective parenting. Working many hours or experiencing a negative workplace atmosphere is associated with reduced parental sensitivity, fewer joint parent-child activities, and poorer cognitive development throughout childhood and adolescence (Brooks-Gunn, Han, & Waldfogel, 2002; Bumpus, Crouter, & McHale, 2006; Strazdins et al., 2006). Negative consequences are magnified when low-SES mothers spend long days at low-paying, physically exhausting jobs—conditions linked to maternal depression and harsh, inconsistent discipline (Raver, 2003). In contrast, part-time employment and flexible work schedules are associated with sensitive, involved parenting and good child adjustment (Buehler & O'Brien, 2011). By preventing work-family role conflict, these arrangements help parents meet children's needs.

Support for Employed Parents and Their Families.

In dual-earner families, the father's willingness to share responsibilities is a crucial factor. If he helps little or not at all, the mother carries a double load, at home and at work, leading to fatigue, distress, and little time and energy for children. Fortunately, compared to three decades ago, today's U.S. fathers are far more involved in child care (see pages 202–203 in Chapter 6). But their increased participation has resulted in a growing number of fathers who also report work-family life conflict (Galinsky, Aumann, & Bond, 2009).

Employed parents need assistance from work settings and communities in their child-rearing roles. Part-time employment, flexible schedules, job sharing, and paid leave when children are ill help parents juggle the demands of work and child rearing. Equal pay and employment opportunities for women are also important. Because these policies enhance financial status and morale, they improve the way mothers feel and behave when they arrive home at the end of the working day.

Child Care for School-Age Children. High-quality child care is vital for parents' peace of mind and children's well-being, even in middle childhood. An estimated 5 million 5- to 14-year-olds in the United States are **self-care children**, who regularly look after themselves for some period of time after school (Afterschool Alliance, 2009). Self-care increases with age and also with SES, perhaps because of the greater safety of higher-income neighborhoods. But when lower-SES parents lack alternatives to self-care, their children spend more hours on their own (Casper & Smith, 2002).

The implications of self-care for development depend on children's maturity and the way they spend their time. Among younger school-age children, those who spend more hours alone have more emotional and social difficulties (Vandell & Posner, 1999). As children become old enough to look after themselves, those who have a history of authoritative child rearing, are monitored by parental telephone calls, and have regular after-school chores appear responsible and well-adjusted. In contrast, children left to their own devices are more likely to

High-quality after-school programs with enrichment activities yield academic and social benefits for low-SES children.

bend to peer pressures and engage in antisocial behavior (Coley, Morris, & Hernandez, 2004; Vandell et al., 2006).

Before age 8 or 9, most children need supervision because they are not yet competent to handle emergencies (Galambos & Maggs, 1991). Also, throughout middle childhood, attending after-school programs with well-trained staffs, generous adult-child ratios, and skill-building activities is linked to good school performance and emotional and social adjustment (Durlak & Weissberg, 2007; Granger, 2008). Low-SES children who participate in “after-care” programs offering academic assistance and enrichment activities (scouting, music and art lessons, clubs) show special benefits. They exceed their self-care counterparts in classroom work habits, academic achievement, and prosocial behavior and display fewer behavior problems (Lauer et al., 2006; Vandell et al., 2006).

Unfortunately, good after-care is in especially short supply in low-income neighborhoods (Afterschool Alliance, 2009; Dearing et al., 2009). A special need exists for well-planned programs in these areas—ones that provide safe environments, warm relationships with adults, and enjoyable, goal-oriented activities.

Some Common Problems of Development

We have considered a variety of stressful experiences that place children at risk for future problems. Next, we address two more areas of concern: school-age children's fears and anxieties and the consequences of child sexual abuse. Finally, we sum up factors that help children cope effectively with stress.

Fears and Anxieties

Although fears of the dark, thunder and lightning, and supernatural beings persist into middle childhood, older children's anxieties are also directed toward new concerns. Common fears of the school years include poor academic performance, peer rejection, the possibility of personal harm (being robbed or shot), threats to parents' health, and media events (Gullone, 2000; Weems & Costa, 2005).

Children's fears are shaped in part by their culture. Children in Western nations mention exposure to negative information in the media as the most common source of their fears, followed by direct exposure to frightening events (Muris et al., 2001). In China, where self-restraint and compliance with social standards are highly valued, more children mention failure and adult criticism as salient fears than in Australia or the United States (Ollendick et al., 1996). Chinese children, however, are not more fearful overall. The number and intensity of fears they report resemble those of Western children.

Most children handle fears constructively, using the more sophisticated emotion regulation strategies that develop in middle childhood. Consequently, fears decline with age, especially for girls, who express more fears than boys throughout childhood and adolescence (Gullone, 2000). But about 5 percent of school-age children develop an intense, unmanageable fear called a **phobia**. Children with inhibited temperaments are at high risk, displaying phobias five to six times as often as other children (Ollendick, King, & Muris, 2002).

For example, in *school phobia*, children feel severe apprehension about attending school, often accompanied by physical complaints (dizziness, nausea, stomachaches, and vomiting). About one-third of children with school phobia are 5- to 7-year-olds for whom the real fear is maternal separation. Family therapy helps these children, whose difficulty can often be traced to parental overprotection (Elliott, 1999).

Most cases of school phobia appear around age 11 to 13, in children who usually find a particular aspect of school frightening—an overcritical teacher, a school bully, or too much parental pressure to achieve. A change in school environment or parenting practices may be needed. Firm insistence that the child return to school, along with training in how to cope with difficult situations, is also helpful (Silverman & Pina, 2008).

Severe childhood anxieties may arise from harsh living conditions. In inner-city ghettos and in war-torn areas of the world, large numbers of children live in the midst of constant danger, chaos, and deprivation. As the Cultural Influences box

on the following page reveals, these youngsters are at risk for long-term emotional distress and behavior problems. Finally, as we saw in our discussion of child abuse in Chapter 8, too often violence and other destructive acts become part of adult-child relationships. During middle childhood, child sexual abuse increases.

Child Sexual Abuse

Until recently, child sexual abuse was considered rare, and adults often dismissed children's claims of abuse. In the 1970s, efforts by professionals and media attention led to recognition of child sexual abuse as a serious and widespread problem. About 65,000 cases in the United States were confirmed in the most recently reported year (U.S. Department of Health and Human Services, 2011b).

Characteristics of Abusers and Victims. Sexual abuse is committed against children of both sexes, but more often against girls. Most cases are reported in middle childhood, but for some victims, abuse begins early in life and continues for many years (Hoch-Espada, Ryan, & Deblinger, 2006; Goodyear-Brown, Fath, & Myers, 2012).

Typically, the abuser is male, either a parent or someone the parent knows well—a father, stepfather, or live-in boyfriend, somewhat less often an uncle or older brother. But in about 25 percent of cases, mothers are the offenders, more often with sons (Boroughs, 2004). If the abuser is a nonrelative, the person is usually someone the child has come to know and trust. However, the Internet and mobile phones have become avenues through which other adults commit sexual abuse—for example, by exposing children and adolescents to pornography and online sexual advances as a way of “grooming” them for sexual acts offline (Wolak et al., 2008).

Abusers make the child comply in a variety of distasteful ways, including deception, bribery, verbal intimidation, and physical force. You may wonder how any adult—especially a parent or close relative—could violate a child sexually. Many offenders deny their own responsibility, blaming the abuse on the willing participation of a seductive youngster. Yet children are not capable of making a deliberate, informed decision to enter into a sexual relationship! Even older children and adolescents are not free to say yes or no. Rather, the responsibility lies with abusers, who tend to have characteristics that predispose them toward sexual exploitation of children. They have great difficulty controlling their impulses and may suffer from psychological disorders, including alcohol and drug abuse. Often they pick out children who are unlikely to defend themselves or to be believed—those who are physically weak, emotionally deprived, socially isolated, or affected by disabilities (Bolen, 2001).

Reported cases of child sexual abuse are linked to poverty, marital instability, and resulting weakening of family ties. Children who live in homes with a constantly changing cast of characters—repeated marriages, separations, and new partners—are especially vulnerable (Goodyear-Brown, Fath, & Myers, 2012). But children in economically advantaged, stable families are also victims, although their abuse is more likely to escape detection.

Cultural Influences

Impact of Ethnic and Political Violence on Children

Around the world, many children live with armed conflict, terrorism, and other acts of violence stemming from ethnic and political tensions. Some children may participate in fighting, either because they are forced or because they want to please adults. Others are kidnapped, assaulted, and tortured. Those who are bystanders often come under direct fire and may be killed or physically maimed. And many watch in horror as family members, friends, and neighbors flee, are wounded, or die. In the past decade, wars have left 6 million children physically disabled, 20 million homeless, and more than 1 million separated from their parents (UNICEF, 2011).

When war and social crises are temporary, most children can be comforted and do not show long-term emotional difficulties. But chronic danger requires children to make substantial adjustments that can seriously impair their psychological functioning. Many children of war lose their sense of safety, become desensitized to violence, are haunted by terrifying intrusive memories, display immature moral reasoning, and build a pessimistic view of the future. Anxiety and depression increase, as do aggression and antisocial behavior (Eisenberg & Silver, 2011; Klingman, 2006). These outcomes appear to be culturally universal, observed among children in every war zone studied—from Bosnia, Angola, Rwanda, and the Sudan to the West Bank, Gaza, Afghanistan, and Iraq (Barenbaum, Ruchkin, & Schwab-Stone, 2004).

Parental affection and reassurance are the best protection against lasting problems.

When parents offer security, discuss traumatic experiences sympathetically, and serve as role models of calm emotional strength, most children can withstand even extreme war-related violence (Gewirtz, Forgatch, & Wieling, 2008). Children who are separated from parents must rely on help from their communities. Orphans in Eritrea who were placed in residential settings where they could form a close emotional tie with an adult showed less emotional stress five years later than orphans placed in impersonal settings (Wolff & Fesseha, 1999). Education and recreation programs are powerful safeguards, too, providing children with consistency in their lives along with teacher and peer supports.

With the September 11, 2001, terrorist attacks on the World Trade Center, some U.S. children experienced extreme wartime violence firsthand. Most children, however, learned about the attacks indirectly—from the media or from caregivers or peers. Although both direct and indirect exposure triggered child and adolescent distress, extended exposure—having a family member affected or repeatedly witnessing the attacks on TV—resulted in more severe symptoms (Agronick et al., 2007; Otto et al., 2007; Rosen & Cohen, 2010). During the following months, distress reactions declined, though more slowly for children with conflict-ridden parent-

child relationships or preexisting adjustment problems.

Unlike many war-traumatized children in the developing world, students in New York's Public School 31, who watched from their classroom windows as the towers collapsed, received immediate intervention—a “trauma curriculum” in which they expressed their emotions through writing, drawing, and discussion and participated in experiences aimed at restoring trust and tolerance (Lagnado, 2001). Older children learned about the feelings of their Muslim classmates, the dire condition of children in Afghanistan, and ways to help victims as a means of overcoming a sense of helplessness.

When wartime drains families and communities of resources, international organizations must step in and help children. Efforts to preserve children's physical, psychological, and educational well-being may be the best way to stop transmission of violence to the next generation.

Consequences. The adjustment problems of child sexual abuse victims—including anxiety, depression, low self-esteem, mistrust of adults, and anger and hostility—are often severe and can persist for years after the abusive episodes. Younger children frequently react with sleep difficulties, loss of appetite, and generalized fearfulness. Adolescents may run away and show suicidal reactions, eating disorders, substance abuse, and delinquency. At all ages, persistent abuse accompanied by force, violence, and a close relationship to the perpetrator (incest) has a

more severe impact (Hornor, 2010; Wolfe, 2006). And repeated sexual abuse, like physical abuse, is associated with central nervous system damage (Gaskill & Perry, 2012).

Sexually abused children frequently display precocious sexual knowledge and behavior. In adolescence, abused young people often become promiscuous, and as adults, they show increased arrest rates for sex crimes (mostly against children) and prostitution (Salter et al., 2003; Whipple, 2006). Furthermore, women who were sexually abused are likely to choose partners

Children in Hyderabad, India, participate in a “Stay Safe” campaign against child abuse and sexual exploitation—part of a global effort to prevent all forms of abuse.

who abuse them and their children. As mothers, they often engage in irresponsible and coercive parenting, including child abuse and neglect (Pianta, Egeland, & Erickson, 1989). In all these ways, the harmful impact of sexual abuse is transmitted to the next generation.

Prevention and Treatment. Because sexual abuse typically appears in the midst of other serious family problems, long-term therapy with both children and parents is often needed (Saunders, 2012). The best way to reduce the suffering of victims is to prevent sexual abuse from continuing. Today, courts are prosecuting abusers more vigorously and taking children’s testimony more seriously (see the Social Issues: Health box on the following page).

Educational programs that teach children to recognize inappropriate sexual advances and identify sources of help reduce the risk of abuse (Finkelhor, 2009). Yet because of controversies over educating children about sexual abuse, few schools offer these interventions. New Zealand is the only country with a national, school-based prevention program targeting sexual abuse. In *Keeping Ourselves Safe*, children and adolescents learn that abusers are rarely strangers. Parent involvement ensures that home and school collaborate in teaching children self-protection skills. Evaluations reveal that virtually all New Zealand parents and children support the program and that it has helped many children avoid or report abuse (Sanders, 2006).

Fostering Resilience in Middle Childhood

Throughout middle childhood—and other periods of development—children encounter challenging and sometimes threatening situations that require them to cope with psychological stress. In this and the previous chapter, we have considered such topics as chronic illness, learning disabilities, achievement expectations, divorce, harsh living conditions and wartime trauma, and sexual abuse. Each taxes children’s coping resources, creating serious risks for development.

Nevertheless, only a modest relationship exists between stressful life experiences and psychological disturbance in childhood (Masten & Reed, 2002). In our discussion in Chapter 3 of the long-term consequences of birth complications, we noted that some children manage to overcome the combined effects of birth trauma, poverty, and troubled family life. The same is true for school difficulties, family transitions, the experience of war, and child maltreatment. Recall from Chapter 1 that four broad factors protect against maladjustment: (1) the child’s personal characteristics, including an easy temperament and a mastery-oriented approach to new situations; (2) a warm parental relationship; (3) an adult outside the immediate family who offers a support system; and (4) community resources, such as good schools, social services, and youth organizations and recreation centers (Commission on Children at Risk, 2008; Wright & Masten, 2005).

Often just one or a few of these ingredients account for why one child is “stress-resilient” and another is not. Usually, however, personal and environmental factors are interconnected: Each resource favoring resilience strengthens others. For example, safe, stable neighborhoods with family-friendly community services reduce parents’ daily hassles and stress, thereby promoting good parenting (Chen, Howard, & Brooks-Gunn, 2011). In contrast, unfavorable home and neighborhood experiences increase the chances that children will act in ways that expose them to further hardship. And when negative conditions pile up, such as marital discord, poverty, crowded living conditions, neighborhood violence, and abuse and neglect, the rate of maladjustment multiplies (Wright & Masten, 2005).

Rather than a preexisting attribute, *resilience* is a capacity that develops, enabling children to use internal and external resources to cope with adversity (Dessel, 2010; Riley & Masten, 2004). Throughout our discussion, we have seen how families, schools, communities, and society as a whole can enhance or undermine school-age children’s developing sense of competence. As the next two chapters will reveal, young people whose childhood experiences helped them learn to control impulses, overcome obstacles, strive for self-direction, and respond considerately and sympathetically to others meet the challenges of the next period—adolescence—quite well.

ASK YOURSELF

REVIEW When children must testify in court cases, what factors increase the chances of accurate reporting?

Social Issues: Health

Children's Eyewitness Testimony

Increasingly, children are being called on to testify in court cases involving child abuse and neglect, child custody, and similar matters. The experience can be traumatic, requiring children to report on highly stressful events and sometimes to speak against a parent or other relative to whom they feel loyal. In some family disputes, they may fear punishment for telling the truth. In addition, child witnesses are faced with an unfamiliar situation—at the very least an interview in the judge's chambers and at most an open courtroom with judge, jury, spectators, and the possibility of unsympathetic cross-examination. Not surprisingly, these conditions can compromise the accuracy of children's recall.

Age Differences

As a result of societal reactions to rising rates of child abuse and the difficulty of prosecuting perpetrators, age requirements for child testimony have been relaxed in the United States (Sandler, 2006). Children as young as age 3 frequently serve as witnesses.

Compared with preschoolers, school-age children are better at giving accurate, detailed narrative accounts of past experiences and correctly inferring others' motives and intentions. Older children are also more resistant to misleading questions that attorneys may ask when probing for more information or, in cross-examination, trying to influence the child's response (Roebbers & Schneider, 2001). Inhibition (ability to ignore irrelevant information), which improves from early to middle childhood, predicts children's resistance to suggestion (Melinder, Endestad, & Magnussen, 2006).

Nevertheless, when properly questioned, even 3-year-olds can recall recent events accurately (Peterson & Rideout, 1998). And in the face of biased interviewing, adolescents and adults often form elaborate, false memories of events (Ceci et al., 2007).

Suggestibility

Court testimony often involves repeated interviews, which by itself impairs children's response consistency and accuracy (Krähenbühl, Blades, & Eiser, 2009). When adults lead witnesses by suggesting incorrect "facts," interrupt their denials, reinforce them for giving desired answers, or use a confrontational questioning style, they increase the likelihood of incorrect reporting (Bruck & Ceci, 2004; Owen-Kostelnik, Reppucci, & Meyer, 2006).

By the time children appear in court, weeks, months, or even years have passed since the target events. When a long delay is combined with biased interviewing and with stereotyping of the accused ("He's in jail because he's been bad"), children can easily be misled into giving false information (Gilstrap & Ceci, 2005; Quas et al., 2007). The more distinctive and personally relevant an event is, the more likely children are to recall it accurately over time. For example, a year later, even when exposed to misleading information, children correctly reported details of an injury that required emergency room treatment (Peterson, Parsons, & Dean, 2004).

In many sexual abuse cases, anatomically correct dolls are used to prompt children's recall. Although this method helps older children provide more detail about experienced events, it increases the suggestibility of preschoolers, who report physical and sexual contact that never happened (Goodman & Melinder, 2007).

Interventions

Adults must prepare child witnesses so they understand the courtroom process and know what to expect. In some places, "court schools" take children through the setting and give them an opportunity to role-play court activities. Practice interviews—in which children learn to provide the most accurate, detailed information possible and

© MICHAEL NEWMAN/PHOTODISC

School-age eyewitnesses are better able than preschoolers to give accurate, detailed descriptions and correctly infer others' motives and intentions. This police officer can promote accurate recall by using a warm, supportive tone and avoiding leading questions.

to admit not knowing rather than agreeing or guessing—are helpful (Saywitz, Goodman, & Lyon, 2002).

At the same time, legal professionals must use interviewing procedures that increase children's accurate reporting. Unbiased, open-ended questions that prompt children to disclose details—"Tell me what happened" or "You said there was a man; tell me about the man"—reduce suggestibility (Steele, 2012). Also, a warm, supportive interview tone fosters accurate recall, perhaps by easing children's anxiety so they feel freer to disagree with an interviewer's false suggestions (Ceci, Bruck, & Battin, 2000).

If children are likely to experience emotional trauma or later punishment (as in a family dispute), courtroom procedures can be adapted to protect them. For example, children can testify over closed-circuit TV so they do not have to face an abuser. When it is not wise for a child to participate directly, impartial expert witnesses can provide testimony that reports on the child's psychological condition and includes important elements of the child's story.

SUMMARY

Erikson's Theory: Industry versus Inferiority (p. 330)

What personality changes take place during Erikson's stage of industry versus inferiority?

- According to Erikson, children who successfully resolve the psychological conflict of **industry versus inferiority** develop a sense of competence at useful skills and tasks, learn the value of division of labor, and develop a sense of moral commitment and responsibility.

Self-Understanding (p. 330)

Describe school-age children's self-concept and self-esteem, and discuss factors that affect their achievement-related attributions.

- During middle childhood, children's self-concepts include personality traits, competencies, and **social comparisons**. The content of self-concept varies from culture to culture.
- Self-esteem differentiates further, becoming hierarchically organized and more realistic. Cultural forces, gender-stereotyped expectations, and child-rearing practices contribute to variations in self-esteem. Authoritative parenting is linked to favorable self-esteem.
- Children who hold **mastery-oriented attributions** believe ability can be improved by trying hard and attribute failure to controllable factors, such as insufficient effort. In contrast, children who receive negative feedback about their ability are likely to develop **learned helplessness**, attributing success to external factors, such as luck, and failure to low ability.

Emotional Development (p. 335)

Cite changes in self-conscious emotions, emotional understanding, and management of emotion in middle childhood.

- Self-conscious emotions of pride and guilt become clearly governed by personal responsibility. Intense shame is particularly destructive, yielding both internalizing and externalizing problems.
- School-age children develop an appreciation of mixed emotions and can reconcile contradictory cues in interpreting another's feelings. Empathy increases and includes sensitivity to both people's immediate distress and their general life condition.
- By age 10, most children shift adaptively between **problem-centered** and **emotion-centered coping** to regulate emotion. Children who acquire a sense of emotional self-efficacy are upbeat, empathic, and prosocial.

Moral Development (p. 336)

Describe changes in moral understanding during middle childhood, including children's understanding of diversity and inequality.

- By middle childhood, children have internalized rules for good conduct. They clarify and link moral imperatives and social conventions and develop a better understanding of personal choice and individual rights.

© SYRACUSE NEWSPAPERS/
J. BERRY/THE IMAGE WORKS

- Children of all races pick up prevailing societal attitudes about race and ethnicity. With age, they come to understand that people who look different need not think, feel, or act differently. Consequently, voicing of prejudice typically declines though automatic prejudice may persist. Children most likely to hold biases are those who believe that personality traits are fixed, who have inflated self-esteem, and who live in a social world that highlights group differences. Long-term intergroup contact is most effective at reducing prejudice.

Peer Relations (p. 339)

How do peer sociability and friendship change in middle childhood?

- Peer interaction becomes more prosocial, and physical aggression declines. By the end of middle childhood, children organize themselves into **peer groups**.

DAVID ROTH/GETTY IMAGES/TAXI

- Friendships develop into mutual relationships based on trust. Children tend to select friends similar to themselves in many ways.

Describe major categories of peer acceptance and ways to help rejected children.

- On measures of **peer acceptance**, **popular children** are well-liked by many agemates; **rejected children** are actively disliked; **controversial children** are both liked and disliked; and **neglected children** arouse little response, either positive or negative.
- **Popular-prosocial children** combine academic and social competence, while **popular-antisocial children** are aggressive but admired. **Rejected-aggressive children** are especially high in conflict and hostility; in contrast, **rejected-withdrawn children** are passive, socially awkward, and frequent targets of **peer victimization**.
- Coaching in social skills, academic tutoring, and training in perspective taking and social problem solving have been used to help rejected children gain in social competence and peer acceptance. Intervening to improve the quality of parent-child interaction is often necessary.

Gender Typing (p. 343)

What changes in gender-stereotyped beliefs and gender identity occur during middle childhood?

- School-age children extend their awareness of gender stereotypes to personality traits and academic subjects. But they also develop a more open-minded view of what males and females can do.
- Boys strengthen their identification with masculine traits, whereas girls more often experiment with “other-gender” activities. Gender identity includes self-evaluations of gender typicality, contentedness, and felt pressure to conform to gender roles—each of which affects adjustment.

Family Influences (p. 345)

How do parent–child communication and sibling relationships change in middle childhood?

- Despite declines in time spent with parents, **coregulation** allows parents to exercise general oversight over children, who increasingly make their own decisions.
- Sibling rivalry tends to increase with participation in a wider range of activities and more frequent parental comparisons. Only children do not differ from children with siblings in self-rated personality traits and are higher in self-esteem, school performance, and educational attainment.

What factors influence children’s adjustment to divorce and blended family arrangements?

- Marital breakup is often quite stressful for children. Individual differences are affected by parental psychological health, child characteristics (age, temperament, and sex), and social supports. Children with difficult temperaments are at greater risk for adjustment problems. Divorce is linked to early sexual activity, adolescent parenthood, and long-term relationship difficulties.

- The overriding factor in positive adjustment following divorce is effective parenting. Positive father–child relationships are protective, as are supports from extended-family members, teachers, siblings, and friends. Divorce mediation can foster parental conflict resolution in the period surrounding divorce. The success of joint custody depends on effective coparenting.
- When divorced parents enter new relationships and form **blended**, or **reconstituted**, **families**, girls, older children, and children in father–stepmother families tend to have more adjustment problems. Stepparents who move into their roles gradually help children adjust.

How do maternal employment and life in dual-earner families affect school-age children?

- When employed mothers enjoy their work and remain committed to parenting, their children benefit from higher self-esteem, more positive family and peer relations, less gender-stereotyped beliefs, and better school grades. In dual-earner families, the father’s willingness to share responsibilities is a crucial factor. Workplace supports help parents in their child-rearing roles.
- Authoritative child rearing, parental monitoring, and regular after-school chores lead **self-care children** to be responsible and well-adjusted. Good “after-care” programs also aid school performance and emotional and social adjustment, with special benefits for low-SES children.

Some Common Problems of Development (p. 352)

Cite common fears and anxieties in middle childhood.

- School-age children’s fears are directed toward new concerns, including physical harm, media events, academic failure, parents’ health, and peer rejection. Children with inhibited temperaments are at higher risk of developing **phobias**. Harsh living conditions can also cause severe anxiety.

Discuss factors related to child sexual abuse, its consequences for children’s development, and its prevention and treatment.

- Child sexual abuse is typically committed by male family members, more often against girls than boys. Abusers have characteristics that predispose them toward sexual exploitation of children. Reported cases are strongly associated with poverty and marital instability. Abused children often have severe adjustment problems.
- Treatment for abused children typically requires long-term therapy with both children and parents. Educational programs that teach children to recognize inappropriate sexual advances and identify sources of help reduce the risk of sexual abuse.

Cite factors that foster resilience in middle childhood.

- Only a modest relationship exists between stressful life experiences and psychological disturbance in childhood. Children’s personal characteristics, a warm family life, authoritative parenting, and school, community, and societal resources predict resilience.

milestones

Development in Middle Childhood

© ELLEN B. SENISI PHOTOGRAPHY

6–8 years

PHYSICAL

- Slow gains in height and weight continue until adolescent growth spurt. (290)
- Permanent teeth gradually replace primary teeth. (290)
- Legibility of writing increases, preparing children to master cursive writing. (295)
- Drawings become more organized and detailed and include some depth cues. (295)
- Games with rules and rough-and-tumble play become common. (296, 297)

COGNITIVE

- Thought becomes more logical, as shown by the ability to pass Piagetian conservation, class inclusion, and seriation problems. (299–300)
- Attention becomes more selective, adaptable, and planful. (303)
- Uses memory strategies of rehearsal and then organization. (304)
- Views the mind as an active, constructive agent, capable of transforming information. (306)

- Awareness of memory strategies and the impact of psychological factors, such as mental inferences, on performance improves. (306)
- Appreciates second-order false beliefs. (306)
- Uses informal knowledge of number concepts and counting to master increasingly complex mathematical skills. (308)

© LAURA DWIGHT PHOTOGRAPHY

LANGUAGE

- Vocabulary increases rapidly throughout middle childhood, eventually exceeding comprehension of 40,000 words. (316)
- Word definitions are concrete, referring to functions and appearance. (316)
- Narratives increase in organization, detail, and expressiveness. (317)
- Transitions from emergent literacy to conventional reading. (308)
- Language awareness improves. (316)
- Conversational strategies become more refined. (316–317)

EMOTIONAL/SOCIAL

- Self-concept begins to include personality traits, competencies, and social comparisons. (330)
- Self-esteem differentiates, becomes hierarchically organized, and declines to a more realistic level. (331)
- Self-conscious emotions of pride and guilt are governed by personal responsibility. (335)
- Recognizes that individuals can experience more than one emotion at a time and that people's expressions may not reflect their true feelings. (335)

© LAURA DWIGHT PHOTOGRAPHY

- Reconciles contradictory facial and situational cues in understanding another's feelings. (335)
- Empathy increases. (335)
- Becomes more independent and trustworthy. (336)
- Constructs a flexible appreciation of moral rules, taking prosocial and antisocial intentions into account. (336)
- Physical aggression declines; verbal and relational aggression continue. (339)
- Resolves conflicts more effectively. (339)

9–11 years

PHYSICAL

- Adolescent growth spurt begins two years earlier in girls than in boys. (290)

© ELLEN B. SENISI PHOTOGRAPHY

- Executes gross-motor skills of running, jumping, throwing, catching, kicking, batting, and dribbling more quickly and with better coordination. (294)
- Steady gains in attention and reaction time contribute to improved motor performance. (295)
- Representation of depth in drawings expands. (295)
- Dominance hierarchies become more stable, especially among boys. (297)

COGNITIVE

- Continues to master Piagetian tasks in a step-by-step fashion. (301)
- Spatial reasoning improves; readily draws and reads maps of large-scale spaces, and grasps the notion of scale. (300)

ANTHONY BRADSHAW/PHOTODISC/GETTY IMAGES

- Selective attention and planning improve further. (303–304)
- Uses memory strategies of rehearsal and organization more effectively. (303)
- Applies several memory strategies simultaneously; begins to use elaboration. (304)
- Long-term knowledge base grows larger and becomes better organized. (305–306)
- Theory of mind becomes more elaborate and refined. (306)
- Cognitive self-regulation improves. (307)

LANGUAGE

- Thinks about and uses words more precisely; word definitions emphasize synonyms and categorical relations. (316)

- Grasps double meanings of words, as reflected in comprehension of metaphors and humor. (316)
- Continues to master complex grammatical constructions. (316)
- Continues to refine conversational strategies. (317)
- Narratives lengthen, become more coherent, and include more evaluative comments. (317)

EMOTIONAL/SOCIAL

- Self-esteem tends to rise (331)
- Distinguishes ability, effort, and external factors (such as luck) in attributions for success and failure. (333)
- Empathic responding extends to general life conditions. (335–336)

© ELLEN B. SENISI PHOTOGRAPHY

- Shifts adaptively between problem-centered and emotion-centered strategies in regulating emotion. (336)

- Becomes more knowledgeable about socially approved ways to display negative emotion. (336)
- Clarifies and links moral rules and social conventions. (337)
- Convictions about matters of personal choice strengthen, and understanding of individual rights expands. (337)
- Overt expressions of outgroup prejudice decline. (338)
- Friendships become more selective and are based on mutual trust. (340)
- Peer groups emerge. (339)

© TOMAS RODRIGUEZ/CORBIS

- Becomes aware of more gender stereotypes, including personality traits and achievement, but has a flexible appreciation of what males and females can do. (343–344)
- Gender identity expands to include self-evaluations of typicality, contentedness, and felt pressure to conform. (344)
- Sibling rivalry tends to increase. (345–346)

chapter 11

© TIM PANNELL/CORBIS

The dramatic physical and cognitive changes of adolescence make it both an exhilarating and apprehensive period of development. Although their bodies are full-grown and sexually mature, these exuberant teenagers have many skills to acquire and hurdles to surmount before they are ready for full assumption of adult roles.

Physical and Cognitive Development in Adolescence

On Sabrina's eleventh birthday, her friend Joyce gave her a surprise party, but Sabrina seemed somber during the celebration. Although Sabrina and Joyce had been close friends since third grade, their relationship was faltering. Sabrina was a head taller and some 20 pounds heavier than most girls in her sixth-grade class. Her breasts were well-developed, her hips and thighs had broadened, and she had begun to menstruate. In contrast, Joyce still had the short, lean, flat-chested body of a school-age child.

Ducking into the bathroom while the other girls put candles on the cake, Sabrina frowned at her image in the mirror. "I'm so big and heavy," she whispered. At church youth group on Sunday evenings, Sabrina broke away from Joyce and joined the eighth-grade girls. Around them, she didn't feel so large and awkward.

Once a month, parents gathered at Sabrina's and Joyce's school to discuss child-rearing concerns. Sabrina's parents, Franca and Antonio, attended whenever they could. "How you know they are becoming teenagers is this," volunteered Antonio. "The bedroom door is closed, and they want to be alone. Also, they contradict and disagree. I tell Sabrina, 'You have to go to Aunt Gina's on Saturday for dinner with the family.' The next thing I know, she's arguing with me."

Sabrina has entered **adolescence**, the transition between childhood and adulthood. In industrialized societies, the skills young people must master are so complex and the choices confronting them so diverse that adolescence is greatly extended. But around the world, the basic tasks of this period are much the same. Sabrina must accept her full-grown body, acquire adult ways of thinking, attain greater independence from her family, develop more mature ways of relating to peers of both sexes, and begin to construct an identity—a secure sense of who she is in terms of sexual, vocational, moral, ethnic, religious, and other life values and goals.

The beginning of adolescence is marked by **puberty**, a flood of biological events leading to an adult-sized body and sexual maturity. As Sabrina's reactions suggest, entry into adolescence can be an especially trying time for some young people. In this chapter, we trace the events of puberty and take up a variety of health concerns—physical exercise, nutrition, sexual activity, substance abuse, and other challenges that many teenagers encounter on the path to maturity.

Adolescence also brings with it vastly expanded powers of reasoning. Teenagers can grasp complex scientific and mathematical principles, grapple with social and political issues, and delve deeply into the meaning of a poem or story. The second part of this chapter traces these extraordinary changes from both Piaget's and the information-processing perspective. Next, we examine sex differences in mental abilities. Finally, we turn to the main setting in which adolescent thought takes shape: the school. ●

PHYSICAL DEVELOPMENT

Conceptions of Adolescence

Why is Sabrina self-conscious, argumentative, and in retreat from family activities? Historically, theorists explained the impact of puberty on psychological development by resorting to extremes—either a biological or a social explanation. Today, researchers realize that biological and social forces jointly determine adolescent psychological change.

The Biological Perspective

TAKE A MOMENT... Ask several parents of young children what they expect their sons and daughters to be like as teenagers. You will probably get answers like these: “Rebellious and irresponsible,” “Full of rages and tempers.” This widespread storm-and-stress view dates back to major early-twentieth-century theorists. The most influential, G. Stanley Hall, based his ideas on Darwin's theory of evolution. Hall (1904) described adolescence as a period so turbulent that it resembled the era in which humans evolved from savages into civilized beings. Similarly, in Freud's psychosexual theory, sexual impulses reawaken in the *genital stage*, triggering psychological conflict and volatile behavior. As adolescents find intimate partners, inner forces gradually achieve a new, mature harmony, and the stage concludes with marriage, birth, and child rearing. In this way, young people fulfill their biological destiny: sexual reproduction and survival of the species.

The Social Perspective

Contemporary research suggests that the storm-and-stress notion of adolescence is exaggerated. Certain problems, such as eating disorders, depression, suicide, and lawbreaking, do occur more often than earlier (Farrington, 2009; Graber, 2004). But the overall rate of serious psychological disturbance rises only slightly from childhood to adolescence, reaching 15 to 20

percent (Merikangas et al., 2010). Though much greater than the adulthood rate (about 6 percent), emotional turbulence is not a routine feature of the teenage years.

The first researcher to point out the wide variability in adolescent adjustment was anthropologist Margaret Mead (1928). She returned from the Pacific islands of Samoa with a startling conclusion: Because of the culture's relaxed social relationships and openness toward sexuality, adolescence “is perhaps the pleasantest time the Samoan girl (or boy) will ever know” (p. 308). Mead offered an alternative view in which the social environment is entirely responsible for the range of teenage experiences, from erratic and agitated to calm and stress-free. Later researchers found that Samoan adolescence was not as untroubled as Mead had assumed (Freeman, 1983). Still, she showed that to understand adolescent development, researchers must pay greater attention to social and cultural influences.

A Balanced Point of View

Today we know that biological, psychological, and social forces combine to influence adolescent development (Susman & Dorn, 2009). Biological changes are universal—found in all primates and all cultures. These internal stresses and the social expectations accompanying them—that the young person give up childish ways, develop new interpersonal relationships, and take on greater responsibility—are likely to prompt moments of uncertainty, self-doubt, and disappointment in all teenagers. Adolescents' prior and current experiences affect their success in surmounting these challenges.

At the same time, the length of adolescence and its demands and pressures vary substantially among cultures. Most tribal and village societies have only a brief intervening phase between childhood and full assumption of adult roles (Weisfield, 1997). In industrialized nations, young people face prolonged dependence on parents and postponement of sexual gratification while they prepare for a productive work life. As a result, adolescence is greatly extended—so much so that researchers commonly divide it into three phases:

1. *Early adolescence* (11–12 to 14 years): This is a period of rapid pubertal change.
2. *Middle adolescence* (14 to 16 years): Pubertal changes are now nearly complete.
3. *Late adolescence* (16 to 18 years): The young person achieves full adult appearance and anticipates assumption of adult roles.

The more the social environment supports young people in achieving adult responsibilities, the better they adjust. For all the biological tensions and uncertainties about the future that teenagers feel, most negotiate this period successfully. With this in mind, let's look closely at puberty, the dawning of adolescent development.

Puberty: The Physical Transition to Adulthood

The changes of puberty are dramatic: Within a few years, the body of the school-age child is transformed into that of a full-grown adult. Genetically influenced hormonal processes regulate pubertal growth. Girls, who have been advanced in physical maturity since the prenatal period, reach puberty, on average, two years earlier than boys.

Hormonal Changes

The complex hormonal changes that underlie puberty occur gradually and are under way by age 8 or 9. Secretions of *growth hormone (GH)* and *thyroxine* (see Chapter 7, page 219) increase, leading to tremendous gains in body size and to attainment of skeletal maturity.

Sexual maturation is controlled by the sex hormones. Although we think of *estrogens* as female hormones and *androgens* as male hormones, both types are present in each sex but in different amounts. The boy's testes release large quantities of the androgen *testosterone*, which leads to muscle growth, body and facial hair, and other male sex characteristics. Androgens (especially testosterone for boys) exert a GH-enhancing effect, contributing greatly to gains in body size. Because the testes secrete small amounts of estrogen as well, 50 percent of boys experience temporary breast enlargement. In both sexes, estrogens also increase GH secretion, adding to the growth spurt and, in combination with androgens, stimulating gains in bone density, which continue into early adulthood (Cooper, Sayer, & Dennison, 2006; Styne, 2003).

Estrogens released by girls' ovaries cause the breasts, uterus, and vagina to mature, the body to take on feminine proportions, and fat to accumulate. Estrogens also contribute to regulation of the menstrual cycle. *Adrenal androgens*, released from the adrenal glands on top of each kidney, influence girls' height spurt and stimulate growth of underarm and pubic hair. They have little impact on boys, whose physical characteristics are influenced mainly by androgen and estrogen secretions from the testes.

As you can see, pubertal changes are of two broad types: (1) overall body growth and (2) maturation of sexual characteristics. We have seen that the hormones responsible for sexual maturity also affect body growth, making puberty the time of greatest sexual differentiation since prenatal life.

Body Growth

The first outward sign of puberty is the rapid gain in height and weight known as the **growth spurt**. On average, it is under way for North American girls shortly after age 10, for boys around age 12½. Because estrogens trigger and then restrain GH secretion more readily than androgens, the typical girl is taller and

© LAURA DWIGHT PHOTOGRAPHY

Sex differences in pubertal growth are obvious among these 11-year-olds. Compared with the boys, the girls are taller and more mature-looking.

heavier during early adolescence (Archibald, Graber, & Brooks-Gunn, 2006; Bogin, 2001). At age 14, however, she is surpassed by the typical boy, whose adolescent growth spurt has now started, whereas hers is almost finished. Growth in body size is complete for most girls by age 16 and for boys by age 17½, when the epiphyses at the ends of the long bones close completely (see Chapter 7, page 217). Altogether, adolescents add 10 to 11 inches in height and 50 to 75 pounds—nearly 50 percent of adult body weight. Figure 11.1 on page 364 illustrates pubertal changes in general body growth.

Body Proportions. During puberty, the cephalocaudal growth trend of infancy and childhood reverses. The hands, legs, and feet accelerate first, followed by the torso, which accounts for most of the adolescent height gain. This pattern helps explain why early adolescents often appear awkward and out of proportion—long-legged, with giant feet and hands.

Large sex differences in body proportions also appear, caused by the action of sex hormones on the skeleton. Boys' shoulders broaden relative to the hips, whereas girls' hips broaden relative to the shoulders and waist. Of course, boys also end up larger than girls, and their legs are longer in relation to the rest of the body—mainly because boys have two extra years of preadolescent growth, when the legs are growing the fastest.

Muscle-Fat Makeup and Other Internal Changes.

Sabrina worried about her weight because compared with her later-developing girlfriends, she had accumulated much more fat. Around age 8, girls start to add fat on their arms, legs, and trunk, a trend that accelerates between ages 11 and 16. In contrast, arm and leg fat decreases in adolescent boys. Although both sexes gain in muscle, this increase is much greater in boys, who develop larger skeletal muscles, hearts, and lung capacity (Rogol, Roemmich, & Clark, 2002). Also, the number of red blood cells—and therefore the ability to carry oxygen from the lungs to the muscles—increases in boys but not in girls.

FIGURE 11.1 Body growth during adolescence. Because the pubertal growth spurt takes place earlier for girls than for boys, Kate reached her adult body size earlier than Steven. Rapid pubertal growth is accompanied by large sex differences in body proportions.

Altogether, boys gain far more muscle strength than girls, a difference that contributes to teenage boys' superior athletic performance (Ramos et al., 1998).

Motor Development and Physical Activity

Puberty brings steady improvements in gross motor performance, but the pattern of change differs for boys and girls. Girls' gains are slow and gradual, leveling off by age 14. In contrast, boys show a dramatic spurt in strength, speed, and endurance that continues through the teenage years. By midadolescence, few girls perform as well as the average boy in running speed, broad jump, or throwing distance, and practically no boys score as low as the average girl (Haywood & Getchell, 2005; Malina & Bouchard, 1991).

Because girls and boys are no longer well-matched physically, gender-segregated physical education usually begins in middle school. Athletic options for both sexes expand as new sports—including track and field, wrestling, tackle football, weight lifting, floor hockey, archery, tennis, and golf—are added to the curriculum.

Among boys, athletic competence is strongly related to peer admiration and self-esteem. Some adolescents become so

obsessed with physical prowess that they turn to performance-enhancing drugs. In recent large-scale studies, about 8 percent of U.S. high school seniors, mostly boys, reported using creatine, an over-the-counter substance that enhances short-term muscle power but carries a risk of serious side effects, including muscle tissue disease, brain seizures, and heart irregularities (Castillo & Comstock, 2007). About 2 percent of seniors, again mostly boys, have taken anabolic steroids or a related substance, androstenedione—powerful prescription medications that boost muscle mass and strength (Johnston et al., 2012). Teenagers usually obtain steroids illegally, ignoring side effects, which range from acne, excess body hair, and high blood pressure to mood swings, aggressive behavior, and damage to the liver, circulatory system, and reproductive organs (Casavant et al., 2007). Coaches and health professionals should inform teenagers of the dangers of these performance-enhancing substances.

In 1972, the U.S. federal government required schools receiving public funds to provide equal opportunities for males and females in all educational programs, including athletics. Since then, high school girls' sports participation has increased, but it still falls far short of boys'. According to a recent survey of all 50 U.S. state high school athletic associations, 41 percent of sports participants are girls, 59 percent boys (National

Federation of State High School Associations, 2012). In Chapter 9, we saw that girls get less encouragement and recognition for athletic achievement, a pattern that starts early and persists into the teenage years (see page 296).

Furthermore, when researchers followed a large, representative sample of U.S. youths from ages 9 to 15, physical activity declined by about 40 minutes per day each year until, at age 15, less than one-third met the U.S. government recommendation of at least 60 minutes of moderate to strenuous physical activity per day (see Figure 11.2) (Nader et al., 2008). In high school, only 57 percent of U.S. boys and 47 percent of girls are enrolled in any physical education, with 31 percent of all students experiencing a daily physical education class (U.S. Department of Health and Human Services, 2012f).

Besides improving motor performance, sports and exercise influence cognitive and social development. Interschool and intramural athletics provide important lessons in teamwork, problem solving, assertiveness, and competition. And regular, sustained physical activity—which required physical education can ensure—is associated with lasting physical and mental health benefits and enjoyment of sports and exercise (Brand et al., 2010). In one study, participating in team or individual sports at age 14 at least once a week for girls and twice a week for boys predicted high physical activity rates at age 31. Endurance sports, such as running and cycling—activities that do not require expensive equipment or special facilities—were especially likely to continue into adulthood (Tammelin et al., 2003). And adolescent exertion during exercise, defined as

AP IMAGES/TED S. WARREN

High school girls' participation in sports has increased but still falls far short of boys'. Yet athletic participation yields many benefits—not just gains in motor skills but important lessons in teamwork, problem solving, assertiveness, and competition.

FIGURE 11.2 Decline in physical activity from ages 9 to 15 among U.S. boys and girls. In a large representative sample of youths followed over six years, time spent exercising dropped sharply until, at age 15, most youths did not meet government recommendations of at least 60 minutes of moderate to vigorous physical activity per day. At all ages, boys spent more time exercising than girls. (Adapted from Nader et al., 2008.)

sweating and breathing heavily, is one of the best predictors of adult physical exercise, perhaps because it fosters high *physical self-efficacy*—belief in one's ability to sustain an exercise program (Motl et al., 2002; Telama et al., 2005).

Sexual Maturation

Accompanying rapid body growth are changes in physical features related to sexual functioning. Some, called **primary sexual characteristics**, involve the reproductive organs (ovaries, uterus, and vagina in females; penis, scrotum, and testes in males). Others, called **secondary sexual characteristics**, are visible on the outside of the body and serve as additional signs of sexual maturity (for example, breast development in females and the appearance of underarm and pubic hair in both sexes). As Table 11.1 on page 366 shows, these characteristics develop in a fairly standard sequence, although the ages at which each begins and is completed vary greatly. Typically, pubertal development takes about four years, but some adolescents complete it in two years, whereas others take five to six years.

Sexual Maturation in Girls. Female puberty usually begins with the budding of the breasts and the growth spurt. **Menarche**, or first menstruation, typically occurs around age 12½ for North American girls, 13 for Western Europeans. But the age range is wide, from 10½ to 15½ years. Following menarche, breast and pubic hair growth are completed, and underarm hair appears.

Notice in Table 11.1 that nature delays sexual maturity until the girl's body is large enough for childbearing; menarche takes place after the peak of the height spurt. As an extra measure of security, for 12 to 18 months following menarche, the menstrual cycle often occurs without the release of an ovum from the ovaries (Archibald, Graber, & Brooks-Gunn, 2006; Bogin, 2001). But this temporary period of sterility does not

TABLE 11.1 Pubertal Development in North American Girls and Boys

GIRLS	AVERAGE AGE ATTAINED	AGE RANGE	BOYS	AVERAGE AGE ATTAINED	AGE RANGE
Breasts begin to “bud”	10	8–13	Testes begin to enlarge	11.5	9.5–13.5
Height spurt begins	10	8–13	Pubic hair appears	12	10–15
Pubic hair appears	10.5	8–14	Penis begins to enlarge	12	10.5–14.5
Peak strength spurt	11.6	9.5–14	Height spurt begins	12.5	10.5–16

occur in all girls, and it does not provide reliable protection against pregnancy.

Sexual Maturation in Boys. The first sign of puberty in boys is the enlargement of the testes (glands that manufacture sperm), accompanied by changes in the texture and color of the scrotum. Pubic hair emerges soon after, about the same time the penis begins to enlarge (Rogol, Roemmich, & Clark, 2002).

As Table 11.1 reveals, the growth spurt occurs much later in the sequence of pubertal events for boys than for girls. When it reaches its peak around age 14, enlargement of the testes and penis is nearly complete, and underarm hair appears. So do facial and body hair, which increase gradually for several years. Another landmark of male physical maturity is the deepening of the voice as the larynx enlarges and the vocal cords lengthen. (Girls’ voices also deepen slightly.) Voice change usually takes place at the peak of the male growth spurt and is often not complete until puberty is over (Archibald, Graber, & Brooks-Gunn, 2006).

While the penis is growing, the prostate gland and seminal vesicles (which together produce semen, the fluid containing sperm) enlarge. Then, around age 13½, **spermarche**, or first ejaculation, occurs (Rogol, Roemmich, & Clark, 2002). For a while, the semen contains few living sperm. So, like girls, boys have an initial period of reduced fertility.

Individual Differences in Pubertal Growth

Heredity contributes substantially to the timing of pubertal changes. Identical twins are more similar than fraternal twins in attainment of most pubertal milestones (Eaves et al., 2004; Mustanski et al., 2004). Nutrition and exercise also make a difference. In females, a sharp rise in body weight and fat may trigger sexual maturation. Fat cells release a protein called *leptin*, which is believed to signal the brain that the girl’s energy stores are sufficient for puberty—a likely reason that breast and pubic hair growth and menarche occur earlier for heavier and, especially, obese girls. In contrast, girls who begin rigorous athletic training at an early age or who eat very little (both of which reduce the percentage of body fat) usually experience later puberty (Kaplowitz, 2007; Lee et al., 2007; Rubin et al., 2009). Few studies, however, report a link between body fat and puberty in boys.

Variations in pubertal growth also exist among regions of the world and among SES and ethnic groups. Physical health plays a major role. In poverty-stricken regions where malnutrition and infectious disease are common, menarche is greatly delayed, occurring as late as age 14 to 16 in many parts of Africa. Within developing countries, girls from higher-income families reach menarche 6 to 18 months earlier than those living in economically disadvantaged homes (Parent et al., 2003).

But in industrialized nations where food is abundant, the joint roles of heredity and environment in pubertal growth are apparent. For example, breast and pubic hair growth begin, on average, around age 9 in African-American girls—a year earlier than in Caucasian-American girls. And African-American girls reach menarche about six months earlier, around age 12. Although widespread overweight and obesity in the black population contribute, a genetically influenced faster rate of physical maturation is also involved. Black girls usually reach menarche before white girls of the same age and body weight (Chumlea et al., 2003; Herman-Giddens, 2006; Hillard, 2008).

Early family experiences may also affect pubertal timing. One theory suggests that humans have evolved to be sensitive to the emotional quality of their childhood environments. When children's safety and security are at risk, it is adaptive for them to reproduce early. Research indicates that girls and (less consistently) boys with a history of family conflict, harsh parenting, or parental separation tend to reach puberty early. In contrast, those with warm, stable family ties reach puberty relatively late (Belsky et al., 2007; Bogaert, 2005; Ellis, 2004; Ellis & Essex, 2007; Mustanski et al., 2004; Tremblay & Frigon, 2005). Critics offer an alternative explanation—that mothers who reached puberty early are more likely to bear children earlier, which increases the likelihood of marital conflict and separation (Mendle et al., 2006). But two longitudinal studies confirm the former chain of influence among girls: from adverse family environments in childhood to earlier pubertal timing to increased sexual risk taking (Belsky et al., 2010; James et al., 2012).

In the research we have considered, threats to emotional health accelerate puberty, whereas threats to physical health delay it. A **secular trend**, or generational change, in pubertal timing lends added support to the role of physical well-being in pubertal development. In industrialized nations, age of menarche declined steadily—by about 3 to 4 months per decade—from 1900 to 1970, a period in which nutrition, health care, sanitation, and control of infectious disease improved greatly. Boys, too, have reached puberty earlier in recent decades (Herman-Giddens et al., 2012). And as developing nations make socioeconomic progress, they also show secular gains (Ji & Chen, 2008).

In the United States and a few European countries, soaring rates of overweight and obesity are responsible for a modest, continuing trend toward earlier menarche (Kaplowitz, 2006; Parent et al., 2003). A worrisome consequence is that girls who reach sexual maturity at age 10 or 11 will feel pressure to act much older than they are. As we will see shortly, early-maturing girls are at risk for unfavorable peer involvements, including sexual activity.

Brain Development

The physical transformations of adolescence include major changes in the brain. Brain-imaging research reveals continued pruning of unused synapses in the cerebral cortex, especially in the prefrontal cortex. In addition, linkages between the two cerebral hemispheres through the corpus callosum, and between

the prefrontal cortex and other areas in the cerebral cortex and the inner brain (including the amygdala), expand, myelinate, and attain rapid communication. As a result, the prefrontal cortex becomes a more effective “executive”—overseeing and managing the integrated functioning of various areas, yielding more complex, flexible, and adaptive thinking and behavior (Blakemore & Choudhury, 2006; Lenroot & Giedd, 2006). Consequently, adolescents gain in diverse cognitive skills, including processing speed and executive function.

But these advances occur gradually over the teenage years. fMRI evidence reveals that adolescents recruit the prefrontal cortex's network of connections with other brain areas less effectively than adults do. Because the *prefrontal cognitive-control network* still requires fine-tuning, teenagers' performance on executive function tasks requiring inhibition, planning, and future orientation (rejecting a smaller immediate reward in favor of a larger delayed reward) is not yet fully mature (McClure et al., 2004; Smith, Xiao, & Bechara, 2012; Steinberg et al., 2009).

Adding to these self-regulation difficulties are changes in the brain's *emotional/social network*. In humans and other mammals, neurons become more responsive to excitatory neurotransmitters during puberty. As a result, adolescents react more strongly to stressful events and experience pleasurable stimuli more intensely. But because the cognitive control network is not yet functioning optimally, most teenagers find it hard to manage these powerful feelings (Ernst & Spear, 2009; Steinberg et al., 2008). This imbalance contributes to teenagers' drive for novel experiences, including drug taking, reckless driving, unprotected sex, and delinquent activity (Pharo et al., 2011). In a longitudinal study of a nationally representative sample of 7,600 U.S. youths, researchers tracked changes in self-reported impulsivity and sensation seeking between ages 12 and 24 (Harden & Tucker-Drob, 2011). As Figure 11.3 on page 368 shows, impulsivity declined steadily with age—evidence for gradual improvement of the cognitive-control network. But

© JEFF GREENBERG/THE IMAGE WORKS

In adolescence, changes in the brain's emotional/social network outpace development of the cognitive-control network. As a result, teenagers do not yet have the capacity to control their powerful drive for new—and sometimes risky—experiences.

FIGURE 11.3 Development of impulsivity and sensation seeking from 12 to 24 years. In this longitudinal study of a large, nationally representative U.S. sample, impulsivity declined steadily, while sensation seeking increased in early adolescence and then diminished more gradually. Findings confirm the challenge posed by the emotional/social network to the cognitive control network. (From K. P. Harden and E. M. Tucker-Drob, 2011, “Individual Differences in the Development of Sensation Seeking and Impulsivity During Adolescence: Further Evidence for a Dual Systems Model,” *Developmental Psychology*, 47, p. 742. Copyright © 2011 by the American Psychological Association. Adapted with permission of the American Psychological Association.)

sensation seeking increased from 12 to 16, followed by a more gradual decline through age 24, reflecting the challenge posed by the emotional/social network.

In sum, changes in the adolescent brain’s emotional/social network outpace development of the cognitive-control network. Only over time are young people able to effectively manage their emotions and reward-seeking behavior. Of course, wide individual differences exist in the extent to which teenagers manifest this rise in risk-taking in the form of careless, dangerous acts—some not at all, and others extremely so (Pharo et al., 2011). But transformations in the adolescent brain enhance our understanding of both the cognitive advances and the worrisome behaviors of this period, along with teenagers’ need for adult patience, oversight, and guidance.

Changing States of Arousal

At puberty, revisions occur in the way the brain regulates the timing of sleep, perhaps because of increased neural sensitivity to evening light. As a result, adolescents go to bed much later than they did as children. Yet they need almost as much sleep as they did in middle childhood—about nine hours. When the school day begins early, their sleep needs are not satisfied.

This sleep “phase delay” strengthens with pubertal growth. But today’s teenagers—who often have evening social activities, part-time jobs, and bedrooms equipped with TVs, computers, and phones—get much less sleep than teenagers of previous

generations (Carskadon et al., 2002; Jenni, Achermann, & Carskadon, 2005). Sleep-deprived adolescents display declines in executive function, performing especially poorly on cognitive tasks during morning hours. And they are more likely to achieve less well in school, suffer from anxiety and depressed mood, and engage in high-risk behaviors (Dahl & Lewin, 2002; Hansen et al., 2005; Talbot et al., 2010). Sleep rebound on weekends sustains the pattern by leading to difficulty falling asleep on subsequent evenings. Later school start times ease but do not eliminate sleep loss. Educating teenagers about the importance of sleep is vital.

The Psychological Impact of Pubertal Events

TAKE A MOMENT... Think back to your late elementary and middle school days. As you reached puberty, how did your feelings about yourself and your relationships with others change? Research reveals that pubertal events affect adolescents’ self-image, mood, and interaction with parents and peers. Some outcomes are a response to dramatic physical change, whenever it occurs. Others have to do with pubertal timing.

Reactions to Pubertal Changes

Two generations ago, menarche was often traumatic. Today, girls commonly react with “surprise,” undoubtedly due to the sudden onset of the event. Otherwise, they typically report a mixture of positive and negative emotions (DeRose & Brooks-Gunn, 2006). Yet wide individual differences exist that depend on prior knowledge and support from family members, which in turn are influenced by cultural attitudes toward puberty and sexuality.

For girls who have no advance information, menarche can be shocking and disturbing. Unlike 50 to 60 years ago, today few girls are uninformed, a shift that is probably due to parents’ greater willingness to discuss sexual matters and to the spread of health education classes (Omar, McElderry, & Zakharia, 2003). Almost all girls get some information from their mothers. And some evidence suggests that compared with Caucasian-American families, African-American families may better prepare girls for menarche, treat it as an important milestone, and express less conflict over girls reaching sexual maturity—factors that lead African-American girls to react more favorably (Martin, 1996).

Like girls’ reactions to menarche, boys’ responses to spermatheche reflect mixed feelings. Virtually all boys know about ejaculation ahead of time, but many say that no one spoke to them before or during puberty about physical changes (Omar, McElderry, & Zakharia, 2003). Usually they get their information from reading material or websites. Even boys who had advance information often say that their first ejaculation occurred earlier than they expected and that they were unprepared for it. As with girls, boys who feel better prepared tend to

react more positively (Stein & Reiser, 1994). But whereas almost all girls eventually tell a friend that they are menstruating, far fewer boys tell anyone about spermarche (DeRose & Brooks-Gunn, 2006; Downs & Fuller, 1991). Overall, boys get much less social support than girls for the physical changes of puberty. They might benefit, especially, from opportunities to ask questions and discuss feelings with a sympathetic parent or health professional.

Many tribal and village societies celebrate the onset of puberty with an *initiation ceremony*, a ritualized announcement to the community that marks an important change in privilege and responsibility. Consequently, young people know that reaching puberty is valued in their culture. In contrast, Western societies grant little formal recognition to movement from childhood to adolescence or from adolescence to adulthood. Ceremonies such as the Jewish bar or bat mitzvah and the *quinceañera* in Hispanic communities (celebrating a 15-year-old girl's sexual maturity and marriage availability), resemble initiation ceremonies, but only within the ethnic or religious subculture. They do not mark a significant change in social status in the larger society.

Instead, Western adolescents are granted partial adult status at many different ages—for example, an age for starting employment, for driving, for leaving high school, for voting, and for drinking. And in some contexts (at home and at school), they may still be regarded as children. The absence of a widely accepted marker of physical and social maturity makes the process of becoming an adult more confusing.

This 13-year-old's bat mitzvah ceremony recognizes her as an adult with moral and religious responsibilities in the Jewish community. In the larger society, however, she will experience no change in status.

Pubertal Change, Emotion, and Social Behavior

A common belief is that puberty has something to do with adolescent moodiness and the desire for greater physical and psychological separation from parents. Let's see what research says about these relationships.

Adolescent Moodiness. Higher pubertal hormone levels are linked to greater moodiness, but only modestly so (Buchanan, Eccles, & Becker, 1992; Graber, Brooks-Gunn, & Warren, 2006). What other factors might contribute? In several studies, the moods of children, adolescents, and adults were monitored by having them carry electronic pagers. Over a one-week period, they were beeped at random intervals and asked to write down what they were doing, whom they were with, and how they felt.

As expected, adolescents reported less favorable moods than school-age children and adults (Larson et al., 2002; Larson & Lampman-Petratis, 1989). But negative moods were linked to a greater number of negative life events, such as difficulty getting along with parents, disciplinary actions at school, and breaking up with a boyfriend or girlfriend. Negative events increased steadily from childhood to adolescence, and teenagers also seemed to react to them with greater emotion than children (Larson & Ham, 1993). (Recall that stress reactivity is heightened by changes in the brain's emotional/social network during puberty.)

Compared with the moods of older adolescents and adults, those of younger adolescents (ages 12 to 16) were less stable, often shifting between cheerful and sad. These mood swings were strongly related to situational changes. High points of adolescents' days were times spent with peers and in self-chosen leisure activities. Low points tended to occur in adult-structured settings—class, job, and religious services. Furthermore, emotional highs coincided with Friday and Saturday evenings, especially in high school. Going out with friends and romantic partners increases so dramatically during adolescence that it becomes a “cultural script” for what is *supposed* to happen (Larson & Richards, 1998). Consequently, teenagers who spend weekend evenings at home often feel profoundly lonely.

Fortunately, frequent reports of negative mood level off in late adolescence (Natsuaki, Biehl, & Ge, 2009). And overall, teenagers with supportive family and peer relationships more often report positive and less often negative moods than their agemates with few social supports (Weinstein et al., 2006). In contrast, poorly adjusted young people—with low self-esteem, conduct difficulties, or delinquency—tend to react with stronger negative emotion to unpleasant daily experiences, perhaps compounding their adjustment problems (Schneiders et al., 2006).

Parent–Child Relationships. Sabrina's father noticed that as his children entered adolescence, they kept their bedroom doors closed, resisted spending time with the family, and became more argumentative. Sabrina and her mother squabbled

over Sabrina's messy room ("It's *my* room, Mom. You don't have to live in it!"). And Sabrina protested the family's regular weekend visit to Aunt Gina's ("Why do I have to go *every* week?"). Research in cultures as diverse as the United States and Turkey shows that puberty is related to a rise in intensity of parent-child conflict, which persists into middle adolescence (Gure, Ucanok, & Sayil, 2006; Laursen, Coy, & Collins, 1998; McGue et al., 2005).

Why should a youngster's more adultlike appearance trigger these disputes? The association may have adaptive value. Among nonhuman primates, the young typically leave the family group around the time of puberty. The same is true in many nonindustrialized cultures (Caine, 1986; Schlegel & Barry, 1991). Departure of young people discourages sexual relations between close blood relatives. But adolescents in industrialized nations, who are still economically dependent on parents, cannot leave the family. Consequently, a substitute seems to have emerged: psychological distancing.

As children become physically mature, they demand to be treated in adultlike ways. And as we will see, adolescents' new powers of reasoning may also contribute to a rise in family tensions. Parent-adolescent disagreements focus largely on everyday matters such as driving, dating partners, and curfews (Adams & Laursen, 2001). But beneath these disputes lie serious concerns: parental efforts to protect teenagers from substance use, auto accidents, and early sex. The larger the gap between parents' and adolescents' views of teenagers' readiness for new responsibilities, the more they quarrel (Deković, Noom, & Meeus, 1997).

Parent-daughter conflict tends to be more intense than conflict with sons, perhaps because parents place more restrictions on girls (Allison & Schultz, 2004). But most disputes are mild and diminish by late adolescence. Parents and teenagers display both conflict and affection, and they usually agree on important values, such as honesty and the importance of education. And as the teenage years conclude, parent-adolescent interactions are less hierarchical, setting the stage for mutually supportive relationships in adulthood (Laursen & Collins, 2009).

LOOK AND LISTEN

Interview several parents and/or their 12- to 14-year-olds about recent changes in parent-child relationships. Has conflict increased? Over what topics? ●

Pubertal Timing

"All our children were early maturers," said Franca during the parents' discussion group. "The three boys were tall by age 12 or 13, but it was easier for them. They felt big and important. Sabrina was skinny as a little girl, but now she says she is too fat and needs to diet. She thinks about boys and doesn't concentrate on her schoolwork."

Findings of several studies match the experiences of Sabrina and her brothers. Both adults and peers viewed early-maturing boys as relaxed, independent, self-confident, and physically attractive. Popular with agemates, they tended to hold leadership positions in school and to be athletic stars. In contrast,

© JEFF GREENBERG/THE IMAGE WORKS

African-American early-maturing girls are more likely to report a positive body image than their Caucasian counterparts. Perhaps because their families and friends tend to welcome menarche, they may escape the adjustment difficulties commonly associated with early pubertal timing.

late-maturing boys expressed more anxiety and depressed mood than their on-time counterparts (Brooks-Gunn, 1988; Huddleston & Ge, 2003). But early-maturing boys, though viewed as well-adjusted, reported more psychological stress, depressed mood, and problem behaviors (sexual activity, smoking, drinking, aggression, delinquency) than both their on-time and later-maturing agemates (Ge, Conger, & Elder, 2001; Natsuaki, Biehl, & Ge, 2009; Susman & Dorn, 2009).

In contrast, early-maturing girls were unpopular, withdrawn, lacking in self-confidence, anxious (especially about others' negative evaluations), and prone to depression, and they held few leadership positions (Blumenthal et al., 2011; Ge, Conger, & Elder, 1996; Graber, Brooks-Gunn, & Warren, 2006; Jones & Mussen, 1958). And like early-maturing boys, they were more involved in deviant behavior (smoking, drinking, sexual activity) (Caspi et al., 1993; Dick et al., 2000; Ge et al., 2006). In contrast, their later-maturing counterparts were regarded as physically attractive, lively, sociable, and leaders at school. In one study of several hundred eighth graders, however, negative effects were not evident among early-maturing African-American girls, whose families—and perhaps friends as well—tend to be more unconditionally welcoming of menarche (see page 365) (Michael & Eccles, 2003).

Two factors largely account for these trends: (1) how closely the adolescent's body matches cultural ideals of physical attractiveness, and (2) how well young people fit in physically with their peers.

The Role of Physical Attractiveness. TAKE A

MOMENT... Flip through your favorite popular magazine. You will see evidence of our society's view of an attractive female as thin and long-legged and of a good-looking male as tall, broad-shouldered, and muscular. The female image is a girlish shape that favors the late developer. The male image fits the early-maturing boy.

Consistent with these preferences, early-maturing Caucasian girls tend to report a less positive **body image**—conception of and attitude toward their physical appearance—than their on-time and late-maturing agemates. Compared with African-American and Hispanic girls, Caucasian girls are more likely to have internalized the cultural ideal of female attractiveness. Most want to be thinner (Rosen, 2003; Stice, Presnell, & Bearman, 2001; Williams & Currie, 2000). Although boys are less consistent, early, rapid maturers are more likely to be satisfied with their physical characteristics (Alsaker, 1995; Sinkkonen, Anttila, & Siimes, 1998).

Body image is a strong predictor of young people's self-esteem (Harter, 2006). But the negative effects of pubertal timing on body image and—as we will see next—emotional adjustment are greatly amplified when accompanied by other stressors (Stice, 2003).

The Importance of Fitting in with Peers. Physical status in relation to peers also explains differences in adjustment between early and late maturers. From this perspective, early-maturing girls and late-maturing boys have difficulty because they fall at the extremes of physical development and feel out of place when with their agemates. Not surprisingly, adolescents feel most comfortable with peers who match their own level of biological maturity (Stattin & Magnusson, 1990).

Because few agemates of the same pubertal status are available, early-maturing adolescents of both sexes seek out older companions, who often encourage them into activities they are not ready to handle emotionally. And hormonal influences on the brain's emotional/social network are stronger for early maturers, further magnifying their receptiveness to sexual activity, drug and alcohol use, and delinquent acts (Ge et al., 2002; Steinberg, 2008). Perhaps as a result, early maturers of both sexes more often report feeling stressed and show declines in academic performance (Mendle, Turkheimer, & Emery, 2007; Natsuaki, Biehl, & Ge, 2009).

At the same time, the young person's context greatly increases the likelihood that early pubertal timing will lead to negative outcomes. Early maturers in economically disadvantaged neighborhoods are especially vulnerable to establishing ties with deviant peers, which heightens their defiant, hostile behavior. And because families in such neighborhoods tend to be exposed to chronic, severe stressors and to have few social supports, these early maturers are also more likely to experience harsh, inconsistent parenting, which, in turn, predicts both deviant peer associations and antisocial behavior (Ge et al., 2002, 2011).

Long-Term Consequences. Do the effects of pubertal timing last? Follow-ups reveal that early-maturing girls, especially, are prone to lasting difficulties. In one study, depression subsided by age 13 in early-maturing boys but tended to persist in early-maturing girls (Ge et al., 2003). In another study, which followed young people from ages 14 to 24, early-maturing boys again showed good adjustment. But early-maturing girls

reported poorer-quality relationships with family and friends, smaller social networks, and lower life satisfaction into early adulthood than their on-time counterparts (Graber et al., 2004).

Recall that childhood family conflict and harsh parenting are linked to earlier pubertal timing, more so for girls than for boys (see page 367). Perhaps many early-maturing girls enter adolescence with emotional and social difficulties. As the stresses of puberty interfere with school performance and lead to unfavorable peer pressures, poor adjustment extends and deepens (Graber, 2003). Clearly, interventions that target at-risk early-maturing youths are needed. These include educating parents and teachers and providing adolescents with counseling and social supports so they will be better prepared to handle the emotional and social challenges of this transition.

ASK YOURSELF

REVIEW Summarize the impact of pubertal timing on adolescent development.

CONNECT How might adolescent moodiness contribute to psychological distancing between parents and adolescents? (*Hint:* Think about bidirectional influences in parent-child relationships.)

APPLY As a school-age child, Chloe enjoyed leisure activities with her parents. Now, at age 14, she spends hours in her room and resists going on weekend family excursions. Explain Chloe's behavior.

REFLECT Recall your own reactions to the physical changes of puberty. Are they consistent with research findings? Explain.

Health Issues

The arrival of puberty brings new health issues related to the young person's efforts to meet physical and psychological needs. As adolescents attain greater autonomy, their personal decision making becomes important, in health as well as other areas. Yet none of the health concerns we are about to discuss can be traced to a single cause. Rather, biological, psychological, family, peer, and cultural factors jointly contribute.

Nutritional Needs

When their sons reached puberty, Franca and Antonio reported a “vacuum cleaner effect” in the kitchen as the boys routinely emptied the refrigerator. Rapid body growth leads to a dramatic increase in nutritional requirements, at a time when the diets of many young people are the poorest. Of all age groups, adolescents are the most likely to skip breakfast (a practice linked to obesity), eat on the run, and consume empty calories (Ritchie et al., 2007; Striegel-Moore & Franko, 2006). Fast-food restaurants,

where teenagers often gather, have begun to offer some healthy menu options. But adolescents need guidance in choosing these alternatives. Eating fast food and school purchases from snack bars and vending machines is strongly associated with consumption of soft drinks and foods high in fat and sugar, indicating that teenagers often make unhealthy food choices (Bowman et al., 2004; Kubik et al., 2003).

The most common nutritional problem of adolescence is iron deficiency. Iron requirements increase to a maximum during the growth spurt and remain high among girls because of iron loss during menstruation. A tired, irritable teenager may be suffering from anemia rather than unhappiness and should have a medical checkup. Most adolescents do not get enough calcium and are also deficient in riboflavin (vitamin B2) and magnesium, both of which support metabolism (Cavadini, Siega-Riz, & Popkin, 2000).

Frequency of family meals is strongly associated with greater intake of fruits, vegetables, grains, and calcium-rich foods and reduced soft drink and fast-food consumption (Burgess-Champoux et al., 2009; Fiese & Schwartz, 2008). But compared to families with younger children, those with adolescents eat fewer meals together. In addition to their other benefits (see page 63 in Chapter 2 and page 291 in Chapter 9), family meals can greatly improve teenagers' diets.

Adolescents—especially girls concerned about their weight—tend to be attracted to fad diets. Unfortunately, most are too limited in nutrients and calories to be healthy for fast-growing, active teenagers (Donatelle, 2012). Parents should encourage young people to consult a doctor or dietitian before trying any special diet.

Eating Disorders

Concerned about her daughter's desire to lose weight, Franca explained to Sabrina that she was really quite average in build for an adolescent girl and reminded her that her Italian ancestors had considered a plump female body more beautiful than a thin one. Girls who reach puberty early, who are very dissatisfied with their body image, and who grow up in homes where concern with weight and thinness is high are at risk for eating problems. Severe dieting is the strongest predictor of the onset of an eating disorder in adolescence (Lock & Kirz, 2008). The two most serious are anorexia nervosa and bulimia nervosa.

Anorexia Nervosa. Anorexia nervosa is a tragic eating disorder in which young people starve themselves because of a compulsive fear of getting fat. It affects about 1 percent of North American and Western European teenage girls. During the past half-century, cases have increased sharply, fueled by cultural admiration of female thinness. Anorexia nervosa is equally common in all SES groups, but Asian-American, Caucasian-American, and Hispanic girls are at greater risk than African-American girls, who tend to be more satisfied with their size and shape (Granillo, Jones-Rodriguez, & Carvajal, 2005; Ozer & Irwin, 2009; Steinhausen, 2006). Boys account for 10 to 15 percent of anorexia cases; about half of these are gay or bisexual

© LAUREN GREENFIELD/INSTITUTE

Aiva, a 16-year-old anorexia nervosa patient, is shown at left on the day she entered treatment—weighing just 77 pounds—and, at right, after a 10-week treatment program. Less than 50 percent of young people with anorexia recover fully.

young people who are uncomfortable with a strong, muscular appearance (Raevuori et al., 2009; Robb & Dadson, 2002).

Individuals with anorexia have an extremely distorted body image. Even after they have become severely underweight, they see themselves as too heavy. Most go on self-imposed diets so strict that they struggle to avoid eating in response to hunger. To enhance weight loss, they exercise strenuously.

In their attempt to reach “perfect” slimness, individuals with anorexia lose between 25 and 50 percent of their body weight. Because a normal menstrual cycle requires about 15 percent body fat, either menarche does not occur or menstrual periods stop. Malnutrition causes pale skin, brittle discolored nails, fine dark hairs all over the body, and extreme sensitivity to cold. If it continues, the heart muscle can shrink, the kidneys can fail, and irreversible brain damage and loss of bone mass can occur. About 6 percent of individuals with anorexia die of the disorder, as a result of either physical complications or suicide (Katzman, 2005).

Forces within the person, the family, and the larger culture give rise to anorexia nervosa. Identical twins share the disorder more often than fraternal twins, indicating a genetic influence. Abnormalities in neurotransmitters in the brain, linked to anxiety and impulse control, may make some individuals more susceptible (Kaye, 2008; Lock & Kirz, 2008). Many young people with anorexia have unrealistically high standards for their own behavior and performance, are emotionally inhibited, and avoid intimate ties outside the family. Consequently, they are often excellent students who are responsible and well-behaved. But as we have also seen, the societal image of “thin is beautiful” contributes to the poor body image of many girls—especially early-maturing girls, who are at greatest risk for anorexia nervosa (Hogan & Strasburger, 2008).

In addition, parent–adolescent interactions reveal problems related to adolescent autonomy. Often the mothers of these

girls have high expectations for physical appearance, achievement, and social acceptance and are overprotective and controlling. Fathers tend to be emotionally distant. These parental attributes may contribute to affected girls' persistent anxiety and fierce pursuit of perfection in achievement, respectable behavior, and thinness (Kaye, 2008). Nevertheless, it remains unclear whether maladaptive parent-child relationships precede the disorder, emerge in response to it, or both.

Because individuals with anorexia typically deny or minimize the seriousness of their disorder, treating it is difficult (Couturier & Lock, 2006). Hospitalization is often necessary to prevent life-threatening malnutrition. The most successful treatment is family therapy plus medication to reduce anxiety and neurotransmitter imbalances (Robin & Le Grange, 2010; Treasure & Schmidt, 2005). Still, less than 50 percent of young people with anorexia recover fully. For many, eating problems continue in less extreme form. About 10 percent show signs of a less severe, but nevertheless debilitating, disorder: bulimia nervosa.

Bulimia Nervosa. In bulimia nervosa, young people (again, mainly girls, but gay and bisexual boys are also vulnerable) engage in strict dieting and excessive exercise accompanied by binge eating, often followed by deliberate vomiting and purging with laxatives (Herzog, Eddy, & Beresin, 2006; Wichstrøm, 2006). Bulimia typically appears in late adolescence and is more common than anorexia nervosa, affecting about 2 to 4 percent of teenage girls, only 5 percent of whom previously suffered from anorexia.

Twin studies show that bulimia, like anorexia, is influenced by heredity (Klump, Kaye, & Strober, 2001). Overweight and early menarche increase the risk. Some adolescents with bulimia, like those with anorexia, are perfectionists. But most are impulsive, sensation-seeking young people who lack self-control in many areas, engaging in petty shoplifting, alcohol abuse, and other risky behaviors (Kaye, 2008). And although girls with bulimia, like those with anorexia, are pathologically anxious about gaining weight, they may have experienced their parents as disengaged and emotionally unavailable rather than controlling (Fairburn & Harrison, 2003).

In contrast to young people with anorexia, those with bulimia usually feel depressed and guilty about their abnormal eating habits and desperately want help. As a result, bulimia is usually easier to treat than anorexia, through support groups, nutrition education, training in changing eating habits, and anti-anxiety, antidepressant, and appetite-control medication (Hay & Bacaltchuk, 2004).

Sexuality

Sabrina's 16-year-old brother Louis and his girlfriend Cassie hadn't planned to have intercourse—it “just happened.” But before and after, a lot of things passed through their minds. After they had dated for three months, Cassie began to wonder, “Will Louis think I'm normal if I don't have sex with him? If he wants to and I say no, will I lose him?” Both young people knew

TOBY BURROWS/PHOTODISC/GETTY IMAGES

Cultural attitudes will profoundly affect the way these young teenagers, who are just beginning to explore their sexual attraction to each other, learn to manage sexuality in social relationships.

their parents wouldn't approve. In fact, when Franca and Antonio noticed how attached Louis was to Cassie, they talked to him about the importance of waiting and the dangers of pregnancy. But that Friday evening, Louis and Cassie's feelings for each other seemed overwhelming. “If I don't make a move,” Louis thought, “will she think I'm a wimp?”

With the arrival of puberty, hormonal changes—in particular, the production of androgens in young people of both sexes—lead to an increase in sex drive (Halpern, Udry, & Suchindran, 1997). In response, adolescents become very concerned about managing sexuality in social relationships. New cognitive capacities involving perspective taking and self-reflection affect their efforts to do so. Yet like the eating behaviors we have just discussed, adolescent sexuality is heavily influenced by the young person's social context.

The Impact of Culture. TAKE A MOMENT... When did you first learn the “facts of life”—and how? Was sex discussed openly in your family, or was it treated with secrecy? Exposure to sex, education about it, and efforts to limit the sexual curiosity of children and adolescents vary widely around the world.

Despite the prevailing image of sexually free adolescents, sexual attitudes in North America are relatively restrictive. Typically, parents provide little or no information about sex, discourage sex play, and rarely talk about sex in children's presence. When young people become interested in sex, only about half report getting information from parents about intercourse, pregnancy prevention, and sexually transmitted disease. Many parents avoid meaningful discussions about sex out of fear of embarrassment or concern that the adolescent will not take

them seriously (Wilson et al., 2010). Yet warm, open give-and-take is associated with teenagers' adoption of parents' views and with reduced sexual risk taking (Jaccard, Dodge, & Dittus, 2003; Usher-Seriki, Bynum, & Callands, 2008).

Adolescents who do not get information about sex from their parents are likely to learn from friends, books, magazines, movies, TV, and the Internet (Jaccard, Dodge, & Dittus, 2002; Sutton et al., 2002). On prime-time TV shows, which adolescents watch more than other TV offerings, 80 percent of programs contain sexual content. Most depict partners as spontaneous and passionate, taking no steps to avoid pregnancy or sexually transmitted disease, and experiencing no negative consequences (Roberts, Henriksen, & Foehr, 2004). In several studies, teenagers' media exposure to sexual content predicted current sexual activity, intentions to be sexually active in the future, and subsequent sexual activity, pregnancies, and sexual harassment behaviors (offensive name-calling or touching, pressuring a peer for a date) even after many other relevant factors were controlled (Brown & L'Engle, 2009; Chandra et al., 2008; Roberts, Henriksen, & Foehr, 2009).

Not surprisingly, adolescents who are prone to early sexual activity choose to consume more sexualized media (Steinberg & Monahan, 2011). The Internet is an especially hazardous "sex educator." In a survey of a large sample of U.S. 10- to 17-year-old Web users, 42 percent said they had viewed online pornographic websites (images of naked people or people having sex) while surfing the Internet in the past 12 months. Of these, 66 percent indicated they had encountered the images accidentally and did not want to view them (Wolak, Mitchell, & Finkelhor, 2007). Youths who felt depressed, had been bullied by peers, or were involved in delinquent activities had more encounters with Internet pornography, which may have intensified their adjustment problems.

Consider the contradictory messages young people receive. On one hand, adults express disapproval of sex at a young age and outside of marriage. On the other hand, the social environment extols sexual excitement, experimentation, and promiscuity. American teenagers are left bewildered, poorly informed about sexual facts, and with little sound advice on how to conduct their sex lives responsibly.

Adolescent Sexual Attitudes and Behavior.

Although differences between subcultural groups exist, sexual attitudes of U.S. adolescents and adults have become more liberal over the past 40 years. Compared with a generation ago, more people believe that sexual intercourse before marriage is all right, as long as two people are emotionally committed to each other (ABC News, 2004; Hoff, Greene, & Davis, 2003). During the past two decades, adolescents have swung back slightly toward more conservative sexual beliefs, largely in response to the risk of sexually transmitted disease, especially AIDS, and to teenage sexual abstinence programs sponsored by schools and religious organizations (Akers et al., 2011; Ali & Scelfo, 2002).

Trends in adolescents' sexual behavior are consistent with their attitudes. Rates of extramarital sex among U.S. young

FIGURE 11.4 U.S. adolescents who report ever having had sexual intercourse. Many young adolescents are sexually active—more than in other Western nations. Boys tend to have their first intercourse earlier than girls. By the end of high school, rates of boys and girls having had sexual intercourse are similar. (From U.S. Department of Health and Human Services, 2012f.)

people rose for several decades, declined during the 1990s, and then stabilized (U.S. Department of Health and Human Services, 2012f). Nevertheless, as Figure 11.4 illustrates, a substantial percentage of U.S. young people are sexually active by ninth grade (age 14 to 15).

Overall, teenage sexual activity rates are similar in the United States and other Western countries: Nearly half of adolescents have had intercourse. But quality of sexual experiences differs. U.S. youths become sexually active earlier than their Canadian and European counterparts (Boyce et al., 2006; U.S. Department of Health and Human Services, 2012f). And about 18 percent of U.S. adolescent boys and 13 percent of girls—more than in other Western nations—have had sexual relations with four or more partners in the past year. Most teenagers, however, have had only one or two sexual partners by the end of high school.

Characteristics of Sexually Active Adolescents.

Early and frequent teenage sexual activity is linked to personal, family, peer, and educational characteristics. These include childhood impulsivity, weak sense of personal control over life events, early pubertal timing, parental divorce, single-parent and stepfamily homes, large family size, little or no religious involvement, weak parental monitoring, disrupted parent-child communication, sexually active friends and older siblings, poor school performance, lower educational aspirations, and tendency to engage in norm-violating acts, including alcohol and drug use and delinquency (Coley, Votruba-Drzal, & Schindler, 2009; Crockett, Raffaelli, & Shen, 2006; Siebenbruner, Zimmer-Gembeck, & Egeland, 2007; Zimmer-Gembeck & Helfand, 2008).

Because many of these factors are associated with growing up in a low-income family, it is not surprising that early sexual activity is more common among young people from economically disadvantaged homes. Living in a neighborhood high in physical deterioration, crime, and violence also increases the likelihood that teenagers will be sexually active (Ge et al., 2002). In such neighborhoods, social ties are weak, adults exert little oversight and control over adolescents' activities, and negative peer influences are widespread. In fact, the high rate of sexual activity among African-American teenagers—60 percent report having had sexual intercourse, compared with 47 percent of all U.S. young people—is largely accounted for by widespread poverty in the black population (Darroch, Frost, & Singh, 2001; U.S. Department of Health & Human Services, 2012b).

Contraceptive Use. Although adolescent contraceptive use has increased in recent years, about 20 percent of sexually active teenagers in the United States are at risk for unintended pregnancy because they do not use contraception consistently (see Figure 11.5) (Fortenberry, 2010). Why do so many fail to take precautions? Typically, teenagers respond, “I was waiting until I had a steady boyfriend,” or “I wasn’t planning to have sex.” As we will see when we take up adolescent cognitive development, although adolescents can consider multiple possibilities when faced with a problem, they often fail to apply this advanced reasoning to everyday situations.

FIGURE 11.5 Contraceptive use by sexually active 15-year-olds in 10 industrialized nations. Sexually active U.S. teenagers are less likely to use contraception (condom, contraceptive pill, or both) consistently than teenagers in other industrialized nations. (Adapted from Godeau et al., 2008; U.S. Department of Health and Human Services, 2012f.)

One reason is that advances in perspective taking lead teenagers, for a time, to be extremely concerned about others' opinions of them. Recall how Cassie and Louis each worried about what the other would think if they decided not to have sex. Also, in the midst of everyday social pressures, adolescents often overlook the potential consequences of risky behaviors. And many teenagers—especially those from troubled, low-income families—do not have realistic expectations about the impact of early parenthood on their current and future lives (Stevens-Simon, Sheeder, & Harter, 2005).

As these findings suggest, the social environment also contributes to teenagers' reluctance to use contraception. Those without the rewards of meaningful education and work are especially likely to engage in irresponsible sex, sometimes within relationships characterized by exploitation. About 12 percent of U.S. girls and 5 percent of boys say they were pressured to have intercourse when they were unwilling (U.S. Department of Health and Human Services, 2012f).

In contrast, teenagers who report good relationships with parents and who talk openly with them about sex and contraception are more likely to use birth control (Henrich et al., 2006; Kirby, 2002a). But few adolescents believe their parents would be understanding and supportive. School sex education classes, as well, often leave teenagers with incomplete or incorrect knowledge. Some do not know where to get birth control counseling and devices. And those engaged in high-risk sexual behaviors are especially likely to worry that a doctor or family planning clinic might not keep their visits confidential (Lehrer et al., 2007). Most of these young people forgo essential health care but continue to have sex without contraception.

Sexual Orientation. So far, we have focused only on heterosexual behavior. About 4 percent of U.S. 15- to 44-year-olds identify as lesbian, gay, or bisexual (Mosher, Chandra, & Jones, 2005). An unknown number experience same-sex attraction but have not come out to friends or family (see the Social Issues: Health box on page 376). Adolescence is an equally crucial time for the sexual development of these young people, and societal attitudes, again, loom large in how well they fare.

Heredity makes an important contribution to homosexuality: Identical twins of both sexes are much more likely than fraternal twins to share a homosexual orientation; so are biological (as opposed to adoptive) relatives (Kendler et al., 2000; Kirk et al., 2000). Furthermore, male homosexuality tends to be more common on the maternal than on the paternal side of families, suggesting that it may be X-linked (see Chapter 2). Indeed, one gene-mapping study found that among 40 pairs of homosexual brothers, 33 (82 percent) had an identical segment of DNA on the X chromosome (Hamer et al., 1993). One or several genes in that region might predispose males to become homosexual.

How might heredity lead to homosexuality? According to some researchers, certain genes affect the level or impact of prenatal sex hormones, which modify brain structures in ways that induce homosexual feelings and behavior (Bailey et al., 1995; LeVay, 1993). Keep in mind, however, that environmental

Social Issues: Health

Lesbian, Gay, and Bisexual Youths: Coming Out to Oneself and Others

Cultures vary as much in their acceptance of homosexuality as in their approval of extramarital sex. In the United States, homosexuals are stigmatized, as shown by the degrading language often used to describe them. This makes forming a sexual identity a much greater challenge for lesbian, gay, and bisexual youths than for their heterosexual counterparts.

Wide variations in sexual identity formation exist, depending on personal, family, and community factors. Yet interviews with gay and lesbian adolescents and adults reveal that many (though not all) move through a three-phase sequence in coming out to themselves and others.

Feeling Different

Many gay men and lesbians recall feeling different from other children when they were young. Typically, this first sense of their biologically determined sexual orientation appears between ages 6 and 12, in play interests more like those of the other gender (Rahman & Wilson, 2003). Boys may find that they are less interested in sports,

more drawn to quieter activities, and more emotionally sensitive than other boys; girls that they are more athletic and active than other girls.

By age 10, many of these children start to engage in *sexual questioning*—wondering why the typical heterosexual orientation does not apply to them. Often, they experience their sense of being different as deeply distressing. Compared with children who are confident of their homosexuality, sexual-questioning children report greater anxiety about peer relationships and greater dissatisfaction with their biological gender over time (Carver, Egan, & Perry, 2004).

Confusion

With the arrival of puberty, feeling different clearly encompasses feeling sexually different. In research on ethnically diverse lesbian, gay, and bisexual youths, awareness of a same-sex physical attraction occurred, on average, between ages 11 and 12 for boys and 14 and 15 for girls, perhaps because adolescent social pressures toward hetero-

sexuality are particularly intense for girls (D'Augelli, 2006; Diamond, 1998).

Realizing that homosexuality has personal relevance generally sparks additional confusion. A few adolescents resolve their discomfort by crystallizing a gay, lesbian, or bisexual identity quickly, with a flash of insight into their sense of being different. But most experience an inner struggle and a deep sense of isolation—outcomes intensified by lack of role models and social support (D'Augelli, 2002; Safren & Pantalone, 2006).

Some throw themselves into activities they associate with heterosexuality. Boys may go out for athletic teams; girls may drop softball and basketball in favor of dance. And many homosexual youths (more females than males) try heterosexual dating, sometimes to hide their sexual orientation and at other times to develop intimacy skills that they later apply to same-sex relationships (D'Augelli, 2006; Dubé, Savin-Williams, & Diamond, 2001). Those who are extremely troubled and guilt-ridden may escape into alcohol, drugs, and suicidal thinking. Suicide attempts are unusually high among lesbian, gay, and bisexual young people (Morrow, 2006; Teasdale & Bradley-Engen, 2010).

factors can also alter prenatal hormones. Girls exposed prenatally to very high levels of androgens or estrogens—either because of a genetic defect or from drugs given to the mother to prevent miscarriage—are more likely to become lesbian or bisexual (Meyer-Bahlburg et al., 1995). Furthermore, gay men tend to be later in birth order and to have a higher-than-average number of older brothers (Blanchard & Bogaert, 2004). One possibility is that mothers with several male children sometimes produce antibodies to androgens, reducing the prenatal impact of male sex hormones on the brains of later-born boys.

Stereotypes and misconceptions about homosexuality persist. For example, most homosexual adolescents are not “gender-deviant” in dress or behavior. And attraction to members of the same sex is not limited to lesbian, gay, and bisexual teenagers. About 50 to 60 percent of adolescents who report having engaged in homosexual acts identify as heterosexual (Savin-Williams & Diamond, 2004). And in a study of lesbian, bisexual,

and “unlabeled” young women over a 10-year period, most reported stable proportions of same-sex versus other-sex attractions over time, providing evidence that bisexuality is not, as often assumed, a transient state (Diamond, 2008).

The evidence to date suggests that genetic and prenatal biological influences are largely responsible for homosexuality. In our evolutionary past, homosexuality may have served the adaptive function of reducing aggressive competition for other-sex mates (Rahman & Wilson, 2003).

Sexually Transmitted Diseases

Sexually active adolescents, both homosexual and heterosexual, are at risk for sexually transmitted diseases (STDs). Adolescents have the highest rates of STDs of all age groups. Despite a recent decline in STDs in the United States, one out of five to six sexually active teenagers contracts one of these illnesses each year—a rate three or more times as high as that of Canada and Western

Self-Acceptance

By the end of adolescence, the majority of gay, lesbian, and bisexual teenagers accept their sexual identity. But they face another crossroad: whether to tell others. The powerful stigma against their sexual orientation leads some to decide that disclosure is impossible: While self-defining as gay, they otherwise “pass” as heterosexual (Savin-Williams, 2001). When homosexual youths do come out, they often face intense hostility, including verbal abuse and physical attacks, because of their sexual orientation. These experiences trigger intense emotional distress, depression, suicidal thoughts, school truancy, and drug use in victims (Almeida et al., 2009; Birkett, Espelage, & Koenig, 2009).

Nevertheless, many young people eventually acknowledge their sexual orientation publicly, usually by telling trusted friends first. Once teenagers establish a same-sex sexual or romantic relationship, many come out to parents. Although few parents respond with severe rejection, lesbian, gay, and bisexual young people report lower levels of family support than their heterosexual agemates (Needham & Austin, 2010; Savin-Williams & Ream, 2003). Yet parental understanding is the strongest predictor of favorable adjustment—including reduced

internalized homophobia, or societal prejudice turned against the self (D’Augelli, Grossman, & Starks, 2008).

When people react positively, coming out strengthens the young person’s view of homosexuality as a valid, meaningful, and fulfilling identity. Contact with other gays and lesbians is important for reaching this phase, and changes in society permit many adolescents in urban areas to attain it earlier than their counterparts did a decade or two ago. Gay and lesbian communities exist in large cities, along with specialized interest groups, social clubs, religious groups, newspapers, and periodicals. But teenagers in small towns and rural areas may have difficulty meeting other homosexuals and finding a supportive environment. These adolescents have a special need for caring adults and peers who can help them find self- and social acceptance.

© MARILYN HUMPHRIES/THE IMAGE WORKS

Lesbian, gay, bisexual, and transgender high school students and their allies participate in an annual Youth Pride Festival and March. When peers react with acceptance, coming out strengthens the young person’s view of homosexuality as a valid and fulfilling identity.

Lesbian, gay, and bisexual teenagers who succeed in coming out to themselves and others integrate their sexual orientation into a broader sense of identity, a process we will address in Chapter 12. As a result, energy is freed for other aspects of psychological growth. In sum, coming out can foster many facets of adolescent development, including self-esteem, psychological well-being, and relationships with family and friends.

Europe (Centers for Disease Control and Prevention, 2011d). Teenagers at greatest risk are the same ones most likely to engage in irresponsible sexual behavior: poverty-stricken young people who feel a sense of hopelessness (Niccolai et al., 2004). Left untreated, STDs can lead to sterility and life-threatening complications.

By far the most serious STD is AIDS. In contrast to other Western nations, where the incidence of AIDS among people under age 30 is low, about 15 percent of U.S. AIDS cases occur in young people between ages 20 and 29. Because AIDS symptoms typically do not emerge until 8 to 10 years after infection with the HIV virus, nearly all these cases originated in adolescence. Drug-abusing teenagers who share needles and male adolescents who have sex with HIV-positive same-sex partners account for most cases, but heterosexual spread of the disease remains high, especially among teenagers with more than one partner in the previous 18 months. It is at least twice as easy for a male to infect a female with any STD, including HIV,

as for a female to infect a male. Currently, females account for about 25 percent of new U.S. cases among adolescents and young adults (Centers for Disease Control and Prevention, 2011b).

As a result of school courses and media campaigns, most adolescents are aware of basic facts about AIDS. But they have limited understanding of other STDs, tend to underestimate their own susceptibility, and are poorly informed about how to protect themselves (Copen, Chandra, & Martinez, 2012; Ethier et al., 2003; Centers for Disease Control and Prevention, 2007).

Furthermore, high school students report engaging in oral sex as early and about as often as intercourse. But few report consistently using STD protection during oral sex, which is a significant mode of transmission of several STDs (Copen, Chandra, & Martinez, 2012). Concerted efforts are needed to educate young people about the full range of STDs and risky sexual behaviors.

Adolescent Pregnancy and Parenthood

Cassie didn't get pregnant after having sex with Louis, but some of her classmates were less fortunate. About 727,000 U.S. teenage girls (12,000 of them younger than age 15)—an estimated 20 percent of those who had sexual intercourse—became pregnant in the most recently reported year. Despite a decline of almost one-half since 1990, the U.S. adolescent pregnancy rate remains higher than that of most other industrialized countries (Ventura, Curtin, & Abma, 2012). Three factors heighten the incidence of adolescent pregnancy: (1) Effective sex education reaches too few teenagers; (2) convenient, low-cost contraceptive services for adolescents are scarce; and (3) many families live in poverty, which encourages young people to take risks without considering the future implications of their behavior.

Because about one-fourth of U.S. adolescent pregnancies end in abortion, the number of American teenage births is considerably lower than it was 50 years ago (Ventura, Curtin, & Abma, 2012). Still, it is up to nine times higher than in most other developed nations (see Figure 11.6). But teenage parenthood is a much greater problem today because adolescents are far less likely to marry before childbirth. In 1960, only 15 percent of teenage births were to unmarried females, compared with 87 percent today (Child Trends, 2011). Increased social acceptance of single motherhood, along with the belief of many teenage girls that a baby might fill a void in their lives, means that very few girls give up their infants for adoption.

FIGURE 11.6 Birth rates among 15- to 19-year-olds in 15 industrialized nations. The U.S. adolescent birth rate greatly exceeds that of most other industrialized nations. (From Centers for Disease Control and Prevention, 2011c.)

Correlates and Consequences of Adolescent Parenthood. Becoming a parent is especially challenging for adolescents, who have not yet established a clear sense of direction for their own lives. Life conditions and personal attributes jointly contribute to adolescent childbearing and also interfere with teenagers' capacity to parent effectively.

Teenage parents are far more likely to be poor than age-mates who postpone parenthood. Their backgrounds often include low parental warmth and involvement, domestic violence and child abuse, repeated parental divorce and remarriage, adult models of unmarried parenthood, and residence in neighborhoods where other adolescents also display these risks. Girls at risk for early pregnancy do poorly in school, engage in alcohol and drug use, have a childhood history of aggressive and anti-social behavior, associate with deviant peers, and experience high rates of depression (Elfenbein & Felice, 2003; Hillis et al., 2004; Luster & Haddow, 2005). A high percentage of out-of-wedlock births are to low-income ethnic minority teenagers. Many turn to early parenthood as a way to move into adulthood when educational and career avenues are unavailable.

The lives of expectant teenagers, already troubled in many ways, tend to worsen in several respects after the baby is born:

- **Educational attainment.** Parenthood before age 18 reduces the likelihood of finishing high school. Only about 70 percent of U.S. adolescent mothers graduate, compared with 95 percent of girls who wait to become parents (National Women's Law Center, 2007).
- **Marital patterns.** Teenage motherhood reduces the chances of marriage and, for those who do marry, increases the likelihood of divorce compared with peers who delay childbearing (Moore & Brooks-Gunn, 2002). Consequently, teenage mothers spend more of their parenting years as single parents. About 35 percent become pregnant again within two years. Of these, about half go on to deliver a second child (Child Trends, 2011).
- **Economic circumstances.** Because of low educational attainment, marital instability, and poverty, many teenage mothers are on welfare or work in unsatisfying, low-paid jobs. Similarly, many adolescent fathers are unemployed or earn too little to provide their children with basic necessities (Bunting & McAuley, 2004). An estimated 50 percent have committed illegal offenses resulting in imprisonment (Elfenbein & Felice, 2003). And for both mothers and fathers, reduced educational and occupational attainment often persists well into adulthood (Taylor, 2009).

Because many pregnant teenage girls have inadequate diets, smoke, use alcohol and other drugs, and do not receive early prenatal care, their babies often experience pregnancy and birth complications—especially preterm and low birth weight (Khashan, Baker, & Kenny, 2010). And compared with adult mothers, adolescent mothers know less about child development, have unrealistically high expectations of infants, perceive their babies as more difficult, interact less effectively with them, and more often engage in child abuse (Moore & Florsheim, 2001;

Pomerleau, Scuccimarri, & Malcuit, 2003; Sieger & Renk, 2007). Their children tend to score low on intelligence tests, achieve poorly in school, and engage in disruptive social behavior.

Furthermore, adolescent parenthood frequently is repeated in the next generation (Brooks-Gunn, Schley, & Hardy, 2002). In longitudinal studies that followed mothers—some who gave birth as teenagers, others who postponed parenting—and their children for several decades, mothers' age at first childbirth strongly predicted the age at which their daughters and sons became parents. The researchers found that adolescent parenthood was linked to a set of related unfavorable family conditions and personal characteristics that negatively influenced development over an extended time and, therefore, often transferred to the next generation. Among influential factors was father absence (Barber, 2001a; Campa & Eckenrode, 2006; Meade, Kershaw, & Ickovics, 2008). Consistent with findings reported earlier for sexual activity and pregnancy, far greater intergenerational continuity, especially for daughters, occurred when teenage mothers remained unmarried.

Even when children born to teenage mothers do not become early childbearers, their development is often compromised, in terms of likelihood of high school graduation, financial independence in adulthood, and long-term physical and mental health (Moore, Morrison, & Greene, 1997; Pogarsky, Thornberry, & Lizotte, 2006). Still, outcomes vary widely. If a teenage parent finishes high school, secures gainful employment, avoids additional births, and finds a stable partner, long-term disruptions in her own and her child's development will be less severe.

Prevention Strategies. Preventing teenage pregnancy means addressing the many factors underlying early sexual activity and lack of contraceptive use. Too often, sex education courses are given late (after sexual activity has begun), last only a few sessions, and are limited to a catalog of facts about anatomy and reproduction. Sex education that goes beyond this minimum does not encourage early sex, as some opponents claim (Kirby, 2002c). It does improve awareness of sexual facts—knowledge that is necessary for responsible sexual behavior.

Knowledge, however, is not enough: Sex education must also help teenagers build a bridge between what they know and what they do. Effective sex education programs include several key elements:

- They teach techniques for handling sexual situations—including refusal skills for avoiding risky sexual behaviors and communication skills for improving contraceptive use—through role-playing and other activities.
- They deliver clear, accurate messages that are appropriate in view of participating adolescents' culture and sexual experiences.
- They last long enough to have an impact.
- They provide specific information about contraceptives and ready access to them.

Many studies show that sex education with these components can delay the initiation of sexual activity, reduce the frequency of sex and the number of sexual partners, increase contraceptive use, change attitudes (for example, strengthen future orientation), and reduce pregnancy rates (Kirby, 2002b; Kirby & Laris, 2009; Thomas & Dimitrov, 2007).

LOOK AND LISTEN

Contact a nearby public school district for information about its sex education curriculum. Considering research findings, do you think it is likely to be effective in delaying initiation of sexual activity and reducing adolescent pregnancy rates? ●

Proposals to increase access to contraceptives are the most controversial aspect of U.S. adolescent pregnancy prevention efforts. Many adults argue that placing birth control pills or condoms in the hands of teenagers is equivalent to approving of early sex. Yet sex education programs encouraging abstinence without encouraging contraceptive use have little or no impact on delaying teenage sexual activity or preventing pregnancy (Rosenbaum, 2009; Underhill, Montgomery, & Operario, 2007). In Canada and Western Europe, where community- and school-based clinics offer adolescents contraceptives and where universal health insurance helps pay for them, teenage sexual activity is no higher than in the United States—but pregnancy, childbirth, and abortion rates are much lower (Schalet, 2007).

Efforts to prevent adolescent pregnancy and parenthood must go beyond improving sex education and access to contraception to build academic and social competence (Allen, Seitz, & Apfel, 2007). In one study, researchers randomly assigned at-risk high school students either to a year-long community service class, called Teen Outreach, or to regular classroom experiences in health or social studies. In Teen Outreach, adolescents spent at least 20 hours per week in volunteer work tailored to their interests. They returned to school for discussions that focused on enhancing their community service skills and their ability to cope with everyday challenges. At the end of the school year, rates of pregnancy, school failure, and school suspension were substantially lower among participants in Teen Outreach, which fostered social skills, connection to the community, and self-respect (Allen et al., 1997).

Finally, teenagers who look forward to a promising future are far less likely to engage in early and irresponsible sex. By expanding educational, vocational, and employment opportunities, society can give young people good reasons to postpone childbearing.

Intervening with Adolescent Parents. The most difficult and costly way to deal with adolescent parenthood is to wait until it happens. Young parents need health care, encouragement to stay in school, job training, instruction in parenting and life-management skills, and high-quality, affordable child care. Schools that provide these services reduce the incidence of low-birth-weight babies, increase educational success, and prevent additional childbearing (Key et al., 2008; Seitz & Apfel, 2005).

Early parenthood imposes lasting hardships on adolescent parents and their newborn babies. But the involvement of a caring father and a stable partnership between the parents can improve outcomes for young families.

Adolescent mothers also benefit from relationships with family members and other adults who are sensitive to their developmental needs. In one study, African-American teenage mothers who had a long-term “mentor” relationship—an aunt, neighbor, or teacher who provided emotional support and guidance—were far more likely than those without a mentor to stay in school and graduate (Klaw, Rhodes, & Fitzgerald, 2003). Home visiting programs are also effective. Return to page 94 in Chapter 3 to review the Nurse–Family Partnership, which helps launch teenage mothers and their babies on a favorable life course.

Programs focusing on fathers attempt to increase their financial and emotional commitment to the baby. Although nearly half of young fathers visit their children during the first few years, contact usually diminishes. By the time the child starts school, fewer than one-fourth have regular paternal contact. As with teenage mothers, support from family members helps fathers stay involved (Bunting & McAuley, 2004). Teenage mothers who receive financial and child-care assistance and emotional support from their child’s father are less distressed and more likely to sustain a relationship with him (Cutrona et al., 1998; Gee & Rhodes, 2003). And infants with lasting ties to their teenage fathers show better long-term adjustment (Florsheim & Smith, 2005; Furstenberg & Harris, 1993).

Substance Use and Abuse

At age 14, Louis waited until he was alone at home, took some cigarettes from his uncle’s pack, and smoked. At an unchaperoned party, he and Cassie drank several cans of beer and lit up marijuana joints. Louis got little physical charge out of these experiences. A good student, who was well-liked by peers and

got along well with his parents, he did not need drugs as an escape valve. But he knew of other teenagers who started with alcohol and cigarettes, moved on to harder substances, and eventually were hooked.

Teenage alcohol and drug use is pervasive in industrialized nations. According to the most recent nationally representative survey of U.S. high school students, by tenth grade, 33 percent of U.S. young people have tried cigarette smoking, 58 percent drinking, and 37 percent at least one illegal drug (usually marijuana). At the end of high school, 11 percent smoke cigarettes regularly, and 27 percent have engaged in heavy drinking during the past month. About 25 percent have tried at least one highly addictive and toxic substance, such as amphetamines, cocaine, phencyclidine (PCP), Ecstasy (MDMA), inhalants, heroin, sedatives (including barbiturates), or OxyContin (a narcotic painkiller) (Johnston et al., 2011).

These figures represent a substantial decline since the mid-1990s, probably resulting from greater parent, school, and media focus on the hazards of drug use. But use of marijuana, inhalants, sedatives, and OxyContin has risen slightly in recent years (Johnston et al., 2011). Other drugs, such as LSD, PCP, and Ecstasy, have made a comeback as adolescents’ knowledge of their risks faded.

In part, drug taking reflects the sensation seeking of the teenage years. But adolescents also live in drug-dependent cultural contexts. They see adults relying on caffeine to stay alert, alcohol and cigarettes to cope with daily hassles, and other remedies to relieve stress, depression, and physical discomfort. And compared to a decade or two ago, today doctors more often prescribe—and parents frequently seek—medication to treat children’s problems (Olfman & Robbins, 2012). In adolescence, these young people may readily “self-medicate” when stressed.

Most teenagers who dabble in alcohol, tobacco, and marijuana are not headed for a life of addiction. These *minimal experimenters* are usually psychologically healthy, sociable, curious young people (Shedler & Block, 1990). As Figure 11.7 shows, tobacco and alcohol use is somewhat greater among European than U.S. adolescents, perhaps because European adults more often smoke and drink. But illegal drug use is far more prevalent among U.S. teenagers. A greater percentage of American young people live in poverty, which is linked to family and peer contexts that promote illegal drug use. At the same time, use of diverse drugs is lower among African Americans than among Hispanic and Caucasian Americans; Native-American youths rank highest in drug taking (Johnston et al., 2011). Researchers have yet to explain these variations.

Adolescent experimentation with any drug should not be taken lightly. Because most drugs impair perception and thought processes, a single heavy dose can lead to permanent injury or death. And a worrisome minority of teenagers move from substance *use* to *abuse*—taking drugs regularly, requiring increasing amounts to achieve the same effect, moving on to harder substances, and using enough to interfere with their ability to meet daily responsibilities.

FIGURE 11.7 Tenth-grade students in the United States and Europe who have used various substances. Rates for tobacco and alcohol are based on any use in the past 30 days. Rates for marijuana and other illegal drugs are based on any lifetime use. Tobacco use and alcohol use are greater for European adolescents, whereas illegal drug use is greater for U.S. adolescents. (Adapted from ESPAD, 2012; Johnson et al., 2011.)

Correlates and Consequences of Adolescent Substance Abuse.

Unlike experimenters, drug abusers are seriously troubled young people. Their impulsive, disruptive, hostile style is often evident in early childhood, and they are inclined to express their unhappiness through antisocial acts. Compared with other young people, their drug taking starts earlier and may have genetic roots (Dick, Prescott, & McGue, 2008; Tarter, Vanyukov, & Kirisci, 2008). But environmental factors also contribute. These include low SES, family mental health problems, parental and older sibling drug abuse, lack of parental warmth and involvement, physical and sexual abuse, and poor school performance. Especially among teenagers with family difficulties, encouragement from friends who use and provide drugs increases substance abuse (Ohannessian & Hesselbrock, 2008; U.S. Department of Health and Human Services, 2010c).

Introducing drugs while the adolescent brain is still a work-in-progress can have profound, lasting consequences, impairing neurons and their connective networks. At the same time, teenagers who use substances to deal with daily stresses fail to learn responsible decision-making skills and alternative coping techniques. They show serious adjustment problems, including chronic anxiety, depression, and antisocial behavior, that are both cause and consequence of heavy drug taking (Kassel et al., 2005; U.S. Department of Health and Human Services, 2010c). And they often enter into marriage, childbearing, and the work world prematurely and fail at them—painful outcomes that further promote addictive behavior.

Prevention and Treatment. School and community programs that reduce drug experimentation typically combine several components:

- They promote effective parenting, including monitoring of teenagers' activities.
- They teach skills for resisting peer pressure.
- They reduce the social acceptability of drug taking by emphasizing health and safety risks (Cuijpers, 2002; Stephens et al., 2009).

But given that adolescent drug taking is widespread, interventions that prevent teenagers from harming themselves and others when they do experiment are essential. Many communities offer weekend on-call transportation services that any young person can contact for a safe ride home, with no questions asked.

Because drug abuse has different roots than occasional use, different prevention strategies are required. One approach is to work with parents early, reducing family adversity and improving parenting skills, before children are old enough for drug involvement (Velleman, Templeton, & Copello, 2005). Programs that teach at-risk teenagers effective strategies for handling life stressors and that build competence through community service reduce alcohol and drug abuse, just as they reduce teenage pregnancy.

When an adolescent becomes a drug abuser, family and individual therapy are generally needed to treat maladaptive parent–child relationships, impulsivity, low self-esteem, anxiety, and depression. Academic and vocational training to improve life success also helps. But even comprehensive programs have alarmingly high relapse rates—from 35 to 85 percent (Brown & Ramo, 2005; Sussman, Skara, & Ames, 2008). One recommendation is to start treatment gradually, through support-group sessions that focus on reducing drug taking (Myers et al., 2001). Modest improvements may increase young people's motivation to make longer-lasting changes through intensive treatment.

COGNITIVE DEVELOPMENT

One mid-December evening, a knock at the front door announced the arrival of Franca and Antonio's oldest son, Jules, home for vacation after the fall semester of his sophomore year at college. The family gathered around the kitchen table. "How did it all go, Jules?" asked Antonio as he served slices of apple pie.

"Well, physics and philosophy were awesome," Jules responded with enthusiasm. "The last few weeks, our physics prof introduced us to Einstein's theory of relativity. Boggles my mind, it's so incredibly counterintuitive."

"Counter-what?" asked 11-year-old Sabrina.

"Counterintuitive. Unlike what you'd normally expect," explained Jules. "Imagine you're on a train, going unbelievably fast, like 160,000 miles a second. The faster you go, approaching the speed of light, the slower time passes and the denser and heavier things get relative to on the ground. The theory revolutionized the way we think about time, space, matter—the entire universe."

Sabrina wrinkled her forehead, baffled by Jules's otherworldly reasoning. "Time slows down when I'm bored, like right now, not on a train when I'm going somewhere exciting. No speeding train ever made me heavier, but this apple pie will if I eat any more of it," Sabrina announced, leaving the table.

Sixteen-year-old Louis reacted differently. "Totally cool, Jules. So what'd you do in philosophy?"

"It was a course in philosophy of technology. We studied the ethics of futuristic methods in human reproduction. For example, we argued the pros and cons of a world in which all embryos develop in artificial wombs."

"What do you mean?" asked Louis. "You order your kid at the lab?"

"That's right. I wrote my term paper on it. I had to evaluate it in terms of principles of justice and freedom. I can see some advantages but also lots of dangers. . . ."

As this conversation illustrates, adolescence brings with it vastly expanded powers of reasoning. At age 11, Sabrina finds it difficult to move beyond her firsthand experiences to a world of possibilities. Over the next few years, her thinking will acquire the complex qualities that characterize the cognition of her older brothers. Jules and Louis consider multiple variables simultaneously and think about situations that are not easily detected in the real world or that do not exist at all. As a result, they can grasp advanced scientific and mathematical principles and grapple with social and political issues. Compared with school-age children's thinking, adolescent thought is more enlightened, imaginative, and rational.

Systematic research on adolescent cognitive development began with testing of Piaget's ideas (Kuhn, 2009). Recently, information-processing research has greatly enhanced our understanding.

Piaget's Theory: The Formal Operational Stage

According to Piaget, around age 11 young people enter the **formal operational stage**, in which they develop the capacity for abstract, systematic, scientific thinking. Whereas concrete operational children can "operate on reality," formal operational adolescents can "operate on operations." They no longer require concrete things or events as objects of thought. Instead, they can come up with new, more general logical rules through internal reflection (Inhelder & Piaget, 1955/1958). Let's look at two major features of the formal operational stage.

Hypothetico-Deductive Reasoning

Piaget believed that at adolescence, young people first become capable of **hypothetico-deductive reasoning**. When faced with a problem, they start with a *hypothesis*, or prediction about variables that might affect an outcome, from which they *deduce* logical, testable inferences. Then they systematically isolate and combine variables to see which of these inferences are confirmed in the real world. Notice how this form of problem solving begins with possibility and proceeds to reality. In contrast, concrete operational children start with reality—with the most obvious predictions about a situation. If these are not confirmed, they usually cannot think of alternatives and fail to solve the problem.

Adolescents' performance on Piaget's famous *pendulum problem* illustrates this approach. Suppose we present several school-age children and adolescents with strings of different lengths, objects of different weights to attach to the strings, and a bar from which to hang the strings (see Figure 11.8). Then we ask each of them to figure out what influences the speed with which a pendulum swings through its arc.

Formal operational adolescents hypothesize that four variables might be influential: (1) the length of the string, (2) the weight of the object hung on it, (3) how high the object is raised before it is released, and (4) how forcefully the object is pushed.

FIGURE 11.8 Piaget's pendulum problem. Adolescents who engage in hypothetico-deductive reasoning think of variables that might possibly affect the speed with which a pendulum swings through its arc. Then they isolate and test each variable, as well as testing the variables in combination. Eventually they deduce that the weight of the object, the height from which it is released, and how forcefully it is pushed have no effect on the speed with which the pendulum swings through its arc. Only string length makes a difference.

By varying one factor at a time while holding the other three constant, they test each variable separately and, if necessary, also in combination. Eventually they discover that only string length makes a difference.

In contrast, concrete operational children cannot separate the effects of each variable. They may test for the effect of string length without holding weight constant—comparing, for example, a short, light pendulum with a long, heavy one. Also, they typically fail to notice variables that are not immediately suggested by the concrete materials of the task—for example, how high the object is raised or how forcefully it is released.

Propositional Thought

A second important characteristic of Piaget's formal operational stage is **propositional thought**—adolescents' ability to evaluate the logic of propositions (verbal statements) without referring to real-world circumstances. In contrast, children can evaluate the logic of statements only by considering them against concrete evidence in the real world.

In a study of propositional reasoning, a researcher showed children and adolescents a pile of poker chips and asked whether statements about the chips were true, false, or uncertain (Osherson & Markman, 1975). In one condition, the researcher hid a chip in her hand and presented the following propositions:

*"Either the chip in my hand is green or it is not green."
"The chip in my hand is green and it is not green."*

In another condition, the experimenter made the same statements while holding either a red or a green chip in full view.

School-age children focused on the concrete properties of the poker chips. When the chip was hidden, they replied that they were uncertain about both statements. When it was visible, they judged both statements to be true if the chip was green and false if it was red. In contrast, adolescents analyzed the logic of the statements. They understood that the "either-or" statement is always true and the "and" statement is always false, regardless of the poker chip's color.

Although Piaget did not view language as playing a central role in children's cognitive development (see Chapter 7), he acknowledged its importance in adolescence. Formal operations require language-based and other symbolic systems that do not stand for real things, such as those in higher mathematics. Secondary school students use such systems in algebra and geometry. Formal operational thought also involves verbal reasoning about abstract concepts. Jules was thinking in this way when he pondered relationships among time, space, and matter in physics and wondered about justice and freedom in philosophy.

Follow-Up Research on Formal Operational Thought

Research on formal operational thought poses questions similar to those we discussed with respect to Piaget's earlier stages: Does formal operational thinking appear earlier than Piaget expected? Do all individuals reach formal operations during their teenage years?

Are Children Capable of Hypothetico-Deductive and Propositional Thinking?

School-age children show the glimmerings of hypothetico-deductive reasoning, although they are less competent at it than adolescents. In simplified situations involving no more than two possible causal variables, 6-year-olds understand that hypotheses must be confirmed by appropriate evidence (Ruffman et al., 1993). But school-age children cannot sort out evidence that bears on three or more variables at once. And as we will see when we take up information-processing research, children have difficulty explaining why a pattern of observations supports a hypothesis, even when they recognize the connection between the two.

With respect to propositional thought, when a simple set of premises defies real-world knowledge ("All cats bark. Rex is a cat. Does Rex bark?"), 4- to 6-year-olds can reason logically in make-believe play. To justify their answer, they are likely to say, "We can pretend cats bark!" (Dias & Harris, 1988, 1990). But in an entirely verbal mode, children have great difficulty reasoning from premises that contradict reality or their own beliefs.

Consider this set of statements: "If dogs are bigger than elephants and elephants are bigger than mice, then dogs are bigger than mice." Children younger than 10 judge this reasoning to be false because some of the relations specified do not occur in real life (Moshman & Franks, 1986; Pillow, 2002). They have more difficulty than adolescents inhibiting activation of well-learned knowledge ("Elephants are larger than dogs") that impedes effective reasoning (Klaczynski, Schuneman, & Daniel,

© CINDY CHARLES/PHOTODEBIT

As these students discuss problems in a social studies class, they reason logically from premises that do not refer to real-world circumstances. They are far better at propositional thought than they were as children.

2004; Simoneau & Markovits, 2003). Partly for this reason, they fail to grasp the *logical necessity* of propositional reasoning—that the accuracy of conclusions drawn from premises rests on the rules of logic, not on real-world confirmation.

As with hypothetico-deductive reasoning, in early adolescence, young people become better at analyzing the *logic* of propositions irrespective of their *content*. And as they get older, they handle problems requiring increasingly complex mental operations. In justifying their reasoning, they more often explain the logical rules on which it is based (Müller, Overton, & Reese, 2001; Venet & Markovits, 2001). But these capacities do not appear suddenly at puberty. Rather, gains occur gradually from childhood on—findings that call into question the emergence of a new stage of cognitive development at adolescence (Kuhn, 2009; Moshman, 2005).

Do All Individuals Reach the Formal Operational Stage? TAKE A MOMENT... Try giving one or two of the formal operational tasks just described to your friends. How well do they do? Even well-educated adults often have difficulty (Kuhn, 2009; Markovits & Vachon, 1990).

Why are so many adults not fully formal operational? One reason is that people are most likely to think abstractly and systematically on tasks in which they have had extensive guidance and practice in using such reasoning. This conclusion is supported by evidence that taking college courses leads to improvements in formal reasoning related to course content. Math and science prompt gains in propositional thought, social science in methodological and statistical reasoning (Lehman & Nisbett, 1990). Like concrete reasoning in children, formal operations do not emerge in all contexts at once but are specific to situation and task (Keating, 2004).

Individuals in tribal and village societies rarely do well on tasks typically used to assess formal operational reasoning (Cole, 1990). Piaget acknowledged that without the opportunity to solve hypothetical problems, people in some societies might not display formal operations. Still, researchers ask, Does formal operational thought largely result from children's and

adolescents' independent efforts to make sense of their world, as Piaget claimed? Or is it a culturally transmitted way of thinking that is specific to literate societies and taught in school? In an Israeli study, after controlling for participants' age, researchers found that years of schooling fully accounted for early adolescent gains in propositional thought (Artman, Cahan, & Avni-Babad, 2006). School tasks, the investigators speculated, provide crucial experiences in setting aside the "if . . . then" logic of everyday conversations that is often used to convey intentions, promises, and threats ("If you don't do your chores, then you won't get your allowance") but that conflicts with the logic of academic reasoning. In school, then, adolescents encounter rich opportunities to realize their neurological potential to think more effectively.

An Information-Processing View of Adolescent Cognitive Development

Information-processing theorists refer to a variety of specific mechanisms, including diverse aspects of executive function, as underlying cognitive gains in adolescence. Each was discussed in previous chapters (Kuhn, 2009; Kuhn & Franklin, 2006; Luna et al., 2004). Now let's draw them together:

- *Attention* becomes more selective (focused on relevant information) and better-adapted to the changing demands of tasks.
- *Inhibition*—both of irrelevant stimuli and of well-learned responses in situations where they are inappropriate—improves, supporting gains in attention and reasoning.
- *Strategies* become more effective, improving storage, representation, and retrieval of information.
- *Knowledge* increases, easing strategy use.
- *Metacognition* (awareness of thought) expands, leading to new insights into effective strategies for acquiring information and solving problems.
- *Cognitive self-regulation* improves, yielding better moment-by-moment monitoring, evaluation, and redirection of thinking.
- *Speed of thinking* and *processing capacity* increase. As a result, more information can be held at once in working memory and combined into increasingly complex, efficient representations, "opening possibilities for growth" in the capacities just listed and also improving as a result of gains in those capacities (Demetriou et al., 2002, p. 97).

As we look at influential findings from an information-processing perspective, we will see some of these mechanisms of change in action. And we will discover that researchers regard one of them—*metacognition*—as central to adolescent cognitive development.

Scientific Reasoning: Coordinating Theory with Evidence

During a free moment in physical education class, Sabrina wondered why more of her tennis serves and returns passed the net and dropped into her opponent's court when she used a particular brand of balls. "Is it something about their color or size?" she asked herself. "Hmm . . . or maybe it's their surface texture—that might affect their bounce."

The heart of scientific reasoning is coordinating theories with evidence. Deanna Kuhn (2002) has conducted extensive research into the development of scientific reasoning, using problems that, like Piaget's tasks, involve several variables that might affect an outcome. In one series of studies, third, sixth, and ninth graders and adults were first given evidence—sometimes consistent and sometimes conflicting with theories—and then questioned about the accuracy of each theory.

For example, participants were given a problem much like Sabrina's: to theorize about which of several features of sports balls—size (large or small), color (light or dark), texture (rough or smooth), or presence or absence of ridges on the surface—influences the quality of a player's serve. Next, they were told about the theory of Mr. (or Ms.) S, who believes that the ball's size is important, and the theory of Mr. (or Ms.) C, who thinks color matters. Finally, the interviewer presented evidence by placing balls with certain characteristics in two baskets, labeled "good serve" and "bad serve" (see Figure 11.9).

The youngest participants often discounted obviously causal variables, ignored evidence conflicting with their own

initial judgments, and distorted evidence in ways consistent with their preferred theory. These findings, and others like them, suggest that on complex, multivariable tasks, children—instead of viewing evidence as separate from and bearing on a theory—often blend the two into a single representation of "the way things are." Children are especially likely to overlook evidence that does not match their prior beliefs when a causal variable is implausible (like color affecting the performance of a sports ball) and when task demands (number of variables to be evaluated) are high (Yang & Tsai, 2010; Zimmerman, 2007). The ability to distinguish theory from evidence and use logical rules to examine their relationship improves steadily from childhood into adolescence, continuing into adulthood (Kuhn & Dean, 2004; Kuhn & Pearsall, 2000).

How Scientific Reasoning Develops

What factors support skill at coordinating theory with evidence? Greater working-memory capacity, permitting a theory and the effects of several variables to be compared at once, is vital. Adolescents also benefit from exposure to increasingly complex problems and to teaching that highlights critical features of scientific reasoning—for example, why a scientist's expectations in a particular situation are inconsistent with everyday beliefs and experiences (Chinn & Malhotra, 2002). This explains why scientific reasoning is strongly influenced by years of schooling, whether individuals grapple with traditional scientific tasks (like the sports-ball problem) or engage in informal reasoning—for example, justifying a theory about what causes children to fail in school (Amsel & Brock, 1996).

Researchers believe that sophisticated *metacognitive understanding* is vital for scientific reasoning (Kuhn, 2009; Kuhn & Pease, 2006). When adolescents regularly pit theory against evidence over many weeks, they experiment with various strategies, reflect on and revise them, and become aware of the nature of logic. Then they apply their appreciation of logic to an increasingly wide variety of situations. The ability to *think about theories*, *deliberately isolate* variables, *consider all influential* variables, and *actively seek* disconfirming evidence is rarely present before adolescence (Kuhn, 2000; Kuhn et al., 2008; Moshman, 1998).

But adolescents and adults vary widely in scientific reasoning skills. Many continue to show a self-serving bias, applying logic more effectively to ideas they doubt than to ideas they favor (Klaczynski & Narasimham, 1998). Reasoning scientifically requires the metacognitive capacity to evaluate one's objectivity—to be fair-minded rather than self-serving (Moshman, 2005). As we will see in Chapter 12, this flexible, open-minded approach is not just a cognitive attainment but a personality trait—one that assists teenagers greatly in forming an identity and developing morally.

Adolescents develop scientific reasoning skills in a similar step-by-step fashion on different types of tasks. In a series of studies, 10- to 20-year-olds were given sets of problems graded in difficulty. One set consisted of quantitative-relational tasks like the pendulum problem in Figure 11.8. Another contained

FIGURE 11.9 Which features of these sports balls—size, color, surface texture, or presence or absence of ridges—influence the quality of a player's serve? This set of evidence suggests that color might be important, since light-colored balls are largely in the good-serve basket and dark-colored balls in the bad-serve basket. But the same is true for texture! The good-serve basket has mostly smooth balls; the bad-serve basket, rough balls. Since all light-colored balls are smooth and all dark-colored balls are rough, we cannot tell whether color or texture makes a difference. But we can conclude that size and presence or absence of ridges are not important, since these features are equally represented in the good-serve and bad-serve baskets. (Adapted from Kuhn, Amsel, & O'Loughlin, 1988.)

Applying What We Know

Handling Consequences of Teenagers' New Cognitive Capacities

Thought expressed as . . .	Suggestion
Sensitivity to public criticism	Refrain from finding fault with the adolescent in front of others. If the matter is important, wait until you can speak to the teenager alone.
Exaggerated sense of personal uniqueness	Acknowledge the adolescent's unique characteristics. At opportune times, encourage a more balanced perspective by pointing out that you had similar feelings as a teenager.
Idealism and criticism	Respond patiently to the adolescent's grand expectations and critical remarks. Point out positive features of targets, helping the teenager see that all societies and people are blends of virtues and imperfections.
Difficulty making everyday decisions	Refrain from deciding for the adolescent. Model effective decision making and offer diplomatic suggestions about the pros and cons of alternatives, the likelihood of various outcomes, and learning from poor choices.

propositional tasks like the poker chip problem on page 384. Still another consisted of causal-experimental tasks like the sports-ball problem in Figure 11.9 (Demetriou et al., 1993, 1996, 2002). In each type of task, adolescents mastered component skills in sequential order by expanding their metacognitive awareness. For example, on causal-experimental tasks, they first became aware of the many variables—separately and in combination—that could influence an outcome. This enabled them to formulate and test hypotheses. Over time, adolescents combined separate skills into a smoothly functioning system, constructing a general model that they could apply to many instances of a given type of problem.

LOOK AND LISTEN

Describe one or more memorable experiences from your high school classes that helped you advance in scientific reasoning—pit theory against evidence and become receptive to disconfirming evidence even for theories you favored. ●

Piaget underscored the role of metacognition in formal operational thought when he spoke of “operating on operations” (see page 382). But information-processing findings confirm that scientific reasoning does not result from an abrupt, stagewise change. Instead, it develops gradually out of many specific experiences that require children and adolescents to match theories against evidence and reflect on and evaluate their thinking.

Consequences of Adolescent Cognitive Changes

The development of increasingly complex, effective thinking leads to dramatic revisions in the way adolescents see themselves, others, and the world in general. But just as adolescents are occasionally awkward in using their transformed bodies,

so they initially falter in their abstract thinking. Teenagers' self-concern, idealism, criticism, and faulty decision making, though perplexing to adults, are usually beneficial in the long run. Applying What We Know above suggests ways to handle the everyday consequences of teenagers' newfound cognitive capacities.

Self-Consciousness and Self-Focusing

Adolescents' ability to reflect on their own thoughts, combined with physical and psychological changes, leads them to think more about themselves. Piaget believed that a new form of egocentrism arises, in which adolescents again have difficulty distinguishing their own and others' perspectives (Inhelder & Piaget, 1955/1958). Piaget's followers suggest that two distorted images of the relation between self and other appear.

The first is called the **imaginary audience**, adolescents' belief that they are the focus of everyone else's attention and concern (Elkind & Bowen, 1979). As a result, they become extremely self-conscious. The imaginary audience helps explain why adolescents spend long hours inspecting every detail of their appearance and why they are so sensitive to public criticism. To teenagers, who believe that everyone is monitoring their performance, a critical remark from a parent or teacher can be mortifying.

A second cognitive distortion is the **personal fable**. Certain that others are observing and thinking about them, teenagers develop an inflated opinion of their own importance—a feeling that they are special and unique. Many adolescents view themselves as reaching great heights of omnipotence and also sinking to unusual depths of despair—experiences that others cannot possibly understand (Elkind, 1994). One teenager wrote in her diary, “My parents' lives are so ordinary, so stuck in a rut. Mine will be different. I'll realize my hopes and ambitions.” Another, upset when a boyfriend failed to return her affections, rebuffed her mother's comforting words: “Mom, you don't know what it's like to be in love!”

ANTONIO MO/PHOTODISC/GETTY IMAGES

This teenager's swagger reflects self-confidence and delight that all eyes are on him. When the personal fable engenders a view of oneself as highly capable and influential, it may help young people cope with the challenges of adolescence.

Although imaginary-audience and personal-fable ideation is common in adolescence, these distorted visions of the self do not result from egocentrism, as Piaget suggested. Rather, they are partly an outgrowth of advances in perspective taking, which cause young teenagers to be more concerned with what others think (Vartanian & Powlishta, 1996).

In fact, certain aspects of the imaginary audience may serve positive, protective functions. When asked why they worry about the opinions of others, adolescents responded that others' evaluations have important *real* consequences—for self-esteem, peer acceptance, and social support (Bell & Bromnick, 2003). The idea that others care about their appearance and behavior also has emotional value, helping teenagers hold onto important relationships as they struggle to establish an independent sense of self (Vartanian, 1997).

With respect to the personal fable, in a study of sixth through tenth graders, sense of omnipotence predicted self-esteem and overall positive adjustment. Viewing the self as highly capable and influential helps young people cope with challenges of adolescence. In contrast, sense of personal uniqueness was modestly associated with depression and suicidal thinking (Aalsma, Lapsley, & Flannery, 2006). Focusing on the distinctiveness of one's own experiences may interfere with forming close, rewarding relationships, which provide social support in stressful times. And when combined with a sensation-seeking personality, the personal fable seems to contribute to adolescent risk taking by reducing teenagers' sense of vulnerability (Alberts, Elkind, & Ginsberg, 2007). Young people with high personal-fable and sensation-seeking scores tend to take more sexual risks, more often use drugs, and commit more delinquent acts than their age mates (Greene et al., 2000).

Idealism and Criticism

Adolescents' capacity to think about possibilities opens up the world of the ideal. Teenagers can imagine alternative family, religious, political, and moral systems, and they want to explore them. They often construct grand visions of a world with no injustice, discrimination, or tasteless behavior. The disparity between teenagers' idealism and adults' greater realism creates tension between parent and child. Envisioning a perfect family against which their parents and siblings fall short, adolescents become fault-finding critics.

Overall, however, teenage idealism and criticism are advantageous. Once adolescents come to see other people as having both strengths and weaknesses, they have a much greater capacity to work constructively for social change and to form positive, lasting relationships (Elkind, 1994).

Decision Making

Recall that changes in the brain's emotional/social network outpace development of the prefrontal cortex's cognitive-control network. Consequently, teenagers often perform less well than adults in decision making, where they must inhibit emotion and impulses in favor of thinking rationally.

Good decision making involves: (1) identifying the pros and cons of each alternative, (2) assessing the likelihood of various outcomes, (3) evaluating their choice in terms of whether their goals were met and, if not, (4) learning from the mistake and making a better future decision. When researchers modified a card game to trigger strong emotion by introducing immediate feedback about gains and losses after each choice, teenagers behaved more irrationally, taking far greater risks than adults in their twenties (Figner et al., 2009). They were more influenced by the possibility of immediate reward (see page 367).

Nevertheless, teenagers are less effective than adults at decision making even under "cool," unemotional conditions (Huizenga, Crone, & Jansen, 2007). They less often carefully

© JEFF GREENBERG/PHOTOEDIT

These high school students attending a college fair will face many choices over the next few years. But in making decisions, teenagers are less likely than adults, to carefully weigh the pros and cons of each alternative.

evaluate alternatives, instead falling back on well-learned intuitive judgments (Jacobs & Klaczynski, 2002). Consider a hypothetical problem requiring a choice, on the basis of two arguments, between taking a traditional lecture class and taking a computer-based class. One argument contains large-sample information: course evaluations from 150 students, 85 percent of whom liked the computer class. The other argument contains small-sample personal reports: complaints of two honor-roll students who both hated the computer class and enjoyed the traditional class. Most adolescents, even those who knew that selecting the large-sample argument was “more intelligent,” based their choice on the small-sample argument, which resembled the informal opinions they depend on in everyday life (Klaczynski, 2001).

Earlier we noted that processing skills governed by the prefrontal cortex’s cognitive-control system, such as decision making, develop gradually. But like other aspects of brain development, the cognitive-control system is affected by experience (Kuhn, 2009). As “first-timers” in many situations, adolescents do not have sufficient knowledge to consider pros and cons and predict likely outcomes. And after engaging in risky behavior without negative consequences, teenagers rate its benefits higher and its risks lower than peers who have not tried it—judgments that increase the chances of continued risk-taking (Halpern-Felsher et al., 2004).

Over time, young people learn from their successes and failures, gather information from others about factors that affect decision making, and reflect on the decision-making process (Byrnes, 2003; Reyna & Farley, 2006). But because taking risks without experiencing harm can heighten adolescents’ sense of invulnerability, they need supervision and protection from high-risk experiences until their decision making improves.

ASK YOURSELF

Sex Differences in Mental Abilities

Sex differences in mental abilities have sparked almost as much controversy as the ethnic and SES differences in IQ considered in Chapter 9. Although boys and girls do not differ in general intelligence, they do vary in specific mental abilities.

Verbal Abilities

Throughout the school years, girls attain higher scores in reading achievement and account for a lower percentage of children referred for remedial reading instruction. Girls continue to score slightly higher on tests of verbal ability in middle childhood and adolescence in every country in which assessments have been conducted (Bussière, Knighton, & Pennock, 2007; Mullis et al., 2007; Wai et al., 2010). And when verbal tests are heavily weighted with writing, girls’ advantage is large (Halpern et al., 2007).

A special concern is that girls’ advantage in reading and writing achievement increases in adolescence, with boys doing especially poorly in writing—trends evident in the United States and other industrialized nations (OECD, 2010a; U.S. Department of Education, 2007b, 2010). These differences in literacy skills are believed to be major contributors to a widening gender gap in college enrollments. Whereas 40 years ago, males accounted for 60 percent of U.S. undergraduate students, today they are in the minority, at 43 percent (U.S. Department of Education, 2012b).

Recall from Chapter 5 that girls have a biological advantage in earlier development of the left hemisphere of the cerebral cortex, where language is usually localized. And fMRI research indicates that in tackling language tasks (such as deciding whether two spoken or written words rhyme), 9- to 15-year-old girls show concentrated activity in language-specific brain areas. Boys, in contrast, display more widespread activation—in addition to language areas, considerable activity in auditory and visual areas, depending on how words are presented (Burman, Bitan, & Booth, 2007). This suggests that girls are more efficient language processors than boys, who rely heavily on sensory brain regions and process spoken and written words differently.

But girls also receive more verbal stimulation from the preschool years through adolescence (Peterson & Roberts, 2003). Furthermore, children view language arts as a “feminine” subject. And as a result of the high-stakes testing movement, students today spend more time at their desks being taught in a regimented way—an approach particularly at odds with boys’ higher activity level, assertiveness, and incidence of learning problems. Clearly, reversing boys’ weakening literacy skills is a high priority, requiring a concerted effort by families, schools, and communities.

Mathematical Abilities

Studies of sex differences in mathematical abilities in the early school grades are inconsistent. Some find no disparities, others

slight disparities depending on the skill assessed (Lachance & Mazzocco, 2006). Girls tend to be advantaged in counting, arithmetic computation, and mastery of basic concepts, perhaps because of their better verbal skills and more methodical approach to problem solving. But by late childhood to early adolescence, when math concepts become more abstract and spatial, boys start to outperform girls, with the difference especially evident on tests of complex reasoning and geometry (Bielinski & Davison, 1998; Gibbs, 2010; Lindberg et al., 2010). In science achievement, too, boys' advantage increases as problems become more difficult (Penner, 2003).

The male advantage is evident in most countries where males and females have equal access to secondary education. But the gap is typically small, varies considerably across nations, and has diminished over the past 30 years (Aud et al., 2011; Lindberg et al., 2010; U.S. Department of Education, 2009). Among the most capable, however, the gender gap is greater. In widely publicized research on more than 100,000 bright seventh and eighth graders invited to take the Scholastic Assessment Test (SAT), boys outscored girls on the mathematics subtest year after year. Yet even this disparity has been shrinking. A quarter-century ago, 13 times as many boys as girls scored over 700 (out of a possible 800) on the math portion of the SAT; today, the ratio is about 4 to 1 for seventh graders and 2 to 1 for high school students (Benbow & Stanley, 1983; Wai et al., 2010).

Some researchers believe that heredity contributes substantially to the gender gap in math, especially to the tendency for more boys to be extremely talented. Accumulating evidence indicates that boys' advantage originates in two skill areas: (1) their more rapid numerical memory, which permits them to devote more energy to complex mental operations; and (2) their superior spatial reasoning, which enhances their mathematical problem solving (Geary et al., 2000; Halpern et al., 2007). Longitudinal evidence on nationally representative samples of U.S. high school students tracked for a decade or more reveals that high spatial ability consistently predicts subsequent advanced educational attainment in math-intensive fields and entry into science, technology, engineering and math (STEM) careers (Wai, Lubinski, & Benbow, 2009). See the Biology and Environment box on page 390 for further consideration of this issue.

Social pressures are also influential. Long before sex differences in math achievement appear, many children view math as a “masculine” subject. Also, many parents think boys are better at it—an attitude that encourages girls to blame their errors on lack of ability and to consider math less useful for their future lives. These beliefs, in turn, reduce girls' confidence and interest in math and their willingness to consider STEM careers in college (Ceci & Williams, 2010; Kenney-Benson et al., 2006; Parker et al., 2012). Furthermore, *stereotype threat*—fear of being judged on the basis of a negative stereotype (see pages 314–315 in Chapter 9)—causes girls to do worse than their abilities allow on difficult math problems (Ben-Zeev et al., 2005; Muzzatti & Agnoli, 2007). As a result of these influences, even girls who are highly talented are less likely to develop effective math reasoning skills.

A positive sign is that today, American boys and girls reach advanced levels of high school math and science study in equal proportions—a crucial factor in reducing sex differences in knowledge and skill (Gallagher & Kaufman, 2005). But boys spend more time than girls with computers, and they tend to use them differently. Whereas girls typically focus on information gathering and social networking, boys more often play video games, create web pages, write computer programs, analyze data, and use graphics programs (Lenhart et al., 2010; Looker & Thiessen, 2003; Rideout, Foehr, & Roberts, 2010). As a result, boys acquire more specialized computer knowledge.

Clearly, extra steps must be taken to promote girls' interest in and confidence at math and science. As Figure 11.10 shows, in cultures that value gender equality, sex differences in math achievement are much smaller and, in one nation, reversed! Icelandic high school girls exceed boys in math scores (Guiso et al., 2008). Similarly, in countries where few individuals view science as “masculine,” secondary school girls equal or exceed boys in science achievement (Nosek et al., 2009).

FIGURE 11.10 Math achievement gender gaps in 10 industrialized nations, arranged in order of increasing gender equality. Math achievement scores are based on 15-year-olds' performance on an identical test in each country. Country gender equality is a composite measure that includes cultural attitudes toward women, women's participation in the labor force and in politics and government, and women's educational attainment and economic opportunities. As country gender equality increases, boys' advantage in math achievement declines; in Iceland, girls' math scores exceed boys'. (Adapted from Guiso et al., 2008.)

Biology and Environment

Sex Differences in Spatial Abilities

Spatial skills are a key focus of researchers' efforts to explain sex differences in complex mathematical reasoning. The gender gap favoring males is large for *mental rotation tasks*, in which individuals must rotate a three-dimensional figure rapidly and accurately inside their heads (see Figure 11.11). Males also do considerably better on *spatial perception tasks*, in which people must determine spatial relationships by considering the orientation of the surrounding environment. Sex differences on *spatial visualization tasks*, involving analysis of complex visual forms, are weak or nonexistent. Because many strategies can be used to solve these tasks, both sexes may come up with effective procedures (Collaer & Hill, 2006; Voyer, Voyer, & Bryden, 1995).

Sex differences in spatial abilities emerge as early as the first few months of life, in male infants' superior ability to recognize a familiar object from a new perspective—a capacity requiring mental rotation (Moore & Johnson, 2008; Quinn & Liben, 2008). The male spatial advantage is present throughout childhood, adolescence, and adulthood in many cultures (Levine et al., 1999; Silverman, Choi, & Peters, 2007). One explanation is that heredity, perhaps by exposing the brain to androgen hormones, enhances right hemispheric functioning, giving males a spatial advantage. (Recall that for most people, spatial skills are housed in the right hemisphere of the cerebral cortex.) In support of this idea, girls and women whose prenatal androgen levels were abnormally high show superior performance on spatial rotation tasks (Berenbaum, 2001; Halpern & Collaer, 2005). And women with a male twin brother,

who are exposed to slightly higher levels of prenatal androgens, outperform women with a female twin sister in spatial rotation (Heil et al., 2011; Vuoksi-maa et al., 2010).

Why might a biologically based sex difference in spatial abilities exist? Evolutionary theorists point out that mental rotation skill predicts rapid, accurate map drawing and interpretation, areas in which boys and men do better than girls and women. Over the course of human evolution, the cognitive abilities of males became adapted for hunting, which required generating mental representations of large-scale spaces to find one's way (Jones, Braithwaite, & Healy, 2003). But this explanation is controversial: Critics point out that female gatherers also needed to travel long distances to find fruits and vegetables that ripened in different seasons (Newcombe, 2007).

Experience also contributes to males' superior spatial performance. Children who engage in manipulative activities, such as block play, model building, and carpentry, do better on spatial tasks (Baenninger & Newcombe, 1995). Furthermore, playing action video games enhances many cognitive processes important for spatial skills, including visual discrimination, speed of thinking, attention shifting, tracking of multiple

objects, mental rotation, and wayfinding—gains that persist and generalize to diverse situations (Spence & Feng, 2010). Boys spend far more time than girls at these pursuits.

Furthermore, spatial skills respond readily to training, with improvements often larger than the sex differences themselves. But because boys and girls show similar training effects, sex differences persist (Liu et al., 2008; Newcombe & Huttenlocher, 2006). In one study of first-graders, however, training in mental rotation strategies over several months—a more intensive approach than previously tried—led girls to reach the same performance level as boys (Tzuril & Egozi, 2010). These findings suggest that the right kind of early intervention can override biologically based sex differences in spatial skills.

FIGURE 11.11 Types of spatial tasks. Large sex differences favoring males appear in mental rotation, and males do considerably better than females in spatial perception. In contrast, sex differences in spatial visualization are weak or nonexistent. (From M. C. Linn & A. C. Petersen, 1985, "Emergence and Characterization of Sex Differences in Spatial Ability: A Meta-Analysis," *Child Development*, 56, pp. 1482, 1483, 1485. © The Society for Research in Child Development. Furthermore, a math curriculum beginning in kindergarten that teaches children how to apply effective spatial strategies—drawing diagrams, mentally manipulating visual images, searching for numerical patterns, and graphing—is vital (Nuttall, Casey, & Pezaris, 2005). Because girls are biased toward verbal processing, they may not attain their math and science potential unless they are taught how to think spatially.

Learning in School

In complex societies, adolescence coincides with entry into secondary school. Most young people move into either a middle or a junior high school and then into a high school. With each change, academic achievement increasingly determines higher education options and job opportunities. In the following sections, we take up various aspects of secondary school life.

School Transitions

When Sabrina started middle school, she left a small, intimate, self-contained sixth-grade classroom for a much larger school. “I don’t know most of the kids in my classes, and my teachers don’t know me,” Sabrina complained to her mother at the end of the first week. “Besides, there’s too much homework. I get assignments in all my classes at once. I can’t do all this!” she shouted, bursting into tears.

Impact of School Transitions. As Sabrina’s reactions suggest, school transitions can create adjustment problems. With each school change—from elementary to middle or junior high and then to high school—adolescents’ grades decline. The drop is partly due to tighter academic standards. At the same time, the transition to secondary school often means less personal attention, more whole-class instruction, and less chance to participate in classroom decision making (Seidman, Aber, & French, 2004).

It is not surprising, then, that students rate their middle- and high school learning experiences less favorably than their elementary-school experiences (Wigfield & Eccles, 1994). They also report that their teachers care less about them, are less friendly, grade less fairly, and stress competition more. Consequently, many young people feel less academically competent, and their liking for school and motivation decline (Barber & Olsen, 2004; Gutman & Midgley, 2000; Otis, Grouzet, & Pelletier, 2005).

Inevitably, students must readjust their feelings of self-confidence and self-worth as they encounter revised academic expectations and a more complex social world. In several studies that followed students across the middle- and high-school transitions, grade point average declined and feelings of anonymity increased after each school change. Girls fared less well than boys. On entering middle school, girls’ self-esteem dropped sharply, perhaps because the transition tended to coincide with

On the first day of school, a teacher’s caring attention helps this sixth grader deal with the stress of moving from a small, self-contained elementary school classroom to a large middle school.

other life changes: the onset of puberty and dating (Simmons & Blyth, 1987). And after starting high school, girls felt lonelier and more anxious than boys, and—although they were doing better academically—their grades declined more rapidly (Benner & Graham, 2009; Russell, Elder, & Conger, 1997).

Adolescents facing added strains at either transition—family disruption, poverty, low parental involvement, or learned helplessness on academic tasks—are at greatest risk for self-esteem and academic difficulties (de Bruyn, 2005; Rudolph et al., 2001; Seidman et al., 2003). Furthermore, high-school transition is especially challenging for African-American and Hispanic students who move to a new school with substantially fewer peers of the same ethnicity (Benner & Graham, 2009). Under these conditions, minority adolescents report decreased feelings of belonging and school liking, and they show steeper declines in grades.

Distressed youths whose school performance either remains low or drops sharply after school transition often show a persisting pattern of poor self-esteem, motivation, and achievement. In another study, researchers compared “multiple-problem” youths (those with both academic and mental health problems), youths with difficulties in just one area (either academic or mental health), and well-adjusted youths (those doing well in both areas) across the transition to high school. Although all groups declined in grade point average, well-adjusted students continued to get high marks and multiple-problem youths low marks, with the others falling in between. And as Figure 11.12 on page 392 shows, the multiple-problem youths showed a far greater rise in truancy and out-of-school problem behaviors (Roeser, Eccles, & Freedman-Doan, 1999). For some, school transition initiates a downward spiral in academic performance and school involvement that leads to dropping out.

FIGURE 11.12 Increase in truancy and out-of-school problem behaviors across the transition to high school in four groups of students. Well-adjusted students, students with only academic problems, and students with only mental health problems showed little change. (Good students with mental health problems actually declined in problem behaviors, so no orange bar is shown for them.) In contrast, multiple-problem students—with both academic and mental health difficulties—increased sharply in truancy and problem behaviors after changing schools from eighth to ninth grade. (Adapted from Roeser, Eccles, & Freedman-Doan, 1999.)

Helping Adolescents Adjust to School Transitions. As these findings reveal, school transitions often lead to environmental changes that fit poorly with adolescents’ developmental needs (Eccles & Roeser, 2009). They disrupt close relationships with teachers at a time when adolescents need adult support. They emphasize competition during a period of heightened self-focusing. They reduce decision making and choice as the desire for autonomy is increasing. And they interfere with peer networks as young people become more concerned with peer acceptance.

LOOK AND LISTEN

Ask several secondary school students to describe their experiences after school transition. What supports for easing the stress of transition did their teachers and school provide?

Support from parents, teachers, and peers can ease these strains. Parental involvement, monitoring, gradual autonomy granting, and emphasis on mastery rather than merely good grades are associated with better adjustment (Grolnick et al., 2000; Gutman, 2006). Adolescents with close friends are more likely to sustain these friendships across the transition, which increases social integration and academic motivation in the new school (Aikens, Bierman, & Parker, 2005). Forming smaller

units within larger schools promotes closer relationships with both teachers and peers and—as we will see later—greater extracurricular involvement (Seidman, Aber, & French, 2004). And a “critical mass” of same-ethnicity peers—according to one suggestion, at least 15 percent of the student body—helps teenagers feel socially accepted and reduces fear of out-group hostility (National Research Council, 2007).

Other, less extensive changes are also effective. In the first year after a school transition, homerooms can be provided in which teachers offer academic and personal counseling. Assigning students to classes with several familiar peers or a constant group of new peers strengthens emotional security and social support. In schools that took these steps, students were less likely to decline in academic performance or display other adjustment problems (Felner et al., 2002).

Academic Achievement

Adolescent achievement is the result of a long history of cumulative effects. Early on, positive educational environments, both family and school, lead to personal traits that support achievement—intelligence, confidence in one’s own abilities, the desire to succeed, and high educational aspirations. Nevertheless, improving an unfavorable environment can foster resilience among poorly performing young people. See Applying What We Know on the following page for a summary of environmental factors that enhance achievement during the teenage years.

Child-Rearing Styles. Authoritative parenting is linked to higher grades in school among adolescents varying widely in SES, just as it predicts mastery-oriented behavior in childhood. In contrast, authoritarian and permissive styles are associated with lower grades (Collins & Steinberg, 2006; Vazsonyi, Hibbert, & Snider, 2003). Uninvolved parenting (low in both warmth and maturity demands) predicts the poorest grades and worsening school performance over time (Glasgow et al., 1997; Kaisa, Stattin, & Nurmi, 2000).

The link between authoritative parenting and adolescents’ academic competence has been confirmed in countries with diverse value systems, including Argentina, Australia, China, Hong Kong, the Netherlands, Pakistan, and Scotland (de Bruyn, Deković, & Meijnen, 2003; Heaven & Ciarrochi, 2008; Steinberg, 2001). In Chapter 8, we noted that authoritative parents adjust their expectations to children’s capacity to take responsibility for their own behavior. Adolescents whose parents engage in joint decision making, gradually permitting more autonomy with age, achieve especially well (Spera, 2005; Wang, Pomerantz, & Chen, 2007). Warmth, open discussion, firmness, and monitoring of the adolescents’ whereabouts and activities make young people feel cared about and valued, encourage reflective thinking and self-regulation, and increase awareness of the importance of doing well in school. These factors, in turn, are related to mastery-oriented attributions, effort, achievement, and high educational aspirations (Aunola, Stattin, & Nurmi, 2000; Gregory & Weinstein, 2004; Trusty, 1999).

Applying What We Know

Supporting High Achievement in Adolescence

Factor	Description
Child-rearing practices	Authoritative parenting Joint parent–adolescent decision making Parent involvement in the adolescent’s education
Peer influences	Peer valuing of and support for high achievement
School characteristics	Teachers who are warm and supportive, develop personal relationships with parents, and show them how to support their teenager’s learning Learning activities that encourage high-level thinking Active student participation in learning activities and classroom decision making
Employment schedule	Job commitment limited to less than 15 hours per week High-quality vocational education for non-college-bound adolescents

Parent–School Partnerships. High-achieving students typically have parents who keep tabs on their child’s progress, communicate with teachers, and make sure their child is enrolled in challenging, well-taught classes. These efforts are just as important during adolescence as they were earlier (Hill & Taylor, 2004). In a large, nationally representative sample of U.S. adolescents, parents’ school involvement in eighth grade strongly predicted students’ grade point average in tenth grade, beyond the influence of SES and previous academic achievement (Keith et al., 1998). Parents who are in frequent contact with the school send a message to their child about the value of education, model constructive solutions to academic problems, and promote wise educational decisions.

The daily stresses of living in low-income, high-risk neighborhoods reduce parents’ energy for school involvement (Bowen, Bowen, & Ware, 2002). Yet stronger home–school links

could relieve some of this stress. Schools can build parent–school partnerships by strengthening personal relationships between teachers and parents, tapping parents’ talents to improve the quality of school programs, and including parents in school governance so they remain invested in school goals.

Peer Influences. Peers play an important role in adolescent achievement, in a way that relates to both family and school. Teenagers whose parents value achievement generally choose friends who share those values (Kiuru et al., 2009; Woolley, Kol, & Bowen, 2009). For example, when Sabrina began to make new friends in middle school, she often studied with her girlfriends. Each girl wanted to do well and reinforced this desire in the others.

Peer support for high achievement also depends on the overall climate of the peer culture, which, for ethnic minority youths, is powerfully affected by the surrounding social order. In one study, integration into the school peer network predicted higher grades among Caucasians and Hispanics but not among Asians and African Americans (Faircloth & Hamm, 2005). Asian cultural values stress respect for family and teacher expectations over close peer ties (Chao & Tseng, 2002; Chen, 2005). African-American minority adolescents may observe that their ethnic group is worse off than the white majority in educational attainment, jobs, income, and housing. And discriminatory treatment by teachers and peers, often resulting from stereotypes that they are “not intelligent,” triggers anger, anxiety, self-doubt, declines in achievement, association with peers who are not interested in school, and increases in problem behaviors (Wong, Eccles, & Sameroff, 2003).

Schools that build close networks of support between teachers and peers can prevent these negative outcomes. One high school with a largely low-income ethnic minority student body (65 percent African American) reorganized into “career academies”—learning communities within the school, each

Social Issues: Education

Media Multitasking Disrupts Attention and Learning

“**M**om, I’m going to study for my biology test now,” called 16-year-old Cassie while shutting her bedroom door. Sitting down at her desk, she accessed a popular social-networking website on her laptop, donned headphones and began listening to a favorite song on her MP3 player, and placed her cell phone next to her elbow so she could hear it chime if any text messages arrived. Only then did she open her textbook and begin to read.

In a survey of a nationally representative sample of U.S. 8- to 18-year-olds, more than two-thirds reported engaging in two or more media activities at once, some or most of the time (Rideout, Foehr, & Roberts, 2010). Their most frequent type of media multitasking is listening to music while doing homework, but many also report watching TV or using the Internet while studying (Jeong & Fishbein, 2007). The presence of a television or computer in the young person’s bedroom is a strong predictor of this behavior (Foehr, 2006). And it extends into classrooms, where students can be seen text-messaging under their desks or surfing the Internet on cell phones.

Research confirms that media multitasking greatly reduces learning. In one experiment, participants were given two tasks: learning to predict the weather in

two different cities using colored shapes as cues and keeping a mental tally of how many high-pitched beeps they heard through headphones. Half the sample performed the tasks simultaneously, the other half separately. Both groups learned to predict the weather in the two-city situation, but the multitaskers were unable to apply their learning to new weather problems (Foerde, Knowlton, & Poldrack, 2006).

fMRI evidence revealed that the participants working only on the weather task activated the hippocampus, which plays a vital role in *explicit memory*—conscious, strategic recall, which enables new information to be used flexibly and adaptively in contexts outside the original learning situation (see page 218 in Chapter 7). In contrast, the multitaskers activated subcortical areas involved in *implicit memory*—a shallower, automatic form of learning that takes place unconsciously.

As early as 1980, studies linked heavy media use with executive-function difficulties (Nunez-Smith et al., 2008). Frequent media multitaskers, who are accustomed

Media multitasking while doing homework fragments attention, yielding superficial learning. Frequent multitaskers are likely to have trouble filtering out irrelevant stimuli even when they are not multitasking.

to continuously shifting their attention between tasks, have a harder time filtering out irrelevant stimuli when they are not multitasking (Ophir, Nass, & Wagner, 2009).

Beyond superficial preparation for her biology test, Cassie is likely to have trouble concentrating and strategically processing new information after turning off her computer and MP3 player. Experienced teachers often complain that compared to students of a generation ago, today’s teenagers are more easily distracted and learn less thoroughly. One teacher reflected, “It’s the way they’ve grown up—working short times on many different things at one time” (Clay, 2009, p. 40).

offering a different career-related curriculum (for example, one focusing on health, medicine, and life sciences, another on computer technology). The smaller-school climate and common theme helped create caring teacher–student relationships and a peer culture that focused on valuing school engagement, collaborating on projects, and academic success (Conchas, 2006). High school graduation and college enrollment rates rose from a small minority to over 90 percent.

Finally, teenagers’ use of text messaging and e-mail to remain continuously in touch with peers—even during class and while working on homework—is an aspect of contemporary peer-group life that poses risks to achievement. Turn to the Social Issues: Education box above to find out about the impact of “media multitasking” on attention and learning.

School Characteristics. Adolescents need school environments that are responsive to their expanding powers of reasoning and their emotional and social needs. Without appropriate learning experiences, their cognitive potential is unlikely to be realized.

Classroom Learning Experiences. As noted earlier, in large, departmentalized secondary schools, many adolescents report that their classes lack warmth and supportiveness, which dampens their motivation. Of course, an important benefit of separate classes in each subject is that adolescents can be taught by experts, who are more likely to encourage high-level thinking, teach effective learning strategies, and emphasize content relevant to students’ experiences—factors that contribute to

interest, effort, and achievement (Eccles, 2004). But many classrooms do not consistently provide stimulating, challenging teaching.

Wide variability in quality of instruction has contributed to increasing numbers of seniors who graduate from high school deficient in basic academic skills. Although the achievement gap separating African-American, Hispanic, and Native-American students from white students has declined since the 1970s, mastery of reading, writing, mathematics, and science by low-SES ethnic minority students remains disappointing (U.S. Department of Education, 2007a, 2009, 2010). Too often these young people attend underfunded schools with rundown buildings, outdated equipment, and textbook shortages. In some, crime and discipline problems receive more attention than teaching and learning. By middle school, many low-SES minority students have been placed in low academic tracks, compounding their learning difficulties.

Tracking. Ability grouping, as we saw in Chapter 9, is detrimental during the elementary school years. At least into middle school, mixed-ability classes are desirable. They support the motivation and achievement of students who vary widely in academic progress (Gillies, 2003; Gillies & Ashman, 1996).

By high school, some grouping is unavoidable because certain aspects of education must dovetail with the young person's future educational and vocational plans. In the United States, high school students are counseled into college preparatory, vocational, or general education tracks. Unfortunately, low-SES minority students are assigned in large numbers to noncollege tracks, perpetuating educational inequalities of earlier years.

Longitudinal research following thousands of U.S. students from eighth to twelfth grade reveals that assignment to a college preparatory track accelerates academic progress, whereas assignment to a vocational or general education track decelerates it (Hallinan & Kubitschek, 1999). Even in secondary schools with no formal tracking program, low-SES minority students tend to be assigned to lower course levels in most or all academic subjects, resulting in *de facto* (unofficial) *tracking* (Lucas & Behrends, 2002).

Breaking out of a low academic track is difficult. Track or course enrollment is generally based on past performance, which is limited by placement history. Interviews with African-American students revealed that many thought their previous performance did not reflect their ability. Yet teachers and counselors, overburdened with other responsibilities, had little time to reconsider individual cases (Ogbu, 2003). And compared to students in higher tracks, those in low tracks exert substantially less effort—a difference due in part to less stimulating classroom experiences (Worthy, Hungerford-Kresser, & Hampton, 2009).

High school students are separated into academic and vocational tracks in virtually all industrialized nations. In China, Japan, and most Western European countries, students' placement in high school is determined by a national exam, which

FIGURE 11.13 High school graduation rates in 10 industrialized nations. The United States ranks below many other developed countries. (From OECD, 2011a.)

usually establishes the young person's future possibilities. In the United States, students who are not assigned to a college preparatory track or who do poorly in high school can still attend college. Ultimately, however, many young people do not benefit from the more open U.S. system. By adolescence, SES differences in quality of education and academic achievement are greater in the United States than in most other industrialized countries (Marks, Cresswell, & Ainley, 2006). And the United States has a higher percentage of young people who see themselves as educational failures and drop out of high school (see Figure 11.13).

Part-Time Work. In high school, about one-fourth of U.S. adolescents are employed—a greater percentage than in other developed countries. But most are middle-SES adolescents in pursuit of spending money rather than vocational exploration and training. Low-income teenagers who need to contribute to family income or to support themselves find it harder to get jobs (U.S. Department of Education, 2012b).

Adolescents typically hold jobs that involve low-level, repetitive tasks and provide little contact with adult supervisors. A heavy commitment to such jobs is harmful. The more hours students work, the poorer their school attendance, the lower their grades, the less likely they are to participate in extracurricular activities, and the more likely they are to drop out (Marsh & Kleitman, 2005). Students who spend many hours at such jobs also tend to feel more distant from their parents and report more drug and alcohol use and delinquent acts (Samuolis et al., 2011; Staff & Uggen, 2003).

In contrast, participation in work–study programs or other jobs that provide academic and vocational learning opportunities is related to positive school and work attitudes, improved achievement, and reduced delinquency (Hamilton & Hamilton, 2000; Staff & Uggen, 2003). Yet high-quality vocational preparation for non-college-bound U.S. adolescents is scarce. Unlike some European nations, the United States has no widespread training system to prepare youths for skilled business and industrial occupations and manual trades. Although U.S. federal and state governments support some job-training programs, most are too brief to make a difference and serve only a small minority of young people who need assistance.

Dropping Out

Across the aisle from Louis in math class sat Norman, who daydreamed, crumpled his notes into his pocket after class, and rarely did his homework. On test days, he twirled a rabbit's foot for good luck but left most questions blank. Louis and Norman had been classmates since fourth grade, but they had little to do with each other. To Louis, who was quick at schoolwork, Norman seemed to live in another world. Once or twice a week, Norman cut class; one spring day, he stopped coming altogether.

Norman is one of about 8 percent of U.S. 16- to 24-year-olds who dropped out of high school and remain without a diploma or a GED (U.S. Department of Education, 2012b). The dropout rate is higher among boys than girls and is particularly high among low-SES ethnic minority youths, especially Native-American and Hispanic teenagers (15 and 18 percent, respectively). The decision to leave school has dire consequences. Youths without upper secondary education have much lower literacy scores than high school graduates; they lack the skills employers value in today's knowledge-based economy. Consequently, dropouts have much lower employment rates than high school graduates. Even when employed, dropouts are far more likely to remain in menial, low-paying jobs and to be out of work from time to time.

Factors Related to Dropping Out. Although many dropouts achieve poorly and show high rates of norm-violating acts, a substantial number, like Norman, have few behavior problems, experience academic difficulties, and quietly disengage from school (Janosz et al., 2000; Newcomb et al., 2002). The pathway to dropping out starts early. Risk factors in first grade predict dropout nearly as well as risk factors in secondary school (Entwisle, Alexander, & Olson, 2005).

Norman had a long history of marginal-to-failing school grades and low academic self-esteem. Faced with a challenging task, he gave up, relying on luck—his rabbit's foot—to get by. As Norman got older, he attended class less regularly, paid little attention when he was there, and rarely did his homework. He didn't join school clubs or participate in sports. As a result, few teachers or students knew him well. By the day he left, Norman felt alienated from all aspects of school life.

As with other dropouts, Norman's family background contributed to his problems. Compared with other students, even those with the same grade profile, dropouts are more likely to have parents who are uninvolved in their teenager's education and engage in little monitoring of their youngster's daily activities (Englund, Egeland, & Collins, 2008; Pagani et al., 2008). Many are single parents, never finished high school themselves, and are unemployed.

Students who drop out often have school experiences that undermine their chances for success: grade retention, which marks them as academic failures; large, impersonal secondary schools; and classes with unsupportive teachers and few opportunities for active participation (Brown & Rodriguez, 2009). In such schools, rule breaking is common and often results in suspension, which—by excluding students from classes—contributes further to academic failure (Christie, Jolivet, & Nelson, 2007). Students in general education and vocational tracks, where teaching tends to be the least stimulating, are three times as likely to drop out as those in a college preparatory track (U.S. Department of Education, 2012).

Prevention Strategies. Among the diverse strategies available for helping teenagers at risk of dropping out, several common themes are related to success:

- *Remedial instruction and counseling that offer personalized attention.* Most potential dropouts need academic assistance combined with social support—intensive remedial instruction in small classes that foster warm, caring teacher–student relationships (Christenson & Thurlow, 2004). In one successful approach, at-risk students are matched with retired adults, who serve as tutors, mentors, and role models in addressing academic and vocational needs (Prevatt, 2003).
- *High-quality vocational training.* For many marginal students, the real-life nature of vocational education is more comfortable and effective than purely academic work (Harvey, 2001). To work well, vocational education must carefully integrate academic and job-related instruction so students see the relevance of classroom experiences to their future goals.
- *Efforts to address the many factors in students' lives related to leaving school early.* Programs that strengthen parent involvement, offer flexible work–study arrangements, and provide on-site child care for teenage parents can make staying in school easier for at-risk adolescents.
- *Participation in extracurricular activities.* Another way of helping marginal students is to draw them into the community life of the school. The most powerful influence on extracurricular involvement is small school size (Crosnoe, Johnson, & Elder, 2004; Feldman & Matjasko, 2007). As high school student body declines—dropping from 2,000 students to 500 to 700 students—at-risk youths are more likely to be needed to help staff activities. As a result, they feel more attached to their school. In large schools, creation of smaller “schools within schools” has the same effect.

St. Paul, Minnesota, police chief Thomas Smith warmly greets one of his student mentees following a high school fundraising event for a charitable organization. Support from a caring adult and extracurricular involvement are effective ways to prevent school dropout.

Moderate (but not excessive) participation in arts, community service, or vocational development activities promotes improved academic performance, reduced anti-social behavior, more favorable self-esteem and initiative, and increased peer acceptance (Fredricks, 2012; Fredricks & Eccles, 2006). Adolescents with academic, emotional, and social problems are especially likely to benefit (Marsh & Kleitman, 2002).

As we conclude our discussion of academic achievement, let's place the school dropout problem in historical perspective. Over the second half of the twentieth century, the percentage of U.S. young people completing high school by age 24 increased steadily, from less than 50 percent to just over 90 percent. Although many dropouts get caught in a vicious cycle in which their lack of self-confidence and skills prevents them from seeking further education and training, about one-third return to finish their secondary education within a few years (U.S. Department of Education, 2012b). And some extend their schooling further as they come to realize how essential education is for a rewarding job and a satisfying adult life.

ASK YOURSELF

REVIEW List ways that parents can promote their adolescent's academic achievement. Explain why each is effective.

CONNECT How are educational practices that prevent school dropout similar to those that improve learning for adolescents in general?

APPLY Tanisha is finishing sixth grade. She can either continue in her current school through eighth grade or switch to a much larger seventh- to ninth-grade middle school. Which choice would you suggest, and why?

REFLECT Describe your own experiences in making the transition to middle or junior high school and then to high school. What did you find stressful? What helped you adjust?

SUMMARY

PHYSICAL DEVELOPMENT

Conceptions of Adolescence

(p. 362)

How have conceptions of adolescence changed over the past century?

- **Adolescence** is the transition between childhood and adulthood. Early theorists viewed adolescence as either a biologically determined period of storm and stress or entirely influenced by the social environment. Contemporary researchers view adolescence as a joint product of biological, psychological, and social forces.
- In industrialized societies, adolescence is greatly extended.

Puberty: The Physical Transition to Adulthood

(p. 363)

Describe body growth, motor performance, and sexual maturation during puberty.

- Hormonal changes under way in middle childhood initiate **puberty**, on average, two years earlier for girls than for boys. The first outward sign is the **growth spurt**. As the body enlarges, girls' hips and boys' shoulders broaden. Girls add more fat, boys more muscle.
- Puberty brings slow, gradual improvements in gross-motor performance for girls, dramatic gains for boys. Nevertheless, participation in regular physical activity declines sharply with age.

- At puberty, changes in **primary** and **secondary sexual characteristics** accompany rapid body growth. **Menarche** occurs late in the girl's sequence of pubertal events, after the growth spurt peaks. In boys, the peak in growth occurs later, preceded by enlargement of the sex organs and **spermarche**.

What factors influence the timing of puberty?

- Heredity, nutrition, exercise, and overall physical health influence the timing of puberty. The emotional quality of family experiences may play a role.
- A **secular trend** toward earlier puberty has occurred in industrialized nations as physical well-being increased. In some countries, rising obesity rates have extended this trend.

What changes in the brain take place during adolescence?

- Pruning of unused synapses in the cerebral cortex continues, and linkages between areas of the brain expand and myelinate. As the prefrontal cortex becomes a more effective “executive,” adolescents gradually gain in processing speed and executive function. But performance on tasks requiring inhibition, planning, and future orientation is not yet fully mature.
- During puberty, neurons become more responsive to excitatory neurotransmitters, heightening emotional reactivity and reward-seeking. Changes in the brain’s emotional/social network outpace development of the cognitive-control network, resulting in self-regulation difficulties.

© JEFF GREENBERG/THE IMAGE WORKS

- Revisions also occur in brain regulation of sleep timing, leading to a sleep “phase delay.” Sleep deprivation contributes to poorer achievement, depressed mood, and high-risk behaviors.

The Psychological Impact of Pubertal Events (p. 368)**Explain adolescents’ reactions to the physical changes of puberty.**

- Girls typically react to menarche with mixed emotions, although those who receive advance information and support from family members respond more positively. Boys, who receive little social support for pubertal changes, react to spermarche with mixed feelings.
- Besides higher hormone levels, negative life events and adult-structured situations are associated with adolescents’ negative moods. Psychological distancing between parent and child at puberty may be a modern substitute for physical departure from the family.

Describe the impact of pubertal timing on adolescent adjustment, noting sex differences.

- Early-maturing boys and late-maturing girls have a more positive **body image** and usually adjust well. In contrast, early-maturing girls and late-maturing boys tend to experience emotional and social difficulties, which—for girls—persist into early adulthood.

Health Issues (p. 371)**Describe nutritional needs during adolescence, and cite factors related to eating disorders.**

- Nutritional requirements increase with rapid body growth, and vitamin and mineral deficiencies may result from poor eating habits. Frequency of family meals is associated with healthy eating.
- Early puberty, certain personality traits, maladaptive family interactions, and societal emphasis on thinness heighten risk of eating disorders such as **anorexia nervosa** and **bulimia nervosa**. Heredity also plays a role.

Discuss social and cultural influences on adolescent sexual attitudes and behavior.

- Although sexual attitudes of U.S. adolescents and adults have become more liberal over the past 40 years, North American attitudes toward adolescent sex remain relatively restrictive. Parents and the mass media deliver contradictory messages.
- Early, frequent sexual activity is linked to factors associated with economic disadvantage. Adolescent cognitive processes and weak social supports for responsible sexual behavior underlie the failure of many sexually active teenagers to practice contraception consistently.

Cite factors involved in the development of homosexuality.

- Biological factors, including heredity and prenatal hormone levels, play an important role in homosexuality. Lesbian, gay, and bisexual teenagers face special challenges in establishing a positive sexual identity.

Discuss factors related to sexually transmitted disease and teenage pregnancy and parenthood, noting prevention and intervention strategies.

- Early sexual activity, combined with inconsistent contraceptive use, results in high rates of sexually transmitted diseases (STDs) among U.S. adolescents.
- Life conditions linked to poverty and personal attributes jointly contribute to adolescent childbearing. Teenage parenthood is associated with school dropout, reduced chances of marriage, greater likelihood of divorce, and long-term economic disadvantage.
- Effective sex education, access to contraceptives, and programs that build academic and social competence help prevent early pregnancy. Adolescent mothers need school programs that provide job training, instruction in life-management skills, and child care. When teenage fathers stay involved, children develop more favorably.

What personal and social factors are related to adolescent substance use and abuse?

- Teenage alcohol and drug use is pervasive in industrialized nations. Drug taking reflects adolescent sensation seeking and drug-dependent cultural contexts. The minority who move to substance abuse tend to start using drugs early and to have serious personal, family, school, and peer problems.
- Effective prevention programs work with parents early to reduce family adversity, strengthen parenting skills, and build teenagers’ competence.

COGNITIVE DEVELOPMENT**Piaget’s Theory: The Formal Operational Stage** (p. 382)**What are the major characteristics of formal operational thought?**

- In Piaget’s **formal operational stage**, adolescents become capable of **hypothetico-deductive reasoning**. To solve problems, they start with a hypothesis; deduce logical, testable inferences; and systematically isolate and combine variables to see which inferences are confirmed.

© CINDY CHARLES/PHOTODISC

- Adolescents also develop **propositional thought**—the ability to evaluate the logic of verbal statements without referring to real-world circumstances.

Discuss follow-up research on formal operational thought and its implications for the accuracy of Piaget’s formal operational stage.

- Adolescents, like adults, are most likely to think abstractly and systematically in situations in which they have had extensive guidance and practice in using such reasoning. Individuals in tribal and village societies rarely do well on tasks typically used to assess formal operational reasoning. Learning activities in school provide adolescents with rich opportunities to acquire formal operations.

An Information-Processing View of Adolescent Cognitive Development

(p. 384)

How do information-processing researchers account for cognitive changes in adolescence?

- Information-processing researchers believe that a variety of specific mechanisms underlie cognitive gains in adolescence: improved attention, inhibition, strategies, knowledge, metacognition, cognitive self-regulation, speed of thinking, and processing capacity.
- The ability to coordinate theory with evidence improves as adolescents solve increasingly complex problems and acquire more sophisticated metacognitive understanding.

Consequences of Adolescent Cognitive Changes (p. 386)

Describe typical reactions of adolescents that result from their advancing cognition.

- As adolescents reflect on their own thoughts, two distorted images of the relation between self and other appear—the **imaginary audience** and the **personal fable**. Both result from heightened social sensitivity and gains in perspective taking.

ANTONIO MO/PHOTODISC/GETTY IMAGES

- Teenagers' capacity to think about possibilities prompts idealistic visions at odds with reality, and they often become fault-finding critics.

- Adolescents are less effective at decision making than adults. They take greater risks in emotionally charged situations, less often weigh alternatives, and more often fall back on intuitive judgments.

Sex Differences in Mental Abilities (p. 388)

What factors contribute to sex differences in mental abilities at adolescence?

- Girls' advantage in reading and writing achievement increases, probably due to earlier development of the left hemisphere of the cerebral cortex, more efficient language processing, and greater verbal stimulation. Gender stereotyping of language arts as "feminine" and regimented teaching may weaken boys' literacy skills.
- By early adolescence, when concepts become more abstract and spatial, boys surpass girls in mathematical performance. Overall, the gender difference is small, but it is greater among the most capable. Boys' superior spatial reasoning enhances their mathematical problem solving. Gender stereotyping of math as "masculine" contributes to boys' greater self-confidence and interest in pursuing STEM careers.

Learning in School (p. 391)

Discuss the impact of school transitions on adolescent adjustment.

- School transitions bring larger, more impersonal school environments, in which grades and feelings of competence decline. Girls experience more adjustment difficulties. Teenagers coping with added stressors are at greatest risk for self-esteem and academic problems.

Discuss family, peer, school, and employment influences on academic achievement during adolescence.

- Authoritative parenting and parents' school involvement promote high achievement. Teenagers whose parents value achievement generally choose friends who share those values. Schools can help by promoting a peer culture that values school engagement.

© MICHAEL DWYER/ALAMY

- Warm, supportive classroom environments that encourage student interaction, and high-level thinking enable adolescents to reach their academic potential.
- By high school, separate educational tracks that dovetail with students' future plans are necessary. However, U.S. high school tracking usually extends the educational inequalities of earlier years.
- The more hours students work at a part-time job, the poorer their school attendance, academic performance, and extracurricular participation. But work-study programs that provide academic and vocational learning opportunities predict positive school and work attitudes and better academic achievement.

What factors increase the risk of high school dropout?

- Factors contributing to the high U.S. dropout rate include lack of parental support for achievement, a history of poor school performance, large impersonal secondary schools, and unsupportive teachers.

chapter 12

JOHN GIUSTINA/ICONICA/GETTY IMAGES

As adolescents spend less time with family members, peer groups become more tightly knit into cliques. Mixed-sex cliques prepare teenagers for dating by providing models of how to interact and opportunities to do so without having to be intimate.

Emotional and Social Development in Adolescence

Louis sat on the grassy hillside overlooking the high school, waiting for his best friend, Darryl, to arrive from his fourth-period class.

The two boys often had lunch together. Watching as hundreds of students poured onto the school grounds, Louis reflected on what he had learned in government class that day. “Suppose I *had* been born in the People’s Republic of China. I’d be sitting here, speaking a different language, being called by a different name, and thinking about the world in different ways. Wow,” Louis pondered. “I am who I am through some quirk of fate.”

Louis awoke from his thoughts with a start to see Darryl standing in front of him. “Hey, dreamer! I’ve been shouting and waving from the bottom of the hill for five minutes. How come you’re so spaced out lately, Louis?”

“Oh, just wondering about stuff—what I want, what I believe in. My older brother Jules—I envy him. He seems to know more about where he’s going. I’m up in the air about it. You ever feel that way?”

“Yeah, a lot,” Darryl admitted, looking at Louis seriously. “I wonder, what am I really like? Who will I become?”

Louis and Darryl’s introspective remarks are signs of a major reorganization of the self at adolescence: the development of identity. Both young people are attempting to formulate who they are—their personal values and the directions they will pursue in life.

We begin this chapter with Erikson’s account of identity development and the research it has stimulated on teenagers’ thoughts and feelings about themselves. The quest for identity extends to many aspects of development. We will see how a sense of cultural belonging, moral understanding, and masculine and feminine self-images are refined during adolescence. And as parent–child relationships are revised and young people become increasingly independent of the family, friendships and peer networks become crucial contexts for bridging the gap between childhood and adulthood. Our chapter concludes with a discussion of several serious adjustment problems of adolescence: depression, suicide, and delinquency. ●

Problems of Development

Depression • Suicide • Delinquency

■ **BIOLOGY AND ENVIRONMENT** Two Routes to Adolescent Delinquency

Erikson's Theory: Identity versus Role Confusion

Erikson (1950, 1968) was the first to recognize **identity** as the major personality achievement of adolescence and as a crucial step toward becoming a productive, content adult. Constructing an identity involves defining who you are, what you value, and the directions you choose to pursue in life. One expert described it as an explicit theory of oneself as a rational agent—one who acts on the basis of reason, takes responsibility for those actions, and can explain them (Moshman, 2005). This search for what is true and real about the self drives many choices—vocation, interpersonal relationships, community involvement, ethnic-group membership, and expression of one's sexual orientation, as well as moral, political, and religious ideals.

Although the seeds of identity formation are planted early, not until late adolescence and early adulthood do young people become absorbed in this task. According to Erikson, in complex societies, teenagers experience an *identity crisis*—a temporary period of distress as they experiment with alternatives before settling on values and goals. They go through a process of inner soul-searching, sifting through characteristics that defined the self in childhood and combining them with emerging traits, capacities, and commitments. Then they mold these into a solid inner core that provides a mature identity—a sense of self-continuity as they move through various roles in daily life. Once formed, identity continues to be refined in adulthood as people reevaluate earlier commitments and choices.

Erikson called the psychological conflict of adolescence **identity versus role confusion**. If young people's earlier conflicts were resolved negatively or if society limits their choices to ones that do not match their abilities and desires, they may appear shallow, directionless, and unprepared for the challenges of adulthood.

Current theorists agree with Erikson that questioning of values, plans, and priorities is necessary for a mature identity, but they no longer describe this process as a "crisis" (Côté, 2009; Kroger, 2007). For most young people, identity development is not traumatic and disturbing but, rather, a process of *exploration* followed by *commitment*. As young people try out life possibilities, they gather important information about themselves and their environment and move toward making enduring decisions. In doing so, they forge an organized self-structure (Arnett, 2000, 2006; Moshman, 2005). In the following sections, we will see that adolescents go about the task of defining the self in ways that closely match Erikson's description.

Self-Understanding

During adolescence, the young person's vision of the self becomes more complex, well-organized, and consistent. Compared with younger children, adolescents engage in evaluations of an increasing variety of aspects of the self. Over time, they construct a balanced, integrated representation of their strengths

and limitations (Harter, 2003, 2006). Changes in self-concept and self-esteem set the stage for developing a unified personal identity.

Changes in Self-Concept

Recall that by the end of middle childhood, children can describe themselves in terms of personality traits. In early adolescence, they unify separate traits ("smart" and "curious") into more abstract descriptors ("intelligent"). But these generalizations are not interconnected and are often contradictory. For example, 12- to 14-year-olds might mention opposing traits—"intelligent" and "dork," "extrovert" and "introvert." These disparities result from the expansion of adolescents' social world, which creates pressure to display different selves in different relationships. As adolescents' awareness of these inconsistencies grows, they frequently agonize over "which is the real me" (Harter, 1998, 2003, 2006).

From middle to late adolescence, cognitive changes enable teenagers to combine their traits into an organized system. Their use of qualifiers ("I have a *fairly* quick temper," "I'm not *thoroughly* honest") reveals an increasing awareness that psychological qualities can vary from one situation to the next. Older adolescents also add integrating principles that make sense of formerly troublesome contradictions. "I'm very adaptable," said one young person. "When I'm around my friends, who think what I say is important, I'm talkative; but around my family I'm quiet because they're never interested enough to really listen to me" (Damon, 1990, p. 88).

Compared with school-age children, teenagers place more emphasis on social virtues, such as being friendly, considerate, kind, and cooperative—traits that reflect adolescents' increasing concern with being viewed positively by others. Among older adolescents, personal and moral values also appear as key themes. As young people revise their views of themselves to include enduring beliefs and plans, they move toward the unity of self that is central to identity development.

Changes in Self-Esteem

Self-esteem, the evaluative side of self-concept, continues to differentiate in adolescence. Teenagers add several new dimensions of self-evaluation—close friendship, romantic appeal, and job competence—to those of middle childhood (see Chapter 10, pages 330–331) (Harter, 1999, 2003, 2006).

Level of self-esteem also changes. Though some adolescents experience temporary or persisting declines after school transitions (see Chapter 11, page 391), self-esteem rises for most young people, who report feeling especially good about their peer relationships and athletic capabilities (Impett et al., 2008; Twenge & Campbell, 2001). Teenagers often assert that they have become more mature, capable, personable, and attractive than in the past. In longitudinal research on a nationally representative sample of U.S. youths, an increasing sense of mastery—feeling competent and in control of one's life—strongly predicted this age-related rise in self-esteem (Erol & Orth, 2011).

During adolescence, self-esteem rises for most young people, who feel especially good about their peer relationships and athletic capabilities.

As in middle childhood, individuals with mostly favorable self-esteem profiles tend to be well-adjusted, sociable, and conscientious, whereas low self-esteem in all areas is linked to adjustment difficulties. But certain self-esteem factors are more strongly related to adjustment. Teenagers who feel highly dissatisfied with parental relationships often are aggressive and

antisocial. Those with poor academic self-esteem tend to be anxious and unfocused, and those with negative peer relationships are likely to be anxious and depressed (Marsh, Parada, & Ayotte, 2004; Rudolph, Caldwell, & Conley, 2005).

In adolescence, authoritative parenting continues to predict high self-esteem, as does encouragement from teachers (Lindsey et al., 2008; McKinney, Donnelly, & Renk, 2008; Wilkinson, 2004). In contrast, teenagers whose parents are critical and insulting have unstable and generally low self-esteem (Kernis, 2002). Feedback that is negative, inconsistent, or not contingent on performance triggers, at best, uncertainty about the self's capacities and, at worst, a sense of being incompetent and unloved. Teenagers who experience such parenting tend to rely only on peers, not on adults, to affirm their self-esteem—a risk factor for adjustment difficulties (DuBois et al., 1999, 2002).

Paths to Identity

Adolescents' well-organized self-descriptions and differentiated sense of self-esteem provide the cognitive foundation for forming an identity. Using a clinical interviewing procedure devised by James Marcia (1980) or briefer questionnaire measures, researchers commonly evaluate progress in identity development on two key criteria derived from Erikson's theory: *exploration* and *commitment*. Their various combinations yield four *identity statuses*, summarized in Table 12.1: **identity achievement**, commitment to values, beliefs, and goals following a period of exploration; **identity moratorium**, exploration without having reached commitment; **identity foreclosure**, commitment in the absence of exploration; and **identity diffusion**, an apathetic state characterized by lack of both exploration and commitment.

Identity development follows many paths. Some young people remain in one status, whereas others experience many

TABLE 12.1 The Four Identity Statuses

IDENTITY STATUS	DESCRIPTION	EXAMPLE
Identity achievement	Having already explored alternatives, identity-achieved individuals are committed to a clearly formulated set of self-chosen values and goals. They feel a sense of psychological well-being, of sameness through time, and of knowing where they are going.	When asked how willing she would be to give up going into her chosen occupation if something better came along, Lauren responded, "Well, I might, but I doubt it. I've thought long and hard about law as a career. I'm pretty certain it's for me."
Identity moratorium	<i>Moratorium</i> means "delay or holding pattern." These individuals have not yet made definite commitments. They are in the process of exploring—gathering information and trying out activities, with the desire to find values and goals to guide their lives.	When asked whether he had ever had doubts about his religious beliefs, Ramón said, "Yes, I guess I'm going through that right now. I just don't see how there can be a God and yet so much evil in the world."
Identity foreclosure	Identity-foreclosed individuals have committed themselves to values and goals without exploring alternatives. They accept a ready-made identity chosen for them by authority figures—usually parents but sometimes teachers, religious leaders, or romantic partners.	When asked if she had ever reconsidered her political beliefs, Emily answered, "No, not really, our family is pretty much in agreement on these things."
Identity diffusion	Identity-diffused individuals lack clear direction. They are not committed to values and goals, nor are they actively trying to reach them. They may never have explored alternatives or may have found the task too threatening and overwhelming.	When asked about his attitude toward nontraditional gender roles, Justin responded, "Oh, I don't know. It doesn't make much difference to me. I can take it or leave it."

status transitions. And the pattern often varies across *identity domains*, such as sexual orientation, vocation, and religious and political values. Most young people change from “lower” statuses (foreclosure or diffusion) to higher ones (moratorium or achievement) between their mid-teens and mid-twenties, but as many remain stable, and some move in the reverse direction (Kroger, 2007; Kroger, Martinussen, & Marcia, 2010; Meeus et al., 2012).

Because attending college provides opportunities to explore values, career options, and lifestyles, college students make more identity progress than they did in high school (Klimstra et al., 2010; Montgomery & Côté, 2003). After college, they often sample a broad range of life experiences before choosing a life course. Those who go to work immediately after high school graduation often settle on a self-definition earlier. But if non-college-bound youths encounter obstacles to realizing their occupational goals because of lack of training or vocational choices, they are at risk for identity foreclosure or diffusion (Cohen et al., 2003; Eccles et al., 2003).

At one time, researchers thought that adolescent girls postponed establishing an identity, focusing instead on Erikson’s next stage, intimacy development. Some girls do show more sophisticated reasoning than boys in identity domains related to intimacy, such as sexuality and family versus career priorities. Otherwise, adolescents of both sexes typically make progress on identity concerns before experiencing genuine intimacy in relationships (Berman et al., 2006; Kroger, 2007).

Identity Status and Psychological Well-Being

A wealth of research verifies that both identity achievement and moratorium are psychologically healthy routes to a mature self-definition. Long-term foreclosure and diffusion, in contrast, are maladaptive.

Adolescents in moratorium resemble identity-achieved individuals in using an active, *information-gathering cognitive style* to make personal decisions and solve problems: They seek out relevant information, evaluate it carefully, and critically reflect on and revise their views (Berzonsky, 2003, 2011). Young people who are identity-achieved or exploring have higher self-esteem, feel more in control of their lives, are more likely to view school and work as feasible avenues for realizing their aspirations, and are more advanced in moral reasoning (Berzonsky et al., 2011; Kroger, 2007; Serafini & Adams, 2002).

Adolescents stuck in either foreclosure or diffusion are passive in the face of identity concerns and have adjustment difficulties. Foreclosed individuals display a *dogmatic, inflexible cognitive style*, internalizing the values and beliefs of parents and others without deliberate evaluation and resisting information that threatens their position (Berzonsky & Kuk, 2000; Berzonsky et al., 2011). Most fear rejection by people on whom they depend for affection and self-esteem. A few foreclosed teenagers who are alienated from their families and society may join cults or other extremist groups, uncritically adopting a way of life different from their past.

Long-term diffused individuals are the least mature in identity development. They typically use a *diffuse-avoidant cognitive style* in which they avoid dealing with personal decisions and problems and, instead, allow current situational pressures to dictate their reactions (Berzonsky & Kuk, 2000; Krettenauer, 2005). Taking an “I don’t care” attitude, they entrust themselves to luck or fate, tend to go along with the crowd, and are focused on short-term personal pleasures. As a result, they experience time management and academic difficulties and, of all young people, are most likely to commit antisocial acts and to use and abuse drugs (Berzonsky et al., 2011; Schwartz et al., 2005). Often at the heart of their apathy is a sense of hopelessness about the future.

Factors Affecting Identity Development

Adolescent identity formation begins a lifelong, dynamic process in which a change in either the individual or the context opens up the possibility of reformulating identity (Kunnen & Bosma, 2003). A wide variety of factors influence identity development.

Identity status, as we have just seen, is both cause and consequence of personality characteristics. Adolescents who assume that absolute truth is always attainable tend to be foreclosed, while those who doubt that they will ever feel certain about anything are more often identity-diffused. Young people who appreciate that they can use rational criteria to choose among alternatives are likely to be in a state of moratorium or identity achievement (Berzonsky & Kuk, 2000; Berzonsky et al., 2011).

Teenagers’ identity development is enhanced when their families serve as a “secure base” from which they can confidently move out into the wider world. Adolescents who feel attached to their parents but also free to voice their own opinions tend to be in a state of moratorium or identity achievement (Berzonsky, 2004; Luyckx, Goossens, & Soenens, 2006; Schwartz

An internship in a veterinary office enables this teenager to explore a real-world career related to her love of animals, thereby fostering identity development.

Applying What We Know

Supporting Healthy Identity Development

Strategy	Explanation
Engage in warm, open communication.	Provides both emotional support and freedom to explore values and goals.
Initiate discussions that promote high-level thinking at home and at school.	Encourages rational and deliberate selection among beliefs and values.
Provide opportunities to participate in extracurricular activities and vocational training programs.	Permits young people to explore the real world of adult work.
Provide opportunities to talk with adults and peers who have worked through identity questions.	Offers models of identity achievement and advice on how to resolve identity concerns.
Provide opportunities to explore ethnic heritage and learn about other cultures in an atmosphere of respect.	Fosters identity achievement in all areas and ethnic tolerance, which supports the identity explorations of others.

et al., 2005). Foreclosed teenagers usually have close bonds with parents but lack opportunities for healthy separation. And diffused young people report the lowest levels of parental support and of warm, open communication (Reis & Youniss, 2004; Zimmerman & Becker-Stoll, 2002).

Interaction with diverse peers through school and community activities encourages adolescents to explore values and role possibilities (Barber et al., 2005). And close friends, like parents, can act as a secure base, providing emotional support, assistance, and models of identity development. In one study, 15-year-olds with warm, trusting peer ties were more involved in exploring relationship issues—for example, thinking about what they valued in close friends and in a life partner (Meeus, Oosterwegel, & Vollebergh, 2002). In another study, young people's attachment to friends predicted progress in choosing a career (Felsman & Blustein, 1999).

Identity development also depends on schools and communities that offer rich and varied opportunities for exploration. Supportive experiences include classrooms that promote high-level thinking, teachers and counselors who encourage low-SES students to go to college, extracurricular activities that offer teenagers responsible roles consistent with their interests and talents, and vocational training that immerses adolescents in the real world of adult work (Coatsworth et al., 2005; Hardy et al., 2011; McIntosh, Metz, & Youniss, 2005).

Culture strongly influences an aspect of mature identity not captured by the identity-status approach: constructing a sense of self-continuity despite major personal changes. In one study, researchers asked Native Canadian and cultural-majority 12- to 20-year-olds to describe themselves in the past and in the present and then to justify why they regarded themselves as the same continuous person (Lalonde & Chandler, 2005). Most cultural-majority adolescents used an individualistic approach: They described an *enduring personal essence*, a core self that remained the same despite change. In contrast, Native Canadian youths took an interdependent approach that emphasized a *constantly transforming self*, resulting from new roles and relationships.

They typically constructed a *coherent narrative* in which they linked together various time slices of their life with a thread that explained how they had changed in meaningful ways.

Finally, societal forces also are responsible for the special challenges faced by gay, lesbian, and bisexual youths (see Chapter 11) and by ethnic minority adolescents in forming a secure identity (see the Cultural Influences box on page 406). Applying What We Know above summarizes ways that adults can support adolescents in their quest for identity.

ASK YOURSELF

REVIEW List personal and contextual factors that promote identity development.

CONNECT Explain the close link between adolescent identity development and cognitive processes.

APPLY Return to the conversation between Louis and Darryl in the opening of this chapter. Which identity status best characterizes each of the two boys, and why?

REFLECT Does your identity status vary across the domains of sexuality, close relationships, vocation, religious beliefs, and political values? Describe factors that may have influenced your identity development in an important domain.

Moral Development

Eleven-year-old Sabrina sat at the kitchen table reading the Sunday newspaper, her eyes wide with interest. “Look at this!” she said to 16-year-old Louis, who was munching cereal. Sabrina held up a page of large photos showing a 70-year-old woman standing in her home. The floor and furniture were piled with stacks of newspapers, cardboard boxes, tin cans,

Cultural Influences

Identity Development Among Ethnic Minority Adolescents

Most adolescents are aware of their cultural ancestry but relatively unconcerned about it. However, for teenagers who are members of minority groups, **ethnic identity**—a sense of ethnic group membership and attitudes and feelings associated with that membership—is central to the quest for identity. As they develop cognitively and become more sensitive to feedback from the social environment, minority youths become painfully aware that they are targets of prejudice and discrimination. This discovery complicates their efforts to develop a sense of cultural belonging and a set of personally meaningful goals.

In many immigrant families from collectivist cultures, adolescents' commitment to obeying their parents and fulfilling family obligations lessens the longer the family has been in the immigrant-receiving country—a circumstance that induces **acculturative stress**, psychological distress resulting from conflict between the minority and the host culture (Phinney, Ong, & Madden, 2000). When immigrant parents tightly restrict their teenagers through fear that assimilation into the larger society will undermine their cultural traditions, their youngsters often rebel, rejecting aspects of their ethnic background.

At the same time, discrimination can interfere with the formation of a positive ethnic identity. In one study, Mexican-American youths who had experienced more discrimination were less likely to explore their ethnicity and to report feeling good about it (Romero & Roberts, 2003). Those with low ethnic pride showed a sharp drop in self-esteem in the face of discrimination.

With age, many minority young people strengthen their ethnic identity. But because the process of forging an ethnic identity can be painful and confusing, others show no change, and still others regress (Huang & Stormshak, 2011). Young people with parents of different ethnicities face extra challenges.

In a large survey of high school students, part-black biracial teenagers reported as much discrimination as their monoracial black counterparts, yet they felt less positively about their ethnicity. And compared with monoracial minorities, many biracial young people—including black-white, black-Asian, white-Asian, black-Hispanic, and white-Hispanic—regarded ethnicity as less central to their identities (Herman, 2004). Perhaps these adolescents encountered fewer opportunities in their homes and communities to forge a strong sense of belonging to either culture.

Adolescents whose family members encourage them to disprove ethnic stereotypes of low achievement or antisocial behavior typically surmount the threat that discrimination poses to a favorable ethnic identity. These young people manage experiences of unfair treatment effectively, by seeking social support and engaging in direct problem solving (Phinney & Chavira, 1995; Scott, 2003). Also, adolescents whose families taught them the history, traditions, values, and language of their ethnic group and who frequently interact with same-ethnicity peers are more likely to forge a favorable ethnic identity (Hughes et al., 2006; McHale et al., 2006).

How can society help minority adolescents resolve identity conflicts constructively? Here are some relevant approaches:

- Promote effective parenting, in which children and adolescents benefit from family ethnic pride yet are encouraged to explore the meaning of ethnicity in their own lives.
- Ensure that schools respect minority youths' native languages, unique learning styles, and right to high-quality education.
- Foster contact with peers of the same ethnicity, along with respect between ethnic groups (García Coll & Magnuson, 1997).

Stilt walkers celebrate their heritage at a Caribbean youth festival. Minority youths whose culture is respected in their community are more likely to incorporate ethnic values and customs into their identity.

A strong, secure ethnic identity is associated with higher self-esteem, optimism, a sense of mastery over the environment, and more positive attitudes toward one's ethnicity (St. Louis & Liem, 2005; Umana-Taylor & Updegraff, 2007; Worrell & Gardner-Kitt, 2006). For these reasons, adolescents with a positive connection to their ethnic group are better-adjusted. They cope more effectively with stress, show higher achievement in school, and have fewer emotional and behavior problems than age-mates who identify only weakly with their ethnicity (Ghavami et al., 2011; Greene, Way, & Pahl, 2006; Seaton, Scottham, & Sellers, 2006; Umana-Taylor & Alfaro, 2006).

Forming a **bicultural identity**—by exploring and adopting values from both the adolescent's subculture and the dominant culture—offers added benefits. Biculturally identified adolescents tend to be achieved in other areas of identity as well and to have especially favorable relations with members of other ethnic groups (Phinney, 2007; Phinney et al., 2001). In sum, achievement of ethnic identity enhances many aspects of emotional and social development.

glass containers, food, and clothing. The accompanying article described crumbling plaster on the walls, frozen pipes, and nonfunctioning sinks, toilet, and furnace. The headline read: “Loretta Perry: My Life Is None of Their Business.”

“Look what they’re trying to do to this poor lady,” exclaimed Sabrina. “They wanna throw her out of her house and tear it down! Those city inspectors must not care about anyone. Here it says, ‘Mrs. Perry has devoted much of her life to doing favors for people.’ Why doesn’t someone help *her*?”

“Sabrina, you’re missing the point,” Louis responded. “Mrs. Perry is violating 30 building code standards. The law says you’re supposed to keep your house clean and in good repair.”

“But Louis, she’s old, and she needs help. She says her life will be over if they destroy her home.”

“The building inspectors aren’t being mean, Sabrina. She’s refusing to obey the law. And she’s not just a threat to herself—she’s a danger to her neighbors, too. Suppose her house caught on fire. You can’t live around other people and say your life is nobody’s business.”

“You don’t just knock someone’s home down,” Sabrina replied angrily. “Why aren’t her friends and neighbors over there fixing up that house? You’re just like those building inspectors, Louis. You’ve got no feelings!”

As Louis and Sabrina’s disagreement over Loretta Perry’s plight illustrates, cognitive development and expanding social experiences permit adolescents to better understand larger social structures—societal institutions and law-making systems—that govern moral responsibilities. As their grasp of social arrangements expands, adolescents construct new ideas about what should be done when the needs and desires of people conflict. As a result, they move toward increasingly just, fair, and balanced solutions to moral problems.

Kohlberg’s Theory of Moral Development

Early work by Piaget on the moral judgment of the child inspired Lawrence Kohlberg’s more comprehensive cognitive-developmental theory of moral understanding. Kohlberg used a clinical interviewing procedure in which he presented a sample of 10- to 16-year-old boys with hypothetical *moral dilemmas*—stories involving a conflict between two moral values—and asked them what the main actor should do and why. Then he followed the participants longitudinally, reinterviewing them at 3- to 4-year intervals over the next 20 years. The best known of Kohlberg’s dilemmas, the “Heinz dilemma,” pits the value of obeying the law (not stealing) against the value of human life (saving a dying person):

In Europe a woman was near death from cancer. There was one drug the doctors thought might save her. A druggist in the same town had discovered it, but he was charging ten times what the drug cost him to make. The sick woman’s husband, Heinz, went to everyone he knew to borrow the money, but he could only get together half of what it cost. The druggist refused to sell the drug for less or let Heinz pay later. So Heinz became desperate and broke into the man’s store to steal the drug for his wife. Should

Heinz have done that? Why or why not? (paraphrased from Colby et al., 1983, p. 77)

Kohlberg emphasized that it is *the way an individual reasons about the dilemma*, not *the content of the response* (whether or not to steal), that determines moral maturity. Individuals who believe Heinz should take the drug and those who think he should not can be found at each of Kohlberg’s first four stages. Only at the two highest stages do moral reasoning and content come together in a coherent ethical system (Kohlberg, Levine, & Hewer, 1983). Given a choice between obeying the law and preserving individual rights, the most advanced moral thinkers support individual rights (in the Heinz dilemma, stealing the drug to save a life). **TAKE A MOMENT...** Does this remind you of adolescents’ efforts to formulate a sound, well-organized set of personal values in constructing an identity? According to some theorists, the development of identity and moral understanding are part of the same process (Bergman, 2004; Blasi, 1994).

Kohlberg’s Stages of Moral Understanding.

Kohlberg organized moral development into three levels, each with two stages, yielding six stages in all. He believed that moral understanding is promoted by the same factors Piaget thought were important for cognitive development: (1) actively grappling with moral issues and noticing weaknesses in one’s current reasoning, and (2) gains in perspective taking, which permit individuals to resolve moral conflicts in more effective ways. **TAKE A MOMENT...** As we examine Kohlberg’s developmental sequence and illustrate it with responses to the Heinz dilemma, look for changes in perspective taking that each stage assumes.

The Preconventional Level. At the preconventional level, morality is externally controlled. Children accept the rules of authority figures and judge actions by their consequences. Behaviors that result in punishment are viewed as bad, those that lead to rewards as good.

- **Stage 1: The punishment and obedience orientation.** Children at this stage find it difficult to consider two points of view in a moral dilemma. As a result, they overlook people’s intentions. Instead, they focus on fear of authority and avoidance of punishment as reasons for behaving morally.

Prostealing: “If you let your wife die, you will . . . be blamed for not spending the money to help her and there’ll be an investigation of you and the druggist for your wife’s death.” (Kohlberg, 1969, p. 381)

Antistealing: “You shouldn’t steal the drug because you’ll be caught and sent to jail if you do. If you do get away, [you’d be scared that] the police would catch up with you any minute.” (Kohlberg, 1969, p. 381)

- **Stage 2: The instrumental purpose orientation.** Children become aware that people can have different perspectives in a moral dilemma, but at first this understanding is concrete. They view right action as flowing from self-interest and understand reciprocity as equal exchange of favors: “You do this for me and I’ll do that for you.”

If the child on the right expects a favor in return for helping her friend, she is at Kohlberg's preconventional level. If she is motivated by ideal reciprocity, as in the Golden Rule, she has advanced to the conventional level.

Prostealing: “[I]f Heinz decides to risk jail to save his wife, it’s his life he’s risking; he can do what he wants with it. And the same goes for the druggist; it’s up to him to decide what he wants to do.” (Rest, 1979, p. 26)

Antistealing: “[Heinz] is running more risk than it’s worth [to save a wife who is near death].” (Rest, 1979, p. 27)

The Conventional Level. At the conventional level, individuals continue to regard conformity to social rules as important, but not for reasons of self-interest. Rather, they believe that actively maintaining the current social system ensures positive relationships and societal order.

- **Stage 3: The “good boy–good girl” orientation, or the morality of interpersonal cooperation.** The desire to obey rules because they promote social harmony first appears in the context of close personal ties. Stage 3 individuals want to maintain the affection and approval of friends and relatives by being a “good person”—trustworthy, loyal, respectful, helpful, and nice. The capacity to view a two-person relationship from the vantage point of an impartial, outside observer supports this new approach to morality. At this stage, individuals understand *ideal reciprocity*: They express the same concern for the welfare of another as they do for themselves—a standard of fairness summed up by the Golden Rule: “Do unto others as you would have them do unto you.”

Prostealing: “No one will think you’re bad if you steal the drug, but your family will think you’re an inhuman husband if you don’t. If you let your wife die, you’ll never be able to look anyone in the face again.” (Kohlberg, 1969, p. 381)

Antistealing: “It isn’t just the druggist who will think you’re a criminal, everyone else will too. . . . [Y]ou’ll feel bad thinking how you’ve brought dishonor on your family and yourself.” (Kohlberg, 1969, p. 381)

- **Stage 4: The social-order-maintaining orientation.** At this stage, the individual takes into account a larger perspective—that of societal laws. Moral choices no longer depend on close ties to others. Instead, rules must be enforced in the same evenhanded fashion for everyone, and each member of society has a personal duty to uphold them. The Stage 4 individual believes that laws should never be disobeyed because they are vital for ensuring societal order and cooperation between people.

Prostealing: “Heinz has a duty to protect his wife’s life; it’s a vow he took in marriage. But it’s wrong to steal, so he would have to take the drug with the idea of paying the druggist for it and accepting the penalty for breaking the law later.”

Antistealing: “Even if his wife is dying, it’s still [Heinz’s] duty as a citizen to obey the law. . . . If everyone starts breaking the law in a jam, there’d be no civilization, just crime and violence.” (Rest, 1979, p. 30)

The Postconventional or Principled Level. Individuals at the postconventional level move beyond unquestioning support for their own society’s rules and laws. They define morality in terms of abstract principles and values that apply to all situations and societies.

- **Stage 5: The social contract orientation.** At Stage 5, individuals regard laws and rules as flexible instruments for furthering human purposes. They can imagine alternatives to their own social order, and they emphasize fair procedures for interpreting and changing the law. When laws are consistent with individual rights and the interests of the majority, each person follows them because of a *social contract orientation*—free and willing participation in the system because it brings about more good for people than if it did not exist.

Prostealing: “Although there is a law against stealing, the law wasn’t meant to violate a person’s right to life. . . . If Heinz is prosecuted for stealing, the law needs to be reinterpreted to take into account situations in which it goes against people’s natural right to keep on living.”

Antistealing: At this stage, there are no antistealing responses.

- **Stage 6: The universal ethical principle orientation.** At this highest stage, right action is defined by self-chosen ethical principles of conscience that are valid for all people, regardless of law and social agreement. Stage 6 individuals typically mention such abstract principles as respect for the worth and dignity of each person.

Prostealing: “It doesn’t make sense to put respect for property above respect for life itself. [People] could live together without private property at all. Respect for human life and personality is absolute and accordingly [people] have a mutual duty to save one another from dying.” (Rest, 1979, p. 37)

Antistealing: At this stage, there are no antistealing responses.

Research on Kohlberg's Stage Sequence. Kohlberg's original research and other longitudinal studies provide the most convincing evidence for his stage sequence. With few exceptions, individuals move through the first four stages in the predicted order (Boom, Wouters, & Keller, 2007; Dawson, 2002; Walker & Taylor, 1991b). Moral development is slow and gradual: Reasoning at Stages 1 and 2 decreases in early adolescence, while Stage 3 increases through midadolescence and then declines. Stage 4 reasoning rises over the teenage years until, among college-educated young adults, it is the typical response.
