Preface to the sixth edition

Haematology continues to advance and change more rapidly than most areas of medicine. This sixth edition of *Postgraduate Haematology* includes much knowledge that has been gained in the five years since the previous edition. Professor Tony Green of the Department of Haematology, University of Cambridge has joined the editors of the last edition to help cover malignant diseases, where major changes have occurred in their classification (WHO, 2008) and in diagnostic procedures and treatment protocols. Haematological oncology now forms the major workload for many consultant haematologists. Nevertheless, benign conditions are a major source of work for the general haematologist and chapters concerning all these conditions have been extensively updated, often by new authors.

Despite increased understanding of the molecular basis of haematological diseases and advances in their investigation and management, we have kept the size of the book unchanged by omitting ten chapters from the fifth edition and incorporating their essential information into the remaining chapters.

As for previous editions, this book is aimed at providing haematologists in training and consultants with up-to-date knowledge of the aetiology of blood diseases combined with a practical guide to their investigation and treatment. The views expressed are those of the individual authors but relevant literature is listed at the end of each chapter to provide additional reference material.

Many of our authors are based outside the UK, particularly in Europe and the USA, and we hope this book will be used by haematologists practising in the UK, Europe and internationally. We are grateful to our publishers Wiley-Blackwell for their unstinting help during the publishing process and particularly to Rebecca Huxley and Jennifer Seward. We also thank Jane Fallows who, as previously, has with great expertise drawn all the scientific diagrams.

London and Cambridge, 2011
AVH, DC, EGDT, ARG

Preface to the first edition

In this book the authors combine an account of the physiological and biochemical basis of haematological processes with descriptions of the clinical and laboratory features and management of blood disorders. Within this framework, each author has dealt with the individual subjects as he or she thought appropriate. Because this book is intended to provide a foundation for the study of haematology and is not intended to be a reference book, it reflects, to some extent, the views of the individual authors rather than providing comprehensive detail and a full bibliography. For these the reader is referred to the selected reading given at the end of each chapter. It is hoped that the book will prove of particular value to students taking either the Primary or the Final Part of the examination for Membership of the Royal College of Pathologists and the Diplomas of Clinical Pathology. It should also prove useful to physicians wishing to gain special knowledge of haematology and to technicians taking the Advanced Diploma in Haematology of the Institute of Medical Laboratory Technology, or the Higher National Certificate in Medical Laboratory subjects.

We wish to acknowledge kind permission from the editors and publishers of the *British Journal of Haematology*, the *Journal*

of the Royal College of Physicians of London and the *Quarterly Journal of Medicine* for permission to reproduce figures 4.1, 4.5, 4.10, 4.11, 4.12, 9.4 and 9.10, also the publishers of *Progress in Haematology* for figure 7.2, and many other publishers who, together with the authors, have been acknowledged in the text. We are particularly grateful to Professor J.V. Dacie for providing material which formed the basis of many of the original illustrations in Chapters 4–8. We are greatly indebted to Mrs T. Charalambos, Mrs J. Cope and Mrs D. Haysome for secretarial assistance and to Mrs P. Schilling and the Department of Medical Illustration for photomicrography, art work and general photography.

Finally, we are grateful for the invaluable help and forbearance we have received from Mr R. Emery and William Heinemann Medical Books.

Introduction

Haemopoietic stem cells (HSCs) are the foundation of the adult blood system and sustain the lifelong production of all blood lineages. These rare cells are generally defined by their ability to self-renew through a process of asymmetric cell division, the outcome of which is an identical HSC and a differentiating cell. Through a series of proliferation and differentiation events, mature blood cells are produced. In health, HSCs provide homeostatic maintenance of the system through their ability to generate the hundreds of millions of erythrocytes and leucocytes needed each day. In trauma and physiological stress, HSCs are triggered to replace the lost or damaged blood cells. The tight regulation of HSC self-renewal ensures the appropriate balance of blood cell production. Perturbation of this regulation and unchecked growth of HSCs and/or immature blood cells results in leukaemia. Over the last 50 years, bone marrow transplantation, and more recently cord blood transplantation, have underscored the medical value of stem cell regenerative therapy. However, insufficient numbers of HSCs are still a major constraint in clinical applications. As the pivotal cells in this essential tissue, HSCs are the focus of intense research to further our understanding of their normal behaviour and the basis of their dysfunction in haemopoietic disease and leukaemia, and to provide insights and new strategies into improved clinical transplantation therapies. This chapter provides current and historical information on the organization of the adult haemopoietic cell differentiation hierarchy, the ontogeny of HSCs, the stromal microenvironment supporting these cells,

and the molecular mechanisms involved in the regulation of HSCs.

Hierarchical organization and lineage relationships in the adult haemopoietic system

The haemopoietic system is the best-characterized cell lineage differentiation hierarchy and, as such, has set the paradigm for the growth and differentiation of tissue-specific stem cells (Table 1.1). HSCs are defined by their high proliferative potential, ability to self-renew and potential to give rise to all haemopoietic lineages. HSCs produce immature progenitors that gradually and progressively, through a series of proliferation and differentiation events, become restricted in lineage differentiation potential. Such restricted progenitors produce the terminally differentiated functional blood cells.

The lineage relationships of the variety of cells within the adult haemopoietic hierarchy (Figure 1.1) are based on results of *in vivo* transplantation assays in radiation chimeric mice and many *in vitro* differentiation assays that became available following the identification of haemopoietic growth factors. These assays facilitated measurement of the maturational progression of stem cells and progenitors, at or near the branch points of lineage commitment. Clonal analyses, in the form of colony-forming unit (CFU) assays, were developed to define the lineage differentiation potential of the stem cell or progenitor, and to quantitate the number/frequency of such cells in the population as a whole. In general, the rarer a progenitor is and the greater its lineage differentiation potential, the closer it is in the hierarchy to the HSC. *In vitro* clonogenic assays measure the most immature progenitor CFU-GEMM/Mix (granulocyte, erythroid, macrophage, megakaryocyte), bipotent progenitors

Table 1.1

Transcription factors involved in haemopoietic and progenitor cell formation, survival and differentiation

Cell	Transcription factors
Stem cells from mesoderm	SCL/TAL-1; LMO2/RBTN-2
Generate and/or maintain stem cells	RUNX-1 ^a /AML-1; TEL-1
Myelopoiesis	MLL; GATA2 ^a PU.1; C/EBP α , C/EBP ϵ GFI-1, EGR-1, NAB2
Erythroid/megakaryocyte/mast cells	GATA2
Erythropoiesis, megakaryopoiesis	GATA2; GATA1; FOG1
Lymphopoiesis	SCL; EKLF; p45NF-E2 IKAROS1
B	E2A; EBF; PAX5
Plasma cell	BLIMP1
T	CSL; GATA3, T-BET, NFATc

Immunophenotype of haemopoietic stem cells

Positive	Negative
CD34	CD33
Thy1	CD38
AC133	Lineage markers
cKIT	HLA DR

^aBased on mouse studies.

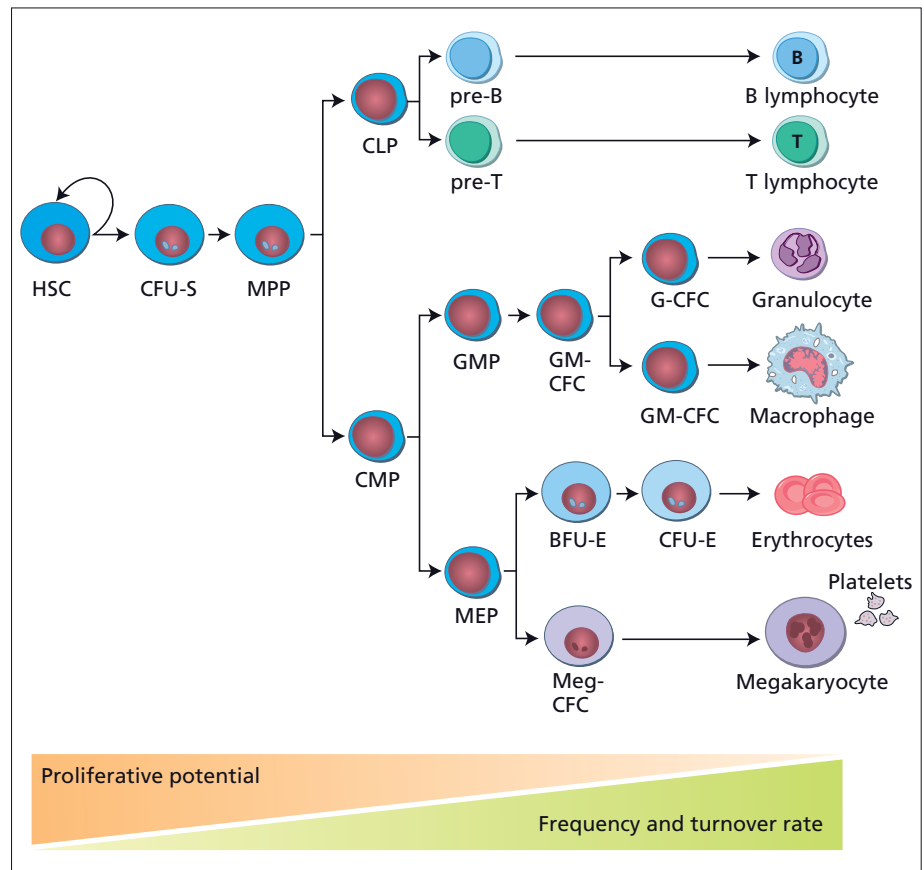

CFU-GM (granulocyte, macrophage) and restricted progenitors CFU-M (macrophage), CFU-G (granulocyte), CFU-E (erythroid) and BFU-E (burst forming unit-erythroid). While such *in vitro* clonogenic assays measure myeloid and erythroid potential, lymphoid potential is revealed only in fetal thymic organ cultures and stromal cell co-cultures in which the appropriate microenvironment and growth factors are present. Long-term culture assays (6–8 week duration), such as the cobblestone-area forming cell (CAFC) and the long-term culture-initiating cell (LTC-IC) assays, reveal the most immature of haemopoietic progenitors.

In vivo, the heterogeneity of the bone marrow population of immature progenitors and HSCs is reflected in the time periods at which different clones contribute to haemopoiesis. Short-term *in vivo* repopulating haemopoietic progenitor cells such as CFU-S (spleen) give rise to macroscopic erythromyeloid colonies on the spleen within 14 days of injection. Bona fide HSCs give rise to the long-term high-level engraftment of all haemopoietic lineages. Serial transplantations reveal the ability of the long-term repopulating HSCs to self-renew. The clonal nature

of engraftment and the multilineage potential of HSCs has been demonstrated through radiation and retroviral marking of bone marrow cells. Moreover, such studies suggest that, at steady state, only a few HSC clones contribute to the haemopoietic system at any one time. Further analyses of bone marrow HSCs show that this compartment consists of a limited number of distinct HSC subsets, each with predictable behaviours as described by their repopulation kinetics in irradiated adult recipients. In general, the bone marrow haemopoietic cell compartment as measured by *in vitro* clonogenic assays and *in vivo* transplantation assays shows a progression along the adult differentiation hierarchy from HSCs to progenitors and fully functional blood cells with decreased multipotency and proliferative potential, and an increased cell turnover rate.

The use of flow cytometry to enrich for HSCs and the various progenitors in adult bone marrow has been instrumental in refining precursor–progeny relationships in the adult haemopoietic hierarchy. HSCs are characteristically small ‘blast’ cells, with a relatively low forward and side light scatter and low metabolic activity. Both mouse and human HSCs are negative for expression of mature haemopoietic lineage cell-surface markers, such as those found on B lymphoid cells (CD19, B220), T lymphoid cells (CD4, CD8, CD3), macrophages (CD15, Mac-1) and granulocytes (Gr-1). Positive selection for mouse HSCs relies on expression of Sca-1, c-kit, endoglin and CD150 markers and for human HSCs on expression of CD34, c-kit, IL-6R, Thy-1 and CD45RA markers. Similarly, cell types at lineage branch points have been identified, including the CMP (common myeloid progenitor), CLP (common lymphoid progenitor) and GMP (granulocyte macrophage progenitor). Recently, using the flt3 receptor tyrosine kinase surface marker along with many other well-studied markers, the LMPP (lymphoid primed multipotent progenitor) has been identified within the lineage negative, Sca-1 positive, c-kit positive (LSK) enriched fraction of HSCs. These cells have granulocyte/macrophage, B lymphoid and T lymphoid potential, but little or no megakaryocyte/erythroid potential. This suggests that the first lineage differentiation event is not a strict separation into common lymphoid and myeloid pathways. While these cell-surface marker changes and functional restriction events are represented by discrete cells in the working model of the haemopoietic hierarchy as depicted in textbooks and Figure 1.1, it is most likely that there is a continuum of cells between these landmarks. The currently identified progenitor cells in the hierarchy represent the cells present at stable and detectable frequencies and for which we currently have markers and functional assays. As more cell-surface markers are identified and sensitivity of detection is increased, more intermediate cell subsets are likely to be identified and it may be possible to determine, throughout the continuum, all the molecular events needed for the differentiation of the haemopoietic system and the transit times necessary for differentiation to the next subset.

Figure 1.1 The adult haemopoietic hierarchy. Haemopoietic stem cells are at the foundation of the hierarchy. Through a series of progressive proliferation and differentiation steps the mature blood cell lineages are produced. Haemopoietic stem cells have the greatest proliferative and multilineage differentiation potential, while the mature blood cells are not proliferative and are lineage restricted. While large numbers of mature cells are found in the blood and turn over rapidly, the bone marrow contains long-lived quiescent haemopoietic stem cells at a very low frequency.

Sites of adult haemopoiesis

Bone marrow, spleen, thymus and lymph nodes are the haemopoietic sites in the adult, and each tissue plays a special role in supporting the growth and differentiation of particular haemopoietic cell lineages and subsets. Equally important is the blood itself, which is a mobile haemopoietic tissue, with mature blood cells travelling through the circulation to function in all parts of the body. Not only do the terminally differentiated cells, such as erythrocytes and lymphocytes, move by means of the circulation, but HSCs (at low frequency) also migrate through the circulation from the bone marrow to other haemopoietic tissues. HSCs are mostly concentrated in the bone marrow and are found in the endosteal and vascular niches (Figure 1.2). HSCs can be induced to circulate by administration of granulocyte colony-stimulating factor (G-CSF) and it is of great interest to determine whether these cells retain all the characteristics of stem cells. Recent improvements in confocal microscopy have allowed the visualization of the migration of circulating HSCs to the bone marrow endosteal niche by time-lapse imaging in the mouse.

The estimated frequency of HSCs is 1 per 10^4 – 10^5 mouse bone marrow cells and 1 per 20×10^6 human bone marrow cells.

HSCs are also found in the mouse spleen at approximately a 10-fold lower frequency and in the circulating blood at a 100-fold lower frequency. The capacity for HSCs to migrate and also be retained in the bone marrow is of relevance to clinical transplantation therapies. HSCs injected intravenously in such therapies must find their way to the bone marrow for survival and effective haemopoietic engraftment. For example, stromal-derived factor (SDF)-1 and its receptor CXCR4 (expressed on HSCs) are implicated in the movement of HSCs and the retention of HSCs in the bone marrow. Indeed, HSC mobilization can be induced through AMD3100, an antagonist of SDF-1, and by the administration of G-CSF. Mobilization strategies with G-CSF are used routinely to stimulate bone marrow HSCs to enter the circulation, allowing ease of collection in the blood rather than through bone marrow biopsy.

Development of HSCs

Waves of haemopoietic generation in embryonic development

Until the mid 1960s it was thought that blood cells were intrinsically generated in tissues such as the liver, spleen, bone marrow

Figure 1.2 The bone marrow haemopoietic niches. Haemopoietic stem cells are found in the endosteal and endothelial niches of the bone marrow. These niches support the maintenance, self-renewal, expansion, differentiation, migration and survival of haemopoietic stem cells through local growth factor production, cell–cell interactions and more distance signals.

and thymus. Survival studies in which cells from unirradiated tissues were injected into lethally irradiated mice showed that it was the bone marrow that contains the potent cells responsible for rescue from haemopoietic failure. Later, through clonal marking studies, it was demonstrated that bone marrow harbours HSCs during the adult stages of life. But where, when and how are HSCs generated during ontogeny? In the 1970s, examination of mouse embryo tissues suggested that adult haemopoietic cells are generated in the yolk sac, migrate and colonize initially the fetal liver and subsequently the bone marrow, where they reside throughout adult life. However, studies in non-mammalian vertebrate models (avian and amphibian) demonstrated that the aorta region in the body of the embryo generates the long-lived adult blood system, while the yolk sac (or equivalent tissue) produces the transient embryonic haemopoietic system. In agreement with these studies, the aorta–gonad–mesonephros (AGM) region of the mouse embryo was later found to generate the first adult HSCs.

The development of the mammalian adult haemopoietic system is complex and begins its development in the mouse embryo during mid-gestation. As a growing organism, the embryo itself needs rapid haemopoiesis to thrive before the adult system is generated. Thus, a simple transient haemopoietic system is generated during early development and rapidly produces primitive erythroid and myeloid cells. In the yolk sac

Figure 1.3 Precursors to haemopoietic cells in embryonic stages. The mesodermal precursor to haemopoietic and endothelial lineages at early stages of development is the haemangioblast. Later, haemogenic endothelial cells are the precursors to haemopoietic stem cells and progenitor cells. These cells appear to exist during a short window of developmental time.

both haemopoietic and endothelial cells are simultaneously generated from a common mesodermal precursor cell, the haemangioblast (Figure 1.3). Thereafter, many haemopoietic progenitor and differentiated cell types are generated in both the yolk sac and the intraembryonic region of the dorsal aorta to create an intermediate haemopoietic system. It is likely that these cells also are derived from a haemangioblast-type precursor or from haemogenic endothelial cells, a specialized population of endothelial cells that have haemogenic potential. At both these early times in ontogeny, the mouse embryo contains no HSCs. Hence, in the absence of HSCs, the embryo generates a haemopoietic system that is short-lived and lacks the important qualitative characteristics (longevity and self-renewability) of the adult haemopoietic system. Independent and distinct waves of haemopoiesis supply the embryo and adult and do not arise from the same cohorts of mesodermal precursor cells (Figure 1.4).

The adult system has its foundation in a cohort of initiating HSCs. The first HSCs are *de novo* generated in the AGM region, only after embryonic haemopoietic cells are differentiated directly from mesodermal precursors. The first adult HSCs are autonomously generated in the mouse AGM at E10.5 and in the human AGM beginning at week 4 of gestation. Recently, the process of HSC generation has been visualized in real time in the mouse embryo (Boisset *et al.*, 2010). This remarkable observation demonstrating that HSCs are derived via a transdifferentiation event in which specialized endothelial cells lining the aorta bud into the lumen to form round cells with HSC fate, confirm the marking and static microscopic studies performed in avian embryos (Figure 1.5). The emerging mouse aortic HSCs are characterized by the loss of cell-surface markers for endothelium, such as Flk-1 and VE-cadherin, and the gain of expression of the haemopoietic markers *c-kit*, CD41 and CD45 and the HSC markers *Sca1*, *c-kit* and endoglin (Boisset *et al.*, 2010). Expression of HSC markers confirms that the emerging

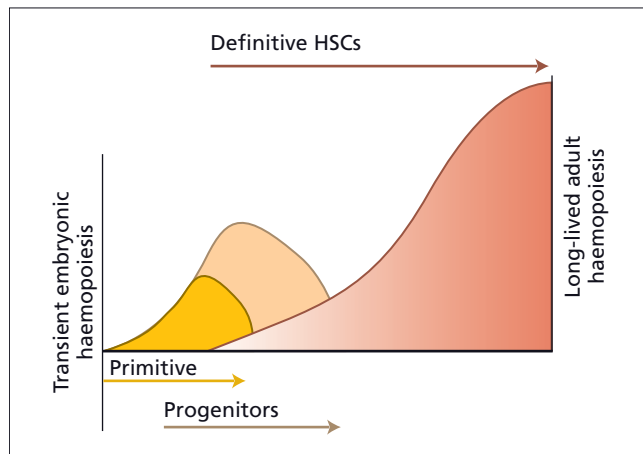

Figure 1.4 Waves of haemopoietic cell emergence during embryonic stages. The earliest haemopoietic cells are produced during the first wave of haemopoietic fate determination. The onset of this wave occurs in the yolk sac blood islands and produces transient primitive erythroid cells. This wave continues with the production of transient haemopoietic progenitors in the absence of bona fide haemopoietic stem cells. True long-lived definitive haemopoietic stem cells (adult repopulating stem cells) are generated in the second wave of haemopoietic cell emergence in the AGM region. In this wave, haemogenic endothelial cells bud into the aortic lumen as these cells take on haemopoietic stem cell fate.

Figure 1.5 Schematic diagram of the aorta–gonad–mesonephros (AGM) region and haemopoietic cell clusters emerging from the dorsal aorta. The haemopoietic stem cell inductive microenvironment is localized in the ventral aspect of the aorta.

AGM cells are HSCs as functionally potent as bone marrow HSCs, since these sorted cells can form a complete long-term haemopoietic system in irradiated adult recipient mice.

Lineage tracing experiments in the mouse embryo have indicated that the adult haemopoietic system is generated during a short window of development, spanning E9–E11. Using Cre-lox

recombination (temporally and cell lineage controlled) to mark VE-cadherin expressing endothelial cells in the mid-gestation embryo, it was found that almost all the blood cells in the circulation and haemopoietic tissues of the adult mice contained the recombination marker, unequivocally demonstrating that adult HSCs are the progeny of embryonic endothelial cells. Moreover, these cells require the Runx1 transcription factor as demonstrated by *Runx1* conditional deletion in this mouse model. Other lineage tracing experiments were also performed using Cre-lox technology so as to mark the earliest cells expressing the Runx1 and SCL transcription factors, both of which are known to be important for haemopoietic cell development. The progeny of marked SCL-expressing (endothelial and haemopoietic) cells and Runx1-expressing (definitive haemopoietic and haemogenic endothelial) cells also contributed to the bone marrow cells in the adult. Thus, the progeny of haemopoietic cells generated from haemogenic endothelium in the embryo contribute to a cohort of adult bone marrow HSCs that form the foundation of haemopoiesis throughout adult life.

Embryonic haemopoietic sites and haemopoietic migration

The AGM and yolk sac are not the only sites where haemopoietic cells are found in the early conceptus. The placenta is a highly haemopoietic tissue and has recently been shown to generate haemopoietic cells *de novo*. Much like the early-stage yolk sac, the mouse placenta can produce erythromyeloid progenitors. Embryos deficient for the *Ncx1* gene, lacking a heartbeat and circulation, have such progenitors in the yolk sac and placenta at early stages, suggesting that haemopoietic progenitors are generated in these tissues. Unfortunately, the embryos die before the onset of HSC generation at mid-gestation, precluding analysis of HSC production in the yolk sac and placenta. In normal embryos where the circulation is established between the embryo body and the extraembryonic tissues at E8.25, HSCs are detected in the placenta and yolk sac only beginning at E11, subsequent to the first HSC generation in the AGM at E10.5. Thus it is uncertain whether the placenta (or the yolk sac) can generate HSCs *de novo*. At present, there is no method by which cells can be uniquely marked in the specific developing tissues to examine this. Nonetheless, quantitative studies in which HSC numbers in each of these tissues was determined suggest that the AGM cannot generate all the HSCs that are eventually found in the fetal liver (a tissue that harbours haemopoietic cells but does not generate them) and later in the adult bone marrow (Figure 1.4). In particular, the placenta at mid-gestation contains an abundance of HSCs, suggesting that this highly vascularized tissue may generate HSCs from haemogenic endothelium and/or that the placenta is a highly supportive and expansive microenvironment for AGM-derived HSCs.

Like the mouse placenta, the developing human placenta contains HSCs. Already at week 6 in gestation HSCs can be

detected, as analysed by *in vivo* xenotransplantation into immunodeficient mice. Also, haemopoietic progenitors are found at these early stages. Phenotypic characterization shows that HSCs and progenitors are in both the CD34-positive and CD34-negative fractions at week 6 of gestation and are exclusively in the CD34-positive fraction by week 19. These cells are in close association with the placental vasculature. Taken together, the development of the haemopoietic system in the human conceptus closely parallels that in the mouse conceptus. Interestingly, together with the umbilical cord blood harvested at birth, the placenta may provide additional haemopoietic progenitors and HSCs for preclinical studies and potential clinical therapies.

HSC quiescence, proliferation and ageing

Somatic stem cells undergo lifelong self-renewal and possess the potential to produce the differentiated cells of the tissue. HSCs are considered to be relatively dormant stem cells, dividing rather infrequently. They are enriched in the quiescent fraction of adult bone marrow and are resistant to antiproliferative drugs such as 5-fluorouracil. Recent studies using a label-retaining method for analysis of cycling versus non-cycling cells shows that dormant HSCs in homeostatic conditions cycle only once every 21 weeks. The adult mouse possesses approximately 600 of these dormant LSK CD150⁺CD48⁻CD34⁻ HSCs. Interestingly, 38% of HSCs in G₀, considered to be the dormant HSCs, can be activated by injury, 5-fluorouracil or G-CSF. These cells can return to the dormant state after the re-establishment of homeostasis.

The maintenance of HSC dormancy is thought to be an important strategy for preventing stem cell exhaustion during adult life. It has been demonstrated by serial transplantation in the mouse that HSC self-renewal is limited to about six rounds of transplantation and that the ability of the transplanted stem cells to repopulate progressively decreases. Studies of chromosome shortening in human HSCs suggest that self-replication is limited to about 50 cell divisions. It has been suggested that accumulating DNA mutations and loss of telomere repeats affect HSC function. Recently, a set of experiments have demonstrated that HSCs are markedly reduced in number and/or function in ageing mice. Comparison of various inbred mouse strains has shown that the rate of haemopoietic cell cycling is inversely correlated with their mean lifespan. The decrease in HSC quantity or quality was due to cell-intrinsic genetic or epigenetic factors. Causative genes were identified by transcriptional profiling comparisons between the HSCs of the different strains. Of particular interest are chromatin modifiers involved in prevention of HSC exhaustion through maintenance of a stem cell-specific transcriptional programme. Changes in chromatin structure associated with high HSC turnover would result in stem cell senescence (which is thought to protect stem cells from malignant transformation by oncogenic events).

Haemopoietic supportive microenvironments

Adult bone marrow microenvironment

Most tissue-specific stem cells are maintained in a special microenvironment to support their long-term growth and self-renewal. To provide the continuous production of human blood over many decades, HSCs are also maintained in a specialized microenvironment, the haemopoietic supportive niches of the adult bone marrow (see Figure 1.2). The importance of the bone marrow haemopoietic niche and the interactions between supportive cells and HSCs was first demonstrated in mice. In transplantation studies of anaemic mouse strains naturally deficient in the c-kit receptor tyrosine kinase (W mice) or kit-ligand (KL; Steel mice) it was revealed that bone marrow from W mutant mice could not repopulate the haemopoietic system of wild-type irradiated recipient mice, while bone marrow from Steel mutant mice could. In contrast, W mutant mice could be repopulated by wild-type donor bone marrow cells, whereas Steel recipients were defective for repopulation by wild-type donor cells. Thus, it was proposed that a receptor–ligand interaction was involved in the support of HSCs within the bone marrow microenvironment and it was subsequently shown that HSCs express c-kit and bone marrow stromal cells express KL. The development of *ex vivo* culture systems to study this complex microenvironment allowed further dissection of the cellular and molecular aspects of the bone marrow microenvironment. These studies were aided by the isolation of mesenchymal stromal cells.

Stromal cell lines have been derived from the adult mouse bone marrow and fetal liver tissues. These are generally of mesenchymal lineage as determined by cell-surface marker expression and their osteogenic and adipogenic potentials. Although widely heterogeneous in their ability to support haemopoiesis, some stromal lines (MS5 and AFT024, for example) have been shown to support the growth and/or maintenance of HSCs in co-cultures for long periods. Moreover, they have been instrumental in further characterization of these haemopoietic supportive niches. Comparative transcriptional profiling and database analysis of HSC supportive and non-supportive stromal cell lines has revealed a complex genetic programme involving a wide variety of known molecules and molecules whose function in haemopoiesis is unknown.

The *in vivo* bone marrow microenvironment is very complex, containing osteoblastic niches and vascular niches localized within the trabecular regions of the long bones. HSCs are maintained in close association with the so-called ‘stromal cells’ of the niches. Some of the key molecular regulators within the bone marrow niches include N-cadherin, CD150 and the SDF1/CXCR4, Notch, Wnt, Hedgehog, Tie2/angiopoietin, transforming growth factor (TGF), bone morphogenetic protein (BMP)

and fibroblast growth factor (FGF) signalling pathway molecules. These regulators are implicated in a variety of cellular processes, such as HSC maintenance, differentiation, self-renewal and homing. Indeed, live tracking of haemopoietic progenitor/stem cells in the mouse model has shown the homing ability of these cells to bone marrow niches, and mouse models as well as *in vitro* culture systems are beginning to reveal the specific molecular mechanisms involved.

Microenvironments important for haemopoietic development in the conceptus

Prior to the necessity for an adult haemopoietic supportive microenvironment, the embryo contains several haemopoietic inductive microenvironments. The extraembryonic tissues, yolk sac and placenta, and the intraembryonic AGM generate haemopoietic progenitor cells, while the AGM region generates HSCs (Figure 1.6). Little is known about the differences between the microenvironments of these three tissues. However, the AGM microenvironment is the most well characterized due to the simplicity of its structure, with the aorta at the midline and the laterally located gonads and mesonephroi (see Figure 1.5). It is known that the avian AGM region contains different types of mesenchymal stem/progenitor cells and a population of aorta-associated stem cells called ‘meso-angioblasts’ contributes to cartilage, bone and muscle tissues and also to blood. In

Figure 1.6 Haemopoietic sites during development. The first haemopoietic stem cells arise in the AGM region. Other haemopoietic cells and progenitors are generated in the yolk sac and placenta. It is as yet undetermined whether the yolk sac and placenta can generate haemopoietic stem cells. Haemopoietic cells generated in these three tissues migrate and colonize the fetal liver. Subsequently, the long-lived haemopoietic cells (primarily the haemopoietic stem cells) migrate and colonize the bone marrow, where they reside in the adult stages of life.

the mouse AGM region, cells more typical of mesenchymal stem/progenitor cells have been found. Interestingly, mapping and frequency analysis of mesenchymal progenitors in the mouse conceptus show that mesenchymal progenitors, with the potential to differentiate into cells of the osteogenic, adipogenic and/or chondrogenic lineages, reside in most of the sites harbouring haemopoietic cells, suggesting that both the HSC and mesenchymal stromal cell microenvironment develop in parallel in the AGM region.

Many stromal cell lines have been established from the AGM region, placenta and fetal liver. Stromal cell lines isolated from both the mid-gestation AGM and placenta can support immature haemopoietic progenitors. *In vivo* assays show that some of the AGM stromal clones are potent supporters of HSCs as compared with adult bone marrow and fetal liver cell lines. Indeed some of these lines can support the haemopoietic differentiation of embryonic stem (ES) cells. Although there is one report in the literature of an AGM stromal cell line with the capacity to induce HSC formation from early embryo cells, these results have not been reproduced. Phenotypic characterization of haemopoietic supportive AGM stromal lines places them in the vascular smooth muscle cell (VSMC) hierarchy, in between a mesenchymal stem cell and a VSMC. Thus, while AGM and other embryonic stromal cell lines can provide important signals for the maintenance of the first HSCs, the lack of firm evidence for HSC induction with such lines suggests that the AGM inductive microenvironment is likely to be complex with a variety of spatial and temporal cues emanating from several cell types.

Within the normal physiology of the embryo, the AGM lies between the ventral tissue that includes the endoderm-derived gut and the dorsal tissue including the notochord and the ectoderm-derived neural tube (see Figure 1.5). Mouse AGM explant culture experiments have shown that dorsal tissues/signals repress AGM HSC activity and ventral tissues/signals enhance HSC emergence. In both mouse and human AGM regions, cells expressing HSC markers are closely adherent to the vascular endothelium on the ventral aspect of the aorta. In the mouse, at precisely E10.5, single endothelial cells bud into the lumen as they take on HSC identity (see Figure 1.5). Importantly, HSC activity as determined by functional transplantation assays is localized exclusively to the ventral aspect of the mouse mid-gestation aorta. Thus there is a strong positive ventral positional influence on HSC generation in the AGM, and morphogens and local signals emanating from the ventral endodermal tissues may be responsible for establishing the HSC inductive microenvironment.

Haemopoietic transcription factors required for HSC generation such as Gata2 and Runx1 are expressed in cells of the ventral aortic clusters and endothelium. Deficiency of Gata2 and Runx1 in mice leads to mid-gestation embryonic lethality, with complete absence of adult haemopoiesis (although embryonic haemopoiesis occurs), thus demonstrating that these two

pivotal transcription factors promote the HSC genetic programme. Zebrafish and frog embryos have been useful models for dissecting the cascade of upstream events that lead to HSC induction. Developmental growth factor signalling pathways, such as the BMP, Hedgehog and Notch pathways, converge to activate expression of the two transcription factors in aortic haemopoietic cells and promote the HSC programme. In both the mouse and human embryo, BMP4 is expressed in the mesenchyme underlying the ventral aspect of the aorta at the time of haemopoietic cluster formation. Culture experiments have demonstrated the positive influence of BMP4 exposure to mouse and human HSC-containing cell populations. However, it remains to be determined whether BMP4 acts directly on HSCs or stimulates the microenvironment to produce HSC effectors. Similarly, Hedgehog signalling regulates HSCs in the AGM region. However, while Hedgehog signalling acts ventrally in zebrafish embryos, in the mouse embryo Hedgehog-activated cells surround the aorta. This lack of ventral restriction suggests a more complex pattern of regulation of this signalling pathway in the mouse embryo. Other ventrally localized HSC regulators include the Notch signalling molecules, as well as Wnt3a and interleukin (IL)-1.

High-throughput chemical screens offer another means of identifying molecules involved in HSC growth, maintenance and expansion. Through such a screen in zebrafish embryos, prostaglandin E₂ (PGE₂) was recently identified as a regulator of HSC number. When tested in the murine transplantation model, *ex vivo* exposure of bone marrow cells to PGE₂ enhanced short-term repopulation by haemopoietic progenitors and increased the frequency of long-term repopulating bone marrow HSCs. It has been shown that PGE₂ modifies the Wnt signalling pathway, which in turn is thought to control HSC self-renewal and bone marrow repopulation. The zebrafish chemical screen also identified chemical blood flow modulators as regulators of HSC development. Nitric oxide synthetase inhibition or deficiency has also been shown to reduce transplantable murine bone marrow HSCs. Thus, these types of modulators hold promise for clinical treatments of bone marrow HSCs and the bone marrow haemopoietic niche. Together with more general physiological cues, such as the haemopoietic growth factors, KL, IL-3, Flt3 and thrombopoietin, these developmental regulators may be useful for expansion of HSC number and enhancement of HSC function for therapeutic purposes.

Haemopoietic regenerative and replacement therapies

Stem cell transplantation

For over 50 years, HSC transplantation has been the most successful and significant clinical cell regenerative therapy. Initially, whole bone marrow was the source of cells used in clinical

transplantation, but through experience and much research new and/or improved sources of transplantable HSCs were found. These now include the CD34⁺CD38⁻ fraction of adult bone marrow, mobilized peripheral blood HSCs and the CD34⁺CD38⁻ fraction of umbilical cord blood. The cumulative data from the large number of patients worldwide receiving a bone marrow transplant provide valuable information on the success of autologous versus allogeneic transplantation, the number of human leucocyte antigen (HLA) differences that are tolerated by the recipient, the incidence of graft-versus-host disease (GVHD), and the unexpected and advantageous graft-versus-leukaemia effect.

Interestingly, umbilical cord blood (UCB) appears to offer an advantageous source of HSCs for several reasons: UCB HSCs are young, being harvested at the neonatal stage of development, thus circumventing concerns about the ageing of HSCs. UCB transplantation induces less frequent and less severe GVHD, since UCB contains many fewer activated T cells than adult bone marrow. Also, UCB HSCs are highly proliferative. However, only relatively small numbers of cells are harvested (approximately 10-fold lower than those in adult bone marrow) and this limits their use to paediatric patients, unless multiple UCB units are transplanted. Nonetheless, the large number of UCB units (400 000) in cord blood banks (>50) around the world (catalogued and recorded by EUROCORD and other coordinating efforts) offer greater availability and HLA donor-cell selection, especially for rare haplotypes.

New sources of HSCs for transplantation

The ability to expand HSCs *ex vivo* is a theoretically practical and attractive means to obtain an accessible and limitless source of HSCs for transplantation therapies. Unfortunately, despite many years of research using different culture systems and combinations of haemopoietic growth factors and proliferation stimulating agents, *ex vivo* expansion of HSCs has not been achieved. However, HSC developmental studies have begun to provide new insights into the processes directing the generation and growth of HSCs.

Haemogenic endothelial cells

As described in this chapter, the temporally and spatially limited production of HSCs in the embryonic aorta, examination of the specific microenvironment, and knowledge of the precursors to these stem cells has yielded insight into how HSCs may be induced and/or expanded without undergoing differentiation. If cells such as the haemogenic endothelial cells lining the ventral wall of the embryonic dorsal aorta are present in the adult vasculature, they could provide a novel source of inducible HSC precursors, particularly if they can be sustained and expanded to large numbers in culture. Alternatively, if haemogenic endothelial cells do not exist in the adult but it is possible to direct endothelium to be haemogenic, potential

therapeutic interventions could include the *in vivo* site-specific stimulation of HSC induction in the vasculature using the same developmental modulators and small molecules that affect the generation of HSCs in the embryonic aortic haemogenic endothelium. Some recent studies have suggested the presence of such cells in the human embryonic liver and fetal bone marrow.

Embryonic stem cells and induced pluripotent stem cells

Pluripotent ES cells have been used to generate differentiated cells in many tissue systems, including the haemopoietic system. Such haemopoietic-directed differentiation of human ES cells towards HSCs would be a potentially attractive alternative to conventional sources of HSCs. ES cells differentiated into embryoid bodies can be induced to differentiate into haemopoietic progenitors in cultures containing BMP4 and a cocktail of haemopoietic growth factors. These haemopoietic cells arise from haemangioblasts and/or primitive endothelial-like cells that express PECAM-1, FLK-1 (KDR) and VE-cadherin and are thought to represent the types of precursors, progenitors and differentiated cells found normally in the yolk sac. However, although ES cells can be induced to produce haemopoietic progenitors and differentiated cells of all haemopoietic lineages (and HoxB4 expression in mouse ES cells can promote granulocytic engraftment of adult irradiated mice), there are no convincing data showing the production of HSCs that are fully

potent in adult transplantation scenarios. This could suggest that the relevant haemopoietic inductive environment such as the AGM region is missing. Bone marrow, fetal liver and AGM stromal cell lines have been used to promote human ES cell haemopoietic differentiation in co-cultures. An AGM stromal cell line appears to significantly enhance spontaneous haemopoietic differentiation in high-density human ES cell co-cultures and provide cells capable of primary and secondary haemopoietic engraftment into immunocompromised NOD/LtSz-Scid $IL2R\gamma^{null}$ recipients. Together, the induction of haemogenic endothelial cells from ES cells followed by haemopoietic induction with factors and/or cells of the AGM micro-environment may yield cells with the functions expected for definitive HSCs.

Recent reports of somatic cell reprogramming by means of induced pluripotency makes the human ES cell differentiation approach an exciting prospect for future cell-based therapies. The ability to produce patient-specific pluripotent cells (induced pluripotent stem or iPS cells) will eliminate all rejection issues that surround transplantation of HSCs from allogeneic donors. Indeed, a proof-of-principle study using gene-corrected mouse iPS cells from a thalassaemic mouse demonstrates the ability of such cells to form after transplantation normal functioning erythroid cells (Figure 1.7). Unfortunately, the presence of definitive adult HSCs was not demonstrated and hence future studies are needed to prove that HSCs can be generated *in vitro* from iPS/ES cells.

Figure 1.7 Experimental approach in which iPS cells were used to treat sickle cell anaemia in a mouse model. (From Hanna *et al.* 2007 with permission of the American Association for the Advancement of Science.)

Introduction

The process of erythropoiesis includes all steps of haemopoiesis, starting with the initial specification of haemopoietic stem cells (HSCs) from mesoderm during embryogenesis. HSCs either undergo self-renewal or, through the process of lineage specification, differentiate and proliferate to form committed erythroid progenitors. Finally, they undergo terminal differentiation through a series of erythroblastic maturation stages to develop into red blood cells.

In a normal adult, the numbers of circulating red blood cells and their precursors remain more or less constant with a balance between the continuous loss of mature cells by senescence and new red cell production in the marrow. There also needs to be adequate reserves to cope rapidly with increased demand as a result of physiological or pathological circumstances. This balance is maintained by an oxygen-sensing system that is affected by the red cell mass and responds via the production of erythropoietin (Epo), which in turn controls red cell production by binding and signalling to committed erythroid progenitors. Many other cytokines, growth factors and hormones also influence erythroid proliferation, differentiation and maturation.

Over the past 20 years, key transcription factors controlling the internal programmes of erythroid progenitors have been identified and some insights into their roles in lineage specification and erythroid differentiation have been discovered. Understanding the basic biology of erythropoiesis provides a

logical basis for the diagnosis and treatment of the inherited and acquired anaemias that are so frequently encountered in clinical practice.

The origins of blood during development

Primitive haemopoiesis in humans (predominantly erythropoiesis) first appears in the blood islands of the extraembryonic yolk sac at around day 21 of gestation. About 1 week later (days 28–40), definitive HSCs emerge from the aorta–gonad–mesonephros (AGM) region, within the ventral wall of the dorsal aorta and are also found in the vitelline and umbilical arteries and the placenta. Both primitive (embryonic) and definitive (fetal/adult) HSCs arise in close association with endothelial cells. Several lines of evidence now suggest that haemopoietic and endothelial cells may emerge from a common progenitor, the haemangioblast, giving rise to both blood cells and blood vessels (see Chapter 1). At about 30–40 days, definitive haemopoiesis starts to occur in the fetal liver and definitive erythroid cells are released into the circulation at about 60 days. By 10–12 weeks, haemopoiesis starts to migrate to the bone marrow, where eventually erythropoiesis is established during the last 3 months of fetal life (Figure 2.1).

Primitive and definitive erythropoietic cells are distinguished by their cellular morphology, cell-surface markers, cytokine responsiveness, growth kinetics, transcription factor programmes and more general patterns of gene expression. In particular, the types of haemoglobin produced are quite distinct in embryonic (Hb Gower I $\zeta_2\varepsilon_2$, Gower II $\alpha_2\varepsilon_2$ and Hb Portland $\zeta_2\gamma_2$), fetal (HbF $\alpha_2\gamma_2$) and adult (HbA $\alpha_2\beta_2$ and HbA₂ $\alpha_2\delta_2$) erythroid cells. These specific patterns of globin expression have provided critical markers for identifying the developmental

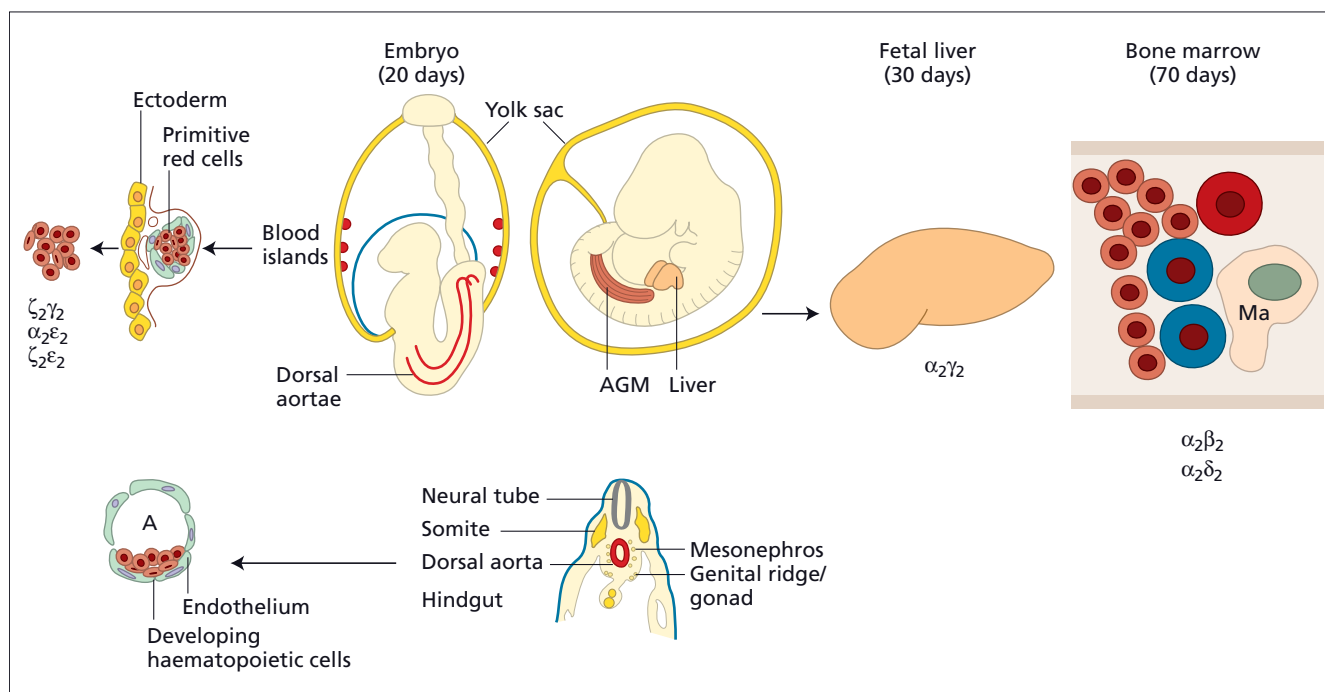

Figure 2.1 An outline of the origin and development of erythropoiesis during embryogenesis. Although both primitive (blood islands) and definitive (AGM, liver and bone marrow) haemopoiesis are derived from mesoderm, probably via a haemangioblast, the true origin of these early cells is not yet clear. The figure shows the formation of embryonic blood islands in the extraembryonic yolk sac and the formation of definitive haemopoiesis initially in the AGM region, with subsequent migration to the liver and bone marrow. 'A' denotes a magnified

image of the early embryonic aortic region. Ma denotes a macrophage. The specific types of haemoglobin formed at each stage of erythropoiesis are indicated. The approximate times at which CD34⁺ cells first appear at each site are given in days of gestation. (Adapted from Dzierzak E, Medvinsky A, de Bruijn M (1998) Qualitative and quantitative aspects of haematopoietic cell development in the mammalian embryo. *Immunology Today* 19: 228–36 with permission.)

stages of erythropoiesis. Nevertheless, it is still not clear whether primitive and definitive haemopoiesis in mammals have entirely separate origins or if they are both derived from common stem cells that arise during early development. Accurately defining the embryological origins of these cells continues to be of considerable importance for understanding the normal mechanisms that establish and maintain HSCs and how these programmes are subverted in common haematological disorders.

Differentiation of HSCs to form erythroid progenitors

At all stages of development there is a continuous need to renew senescent blood cells that are ultimately lost from the peripheral blood days, weeks or months after undergoing terminal differentiation. For example, throughout adult life approximately 10^{11} senescent red cells must be replaced every day, and there are similar requirements for other mature blood cells (e.g. gran-

ulocytes). To prevent depletion of the haemopoietic cells requires a system that not only maintains a self-renewing stem cell pool, but also has the potential to differentiate into all types of highly specialized mature blood cells through a process referred to as lineage specification.

At present, the mechanisms underlying self-renewal and the early events committing multipotential HSCs to an increasingly restricted repertoire of lineage(s) are not fully understood. The probability of commitment to any particular lineage may be influenced by a complex interplay between the internal transcriptional programmes and epigenetic patterns (e.g. changes in nuclear position, replication timing, chromatin modification, DNA methylation) with external signals from the micro-environment (e.g. cytokines, growth factors and cell–cell interactions) acting via signal transduction pathways.

Microarray analyses of HSCs and their progeny consistently show a very wide range of gene expression in the earliest cell populations. Furthermore, many of the genes that are specific to individual lineages (e.g. erythroid, myeloid or lymphoid) are already transcribed, albeit at low levels, in HSCs. In other

words, HSCs appear to show ‘multilineage priming’ and, as their progeny become committed to one pathway of differentiation, that lineage-specific gene expression programme becomes reinforced, whereas those of other lineages are suppressed.

In human adult bone marrow, approximately 1 per 10⁴–10⁶ nucleated cells are long-lived, multipotential HSCs that can be enriched on the basis of their cell-surface markers (e.g. CD33⁺ and CD34⁺ and lack of lineage-specific markers; see Figures 2.2 and 2.3), but such markers do not exclusively select stem cells

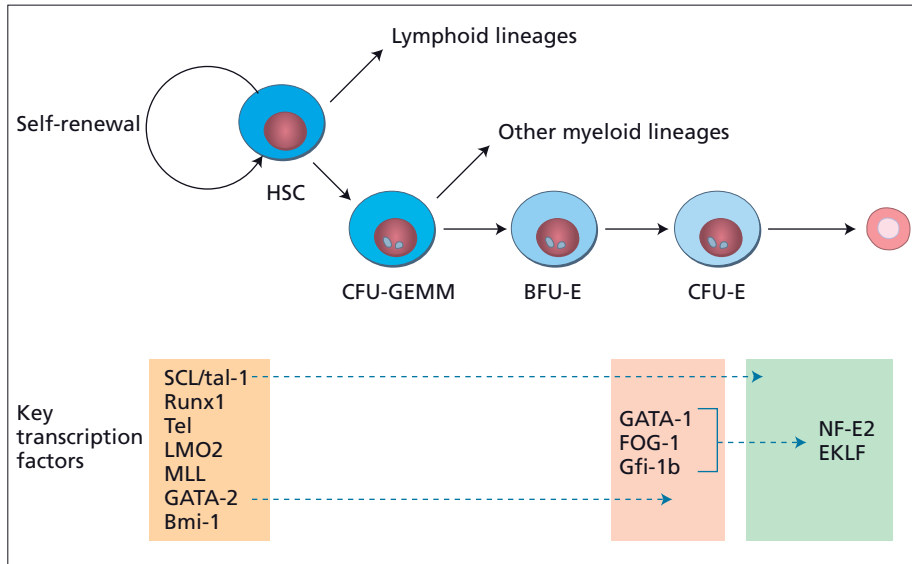

Figure 2.2 Summary of some steps in self-renewal, lineage specification and differentiation of haemopoietic stem cells to red cells. Some of the key transcription factors involved in this process are summarized beneath the diagram.

Figure 2.3 The specification and terminal differentiation of erythroid cells from haemopoietic stem cells. At the top, the estimated times for maturation of terminally differentiating cells are shown. The precursors are as follows: pronormoblasts (Pro), basophilic erythroblasts (Bas), polychromatic erythroblasts (Pol),

orthochromatic erythroblasts (Ort), reticulocytes (Retic), mature red blood cells (RBCs). The number of divisions from pronormoblasts to orthochromatic normoblasts (1–16) are also shown. Some examples of the expression patterns of key cell-surface markers are shown below.

(see Chapter 1). The only rigorous assay for bona fide HSCs is to measure their ability to contribute, throughout life, to all haemopoietic lineages *in vivo*. This has been amply demonstrated in mice, and the repeated, predictable success of human bone marrow transplantation clearly demonstrates the existence of such cells in humans.

The pathway of differentiation from HSCs to committed erythroid progenitors is still the topic of some debate. One model (proposed by Weissman) posits a common myeloid progenitor from which the granulocyte/monocyte, erythroid and megakaryocyte lineages develop. In a second model (Jacobsen) erythroid/megakaryocytic progenitors split before the separation of lymphoid and granulocyte/monocyte lineages. As stem cells differentiate, they form multipotential progenitor cells that have short-term repopulating ability but have lost long-term repopulating ability. Such cells can be assayed *in vitro* by their ability to form 'cobblestone' areas under stromal cells in long-term marrow cultures. Further differentiation progressively restricts the lineage potential of these cells as well as reducing their proliferative capacity, resulting in tripotential, bipotential and unipotential progenitors. These progenitor cells are functionally defined by their ability to produce clonal colonies in semisolid medium supplemented with a cocktail of haemopoietic cell growth factors permissive for the growth of all lineages.

Erythroid cells can be found in multilineage colonies (CFU-GEMM), which include granulocytes, macrophages and megakaryocytes, and in bipotential colonies with megakaryocytes (CFU-E/Mk). The earliest progenitors that are restricted to the erythroid lineage produce large colonies *in vitro*, consisting of several subunits, known as erythroid bursts (BFU-E, containing from several hundred up to 30 000 cells) after 12–14 days of growth. Their frequency in bone marrow is approximately 4–10 per 10^4 nucleated cells. Late erythroid progenitors form colonies (CFU-E) of 8–64 cells after about 7 days *in vitro* and constitute 20–60 per 10^4 bone marrow cells. CFU-Es defined in these culture systems most closely correspond *in vivo* to pronormoblasts (also known as proerythroblasts), the earliest morphologically recognizable erythroid precursor in the bone marrow. Once formed, these cells are destined to undergo terminal differentiation to form mature red cells, as discussed later.

Erythroid differentiation and maturation within the adult bone marrow *in vivo* is dependent on the microenvironment provided by the stromal cells (fibroblasts, fat cells, endothelial cells, macrophages and smooth muscle cells). There are also immunoregulatory cells (monocytes, macrophages and lymphocytes) that contribute to local cytokine production. Erythroblasts are not randomly distributed in the bone marrow but are organized into erythroblastic islands containing one or two central macrophages, surrounded by layers of erythroblasts at different stages of maturation (Figure 2.1).

A number of techniques have been described for the production of erythroblasts in liquid cultures. The great advantage of

these techniques is that they allow the production of large numbers of erythroblasts from peripheral blood samples, enabling functional analyses of normal or abnormal erythropoiesis without the need for bone marrow sampling.

The transcription factor programme underlying erythropoiesis

As discussed above in the stochastic model of cell differentiation, many factors must be integrated for a cell to make the decision to undergo self-renewal or differentiation, become quiescent, proliferate or undergo apoptosis. Over the past few years, it has emerged that key transcription factors play a major role in regulating the formation, survival, proliferation and differentiation of multipotent stem cells as they undergo the transition to erythroid cells. These transcription factors may operate on their own or as members of multicomponent complexes involved in activation and/or repression. Many of the key transcription factors were originally identified because they are associated with chromosomal translocations found in leukaemia. This supports a model in which dysregulation of the normal transcriptional programme plays a causal role in haematological malignancies.

At present, the key transcription factors known to be involved in specifying HSCs as they develop during embryogenesis and in maintaining them throughout life include Runx1 (AML-1), SCL (tal-1), LMO2 (rhombotin), Tel (ETV6), MLL and GATA-2 (see Figure 2.2). In addition, the homeobox (Hox) genes and proteins that modify their expression (e.g. Bmi-1) have also been shown to play a role in haemopoiesis. Many of these factors (e.g. SCL, Runx1) appear to act quite differently in primitive as opposed to definitive haemopoiesis. Furthermore, not only is their importance in early definitive progenitors well established, but also many of these transcription factors play additional roles, later in differentiation, in specific haemopoietic lineages, including erythropoiesis.

Once progenitor cells have been committed to become erythroid cells, the most important transcription factors that enable them to proceed through terminal differentiation are GATA-1 and its cofactor FOG-1 (friend of GATA-1). GATA-1 was first identified by its ability to bind functionally important regulatory sequences in the globin genes. Since then, GATA-binding motifs have been found in the promoters and/or enhancers of virtually all erythroid-specific genes studied, including haem biosynthetic enzymes, red cell membrane proteins (including blood group antigens) and erythroid transcription factors such as erythroid Kruppel-like factor (EKLF) and GATA-1 itself. GATA-1 expression is restricted to erythroid, megakaryocytic, eosinophilic, mast cell and multipotential progenitors of the haemopoietic system. However, GATA-1 expression is highly upregulated in pronormoblasts and basophilic erythroblasts (see Figures 2.2 and 2.3).

Gene targeting studies in mice have shown that GATA-1 is essential for normal erythropoiesis. Mice that produce no GATA-1 die from severe anaemia. Although they produce adequate numbers of erythroid colonies (CFU-E), there is an arrest in erythroid maturation at the pronormoblast stage of differentiation. *In vitro* differentiated mouse embryonic stem cells lacking GATA-1 also fail to mature past the pronormoblast stage and undergo rapid apoptosis, indicating a role for GATA-1 in survival and maturation of erythroblasts.

GATA-1 may protect mature erythroblasts from apoptosis by directly or indirectly inducing expression of the anti-apoptotic protein Bcl-X_L. GATA-1 almost certainly regulates gene expression working as part of multiprotein complexes interacting, for example, with FOG-1, LMO2, SCL and a variety of ubiquitously expressed transcription factors. FOG-1 is a protein containing multiple zinc fingers, four of which interact with GATA-1. Like GATA-1, FOG-1 is expressed in erythroid and megakaryocytic cells and is coexpressed and directly interacts with GATA-1 during development. Genetically modified mice that express no FOG-1 also die in mid-gestation as a result of severe anaemia with arrest in erythroid maturation at the pronormoblast stage.

GATA-2 is a second member of the GATA family of proteins that is involved in haemopoiesis. Both GATA-1 and GATA-2 are particularly relevant for erythropoiesis. Both are expressed in multipotent progenitors, although GATA-2 appears to be more important than GATA-1 at this stage, when GATA-2 plays an important role in the expansion and maintenance of haemopoietic progenitors. During erythroid differentiation the level of GATA-2 declines as GATA-1 increases. In mouse embryos lacking GATA-2, erythrocytes are present, but in severely reduced numbers. There appears to be some overlap and redundancy between the roles of GATA-1 and GATA-2; in the absence of GATA-1 increased levels of GATA-2 may fulfil some, but not all, of the normal roles of GATA-1. Furthermore, there is evidence that the level of GATA-2 is regulated by the level of GATA-1. During normal erythroid development, it appears that GATA-2 may initiate the erythroid programme to be replaced later by GATA-1 during terminal erythroid maturation.

Expression of the two related zinc-finger DNA-binding proteins Gfi-1 and Gfi-1b is restricted to haemopoietic cells. Gfi-1b is expressed only in multipotent progenitors, megakaryocytes and erythroblasts, in which its pattern of expression mimics that of GATA-1. Gfi-1b-deficient mouse embryos die with a failure to produce mature red cells, although early precursors are formed normally. This is very similar to the phenotype observed in GATA-1-deficient embryos. However, from *in vitro* colony assays in which Gfi-1b is overexpressed, it appears that its effect is not on erythroid commitment, but rather it promotes the proliferation of erythroid progenitors as they undergo the transition from late BFU-Es to CFU-Es.

EKLF is a zinc finger-like protein of the Kruppel family, which binds the consensus sequence 5'-NCNCNCCCN-3' and

is mainly restricted to erythroid cells. These binding sites are found in the regulatory elements of several erythroid-specific genes, including the β -globin gene. Disruption of binding at this site gives rise to β thalassaemia. Mice in which EKLF is absent die from severe anaemia at the fetal liver stage caused in part by β thalassaemia, but also due to the failure to synthesize correctly other EKLF-regulated proteins (e.g. the red cell membrane protein Band3 and the α -globin stabilizing protein AHSP) required for red cell maturation. Therefore, EKLF may play a wider role than originally predicted in coordinating erythroid cell maturation and globin gene regulation.

Sequence motifs of the general class (T/C)GCTGA(G/C)TCA(T/C), called Maf recognition elements (MAREs), have been found in the enhancers of many erythroid-specific genes (e.g. globins, haem synthesis enzymes), and it was shown that they bind the transcription factor NF-E2. Purification of NF-E2 revealed that it consists of two subunits, p45NF-E2 and p18NF-E2 (now known as MafK). Both proteins contain basic zipper (B-ZIP) domains through which they form heterodimers and bind DNA. p45 is expressed mainly in erythroid cells, whereas p18 is widely expressed, although it is the predominant small Maf family member in erythroid cells. Furthermore, it is now known that both p45 and p18 are members of larger groups of proteins with overlapping functions. Other p45-like molecules include Nrf1, 2 and 3 and Bach1 and 2. All these proteins bind as obligate heterodimers with Maf proteins. It seems likely that binding to MARE elements is an important aspect of erythroid-specific activation, but it is not clear which proteins in this family bind the key sites or whether there is redundancy in the need for specific members of this family.

At present it is not fully understood how these transcription factors combine to commit cells to the erythroid lineage and terminal erythroid differentiation. However, this could involve the presence or absence of specific transcription factors, changes in the levels of the proteins and/or protein modification. One principle that seems to be emerging is that factors affiliated with different lineages such as GATA-1 (erythroid) and PU1 (lymphocytes and granulocytes) are both present in uncommitted progenitors, reflecting the potential to develop along alternative different pathways (so-called multilineage priming). It is now known that GATA-1 and PU1 interact and cross-antagonize each other. Therefore, as cells differentiate, reinforcement of the transcriptional programme of one lineage may actively suppress an alternative lineage.

Terminal maturation of committed erythroid cells

After the erythroid programme has been specified, the final phase of erythropoiesis involves the maturation of committed erythroid progenitors to fully differentiated red cells. The earliest recognizable erythroid precursor cell in the bone marrow is

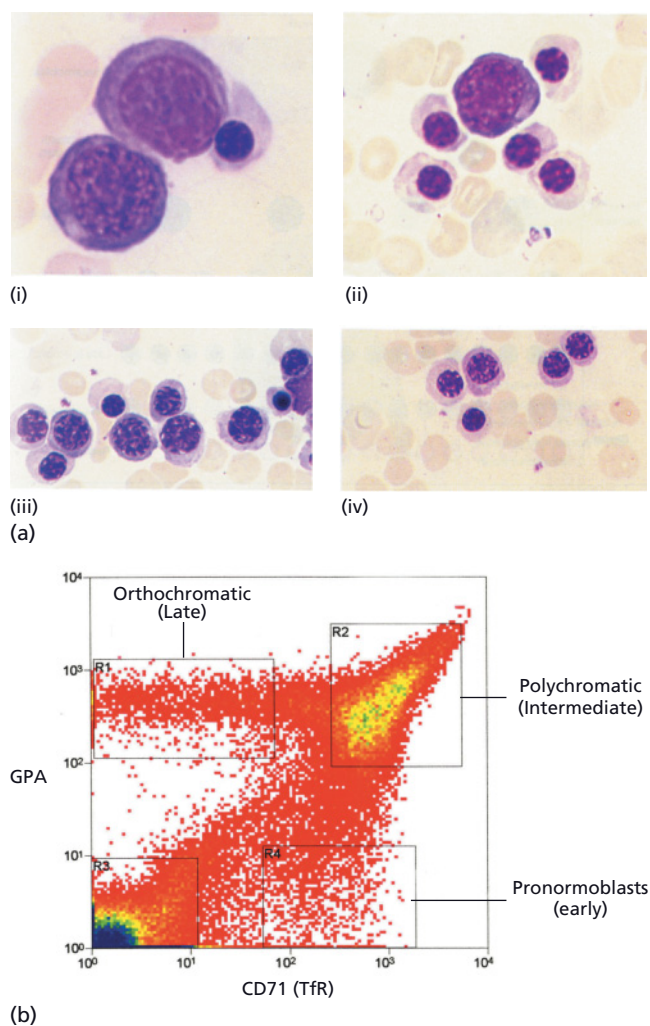

Figure 2.4 (a) Examples of pronormoblasts (i), basophilic and polychromatic erythroblasts (ii) and polychromatic and orthochromatic erythroblasts (iii and iv). All these different cell types can also be conveniently viewed at <http://hsc.virginia.edu/medicine/clinical/pathology/educ/innes/text/nh/mature.html>. (b) An example of early (pronormoblasts), intermediate (polychromatic erythroblasts) and late (orthochromatic erythroblasts) erythroid precursors separated on the basis of their cell-surface markers (CD71 and GPA).

the pronormoblast (Figure 2.4a, i) which, as discussed above, corresponds to the CFU-Es identified *in vitro*. The pronormoblast is a relatively large cell (12–20 μm) with a non-granular deep-blue cytoplasm and a large nucleus occupying about three-quarters of the cell that has a finely stippled chromatin pattern containing one or more prominent nucleoli.

The cytoplasm contains numerous ribosomes, several mitochondria, centrioles, a prominent Golgi apparatus and a few strands of rough endoplasmic reticulum. Division of these

cells leads to smaller (10–16 μm) basophilic normoblasts (Figure 2.4a, ii). Again, the cytoplasm stains deep blue and the nucleus occupies a large proportion of the cell but has a coarser reticular chromatin pattern with a few small masses of condensed chromatin adjacent to the nuclear membrane. Further divisions form early polychromatic and late polychromatic normoblasts (10–12 μm), with increasing development of a pink cytoplasm and condensed (6 μm) nuclei (Figure 2.4a, iii). Late polychromatic/orthochromatic normoblasts (Figure 2.4a, iv) are non-dividing cells with deeply staining structureless nuclei.

As the cell proceeds through terminal differentiation, nucleoli disappear and the nucleus condenses further and is eventually extruded. Such nuclei are phagocytosed and degraded by the macrophages of the bone marrow. Ultrastructural studies have shown that nuclear extrusion usually occurs outside the sinusoids of the bone marrow, and that newly formed reticulocytes usually pass through pre-existing gaps in the walls of these sinusoids by diapedesis. Thus, the mature reticulocyte has no nucleus but has a few mitochondria and ribosomes and its cytoplasm stains predominantly pink because of the high concentration of haemoglobin. The cytoplasm still has a greyish tint due to the presence of ribosomes. When stained supravivally, the ribosomes precipitate into basophilic granules or a reticulum. Reticulocytes continue to synthesize haemoglobin for 24–48 hours after release from the bone marrow. On average, these cells are about 20% larger than mature red cells, which are circular, flat, biconcave discs with a mean diameter of 8.5 μm .

It has been estimated that, on average, four divisions occur within the morphologically recognizable proliferating precursor pool, so that each newly formed pronormoblast develops into 16 red cells (see Figure 2.3). As a small amount of cell death (ineffective erythropoiesis) normally occurs, the average amplification is slightly less than 16-fold. The majority (60–80%) of pronormoblasts, basophilic normoblasts and early polychromatic normoblasts are in cell cycle, mostly in S phase, with G_1 and G_2 stages lasting only a few hours. At any time, about 3% pronormoblasts, 5% basophilic erythroblasts and 6% polychromatic normoblasts are undergoing mitosis, which has been variously estimated to last for between 60 and 100 min. Erythroid cells eventually exit the cell cycle and, consistent with this, late polychromatic/orthochromatic erythroblasts are post-mitotic, non-dividing cells.

Changes in the cell-surface phenotype that accompany erythroid differentiation and maturation

The cell-surface phenotypes of erythroid progenitors and precursors are quite distinctive, reflecting the different signalling programmes of the cells as they differentiate. These markers are

also of value in the analysis of erythroid progenitors and precursors as they can be used to identify and purify subpopulations of cells. CD34 is present on nearly all multipotent progenitors and committed BFU-Es but is lost on later erythroid progenitors (CFU-E) and all precursors.

A similar pattern of expression is shown for the receptor c-Kit. Epo receptor (see below) first appears in small numbers (20–50 copies per cell) on late BFU-Es, increases in CFU-Es and pronormoblasts (~1000 copies per cell) and subsequently declines and disappears in later erythroid precursors. CD71 (transferrin receptor, TfR) allows transferrin-bound iron to be taken into the cell and is present on early haemopoietic cells but is considerably upregulated on cells that are actively synthesizing haemoglobin, reaching a peak of 800 000 molecules per cell on polychromatic normoblasts. CD71 levels diminish in the late phase of terminal differentiation and the receptor is not detectable on mature erythrocytes. Glycophorin A (GPA) is a membrane sialoglycoprotein whose expression is highly upregulated as erythroid progenitors mature from pronormoblasts. Combinations of these cell-surface markers can be used to distinguish early, intermediate and late erythroid precursors (Figure 2.4b). Developing erythroid cells express cell-surface adhesion molecules that interact with the extracellular matrix; these include ICAM-1 (a member of the immunoglobulin superfamily) and integrin $\alpha_4\beta_1$ VLA4 (CD29/CD49d), which interacts with fibronectin. These adhesion molecules are most highly expressed in the early precursors and lost as maturation proceeds, freeing erythroid cells to exit the bone marrow.

Changes in gene expression in erythroid differentiation and maturation

As cells go through the final divisions of erythropoiesis and post-mitotic maturation there is progressive condensation of chromatin accompanied by complex changes in gene expression. When assessed by microarray analysis, many mRNAs are downregulated as multipotent progenitors enter terminal differentiation, reflecting the commitment of multipotent cells to a single specialized lineage. A subset of general mRNAs associated with proliferation, replication and cell cycle control show alterations as the growth characteristics of the cells change. mRNAs encoding proteins that characterize the red cell phenotype are, in general, upregulated. Examples include blood group antigens, red cell membrane proteins (e.g. spectrin, ankyrin, actin, protein 4.1), red cell glycolytic pathway enzymes, carbonic anhydrase and enzymes of the haem synthesis pathway such as δ -aminolaevulinic acid synthase (ALAS). A full catalogue of these changes in gene expression can be found at <http://hembase.niddk.nih.gov>.

The main purpose of erythropoiesis is to synthesize large amounts of haemoglobin (Figures 2.3–2.5). Globin mRNA sequences are first expressed in pronormoblasts and early basophilic erythroblasts. Globin chain synthesis parallels accumulation of globin mRNA, increasing at the polychromatic and orthochromatic stages. The amount of globin mRNA reaches 20 000 molecules per cell in late polychromatic and

Figure 2.5 Coordination of globin synthesis, haem synthesis and iron regulation. Blue lines indicate some of the known regulatory feedback systems. The red shaded box indicates reactions

occurring in the mitochondria. Rate-limiting controls of haem synthesis are shown in black boxes. ALA, δ -aminolaevulinic acid; PBG, porphobilinogen.

orthochromatic erythroblasts. During the later stages of erythroid cell maturation, the amount of RNA per cell and the rate of total protein synthesis declines, but the relative stability of globin mRNA ensures that globin becomes the predominant polypeptide made in late erythroblasts and reticulocytes.

The individual components of the haemoglobin synthetic pathway (iron, free porphyrins, haem and monomeric globin chains) are all extremely toxic to the cell, and consequently many positive and negative feedback loops have evolved and been incorporated into this process. The synthesis of globin must be very accurately matched with the synthesis of haem in which some steps occur in the cytoplasm and others in the mitochondria (Figure 2.5). mRNAs encoding many components of the haem biosynthetic pathway (e.g. ALAS and porphobilinogen deaminase) are coordinately upregulated in terminal erythroid differentiation and their genes contain similar *cis*-regulatory elements.

Continued translation of globin chains from mRNA only occurs in the presence of adequate haem. Reduced levels of haem rapidly trigger the formation of the haem-regulated inhibitor (HRI), a kinase that interacts with the translation initiating factor eIF-2 α and prevents translation of α - and β -globin mRNA. The synthesis of haem itself is also regulated at many points and is particularly sensitive to the levels of available iron. Via a well-characterized pathway involving the iron-regulatory proteins (IRP1 and IRP2), binding to iron response elements (IREs) in the mRNA transcripts of ferritin, TfR and ALAS, the level of intracellular iron thus controls the translation of RNAs involved in iron storage, iron transport and haem synthesis (see Chapter 3). The discovery of hepcidin, which controls the uptake of iron from the gut, iron transport across the placenta and iron release from macrophages, adds another level of control to this complex system (see Chapter 3). Not surprisingly, diseases affecting the supply of iron (iron deficiency and the anaemia of chronic disease), the synthesis of haem (sideroblastic anaemia, lead poisoning, alcohol ingestion) or the synthesis of globin (thalassaemia) have interrelated effects on globin synthesis, haem synthesis and iron metabolism (Figure 2.5).

No mechanistic connection between haemoglobin synthesis and erythroid proliferation or differentiation has yet been established. However, it has been postulated that haemoglobin content and/or haemoglobin concentration *per se* may be a negative regulator of cell division. When haemoglobin synthesis is reduced or delayed, as in iron deficiency, the cells may undergo an extra division, yielding smaller hypochromic cells. Alternatively, when haemoglobin synthesis exceeds DNA synthesis, as in megaloblastic anaemias, the cells may skip a division and nuclear extrusion may occur early, resulting in macrocytosis. Although plausible, these hypotheses remain unproven.

The regulation of erythropoiesis by signalling pathways

The normal red cell lifespan is 120 days and therefore, to maintain equilibrium, approximately 1% of the circulating red cell pool must be replaced daily. For a total of about 3×10^{13} circulating erythrocytes and a lifespan of 120 days, the erythrocyte production rate needs to be maintained at approximately 10^{10} /hour in the steady state. Erythropoiesis accounts for about 20% of the nucleated cells in a normal bone marrow reflected in the myeloid/erythroid ratio (usually about 4:1). As committed erythroid cells become late BFU-E and CFU-E, they upregulate expression of the receptor for erythropoietin (EpoR). It is estimated that in the steady state, with low levels of circulating Epo, a high proportion of erythroid cells die through apoptosis. This provides a reserve that can be rescued by the increase in Epo levels that accompany anaemia. Signalling through EpoR not only prevents apoptosis but also stimulates proliferation. It is at the late progenitor/early precursor stages (CFU-E/pronormoblast) that there is considerable proliferative potential for expanding the overall level of erythropoiesis. Soon after reaching the CFU-E stage, erythroid cells enter the phase of terminal differentiation, after which there is only limited potential for further expansion. The two major components regulating erythropoiesis include sensing hypoxia and regulating the supply of erythroid precursors, mainly by controlling the numbers of erythroid progenitors via the Epo–EpoR signalling pathway.

Sensing hypoxia

Tissue hypoxia induces a variety of physiological responses in addition to activation of the Epo–EpoR pathway (see below). Parallel responses include the stimulation of new blood vessels by vascular endothelial growth factor (VEGF) and metabolic changes (e.g. in glycolytic pathway enzymes) that enable continued energy production despite inadequate oxygen availability. In addition, expression of TfR is upregulated. Over the past 20 years the mechanisms by which cells sense hypoxia and orchestrate their response have been discovered. It has been shown that the most important mediator of this cellular response is a transcription factor called HIF (hypoxia-inducible factor), which activates the genes that influence the adaptive responses to hypoxia including those encoding Epo, glycolytic pathway enzymes, TfR and VEGF (Figure 2.6).

HIF is a heterodimer constituting one of three α -subunits (HIF1- α , HIF2- α or HIF3- α) bound to the aryl hydrocarbon receptor nuclear translocator (ARNT), also known as HIF1- β . HIF1- α is a member of the basic helix–loop–helix (bHLH) family of transcription factors in which the HLH domains mediate subunit dimerization, whereas the basic domains bind

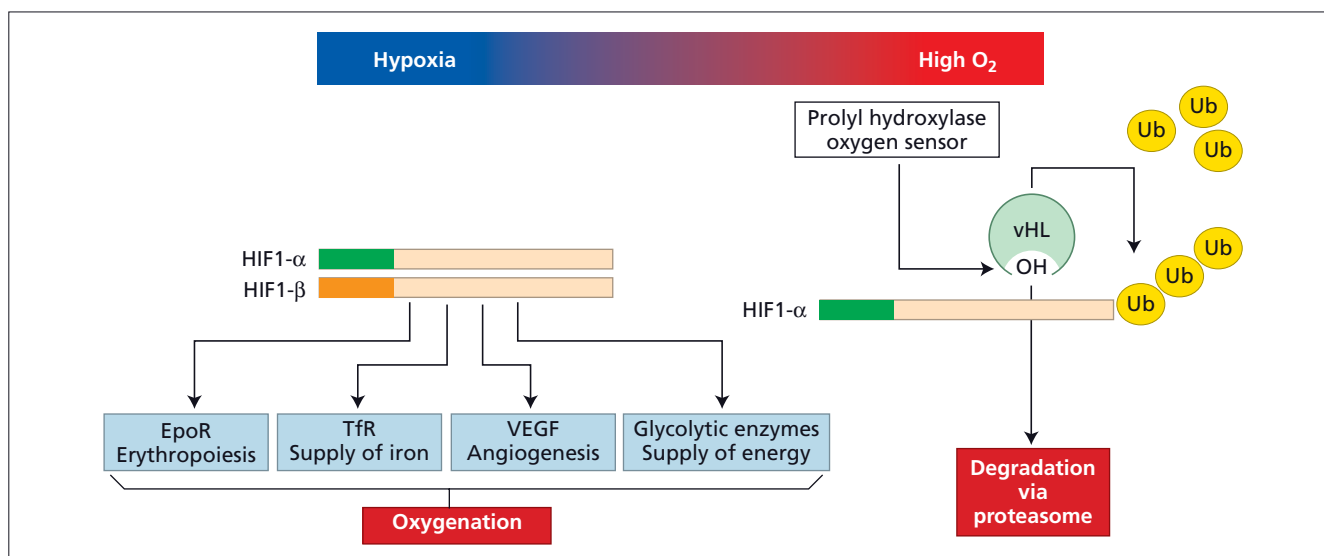

Figure 2.6 The oxygen-sensing system. Ub, ubiquitination; vHL, von Hippel–Lindau protein.

DNA. HIF binds to hypoxia-response elements (HREs, 5'-TACGTG-3') located in the regulatory regions of hypoxia-inducible genes such as the gene encoding Epo (see below). Whereas changes in oxygen levels do not affect the levels of HIF1- β , which is expressed constitutively, hypoxia elevates the levels of HIF1- α subunits by increasing protein stability.

The oxygen sensor is a ferrous iron prolyl hydroxylase that requires molecular oxygen as a cosubstrate to hydroxylate specific proline residues in the α -subunits of HIF. Once hydroxylated, HIF1- α subunits become targets for ubiquitination by the widely expressed von Hippel–Lindau (vHL) protein and are thus targeted for proteosomal degradation. Under normal circumstances the α -subunits are undetectable but, when cells are exposed to hypoxic stimuli, the oxygen sensor can no longer hydroxylate the α -subunits of HIF. In this situation, α -subunits accumulate as they are no longer polyubiquitinated and degraded. This allows the α -subunits to heterodimerize with HIF1- β and activate the hypoxia-response genes. If the vHL protein is mutated (vHL syndrome), there is prolonged stimulation by HIF, leading to the development of polycythaemia (Epo stimulation) and vascular tumours (VEGF stimulation).

Erythropoietin and the erythropoietin receptor

The main initial site of Epo production is the fetal liver, with production largely switching to the kidney shortly after birth. Under normoxic conditions, little or no Epo mRNA is detectable in the kidneys but hypoxia results in its accumulation within 30 min in the peritubular interstitial cells and levels can increase 200-fold over baseline. Epo is a 166-amino-acid 34.4-kDa glycoprotein, found in serum at baseline levels

of 1–30 mU/mL that can be elevated 1000-fold by severe anaemia. It contains about 40% carbohydrate, rich in sialic acid residues, and has a half-life of 7–8 hours in plasma, whereas non-glycosylated Epo is cleared rapidly from the circulation. There are no preformed stores of Epo and, normally, 90% of the hormone is produced in the kidney and 10% in the liver and elsewhere.

The Epo gene contains a hypoxia-response element at its 3'-end, and in the kidney and liver a cooperative interaction of HIF with HNF-4, including recruitment of the coactivator CBP/p300, leads to a significant increase in transcription and increased serum levels of the protein. The binding of Epo to EpoR results in signal transduction to the nucleus, and this constitutes the most important pathway for controlling definitive erythropoiesis. Careful clinical and haematological studies, together with the analysis of experimental animal models, have been important in establishing exactly which aspects of erythropoiesis are regulated by the Epo–EpoR system. Fetal livers of genetically modified mice in which Epo or EpoR has been deleted are devoid of late erythroid cells but contain normal numbers of BFU-E, demonstrating that this signalling system is not required for lineage specification but is essential for proliferation and differentiation of erythroid precursors into mature cells.

When tissue oxygenation is compromised owing to reduced ambient oxygen tension, blood loss, shortened red cell survival or any uncompensated need for increased oxygen delivery, the level of Epo rises, stimulating red cell production. The low numbers (20–50) of EpoRs on BFU-E explain the relative Epo non-responsiveness of these cells, and much higher levels (~1000) are found in CFU-E, pronormoblasts and basophilic erythroblasts. When circulating Epo increases, apoptosis of

these erythroid progenitors decreases and CFU-Es rapidly respond by proliferating and differentiating. Therefore, the most important effect of Epo is to increase the number of progenitor cells that develop into viable pronormoblasts. It has also been suggested that Epo is able to speed up the rate of terminal differentiation by shortening the cell cycle and maturation times of erythroblasts, thereby explaining the macrocytosis that often accompanies 'stress' erythropoiesis; this remains to be confirmed.

The erythropoietin signalling system is relatively well understood. EpoR belongs to the cytokine receptor superfamily. Like other members of this family (growth hormone, prolactin and G-CSF), Epo was thought to induce dimerization of cell-surface receptors (EpoRs), triggering autophosphorylation and activation of the Janus family of protein tyrosine kinases (JAK2). More recent data suggest an alternative model in which unliganded EpoR dimers exist in a conformation that prevents activation of JAK2, but the receptor may undergo a ligand-induced conformational change that allows JAK2 to be activated. JAK2 and/or other kinases then phosphorylate specific tyrosine residues in EpoR, creating docking sites for the SH2 domains of several signal transduction proteins, which eventually results in the activation of at least three signal transduction pathways: STAT5, Ras/MAP kinase and phosphatidylinositol 3-kinase (PI3-K) (Figures 2.7 and 2.8).

Considerable interest has concentrated on the JAK2–STAT5 pathway. JAK2 is essential for erythropoiesis, and genetically modified mice in which JAK2 expression has been eliminated

die as embryos, with a phenotype similar to mice deficient in Epo or EpoR. However, the numbers of erythroid progenitors are more severely diminished, suggesting that JAK2 is required earlier in erythropoiesis than Epo–EpoR. JAK2 is rapidly phosphorylated in response to Epo stimulation. Dimerization or conformational changes of EpoR brings the associated JAK2 molecules into close proximity, enabling them to transphosphorylate and activate each other (Figures 2.7 and 2.8). STAT5 is phosphorylated and activated by EpoR. Phosphorylated STAT5 dissociates from the receptor, dimerizes and moves to the nucleus, where it activates gene expression and is thought to be important as an anti-apoptotic signal. Both fetal and adult mice defective in STAT5 have a defect in regulating survival of early erythroblasts, leading to a persistent anaemia.

Activation of the PI3-K and Ras-MAP kinase pathway (Figure 2.8) may be sufficient for normal erythroid differentiation, although they may not be essential as other pathways can compensate for loss of signalling through PI3-K. Therefore, in erythroid cells, activation of several, apparently redundant intracellular signalling pathways can support differentiation. Nevertheless, it is thought at present that these pathways may converge by activating a few important anti-apoptotic proteins, including Bcl-2, Bcl-X_L and protein kinase B (also known as Akt) (Figure 2.8).

The full control of this system is complex and it should be noted that the EpoR pathway can also be activated by other mechanisms. For example, activation of c-Kit by its ligand, stem cell factor (SCF), causes tyrosine phosphorylation of EpoR and

Figure 2.7 A summary of signalling via the erythropoietin (Epo) receptor as described in the text. P denotes regions of phosphorylation. The diagram shows Epo-induced dimerization or conformational change with transphosphorylation of JAK2,

followed by phosphorylation of the Epo receptor. This is followed by binding and phosphorylation of STAT5. Binding of SHP1 (far right) to the Epo receptor activates its phosphatase activity, which can then dephosphorylate JAK2 and terminate signalling.

Figure 2.8 A summary of the apoptotic pathways (Epo and Fas) in erythroid progenitors. These cells (BFU-E and CFU-E) undergo apoptosis in the absence of Epo signalling or in the

presence of Fas signalling. Bcl-X_L may be the key pathway through which these effects are mediated.

a functional interaction between the two receptors is essential for normal erythropoiesis.

Mechanisms for switching off the Epo–EpoR signalling pathway also exist. Specific phosphorylated tyrosines that occur on the Epo-stimulated dimerized EpoR provide docking sites for the SH2 domains of protein tyrosine phosphatases such as SHP1. Binding activates the phosphatase, which removes the activating phosphates from JAK2, terminating the positive signal from this pathway (Figure 2.7).

Other signalling pathways

Erythropoiesis is also influenced by pathways other than Epo–EpoR. Erythroid progenitors express receptors for SCF, insulin-like growth factor (IGF-1) and insulin. After Epo, the second most important signalling system for erythropoiesis involves SCF (Kit ligand) and its receptor (c-Kit). Activation by SCF induces tyrosine phosphorylation of its own receptor. SCF was originally identified by its ability to stimulate proliferation of multipotent haemopoietic progenitors, but it is also effective in supporting growth of committed progenitors, including erythroid progenitors, acting synergistically with Epo.

In addition to SCF and Epo, recent observations have shown that stimulation of the nuclear hormone receptors for dexamethasone (glucocorticoid receptor) and estrogen (estrogen receptor) produces sustained proliferation of erythroid progenitors. Furthermore, the nuclear hormone receptors for thyroid hormone (c-Erba/thyroid hormone receptor), all-*trans* retinoic acid (retinoic acid receptor) and 9-*cis*- retinoic acid (RXR) were found to promote erythroid differentiation. Such observations are consistent with previous reports showing that patients with a wide range of endocrine disorders (hypothyroidism, hypopituitarism, Addison’s disease and male hypogonadism) all have variable degrees of normochromic normocytic anaemia. It appears, therefore, that many hormones of the endocrine system can modify erythropoiesis.

Apoptosis during normal erythropoiesis

Programmed cell death (apoptosis) plays an important role in normal erythropoiesis (Figure 2.8), helping to regulate the accumulation of erythroid precursors to match the need for new mature red cells. Excess erythroid precursors are removed

by apoptosis, and at least two pathways seem to be involved. First, it appears that late BFU-E, CFU-E and pronormoblasts may all require continuous signalling via EpoR, which is highly expressed on the surface of these cells, to prevent apoptosis. In the absence of Epo, these cells rapidly undergo programmed cell death in culture. It has been shown that, in part, this reflects a need for signals from EpoR, via the JAK2–STAT5 pathway, to induce or stabilize expression of the anti-apoptotic protein Bcl-X_L.

Apoptosis of erythroid precursors may also occur as a result of activation of the Fas receptor (FasR, known as CD95) that is present on both early and late erythroid precursors, although its activating ligand (FasL, known as CD95L) appears only on late erythroblasts. Binding of FasL to FasR activates proteolytic caspases that cleave intracellular proteins, possibly including the erythroid transcription factor GATA-1, with subsequent loss of Bcl-X_L. This regulation of erythropoiesis by negative feedback is thought to take place in the erythropoietic islands of the bone marrow, where the number of mature erythroblasts may control the expansion and differentiation of their less mature precursors.

As well as extracellular anti-apoptotic signals, erythroblasts also use internal programmes to ensure their own survival. The transcription factor GATA-1 is essential for maturation of erythroblasts; the absence of GATA-1 leads to apoptosis and a block in maturation. Some of the target genes regulated by GATA-1 are likely to be important for cell survival. Although many of the targets are unknown, it is clear that GATA-1 strongly induces expression of Bcl-X_L and may therefore cooperate with EpoR signalling. In this way, Epo signalling, Fas-mediated signalling and GATA-1 converge on Bcl-X_L, which represents a key target of the erythroid cell survival programme.

Erythropoiesis in clinical practice

Erythropoiesis is disturbed to a greater or lesser extent in almost all multisystem diseases and so the reader is referred to other

chapters and references for specific examples. The aim of this chapter is to provide a framework for thinking about the process of erythropoiesis in clinical practice. The first stage involves the production of committed erythroid progenitors. The second involves controlling red cell production, which is mainly achieved via the oxygen sensor influencing the level of Epo, which in turn controls the numbers of late BFU-Es and CFU-Es, although many other hormones, cytokines and growth factors may modify the response. The third phase requires terminal erythroid differentiation to mature red cells containing large amounts of specific proteins such as haemoglobin. This phase makes significant demands on a variety of nutritional factors and cofactors, particularly iron, vitamin B₁₂ and folate, but also manganese, cobalt, vitamin C, vitamin E, vitamin B₆ (pyridoxine), thiamine, riboflavin, pantothenic acid and amino acids. Absolute or relative deficiencies of these cofactors can negatively regulate erythropoiesis. The output from this process (red cell mass) is required to meet the demands for adequate tissue oxygenation, which itself has a major influence on the production of Epo, thus completing the regulatory loop (Figure 2.9).

Simple diagnostic tools are available to test the circuit in a logical manner (see also Chapter 6). First, one can evaluate the overall level of erythropoiesis by estimating the ratio of myeloid precursors to erythroid precursors in the marrow (normally about 4:1, but with a very broad normal range). Total erythropoiesis can be measured accurately using radioactive (⁵⁹Fe) ferrokinetic assays. The plasma iron turnover measures the total (i.e. effective and ineffective) amount of erythropoiesis, whereas the red cell iron utilization assay measures effective erythropoiesis. To a large extent, these two parameters can now be assessed much more easily by measuring the levels of soluble TfR and the reticulocyte count. Soluble TfR is a truncated form of the receptor that circulates in a complex with transferrin. The erythroblasts rather than the reticulocytes are the main source of soluble TfR and, when iron stores are adequate and available, measuring the level of soluble TfR (normal range 5.0 ± 1.0 mg/mL) is a good guide to the total level of erythropoiesis. Soluble TfR levels are increased when erythropoiesis is stimulated and

Figure 2.9 Summary of the regulation of erythropoiesis with the key points for assessment boxed in blue. ME denotes assessment of the myeloid/erythroid ratio in the bone marrow. Hct, haematocrit.

decreased when diminished. The interpretation of soluble TfR levels is complicated in iron deficiency as this condition independently raises the level of soluble TfR. The reticulocyte count (0.5–2.0% or $25\text{--}75 \times 10^9/\text{L}$) is raised in proportion to the degree of anaemia when erythropoiesis is effective (e.g. uncomplicated response to bleeding), but is relatively low when erythropoiesis is ineffective (e.g. β thalassaemia) or an abnormality prevents a normal response (e.g. nutritional deficiency).

The output of the system, the red cell mass, can be accurately measured by radioactive dilution techniques using ^{51}Cr , but can often be reliably estimated from the haematocrit or concentration of haemoglobin. Changes in red cell size, shape and haemoglobin content, often reflected in the red cell morphology, may provide important guides to specific abnormalities in red cell maturation (e.g. haemoglobinopathies, thalassaemia, nutritional deficiencies). If the red cell mass is appropriate to meet the demands for oxygenation, then Epo production will be suppressed and the serum level will be in the normal range ($\sim 25\text{--}50$ mU/mL in cord blood and $\sim 10\text{--}30$ mU/mL in adults). If there is inadequate oxygenation, the level of Epo will generally be raised in proportion to the degree of anaemia (e.g. up to $3\text{--}10$ U/mL after severe blood loss) unless there is some impediment to Epo production (e.g. chronic renal failure, anaemia of chronic diseases). For any given degree of anaemia the level of Epo in the blood may vary depending on the underlying conditions. For example, levels tend to be very high in aplastic anaemia and less than anticipated in thalassaemia. This may reflect the different numbers of precursors in the marrow that are able to bind available Epo molecules, thus altering the number of free Epo molecules that are measured.

These apparently straightforward assessments may be more difficult to interpret when there are multiple causes of abnormal erythropoiesis, and in particular when complicated by nutritional deficiencies, which should always be evaluated in parallel with these studies. In addition to the common nutritional anaemias, the vast number of specific diagnostic tests to determine the inherited or acquired disorders that may perturb each phase of erythropoiesis are described elsewhere in this book.

Proper oxygen delivery to the tissues requires sufficient circulating mature red cells, and any appropriate therapy should be aimed at correcting this. An important caveat is that excessive red cells may cause a sluggish circulation that can cause ischaemia, leading to serious complications (e.g. myocardial infarction and stroke). The simplified circuit presented here to describe the process of erythropoiesis (Figure 2.9) indicates three potential routes for therapeutic intervention. The first is to correct nutritional deficiencies, usually iron and less commonly folate or vitamin B_{12} . The discovery of the role of the iron-regulatory peptide hepcidin in the anaemias of chronic disorders suggests that some remaining common forms of anaemia related to this class (caused by inability to use stored iron) may be amenable to rational treatment in the not too

distant future. A second frequently used approach is to correct anaemia, of any cause, with red cell transfusion, and the criteria for such treatment are set out in other sections of this book. The final approach is to increase erythropoiesis by administering recombinant human erythropoietin (rHuEpo). Following its considerable benefit to patients with the anaemia of chronic renal failure who are not capable of producing normal levels of Epo, rHuEpo has been assessed in a wide range of disorders (e.g. aplastic anaemia, red cell aplasia, thalassaemia intermedia, cancer of all types, haematological malignancy, myelodysplastic syndrome, rheumatoid arthritis, autologous blood donors, after stem cell transplantation and more). Modified forms of Epo, with a higher carbohydrate content and longer half-lives *in vivo*, have been developed and approved for clinical use, while small-molecule Epo mimetics with higher affinity for EpoR are under investigation. A review of the effectiveness of these therapeutic alternatives is beyond the scope of this chapter, but the considerable expense involved in treating patients, often over relatively long periods of time, with a hormone that does not always directly address the known pathophysiology of the anaemia requires careful consideration.

Finally, there are some conditions in which hormonal deficiency is known to contribute to anaemia (e.g. hypothyroidism, Addison's disease). In these cases appropriate correction of the hormonal deficiency logically helps correct the anaemia. Some rare forms of anaemia respond to a variety of therapies for unexplained reasons. For example, some cases of Diamond–Blackfan anaemia respond to corticosteroids, and some cases of congenital dyserythropoietic anaemia respond to interferon alfa, suggesting that there are still many unknown aspects to this clinically important and intellectually fascinating process of erythropoiesis.

Introduction

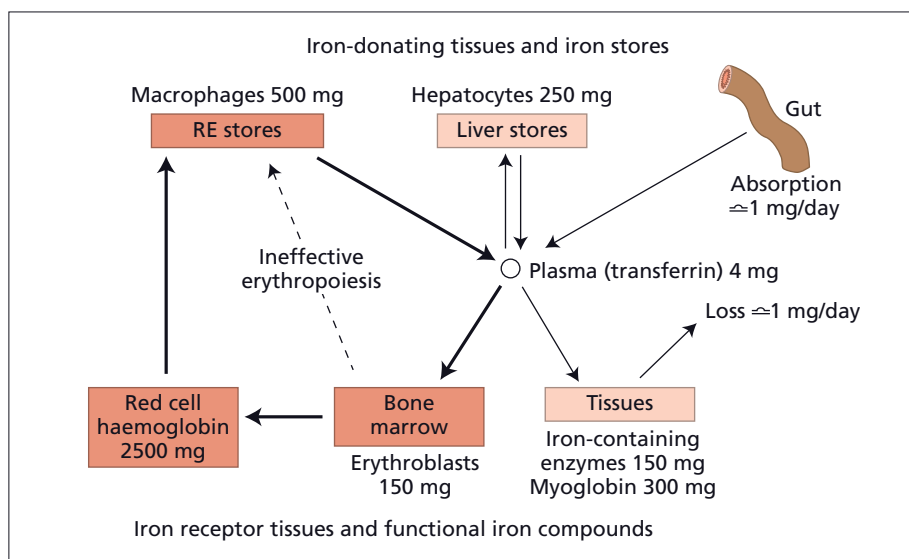

Iron (atomic weight 55.85) is essential for many metabolic processes. It shares with other transition metals two properties of particular importance in biology: the ability to exist in more than one relatively stable oxidation state and the ability to form many complexes. Its ability to exist in both ferric and ferrous states underlies its role in critical enzyme reactions concerned with oxygen and electron transport and the cellular production of energy. As well as physiologically active iron compounds, many of which are haem proteins, there are also specialized proteins of iron transport and storage. The latter are necessary to enable iron to remain in solution at neutral pH, at which ferric iron is insoluble, and to limit the potential toxicity of this reactive metal. The insolubility of ferric iron also means that although the earth's crust contains approximately 4% iron and iron may be plentiful in the diet, much of this is unavailable. As

a result, the body is limited in the adjustments it can make to excessive loss of iron, which frequently occurs due to haemorrhage, and iron deficiency is the most common cause of anaemia throughout the world. The general need to conserve the metal is reflected in the absence of any physiological mechanism for excretion of iron, control of iron balance being at the level of iron absorption. This is important in the rarer but potentially fatal disorders of iron overload (see Chapter 4).

Distribution of body iron

The concentration of iron in the adult human body is normally about 50 mg/kg in males and 40 mg/kg in females. The largest component is circulating haemoglobin, with 450 mL (1 unit) of whole blood containing about 200 mg of iron (Figure 3.1). Much of the remainder is contained in the storage proteins ferritin and haemosiderin. These are found mainly in the reticuloendothelial cells of the liver, spleen and bone marrow (which gain iron from breaking down red cells), and in parenchymal liver cells (which normally gain most of their iron from the plasma iron-transporting protein transferrin).

Figure 3.1 The major compartments of iron in a 70-kg man. Iron supply for erythropoiesis and release of iron from senescent red cells dominate internal iron exchange. RE, reticuloendothelial.

Proteins important in iron metabolism

Haemoglobin

Haemoglobin (molecular weight 64 500) contains four haem groups linked to four globin chains, and can bind four molecules of oxygen. Myoglobin (molecular weight 17 000) accounts for 4–5% of body iron and has a single haem group attached to its one polypeptide chain. It has a higher affinity for oxygen than haemoglobin and behaves as an oxygen reserve in muscles. The mitochondria contain a series of haem and non-haem iron proteins (including the cytochromes *a*, *b* and *c*, succinate dehydrogenase and cytochrome oxidase) that form an electron transport pathway responsible for the oxidation of intracellular substrates and the simultaneous production of adenosine triphosphate (ATP). Haem is an essential component of microsomal and mitochondrial cytochrome P450, which is concerned with hydroxylation reactions (including drug detoxification by the liver), and of cyclooxygenase, involved in prostaglandin synthesis. Other haem proteins include the enzymes catalase and lactoperoxidase, which are concerned with peroxide breakdown, and tryptophan pyrrolase, involved in the oxidation of tryptophan to formylkynurenine. There is a smaller group of iron sulphur proteins (e.g. xanthine oxidase, reduced nicotinamide adenine dinucleotide dehydrogenase and aconitase). Iron is also necessary for the function of ribonucleotide reductase, a key enzyme in DNA synthesis.

Ferritin and haemosiderin

Ferritin is the primary iron storage protein and provides a reserve of iron. It consists of an approximately spherical apo-

protein shell (molecular weight 480 000) enclosing a core of ferric hydroxyphosphate (up to 4000 iron atoms). Human ferritin is made up from 24 subunits (molecular weight about 20 000) of two immunologically distinct types: H and L. There are multiple gene copies, which are mostly pseudogenes, on 12 different chromosomes. The coding loci are located at 11q12–q13 for the heavy chain and 19q13.3–q13.4 for the light chain. An intronless gene on chromosome 5 (q23.1) codes for mitochondrial ferritin, a novel H-type ferritin. The internal cavity of the ferritin molecule communicates with the exterior via six channels, through which ferrous iron may enter (to interact with a ferroxidase centre on the ferritin H subunit) or leave (after reduction, e.g. by dihydroflavins or ascorbic acid).

The way in which ferritin iron is mobilized is poorly understood, and a process in which the entire ferritin molecule is degraded within lysosomes prior to iron release has also been suggested. Variation in the proportion of H to L subunits explains the heterogeneity of ferritin from different tissues on isoelectric focusing: L-rich ferritins (from spleen and liver) are more basic than H-rich ferritins (from heart and red cells). The small amount of ferritin normally present in serum contains little iron and consists almost exclusively of L subunits. It is also heterogeneous, owing to glycosylation. This glycosylation and the direct relationship of serum concentration to storage iron in macrophages suggest that serum ferritin is secreted by macrophages in response to changing iron levels.

Haemosiderin, unlike ferritin, is a water-insoluble, crystalline, protein–iron complex that is visible by light microscopy when stained by the Prussian blue (Perls') reaction. It has an amorphous structure, with a higher iron/protein ratio than ferritin, and is probably formed by the partial digestion of ferritin aggregates by lysosomal enzymes. In normal subjects, the

majority of storage iron is present as ferritin, and haemosiderin is predominantly found in macrophages rather than hepatocytes. In iron overload, the proportion present as haemosiderin increases considerably in both cell types.

Transferrin and transferrin receptors

Transferrin is a single-chain polypeptide (molecular weight 79 500) present in plasma (1.8–2.6 g/L) and extravascular fluid (Table 3.1). It has a plasma half-life of 8–11 days. The protein is synthesized predominantly by the liver, synthesis being inversely related to iron stores. Two atoms of ferric iron bind to each molecule. Although transferrin contains only about 4 mg of body iron at any time, it is vital to iron transport, with over 30 mg iron passing through this compartment each day (Figure 3.1). The binding sites (N-terminus and C-terminus) contain three tyrosine and two histidine residues and an arginine group. The uptake of iron from transferrin requires that the protein is attached to specific receptors on the cell surface. The transferrin receptor gene (*TFRC*) codes for TFR1, a transmembrane protein (identified as CD71), each molecule of two subunits binding one transferrin molecule. A second receptor, TFR2, also binds transferrin (Table 3.1). Through their binding with HFE, TFR1 and TFR2 are involved in regulating hepcidin synthesis (see Figure 3.2).

Lactoferrin is a glycoprotein (molecular weight 77 000) that is structurally related to transferrin. It is found in milk and other secretions and in neutrophils. It is thought to have a bacteriostatic action at secreting surfaces by depriving microorganisms of the iron needed for their growth.

Divalent metal transporter 1

Divalent metal transporter (DMT)1 is an electrogenic pump that requires proton cotransport in order to transfer Fe^{2+} across cell membranes. This occurs at the apical membrane and subapical endosomes of the duodenal enterocyte and the transferrin-cycle endosome, both of which have a low pH. The intestinal DMT is produced by different mRNA splicing from that which produces endosomal DMT1. DMT1 expression is upregulated in iron deficiency (see later) and may be involved in absorption of other divalent metal cations including Mn^{2+} , Co^{2+} , Zn^{2+} , Cu^{2+} and Pb^{2+} , although this is not established as a major function.

Ferroportin (SLC40A1)

This transmembrane domain protein is the basolateral transporter of iron, essential for iron release from macrophages, the intestinal absorptive enterocyte and placental syncytiotrophoblasts. It is also present in intracellular compartments. Caeruloplasmin is required for the cell surface localization of ferroportin, whose concentration is controlled by hepcidin,

which triggers its tyrosine phosphorylation, internalization and degradation by ubiquitin in lysosomes.

Growth differentiation factor and twisted gastrulation protein

Growth differentiation factor (GDF)-15 is a member of the transforming growth factor (TGF)- β superfamily of proteins, which also includes the bone morphogenetic proteins (BMPs). GDF-15 exerts different functions according to the cell context, inhibiting hepcidin synthesis, macrophage activation, proliferation of immature haemopoietic progenitors and growth of tumour cell lines. It is strongly expressed during erythroblast maturation with lower levels in the other tissues. It is inducible by iron depletion and by hypoxia but is independent of hypoxia-inducible transcription factors (HIFs).

A second erythroid regulator of hepcidin expression, twisted gastrulation protein (TWSG1), has been identified. It is produced during the early stages of erythropoiesis and interferes with BMP-mediated hepcidin synthesis.

Other proteins

The roles in iron metabolism of hemojuvelin (HJV), BMP-6, SMADs, ferrioxidative and reduction enzymes, and caeruloplasmin are discussed under the headings of hepcidin regulation, iron absorption, iron uptake by erythroid cells and haem synthesis.

Hepcidin

Hepcidin has a central role in the regulation of iron metabolism and absorption (Figure 3.2). A product of the *HAMP* gene (Table 3.1), it is a small peptide (25 amino acids) with several isoforms and is released from a large prepropeptide of 84 amino acids. It is predominantly expressed in the liver. It regulates iron homeostasis by binding to cell-surface ferroportin, causing its tyrosine phosphorylation, internalization, ubiquitination and degradation in lysosomes. It therefore acts to inhibit iron absorption, iron release from macrophages and iron transport across the placenta. It is bound in plasma to α_2 -macroglobulin and the major route of clearance is the kidney. Hepcidin can be measured in serum or urine by ELISA or mass spectrometry-based techniques. These have shown low or undetectable levels in iron deficiency and extremely high levels in inflammatory conditions, with inappropriately low levels in haemochromatosis and iron-loading anaemias.

Regulation of hepcidin expression

The regulation of hepcidin expression is transcriptional. Hepcidin expression is increased in response to raised serum iron, iron overload and inflammation, and is suppressed by

Figure 3.2 Stimulatory and inhibitory signals of hepcidin regulation. Hepcidin, as well as hemojuvelin (HJV), transferrin receptor 2 (TFR2) and HFE, are all produced in the hepatocyte. High plasma iron and inflammation stimulate hepcidin synthesis. This is mediated by SMADs and STAT3 respectively. Conversely, low plasma iron, increased rates of erythropoiesis (including ineffective erythropoiesis) and hypoxia inhibit hepcidin production. This is mediated by matriptase, growth differentiation factor (GDF)-15, twisted gastrulation protein (TWSG1) and HIF1- α respectively. Hepcidin binds ferroportin (FPN), causing its destruction and so inhibits iron absorption and iron release from macrophages into plasma and from intracellular compartments. BMP, bone morphogenetic protein.

iron deficiency, hypoxia and increased erythropoietic activity. Under basal conditions, expression depends on signalling through the BMP/SMAD pathway (Figure 3.2). HJV is a member of the repulsive guidance molecules (RGM) family that is highly expressed in liver, skeletal muscles and the heart. It is either associated with cell membranes through a glycosylphosphatidylinositol anchor or released as a soluble form. Membrane-bound HJV participates in the pathway regulating hepcidin expression as a BMP coreceptor, whereas soluble HJV antagonizes BMP-6. BMP-6 is the master hepcidin activator *in vivo*.

HFE and TFR2 are also involved in hepcidin expression (Figure 3.2). HFE is able to bind TFR1 and TFR2. During low

or basal serum iron conditions, HFE and TFR1 exist as a complex at the plasma membrane, TFR1 serving to sequester HFE to silence its activity. Diferric serum transferrin (Fe^{2+} -TF) competes with HFE for binding to TFR1. Increased serum transferrin saturation therefore results in dissociation of HFE from TFR1. Acting as an iron sensor, HFE then binds to TFR2 and conveys the Fe^{2+} -TF status to the signal transduction effector complex. HJV binds to BMP, then phosphorylates SMADs to form an SMAD-1/-5/-8-SMAD-4 complex, which translocates to the nucleus and stimulates hepcidin production by activating its promoter. In keeping with this model, genetic mutations of HFE, TFR2, HJV and hepcidin all result in haemochromatosis with low serum hepcidin levels (see

Chapter 4). Iron levels also seem to control BMP-6 production but whether this is through liver iron or circulating transferrin is unclear.

A second type of transcriptional hepcidin regulation occurs in inflammation. Interleukin (IL)-6 and IL-1 β induce transcription of the hepcidin gene by activating STAT3 (signal transducer and activator of transcription 3) and its binding to a regulatory element in the hepcidin promoter. It may converge on a final shared SMAD-4-dependent pathway.

The hepcidin response is remarkably rapid. In humans, iron ingestion results in a sharp increase in urinary hepcidin excretion within 12–24 hours of starting treatment. Likewise, infusion of recombinant IL-6 results in significant increase in urinary hepcidin and decreased serum iron and transferrin saturation within 2 hours of infusion. These observations imply that hepcidin expression is directly controlled by serum iron (probably by transferrin saturation) and IL-6 and not by long-term gradual accumulation of iron in tissues.

Response to anaemia and hypoxia

Hepcidin levels can be measured in patient serum or urine by ELISA or mass spectrometry. Hepcidin levels are reduced or undetectable in iron deficiency anaemia and extremely high in inflammatory conditions. Iron absorption is accelerated in iron deficiency, ineffective erythropoiesis and hypoxia (Figure 3.2). Erythroid precursors secrete GDF-15 and TWSG1, which inhibit hepcidin production by the liver. Serum concentrations of GDF-15 are grossly increased in thalassaemia major and other conditions associated with ineffective erythropoiesis and in iron deficiency, resulting in hepcidin suppression and so inability to turn off intestinal iron absorption. In addition, other studies indicate that the von Hippel–Lindau hypoxia inducible factors (HIFs), which stimulate erythropoietin synthesis, control iron homeostasis by the downregulation of hepcidin, repressing its promoter with the upregulation of ferroportin. Under normal conditions, HIFs play a useful role by mobilizing iron and supporting erythrocyte production in response to anaemia/hypoxia. However, the same mechanism may contribute to the harmful accumulation of iron in response to chronic anaemia associated with ineffective erythropoiesis in thalassaemia and other dyserythropoietic anaemias. In addition, soluble HJV *in vitro* and *in vivo* and erythropoietin itself in cell models are able to inhibit hepcidin transcription.

Matriptase-2 (TMPRSS6)

This is a type 2 member of the transmembrane serine protease family mainly expressed in the liver. Membrane-bound matriptase-2 regulates hepcidin expression by cleaving membrane-bound HJV, releasing soluble HJV fragments. The reduction in membrane-bound HJV and the presence of soluble HJV both result in reduced hepcidin transcription. The factors

which regulate matriptase-2 expression need to be elucidated. Matriptase-2 activity overrides all known activating stimuli of hepcidin synthesis. Homozygous *TMPRSS6*^{-/-} mutations in mice and humans result in marked upregulation of hepcidin and blockade of intestinal and macrophage iron transport into plasma, leading to a refractory hypochromic microcytic anaemia (see pp. 41, 51).

Intracellular iron homeostasis

Synthesis of several of the proteins involved in iron metabolism is regulated at the level of RNA translation by two cytoplasmic iron-dependent proteins, namely IRP1 and IRP2 (Table 3.1). These are capable of binding to mRNAs that contain a sequence forming a stem-and-loop structure called an *iron-responsive element* or IRE (Figure 3.3). IRP1 (molecular weight 98000) contains an iron–sulphur (4Fe–4S) cluster and functions as a cytoplasmic aconitase with low affinity for the IRE when intracellular iron is abundant. When iron is scarce, however, the iron–sulphur cluster is no longer present and IRP1 binds to the IRE with high affinity. IRP2 (molecular weight 105000) is expressed ubiquitously but is less abundant than IRP1. IRP2 has an extra section of 73 amino acids rich in proline, serine and cysteine that mediates IRP2 degradation in iron-replete cells. Activation of IRP2 requires accumulation of the protein as a result of new synthesis. Degradation takes place in the proteasome after addition of iron.

The 3′-untranslated region (3′-UTR) of TFR1 contains five IREs, whereas the 5′-UTR region of ferritin mRNA contains a single IRE. Binding of IRP when there are low levels of intracellular iron protects TFR1 mRNA from cytoplasmic degradation but inhibits translation of ferritin mRNA by interfering with the binding of initiation factors. In contrast, when intracellular iron is increased, the opposite effects occur. Thus, coordinated regulation of TFR1 and ferritin acts to maintain a constant intracellular iron content over the short term by balancing cellular iron uptake and storage.

Erythroid δ -aminolaevulinic acid synthase (ALAS2) mRNA also has an IRE in its 5′-UTR region, whereas ‘housekeeping’ ALAS1 mRNA does not. The IRP–IRE system is therefore involved in matching iron supply to haem synthesis, with repression of protoporphyrin synthesis in iron-deficient erythroblasts (see p. 38). Mitochondrial aconitase interconverts citrate and isocitrate and has a putative IRE at the 5′-UTR of its mRNA. DMT1 like TFR1 has a 3′-IRE and is upregulated in iron deficiency. Ferroportin 1 has a 5′-IRE (Table 3.1) but binding of IRP is weak compared with the TFR1, ferritin and DMT1 IREs. However, as occurs for DMT1, ferroportin 1 may be translated in a non-IRE isoform that escapes the IRP control in some tissues, for example in duodenal cells.

Figure 3.3 Coordinate regulation of expression of ferritin and transferrin receptor: the role of the iron response element (IRE)–iron regulatory protein (IRP) mechanism. When cellular iron levels are low, IRP binds to the IRE stem and loop structures of mRNA to inhibit translation of ferritin and ALA-S, but increases translation of transferrin receptors (TFR) and DMT1 by preventing degradation of the mRNA. When iron levels are high, the IRP functions as a cytoplasmic aconitase and no longer binds to the IREs. Ferritin synthesis can thus proceed, while TFR synthesis is reduced. IRP2 binds to IREs when iron levels are low, but is degraded after ubiquitination (initiated by haem-induced oxidation) when iron levels are high. The IRPs therefore provide two ways of sensing iron requirements either involving Fe–S proteins or haem proteins.

Normal iron balance

The amount of iron in the body at birth depends on the blood volume and haemoglobin concentration, the birth weight (which determines blood volume) being particularly important. Delay in clamping the cord leads to an increased red cell mass by placental transfusion. The level of maternal iron stores has little effect on fetal iron. The newborn contains about 80 mg/kg at full term. Neonatal iron reserves are utilized for growth, and from 6 months to 2 years virtually no iron stores are present. Thereafter, iron stores gradually accumulate during childhood to around 5 mg/kg. In men, there is a further increase between 15 and 30 years to about 10–12 mg/kg (total up to approximately 1 g), whereas iron stores remain lower in women (average

Table 3.2 Daily iron losses and requirements.

Lactating [‡]	1.15	–	–	1.15

*Non-menstruating.

[†]Median loss.

[‡]Average dietary requirement during pregnancy is 3–4 mg.

Source: WHO (2001).

300 mg) until the menopause. It would take 4 years or more for a man to deplete body iron stores and start developing iron deficiency anaemia solely due to lack of dietary intake or malabsorption.

Requirements are higher in menstruating women and during periods of rapid growth in infancy and adolescence (Table 3.2). Menstrual blood loss has a median value of 30 mL, but the 95th centile value is 118 mL per month (equivalent to 1.9 mg iron per day), which has been found to be significantly associated with iron deficiency. Requirements are highest of all in pregnancy.

Iron absorption

Iron absorption depends not only on the amount of iron in the diet but also, and more importantly, on the bioavailability of that iron, as well as the body's needs for iron. A normal Western diet provides approximately 15 mg of iron daily. Of that iron, digestion within the gut lumen releases about half in a soluble form, from which about 3 mg may be taken up by mucosal cells and only about 1 mg (or 5–10% of dietary iron) transferred to

Figure 3.4 Molecular pathways of iron absorption. The area enclosed in the dotted box refers to the uptake of iron from the plasma in the developing enterocyte in the intestinal crypt. Otherwise, the diagram refers to iron absorption by the villous epithelial cell. DMT1, divalent metal transporter 1; FPN, ferroportin; Hp, hephaestin; TE, transferrin; TFR, transferrin receptor. For further details see text and Table 3.1.

the portal blood in a healthy man. Iron absorption can thus be influenced at several different stages.

Dietary and luminal factors

Much of dietary iron is non-haem iron derived from cereals (commonly fortified with additional iron in the UK), with a lesser component of haem iron from meat and fish. Even in iron deficiency, the maximum iron absorption from a mixed Western diet is no more than 3–4 mg daily. This figure is much less with the predominantly vegetarian, cereal-based diets of most of the world's population. Iron is better absorbed from animal than vegetable sources.

Iron is released from protein complexes by acid and proteolytic enzymes in the stomach and small intestine, and haem is liberated from haemoglobin and myoglobin. Iron is maximally absorbed from the duodenum and less well from the jejunum, probably because the increasingly alkaline environment leads to the formation of insoluble ferric hydroxide complexes. Acid pH, vitamin C and some low-molecular-weight chelates (e.g. sugars, amino acids) enhance absorption. Therapeutic ferrous iron salts are well absorbed on an empty stomach, but when taken with a meal absorption is reduced as a result of the same ligand-binding processes that affect dietary non-haem iron; phytates, tannates in tea and bran inhibit absorption.

Mucosal factors: molecular aspects of iron absorption and its regulation

A variety of mechanisms for the binding of non-haem iron to the mucosal membrane have been described. Specific, saturable and receptor-mediated mechanisms, and passive diffusion at higher doses, may occur.

The proposed process is illustrated in Figure 3.4. Non-haem iron is released from food as Fe^{3+} and reduced by duodenal cytochrome b_1 (DCytb) to Fe^{2+} . This is transported across the brush border membrane by DMT1, which is upregulated in iron deficiency. It is assumed that iron enters the labile pool and some may be incorporated into ferritin and lost when the cells are exfoliated. Iron destined for retention by the body is transported across the serosal membrane by ferroportin before uptake by transferrin as Fe^{3+} . The regulation of duodenal cell iron release by hepcidin through its action on ferroportin is rapid and occurs for all absorptive cells, including those at the tip of the villus. Hephaestin is a copper-containing ferroxidase expressed predominantly in villous cells of the small intestine that converts Fe^{2+} to Fe^{3+} in the basolateral transfer step of iron absorption.

Haem iron is initially bound by haem receptors at the brush border membrane and released intracellularly by haem oxygenase before entering the labile iron pool and following a common pathway with iron of non-haem origin.

Iron absorption is regulated both at the stage of mucosal uptake and at the stage of transfer to the blood. DMT1 levels increase when intracellular iron is low and ferroportin concentration is also high due to low plasma hepcidin levels. The amount of iron transported to the plasma through ferroportin is hepcidin-dependent.

Iron uptake by erythroid cells

About 85% of transferrin iron normally enters developing red cells for incorporation into haemoglobin. This tissue distribution of transferrin-bound iron reflects the expression of transferrin receptors, which are present in high concentration on

cells with a high iron requirement. The latter includes any rapidly dividing cells but is normally dominated by the cells of the erythron. A soluble truncated form of the transferrin receptor derived from these cell surfaces is detectable in serum.

Transferrin receptors have the highest affinity for diferric transferrin. The transferrin–receptor complex is taken up by a process of receptor-mediated endocytosis (Figure 3.5). The iron is released at the low pH of the endosome, reduced from Fe^{3+} to Fe^{2+} by STEAP3, a ferrireductase, before the apotransferrin and receptor are recycled to the plasma and the cell membrane respectively. Iron release from the endosome is via DMT1 (Figure 3.5) and the iron is transported into mitochondria by mitoferrin or enters ferritin. Recently, direct endosome–mitochondrial iron transfer has also been suggested. A mitochondrial version of ferritin exists, coded by a gene on chromosome 5. Its physiological role is unknown but it is elevated in sideroblastic anaemias due to ALAS2 defects or myelodysplasia. Direct transfer of storage iron from macrophages to erythroblasts (rhopheocytosis) may also occur.

Some 80–90% of iron taken into developing erythroblasts is converted to haem within 1 hour. Any iron taken up in excess of the requirement for haem synthesis is incorporated in ferritin (Figure 3.5). The red cell ferritin content is therefore increased when haemoglobin synthesis is impaired, as in thalassaemia syndromes or sideroblastic anaemia. Excess iron may be seen in the cytoplasm of mature red cells as one or more siderotic granules. These are composed of haemosiderin and stain blue with Perls' reaction and purplish blue with Romanowsky stains,

Figure 3.5 Incorporation of iron from plasma transferrin into haemoglobin in developing red cells. Uptake of transferrin iron is by receptor-mediated endocytosis.

when they are called Pappenheimer bodies. The spleen removes these granules by its pitting action.

Haem synthesis and mitochondrial iron metabolism

Haem consists of a protoporphyrin ring with an iron atom at its centre. Haem is synthesized from the precursors succinyl-CoA and glycine, which condense to form δ -aminolaevulinic acid (ALA) under the action of ALAS, with pyridoxal phosphate as a coenzyme (see Chapter 2; see also p. 39). Housekeeping ALAS (ALAS1) is coded by a gene on chromosome 3, but in erythroid cells erythroid-specific ALAS2 predominates and is encoded on the X chromosome. ALA can be utilized for the formation of both purines and haem. Four molecules of porphobilinogen condense under the influence of porphobilinogen deaminase and uroporphyrinogen cosynthase to form the tetrapyrrole ring compound uroporphyrinogen III. The latter is converted to protoporphyrin IX. Finally, iron in the ferrous form is incorporated under the influence of the enzyme ferrochelatase. Iron in haem has six coordinating valencies: four link the iron to nitrogen atoms in each pyrrole ring, whereas the remaining two link haem to histidine residues in the globin chain, the distal bond being unstable and easily replaced by oxygen to form oxyhaemoglobin.

The mitochondria play a major role in haem synthesis as they contain ALAS, coproporphyrinogen oxidase and ferrochelatase, the enzyme sequence from ALA to coproporphyrinogen being situated in the cytoplasm. Besides haem, mitochondria utilize iron in the synthesis of iron–sulphur clusters, prosthetic groups essential for the function of several mitochondrial (respiratory chain complexes, ferrochelatase) and cytosolic (aconitase) proteins. A connection exists between haem synthesis and sulphur cluster biogenesis, because the activity of the iron regulatory protein IRP1, which controls ALAS2, is iron–sulphur cluster-dependent and because ferrochelatase, the last enzyme in haem synthesis, has an iron–sulphur cluster.

The assembly of iron–sulphur clusters is a complex, incompletely understood process that requires multiple proteins. The best known is frataxin, a likely iron donor in this pathway. The gene encoding frataxin is mutated in Friedreich ataxia (see pp. 43, 44, 53). An enzyme active in the pathway, whose function is still unclear, is glutaredoxin-5, which has been found mutated in a rare recessive form of sideroblastic anaemia (see pp. 43, 44). ABCB7, a member of a family of transmembrane proteins characterized by the ABC domain that binds and hydrolyses ATP, transfers iron–sulphur clusters from mitochondria to the cytosol. Mutations of ABCB7 cause an X-linked form of sideroblastic anaemia with ataxia (see pp. 43, 44).

The mitochondria are also the site of the citric acid cycle, which supplies succinate. The mature red cell, which lacks mitochondria, is therefore unable to synthesize haem.

A number of porphyrins are formed by side reactions during the synthesis of protoporphyrin. In the porphyrias (see p. 41), many of these compounds accumulate in the major sites of haem synthesis, the liver and the red cells. A haem exporter, FLVCR (Table 3.1), is present in erythroid cells and rids the cell of any haem made in excess.

Intracellular transit iron and plasma non-transferrin-bound iron

It has been suggested but not proved that there is a transit pool of 'metabolically active' or 'labile' iron within cells, which receives iron from degraded haem or ferritin, exchanges with transferrin and is incorporated into newly synthesized iron-containing proteins. This iron is considered to be sensed by iron regulatory proteins and available for chelation. Within cells, low-molecular-weight chelates (e.g. with citrate) may be present. However, recent work questions the existence of these chelates and a model of iron transfer requiring direct protein–protein interaction that could involve interaction of organelles has been proposed. It is suggested that transferrin-containing endosomes may transfer iron directly to mitochondria. Within plasma in iron overload, non-transferrin-bound iron may also exist as oligomeric iron oxide, either free or bound to albumin, and is particularly toxic to various organisms (see Chapter 4).

Breakdown of haemoglobin

After phagocytosis by macrophages, haem from senescent red cells is broken down by haem oxygenase (HMOX1) to release iron (see Chapter 8). As ferrous iron, it can then either enter ferritin (where it is oxidized to ferric iron by the ferritin protein) or be released into plasma (via ferroportin 1), where its binding to transferrin (also as the ferric form) may be facilitated by a plasma ferrous oxidase (e.g. caeruloplasmin). The release of macrophage iron is controlled by hepcidin, with high levels, as in inflammation or iron overload, reducing iron release. Changes in the release of iron from macrophages are thought to account for the diurnal rhythm of serum iron concentration, which is highest in the morning and lowest in the evening. A diurnal increase in serum hepcidin at noon and 8 p.m. is observed in healthy volunteers.

Diagnostic methods for investigating iron metabolism

The large amount of iron present as haemoglobin means that the degree of any anaemia must always be considered in assessing iron status. Reduced amounts of haemoglobin accompany

an overall reduction in body iron in iron deficiency anaemia or after acute blood loss. In other anaemias, including the anaemia of chronic disease and most haemolytic and megaloblastic anaemias, iron is redistributed from the red cells to macrophage iron stores, with a corresponding increase in marrow-stainable iron and serum ferritin. The various measurements of iron status are listed in Table 3.3 and described below. No single measurement is ideal for all clinical circumstances, as all are affected by confounding factors (Table 3.3) and changes may develop sequentially (as in progressive negative iron balance) or may affect particular body iron compartments. Reference ranges for haemoglobin and the various measures of iron status are given in Appendix 1. Table 3.4 summarizes the changes in measures of iron status accompanying various types of hypochromic anaemia. The assessment of *iron overload* is discussed in Chapter 4.

Storage iron

Serum ferritin

In healthy subjects, the serum ferritin concentration correlates with iron stores, as assessed by quantitative phlebotomy or tissue biopsy. Normal concentrations of serum ferritin range from about 15 to 300 µg/L, and are higher in men (median about 90 µg/L) than in premenopausal women (median 30 µg/L). In neonates, the concentration in cord blood (median approximately 100 µg/L) rises further over the first 2 months of life as fetal haemoglobin is broken down, and thereafter falls to low levels (median 20–30 µg/L) throughout childhood and adolescence.

Serum ferritin concentrations below 15 µg/L are virtually specific for storage iron depletion, but normal values do not exclude this and values above 300 µg/L do not necessarily, or even usually, indicate iron overload. This is because ferritin synthesis is influenced by factors other than iron (in particular, it behaves as an acute-phase reactant in many inflammatory diseases). For this reason, serum ferritin concentrations below 50 µg/L may be associated with a lack of storage iron in patients with the anaemia of chronic disease. A ferritin concentration above 100 µg/L suggests the presence of storage iron.

Bone marrow aspiration

Staining the bone marrow for iron gives an indication of reticuloendothelial iron stores as well as erythroblast iron (Figure 3.6a). In iron deficiency anaemia, reticuloendothelial iron and erythroblast iron are absent (Figure 3.6b).

Iron supply to the tissues

Serum iron and iron-binding capacity

The serum iron and, more particularly, the saturation of the total iron-binding capacity of transferrin (TIBC) give a measure of the iron supply to the tissues. A serum transferrin saturation

Table 3.3 Potential confounding factors in the interpretation of measures of iron status.

Measurement	Confounding factors
<i>Iron stores</i>	
Serum ferritin	Increased: as an acute-phase protein (e.g. in infection, inflammation or malignancy) and by release of tissue ferritins by damage, especially to iron-rich organs (e.g. with hepatic necrosis, chronic liver disease, splenic or bone marrow infarction in sickle cell disease) Decreased: by ascorbate deficiency
<i>Tissue iron supply</i>	
Serum iron and transferrin saturation	Labile measures: normal short-term fluctuations mean that a single value may not reflect iron supply over a longer period
Serum transferrin receptor	Directly related to extent of erythroid activity as well as being inversely related to iron supply to cells
Red cell protoporphyrin/red cell ferritin/% hypochromic red cells/reticulocyte haemoglobin content	Stable measures: reduced iron supply at time of red cell formation leads to increases in protoporphyrin and reticulocyte haemoglobin content and hypochromic red cells, and reduced red cell ferritin. However, values may not reflect current iron supply. May be affected by other causes of impaired iron incorporation into haem (e.g. lead poisoning, sideroblastic anaemias)
<i>Functional iron</i>	
Haemoglobin concentration	Other causes for anaemia besides iron deficiency; a reciprocal relationship with iron stores should be expected in all anaemias except in iron deficiency anaemia
Red cell MCV, MCH	May be reduced in other disorders of haemoglobin synthesis (e.g. thalassaemia, sideroblastic anaemias) in addition to iron deficiency

MCH, mean corpuscular haemoglobin; MCV, mean corpuscular volume.

Table 3.4 Differential diagnosis of hypochromic anaemia.

	<i>Iron deficiency</i>	<i>Chronic disease</i>	<i>Thalassaemia trait (α or β)</i>	<i>Sideroblastic anaemia</i>	<i>IRIDA</i>
MCV/MCH	↓	↓ or N	↓	↓ (congenital) ↑N (acquired)	↓
Serum iron	↓	↓	N	↑	↓
TIBC	↑	↓ or N	N	N	↓
Transferrin saturation	↓	↓	N	↑	↓
Serum ferritin	↓	N or ↑	N	↑	N
Serum TFR	↑	N	N	N or ↑	↑
Serum hepcidin	↓	↑	N	↓	N or ↑
Bone marrow iron stores	↓	N or ↑	N	N or ↑	↑
Erythroblast iron	↓	↓	N	Ring forms

less than 15% is insufficient to support normal erythropoiesis. A rise in TIBC is characteristic of iron deficiency. A reduced serum iron concentration with a normal or reduced TIBC is a characteristic response to inflammation (see below).

Serum transferrin receptors

Plasma concentrations reflect both the number of erythroid precursors and iron supply to the bone marrow. In clinical practice, these two factors must be considered in interpreting

(a)

(b)

(c)

Figure 3.6 (a) Normal bone marrow showing plentiful iron in macrophages (Perls stain) with iron granules in erythroblasts (insets). (b) Iron deficiency: bone marrow showing absence of stainable iron (Perls stain). (c) Iron deficiency: peripheral blood film showing hypochromic microcytic red cells.

transferrin receptor levels. In the anaemia of chronic disease, the assay provides a valuable indicator of deficiency of body iron stores. Serum transferrin receptor levels only increase in this situation in the absence of storage iron.

Red cell protoporphyrin

When iron supply to the erythron is limited, iron incorporation into haem is restricted, leading to accumulation of the immediate precursor, protoporphyrin IX. This is lost only slowly from circulating red cells; concentrations greater than the normal upper limit of $80\mu\text{mol/mol}$ haemoglobin therefore indicate that a reduction in iron supply has been present over the previous few weeks. Protoporphyrin levels may also increase in patients with sideroblastic anaemias and lead poisoning. Analysers that are portable and easy to operate are useful in large-scale field studies of iron deficiency anaemia as an initial screening test.

Percentage of hypochromic red cells

As iron supply to the erythron diminishes, the new red cells produced are increasingly hypochromic. Assessment of the haemoglobin content of individual red cells, which is possible using some automated cell counters, allows measurement of the percentage of hypochromic cells. Values rising to above 6% may help in the early identification of impaired iron supply in patients with chronic renal failure who are receiving treatment with recombinant erythropoietin, when associated inflammatory disease means that other measures of iron status can be misleading.

Reticulocyte haemoglobin content

Reticulocyte haemoglobin content (CHr) is useful in screening iron status, particularly in dialysis patients. A CHr cut-off value of 32pg is appropriate for the assessment of iron-deficient erythropoiesis. Moreover, CHr may serve as a predictor of the response of anaemia to iron treatment. When response to treatment is favourable, an increase in CHr may be discerned within a few days of starting treatment before overall mean corpuscular haemoglobin (MCH) has changed.

Iron deficiency anaemia

Sequence of events

Depletion of iron stores

When the body is in a state of negative iron balance, the first event is depletion of body stores, which are mobilized for haemoglobin production. Iron absorption is increased when stores are reduced, before anaemia develops and even when the serum iron level is still normal, although the serum ferritin will have already fallen.

Iron-deficient erythropoiesis

With further iron depletion, manifested by a serum ferritin below $15\mu\text{g/L}$ and fall in serum transferrin saturation to less than 15%, iron-deficient erythropoiesis develops with increasing concentrations of serum transferrin receptor and red cell

protoporphyrin. At this stage, the haemoglobin, mean corpuscular volume (MCV) and MCH may still be within the reference range, although they may rise significantly when iron therapy is given.

Iron deficiency anaemia

If the negative balance continues, frank iron deficiency anaemia develops. The red cells become obviously microcytic and hypochromic (Figure 3.6c), and poikilocytosis becomes more marked. The MCV and MCH are reduced, and target cells may be present. The reticulocyte count is low for the degree of anaemia. The serum TIBC rises and the serum iron falls, so that the percentage saturation of TIBC is usually less than 10%.

The number of erythroblasts containing cytoplasmic iron (sideroblasts) is reduced at an early stage in the development of deficiency, and siderotic granules are entirely absent from these cells when iron deficiency anaemia is established. The erythroblasts have a ragged vacuolated cytoplasm and relatively pyknotic nuclei. The bone marrow macrophages show a total absence of iron, except where very rapid blood loss outstrips the ability to mobilize the storage iron. Platelets are frequently increased.

Tissue effects of iron deficiency

When iron deficiency is severe and chronic, widespread tissue changes may be present, including koilonychia (ridged nails, breaking easily), hair thinning, angular stomatitis (especially in those with badly fitting dentures), glossitis and pharyngeal webs (Paterson–Kelly syndrome). Partial villous atrophy, with minor degrees of malabsorption of xylose and fat, reversible by iron therapy, has been described in infants suffering from iron deficiency, but not in adults. Pica is sometimes present; in some who eat clay or chalk, this may be the cause rather than the result of iron deficiency.

Iron-dependent enzymes in the tissues are usually better preserved than other iron-containing compounds. In severe iron deficiency, however, these enzymes are not inviolate and their levels may fall. This may be partly responsible for the general tissue changes, with mitochondrial swelling in many different cells (including, in the experimental animal, hepatic and myocardial cells), poor lymphocyte transformation and diminished cell-mediated immunity, and impaired intracellular killing of bacteria by neutrophils.

A particular concern has been the finding that infants with iron deficiency anaemia may have impaired mental development and function, and that this deficit may not be completely restored by iron therapy. There is recent evidence that premature labour is more frequent in mothers with iron deficiency anaemia. It remains controversial whether impaired work performance seen in adults results from the anaemia or from depletion of mitochondrial iron-containing enzymes. It is also unclear to what extent some of the other tissue effects of iron deficiency can occur even in the absence of anaemia.

Table 3.5 Causes of iron deficiency.

Blood loss

Uterine: menorrhagia, post-menopausal bleeding, parturition
 Gastrointestinal: oesophageal varices, hiatus hernia, *Helicobacter pylori*, peptic ulcer, aspirin ingestion, hookworm, hereditary telangiectasia, carcinoma of the stomach, caecum or colon, ulcerative colitis, angiodysplasia, Meckel diverticulum, diverticulosis, haemorrhoids, etc.
 Renal tract: haematuria (e.g. renal or bladder lesion), haemoglobinuria (e.g. paroxysmal nocturnal haemoglobinuria)
 Pulmonary tract: overt haemoptysis, idiopathic pulmonary haemosiderosis
 Widespread bleeding disorders
 Self-inflicted

Malabsorption

Gluten-induced enteropathy (child or adult), gastrectomy, atrophic gastritis, chronic inflammation, clay eating, etc.

Dietary

Especially vegetarian diet

Causes of iron deficiency (Table 3.5)

Diet

Defective intake of iron is rarely the sole or major cause of iron deficiency in adults in Western communities. The diet may contain insufficient or poorly available iron as a result of poverty, religious tenets or food faddism. Iron deficiency is more likely to develop in subjects taking a largely vegetarian diet – the majority of the world's population – who also have increased physiological demands for iron.

Increased physiological iron requirements

Iron deficiency is common in infancy, when demands for growth may be greater than dietary supplies. It is aggravated by prematurity, infections and delay in mixed feeding. It is also frequent in adolescence, in females and in pregnancy (Table 3.2). The fetus acquires about 280 mg of iron and a further 400–500 mg is required for the temporary expansion of maternal red cell mass. Another 200 mg of iron is lost with the placenta and with bleeding at delivery. Although iron absorption increases throughout pregnancy and increased requirements are partly offset by amenorrhoea, this may not be sufficient to meet the resultant net maternal outlay of over 600 mg iron.

Blood loss

Blood loss is the most common cause of iron deficiency in adults. A loss of more than about 6–8 mL of blood (3–4 mg iron) daily becomes of importance, as this equals the maximum amount of iron that can be absorbed from a normal diet. The

loss is usually from the genital tract in women or from the gastrointestinal tract in either sex. The most common cause on a worldwide basis is infestation with hookworm, in which anaemia is related to the degree of infestation. In the UK, menorrhagia, haemorrhoids and peptic ulceration are common, as well as gastric bleeding because of salicylates or other non-steroidal anti-inflammatory drugs, hiatus hernia, colonic diverticulosis and bowel tumours (Table 3.5). Some unusual causes of blood loss deserve mention. Cow's milk intolerance in infants may lead to gastrointestinal haemorrhage. Self-induced haemorrhage may occur as an unusual form of Munchausen syndrome. Chronic intravascular haemolysis, such as that in paroxysmal nocturnal haemoglobinuria or mechanical haemolytic anaemia, may be a serious source of urinary iron loss.

Malabsorption

Malabsorption may be the primary cause of iron deficiency or it may prevent the body adjusting to iron deficiency from other causes. Dietary iron is poorly absorbed in gluten-induced enteropathy, in both children and adults. Gluten-induced enteropathy is encountered in about 5% of patients presenting with unexplained iron deficiency anaemia and, conversely, about 50% of patients with newly diagnosed coeliac disease have co-existent iron deficiency anaemia. Patients with this disease often show decreased or no response to oral therapy with inorganic iron.

Helicobacter pylori gastritis appears to be a common cause of iron deficiency, responding favourably to eradication with triple therapy. *Helicobacter pylori* gastritis inhibits gastric hydrochloric acid secretion, interfering with the solubilization and absorption of inorganic food iron but it is also possible that gastrointestinal blood loss plays a significant role in the causation of iron deficiency associated with *H. pylori* infection. Lastly, achlorhydria associated with autoimmune gastritis, an entity preceding and closely related to pernicious anaemia, is an important cause of iron malabsorption due to impaired food iron solubilization. It is encountered in about 20% of patients with unexplained or refractory iron deficiency anaemia, mostly women of fertile age in whom achlorhydria aggravates the consequences of menstrual blood loss.

Iron deficiency occurs in congestive heart failure due to malabsorption and iron loss and these patients may also have the features of the anaemia of chronic disorders. Intravenous iron benefits functional capacity and quality of life even in the absence of anaemia.

Management of iron deficiency

Management entails (i) identification and treatment of the underlying cause and (ii) correction of the deficiency by therapy with inorganic iron. Iron deficiency is commonly due to blood loss and, wherever possible, the site of this must be identified and the lesion treated.

Oral therapy

In most patients, body stores of iron can be restored by oral iron therapy. Iron is equally well absorbed from several simple ferrous iron salts, and as ferrous sulphate is the cheapest, this is the drug of first choice – 200 mg of ferrous sulphate contains 67 mg of iron. Where smaller doses are required, 300 mg of ferrous gluconate provides 36 mg of iron. It is usual to give 100–200 mg of elemental iron each day to adults and about 3 mg/kg per day as a liquid iron preparation to infants and children. The side-effects of oral iron, such as nausea, epigastric pain, diarrhoea and constipation, are related to the amount of available iron they contain. If iron causes gastrointestinal symptoms, these can usually be ameliorated by reducing the dose or taking the iron with food, but this also reduces the amount absorbed. Enteric-coated and sustained-release preparations should not be used, as much of the iron is carried past the duodenum to sites of poor absorption. Iron reduces absorption of tetracyclines (and vice versa) and of ciprofloxacin.

The minimum rate of response should be a 20 g/L rise in haemoglobin every 3 weeks, and the usual rate is 1.5–2.0 g/L daily. This will be slower when the dose tolerated is less than 100 mg/day, but this is seldom of clinical importance. It is usually necessary to give iron for 3–6 months to correct the deficit of iron in circulating haemoglobin and in stores (shown by a rise in serum ferritin to normal).

Failure to respond to oral iron is most commonly due to the patient not taking it, although there may be continued haemorrhage or malabsorption. In non-responding patients it is important to reassess the diagnosis to exclude other causes of microcytic anaemia such as iron-loading anaemias. For instance, many patients with thalassaemia trait, sideroblastic anaemia or other anaemias have been treated with iron before haemoglobin studies, bone marrow examination or other tests have revealed the correct diagnosis. A poor response may also be obtained if the patient has an infection, renal or hepatic failure, an underlying malignant disease or anaemia of inflammation due to high hepcidin levels (which inhibits absorption of therapeutic oral iron) and any other cause of anaemia in addition to iron deficiency.

Parenteral iron therapy

This is usually unnecessary, but it may be given if subjects genuinely cannot tolerate oral iron, particularly if gastrointestinal disease, such as inflammatory bowel disease, is present. It is also occasionally necessary in gluten-induced enteropathy and when it is essential to replete body stores rapidly (e.g. where severe iron deficiency anaemia is first diagnosed in late pregnancy) or when oral iron cannot keep pace with continuing haemorrhage (e.g. in patients with hereditary haemorrhagic telangiectasia). Patients with chronic renal failure who are being treated with recombinant erythropoietin are also likely to require parenteral iron therapy. In this situation, the demand for iron by the expanded erythron may outstrip the ability to

mobilize iron from stores, leading to a 'functional' iron deficiency. Increased red cell loss at dialysis contributes to iron needs and oral iron therapy is usually inadequate to prevent an impaired response to erythropoietin. Serum ferritin in this setting is, as in other chronic inflammatory conditions, an unreliable indicator of iron deficiency. The use of transferrin iron saturation, percentage of hypochromic red cells or reticulocyte haemoglobin content for detection of functional iron deficiency is discussed on p. 38. A transferrin saturation of less than 20% indicates functional iron deficiency. Intravenous ferric carboxymaltose has been shown to benefit patients with congestive heart failure and iron deficiency with or without anaemia.

From all parenteral preparations, the iron complex is taken up by macrophages of the reticuloendothelial system, from which iron is released to circulating transferrin, which then transports it to the marrow. In the UK, three preparations are available. Iron dextran (CosmoFer) is given intravenously by slow injection or infusion or deep intramuscularly into the gluteal muscle. An iron–sucrose complex, Venofer, is given by slow intravenous infusion or injection. The deficit in body iron should be calculated from the degree of anaemia; it is usually 1–2 g. In patients receiving erythropoietin treatment in chronic renal failure, smaller intravenous doses of Venofer (25–150 mg/week) may be used, with regular monitoring of serum ferritin to avoid iron overload. Ferrinject is a macromolecular iron(III)-hydroxide carbohydrate complex (molecular weight approximately 150 000). It can be administered as an intravenous bolus (maximum single dose 200 mg) or slow infusion (maximum single dose 1000 mg). Newer intravenous preparations including ferumoxytol and ferrous gluconate (Ferrlecit) may become available.

Parenteral iron should not be used if there is a history of allergy as anaphylaxis occasionally occurs. For iron dextran, a test dose should therefore be given slowly, followed by close medical supervision of the rest of the infusion. Headache, flushing, nausea, skin rashes, urticaria, shivering, general aches and pains, dyspnoea and syncope are possible immediate adverse effects. Delayed reactions, including arthralgia, fever and lymphadenopathy, are well described and can persist for several days. An exacerbation of rheumatoid arthritis may also be precipitated.

Iron refractory iron deficiency anaemia

Homozygous or doubly heterozygous germline frameshift, splice junction or missense mutations of matriptase-2 (*TMPRSS6*) are a cause of iron refractory iron deficiency anaemia. The mutations may affect different conserved domains of the protein, including a trypsin-like serine protease domain. The patients show a microcytic hypochromic anaemia with normal or raised serum and urine hepcidin levels and low serum iron and percentage saturation of iron-binding capacity.

The patients absorb iron poorly and are refractory to oral iron therapy but are partially responsive to parenteral iron.

A microcytic hypochromic anaemia with liver iron overload has also been described in a few patients with homozygous or doubly heterozygous mutations of *DMT1*. Liver iron stores are increased but erythroid iron utilization is impaired and serum hepcidin levels are low for the degree of iron overload. These patients may respond to erythropoietin injections. The patients are susceptible to infections.

Deficiency of serum transferrin due to mutations of the transferrin gene causes a hypochromic microcytic anaemia with tissue iron overload caused by increased plasma non-transferrin-bound iron and low hepcidin levels. Treatment has been with infusions of fresh frozen plasma or apotransferrin. Deficiency of caeruloplasmin also causes a mild hypochromic microcytic anaemia with iron overload in the liver and progressive neurodegeneration. There is failure of ferroxidase activity, which impairs iron mobilization from stores.

Pathological alterations in haem synthesis

Porphyrias

These are a group of inherited or acquired diseases, each characterized by a partial defect in one of the enzymes of haem synthesis (see Chapter 2). Increased amounts of the intermediates of haem synthesis accumulate, the disorders being classified by whether the effects are predominantly in the liver or the erythron (Table 3.6). A full discussion of these disorders is beyond the scope of this chapter, but those with a particular haematological overlap are mentioned briefly.

Congenital erythropoietic porphyria

This is a very rare autosomal recessive disorder that is due to reduced uroporphyrinogen III synthase activity. Most patients are heteroallelic for mutations in the uroporphyrinogen III synthase gene. A single case with a germline mutation of the X-linked erythroid-specific transcription factor GATA binding protein (*GATA-1*) has been described. Large amounts of porphyrinogens accumulate, and their conversion by spontaneous oxidation to photoactive porphyrins leads to severe, and disfiguring, cutaneous photosensitivity and dermatitis, as well as a haemolytic anaemia with splenomegaly. Increased amounts of uroporphyrin and coproporphyrin, mainly type I, are found in bone marrow, red cells, plasma, urine and faeces. Ring sideroblasts have been found in the marrow in some cases but rarely in large numbers. The age of onset and clinical severity of the disease are highly variable, ranging from non-immune hydrops fetalis to a later onset in which there are only cutaneous lesions. Treatment, including avoidance of sunlight and splenectomy to improve red cell survival, is only partially effective. High-level

Table 3.6 Human porphyrias.

<i>Form</i>	<i>Inheritance</i>	<i>Enzyme defect</i>	<i>Clinical features*</i>
<i>Hepatic</i>			
Acute intermittent porphyria	Autosomal dominant	Porphobilinogen deaminase	A
Hereditary coproporphyria	Autosomal dominant	Coproporphyrinogen oxidase	A + P
Porphyria variegata	Autosomal dominant	Protoporphyrinogen oxidase	A + P
Porphyria cutanea tarda	Acquired or (rare) autosomal dominant	Uroporphyrinogen decarboxylase	P
<i>Erythropoietic</i>			
Congenital erythropoietic porphyria	Autosomal recessive	Uroporphyrinogen cosynthase	P
Erythropoietic protoporphyria	Autosomal dominant	Ferrochelatase	P

*Acute attacks (A) of the gastrointestinal and/or nervous system are related to the accumulation of porphyrin precursors (δ -aminolaevulinic acid and porphobilinogen). Photosensitive skin lesions (P) are seen when the level of the enzyme defect in the haem synthetic pathway leads to the accumulation of formed porphyrins.

blood transfusions to suppress erythropoiesis (combined with iron chelation therapy) have been used to reduce porphyrin production sufficiently to abolish the clinical symptoms. Allogeneic bone marrow transplantation has been successful.

Erythropoietic protoporphyria

This is the most common erythropoietic porphyria and is usually caused by an autosomal dominant inherited deficiency of ferrochelatase, which results in increased free (not Zn) protoporphyrin concentrations in bone marrow, red cells, plasma and bile. Bone marrow reticulocytes are the primary source of the excess protoporphyrin. This leaks from cells and is excreted in the bile and faeces. Molecular analysis of the ferrochelatase gene has revealed a variety of missense, nonsense and splicing mutations as well as deletions and insertions. The onset of the disease is usually in childhood.

Expression of the gene is variable, and photosensitivity and dermatitis range from mild or absent to moderate in degree. There is little haemolysis, but a mild hypochromic anaemia may occur, and accumulation of protoporphyrins can occasionally lead to severe liver disease. Treatment is by the avoidance of sunlight; β -carotene may also diminish photosensitivity. Iron deficiency should be avoided as this may increase the amount of free protoporphyrin.

Other groups of patients with a variant of erythropoietic protoporphyria have been discovered to have mutations of mitoferrin or gain-of-function mutation of ALAS2.

Porphyria cutanea tarda

This is the most common of the hepatic porphyrias and occurs worldwide. The incidence in the UK has been estimated at 2–5 per million. Type I or ‘sporadic’ porphyria cutanea tarda (PCT) accounts for 80% of cases of PCT. The underlying metabolic

abnormality is decreased activity of uroporphyrinogen decarboxylase (UROD) in the liver. Type II disease is an autosomal dominant disorder caused by mutations in the *UROD* gene. Type III disease is a rare familial form and appears to result from unknown inherited defects that affect hepatic UROD activity. There is a marked increase in porphyrins in liver, plasma, urine and faeces. In the urine, uroporphyrin and heptacarboxylporphyrin predominate, with lesser amounts of coproporphyrin and pentacarboxylporphyrin and hexacarboxylporphyrin. The disease is characterized by photosensitivity and dermatitis. It is precipitated in middle or later life, more often in men than women, by factors such as liver disease, alcohol excess or estrogen therapy. A modest increase in liver iron is a common feature.

Either the homozygous or heterozygous presence of the C282Y and H63D mutations in the *HFE* gene may predispose to the development of PCT. Prevalence of the C282Y mutation is increased in both sporadic (type I) and familial (type II) PCT. In the UK, only homozygosity for C282Y (found in about 25% of patients) is significantly more common than in the general population (0.7%). In southern Europe, where C282Y is much less common, the H63D mutation is associated with PCT. Iron is known to inhibit UROD. Removal of the iron by repeated phlebotomy is standard treatment, usually leading to remission.

Lead poisoning

Chronic ingestion of lead in humans causes an anaemia that is usually normochromic or slightly hypochromic. Red cell lifespan is shortened and there is a mild rise in reticulocytes, but jaundice is rare. Basophilic stippling is a characteristic, though not universal, finding and it is thought to be due to

precipitation of RNA, resulting from inhibition of the enzyme pyrimidine 5'-nucleotidase. Siderotic granules, and occasionally Cabot rings, are found in circulating red cells. The bone marrow shows increased sideroblasts, in some patients with ring sideroblasts. Red cell protoporphyrin and coproporphyrin are raised, as is urinary excretion of ALA, coproporphyrin III and uroporphyrin I.

The cause of the anaemia appears to be multifactorial. Haemolysis, probably due to the blocking of sulphhydryl groups with consequent denaturation of structural proteins, and damage to mitochondria, with defective haemoglobin production due to inhibition of the enzymes of haem synthesis, are the major factors.

Sideroblastic anaemia

The sideroblastic anaemias comprise a group of refractory anaemias (Table 3.7) in which there are variable numbers of hypochromic cells in the peripheral blood, with an excess of iron in the bone marrow; at least 15% of the developing eryth-

roblasts in the primary forms of anaemia contain iron granules arranged in a ring around the nucleus (Figure 3.7). These ring sideroblasts (Table 3.8) (more than four perinuclear granules per cell and covering one-third or more of the nuclear circumference) are the diagnostic feature of the anaemia. Ring sideroblasts may comprise a small (<15%) population of the erythroblasts in a wide variety of clinical disorders.

Figure 3.7 Sideroblastic anaemia. Erythroblasts showing perinuclear rings of iron (Perls stain).

Table 3.7 Sideroblastic anaemias.

Hereditary

X-linked

Erythroid-specific ALAS2 (Xp11.21) mutations

Associated with spinocerebellar ataxia: mitochondrial ATP-binding cassette (*ABCB7*) mutations

Autosomal

Thiamine responsive, THTR-1 (*SLC19A2*) mutations:

DIDMOAD syndrome

Glutaredoxin-5 (*GLRX5*) mutations

Associated mitochondrial myopathy: pseudouridine synthase-1 mutations

SLC25 family transporter mutations

Mitochondrial

Pearson (marrow-pancreas) syndrome

Kearns-Sayre syndrome

Acquired

Primary

Refractory anaemia with ring sideroblasts

Secondary

Drugs: isoniazid, pyrazinamide, cycloserine, chloramphenicol, penicillamine

Mitochondrial toxicity: alcohol, lead poisoning

Copper deficiency systemic disease: carcinoma, rheumatoid arthritis

DIDMOAD, diabetes insipidus, diabetes mellitus, optic atrophy and deafness.

Table 3.8 Siderocytes and sideroblasts.

Siderocyte	Mature red cell containing one or more siderotic granules (Pappenheimer bodies)
Normal sideroblast	Nucleated red cell containing one or more siderotic granules, granules few, difficult to see, randomly distributed in the cytoplasm, reduced proportion of sideroblasts in iron deficiency and anaemia of chronic disorders
Abnormal sideroblasts	Cytoplasmic iron deposits (ferritin aggregates): increased granulation, granules larger and more numerous than normal, easily visible and randomly distributed, proportion of sideroblasts usually parallels the percentage saturation of transferrin (e.g. haemolytic anaemia, megaloblastic anaemia, iron overload, thalassaemia disorders) Mitochondrial iron deposits (non-ferritin iron): ring sideroblasts in inherited and acquired sideroblastic anaemias

Inherited sideroblastic anaemias

These are rare disorders manifesting mainly in males, usually in childhood or adolescence, but occasionally presenting late in life, when they need to be distinguished from the more common acquired form termed 'refractory anaemia with ring sideroblasts'.

X-linked

ALAS2 mutations

In most reported families, inheritance has followed an X-linked pattern. More than 25 different mutations of the gene for erythroid-specific ALAS2, located at Xp11.21, have been identified. All have been single-base substitutions. Most lead to changes in protein structure, causing instability or loss of function. They are found scattered over the seven exons (out of 11) encoding the C-terminal, catalytically active part of the protein. Mutations affecting the promoter have also been shown to cause disease. Function may be rescued to a variable degree by administration of pyridoxal phosphate (the essential cofactor for ALAS2), the best responses occurring when the mutation affects the pyridoxal phosphate-binding domain of the enzyme. The response is better if iron overload is reduced by phlebotomy or chelation.

Female carriers of X-linked sideroblastic anaemia may show partial haematological expression, usually with only mild or no anaemia, although rarely a severe dimorphic anaemia occurs. This may depend on variation in the severity of the defect, as well as the degree of lyonization of the affected X chromosome. Late onset in some patients suggests that the degree of lyonization may change with age. Iron loading may also aggravate the defect in haem synthesis in both males and females with sideroblastic anaemia.

Patients with X-linked sideroblastic anaemia show a hypochromic, often microcytic, anaemia. There may be a few circulating siderocytes, normoblasts and cells with punctate basophilia, but these features become pronounced only if the spleen has been removed. The bone marrow shows erythroid hyperplasia and the erythroblasts tend to be microcytic with a vacuolated cytoplasm. There are more than 15% ringed sideroblasts. The ineffective erythropoiesis is not usually accompanied by bone deformities, but some bossing of the skull and enlargement of the facial bones may result from the erythroid expansion. The spleen may be enlarged. Patients may present with severe iron overload even when the anaemia is relatively mild, but the rate of iron loading is accelerated if red cell transfusions are needed. Iron loading, however, aggravates the anaemia.

ABCB7 mutations

A rare form of X-linked sideroblastic anaemia is caused by abnormalities in the ATP-binding cassette transporter gene (*ABCB7*) at Xq13.3. This form is associated with early-onset, non-progressive cerebellar ataxia. A useful diagnostic distinction is the presence within the red cells of increased zinc pro-

toporphyrin, despite adequate iron stores, rather than the low/normal levels found in patients with abnormalities in ALAS2. The anaemia is mild to moderately severe. Three abnormalities of protein structure have been described, and these lie within 34 amino acids of one another at the C-terminal end of the transmembrane domain. The enzyme deficiency induces disruption in the maturation of cytosolic iron-sulphur clusters. The ataxia may be due to iron damage to mitochondria in neural cells.

Autosomal

Mitochondrial myopathy and sideroblastic anaemia

This results from a homozygous mutation in the nuclear-encoded gene for pseudouridine synthase. As in Pearson syndrome, there are defects of the mitochondrial electron transport chain affecting reduced access to ferrochelatase. It has been proposed that deficient pseudouridylation of mitochondrial tRNAs underlies this condition.

Abnormalities of a high-affinity transporter of thiamine

A gene (*SLC19A2*) encoding a putative thiamine transporter (THTR-1) that is widely and variably expressed has now been mapped to the long arm of chromosome 1 (1q23.3). Abnormalities in this gene are responsible for thiamine-responsive megaloblastic anaemia (Roger syndrome). This syndrome is inherited in an autosomal recessive manner and combines diabetes insipidus, diabetes mellitus, optic atrophy and deafness (DIDMOAD), which respond in varying degrees to pharmacological doses of thiamine (vitamin B₁). Ring sideroblasts in varying numbers are typically present and onset is usually in childhood, although some symptoms may be present in infancy. A direct link between the presence of the mutation and mitochondrial iron loading has yet to be demonstrated.

There are still a substantial number of cases of inherited sideroblastic anaemias in which the exact underlying genetic defect remains obscure. These cases may or may not show sex-linked inheritance and often show a macrocytic or dimorphic picture.

Mutations of glutaredoxin-5 (GLRX5)

This enzyme participates in iron-sulphur cluster formation. A single patient has been described with autosomal recessive hypochromic microcytic anaemia with ring sideroblasts with inherited mutations of the enzyme.

SLC25A38 mutations

This protein is a transporter that may be involved in glycine transfer to the mitochondria, an essential step in synthesis of ALA. Mutation in congenital sideroblastic anaemia is described.

Mitochondrial DNA mutations

Deletions of mitochondrial DNA, sometimes associated with duplications, are known to be the cause of the Pearson marrow-

pancreas syndrome, typically consisting of sideroblastic anaemia, pancreatic exocrine dysfunction and lactic acidosis. This is a severe disorder of early onset, presenting usually with failure to thrive, persistent diarrhoea and lactic acidosis. All haemopoietic cell lineages can be affected, and the anaemia is typically macrocytic with prominent vacuoles in cells of both myeloid and erythroid lineages.

Mitochondrial DNA has its own genetic code and encodes mitochondrial tRNA and ribosomal RNA as well as several mitochondrial proteins. In Pearson syndrome, deletions may encompass tRNA as well as mitochondrial genes and therefore have an effect on the function of all mitochondrion-encoded proteins, causing considerable loss of mitochondrial function. The presence of many different mitochondria within nucleated cells enable the coexistence of normal and abnormal species, the proportion of which is likely to vary within different tissues, a phenomenon known as *heteroplasmy*. The extent to which different tissues are affected depends to some extent on this proportion and detection often requires the study of different tissues. Inheritance is difficult to determine for the same reason and most cases are described as of 'sporadic' occurrence.

Acquired sideroblastic anaemias (see also Chapter 28)

Refractory anaemia with ring sideroblasts

This is a form of myelodysplasia and arises as a clonal disorder of haemopoiesis. The anaemia is often macrocytic with raised red cell protoporphyrin concentrations, in contrast to X-linked sideroblastic anaemia. Marked erythroid hyperplasia may be present, together with increased iron stores. In these patients, abnormalities in the white cell or platelet precursors are usually absent and the risk of transformation to acute myeloid leukaemia appears less than in other myelodysplastic disorders. Smaller numbers (<15%) of ring sideroblasts may be present in patients with any of the other myelodysplastic and myeloproliferative diseases. Recent data suggest that acquired defects of mitochondrial DNA may underlie iron transport abnormalities in refractory anaemia with ring sideroblasts.

Secondary sideroblastic anaemias

Sideroblastic anaemia associated with pyridoxine deficiency has been described, although not completely documented, in a few patients with gluten-induced enteropathy, in pregnancy, and with haemolytic anaemias, such as sickle cell disease and mechanical or autoimmune haemolytic anaemia. Sideroblastic anaemia may be found as a complication of antituberculous chemotherapy, particularly with isoniazid and cycloserine (pyridoxine antagonists). Sideroblastic anaemia occurs in alcoholism if there is associated malnutrition and folate deficiency. Suggested mechanisms include interference with haem formation and pyridoxine metabolism. The anaemia rapidly reverses with abstinence from alcohol, a normal diet and pyridoxine therapy. Chloramphenicol inhibits mitochondrial protein syn-

thesis and in some patients causes ring sideroblast formation, presumably as a result of impaired haem formation in the mitochondria. Lead inhibits several enzymes involved in haem synthesis and may damage structural mitochondrial proteins. In some cases, ring sideroblasts are visible in the marrow. Ring sideroblasts may occur in erythropoietic porphyrias (see p. 41).

Treatment

Pyridoxine

Some patients with X-linked sideroblastic anaemia respond to pyridoxine, given initially in doses of 100–200 mg daily. The response is usually partial. Patients may require only small doses (less than 10 mg daily) to maintain a higher haemoglobin concentration.

Pyridoxine therapy is almost always ineffective in refractory anaemia with ring sideroblasts. However, some secondary sideroblastic anaemias may be completely reversed by pyridoxine therapy. This has been described in alcoholism, haemolytic anaemia and gluten-induced enteropathy, as well as in patients receiving antituberculous chemotherapy, in whom the drugs have been stopped and pyridoxine administered.

Other forms of treatment

Folic acid may benefit patients with secondary anaemia. For refractory patients, the anaemia may remain stable and, if the patient is transfusion independent, no treatment is needed. Patients requiring regular red cell transfusions require iron chelation therapy. Iron loading may aggravate the anaemia and, in some patients, improvement in the anaemia has followed iron removal by phlebotomy or iron chelation therapy. Splenectomy should usually be avoided, as it does not benefit the anaemia and leads to persistently high platelet counts postoperatively, with a high incidence of thromboembolism.

Selected bibliography, 59**Introduction**

Excessive iron accumulation may eventually lead to tissue damage. Iron overload of the parenchymal cells of the liver commonly arises when there is excessive iron absorption, whereas iron administered parenterally (e.g. as multiple transfusions) is first taken up in senescent red cells by macrophages. However, there is no absolute distinction between the two sources of iron loading, as iron in macrophages is slowly released to transferrin, from which it can be taken up by parenchymal cells. Causes of iron overload are shown in Table 4.1. Severe iron overload, arbitrarily defined as an excess of more than 5 g, is confined to the genetic haemochromatoses, together with the iron-loading anaemias and sub-Saharan African dietary iron overload.

Genetic haemochromatosis**Classification**

Genetic haemochromatosis is now classified according to the genetic defect causing iron overload (Table 4.2). The vast majority of cases are of type 1, involving the *HFE* gene (see Chapter 3). In populations of northern European origin, about 90% of patients with haemochromatosis are homozygous for the *HFE* Cys282Tyr mutation (C282Y). In southern Europe, homozygosity for C282Y is found in only about 60% of patients

with haemochromatosis. Type 2, the severe juvenile haemochromatosis caused by mutations of the hemojuvelin or hepcidin genes, type 3, due to mutations of transferrin receptor 2, and type 4, due to mutations of ferroportin, are all very rare disorders reported mainly in European countries but also identified in some Asian patients with novel mutations. Types 1, 2 and 3 are autosomal recessive diseases and share common features due to hepcidin deficiency, including high transferrin saturation and hepatocyte iron accumulation. Type 4 haemochromatosis, inherited as a dominant condition, is a heterogeneous disease with variable clinical phenotype.

Type 1 haemochromatosis

This is one of the most common genetic conditions found in populations of northern European origin but it also occurs in African and Asian populations at very low gene frequency. In the UK, about one in eight people are carriers of the C282Y mutation of the *HFE* gene, and about 1 in 200 are homozygous for this mutation. Homozygosity is strongly associated with haemochromatosis, with about 90% of patients with genetic iron overload having this genotype. In homozygotes, there is a gradual accumulation of iron, leading to tissue damage, which may present as cirrhosis of the liver, diabetes, hypogonadism, cardiomyopathy, arthritis and a slate-grey skin pigmentation. Hepatocellular carcinoma develops in 25% of established cases with cirrhosis. Most patients present between the ages of 40 and 60 years, but the clinical penetrance is low (see p. 50). Full phenotypic expression of the disorder is dependent on other factors, including dietary iron intake, blood donations or blood loss and other genetic factors modifying the genotype. Menstrual losses and pregnancies account for a generally delayed onset in women.

Nature of the defect

A defect in the regulation of intestinal iron absorption leading to increased mucosal iron transfer to plasma is due to deficient hepcidin production. The responsible gene, *HFE*, is an atypical MHC class I-like gene that maps to the short arm of chromosome 6. The reported association with HLA-A3 and, to a lesser extent, B7 suggested a founder mutation in a chromosome carrying the A3, B7 haplotype. In over 80% of patients there is homozygosity for a G→A substitution at nucleotide 845 of the *HFE* gene that results in a cysteine to tyrosine substitution at

amino acid 282 (C282Y). A second variant (187C→G) results in a histidine to aspartic acid substitution at amino acid 63 (His63Asp or H63D). This is carried by about 20% of the general population. In the UK, about 90% of patients presenting with haemochromatosis are homozygous for *HFE* C282Y, and another 4% are compound heterozygotes for the two mutations. That *HFE* was the haemochromatosis gene was confirmed by the demonstration that *HFE* knockout mice and mice homozygous for the C282Y mutation develop iron overload.

Hepcidin synthesis requires expression of *HFE* and in mice lacking *HFE* or expressing the C282Y protein hepcidin is low or at least inappropriate to the degree of iron overload (see Chapter 3). In addition, tissue-specific inactivation of HFE protein in hepatocytes but not in duodenal cells or macrophages leads to iron overload, indicating a specific function of HFE in the liver. Hepcidin is a negative regulator of iron absorption by binding ferroportin and causing its internalization and lysosomal degradation. Lack of hepcidin upregulates ferroportin expression in duodenal mucosa, thus increasing mucosal iron transfer to transferrin and leaving the duodenal cells iron deficient. Hepcidin also controls iron release from macrophages. Low hepcidin explains the findings in the early stages of haemochromatosis: increased iron absorption, a raised serum iron and a paucity of iron in macrophages. Most recent data suggest that all types of haemochromatosis (except Type 4; Table 4.2) are characterized by low hepcidin secretion, the defect being the most severe in juvenile haemochromatosis. The more recent model of the pathophysiology of the disease suggests that HFE competes with diferric transferrin for TFR1 binding and that when diferric transferrin binds TFR1, HFE is free to bind TFR2, thus forming a complex that results in hepcidin synthesis (see Chapter 3). Lack of HFE on the hepatic cell plasma membrane in the case of C282Y homozygosity will lead to decreased hepcidin synthesis.

Table 4.1 Causes of iron overload.

Severe iron overload (>5 g excess)

Excess iron absorption

Hereditary haemochromatosis

Massive ineffective erythropoiesis (e.g. β-thalassaemia intermedia, sideroblastic anaemia, congenital dyserythropoietic anaemia)

Increased iron intake

Sub-Saharan dietary iron overload (in combination with a genetic determinant of increased absorption)

Excess parenteral iron therapy

Repeated red cell transfusions

Congenital anaemias (e.g. β-thalassaemia major, sickle cell anaemia, red cell aplasia)

Acquired refractory anaemias (e.g. myelodysplasia, aplastic anaemia)

Modest iron overload (<5 g excess)

Chronic liver disease (e.g. alcoholic cirrhosis)

Porphyria cutanea tarda

Rare genetic disorders of iron metabolism (e.g. atransferrinaemia, acaeruloplasminaemia, DMT1 mutations)

Focal iron overload*

Pulmonary haemorrhage, idiopathic pulmonary hemosiderosis

Chronic haemoglobinuria (e.g. paroxysmal nocturnal haemoglobinuria)

*May occur in association with general body iron deficiency.

***HFE* mutation frequencies worldwide**

HFE genotypes have been reported from large population studies throughout the world. In a study of 100 000 multiethnic participants from primary care practices, the estimated prevalence of the C282Y homozygous genotype was higher in white

Table 4.2 Classification of genetic haemochromatosis.

Type	Gene	Inheritance and phenotype	Severity	Incidence
1	<i>HFE</i>	AR, parenchymal iron overload	Highly variable	Common
2 (juvenile)	Hemojuvelin (<i>HFE2</i>)	AR, parenchymal iron overload	Severe	Rare
	Hepcidin (<i>HAMP</i>)	AR, parenchymal iron overload	Severe	Rare
3	<i>TFR2</i>	AR, parenchymal iron overload	Variable	Rare
4	Ferroportin 1 (<i>SLC11A3</i>)	AD, RE iron or parenchymal iron	Variable	Rare

AD, autosomal dominant; AR, autosomal recessive; RE, reticuloendothelial.

For gene symbols see Table 3.1.

(1 in 227, 0.44%) than in black or Asian people, in whom it was extremely rare. The frequency is higher in northern Europe and lower in southern Italy and Greece. The H63D mutation is found throughout the world but is most common in Europe, where allele frequencies vary from 10 to 20%, with a mean of 15%. Other *HFE* gene mutations associated with iron accumulation have been described mostly in individual families.

***HFE* mutations and iron status**

The haemochromatosis gene may have increased in frequency because of a selective advantage for heterozygotes, namely protection against iron deficiency anaemia. Homozygotes would be unlikely to suffer the effects of iron overload before reproducing. Transferrin saturation and serum ferritin are significantly higher in C282Y/C282Y subjects than in other genotypes. Increased levels of iron parameters are present in 75–100% of males and 40–60% of females in different studies. In population surveys slight but significantly higher values for serum iron and transferrin saturation have been found in heterozygotes for either C282Y or H63D compared with subjects lacking these mutations. The differences in ferritin levels are smaller and not significant. In compound heterozygotes, and those homozygous for H63D, there are larger increases in transferrin saturation and serum ferritin, although significant iron accumulation is rare. In heterozygotes for C282Y or H63D, haemoglobin levels are slightly higher than in subjects lacking these mutations, but it has not been clearly demonstrated that this leads to a lower prevalence of anaemia among women carrying either mutation.

***HFE* mutations and morbidity**

Although advanced haemochromatosis is characterized by diabetes, arthritis and cirrhosis, there is no evidence that possession of *HFE* mutations is a risk factor for these conditions except through iron overload. The frequency of homozygosity or heterozygosity for C282Y or H63D mutations is not generally increased in patients with arthritis, diabetes and heart disease. Homozygosity for C282Y is more frequent in patients with cirrhosis and hepatoma than in the general population. Alcohol is a definite risk factor for the development of cirrhosis in patients homozygous for C282Y. The significance of other genetic modifiers remains uncertain.

Diagnosis: clinical

The variety of clinical presentations and their lack of specificity for haemochromatosis means that a high degree of clinical suspicion is needed. Fatigue, diabetes mellitus, signs and symptoms of gonadal failure and arthritis may be present for several years before the diagnosis is made. Arthritis particularly affects the second and third metacarpophalangeal joints (Figure 4.1), and destructive arthropathy of hip and knee joints occurs in 10% of patients. There is chondrocalcinosis with pyrophosphate deposition in the joints. Abdominal pain may result from

Figure 4.1 Radiograph of hand: patient with haemochromatosis showing loss of joint space and erosion of cartilage at the metacarpophalangeal joints.

hepatic enlargement or hepatocellular carcinoma. Grey skin pigmentation results from excess melanin deposition.

Diagnosis: iron status

Transferrin saturation and serum ferritin

In asymptomatic subjects, iron accumulation is indicated by a raised transferrin saturation (> 45%). Most men and about 50% of women who are homozygous for *HFE* C282Y will have a raised transferrin saturation. As iron accumulates, the serum ferritin concentration rises, and values in excess of 200 µg/L (women) and 300 µg/L (men) suggest iron overload. Serum ferritin concentrations largely reflect iron turnover in phagocytic cells and do not provide an early indication of iron accumulation in liver parenchymal cells. Thus, measurement of transferrin saturation is essential for early detection of iron loading. However, in patients with infection, inflammation or malignancy or in those undergoing surgery, transferrin

saturation may be depressed and the serum ferritin concentration elevated. In most cases, *HFE* genotyping will confirm the diagnosis of haemochromatosis.

Liver biopsy

Since the advent of genetic testing, confirmation of iron overload by liver biopsy is not usually performed and is not necessary in the absence of liver damage. In patients homozygous for C282Y with evidence of liver disease and serum ferritin concentration above 1000 µg/L, liver biopsy is essential to assess tissue damage. In patients with an unexplained raised transferrin saturation and serum ferritin, who are not homozygous for C282Y, a liver biopsy may be required to confirm iron overload and to address the subsequent diagnostic process (Figure 4.2). The availability of non-invasive measurement of liver iron concentration has restricted the diagnostic use of liver biopsy.

(a)

(b)

Figure 4.2 Liver histology (Perls stain). (a) Liver biopsy from a patient with type 1 haemochromatosis, showing staining predominantly in parenchymal cells. (b) Liver biopsy from a patient with type 4 haemochromatosis, showing iron staining predominantly in Kupffer cells.

Liver iron concentration can be measured on a dried fragment of liver biopsy. Values in excess of 80 µmol/g dry weight (4.5 mg/g dry weight) indicate iron overload. Since in haemochromatosis there is a progressive increase in liver iron concentration with age in some cases, it is useful to express the result as the 'hepatic iron index' (µmol iron/g dry weight divided by age in years).

Non-invasive methods

Techniques using magnetic resonance imaging (MRI) are being increasingly used as an indirect non-invasive measure of both liver and heart iron (see p. 55). They require special analytical skill. Although most experience is with secondary iron overload, MRI is also increasingly used in genetic haemochromatosis.

The superconducting quantum interface device (SQUID) biosusceptometry technique is sensitive, accurate and reproducible. It depends on the paramagnetic properties of haemosiderin and ferritin. Unlike MRI, it does not distinguish parenchymal from reticuloendothelial iron, but the result closely correlates with chemical estimation of liver iron, except when fibrosis is present. Machines are expensive to build and run and at present there are only four worldwide (none in the UK).

Mobilization of iron by phlebotomy to calculate iron stores

The amount of iron removed to reach iron depletion can be calculated (see Treatment) and provides a good estimate of total body iron. Since the advent of genetic testing, confirmation of iron overload by liver biopsy is not necessary in the absence of liver damage and quantitative phlebotomy provides the only practical way of confirming the presence of iron overload. The amount of iron removed at each venesection is calculated by weighing the blood bag before and after venesection (density of blood is 1.05 g/mL) and assuming that 450 mL of blood (haemoglobin concentration 13.5 g/dL) contains 200 mg of iron. Iron absorption should be allowed for at the rate of 3 mg daily (20 mg/week). With these assumptions, 25 weekly venesections will remove 4.5 g of iron. The amount of storage iron measured by the technique in normal adults has been shown to be about 750 mg in men and 250 mg in women.

Clinical penetrance

Before the discovery of the *HFE* gene, it was assumed that every family member who was homozygous for haemochromatosis would eventually accumulate sufficient iron to cause tissue damage. Recent studies, in which subjects homozygous for *HFE* C282Y have been compared with 'wild-type' subjects, have shown that the frequencies of lethargy, arthralgia and diabetes are the same. There is, however, a small but significant increase in the percentage of subjects with either raised serum transaminase activity or fibrosis/cirrhosis in the C282Y homozygous

group in several studies. Population surveys have shown that less than 5% of subjects homozygous for C282Y ever receive a diagnosis of haemochromatosis. Despite much debate about ascertainment bias in family and population surveys, it is becoming clear that most men who are homozygous for C282Y will have a raised transferrin saturation before the age of 30 years; a proportion will have an elevated serum ferritin concentration, but only a minority will eventually develop fibrosis and cirrhosis of the liver. Studies in Australia and Norway found that 5% of homozygote males but no females showed cirrhosis. There is evidence that ferritin concentration above 1000 µg/L is a risk factor for liver fibrosis in different studies. These patients should undergo liver biopsy and complete cardiac and endocrinological evaluation. Only about 50% of homozygous women have a raised transferrin saturation, and progression through iron accumulation and tissue damage is usually, but not always, slower. In one population study in the USA, based on reported clinical complications, the clinical penetrance was estimated to be as low as 1%. In a more recent study, which evaluated for 12 years a cohort of C282Y homozygous patients of middle age (40–69 years) using strict criteria to define liver disease, this clinical complication was estimated to be present in about 30% of males and 1% of females. However, the iron accumulation rate of C282Y patients is not constant and may vary greatly from patient to patient. Many homozygotes followed for 10 years or more have shown no change in serum ferritin.

Family testing

Physicians should discuss with the patient the desirability of testing all first-degree relatives over the age of consent in order to identify those at risk. Transferrin saturation and serum ferritin concentration should be measured along with *HFE* genotyping. Genetic testing may identify other family members homozygous for *HFE* C282Y. If the serum ferritin concentration is normal and there is no evidence of liver disease, transferrin saturation and serum ferritin should be measured at yearly intervals and treatment instituted if necessary. Compound heterozygotes are at lesser risk of iron overload but should also be tested by measuring transferrin saturation and serum ferritin, perhaps at 3-yearly intervals. Iron status should be determined in heterozygotes and, if normal, reassessed after 5 years to ensure that no other iron-loading genes are present.

Associations with other conditions

The *HFE* C282Y mutation is relatively common; heterozygosity, and even homozygosity, may occur with other haematological conditions, including inherited sideroblastic anaemia. The occasional presence of iron overload in patients with haematological disorders such as congenital spherocytosis, in whom it is otherwise uncommon, may be due to a combined effect on iron absorption of increased erythropoiesis and coincidental inheritance of the heterozygous state for haemochromatosis.

Porphyria cutanea tarda, which may be associated with iron overload, an important trigger of disease manifestations, is discussed in Chapter 3.

Population screening

Widespread population screening by iron status or genetic testing is considered unwarranted as the level of risk for a C282Y homozygote developing iron overload appears to be low. Once the factors that convey a high risk of developing significant iron overload and tissue damage have been identified, it may be appropriate to reconsider this question but at present screening should be limited to at-risk populations.

Treatment

Removal of excess iron by regular phlebotomy greatly reduces the mortality from cardiac and hepatic failure, although hepatocellular carcinoma accounts for a substantial proportion of deaths in those with established disease. Early diagnosis is therefore a priority, as patients identified and treated before the onset of cirrhosis of the liver have a normal life expectancy.

Since no test is available to identify those patients who will progress to fibrosis and those who will not, the present recommendation is to phlebotomize all patients with evidence of iron overload. Phlebotomy should be at a rate of 450 mL of blood each week and should be performed until iron depletion is reached (serum ferritin <20 µg/L and transferrin saturation <16%). Haemoglobin levels should be measured weekly and the rate of venesection reduced if anaemia develops. Serum ferritin should be monitored monthly. The transferrin saturation should be measured weekly when the ferritin concentration drops below 50 µg/L.

Weekly phlebotomy will need to be continued for at least 6 months to remove total iron excess, which is usually greater than 5 g in established symptomatic disease but may be more than 20 g. When iron stores are exhausted, the frequency of phlebotomy should be reduced to two to four units each year, to continue indefinitely. The aim is to maintain a normal transferrin saturation (<50%) and a serum ferritin in the low-normal range (<50 µg/L). Fatigue and transaminase elevation usually reverse on venesection. In some patients, diabetes mellitus, hypogonadism and arthralgia improve, but cirrhosis and arthritis are not reversible. Early cardiac disease may respond to phlebotomy but severe cardiomyopathy does not and requires iron chelation.

Iron chelation with subcutaneous desferrioxamine (DFX) may be used in patients who do not tolerate phlebotomy or have concomitant anaemia. DFX given as a continuous intravenous infusion with or without an oral iron chelator (see below) may have a role in the short-term management of patients with life-threatening cardiac failure. Well-tolerated oral iron chelators are likely to become an option for treatment of selected patients in the future.

Type 2 (juvenile) haemochromatosis

Juvenile haemochromatosis is a rare autosomal recessive disease, with clinical symptoms related to iron overload appearing in the second and third decades of life. The disease is genetically heterogeneous since it can be due either to hemojuvelin mutations or, more rarely, to mutations in the hepcidin (*HAMP*) gene (see Chapter 3). More than 30 hemojuvelin mutations have been reported in European and Asian families with G320V being the most frequent. The age of onset has been as low as 5 years but the disease usually presents in teenagers or those in their early twenties. Hemojuvelin modulates hepcidin expression by acting as a coreceptor of bone morphogenetic proteins (see Chapter 3). Inactivation of hemojuvelin strongly decreases hepcidin production. This explains why the clinical phenotypes of *HAMP* or hemojuvelin (*HFE2*) mutations are indistinguishable. In both cases iron absorption is greater than in type 1 haemochromatosis and iron deposition occurs not only in the hepatocytes but also in cardiac myocytes, pancreas and pituitary; liver disease is present but symptoms related to cardiomyopathy, diabetes and hypogonadism are more prominent.

Digenic disease has been rarely described in patients with severe disease expression who are heterozygous for *HFE* C282Y and have a mutation in the *HAMP* (hepcidin) gene.

Type 3 haemochromatosis

Haemochromatosis type 3 is a rare autosomal recessive disease reported in those of European and Asian ancestry. It is phenotypically similar to type 1 haemochromatosis, although it may have an earlier age of onset. It is due to mutations in the gene for transferrin receptor 2 (*TFR2*) (see Table 4.2). *TFR2* shows moderate homology to *TFR1*, may bind transferrin but is not iron regulated. Hepcidin levels are very low in type 3 haemochromatosis, disproportionate to the degree of iron overload (see Table 3.1). *TFR2* binds *HFE* when transferrin saturation is high and this complex activates hepcidin (see Chapter 3). Thus mutations of either *HFE* or *TFR2* cause a similar disorder.

Type 4 haemochromatosis (ferroportin disease)

Haemochromatosis type 4 has peculiar genetic and clinical features compared with the other forms. First, it is inherited as an autosomal dominant trait. Second, all patients have increased serum ferritin levels, but some have a normal transferrin saturation. Third, at liver biopsy iron is usually increased in the reticuloendothelial cells, as well as in hepatocytes, features that suggest a different pathophysiology of the disease. Haemochromatosis type 4 is due to heterozygous missense mutations in the gene for the iron exporter ferroportin, located

on chromosome 2q32. In the typical form (type 4a), so-called ferroportin disease, the phenotype differs from haemochromatosis and is similar to that found in the anaemia of chronic disease (see Figure 4.2b), with iron accumulation predominantly in the macrophages and normal or low transferrin saturation. These cases are due to loss-of-function ferroportins that are unable to target correctly to the cell surface and so export iron from macrophages. It seems that reticuloendothelial iron is less toxic than parenchymal iron. For this reason and because some of these patients develop mild anaemia, tolerance to phlebotomy should be carefully monitored and intensive regimens are not indicated. In the rare type 4b with mutations occurring in the binding site of ferroportin for hepcidin, mutant ferroportins reach the cell surface but are resistant to the effect of hepcidin, causing increased iron export to plasma, saturation of transferrin and iron deposition in hepatocytes similar to *HFE* haemochromatosis.

In people of African origin, the Gln248His mutation in ferroportin is a common variant that may be associated with a tendency to iron loading and mild anaemia.

Neonatal haemochromatosis

This is a condition that is recognized at birth but may occur *in utero*. It is characterized by heavy parenchymal iron deposition in several organs and irreversible liver failure. The only therapeutic option used to be liver transplantation. No mutations in the known haemochromatosis genes have been reported and a genetic cause has been more recently doubted in favour of an immunological pathogenesis, but heterogeneous causes cannot be ruled out. Neonatal haemochromatosis has been linked in some cases to the presence of a maternal factor, for example an antiribonuclear factor antibody. Infusions of gammaglobulin in pregnancy appear to reduce the severity of the condition and it has been proposed that the disease is due to an alloantibody (as rhesus incompatibility) but the target antigen is unknown.

Increased iron intake

African iron overload (Bantu siderosis) results from the combination of a dietary component (a traditional beer that contains iron) and an unknown susceptibility gene. Mutations in the *HFE* gene have been excluded but mutations of the ferroportin gene may play a role (see above). Iron deposition, as in type 4 haemochromatosis, occurs in both hepatocytes and reticuloendothelial cells. Serum ferritin is usually elevated, but transferrin saturation may be normal. The condition occurs in sub-Saharan Africa. It is a cause of hepatic fibrosis and cirrhosis, and associations with diabetes mellitus, peritonitis, scurvy and osteoporosis have been described. The iron overload is associated with a poor outcome of tuberculosis, an infection that is highly prevalent in sub-Saharan Africa.

Other causes of iron overload

Atransferrinaemia

This is a rare recessive genetic disorder associated with a severe hypochromic anaemia with, in some cases, excessive deposition of non-transferrin-bound iron (NTBI) in the parenchymal cells. In all cases tested, some iron-transferrin has been detected by iron-binding ability or immunologically defining a type of hypotransferrinaemia. Complete absence of transferrin would presumably lead to fetal death.

Iron and neurodegeneration

Acaeruloplasminaemia

This is also a rare recessive disorder in which there is a deficiency of ferroxidase activity as a consequence of mutations in the caeruloplasmin gene. Clinically, the condition presents in middle age, with progressive degeneration of the retina and basal ganglia and with diabetes mellitus. Iron accumulates in the liver, pancreas and brain with smaller amounts in the heart, kidneys, thyroid, spleen and retina. The serum iron is low and mild anaemia may be present. The total iron-binding capacity of transferrin (TIBC) is normal and ferritin is normal or raised. Unfortunately, no effective treatment is available to reduce neurodegeneration but deferiprone, which penetrates the blood–brain barrier, may be an option.

Hallervorden–Spatz syndrome

This is an autosomal recessive neurodegenerative disorder associated with iron accumulation in the brain. Clinical features include extrapyramidal dysfunction, onset in childhood and a relentlessly progressive course. Histological study reveals iron deposits in the basal ganglia. Hallervorden–Spatz syndrome is caused by a defect in a novel pantothenate kinase gene that causes accumulation of cysteine. Iron binding by cysteine may cause iron accumulation and oxidative stress, which is a likely explanation for the pathophysiology of the disease.

Neuroferritinopathy

A rare, dominantly inherited, late-onset basal ganglia disease that variably presents with extrapyramidal features similar to those of Huntington disease or parkinsonism also shows iron accumulation in the forebrain and cerebellum. The responsible gene (*FTL*) codes for ferritin light-chain polypeptide. An adenine insertion at position 460–461 was found that was predicted to alter carboxy-terminal residues of the gene product. Abnormal aggregates of ferritin and iron in the brain contrasted with low serum ferritin levels.

These diseases may serve as a model for complex neurodegenerative diseases such as Parkinson disease, Alzheimer disease and Huntington disease, in which accumulation of iron in the brain is also observed. Possession of the C282Y mutation of the *HFE* gene does not appear to be a risk factor for these conditions.

Friedreich ataxia

This is a neurodegenerative disease characterized by loss of sensory neurones in the spinal cord and dorsal root ganglia. There is mitochondrial iron overload and loss of activity of iron–sulphur cluster-containing enzymes. Patients frequently die from cardiomyopathy. The majority of cases of Friedreich ataxia result from the expansion of triple nucleotide repeats within an intron of the *FXN* gene, leading to reduced expression of frataxin mRNA and protein. Point mutations have also been identified in a small number of cases. Frataxin is found in the mitochondria where, in Friedreich ataxia, there is increased oxidative stress and decreased activity of iron–sulphur proteins. Oxidative damage following iron accumulation is thought to precipitate the neurone loss. This is confirmed by experiments in yeast that show that iron is redistributed to the mitochondria of Yfh (yeast frataxin homologue)-deficient yeast and that this iron accumulation precedes oxidative damage. Frataxin shows structural similarity to ferritin, suggesting that frataxin may regulate mitochondrial iron homeostasis by storing excess iron. A preliminary trial of deferiprone therapy has shown some improvement in neuropathy and gait in the youngest patients and larger-scale trials are now in progress.

Hereditary hyperferritinaemia–cataract syndrome

This syndrome is characterized by elevated serum ferritin levels, early-onset bilateral cataracts and normal or low serum iron and transferrin saturation. It is usually due to heterozygous point mutations in the L-ferritin iron-response element so that a monoclonal ferritin is synthesized due to impaired negative feedback of ferritin synthesis. There is no general tissue iron overload and serum transferrin saturation is normal, but ferritin accumulates in the lens causing cataracts. In a few cases, the mutation is in the coding regions of the gene.

Iron-loading anaemias

Removal of iron is essential in patients with transfusion-dependent anaemias, such as thalassaemia major, to prevent death from iron overload, usually caused by cardiac failure or arrhythmia. Red blood cell requirements are about 160 mL/kg annually in non-splenectomized and 120 mL/kg annually in splenectomized patients with thalassaemia major. The iron content of each transfusion is determined by volume (mL) \times haematocrit \times 1.16 mg. Intake of iron ranges from 0.32 to 0.64 mg/kg body weight daily. Patients with anaemias associated with increased iron absorption (e.g. thalassaemia intermedia), who are too anaemic to be venesectioned to remove iron, may also require iron chelation therapy, although the rate of iron loading is considerably lower at about 0.1 mg/kg daily. The iron-chelating drug widely available is desferrioxamine (DFX).

Table 4.3 Characteristics of desferrioxamine, deferiprone and deferasirox.

	<i>Desferrioxamine</i>	<i>Deferiprone</i>	<i>Deferasirox</i>
Structure	Hexadentate	Bidentate	Tridentate
Molecular weight	560	139	373
Iron–chelator complex	1 : 1	1 : 3	1 : 2
Plasma clearance ($t_{1/2}$)	20 min	53–166 min	1–16 hours
Absorption	Negligible	Peak 45 min	Peak 1–2.9 hours
Iron excretion	Urine + faecal	Urine	Faecal
Therapeutic daily dose	40 mg/kg	75–100 mg/kg	20–30 mg/kg
Route	Parenteral	Oral	Oral
Clinical experience	>40 years	>20 years	>8 years
Side-effects	Ototoxicity, retinal toxicity, growth defects, cartilage and bone abnormalities	Agranulocytosis, arthropathy, gastrointestinal disturbance, transient transaminitis, zinc deficiency	Skin rashes, gastrointestinal disturbance, rising serum creatinine

This is orally inactive and given by slow subcutaneous or intravenous infusion. Deferiprone, an orally active iron chelator first used clinically in 1987, is now licensed in 61 countries. A third drug, deferasirox, is orally active and was introduced into clinical practice in 2002 and is now widely prescribed (Table 4.3 and see Figure 4.5).

Iron chelation therapy is monitored by:

- 1 tests of body iron burden;
- 2 tests of function of the organs sensitive to iron overload (Table 4.4);
- 3 tests to detect potential side-effects of the particular chelating drug being used.

Tests (1) and (2) are discussed first. The results and side-effects with the individual iron-chelating drugs are then described.

Tests of body iron burden

Serum ferritin

Serum ferritin is useful in monitoring changes in body iron, although the absolute level is an imprecise measure of total body iron. There is a wide range of liver iron at any given serum ferritin level. This is partly because serum ferritin mainly reflects reticuloendothelial iron and partly because inflammation, (e.g. hepatitis C infection) raises the level, whereas vitamin C deficiency, frequent in iron overload, lowers it. The Thalassaemia International Federation (TIF) guidelines recommend maintaining the level below 1000 µg/L in thalassaemia major.

Liver iron

Liver iron may be measured chemically after liver biopsy, by MRI or, in a few specialized units, by SQUID (see p. 50). Chemical estimation is the gold standard but can be inaccurate

Table 4.4 Monitoring for iron-induced organ damage.

<i>Cardiac function</i>

if fibrosis is present. Levels greater than 15 mg/g dry weight have been associated in DFX-treated patients with a high risk of cardiac disease, liver fibrosis and cirrhosis. Levels between 7 and 15 mg/g dry weight are associated with liver damage only if

Figure 4.3 Magnetic resonance imaging T2* technique. Tissue appearances of liver and spleen: (a) normal; (b) tissue iron overload; (c) severe liver iron overload with normal cardiac iron;

(d) severe cardiac iron deposition with minimal liver iron deposition. (From Anderson *et al.* 2001 with permission.)

there is also hepatitis C infection and have been considered indicative of relative safety from cardiac disease but are associated with damage to the endocrine organs. Levels less than 7 mg/g dry weight are found in carriers of haemochromatosis and are considered safe.

MRI techniques are being increasingly used as indirect measures of liver and cardiac iron (Figure 4.3). They have the advantage of being non-invasive and are more widely available than SQUID (which is suitable for liver but not cardiac iron). MRI is also the only practical method of performing sequential studies of iron in the heart, pituitary or other endocrine organs. Different MRI techniques have been used. They all rely on a shortening of relaxation time and thus reduction in signal intensity with iron overload. Gradient-echo imaging with the calculation of the T2* has a short total imaging time, reducing movement artefacts. It is also extremely sensitive and reproducible. The spin-echo technique is less sensitive to iron and requires longer imaging time, making it less valuable for testing cardiac iron.

Cardiac iron

As cardiac failure or arrhythmia is the usual cause of death in transfusional iron overload, it is essential to monitor cardiac iron. Iron is deposited in myocytes and interstitial fibrosis develops. Direct measurement of cardiac iron by endomyocardial biopsy is inappropriate as the technique is highly invasive and inaccurate as iron localizes mainly in the ventricular myocardium and epicardium. T2* cardiovascular magnetic resonance offers a reproducible (around 5% coefficient of variation between different observers or between two studies of the same patient), sensitive, albeit indirect measure: the lower the T2* value, the greater the cardiac iron (Figure 4.3). The majority of patients with T2* greater than 20 ms have normal left ventricular function. A T2* below 20 ms correlates with the presence of cardiac dysfunction detected by echocardiography (left and right ventricles) or by 24-hour rhythm monitoring or the need for cardiac therapy (Figure 4.4). The great majority of patients

Figure 4.4 Relationships of myocardial T2* and left ventricular ejection fraction in patients with thalassaemia major and iron overload. (From Anderson *et al.* 2001 with permission.)

who develop cardiac failure have T2* less than 10 ms. Poor correlation has been found between myocardial iron and liver iron (MRI derived) or serum ferritin in patients receiving DFX, so serum ferritin and liver iron cannot be used as surrogate measures of cardiac iron.

Urine iron excretion

Iron excretion after a single infusion of a standard dose of DFX or oral dose of deferiprone is related to body iron. Urine iron is derived from the labile iron pool chelated mainly extracellularly with DFX and probably intracellularly with deferiprone. With DFX (but not deferiprone) urine iron excretion is increased by ascorbate and is proportionately higher if the haemoglobin is lower. The test is useful when commencing therapy with DFX or deferiprone, with which iron excretion is highly dose related, and for monitoring therapy, in some studies correlating closely with liver and cardiac iron. However, several estimations must be performed at any given dose in view of the variability found.

Non-transferrin-bound iron

This is present in plasma in patients with gross iron overload and 100% saturation of transferrin. It is highly toxic, promoting the formation of free radicals that cause peroxidation of membrane lipids. Part of the early improvement in liver and cardiac function with chelation therapy may be due to removal of this fraction, even before iron burden is substantially lowered. Its clearance by DFX is short-lived as it reappears in plasma within hours of stopping an infusion. Deferasirox, with its long clearance time, provides 24-hour removal of NTBI after a single oral dose. Deferiprone removes NTBI for about 6 hours after a single dose. NTBI is absent from plasma of well-chelated patients.

Tests of organ function

The tests that are usually needed are listed in Table 4.4. Heart function is best tested by measurement of left ventricular ejection fraction and by tests for rhythm disturbance. Liver function assessment requires routine liver function tests as well as liver biopsy to assess liver structure and liver iron burden (histologically and chemically). The endocrine system is also damaged by iron and appropriate tests are listed in Table 4.4. The anterior pituitary is particularly sensitive, with damage resulting in reduced growth and impaired sexual maturation. Direct damage to the ovaries or testes may also occur but is usually less important. Hypogonadic hypogonadism, defects of growth hormone secretion and in its receptor, and deficiency of insulin-like growth factor mainly account for growth failure; DFX may also cause this. Diabetes mellitus and pre-diabetes, due to iron deposition in the pancreatic islets, are frequent, especially in patients with genetic susceptibility. Hypothyroidism and hypoparathyroidism are also common in poorly chelated patients. Osteoporosis is well recognized in iron-overloaded thalassaemia patients; it is due to multiple factors and is detected by bone density studies.

Iron chelation therapy

Desferrioxamine

Pharmacokinetics

Desferrioxamine mesylate is licensed in all countries. It is not absorbed orally, and after parenteral injection is rapidly cleared from the plasma, being excreted in the urine, taken up by hepatocytes or metabolized in the tissues (Table 4.3). This accounts for the much greater mobilization of iron by continuous intravenous or slow subcutaneous infusions, which allow more prolonged exposure of the drug to the chelatable iron than with intramuscular injection.

DFX is a trihydroxamic acid (hexadenate) (Figure 4.5), one molecule binding covalently to all six oxygen sites on one ferric ion to form the red chelate, ferrioxamine. This is excreted in

Figure 4.5 Chemical structures of three iron chelators: (a) deferasirox; (b) deferiprone; (c) desferrioxamine.

urine and bile. Faecal iron is derived from hepatocytes. Urine iron also derives, at least partly, from hepatocytes, although other body sources, especially iron released from macrophages, contribute. Urinary iron excretion tends to level off at higher doses, but this does not occur with bile excretion so bile iron may therefore predominate at high doses, and this is also the major route of excretion when total body iron has been reduced to relatively low levels. Increased erythropoiesis, as in haemolytic anaemias, is associated with an increase in urine iron excretion in relation to body iron stores.

Clinical studies

Most studies have involved thalassaemia major, but patients with other inherited anaemias (e.g. Diamond–Blackfan syndrome, Fanconi anaemia, sickle cell anaemia, sideroblastic anaemia) or acquired disorders, especially myelodysplasia, myelofibrosis, red cell aplasia or aplastic anaemia, may require iron chelation therapy. In these conditions, as well as in elderly patients with acquired, transfusion-dependent, refractory anaemias and otherwise good prognosis, deferasirox is widely used if iron overload is likely to cause significant morbidity or mortality. In children, tissue damage from iron may be present from very early life; regular iron chelation should begin in thalassaemia major after transfusion of about 12 units of blood or when serum ferritin exceeds 1000 µg/L. In young children, treatment with DFX should be started at 20 mg/kg to prevent tissue damage due to iron without causing toxicity due to excess DFX. A local anaesthetic cream (e.g. EMLA) reduces pain from the needle insertion. Oral chelation may be preferred to DFX.

The standard adult dose of DFX is 40 mg/kg s.c., given as an 8–12 hour infusion on at least 5 days each week.

Repletion of ascorbic acid deficiency, which sometimes accompanies iron overload, or ascorbate therapy even in those with normal tissue levels of ascorbate, increases urinary iron excretion with DFX. Vitamin C supplements should be given at a dose of 100–200 mg per day.

For those with iron-induced cardiomyopathy, continuous intravenous DFX may be given via an indwelling catheter (e.g. Hickman) or Port-a-Cath chamber. Removal of liver iron is more rapid than removal of cardiac iron with this intensive chelation regimen. Combined therapy with deferiprone may also be used. Studies with deferiasirox are in progress.

Body iron stores can be restricted to 5–10 times normal in well-chelated, regularly transfused patients. There is improved cardiac function and survival in patients who comply with DFX therapy. Growth and pubertal development are improved in many, but not all, patients; diabetes and other endocrine abnormalities still occur frequently. Serum ferritin levels in well-chelated with DFX thalassaemia major patients usually plateau between 1500 and 2500 µg/L. Unfortunately, through lack of compliance with DFX, premature deaths usually from iron-induced cardiac damage may occur in a proportion of thalassaemia major patients. Combination therapy or orally active drugs alone should be used in these patients.

Side-effects

These include rare generalized sensitivity reactions, local soreness related to the site of injection (usually due to the needle being inserted too superficially) and exacerbation of some infections, notably of the urinary tract and precipitation of *Yersinia* enterocolitis. Auditory (high-tone sensorineural hearing loss) and visual neurotoxicity (night blindness, visual field loss, retinal pigmentation and changes on electrical tests) are relatively frequent. Growth and bone defects may also occur. The spine may be affected, with sitting height reduced; rickets-like bone lesions, genu valgum and metaphyseal changes are described, especially in children (Figure 4.6).

Auditory, visual and growth side-effects of DFX occur mainly if the body iron burden is low and doses of DFX high, particularly in children. A therapeutic index can be calculated as follows: mean daily dose (mg/kg)/current serum ferritin (µg/L). If this is below 0.025 at all times, these side-effects of DFX do not occur.

Deferiprone

Pharmacokinetics

Deferiprone (1,2-dimethyl-3-hydroxypyrid-4-one) is rapidly absorbed, appearing in plasma within 15 min of ingestion (see Table 4.3). The chelator–iron complex is excreted with the free drug and glucuronide derivative in urine. Its iron chelation site

Figure 4.6 Bone and cartilage defects due to desferrioxamine.

is inactivated by glucuronidation, the speed of which varies from patient to patient. This explains much of the individual variation in response. It is available both as tablets (500 mg) and as a liquid formulation containing 100 mg/mL.

Deferiprone mobilizes iron from parenchymal and reticuloendothelial pools and from transferrin, ferritin and haemosiderin. The enhanced ability of deferiprone to cross cell membranes may underlie its superior ability compared with DFX to protect the heart from iron and also the ‘shuttle’ effect for iron when the two drugs are given simultaneously (see p. 59 and Figure 4.7). Deferiprone crosses the blood–brain barrier to treat neurological conditions with iron loading in the brain. Few balance studies have been performed. These suggest that, on average, deferiprone 75 mg/kg is about as effective as DFX 40 mg/kg. Wide individual variations occur, especially with deferiprone. Moreover, it is easier for patients to comply with deferiprone than DFX on all 7 days each week.

Clinical studies

The usual dose used has been 75–100 mg/kg daily. Serum ferritin levels tend to plateau around 2000–2500 µg/L. MRI studies suggest that liver iron may generally be higher in patients treated with deferiprone (75 mg/kg 7 days per week) compared with those treated with DFX (40 mg/kg 5 days per week). In the liver, DFX has the advantage of facilitated transport into cells by an active mechanism. Deferiprone, on the other hand, may have greater penetration of myocardial cells because of its lower molecular weight and because it is lipophilic. Retrospective and prospective studies have shown, on the basis of T2* MRI measurement of cardiac iron, echocardiography, clinical incidence of cardiac disease, need for cardiac therapy and survival, that

Figure 4.7 The concept of combination therapy: DFO, desferrioxamine; DFP, deferiprone; NTBI, non-transferrin-bound iron.

deferiprone 75 mg/kg is more effective than DFX at protecting the heart from iron-induced cardiomyopathy in routine clinical practice.

Side-effects

The most severe is agranulocytosis (neutrophils $< 0.5 \times 10^9/L$ on two consecutive counts), with an estimated incidence of around 0.5–1.0% (0.2–0.3 episodes per 100 patient-years). It is most frequent in the first year of therapy. Lesser degrees of neutropenia ($0.5\text{--}1.5 \times 10^9/L$) are more frequent, around 3.5–8.5%, occurring more frequently in non-splenectomized patients. Agranulocytosis and neutropenia spontaneously recover when the drug is discontinued, usually within 4–28 days (median duration 9 days) but occasionally are more prolonged. Granulocyte colony-stimulating factor produces a faster recovery. The mechanism appears to be idiosyncratic, more common in females, with no definite evidence of an immune mechanism established. Patients should be monitored by blood counts every week for at least the first 8–12 weeks of therapy and every 2 weeks thereafter for 2 years. Agranulocytosis may be more frequent in patients with stem cell or progenitor cell defects, for example aplastic anaemia, Diamond–Blackfan syndrome or myelodysplasia. Deferasirox may be safer for these conditions.

Painful joints, especially the knees, occur in around 5–10% in most large series. The incidence has been highest in Indian patients. Some but not all studies show that this complication is most frequent in the most iron-loaded patients and with higher doses of deferiprone. It usually, but not invariably, resolves with withdrawal of the drug and it is often possible to reintroduce the drug, commencing with lower doses. About 2.0% of patients permanently discontinue therapy because of joint symptoms.

Gastrointestinal side-effects (e.g. nausea and abdominal pain) occur in about 30% of patients in the first year but decrease to 3% in subsequent years. In most the drug can be

reintroduced long term, initially at a lower dose. The liquid preparation appears to produce fewer gastrointestinal symptoms. Zinc deficiency has been described in diabetic and pre-diabetic patients. Rarely, it can lead to clinical features, such as skin rashes and hair loss. It is easily treated by oral zinc therapy. Liver fibrosis was suggested as a complication of deferiprone therapy in one study, but larger studies show that liver fibrosis is not a consequence of deferiprone. Nevertheless, transient increases in liver enzymes have been associated with deferiprone therapy in about 7% of patients and about 1% of patients have been withdrawn from therapy because of a persistent rise in liver enzyme levels. There have been no reports of renal, cardiac or neurological side-effects. Embryo toxicity and teratogenicity have been reported in non-iron-loaded animals treated with deferiprone. Women of childbearing age should be counselled to avoid the drug or use contraception but a few uneventful pregnancies with healthy newborns have been reported.

Combination therapy

Urine iron excretion when DFX and deferiprone are given simultaneously is equivalent to the sum of the excretion when the drugs are given on separate days. There is evidence for a ‘shuttle’ effect in which deferiprone enters cells, chelates iron and then returns to plasma, where the iron is transferred to DFX for excretion in urine or bile (Figure 4.7). All studies of combination therapy, for example deferiprone on 7 days a week and DFX on 2 days, have shown a significant fall in serum ferritin and improvement in cardiac and liver iron over 6–18 months. It has been associated with improved survival and reversal of endocrinological complications including diabetes, hypothyroidism and hypogonadism. The combination has also proved successful in reversing severe myocardial siderosis. Alternating therapy has also been studied, for example 4 or 5 days of deferiprone and 2 or 3 days of DFX each week, with improved compliance and improved iron status in previously poorly compliant (with DFX) children or adults.

Deferasirox

Pharmacokinetics

Deferasirox, 4-[3,5-bis(2-hydroxyphenyl)-1,2,4-triazol-1-yl] benzoic acid (Figure 4.5), is a tridentate chelator forming a 2:1 chelator–iron complex and increases predominantly faecal iron excretion. After a single oral dose, only 6% of iron excretion occurs in the urine (see Table 4.3). It is highly selective for iron. Peak plasma concentration after a single oral dose occurs at about 2 hours, and the drug is still detectable in plasma in almost all patients at 24 hours, with a mean elimination half-life of between 11 and 19 hours after multiple-dose administration. The single daily dose ranges from 20 to 40 mg/kg.

Clinical studies

Deferasirox has been shown to be effective at eliminating NTBI in plasma and reducing serum ferritin and liver iron in heavily iron-loaded patients. The effect is dependent on dose and on transfusion requirements of the patient. The drug has been shown to be safe and effective in children as young as 2 years. The starting dose in children is 20 mg/kg daily with subsequent dose adjustments. In adults 30–40 mg/kg daily may be required according to iron stores. Trials lasting for up to 5 years on children and adults have not shown any progressive renal, hepatic or bone marrow dysfunction and there are no reports of deferasirox having negative impact on growth or sexual development.

Emerging data suggest that deferasirox is effective at removing cardiac iron and preventing cardiac siderosis in thalassaemia major. It has also been shown to maintain or reduce iron overload in transfusion-dependent patients with myelodysplasia, Diamond–Blackfan anaemia and aplastic anaemia and in iron-loaded sickle cell anaemia patients. Adverse effects in these groups appear similar to those with thalassaemia major. The use of deferasirox is also being explored in hereditary haemochromatosis, chronic hepatitis C infection, porphyria cutanea tarda and mucormycosis.

The most common adverse effects have been abdominal pain, nausea, diarrhoea, vomiting and skin rashes. These decrease in frequency annually. They usually respond to dose adjustments, taking the drug in the evening or adding products such as Lactaid to the diet. Non-progressive increases in serum creatinine (defined as a rise above the mean pretreatment measurement by more than 33% on two consecutive tests) occur in about one-third of patients. These increases are dose dependent and resolve spontaneously. Serum creatinine should be measured in duplicate before therapy and then monthly, with significantly increased levels managed by dose reduction or interruptions.

Thalassaemia intermedia

For these patients, and other severely anaemic patients who are not transfusion dependent or only need a few transfusions each

year, iron loading occurs mainly through increased iron absorption. When anaemia is too severe for venesection, DFX has been used but oral iron chelation with deferasirox or deferiprone, more easily managed and with better patient compliance, has been shown effective in ‘de-ironing’ such patients, potentially reducing serum ferritin and liver iron to normal. A rise in haemoglobin level may occur. This may be due to removal of iron from the renal oxygen sensor, augmenting the effect of hypoxia and increasing erythropoietin secretion from the kidney. The rise in haemoglobin may also be a result of deferiprone directly removing iron from erythroblasts and mature red cells, reducing ineffective erythropoiesis and haemolysis. Improved haemopoiesis has also been described in myelodysplasia after chelation with DFX.

Acute iron poisoning

Acute oral iron poisoning produces a severe necrotizing gastritis and enteritis, followed by metabolic acidosis and, after a day or two, cardiovascular collapse and evidence of liver damage. DFX should be given both orally and parenterally. The instillation of 5 g into the stomach after a 1% sodium bicarbonate gastric lavage (to reduce further absorption) and an injection of 1–2 g i.m. may be tried. If a large number of tablets have been taken, an intravenous DFX infusion up to a maximum dose of 80 mg/kg in 24 hours should be used. Deferiprone and deferasirox have not yet been used in this setting.

Introduction

The megaloblastic anaemias are a group of disorders characterized by the presence of distinctive morphological appearances of the developing red cells in the bone marrow. The cause is usually deficiency of either cobalamin (vitamin B₁₂) or folate, but megaloblastic anaemia may arise because of inherited or acquired abnormalities affecting the metabolism of these vitamins or because of defects in DNA synthesis not related to cobalamin or folate (Table 5.1).

Underlying basic science

Biochemical basis of megaloblastic anaemia

The common feature of all megaloblastic anaemias is a defect in DNA synthesis that affects rapidly dividing cells in the bone marrow and other tissues. All conditions that give rise to megaloblastic changes share in common a disparity in the rate of synthesis or polymerization of the four immediate precursors

of DNA: the deoxyribonucleoside triphosphates (Figure 5.1). In deficiencies of either folate or cobalamin there is a failure to convert deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP). The coenzyme 5,10-methylene tetrahydrofolate polyglutamate is needed for this reaction and the availability of this coenzyme is reduced in either cobalamin deficiency or folate deficiency (see below).

The reduced supply of deoxythymidine triphosphate (dTTP) in megaloblastic anaemia owing to folate or cobalamin deficiency slows elongation of newly originated replicating segments from multiple sites of origin. Thus small fragments accumulate, single-stranded areas become points of weakness where mechanical or enzymatic breakage may occur, and the failure to form bulk DNA impairs contraction of newly replicated lengths of DNA, leaving the chromosomes elongated, despiralled and with random breaks. Late-replicating DNA is particularly affected and some cells become arrested and die at this stage by apoptosis, which can be prevented *in vitro* by preformed thymidine. Surprisingly, measurements of dTTP concentration in megaloblasts have not shown a deficiency. This may be because the overall cell concentration masks a localized deficiency at the multienzyme complex directly concerned with DNA replication.

An alternative hypothesis for megaloblastic anaemia in cobalamin or folate deficiency is the misincorporation of uracil into DNA because of a build-up of deoxyuridine triphosphate

Table 5.1 Causes of megaloblastic anaemia.

Cobalamin deficiency or abnormalities of cobalamin metabolism (Table 5.4)
Folate deficiency or abnormalities of folate metabolism (Table 5.7)
Therapy with antifolate drugs (e.g. methotrexate)
Independent of either cobalamin or folate deficiency and refractory to cobalamin and folate therapy:
Some cases of acute myeloid leukaemia, myelodysplasia*
Therapy with drugs interfering with DNA synthesis (e.g. cytarabine, hydroxycarbamide, 6-mercaptopurine, azidothymidine)
Orotic aciduria (responds to uridine)
Lesch–Nyhan syndrome (? responds to adenine)

*Folate deficiency also occurs frequently in these diseases.

Figure 5.1 Role of folate (as 5,10-methylene-THF polyglutamate and methylcobalamin) in DNA synthesis. THF, tetrahydrofolate; MP, monophosphate; TP, triphosphate; d, deoxyribose; A, adenine; T, thymine; C, cytosine; G, guanine.

(dUTP) at the replication fork as a consequence of the block in conversion of dUMP to dTMP (Figure 5.1). There is a mechanism for recognition of this aberrant material for excision and repair, but with dTTP in short supply this may not be possible. Repeated cycles of futile excision and misrepair may occur, with disruption of the normal programme of DNA synthesis leading to apoptotic cell death. Data on this hypothesis are conflicting. It does not explain megaloblastic anaemia due to defects of DNA synthesis at sites other than thymidylate synthesis, for example with drugs such as hydroxycarbamide (hydroxyurea), cytarabine or 6-mercaptopurine, or with enzyme deficiencies such as orotic aciduria or thiamine-responsive megaloblastic anaemia (see below).

Cobalamin–folate relationship

Folate is required for many other reactions in mammalian tissues, including two in purine synthesis (Table 5.2), but impairment of these is far less important clinically.

Only two reactions in the body are known to require cobalamin (Figure 5.2). Methylmalonyl-CoA isomerization, which requires deoxyadenosyl(ado)-cobalamin, is discussed later. The methylation of homocysteine to methionine requires both 5-methyltetrahydrofolate (methyl-THF) as methyl donor and methylcobalamin as coenzyme (Figure 5.3). This reaction, which is almost completely irreversible, is the first step in the pathway by which methyl-THF, which enters bone marrow and other cells from plasma, is converted into all the intracellular folate coenzymes (Figure 5.3). The coenzymes are all polyglutamated (the larger size aiding retention in the cell), but the enzyme folate polyglutamate synthase requires THF and not methyl-THF as substrate. In cobalamin deficiency, methyl-THF accumulates in the plasma, while intracellular folate concentrations fall due to failure of formation of intracellular folate polyglutamates because of ‘THF starvation’ or ‘methylfolate trapping’.

This theory explains the abnormalities of folate metabolism that occur in cobalamin deficiency (high serum folate, low cell folate, reduced thymidylate synthesis, positive purine precursor AICAR excretion; Table 5.2) and also why the anaemia that occurs in cobalamin deficiency will respond to folic acid in large doses. The explanation of why serum cobalamin falls in folate deficiency may also be related to impairment of the homocysteine–methionine reaction, with reduced formation of methylcobalamin, the main form of cobalamin in plasma, but other mechanisms may be responsible.

Clinical features

Many symptomless patients are detected through the finding of a raised mean corpuscular volume (MCV) on a routine blood

Table 5.2 Biochemical reactions of folate coenzymes.

Reaction	Coenzyme form of folate involved	Single-carbon unit transferred	Importance
<i>Formate activation</i>	THF	–CHO	Generation of 10-formyl-THF
<i>Purine synthesis</i>			
Formation of glycinamide ribonucleotide	5,10-Methenyl-THF	–CHO	Formation of purines needed for DNA, RNA synthesis, but reactions probably not rate limiting
Formylation of amino-imidazole-carboxamide-ribose (AICAR)	10-Formyl-THF	–CHO	
<i>Pyrimidine synthesis</i>			
Methylation of deoxyuridine monophosphate (dUMP) to thymidine monophosphate (dTMP)	5,10-Methenyl-THF	–CH ₃	Rate limiting in DNA synthesis Oxidizes THF to DHF Some breakdown of folate at the C-9–N-10 bond
<i>Amino acid interconversion</i>			
Serine–glycine interconversion	THF	=CH ₂	Entry of single-carbon units into active pool
Homocysteine to methionine	5-Methyl-THF	–CH ₃	Demethylation of 5-methyl-THF to THF; also requires cobalamin, flavine adenine dinucleotide, ATP and adenosylmethionine
Forminoglutamic acid to glutamic acid in histidine catabolism	THF	–HN–CH=	Basis of the Figlu test (now obsolete)

DHF, dihydrofolate; THF, tetrahydrofolate.

Figure 5.2 Intracellular cobalamin metabolism. Cbl¹⁺, Cbl²⁺ and Cbl³⁺ refer to the oxidation state of the central cobalt atom of cobalamin. A–G refer to the sites of blocks that have been identified by complementation analysis in infants with metabolic defects. AdoCbl, adenosylcobalamin; MeCbl, methylcobalamin; TC, transcobalamin. The mitochondrial, lysosomal and cytoplasmic compartments are indicated. (From Lilleyman JS, Hann IM, Blanchette VS (eds) (1999) *Paediatric Haematology*, 2nd edn. Churchill Livingstone, Edinburgh with permission.)

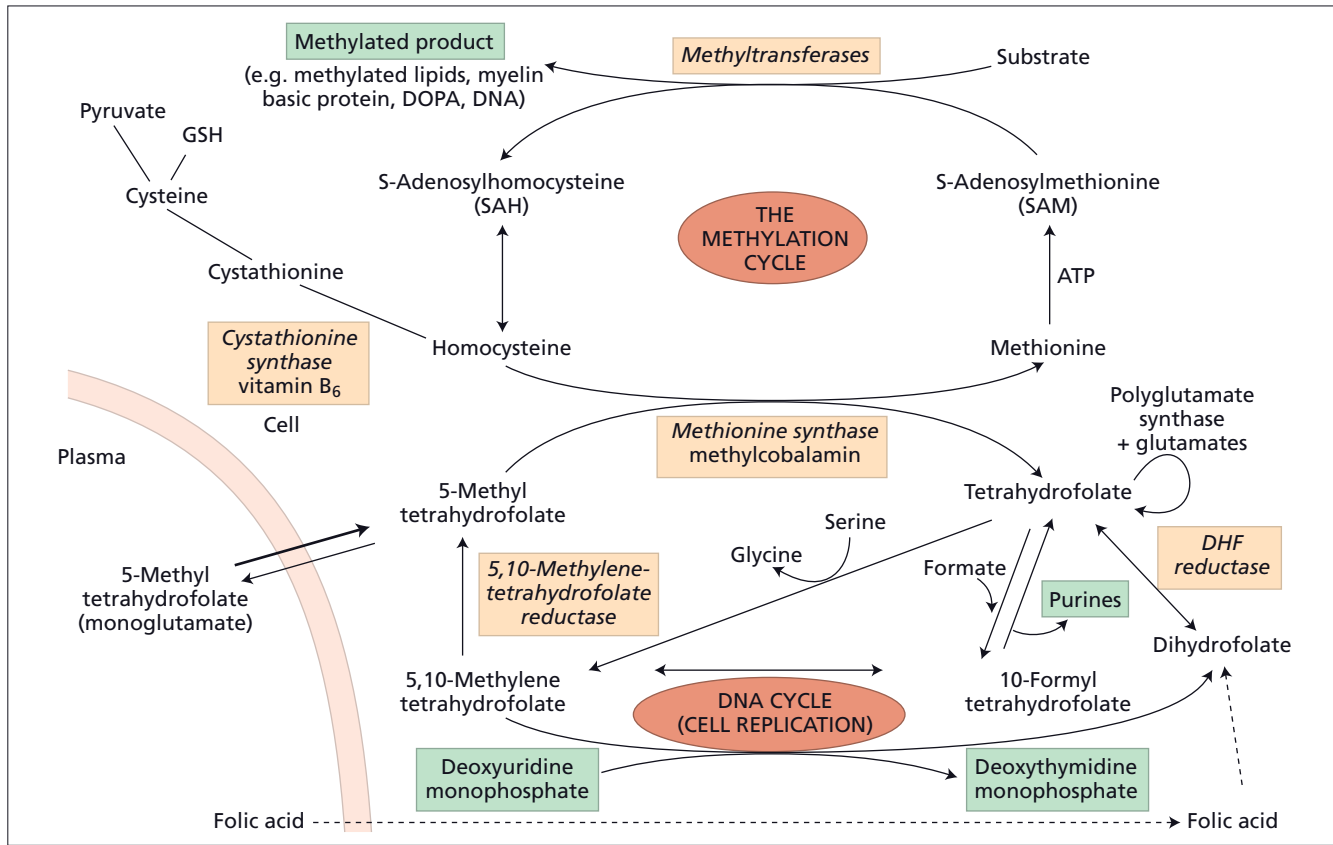

Figure 5.3 The role of folates in DNA synthesis and in formation of *S*-adenosylmethionine (SAM), which is involved in numerous methylation reactions. Enzymes are shown in yellow boxes. (Figure prepared in conjunction with Professor John Scott.)

count. The main clinical features in more severe cases are those of anaemia. Anorexia is usually marked and there may be weight loss, diarrhoea or constipation. Other particular features include glossitis, angular cheilosis, a mild fever in the more severely anaemic patients, jaundice (unconjugated) and reversible melanin skin hyperpigmentation, which may occur with either deficiency. Thrombocytopenia sometimes leads to bruising (and this may be aggravated by vitamin C deficiency in malnourished patients). The (anaemia and) low leucocyte count may predispose to infections, particularly of the respiratory or urinary tracts. Cobalamin deficiency has also been associated with impaired bactericidal function of phagocytes.

General tissue effects of cobalamin and folate deficiencies

Epithelial surfaces

These deficiencies, when severe, affect all rapidly growing (DNA-synthesizing) tissues. After the marrow, the next most affected tissues are the epithelial cell surfaces of the mouth, stomach, small intestine and respiratory, urinary and female genital tracts. The cells show macrocytosis, with increased

numbers of multinucleate and dying cells. The deficiencies may cause cervical smear abnormalities.

Complications of pregnancy

The gonads are also affected and infertility is common in both men and women with either deficiency if severe. Maternal folate deficiency has been implicated as a cause of prematurity and both folate and cobalamin deficiency have been implicated in recurrent fetal loss.

Neural tube defects

Folic acid supplements at the time of conception and in the first 12 weeks of pregnancy reduce by about 70% the incidence of neural tube defects (NTDs) – anencephaly, meningomyelocele, encephalocele and spina bifida – in the fetus. Most of this protective effect can be achieved by taking folic acid 0.4mg daily. The incidence of cleft palate and harelip can also be reduced by prophylactic folic acid. There is no clear simple relationship between maternal folate status and these fetal abnormalities, although the lower the maternal folate, the greater the risk to the fetus. NTDs can also be caused by antifolate and antiepileptic drugs.

An underlying maternal folate metabolic abnormality has also been postulated. One abnormality has been identified: reduced activity of the enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR) (Figure 5.3) caused by a common 677C→T polymorphism in the *MTHFR* gene. In one study, the prevalence of this polymorphism was found to be higher in the parents of NTD fetuses and in the fetuses themselves: homozygosity for the TT mutation was found in 13% compared with 5% in control subjects. The polymorphism codes for a thermolabile form of MTHFR. The homozygous state results in lower mean serum and red cell folate compared with control subjects, as well as significantly higher serum homocysteine levels. Tests for mutations in other enzymes possibly associated with NTDs, for example methionine synthase or serine–glycine hydroxymethylase, have been negative. Autoantibodies to folate receptors (see p. 77) had been suggested to cause NTDs but this has not been confirmed in a recent large study.

Cardiovascular disease

Children with severe homocystinuria (blood levels of 100 µmol/L or more) due to deficiency of one of three enzymes, methionine synthase, MTHFR or cystathionine synthase (Figure 5.3), suffer from vascular disease (e.g. ischaemic heart disease, cerebrovascular disease or pulmonary embolus) as teenagers or in young adulthood. Meta-analysis shows a significant association between lesser degrees of raised serum homocysteine (normal range 5–15 µmol/L) and of homozygosity for mutated *MTHFR* with ischaemic heart disease, stroke, deep vein thrombosis and pulmonary embolism. The odds ratios for a 5-µmol/L increase in serum homocysteine were 1.42 in 72 genetic (*MTHFR*) studies and 1.32 in 20 prospective studies of serum homocysteine, 1.60 for deep vein thrombosis with or without pulmonary embolism in genetic studies, and for stroke 1.65 in genetic studies and 1.59 in prospective studies. As the genetic and prospective studies do not share the same potential sources of error but both yield highly significant results, the authors considered the results strong evidence of a causal association between homocysteine and cardiovascular disease.

Heterozygosity for the C677T mutation has also been shown to be associated with an increase in the risk of thrombosis in subjects heterozygous for factor V Leiden. It remains possible that homocysteine levels may be high as a consequence of the vascular damage or may merely be a marker for some other underlying factor that is responsible for both the vascular damage and the raised homocysteine. Folate deficiency, for example, may be such a factor. Folate levels have been found in various studies to be lower in patients with myocardial infarct and carotid artery disease than control subjects. There are some reports of prevention of arterial disease recurrence or progression by prophylactic folic acid or cobalamin but the results are conflicting. Meta-analysis of data from large multicentre prospective trials of folic acid in prevention of coronary vascular disease do not show a positive effect. Meta-analysis

does suggest that folic acid supplementation reduces the risk of stroke by 18% but even this is not certain, depending on which data are included in the analysis. Extremely high levels of homocysteine (>50 µmol/L) are toxic to endothelia. When homocysteine levels are only mildly (15–25 µmol/L) or moderately (25–50 µmol/L) elevated, then another mechanism needs to be invoked to explain vascular damage or increased risk of thrombosis. Several mechanisms have been proposed, including oxidant damage through the generation of peroxide produced during thiol oxidation to form disulphides and interaction of free reduced homocysteine with cysteine residues on coagulation factors, platelets, adhesion molecules or endothelial cells. Promotion of vascular wall inflammation through the generation of proinflammatory cytokines and interference with key methylation reactions are also possible mechanisms.

Malignancy

Prophylactic folic acid in pregnancy has been found in some but not all studies to reduce the subsequent incidence of acute lymphoblastic leukaemia (ALL) in childhood. A significant negative association has been found with the *MTHFR* 677C→T and 1298A→C polymorphisms and the incidence of both paediatric and adult ALL. There are various positive and negative associations between polymorphisms in other folate-dependent enzymes and the incidence of paediatric and adult ALL. Other tumours that have been associated with folate polymorphisms or status include follicular lymphoma, breast cancer and gastric cancer.

The C677T polymorphism is thought to lead to increased thymidine pools and ‘better quality’ of DNA synthesis by shunting one-carbon groups towards thymidine and purine synthesis. This may also explain its reported association with a lower risk for colorectal and gastric cancer. The incidence of colon cancer was also lower in subjects taking vitamin supplements containing folic acid and in those with higher folate intake compared with control subjects in the Nurses Health Study, and increased folate intake may mask the protective effect of the C677T and A1298C polymorphisms. There is no correlation between pre-diagnostic plasma folate and risk of death in patients with colorectal cancer. One study showed no overall difference in incidence of colonic adenoma in subjects taking folic acid or controls but a higher incidence of multiple (>3) adenomas in those taking folic acid. However, the statistics have been questioned and other studies have shown a lower incidence of colonic adenoma with higher folate intake. Folate deficiency is postulated to predispose to malignancy by reducing the ratio of *S*-adenosylmethionine (SAM) to *S*-adenosylhomocysteine (SAH), causing DNA hypomethylation and, by resulting in uracil misincorporation into DNA, possibly leading to double-strand breaks. Most recent data from large prospective trials suggest no significant effect of folic acid on the incidence or progress of any cancer.

Other tissues

Folate deficiency causes reduced regeneration of cirrhotic liver. Patients with gluten-induced enteropathy and those with sickle cell anaemia have also been reported to show stunted growth, which has been improved coincidentally with commencement of folic acid therapy, but it is not certain how much the growth improvement in these children was due to folic acid and how much to other, simultaneously administered vitamins. In the fragile X syndrome, sister chromatid exchange and DNA breaks are increased *in vitro* in a folate-deficient medium, apparently at the Xq28 site. No *in vivo* abnormality of folate metabolism can be detected.

Neurological manifestations

Cobalamin deficiency may cause bilateral peripheral neuropathy or degeneration (demyelination) of the posterior and pyramidal tracts of the spinal cord and, less frequently, optic atrophy or cerebral symptoms. The patient classically presents with paraesthesiae, muscle weakness or difficulty in walking and sometimes dementia, psychotic disturbances or visual impairment. Long-term nutritional cobalamin deficiency in infancy leads to poor brain development and impaired intellectual development. Folate deficiency may cause mental changes such as depression and slowness and has been suggested to cause organic nervous disease, but this is uncertain. Autoantibodies to the folate receptor involved in transport of folate into cerebrospinal fluid have been postulated to be associated with autism-associated neurological abnormalities. Methotrexate injected into the cerebrospinal fluid may cause brain or spinal cord damage. Neural tube defects in the fetus are discussed above.

The biochemical basis for cobalamin neuropathy remains obscure. Its occurrence in the absence of methylmalonic aciduria in transcobalamin deficiency, and in monkeys given nitrous oxide (N₂O), suggests that the neuropathy is related to the defect in conversion of homocysteine to methionine. Accumulation of SAH in the brain, resulting in inhibition of transmethylation reactions due to an altered SAM to SAH ratio, has been suggested. SAM is needed in methylation of biogenic amines (e.g. dopamine), as well as of proteins, phospholipids and neurotransmitters in the brain (see Figure 5.3). A reduced ratio of SAM to SAH is postulated to result in reduced methylation. However, measurements of methylation of arginine in myelin basic protein in fruit bats with cobalamin neuropathy, or in rats exposed to N₂O, showed no defect of methylation. Psychiatric disturbance is common in both folate and cobalamin deficiencies. Loss of cognitive function in the elderly has been associated with high plasma homocysteine and low vitamin B₁₂ and folate levels. This, like the neuropathy, has been attributed to a failure of the synthesis of SAM.

Plasma homocysteine is a risk factor for dementia and Alzheimer disease, shown in a median follow-up period of 8 years in one study of 1092 subjects. Studies showing an association between lower serum levels of folate or cobalamin and

higher homocysteine levels and Alzheimer disease, loss of cognitive function or brain volume loss have been reported. However, trials of supplementation with folic acid, vitamin B₁₂ and vitamin B₆ have not shown a benefit in preventing progression of the dementia compared with a control group, or in improving cognitive function.

Haematological findings

Peripheral blood

Oval macrocytes, usually with considerable anisocytosis and poikilocytosis, are the main feature (Figure 5.4a). The MCV is usually more than 100 fL unless a cause of microcytosis (e.g. iron deficiency or thalassaemia trait) is present, when there is a raised red cell distribution width (RDW) and the film is dimorphic. In other cases, the MCV may be normal owing to excess fragmentation of red cells. Some of the neutrophils are hypersegmented (more than five nuclear lobes). Both macrocytosis and hypersegmented neutrophils may also occur in other situations (Table 5.3). Together, however, they strongly suggest megaloblastic haemopoiesis. There may be leucopenia due to a reduction in granulocytes and lymphocytes; the platelet count may be moderately reduced, rarely to less than $40 \times 10^9/L$. Occasionally, a leucoerythroblastic blood picture is seen. In the non-anaemic patient, the presence of a few macrocytes and

Table 5.3 Conditions in which macrocytosis or hypersegmented neutrophils may occur in the absence of megaloblastic anaemia.

Macrocytosis

Alcohol
Liver disease (especially alcoholic)
Reticulocytosis (haemolysis or haemorrhage)
Aplastic anaemia or red cell aplasia
Hypothyroidism
Myelodysplasia
Myeloma and macroglobulinaemia
Leucoerythroblastic anaemia
Myeloproliferative disease
Pregnancy
Newborn
Congenital dyserythropoietic anaemia (type II)
? Chronic respiratory failure

Hypersegmented neutrophils

Renal failure
Congenital (familial)
? Iron deficiency

Note: Falsely high MCV recorded when cold agglutinins, paraproteins or marked leucocytosis are present.

Figure 5.4 Severe megaloblastic anaemia: (a) peripheral blood; (b) bone marrow.

hypersegmented neutrophils in the peripheral blood may be the only abnormalities.

Bone marrow

In the severely anaemic patient, the marrow is hypercellular with accumulation of primitive cells due to selective death of more mature forms. The most characteristic finding is dissociation between nuclear and cytoplasmic development in the erythroblasts, with the nucleus maintaining a primitive appearance despite maturation and haemoglobinization of the cytoplasm; fully haemoglobinized (orthochromatic) erythroblasts, which retain nuclei, may be seen. The nucleus of the megaloblast has an open, fine, lacy appearance; the cells are larger than normoblasts and an increased number of cells with eccentric lobulated nuclei or nuclear fragments may be present (Figure 5.4b). Mitoses and dying cells are more frequent than normal. Giant and abnormally shaped metamyelocytes and enlarged hyperpolypliod megakaryocytes are characteristic. Severe florid megaloblastic changes may be confused with acute erythroid leukaemia. Rarely, the marrow may be hypocellular or red cell precursors are lost almost completely from the marrow and a mistaken diagnosis of myeloid leukaemia may be made. Iron staining shows increase in both reticuloendothelial stores and in the developing megaloblasts.

In less anaemic patients, the changes in the marrow may be difficult to recognize. The terms 'intermediate', 'mild' and 'early' have been used. The changes may be mild and difficult to recognize, even in a severely anaemic patient, if the anaemia is largely due to other factors (e.g. iron deficiency, infection,

malignant disease, haemolysis) and the megaloblastosis is an incidental phenomenon. The term 'megaloblastoid' has several different connotations including the dysplastic changes seen in the myelodysplastic syndromes and is best avoided.

Chromosomes

Bone marrow cells, transformed lymphocytes and other proliferating cells in the body show a variety of changes including random breaks, reduced contraction, spreading of the centromere, and exaggeration of secondary chromosomal constrictions and overprominent satellites. Similar abnormalities may be produced by antimetabolite drugs (e.g. cytarabine, hydroxycarbamide and methotrexate) that interfere with either DNA replication or folate metabolism and which also cause megaloblastic appearances.

Ineffective haemopoiesis

There is accumulation of unconjugated bilirubin in plasma due to the death of nucleated red cells in the marrow (ineffective erythropoiesis). Other evidence for this includes raised urine urobilinogen, reduced haptoglobins and positive urine haemosiderin, raised serum lactate dehydrogenase to values between 1000 and 10 000 IU/dL, and raised serum iron, non-transferrin-bound iron and ferritin levels. Carbon monoxide production is also increased. Serum lysozyme may also be raised, suggesting ineffective granulopoiesis.

In rare patients, ineffective haemopoiesis is associated with features of disseminated intravascular coagulation, with raised

serum fibrin degradation products. Thrombocytopenia, when it occurs, is usually caused by ineffective megakaryopoiesis. A weakly positive direct antiglobulin test due to complement can lead to a false diagnosis of autoimmune haemolytic anaemia.

Cobalamin

Cobalamin (vitamin B₁₂) exists in a number of different chemical forms. The molecule consists of two halves: a planar group and a nucleotide set at right angles to it (Figure 5.5). The planar group is a corrin ring and the nucleotide consists of a base, 5,6-dimethylbenzimidazole, and a phosphorylated sugar, ribose-5-phosphate. In nature, the vitamin is mainly in the 5'-deoxyadenosyl (ado) form. This is the main form in human tissues and is located in the mitochondria. It serves as the cofactor for methylmalonyl-CoA mutase. The other major natural cobalamin is methylcobalamin, the main form in human plasma and cell cytoplasm. It serves as the cofactor for methionine synthase. There are also minor amounts of hydroxocobalamin, the form to which methyl- and ado-cobalamin are rapidly converted by exposure to light, hydroxocobalamin having its cobalt atom in the fully oxidized Cbl³⁺ state, whereas the cobalt exists as reduced Cbl¹⁺ in the methyl- and ado-cobalamin forms (see Figure 5.2). A glutathionyl cobalamin form has also been identified.

Dietary sources and requirements

Cobalamin is synthesized solely by microorganisms. Ruminants obtain cobalamin from the foregut but the only source for

humans is food of animal origin. The highest amounts are found in liver and kidney (up to 100 µg per 100 g), but it is also present in shellfish, organ and muscle meats, fish, chicken and dairy products (eggs, cheese and milk) in small amounts (6 µg/L). Vegetables, fruits and all other foods of non-animal origin are free from cobalamin unless they are contaminated by bacteria. Cooking does not usually destroy cobalamin.

A normal Western diet contains 5–30 µg of cobalamin daily. Adult daily losses (mainly in the urine and faeces) are about 1–2 µg (about 0.1% of body stores) and because the body does not have the ability to degrade cobalamin, daily requirements are also about 1 µg. Body stores are of the order of 2–3 mg and are sufficient for 3–4 years if supplies are completely cut off.

Absorption

Two mechanisms exist for cobalamin absorption. One is passive, occurring equally through the duodenum and the ileum; it is rapid but extremely inefficient as less than 1% of an oral dose can be absorbed by this process. Passive absorption of cobalamin can also occur through other mucous membranes such as the sublingual and nasal mucosae. The other mechanism is active; it occurs through the ileum in humans and is efficient for small (a few micrograms) oral doses of cobalamin. This is the normal mechanism by which the body acquires cobalamin and is mediated by gastric intrinsic factor (IF).

Dietary cobalamin is released from protein complexes by enzymes in the stomach, duodenum and jejunum; it combines rapidly with a salivary glycoprotein (R binder) related to plasma transcobalamin I (TCI). These belong to the family of cobalamin-binding proteins known as haptocorrins (HCs), which differ only in glycosylation. They are products of a single gene (*TCN1*), and they occur in saliva, gastric juice, bile, milk and other body fluids. Subsequently, HC is digested by pancreatic trypsin and the cobalamin transferred to IF. Binding of cobalamin to IF is favoured by an alkaline pH; it binds one molecule for one molecule. All forms of cobalamin are absorbed by the same IF mechanism (Figure 5.6). Pseudo-cobalamin compounds, in which the 5,6-dimethylbenzimidazole nucleotide is replaced by other nucleotides that may attach to HC, do not attach to IF and therefore remain unabsorbed.

Intrinsic factor is a glycoprotein (molecular weight 45 000) encoded by a gene on chromosome 11q13. It is produced in gastric parietal cells in the fundus and body of the stomach. The IF–cobalamin complex, in contrast with free IF, is resistant to enzyme digestion, having a more closed structure. The IF–cobalamin complex passes to the ileum, where IF attaches to a specific receptor (cubilin, molecular weight 460 000) on the microvillus membrane of the brush border surface of the ileal absorptive cells. Cubilin (gene located on chromosome 10p12.1) is also present in yolk sac and renal proximal tubular epithelium. The attachment of the IF–cobalamin complex requires calcium ions and a pH around neutral. It is probably a physical

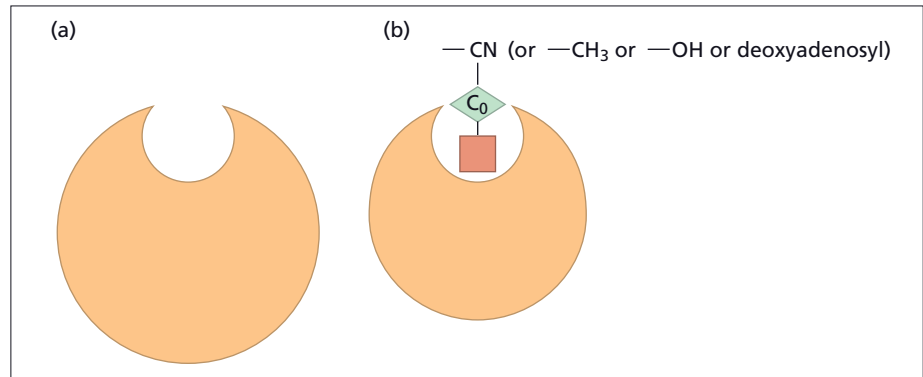

Figure 5.5 The structure of vitamin B₁₂ (cyanocobalamin).

Figure 5.6 (a) Intrinsic factor; (b) intrinsic factor–cobalamin complex. Intrinsic factor has been estimated to have a molecular radius of 3.6 nm, vitamin B₁₂ 0.8 nm and the complex 3.2 nm.

process, not requiring energy. Cubulin traffics by means of the protein amnionless (AMN, molecular weight 480 000). Cubulin and AMN are subunits of a novel complex in which AMN binds tightly to cubulin and directs sublocalization and endocytosis of cubulin with its ligand (IF–cobalamin complex). Defects in cubulin and AMN are implicated in autosomal recessive megaloblastic anaemia, characterized by intestinal malabsorption of cobalamin (see p. 73). A third protein, megalin (LRP2), has been suggested to play a role in stabilizing the cubilin–AMN complex.

Cobalamin then enters the ileal cell, but the exact fate of IF is unknown. IF does not enter the bloodstream as such, as after a delay of about 6 hours absorbed cobalamin appears in portal blood attached to transcobalamin (TCII), which is probably synthesized in the ileum, either by mucosal cells or by venous endothelial cells in the submucosa.

The ileum has a restricted capacity to absorb cobalamin because of limited receptor sites. Although 50% or more of a single dose of 1 µg of cobalamin may be absorbed, with doses above 2 µg the proportion absorbed falls rapidly. Moreover, after one dose of IF–cobalamin complex has been presented, the ileal cells become refractory to further doses for about 6 hours.

Enterohepatic circulation

Between 0.5 and 5.0 µg of cobalamin enter the bile each day. This binds to IF and a portion of biliary cobalamin is normally reabsorbed together with cobalamin derived from sloughed intestinal cells. Bile may enhance cobalamin absorption. Cobalamin deficiency develops more rapidly in individuals who malabsorb cobalamin than it does in vegans, who ingest no cobalamin but in whom reabsorption of biliary cobalamin is intact.

Transport

Two main cobalamin-binding proteins exist in human plasma; they both bind cobalamin one molecule for one molecule

Figure 5.7 The serum cobalamin-binding proteins (TCs, transcobalamins). Dark blue rectangles indicate endogenous serum cobalamin; light blue rectangles indicate unsaturated cobalamin-binding protein; HCs, haptocorrins.

(Figure 5.7). One HC (also known as TCI) is a glycoprotein. TCIII was a name used to describe a minor isoprotein of TCI in plasma. These HCs are derived primarily from the specific granules in neutrophils and are normally about two-thirds saturated with cobalamin, which they bind tightly. They do not enhance cobalamin entry into tissues. Glycoprotein receptors on liver cells are concerned in the removal of HCs from plasma, and HC may have a role in the transport of cobalamin analogues to the liver for excretion in bile. The gene, *TCN1*, is located on chromosome 11q11–q12.3, has nine exons and codes a protein of 433 amino acids. Heterozygous, homozygous or compound heterozygous mutations in the gene may cause mild or severe reductions in serum vitamin B₁₂ respectively with no known clinical consequences.

The other major cobalamin transport protein in plasma is transcobalamin (TC, also known as TCII). TC is a β -globulin (molecular weight 38 000) synthesized by liver, and by other tissues including macrophages, endothelial and possibly ileal cells. It normally carries only 20–60 ng of cobalamin per litre of plasma and readily gives up cobalamin to marrow, placenta and other tissues, which it enters by receptor-mediated endocytosis via clathrin-coated pits. TC is not reutilized. The gene is on chromosome 22q11–q13.1 and, as for IF and HC, there are nine exons. The three proteins are likely to have a common ancestral origin. TC has 20% amino acid homology and more than 50% nucleotide homology with human HC and with rat IF. The regions of homology of HC, TC and IF are involved in cobalamin binding. Five different inherited isoproteins of TC, separated by polyacrylamide gel electrophoresis, have been described; all are functionally active. TC occurs in cerebrospinal fluid and binds cobalamin (approximately 10 ng/L) there. Alterations may occur in TC and HC levels in a variety of disease states (Table 5.4). In general, an increase in HC causes an increase in serum cobalamin, whereas an increase in TC does not.

The TC receptor belongs to the low-density lipoprotein receptor family. It is composed of 282 amino acids and is heavily

glycosylated; the gene is located at chromosome 19p15.2. It is more heavily expressed in dividing than quiescent cells, and is recycled to the cell surface. Megalin (LRP-2) is also involved in the endocytosis of TC–cobalamin.

Cobalamin analogues

Cobalamin analogues are corrinoids, which exist as cobamides (containing substitutions in the place of ribose, e.g. adenosyl) or as cobinamides (which have no nucleotide whatever). HC may carry analogues to the liver for excretion in the bile. It is unclear whether they are inert or inhibit cobalamin-dependent reactions. The proportion of analogues derived from diet, gut bacteria or endogenous breakdown of cobalamins is unknown. They are present in fetal blood and tissues.

Causes of cobalamin deficiency

Cobalamin deficiency is usually due to malabsorption. The only other cause is inadequate dietary intake. Cobalamin deficiency due to excess degradation occurs as a result of exposure to the anaesthetic gas N_2O . N_2O causes irreversible oxidation of the active Cbl^{1+} during catalytic shunting of labile methyl groups in the methionine synthase reaction (see Figure 5.2).

Table 5.4 Alterations in plasma cobalamin-binding proteins in disease.

Haptocorrin

- Increased (usually with elevated serum cobalamin)
 - Myeloproliferative diseases, especially chronic myeloid leukaemia, myelosclerosis, polycythaemia vera
 - Hepatoma
 - Increased granulocyte production (e.g. inflammatory bowel disease, liver abscess)
 - Eosinophilia due to hypereosinophilic syndrome
- Congenital absence
 - Low total serum cobalamin
 - No clear clinical abnormality

Transcobalamin (II)

- Increased (sometimes with no elevation of serum cobalamin)
 - Liver disease
 - Gaucher disease
 - Autoimmune disease
 - Long-continued hydroxocobalamin therapy
- Congenital absence
 - Normal or decreased total serum cobalamin
 - Megaloblastic anaemia or pancytopenia within a few weeks of birth
 - Impaired cobalamin absorption, may be associated with defective cellular and humoral immunity

Inadequate dietary intake

Adults

Dietary cobalamin deficiency arises in vegans who omit meat, fish, eggs, cheese and other animal products from their diet. The largest group in the world consists of Hindus, and many millions of Indians are at risk of deficiency on a nutritional basis. However, not all vegans develop cobalamin deficiency of sufficient severity to cause anaemia or neuropathy, even though subnormal cobalamin levels have been found in up to 50% of randomly selected, young, adult Indian vegans. Dietary cobalamin deficiency may also arise rarely in non-vegetarian subjects who exist on grossly inadequate diets because of poverty or psychiatric disturbance. Explanations of why nutritional cobalamin deficiency may not progress to megaloblastic anaemia include the following.

- 1 The diet of most vegans is probably not totally lacking cobalamin. The serum cobalamin level may not be an accurate measure of their body stores.
- 2 The enterohepatic circulation of cobalamin is still intact in vegans and thus losses are less (about 1 μ g daily) than in conditions of malabsorption (about 2 μ g daily).
- 3 Daily losses of cobalamin are thought to be related to body stores; therefore, as the body stores become depleted, daily losses become smaller and the amount of cobalamin needed to maintain the status quo may also become smaller.

Ileal resection and Crohn's disease

Selective malabsorption with proteinuria

Tropical sprue

Transcobalamin deficiency

Fish tapeworm

Infants

Cobalamin deficiency has been described in infants born to severely cobalamin-deficient mothers. These infants develop megaloblastic anaemia at about 3–6 months of age since they are born with low stores of cobalamin and are then fed breast milk of low cobalamin content. This occurs most commonly in Indian vegans, but a similar condition has also been described in unrecognized maternal pernicious anaemia and in strict practitioners of veganism living in Western countries whose offspring have shown growth retardation, impaired psychomotor development and other neurological sequelae.

Gastric causes of cobalamin malabsorption
(Tables 5.5 and 5.6)**Pernicious anaemia**

Pernicious anaemia (PA) may be defined as a severe lack of IF due to gastric atrophy. It is a common disease in northern Europeans but occurs in all countries and ethnic groups. The overall incidence is about 120 per 100 000 population in the UK, but there is wide variation between one area and the next. The prevalence rate in Western countries may be as high as 2–3%. The ratio of incidence in men and women is approximately 1:1.6 and the peak age of onset is 60 years, with only 10% of patients presenting being less than 40 years of age. In some ethnic groups, notably black people and Latin Americans, the age of onset of PA is generally lower. The disease occurs more commonly than by chance in close relatives, in subjects with other organ-specific autoimmune diseases (see below), in those

Table 5.6 Malabsorption of cobalamin may occur in the following conditions but is not usually sufficiently severe and prolonged to cause megaloblastic anaemia.

Gastric causes

Simple atrophic gastritis (food cobalamin malabsorption)

with premature greying, blue eyes and vitiligo, and in persons of blood group A. An association with human leucocyte antigen (HLA)-3 has been reported in some but not all series and in those with endocrine disease, with HLA-B8, -B12 and -BW15. The life expectancy has been estimated as normal in women once regular treatment has begun. Men have a slightly subnormal life expectancy as a result of a higher incidence of carcinoma of the stomach than in control subjects.

Diagnosis

This is usually suspected from the clinical picture and the findings of megaloblastic anaemia due to cobalamin deficiency. A lack of IF has been demonstrated by cobalamin absorption studies but this test is no longer available in most countries. Tests for circulating gastric autoantibodies are also important. Direct measurements on gastric juice following pentagastrin stimulation are now rarely performed. Hydrochloric acid or pepsin production and IF output were previously measured. The serum gastrin level is usually raised in PA (>200 µg/L), the hormone coming from endocrine cells in the gastric fundus. Raised serum gastrin also occurs in simple atrophic gastritis. Serum pepsinogen I levels are low (< 30 µg/L) in over 90% of those affected and a low ratio of serum pepsinogen I to pepsinogen II correlates with the presence of chronic atrophic gastritis.

Gastric biopsy

This usually shows atrophy of all layers of the body and also fundal atrophy, with loss of glandular elements, an absence of parietal and chief cells and replacement by mucous cells, a mixed inflammatory cell infiltrate and perhaps intestinal metaplasia. The infiltrate of plasma cells and lymphocytes contains an excess of CD4 cells. The antral mucosa is usually well preserved. *Helicobacter pylori* infection is infrequent in PA, but it has been suggested that *H. pylori* gastritis may represent an early phase of atrophic gastritis, which is gradually replaced, in some individuals, by an immune process with disappearance of *H. pylori* infection.

Immune phenomena

In addition to the appearance of the gastric mucosa, there is a large body of evidence that suggests that immune mechanisms play an important role in the pathogenesis of PA. This aspect of the disease is discussed under four main headings.

Antibodies to gastric antigens

1 IF antibodies. Two types of IF antibody may be found in the sera of patients with PA, both being IgG. One, the 'blocking' or 'type I' antibody, prevents the combination of IF and cobalamin, whereas the other, the 'binding', 'type II' or 'precipitating' antibody, which attaches to IF whether joined to cobalamin or not, prevents attachment of IF to ileal mucosa. The blocking antibody occurs in the serum of about 55% of patients and the binding antibody in 35%. IF antibodies cross the placenta and cause temporary IF deficiency in the newborn infant. Patients with PA also show cell-mediated immunity to IF. An increased CD4/CD8 lymphocyte ratio in blood has been described in PA patients with IF antibodies. IF antibodies are rarely found in conditions other than PA. Type I antibody has been detected rarely in the sera of patients without PA but with thyrotoxicosis, myxoedema, Hashimoto disease or diabetes mellitus, and in relatives of PA patients. IF antibodies have also been detected in gastric juice in about 80% of patients with PA. These antibodies may reduce absorption of dietary cobalamin by combining with small amounts of remaining IF in the gastric juice. Achlorhydria favours the formation of this antigen-antibody complex.

2 Parietal cell and gastrin receptor antibodies. Parietal cell antibody is present in the sera of almost 90% of adult patients with PA, but it is frequently present in other subjects. Thus, it occurs in as many as 16% of randomly selected female subjects aged over 60 years and in a smaller proportion of younger control subjects; it is found more frequently than in control subjects in relatives of PA patients. These antibodies are also found more frequently in patients with simple atrophic gastritis, chronic active hepatitis and thyroid disorders and their relatives, as well as in Addison disease, rheumatoid arthritis and other conditions. The parietal cell antibody is directed against the α - and β -subunits of the gastric proton pump (H^+/K^+ -

ATPase). The sera of PA patients may also contain an autoantibody to the gastrin receptor, although this test is not used clinically.

Association with other 'autoimmune' diseases

There is a clinical association between PA and thyroid diseases, vitiligo, hypoparathyroidism and Addison disease. These diseases are often found in close relatives of patients with overt disease due to one of these conditions.

Response to steroid therapy

Steroid therapy improves the gastric lesion, at least temporarily, in a proportion of patients with PA. There may be regeneration of the mucosa with a return of secretion of acid and IF, and an improvement in cobalamin absorption. When steroid therapy is withdrawn, there is relapse within a few weeks. These findings suggest that an autoimmune process is continuously damaging the gastric mucosa in PA and preventing regeneration.

Hypogammaglobulinaemia

PA is found more often than by chance in patients with a deficiency of IgA or with complete hypogammaglobulinaemia. These subjects resemble others with PA, except that they often present relatively early (before the age of 40 years), they have a lower incidence of serum IF and parietal cell antibodies, and they may show intestinal malabsorption. They may also have a history of recurrent infections. The gastric lesion is similar to that in other causes, except that plasma cells are absent from the inflammatory cell infiltrate and the antrum is involved. Serum gastrin levels are normal.

Juvenile pernicious anaemia

This usually occurs in older children and resembles PA of adults. Gastric atrophy, achlorhydria and serum IF antibodies are all present, although parietal cell antibodies are usually absent. About half of these patients show an associated endocrinopathy such as autoimmune thyroiditis, Addison disease or hypoparathyroidism; in some, mucocutaneous candidiasis occurs.

Congenital intrinsic factor deficiency or functional abnormality

The affected child usually shows no demonstrable IF but has a normal gastric mucosa and normal secretion of acid. The inheritance is autosomal recessive. These patients usually present with megaloblastic anaemia in the first, second or third year of life when stores of cobalamin accumulated from the mother *in utero* are used up; a few have presented as late as the second decade. Parietal cell and IF antibodies are absent. Variants have been described in which the child is born with IF that can be detected immunologically but which is unstable or functionally inactive, being unable either to bind cobalamin or to facilitate its uptake by the ileum.

Gastrectomy

Following total gastrectomy, cobalamin deficiency is inevitable and prophylactic cobalamin therapy should be commenced immediately following the operation. After partial gastrectomy, 10–15% of patients also develop this deficiency. The exact incidence and time of onset are most influenced by the size of the resection and the pre-existing size of the cobalamin body store.

Simple atrophic gastritis (food cobalamin malabsorption)

The normal IF-mediated mechanism of cobalamin absorption requires adequate gastric output of acid and pepsin to ensure the release of food cobalamin. Failure of this mechanism is believed to be responsible for a condition more common in the elderly known as *food cobalamin malabsorption*, but there is no definitive proof of this. The syndrome has also been described in association with *H. pylori* infection, long-term use of histamine H₂-receptor antagonists and proton-pump inhibitors, chronic alcoholism, pancreatic exocrine failure, Sjögren syndrome and systemic sclerosis. The syndrome is associated with low serum cobalamin levels, with or without evidence of cobalamin deficiency, such as raised serum levels of methylmalonic acid and homocysteine. A minority of patients with food cobalamin malabsorption may go on to develop clinically significant cobalamin deficiency including polyneuropathy, confusion, dementia and subacute combined degeneration of the cord and anaemia, but the frequency of occurrence and reasons for this progression are not clear.

Intestinal causes of cobalamin malabsorption

Malabsorption of cobalamin occurs in a variety of intestinal lesions in which there is colonization of the upper small intestine by faecal organisms. This may occur in patients with jejunal diverticulosis, enteroanastomosis, intestinal stricture or fistula, or with an anatomical blood loop due to Crohn's disease, tuberculosis or an operative procedure. Bacterial overgrowth in the small intestine may also cause spurious elevation of serum methylmalonate (see below). Some bacteria produce copious quantities of propionate, the immediate precursor of methylmalonate. Removal of 1.2 m or more of terminal ileum causes malabsorption of cobalamin. In some patients, following ileal resection, particularly if the ileocaecal valve is incompetent, colonic bacteria may contribute further to the onset of cobalamin deficiency.

Nearly all patients with acute and subacute tropical sprue show malabsorption of cobalamin; this may persist as the principal abnormality in the chronic form of the disease, when the patient may present with megaloblastic anaemia or neuropathy due to cobalamin deficiency. Absorption of cobalamin usually improves after antibiotic therapy and, in the early stages, after folic acid therapy. Malabsorption of cobalamin occurs in about 30% of untreated patients with gluten-induced enteropathy and correlates with the degree of steatorrhoea. Cobalamin defi-

ciency is not usually severe in these patients and is probably never the cause of megaloblastic anaemia unless another lesion causing malabsorption of cobalamin (e.g. stagnant loop syndrome) is present. The absorption improves when these patients are treated with a gluten-free diet.

Selective malabsorption of cobalamin with proteinuria (also known as Imerslünd syndrome, Imerslünd–Grasbeck syndrome, congenital cobalamin malabsorption or autosomal recessive megaloblastic anaemia MGA1) is an autosomal recessive disease and is the most common cause of megaloblastic anaemia due to cobalamin deficiency in infancy in Western countries. More than 200 cases have been reported, with familial clusters in Finland, Norway, the Middle East and North Africa. The patients usually present with megaloblastic anaemia between the ages of 1 and 5 years, and secrete normal amounts of IF and gastric acid. In some cases, such as in Finland, impaired synthesis, processing or ligand binding of cubilin due to inherited mutations, for example 391C→T (named FM1) and a mutation at an intron causing a truncated protein (FM2), have been implicated. In others, for example in Norway, mutation of the gene for AMN has been reported. Other tests of intestinal absorption are normal. Over 90% of these patients show non-specific proteinuria but renal function is otherwise normal and renal biopsy has not shown any consistent renal defect. A few of these patients have shown aminoaciduria and congenital renal abnormalities, such as duplication of the renal pelvis.

The fish tapeworm (*Diphyllobothrium latum*) lives in the small intestine of humans and accumulates cobalamin from food, rendering this unavailable for absorption. People acquire the worm by eating raw or partly cooked fish. Infestation is common around the lakes of Scandinavia, Germany, Japan, North America and Russia. Megaloblastic anaemia or cobalamin neuropathy occurs only in those with a heavy infestation, with the worm high in the small intestine. Many carriers have no cobalamin deficiency.

In severe chronic pancreatitis, lack of trypsin is thought to be the reason why dietary cobalamin attached to gastric non-IF (R) binder is unavailable for absorption. It has also been proposed that in pancreatitis, the concentration of calcium ions in the ileum falls below the level needed to maintain normal cobalamin absorption.

Serum cobalamin levels tend to fall in patients with HIV infection and are subnormal in 10–35% of those with AIDS. Increased levels of apoTC, possibly derived from macrophages, are usual. Malabsorption of crystalline cobalamin not corrected by IF has been shown in some, but not all, patients with subnormal serum cobalamin levels. Cobalamin deficiency sufficiently severe to cause megaloblastic anaemia or neuropathy is rare.

Malabsorption of cobalamin has been reported in Zollinger–Ellison syndrome. It is thought that there is a failure to release cobalamin from R binding protein due to inactivation of pancreatic trypsin by high acidity, as well as interference with IF binding of cobalamin.

Both total body irradiation and local radiotherapy to the ileum (e.g. as a complication of radiotherapy for carcinoma of the cervix) may cause malabsorption of cobalamin. Graft-versus-host disease commonly affects the small intestine: malabsorption of cobalamin due to abnormal gut flora, as well as damage to ileal mucosa, is frequent.

Neomycin, colchicine, phenytoin, *p*-aminosalicylic acid, phenformin, metformin, slow-release potassium chloride and alcohol have all been reported to cause malabsorption of cobalamin; rarely, megaloblastic anaemia due to cobalamin deficiency has been reported with phenformin therapy. The use of histamine H₂-blockers for treatment of peptic ulcer disease causes a decrease in cobalamin absorption, and continued use may lead to lowering of the serum cobalamin level.

Both severe cobalamin and folate deficiencies affect the function of the small intestine; malabsorption of cobalamin due to ileal dysfunction may be found in patients with either deficiency. It may take several weeks of cobalamin therapy to correct the ileal absorptive defect in patients with PA. Deficiencies of protein, riboflavin and pyridoxine have also been reported to cause malabsorption of cobalamin.

Abnormalities of cobalamin metabolism

Congenital transcobalamin deficiency or abnormality

Infants with TC deficiency usually present with megaloblastic anaemia within a few weeks of birth. Serum cobalamin and folate levels are normal but the anaemia responds to massive (e.g. 1 mg three times weekly) injections of cobalamin, which cause free cobalamin to enter marrow cells by passive diffusion in the absence of functional TC. Some cases show neurological complications. In some cases, the protein is present in normal amounts but is unable to bind cobalamin or to attach to the cell surface and so is functionally inert. Genetic abnormalities so far found include mutations of an intra-exonic cryptic splice site, extensive or single nucleotide deletion, nonsense mutation and an RNA editing defect. These infants do not show methylmalonic aciduria, but malabsorption of cobalamin occurs in all cases and reduced immunoglobulins in some. Less severe cases present later in childhood. Failure to institute adequate cobalamin therapy or treatment with folic acid may lead to neurological damage.

Congenital methylmalonic acidemia and aciduria

Infants with this abnormality are ill from birth, with vomiting, failure to thrive, severe metabolic acidosis, ketosis and mental retardation. Anaemia, if present, is normocytic and normoblastic. The condition may arise as a result of a functional defect in either the mitochondrial methylmalonyl-CoA mutase or its cofactor ado-cobalamin (see Figure 5.2). Mutations in methylmalonyl-CoA mutase are not responsive, or only poorly responsive, to treatment with cobalamin. Two disorders result in

cobalamin-responsive methylmalonic acidemia. In cobalamin (Cbl)A disease, there is failure of reduction of cobalamin III (Cbl³⁺) or cobalamin II (Cbl²⁺) to cobalamin I (Cbl¹⁺) in mitochondria; in CblB disease, there is a defect of an adenosyltransferase required for synthesis of ado-cobalamin (see Figure 5.2). A proportion of infants with CblA and CblB disease respond to cobalamin in large doses, whereas others are unresponsive. In those who do not respond to cobalamin, the enzyme methylmalonyl-CoA mutase is lacking (mut⁰) or defective (mut⁻). Some children have combined methylmalonic aciduria and homocystinuria due to defective formation of both cobalamin coenzymes. The defects are in the transfer of cobalamin from the endocytic compartment of lysosomes to the cytoplasm (CblF disease) or in the reduction of cobalamin 3⁺ to cobalamin 2⁺ after transfer to the cytoplasm (CblC and CblD diseases). Over 100 cases of CblC disease have been described. It usually presents in the first year of life with feeding difficulties, developmental delay, microcephaly, seizures, hypotonia and megaloblastic anaemia.

Some patients present with homocystinuria and megaloblastic anaemia, often with neurological defects but without methylmalonic aciduria. There is a selective deficiency of methylcobalamin. These conditions have been termed CblE and CblG disease (lack of association of methylcobalamin with methionine synthase).

Acquired abnormality of cobalamin metabolism: nitrous oxide inhalation

N₂O irreversibly oxidizes methylcobalamin from its active, fully reduced Cbl¹⁺ state to an inactive Cbl²⁺ precursor. This has been shown to inactivate methylcobalamin and methionine synthase. This occurs in both humans and experimental animals and was of importance in the megaloblastic anaemia that occurred in patients undergoing prolonged N₂O anaesthesia (e.g. in intensive care units). A neuropathy resembling cobalamin neuropathy has been described in dentists and anaesthetists who are repeatedly exposed to N₂O and in monkeys exposed to the gas for many months. In patients with low cobalamin stores, megaloblastic anaemia or cobalamin neuropathy may be precipitated after shorter exposure to N₂O. Recovery from N₂O exposure requires regeneration of methionine synthase, as this protein is damaged by active oxygen derived from the N₂O-cobalamin reaction. Methylmalonic aciduria does not occur at first as ado-cobalamin is not inactivated by N₂O. Later, however, after generalized depletion of cobalamin, methylmalonate levels in serum, urine and cerebrospinal fluid rise.

Diagnosis of cobalamin deficiency

The diagnosis of cobalamin or folate deficiency has traditionally depended on the recognition of the relevant abnormalities in the peripheral blood and/or bone marrow and subsequent

analysis of the blood levels of the vitamins. Other causes of macrocytosis and hypersegmented neutrophils are listed in Table 5.3. However, assays of serum methylmalonic acid and homocysteine (see below) have shown these to be raised in some subjects without haematological abnormalities, including a proportion with normal levels of serum cobalamin and folate in whom, nevertheless, the levels of the metabolites fall to normal with cobalamin and/or folate therapy. The significance of these biochemical changes remains controversial. They may imply functional cobalamin or folate deficiency, not reflected by subnormal levels of the vitamins or by disturbed haemopoiesis. If so, it would imply that the accepted normal serum and red cell levels of the vitamins reflect body stores which are sufficiently high to prevent haematological changes but which in some subjects may not be optimal for prevention of other complications of the deficiencies including vascular disease and NTDs in the fetus.

Measurement of serum cobalamin

Serum cobalamin is usually measured by one of a number of enzyme-linked immunosorbent assays. These are frequently automated. Normal serum cobalamin levels range from 160–200 ng/L to about 1000 ng/L ($\text{ng} \times 0.738 = \text{pmol}$, so 200 ng/L = 148 pmol/L). In patients with megaloblastic anaemia due to cobalamin deficiency, the level is usually less than 100 ng/L. In general, the more severe the deficiency, the lower the serum cobalamin level. In patients with spinal cord damage due to the deficiency, levels are very low even in the absence of anaemia. Values of between 100 and 200 ng/L are regarded as borderline. They may occur, for instance, in pregnancy, in patients with megaloblastic anaemia due to folate deficiency, and in patients with heterozygous, homozygous or compound heterozygous mutations of the *TCN1* gene that codes for HC (TCI). The relative concentrations of HC and TC also influence the total serum cobalamin level. Raised serum cobalamin levels (if not due to recent therapy) are usually due to a rise in HC (Table 5.4), or to liver or renal disease with increased saturation of HC and TC.

Serum holotranscobalamin (holoTCII, holoTC)

Since TC is the plasma cobalamin transport protein that is responsible for cellular uptake and delivery of cobalamin, the notion was put forward that measurement of circulating cobalamin that was bound to TC (holoTC) would provide a more meaningful measure of cobalamin status than total serum cobalamin. However, measurement of holoTC is not available or used diagnostically except in research studies.

Serum methylmalonate and homocysteine levels

In patients with cobalamin deficiency sufficient to cause anaemia or neuropathy, the serum methylmalonate (MMA) and homocysteine levels are raised. Sensitive methods for measuring MMA and homocysteine in serum have been introduced and recommended for the early diagnosis of cobalamin defi-

ciency, even in the absence of haematological abnormalities or subnormal levels of serum cobalamin or folate. However, serum MMA fluctuates in patients with renal failure. Mildly elevated serum MMA and/or homocysteine levels occur in up to 30% of apparently healthy volunteers, with serum cobalamin levels up to 350 ng/L and normal serum folate levels; 15% of elderly subjects, even with cobalamin levels above 350 ng/L, have this pattern of raised metabolite levels. These findings bring into question the exact cut-off points for normal MMA and homocysteine levels. It is also unclear at present whether these mildly raised metabolite levels have clinical consequences and how many of the subjects will progress to clinically overt cobalamin deficiency. When cobalamin supplies to the cell are suboptimal, there may be preferential use of methylcobalamin for methionine synthesis compared with ado-cobalamin for MMA metabolism. Urinary MMA excretion may also be used to screen for cobalamin deficiency but this is also increased in aminoaciduria (e.g. Fanconi syndrome).

Homocysteine exists in plasma as single molecules, as two molecules linked together (homocystine) and as mixed homocysteine–cysteine disulphides. Serum homocysteine levels are raised in both early cobalamin and folate deficiency, but they may be raised in other conditions, for example chronic renal disease, alcoholism, smoking, pyridoxine deficiency, hypothyroidism, therapy with steroids, ciclosporin and other drugs. Levels are also higher in serum than in plasma, in men than in premenopausal women, in women taking hormone replacement therapy or oral contraceptive users and in elderly subjects and patients with several inborn errors of metabolism affecting enzymes in trans-sulphuration pathways of homocysteine metabolism. Thus, homocysteine levels are not widely used for diagnosis of cobalamin or folate deficiency. However, homocysteine levels are used in thrombophilia screening and in assessing for cardiovascular risk factors (see Chapter 46).

Tests for the cause of cobalamin deficiency

Studies of cobalamin absorption were used but because of the unavailability of radioactive cobalamin have become obsolete. The urinary excretion (Schilling) test is therefore only briefly described here. Serum tests for gastrin and antibodies to parietal cells and intrinsic factor aid in the diagnosis of PA. Upper GI endoscopy including gastric biopsy helps to confirm the diagnosis and exclude gastric neoplasms.

Cobalamin absorption

The urinary secretion (Schilling) test was carried out with an oral trace dose of crystalline radioactive cyanocobalamin with or without oral IF and a ‘flushing’ intramuscular dose of hydroxocobalamin or cyanocobalamin so that any labelled cobalamin absorbed would appear in a 24-hour urine. Radioactive cyanocobalamin is no longer available and the test

is obsolete, as are similar tests of food absorption using radioactively labelled cobalamin.

Folate

Dietary folate

Folic acid (pteroylglutamic acid) is a yellow, crystalline, water-soluble substance (molecular weight 441). It is the parent compound of a large family of folate compounds. Pteroylglutamic acid consists of three parts: pteridine, *p*-aminobenzoate and γ -glutamic acid (Figure 5.8). It is only a minor component of normal food folates (probably less than 1%), which differ from it in three respects (Figure 5.8): (i) they are partly or completely reduced at positions 4, 5, 7 and 8 in the pteridine portion to dihydrofolate or THF derivatives; (ii) they usually contain a single carbon unit of varying degrees of reduction, such as a methyl group at N-5 or N-10; and (iii) 70–90% of natural folates contain a chain of three or more glutamate residues linked to each other by the unusual γ -peptide bond and are called pteroyl- or folate-polyglutamates. In human cells, four, five and six glutamate residues are usual.

Most foods contain some folate. The highest concentrations are found in liver and yeast (>200 μg per 100 g), spinach, other greens and nuts (>100 μg per 100 g). The total folate content of an average Western diet is about 250 μg daily, but the amount varies widely according to the type of food eaten and the method of cooking. Folate is easily destroyed by heating, particularly in large volumes of water; over 90% may be lost.

Body stores and requirements

Total body folate in the adult is about 10 mg, the liver containing the largest store. Daily adult requirements are about 100 μg . Up to 13 μg of folate is lost as such in the urine each day, but breakdown products of folate are also lost in urine. Losses of folate also occur in sweat and skin; faecal folate is largely derived from colonic bacteria. Stores are only sufficient for about 4 months in normal adults, so severe folate deficiency may develop rapidly.

Absorption

The principal site of folate absorption is the upper small intestine, and there is a steep fall-off in absorptive capacity in the lower jejunum and ileum. The absorption of all forms tested is rapid, a rise in blood level occurring within 15–20 min of ingestion.

The small intestine has a tremendous capacity to absorb folate monoglutamates: about 90% of a single dose is absorbed regardless of whether this is small (100 μg) or large (15 mg). A proton-coupled high-affinity folate transporter with a low pH optimum, termed PCFT/HCP1, is located at the apical brush border of the duodenal, and to a lesser extent jejunal mucosa and in other cells, including the blood–brain barrier. It accounts for the bulk of folate absorption including of folic acid itself, and loss of function in hereditary folate malabsorption is not compensated by other folate transporters expressed on intestinal cells.

The absorption of folate polyglutamates with higher numbers of glutamate residues is less. This may be due to the limited capacity of the small intestine to hydrolyse these compounds or to their limited transfer in the mucosal cell. On average, about 50% of food folates is absorbed.

Polyglutamate forms are hydrolysed by pteroylpolyglutamate hydrolase (PPH, also known as folylpoly- γ -glutamate carboxypeptidase) to the monoglutamate derivatives, either in the lumen of the intestine or within the mucosa; they do not enter portal blood intact. Monoglutamate or polyglutamate forms of dietary folate, which are already partly or completely reduced, are converted to 5-methyl-THF within the small intestinal mucosa before entering the portal plasma. The monoglutamates are actively transported across the enterocyte by a carrier-mediated mechanism. Pteroylglutamic acid at doses greater than 400 μg is absorbed largely unchanged and converted to natural folates in the liver. Lower doses are converted to 5-methyl-THF during absorption through the intestine.

Enterohepatic circulation

About 60–90 μg of folate enters the bile each day and is excreted into the small intestine. Loss of this folate, together with the folate of sloughed intestinal cells, accelerates the speed with which folate deficiency develops in malabsorption conditions.

Figure 5.8 The structure of folic acid (pteroylglutamic acid).

Transport

Folate is transported in plasma, about one-third loosely bound to albumin and two-thirds unbound. In all body fluids (plasma, cerebrospinal fluid, milk, bile) folate is largely, if not entirely, 5-methyl-THF in the monoglutamate form. A carrier-mediated active process is involved in the entry of folate into cells, the rate of uptake being linked to the rate of folate polyglutamate synthesis in the cell, which in replicating cells is related to the rate of DNA synthesis. Reduced folates are more rapidly taken up than oxidized folates. In most cells, folates are retained with tight binding to folate-binding proteins, three of which are enzymes involved in methyl group metabolism (sarcosine dehydrogenase, dimethylglycine dehydrogenase and glycine *N*-methyltransferase), until the cell dies. Intact liver cells can release folate. Two types of folate-binding protein are involved in entry of methyl-THF into cells. The reduced folate carrier SLC19A1 is a facilitative transporter with a pH optimum of 7.4 and the characteristics of an anion exchanger. Two glycosylphosphatidylinositol (GPI)-linked folate receptors mediate cellular folate uptake by an endocytic mechanism, with internalization in a vesicle (caveola) which is then acidified, releasing folate into the vesicle lumen. Folate is then carried by the membrane folate transporter PCFT/HCP1 into the cytoplasm; the caveola recycles to the cell surface, where its high-affinity receptors are reutilized. The GPI-linked transporters may be involved in transport of oxidized folates and folate breakdown products to the liver for excretion in bile.

Biochemical functions

Folates (as the intracellular polyglutamate derivatives) act as coenzymes in the transfer of single-carbon units from one compound to another (see Figure 5.3 and Table 5.2). Two of these reactions are involved in purine and one in pyrimidine synthesis necessary for DNA and RNA replication. Folate is coenzyme in another reaction, methionine synthesis, in which cobalamin is also involved and THF is regenerated. THF is the acceptor of single-carbon units newly entering the active pool via conversion of serine to glycine. Methionine, the other product of the methionine synthase reaction, is the precursor for SAM, the universal methyl donor involved in over 100 methyltransferase reactions.

During thymidylate synthesis, 5,10-methylene-THF is converted to dihydrofolate (Figure 5.3). The enzyme dihydrofolate reductase converts this to THF. The drugs methotrexate, pyrimethamine and, mainly in bacteria, trimethoprim inhibit dihydrofolate reductase, and this prevents formation of the active folate coenzymes from dihydrofolate. A small fraction of the folate coenzyme is not recycled during thymidylate synthesis but is degraded at the C-9–N-10 bond.

Table 5.7 Causes of folate deficiency.

Dietary

Particularly in old age, infancy, poverty, alcoholism, chronic invalids and the psychiatrically disturbed; may be associated with scurvy or kwashiorkor

Malabsorption

Major causes of deficiency

Tropical sprue, gluten-induced enteropathy in children and adults, and in association with dermatitis herpetiformis, specific malabsorption of folate, intestinal megaloblastosis caused by severe cobalamin or folate deficiency

Minor causes of deficiency

Extensive jejunal resection, Crohn's disease, partial gastrectomy, congestive heart failure, Whipple disease, scleroderma, amyloid, diabetic enteropathy, systemic bacterial infection, lymphoma, sulfasalazine

Excess utilization or loss

Physiological

Pregnancy and lactation, prematurity

Pathological

Haematological diseases: chronic haemolytic anaemias, sickle cell anaemia, thalassaemia major, myelofibrosis

Malignant diseases: carcinoma, lymphoma, leukaemia, myeloma

Inflammatory diseases: tuberculosis, Crohn's disease, psoriasis, exfoliative dermatitis, malaria

Metabolic disease: homocystinuria

Excess urinary loss: congestive heart failure, active liver disease

Haemodialysis, peritoneal dialysis

Antifolate drugs

Anticonvulsant drugs (phenytoin, primidone, barbiturates), sulfasalazine

Nitrofurantoin, tetracycline, anti-tuberculosis (less well documented)

Mixed causes

Liver diseases, alcoholism, intensive care units

Note: In severely folate-deficient patients with causes other than those listed under Dietary, poor dietary intake is often present.

Causes of folate deficiency (Table 5.7)

Nutritional

Dietary folate deficiency is common. Indeed, in most patients with folate deficiency a nutritional element is present. Certain individuals are particularly likely to have diets containing inadequate amounts of folate, including the old, edentulous, poor, alcoholic and psychiatrically disturbed, and patients after gastric operations. In relation to the size of the total body folate stores,

which are in the order of 15–25 mg, the daily requirement of 100–200 mg is large. Consequently, with total cessation of intake or absorption, depletion of stores will occur in 3–6 months. In the USA and other countries where fortification of the diet with folic acid has been adopted to reduce the incidence of NTDs, the prevalence of folate deficiency has dropped dramatically and is now almost restricted to high-risk groups with increased folate needs. Nutritional folate deficiency occurs in kwashiorkor and scurvy, and in infants with repeated infections or who are fed solely on goats' milk, which has a low folate content (6 µg/L) compared with human or cows' milk (50 µg/L) as well as high concentrations of a high-affinity folate-binding protein.

Malabsorption

Malabsorption of dietary folate occurs in tropical sprue and in gluten-induced enteropathy in children and in adults, when it is associated with dermatitis herpetiformis. In the rare recessive congenital syndrome of selective malabsorption of folate, there is an associated defect of folate transport into the cerebrospinal fluid, and these patients show megaloblastic anaemia from the age of a few months, responding to physiological doses of folic acid given parenterally but not orally or large oral doses of 5-formyl-THF. These patients also show mental retardation, convulsions and other central nervous system abnormalities. Loss-of-function mutations, usually homozygous in the gene coding for the low pH transporter PCFT/HCP1, underlie the disease. Minor degrees of malabsorption may also occur following jejunal resection or partial gastrectomy, in Crohn's disease and in systemic infections but, in these conditions, if severe deficiency occurs, it is usually largely due to poor nutrition.

Malabsorption of folate has been described in patients receiving sulfasalazine, cholestyramine and triamterene. It has also been associated with anticonvulsant drug therapy, alcohol abuse and folate deficiency, but these relationships are less well established. In the intestinal stagnant loop syndrome, the predominant effect of the small intestinal bacteria is to cause a rise in serum, red cell and urinary folate by synthesizing folate, which is then absorbed.

Excess utilization or loss

Pregnancy

Folate requirements are increased by 200–300 µg to about 400 µg daily in a normal pregnancy, partly because of transfer of the vitamin to the fetus, but mainly because of increased folate catabolism due to cleavage of folate coenzymes in rapidly proliferating tissues at the C-9–N-10 bond. Megaloblastic anaemia due to this deficiency is now largely prevented by prophylactic folic acid therapy. It occurred in 0.5% of pregnancies in the UK and other Western countries, but the incidence is much higher in countries where the general nutritional status is poor. The deficiency is more common in pregnant women who also suffer from iron deficiency, probably because these

patients have a poor diet. The usual presentation of the anaemia is similar to that of other megaloblastic anaemias, but occasionally, when there is an associated infection, acute arrest of haemopoiesis with pancytopenia may occur; this resembles aplastic anaemia, except that the marrow shows obvious megaloblastic changes.

A number of consequences of folate deficiency in pregnancy have been described, including antenatal and postpartum haemorrhages, prematurity and congenital malabsorption in the fetus. These have not been fully established, but several studies have shown that prophylactic folic acid therapy reduces the incidence of NTDs (see p. 64).

Prematurity

The newborn infant, whether full term or premature, has higher serum and red cell folate concentrations than the adult, but the newborn infant's demand for folate has been estimated to be up to 10 times that of adults on a weight basis and the neonatal folate level falls rapidly to the lowest values at about 6 weeks of age. The falls are steepest and liable to reach subnormal levels in premature babies, a number of whom develop megaloblastic anaemia responsive to folic acid at about 4–6 weeks of age. This occurs particularly in the smallest babies (<1500 g birth weight) and in those who have feeding difficulties or infections, or who have undergone multiple exchange transfusions. In these babies, prophylactic folic acid should be given.

Haematological disorders

Folate deficiency frequently occurs in chronic haemolytic anaemia, particularly in sickle cell disease, autoimmune haemolytic anaemia and congenital spherocytosis. In these and other conditions of increased cell turnover, folate deficiency arises because it is not completely reutilized after performing coenzyme functions, and it is partly lost as pteridines in the urine due to cleavage at the C-9–N-10 bond. Patients with primary myelofibrosis may develop folate deficiency at some stage of the illness. There is also a high incidence of mild folate deficiency in patients with leukaemia, lymphoma, myeloma or carcinoma, although it is unusual for this to progress to megaloblastic anaemia. Treatment with folic acid should be avoided (as it may 'feed' the tumour) unless severe megaloblastic anaemia due to folate deficiency is clinically important.

Inflammatory conditions

Chronic inflammatory diseases, such as tuberculosis, rheumatoid arthritis, Crohn's disease, psoriasis, exfoliative dermatitis, bacterial endocarditis and chronic bacterial infections, cause deficiency by reducing the appetite and by increasing the demand for folate. Systemic infections may also cause malabsorption of folate. Severe deficiency is virtually confined to those patients with the most active disease and the poorest diet. Fever *per se* has also been suggested to interfere with folate metabolism by inhibiting temperature-dependent folate enzymes. In patients with subclinical folate deficiency from

causes other than infections, intercurrent infections often precipitate severe megaloblastic anaemia.

Homocystinuria

This is a rare metabolic defect in the conversion of homocysteine to cystathionine. Folate deficiency occurring in most of these patients may be due to excessive utilization because of compensatory increased conversion of homocysteine to methionine.

Long-term dialysis

As folate is only loosely bound to plasma proteins, it is easily removed from plasma by haemodialysis or peritoneal dialysis (in contrast, cobalamin is not removed from plasma by dialysis as it is firmly protein bound). The amount of body folate that can be removed in this way is relatively small. Nevertheless, in patients with anorexia, vomiting, infections and haemolysis, folate stores may become depleted and megaloblastic anaemia can supervene. Routine folate prophylaxis is now given.

Congestive heart failure, liver disease

Excess urinary folate losses of more than 100 µg per day may occur in some of these patients. The explanation appears to be release of folate from damaged liver cells.

Antifolate drugs

A large number of epileptics who are receiving long-term therapy with phenytoin (Dilantin) or primidone (Mysoline), with or without barbiturates, develop low serum and red cell folate levels. In some of these patients, megaloblastic anaemia supervenes. A number of mechanisms have been suggested: inhibition of folate absorption, inhibition of the action or synthesis of folate-dependent enzymes, displacement of folate from its plasma transport protein and induction of folate-utilizing enzymes. A dietary element is present in the patients with the severest deficiencies.

Alcohol may also be a folate antagonist, as patients who are drinking spirits may develop megaloblastic anaemia that will respond to normal quantities of dietary folate or to physiological doses of folic acid only if the alcohol is withdrawn. Chronic alcohol intake is associated with macrocytosis even when folate levels are normal. Inadequate folate intake is the major factor in the development of deficiency in spirit-drinking alcoholics. Beer is relatively folate-rich in some countries, depending on the technique used for brewing.

The drugs that inhibit dihydrofolate reductase include methotrexate, pyrimethamine and trimethoprim. Methotrexate has the most powerful action against the human enzyme, whereas trimethoprim is most active against the bacterial enzyme and is only likely to cause megaloblastic anaemia when used in conjunction with sulfamethoxazole in patients with pre-existing folate or cobalamin deficiency. The activity of pyrimethamine

is intermediate. The antidote to these drugs is folinic acid (5-formyl-THF).

Congenital abnormalities of folate metabolism

A number of infants have been described with congenital defects of folate enzymes (e.g. cyclohydrolase or methionine synthase). Some had megaloblastic anaemia.

Diagnosis of folate deficiency

Serum folate

This is measured by an enzyme-linked immunosorbent assay (ELISA). The serum folate level is low in all folate-deficient patients. In most laboratories, the normal range is from 2.0 µg/L (11 nmol/L) to about 15 µg/L. The serum folate is markedly affected by recent diet; inadequate intake for as little as 1 week may cause the level to become subnormal.

The serum folate level rises in severe cobalamin deficiency because of blockage in conversion of methyl-THF, the major circulating form, to THF; raised levels have also been reported in the intestinal stagnant loop syndrome, acute renal failure and active liver damage. (High levels are also obtained when the patient is receiving folic acid therapy, when the serum is contaminated with folate or folate-producing bacteria or, if a sample is haemolysed, because of the high concentration of folate in red cells.)

Red cell folate

The red cell folate assay is a valuable test of body folate stores. It is less affected by recent diet and traces of haemolysis than is the serum assay. In normal adults, concentrations range from 160 to 640 µg/L of packed red cells. Subnormal levels occur in patients with megaloblastic anaemia due to folate deficiency but also occur in nearly two-thirds of patients with megaloblastic anaemia due to cobalamin deficiency. If cobalamin deficiency is excluded, however, a low red cell folate can be used as an indication that severe folate deficiency is present and warrants full investigation and treatment. False normal results may occur if the folate-deficient patient has received a recent blood transfusion (as the folate content of the transfused red cells will be measured) or if the patient has a raised reticulocyte count (e.g. due to haemorrhage or haemolytic anaemia).

Serum homocysteine (see p. 75)

General management of megaloblastic anaemia

It is usually possible to establish which of the two deficiencies, folate or cobalamin, is the cause of the anaemia and to treat only with the appropriate vitamin. In patients who enter hospital severely ill, however, it may be necessary to treat with both

vitamins in large doses once blood samples have been taken for cobalamin and folate assay and a bone marrow has been performed (if deemed necessary). Transfusion is usually unnecessary and inadvisable. If it is essential, packed red cells should be given slowly and one or two units will be ample. Exchange transfusion, as well as the usual treatment for heart failure, should be considered in patients with extreme anaemia and congestive heart failure. Platelet concentrates are of value in reducing spontaneous bleeding in the rare patients with severe thrombocytopenia. Potassium supplements have been recommended to obviate the danger of the hypokalaemia that has been recorded in some patients during the initial haematological response, but there is little evidence for this.

Treatment of cobalamin deficiency

It is usually necessary to treat patients who have developed cobalamin deficiency with lifelong regular cobalamin therapy. In the UK, the form used is hydroxocobalamin; in the USA cyanocobalamin is used. In a few instances, the underlying cause of cobalamin deficiency can be permanently corrected, for instance the fish tapeworm, tropical sprue or an intestinal stagnant loop that is amenable to surgery.

The indications for starting cobalamin therapy are a well-documented megaloblastic anaemia or neuropathy due to the deficiency. It is also necessary to treat any patients with haematological abnormalities due to cobalamin deficiency, even in the absence of anaemia (e.g. hypersegmented neutrophils or megaloblastic erythropoiesis). Patients with borderline serum cobalamin levels but no haematological or other abnormality should if practicable be followed, for example at yearly intervals, to ensure that the cobalamin deficiency does not progress. If malabsorption of cobalamin or rises in serum MMA levels have also been demonstrated, patients should also be given regular maintenance cobalamin therapy. Cobalamin should be given routinely to all patients who have had a total gastrectomy or ileal resection. Patients who have undergone gastric reduction for control of obesity or who are receiving long-term treatment with proton pump inhibitors should be screened and given cobalamin replacement as necessary.

Replenishment of body stores should be complete with six 1000- μg intramuscular injections of *hydroxocobalamin* given at 3–7 day intervals. More frequent doses are usually used in patients with cobalamin neuropathy, but there is no evidence that these produce a better response. For maintenance therapy, hydroxocobalamin 1000 μg i.m. once every 3 months is satisfactory. In the USA, hydroxocobalamin has not yet been approved and marketed for purposes of routine cobalamin replacement. Because of the poorer retention of cyanocobalamin maintenance treatment, protocols generally use higher and more frequent doses (1000 μg i.m. monthly).

Toxic reactions to cobalamin therapy are extremely rare and are usually due to contamination in its preparation rather than

to cobalamin itself. Even when there is complete failure of the physiological IF-dependent mechanism, large daily oral doses (1000 μg) of cyanocobalamin can be used for replacement and maintenance of normal cobalamin status, for example in those who cannot have injections. If this approach is used, it is important to monitor compliance, particularly with elderly forgetful patients. Sublingual and nasal routes have also been proposed but no long-term follow-up data are available.

Treatment of folate deficiency

There is probably never any need to give folic acid parenterally, except in patients receiving parenteral nutrition who cannot swallow tablets. Oral doses of 5–15 mg folic acid daily are satisfactory, as sufficient folate is absorbed from these extremely large doses even in patients with severe malabsorption. The length of time therapy must be continued depends on the underlying disease. It is customary to continue therapy for about 4 months, when all folate-deficient red cells will have been eliminated and replaced by new folate-replete populations.

Before large doses of folic acid are given, cobalamin deficiency must be excluded and, if present, corrected, otherwise cobalamin neuropathy may develop, despite response of the anaemia of cobalamin deficiency to folate therapy. Studies suggest that there has been no increase in the proportion of subjects with low serum cobalamin levels and no anaemia since fortification of the diet in the USA.

Long-term folic acid therapy is required when the underlying cause of the deficiency cannot be corrected and the deficiency is likely to recur, for instance in chronic haemolytic anaemias such as thalassaemia major and sickle cell anaemia, and in primary myelofibrosis. It may also be necessary in gluten-induced enteropathy if this does not respond to a gluten-free diet. Where mild but chronic folate deficiency occurs, it is preferable to encourage any improvement in the diet after correcting the deficiency with a short course of folic acid. In any patient receiving long-term folic acid therapy, it is important to measure the serum cobalamin level at regular (e.g. once yearly) intervals to exclude the coincidental development of cobalamin deficiency.

Folinic acid (5-formyl-THF)

This is a stable form of fully reduced folate. It is given orally or parenterally to overcome the toxic effects of methotrexate or other dihydrofolate reductase inhibitors (as present in co-trimoxazole).

Prophylactic folic acid

In many countries, food is fortified with folic acid (in grain or flour) to reduce the incidence of NTDs. As yet there is no defi-

nite proof that folic acid prevents cardiovascular (other than stroke), neurological or psychiatric disease. There is some evidence it may reduce the risk of certain forms of cancer, but this remains controversial.

Pregnancy

Folic acid 400 µg daily should be given as a supplement throughout pregnancy. In women who have had a previous fetus with an NTD, 5 mg daily is recommended when pregnancy is contemplated and throughout the subsequent pregnancy. In women of childbearing age, a supplementary intake of folic acid 400 µg daily is recommended, so that this extra intake will be present from conception.

Prematurity

The incidence of folate deficiency is so high in the smallest premature babies during the first 6 weeks of life that folic acid (e.g. 1 mg daily) should be given routinely to babies weighing less than 1500 g at birth and to larger premature babies who require exchange transfusions or develop feeding difficulties, infections or vomiting and diarrhoea.

Haemolytic anaemia and dialysis

Prophylactic folic acid is usually also given to patients with chronic haemolytic anaemia or those who are undergoing long-term haemodialysis.

Megaloblastic anaemia not due to cobalamin or folate deficiency or altered metabolism

This may occur with many antimetabolic drugs (e.g. hydroxycarbamide, cytarabine, 6-mercaptopurine) that inhibit DNA replication at a particular point in the supply of precursors or by inhibiting DNA polymerase. In the rare disease orotic aciduria, two consecutive enzymes in purine synthesis are defective. The condition responds to therapy with uridine, which bypasses the block. In thiamine-responsive megaloblastic anaemia, there is a genetic defect in the high-affinity thiamine transport (*SLC19A2*) gene. This causes defective RNA ribose synthesis through impaired activity of transketolase, a thiamine-dependent enzyme in the pentose cycle. This leads to reduced nucleic acid production and consequent induction of cell cycle arrest or apoptosis. It may be associated with diabetes mellitus and deafness and the presence of many ringed sideroblasts in the marrow (see p. 44). The biochemical explanation is unclear for megaloblastic changes in the marrow in patients with acute myeloid leukaemia, and other leukaemias and myelodysplasia in the absence of cobalamin or folate deficiency.

Other nutritional anaemias

Protein deficiency

Anaemia is usual in children and adults with severe protein deficiency (kwashiorkor). The anaemia, which may be partly masked by haemoconcentration, is usually normoblastic, but megaloblastic changes have been described in 10–60% of patients in different series. Hypoplasia, or even aplasia, of the marrow has also been reported. The mechanism by which protein deficiency causes anaemia is not completely understood. Lack of protein does not seem to reduce haemoglobin synthesis directly. Studies in experimental animals suggest that the major factor is diminution of erythropoietin secretion. This is probably due to a reduction in general tissue metabolism and therefore oxygen consumption, with a consequent reduced stimulus for erythropoietin secretion. In most patients, other factors contribute to the anaemia. These include infections, deficiencies of folate and iron, and also, possibly, deficiencies of vitamins C, E and B₁₂ and other trace substances. Riboflavin deficiency may also contribute to the anaemia and become apparent only during the response to protein.

Scurvy

There is usually a moderate or severe normocytic, normochromic anaemia in scurvy because of external haemorrhage and haemorrhage into tissues, and from impaired erythropoiesis. In some patients, the anaemia is megaloblastic, which appears to be partly due to associated nutritional folate deficiency and partly due to impairment of folate metabolism caused by vitamin C deficiency. However, vitamin C is not established as playing a role in normal folate metabolism.

Other deficiencies

Deficiencies of nicotinic acid and panthothenic acid cause anaemia in experimental animals but have not been shown to do so in humans. However, riboflavin deficiency may cause anaemia in humans, resembling the anaemia of protein deficiency. Copper is essential for haemopoiesis and normal iron metabolism, and deficiency of copper causes an anaemia resembling that in iron deficiency in experimental animals. However, anaemia due to copper deficiency has never been documented in humans. Copper excess (as in Wilson disease) causes a haemolytic anaemia.

Introduction

The inherited disorders of haemoglobin are the commonest single-gene disorders, with an estimated carrier rate of 7% among the world population. They occur at particularly high frequencies in populations of the tropical and subtropical belt, and consist mainly of the α and β thalassaemias, and the haemoglobin variants S, C and E. In many developing countries, as economic conditions improve and infant death rates from infection and malnutrition fall, the genetic disorders of haemoglobin start to place a major burden on the health services, a phenomenon that has already been observed in many parts of the world. As a result of migrations of populations, these conditions are being seen with increasing frequency in many countries in which they had not been recognized previously.

The structure, genetic control and synthesis of haemoglobin

Different haemoglobins are synthesised in the embryo, fetus and adult, each adapted to their particular oxygen requirements. They all have a tetrameric structure made up of two different pairs (one α -like and one β -like) of globin chains, each

attached to one haem molecule, the moiety responsible for the reversible binding and transfer of oxygen (Figure 6.1).

The embryonic haemoglobins include Hb Portland ($\zeta_2\gamma_2$), Hb Gower 1 ($\zeta_2\epsilon_2$), and Hb Gower 2 ($\alpha_2\epsilon_2$). In the fetus, HbF ($\alpha_2\gamma_2$) predominates; in adults, HbA ($\alpha_2\beta_2$) comprises over 95% of the total haemoglobin, with a minor component of HbA₂ ($\alpha_2\delta_2$) in the red blood cells. There are two kinds of HbF composed of γ -chains that differ in their amino acid composition at position 136, where they have either glycine or alanine; those with glycine are called $^G\gamma$ -chains and those with alanine $^A\gamma$ -chains. The $^G\gamma$ and $^A\gamma$ chains are the products of separate globin gene loci ($^G\gamma$ and $^A\gamma$). These different types of haemoglobin are adapted to the changes in physiological requirements that occur during development. Fetal haemoglobin (HbF) exhibits a higher oxygen affinity than adult haemoglobins *in vivo*; the higher oxygen affinity of HbF relative to adult haemoglobin facilitates the transfer of oxygen across the placenta from the maternal to the fetal circulation.

The sigmoid shape of the oxygen dissociation curve, which reflects the allosteric properties of haemoglobin, ensures that oxygen is rapidly taken up at the high oxygen tensions found in the lungs and is released readily at the low tensions encountered in the tissues. It is quite different to myoglobin, a molecule that consists of a single globin chain with haem attached to it and which has a hyperbolic dissociation curve. The transition from a hyperbolic to a sigmoid curve reflects cooperativity between the four haem molecules. When one haem takes on oxygen, the affinity for oxygen of the remaining haems of the tetramer increases markedly. This is because haemoglobin can exist in

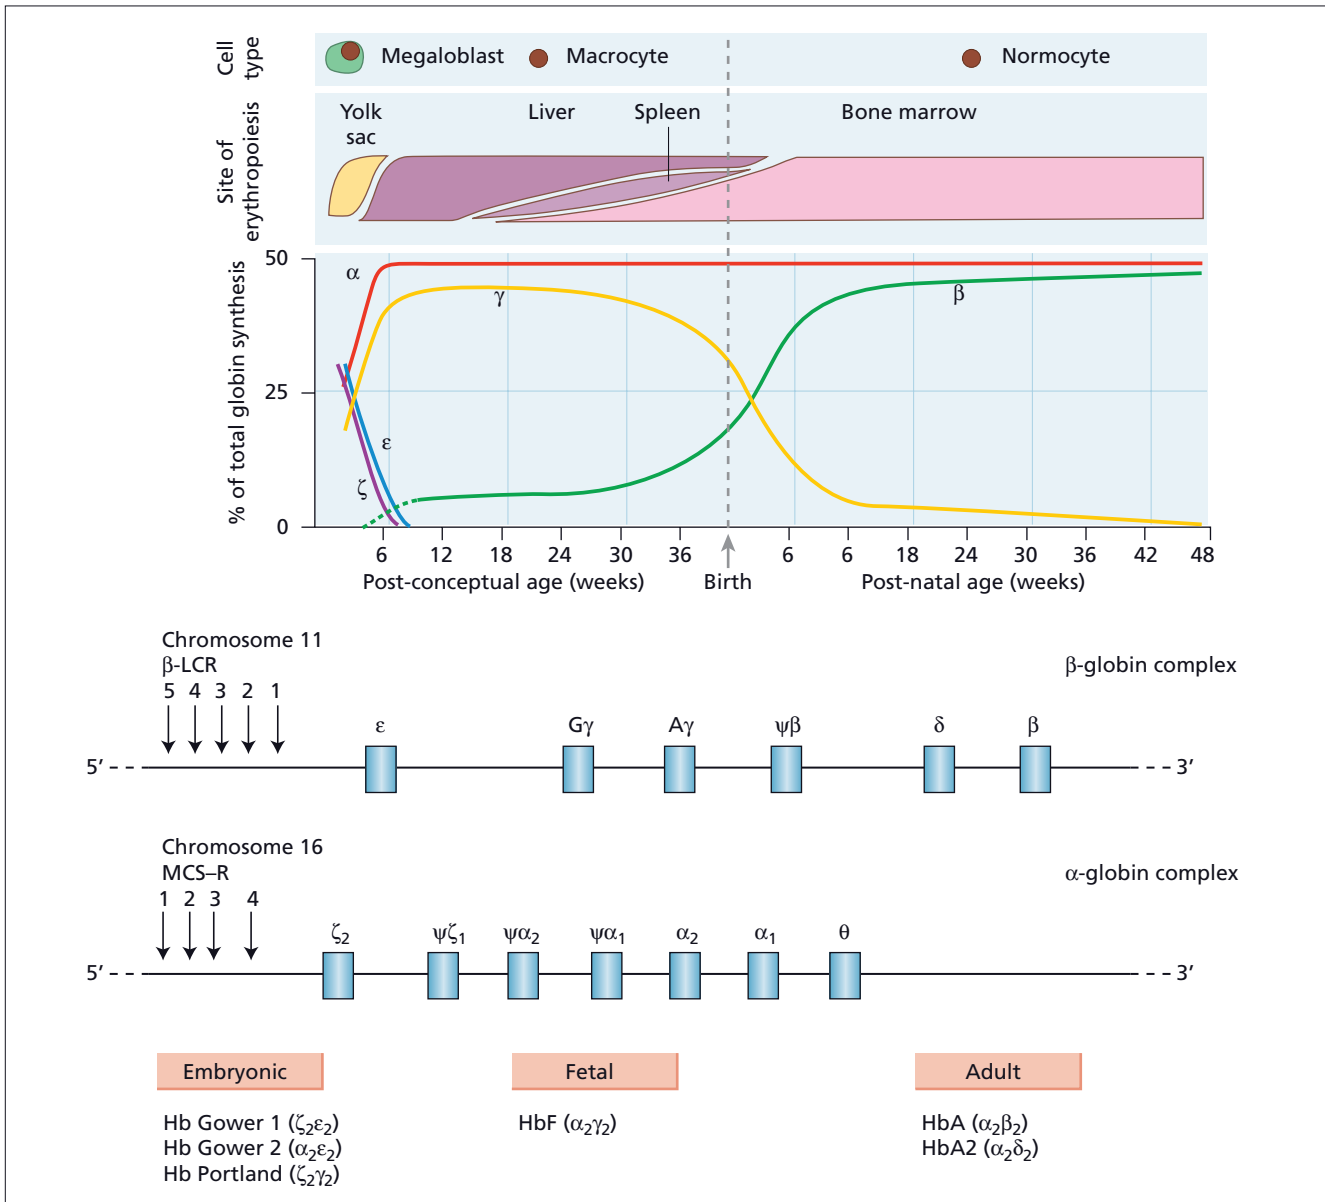

Figure 6.1 The genetic control of haemoglobin synthesis. (Adapted from Weatherall 2001 with permission.)

two configurations, deoxy(T) and oxy(R) (T and R stand for tight and relaxed states respectively). The T form has a lower affinity than the R form for ligands such as oxygen. At some point during the sequential addition of oxygen to the four haems, transition from the T to R configuration occurs and the oxygen affinity of the partially liganded molecule increases dramatically. The oxygen dissociation curve, which reflects these changes, can be modified in several ways. First, oxygen affinity is decreased with increasing CO₂ tensions – the Bohr effect. This facilitates oxygen loading to the tissues, where a drop in pH due to CO₂ influx lowers oxygen affinity. In contrast, in the lungs, efflux of CO₂ and an increase in intracellular pH increases

oxygen affinity and hence uptake. Oxygen affinity is also modified by the level of 2,3-diphosphoglycerate (2,3-DPG) in the red cell. Increasing concentrations shift the oxygen dissociation curve to the right (i.e. reduce oxygen affinity), whereas diminishing concentrations have the opposite effect.

Genetic control, regulation and synthesis

Human haemoglobin production is characterized by two ‘switches’. The switch from embryonic to fetal haemoglobin production begins as early as week 5 of gestation and is completed by week 10 (Figure 6.1). Expression of β-globin starts as

early as week 8 but synthesis remains low, increasing to approximately 10% at weeks 30–35 of gestation with a dramatic upregulation of β -globin synthesis just before birth, coinciding with a decrease in γ -globin expression that constitutes the fetal to adult haemoglobin switch. At birth, HbF ($\alpha_2\gamma_2$) comprises 60–80% of the total haemoglobin, falling to about 5% at 6 months of age and eventually reaching the adult level of 0.5–1.0% at 2 years. The relative synthesis of $^G\gamma$ and $^A\gamma$ chains also changes with the switch, from a $^G\gamma/{}^A\gamma$ ratio of 3:1 in fetal life to a ratio of 2:3 in adults. The switch from fetal to adult haemoglobin production is not total, production of variable levels of HbF persisting throughout adult life. These residual amounts are unevenly distributed; erythrocytes that contain measurable amounts of HbF are termed F cells.

Each of the α -like and β -like globin chains is encoded by genetically distinct loci, the α -like cluster on the tip of chromosome 16p and the β -like cluster on chromosome 11p15.5 (Figure 6.1). In both clusters, the genes are arranged along the chromosome in the order in which they are expressed during development: 5'- ϵ - $^G\gamma$ - $^A\gamma$ - $\psi\beta$ - δ - β -3' and 5'- ζ - $\psi\zeta$ - $\psi\alpha 2$ - $\psi\alpha 1$ - $\alpha 2$ - $\alpha 1$ -3'. The $\psi\beta$, $\psi\zeta$ and $\psi\alpha$ genes are pseudogenes, that is they have sequences that resemble the β , ζ or α genes but contain inactivating mutations that prevent them from being expressed. They may be 'burnt out' remnants of genes that were functional at an earlier stage of evolution. Like most mammalian genes, the globin genes have one or more non-coding inserts, called intervening sequences or introns, interrupting the coding sequences or exons.

The β -like globin genes have similar structures, with three exons (coding regions) interrupted by two intervening sequences or introns of 122–130 and 850–900 bp, respectively. The β genomic sequence codes for 146 amino acids; intron 1 interrupts the sequence between codons 30 and 31, and intron 2 between codons 104 and 105. The α -globin genes code for 141 amino acids and contain similar but smaller introns between codons 30 and 31 and between codons 99 and 100. Within each α - and β -globin complex, in addition to the primary *cis* determinants of individual globin gene expression which are found in the immediate vicinity and within each gene, there are other local regulatory elements known as enhancers which are located at variable distances from the individual genes.

The local *cis*-acting sequences controlling globin gene expression include the promoter region, splicing donor and acceptors, and poly-A addition sites. The promoter, in the 5' flanking region, includes blocks of nucleotide homology that are found in analogous positions in many species (Figure 6.2). The three positive *cis*-acting elements include the TATA box (position -28 to -31, i.e. between 28 and 31 bases upstream from the mRNA 'cap' site), a CCAAT box (position -72 to -76), and a CACCC motif which may be inverted or duplicated (position -80 to -140). These promoter elements are recognized by transcription factors and are involved in the initiation of transcription. It is interesting that while the CCAAT and TATA

elements are found in many eukaryotic promoters, the CACCC sequence is found predominantly in erythroid cell-specific promoters.

The 5' untranslated region (UTR) occupies a region of about 50 nucleotides between the 5' terminus or 'cap' site of globin mRNA and the initiation (ATG) codon. The cap appears to be important for maintaining the stability of the nuclear precursor mRNA. Within the 5'-UTR of the various globin genes there are conserved sequences that are important in the regulation of gene expression. The 3'-UTR constitutes the region between the termination codon and the poly-A tail. It consists of about 130 nucleotides with one conserved sequence, AATAAA, located 20 nucleotides upstream of the poly-A tail. The conserved hexanucleotide AATAAA acts as a signal for cleavage of the 3' end of the primary transcript and addition of the poly-A tail, which confers stability on the processed mRNA and enhances translation. The importance of all these *cis* elements for normal globin gene expression has been validated by the discovery of thalassaemias caused by several mutations affecting these regions, as well as by deletion experiments.

Throughout development, the appropriate genes of the α - and β -globin gene clusters are coordinately expressed, maintaining a balance in the production of α - and β -like globins needed for the synthesis of normal haemoglobin. The regulation of globin gene expression is mediated at several levels; although most occurs at the transcriptional level, there is some fine-tuning during and after translation. Most DNA that is not involved in gene transcription is tightly packaged into a compact, chemically modified form that is inaccessible to transcription factors and polymerases and which is heavily methylated. Activity is associated with a change in the structure of the chromatin surrounding a gene, which can be identified by enhanced sensitivity to nucleases. Erythroid lineage-specific nuclease hypersensitivity sites are found at several locations in both the β -globin and α -globin gene clusters. A set of five DNase I hypersensitivity sites (designated HSs1–5), distributed 5–25 kb 5' of the ϵ -globin gene, constitute the β locus control region (β LCR) (see Figure 6.1). This region was originally implicated in the control of the β -globin complex by the discovery of natural mutants that removed sequences upstream but left the globin genes intact and yet resulted in no output from the cluster. The human β LCR was the first LCR to be identified and was functionally defined as a DNA element that provides high levels of tissue-specific expression to a *cis*-linked gene in a copy number-dependent manner, and which is independent of host-genome integration site. The corresponding region in the α -globin cluster consists of four multispecies conserved sequence (MCS) regions lying 30–70 kb upstream of the α -globin genes called MCS-R1 to MCS-R4. Of these elements, only MCS-R2, which consists of a single DNase hypersensitive site, has been shown to be essential for α -globin expression. MCS-R2, which lies 40 kb upstream of the cluster, is also known as HS-40. The β LCR establishes a transcriptionally active

Figure 6.2 A prototype globin gene and the genetic control of globin chain synthesis. Levels of action of mutations are indicated on the right.

chromatin domain that encompasses the whole β -globin cluster and acts as a unique enhancer, whereas the α -globin MCS-R2 is most similar to HS2 of the β LCR and acts as an enhancer. In both clusters, expression of the respective genes is critically dependent on the presence of the upstream regulatory elements.

Several other enhancer sequences have also been identified in both globin gene clusters. All these regulatory regions bind a number of erythroid-specific transcription factors, notably GATA-1, NF-E2 and EKLF, as well as factors that are more ubiquitous in their tissue distribution such as Sp1. Tissue-specific expression may be explained by the presence of binding sites for the erythroid-specific transcription factors. The binding of haemopoietic-specific factors activates the LCR, which renders the entire β -globin gene cluster transcriptionally active. Transcription factors also bind to enhancer and local promoter sequences within each gene, which work in tandem to regulate the expression of the individual genes in the clusters. Some of the transcription factors are developmental stage specific and

may be involved in the (still poorly understood) differential expression of embryonic, fetal and adult globin genes.

The mechanisms by which developmental regulation is controlled are less clear. A dual mechanism has been proposed: autonomous gene silencing and gene competition for a direct interaction with the upstream LCR. It appears that the ϵ and ζ genes are switched on in embryonic cells and autonomously switched off in definitive cells (liver and bone marrow) in which they cannot be substantially reactivated. The second switch, from γ to β gene expression, is more complex and involves both autonomous silencing of the γ genes and competition between the γ and β genes for the β LCR. The transcriptional factor environment is critical in determining the balance between γ and β gene expression and is thought to be mediated by changes in the repertoire and/or abundance of various nuclear factors favouring particular promoter–LCR interactions. So far, the best-defined example of a developmental stage-specific regulatory factor is the erythroid Krüppel-like factor (EKLF) without which the β genes cannot be fully activated in the definitive

cells. Not only is EKLF expression restricted mainly to erythroid cells but it is also a highly promoter-specific activator, binding with high affinity to the β -globin CACCC box. Its greater affinity for the β -globin than the γ -globin promoter accelerates the shutdown of γ in transgenic mice overexpressing EKLF, which suggests a role for EKLF in the γ -globin to β -globin switching process. However, EKLF is unlikely to be the only factor because (i) γ -globin silencing can also occur in the absence of a competing β -globin promoter and (ii) EKLF expression is equivalent at all developmental stages. The erythroid-specific transcription factors can be part of multiprotein complexes that also involve ubiquitous transcription factors such as Sp1.

Transcription and processing of mRNA

Genetic information in the DNA of the globin genes is transcribed into an RNA copy which is then translated into a specific globin chain (Figure 6.2). The TATA box acts as the initial DNA target for the progressive assembly of an initial transcription complex, which involves the interaction of transcription factors, TATA-binding protein and other proteins with the β LCR or α MCS, mediated by RNA polymerase II.

The primary transcript is a large mRNA precursor (pre-mRNA) that contains both introns and exons. While in the nucleus, it undergoes a number of modifications before it can be translated into protein (Figure 6.2). This includes the removal of introns by a complex series of reactions involving several different proteins that constitute the spliceosome, and splicing of the exons. Consensus sequences are universally found encompassing the 5' (donor) and 3' (acceptor) ends. Each intron invariably starts with the dinucleotide GT (5') and finishes with AG (3'). Mutations that alter the normal consensus sequences or mutations that create similar consensus sequences at new sites in globin genes cause aberrant splicing and constitute the molecular basis of many types of thalassaemia. Other modifications of the nascent mRNAs include the addition of a 'cap' structure at the 5' end and the addition of a string of adenylic acid residues (poly-A) at the 3' end. Proper cleavage of the primary RNA transcript and polyadenylation of the 3' ends of mRNA is guided by a consensus hexanucleotide (AATAAA) sequence about 20 nucleotides upstream of the poly-A tail. The processed mRNA now moves into the cytoplasm to act as a template for globin chain production on defined organelles known as ribosomes.

Translation

Amino acids are transported to the mRNA template on carriers called transfer RNAs; there are specific transfer RNAs for each amino acid. The order of amino acids in a globin chain is determined by the order of nucleotides (reading frame); three bases (codon) code for a particular amino acid. The transfer RNAs also contain three bases, the anticodon, which are complementary to mRNA codons for particular amino acids. The transfer

RNAs carry amino acids to the template, where they find the right position by codon–anticodon base-pairing. The mRNA is translated from the 5' to the 3' end (left to right) starting with a specific initiation codon (AUG) and ending with a termination codon (UAA, UAG, UGA). When the ribosome reaches the termination codon, translation ceases, the completed globin chain is released, and the ribosomal subunits fall apart and are recycled. Individual globin chains combine with haem, which is synthesized through a separate pathway, and with themselves to form definitive haemoglobin molecules.

Termination codons are also called nonsense codons because they do not usually encode any amino acid. Approximately 50% of the mutations causing β thalassaemia are caused by termination codons that are premature. Premature termination codons (PTCs) can result from different types of mutations. Single nucleotide substitutions can convert a sense codon to a nonsense codon and are often referred to as nonsense mutations. Frameshift mutations are insertions or deletions of a few bases that are not multiples of three that shift the reading frame, resulting in a nonsense codon that is premature (i.e. PTC). mRNAs with PTCs lead to production of encoded truncated proteins that are potentially harmful. They are kept in check by a cellular surveillance mechanism referred to as nonsense-mediated mRNA decay (NMD). NMD is usually triggered when translation stops prematurely at PTCs, resulting in termination of the mutant mRNA transcript and thus absence of abnormal protein. However, PTCs situated less than 50–55 nucleotides upstream of the 3'-most exon–exon junction or downstream of this junction generally fail to trigger NMD, and result in production of abnormal mRNA species. In the case of the β -globin gene, PTCs within the last exon (exon 3) and 3' half of exon 2 result in the production of highly unstable β -globin variant chains and a dominantly inherited form of β thalassaemia, illustrating the importance of downregulating mRNAs that encode truncated proteins. However, there are exceptions to the 50–55 rule; PTCs within β -globin exon 1 and a PTC within exon 2 have been reported to fail to elicit NMD efficiently despite residing more than 55 nucleotides upstream of the exon 2–exon 3 junction.

The multistep process in the conversion of DNA into protein offers numerous opportunities for mishaps to occur that result in downregulation of gene expression, clearly illustrated by the different mutations causing thalassaemias and haemoglobinopathies (Figure 6.2).

Classification of the disorders of haemoglobin

Mutations in the globin genes can cause either a quantitative reduction in output from that gene or alter the amino acid sequence of the protein produced (Table 6.1). Quantitative

defects cause thalassaemia whereas qualitative changes, referred to as haemoglobin variants, cause a wide range of problems including sickle cell disease, unstable haemoglobins, decreased oxygen affinity, increased oxygen affinity and methaemoglobinemia; however, the majority of qualitative mutations cause no significant change in haemoglobin properties or clinical problems. Some mutations combine both features, resulting in a haemoglobin variant which is made in reduced amounts; HbE ($\beta 26 \text{ Glu} \rightarrow \text{Lys}$) is the most common example of this. The substitution at codon 26 ($\text{GAG} \rightarrow \text{AAG}$) which causes HbE also causes alternative splicing of the β -globin mRNA, leading to a reduction in the normally spliced β message encoding the variant, and a thalassaemia phenotype. Other haemoglobin variants result in a thalassaemia phenotype caused by extreme instability and functional deficiency of the globin chain variant; for example, Hb Geneva, a dominantly inherited β thalassaemia. Other mutations in the globin gene complex might alter the switch from fetal to adult haemoglobin synthesis, and result in hereditary persistence of fetal haemoglobin (HPFH).

The thalassaemias and related disorders

The thalassaemias are the commonest single-gene disorders. Thalassaemia was first recognized by Cooley and Lee in 1925 as a form of severe anaemia associated with splenomegaly and bone changes in children. The term 'thalassaemia' is derived from the Greek $\theta\alpha\lambda\alpha\sigma\sigma\alpha$ (meaning 'the sea') since many of the early cases came from the Mediterranean region. However, it is now clear that the disorder is not just limited to the Mediterranean region but occurs throughout the world, prevalent in the tropical and subtropical regions including the Middle East, parts of Africa, Indian subcontinent and Southeast Asia. It appears that heterozygotes for thalassaemia are protected from the severe effects of malaria and natural selection has increased and maintained their gene frequencies in these malarious regions.

Definition and classification

The thalassaemias are classified into α , β , $\delta\beta$, $\gamma\delta\beta$, δ , γ and $\epsilon\gamma\delta\beta$ thalassaemias according to the type of globin chain(s) that is produced in reduced amounts (Table 6.1). The two major categories are the α and β thalassaemias while the rare forms include the γ , δ and $\epsilon\gamma\delta\beta$ thalassaemias.

Functionally, some thalassaemia mutations cause a complete absence of globin chain synthesis, and these are called α^0 or β^0 thalassaemias; in others, the globin chain is produced at a reduced rate and these are designated α^+ or β^+ thalassaemias. The $\delta\beta$ thalassaemias are subdivided in the same way. HPFH syndromes refer to the group of disorders in which the switch from fetal to adult haemoglobin production is incomplete and fetal haemoglobin levels are variably increased in otherwise normal individuals. Because of their concomitant increased HbF levels, the $\delta\beta$ and $\gamma\delta\beta$ thalassaemias are often considered with the HPFH syndromes.

Because thalassaemia occurs in populations in which structural haemoglobin variants are common, it is not unusual to inherit a thalassaemia gene from one parent and a gene for a structural haemoglobin variant from the other. Furthermore, both α and β thalassaemia occur commonly in some countries, and individuals may co-inherit genes for both types. These different interactions produce a clinically diverse family of genetic disorders that range in severity from death *in utero* to extremely mild, symptomless, hypochromic anaemias.

Most thalassaemias are inherited in a Mendelian recessive fashion. Heterozygotes are mostly symptomless, although usually they can be recognized by simple haematological analysis. More severely affected patients are either homozygotes for α or β thalassaemia or compound heterozygotes for different molecular forms of α or β thalassaemia or for one or other form of thalassaemia and a gene for a haemoglobin variant. Clinically, the thalassaemias are classified according to their severity into

major, intermediate and minor forms. Thalassaemia major is a severe and transfusion-dependent disorder. Thalassaemia minor is the symptomless trait or carrier state. Thalassaemia intermedia is characterized by anaemia (with or without splenomegaly), though not of such severity as to require regular transfusion. In practice, thalassaemia intermedia encompasses a wide spectrum of clinical severities intermediate between the two extremes of thalassaemia major and trait.

The β thalassaemias

The β thalassaemias pose by far the most important public health problems because they are common and usually produce severe anaemia in their homozygous and compound heterozygous states.

Distribution

The β thalassaemias occur widely in a broad belt, ranging from the Mediterranean and parts of North and West Africa through the Middle East and Indian subcontinent to Southeast Asia. The disease is particularly common in Southeast Asia, where it occurs in a line starting in southern China and stretching down through Thailand and the Malay peninsula and Indonesia to some of the Pacific island populations. In this region, and in some of the Mediterranean island and mainland countries, gene frequencies range between 2 and 30%. It should be remembered that β thalassaemia is not confined entirely to these high-incidence regions and it occurs sporadically in every racial group.

Genetic basis of disease: molecular pathology

The β thalassaemias are considered to be autosomal recessive disorders since individuals who have inherited one abnormal β gene (carrier) are asymptomatic and the inheritance of two abnormal β globin genes is required to produce a clinically detectable phenotype. Molecular analysis of the β thalassaemia genes has demonstrated a striking heterogeneity. Although almost 300 β thalassaemia alleles (including deletions) have been characterized, population studies indicate that probably only 20 β thalassaemia alleles account for more than 80% of the β thalassaemia mutations in the whole world. This is because in each of the high-frequency areas, only a few (four to six) mutations are common, reflecting local selection due to malaria, with a varying number of rare ones. Each of these populations thus has its own unique group of mutations.

The vast majority (approximately 250) of β thalassaemia mutations are point mutations (i.e. single-base substitutions) and small insertions or deletions of one to two bases. These may involve any step in globin chain production: transcription, translation or post-translational stability of the globin gene product (Figure 6.2). Approximately half of these mutations completely inactivate the β gene with no β -globin production resulting in β^0 thalassaemia. Mutations that allow the production of some β -globin cause β^+ or β^{++} thalassaemia depending

on whether there is a marked or mild reduction in the output of β chains, respectively.

Transcription

The mutations that interfere with transcription include deletions and point mutations involving the globin gene promoter regions. With the exception of a deletion of about 600 bases at the 3' end of the β -globin gene, which is restricted to certain Indian populations, major deletions are uncommon. A large number of point mutations involve the promoters or adjacent regions, most of which downregulate the β -globin gene to a variable degree and cause relatively mild forms of β thalassaemia.

A couple of β thalassaemia mutations in this class are 'silent': carriers do not have any evident haematological phenotypes, with red cell indices and HbA₂ levels within the normal range, the only abnormality being imbalanced globin chain synthesis. These β thalassaemia mutations have usually been 'discovered' in individuals with thalassaemia intermedia resulting from compound heterozygosity for one of those 'silent' mutations in combination with a typical β thalassaemia mutation. In this case, one parent has typical β thalassaemia trait and the other is apparently normal. Overall, the 'silent' β thalassaemia alleles are uncommon except for the -101 C→T mutation that has been observed fairly frequently in the Mediterranean region, where it interacts with a variety of more severe β thalassaemia mutations to produce milder forms of β thalassaemia intermedia.

Processing

A wide variety of mutations interfere with processing of the primary mRNA transcript. Those involving the invariant GT or AG sequences at intron-exon junctions prevent splicing altogether and cause β^0 thalassaemia. Mutations involving the consensus sequences adjacent to the GT or AG dinucleotides in the introns allows some normal splicing and causes β^+ thalassaemia. Several β thalassaemia mutations involve other parts of the introns; alternative splicing sites are produced leading to variable degrees of both normal and abnormal mRNA synthesis. An incorrectly spliced mRNA is not functional because it contains intron sequences, generating a frameshift and a PTC. Sequences that resemble the consensus sequences at intron-exon junctions are also present in exons. Mutations may activate these 'cryptic' sites, again leading to abnormal splicing.

Translation

About half of the β thalassaemia alleles completely inactivate the gene, mostly by generating PTCs, either by single-base substitution to a nonsense codon or through a frameshift mutation. As part of the surveillance mechanism that is active in quality control of the processed mRNA, mRNA harbouring a PTC is destroyed and not transported to the cytoplasm (a phenomenon called NMD) to prevent the accumulation of mutant

mRNAs coding for truncated peptides. However, some in-phase PTCs that occur later in the β sequence, in the 3' half of exon 2 and in exon 3, escape NMD and are associated with substantial amounts of mutant β mRNA, leading to synthesis of β -chain variants that are highly unstable and non-functional with a dominant negative effect (see next section). Other mutations of RNA translation involve the initiation (ATG) codon. Nine of these have been described; apart from an insertion of 45bp, all are single base substitutions and again result in β^0 thalassaemia.

Mutations affecting post-translational stability

Instability of the β -globin gene product is the basis for the dominantly inherited β thalassaemias (Figure 6.3). As discussed earlier, in-phase PTCs within the 3' half of exon 2 and in exon 3 cannot efficiently elicit NMD and hence abnormal mRNA containing the PTCs are transported to the cytoplasm and translated. However, these truncated variant β -chains are highly unstable, non-functional and not able to form viable tetramers. They precipitate in the erythroid precursors together with the redundant α chains, causing premature death of these cells, and accentuating the ineffective erythropoiesis. Severe anaemia and clinical disease results even in the heterozygous state. Highly unstable β -globin chains can also result from single-base substitutions or minor insertions/deletions that affect a critical amino acid of the β -globin peptide that is involved in α/β dimer formation or haem binding. In other cases, the minor insertions/deletions lead to shifts in the reading frame resulting in long unstable β -globin gene products that form prominent inclusion bodies in red cell precursors.

Deletions restricted to the β -globin gene

β Thalassaemia is rarely caused by deletions (Figure 6.4). Of these, only the 619-bp deletion at the 3' end of the β gene is

common, but even that is restricted to the Sind populations of India and Pakistan where it constitutes about 30% of the β thalassaemia alleles. The other deletions, although extremely rare, are of particular clinical interest because they are associated with an unusually high levels of HbA₂ and HbF in heterozygotes. The increase in HbF is adequate to compensate for the complete absence of HbA in homozygotes for these deletions. The mechanism underlying the elevated levels of HbA₂ and HbF appears to be related to removal of the 5' promoter region of the β -globin gene, which removes competition for the upstream β LCR and limiting transcription factors, resulting in increased interaction of the LCR with the γ and δ genes in *cis*, thus enhancing their expression. This mechanism may also explain the unusually high HbA₂ levels that accompany the point mutations in the β promoter region.

Unusual causes of β thalassaemia

These are extremely rare and are mentioned here not just for the sake of completeness but also to illustrate the numerous molecular mechanisms that downregulate the β -globin gene. Transposable elements may occasionally disrupt human genes and result in their activation. The insertion of such an element, a retrotransposon of the LI family, into intron 2 of the β -globin gene has been reported to cause β^+ thalassaemia. Rarely, mutations in other genes distinct from the β -globin complex can downregulate β -globin expression. Such *trans*-acting mutations have been described affecting the XPD protein that is part of the general transcription factor TF11H, and the erythroid-specific GATA-1. Somatic deletion of the β -globin gene contributed to thalassaemia intermedia in three unrelated families of French and Italian origins. The affected individuals with thalassaemia intermedia were constitutionally heterozygous for β^0 thalassaemia but subsequent investigations revealed a somatic deletion of chromosome 11p15, including the β -globin gene

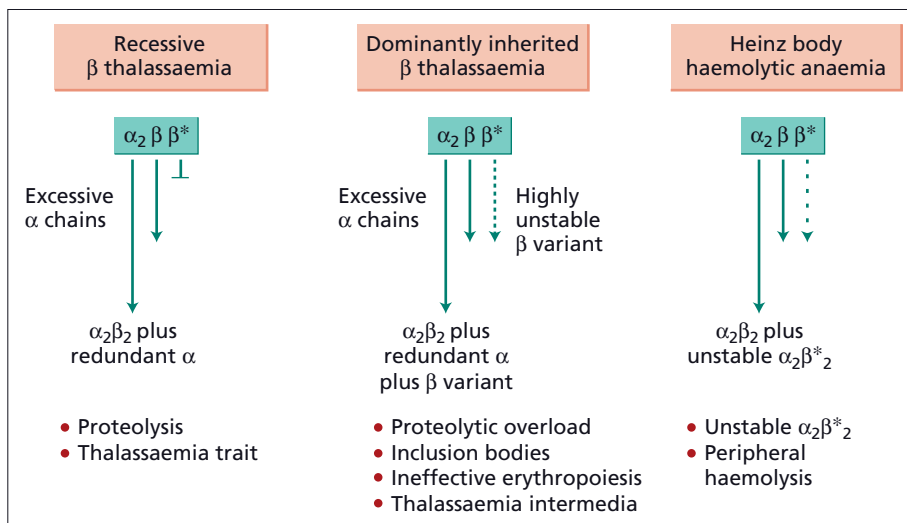

Figure 6.3 Heterozygous mutations in the β -globin gene and the different phenotypes.

Figure 6.4 Deletions causing β thalassaemia. The vertical bar indicates the β -globin promoter region that is removed in common by these deletions, except for the 619 bp deletion. The horizontal arrows indicate that the 3' end of the deletions have not been defined.

complex, in *trans* to the mutation in a subpopulation of erythroid cells. This results in a somatic mosaic: 10–20% of the cells were heterozygous with one normal copy of the β -globin gene, and the rest hemizygous (i.e. without any normal β -globin gene). In another case, thalassaemia major in a Chinese patient was caused by homozygosity for a paternal β thalassaemia allele due to unipaternal isodisomy of chromosome 11p15.5 that encompassed the β -globin gene cluster.

Pathophysiology

The molecular defects in β thalassaemia result in absent or reduced β -chain production while α -chain synthesis is unaffected. The imbalance in globin chain production leads to an excess of α -chains. The free α -globin chains are highly unstable and precipitate in red cell precursors, forming intracellular inclusions that interfere with red cell maturation (Figure 6.5). Hence there is a variable degree of intramedullary destruction of erythroid precursors (i.e. ineffective erythropoiesis) that characterizes all β thalassaemias. Those red cells which mature and enter the circulation contain α -chain inclusions that interfere with their passage through the microcirculation, particularly in the spleen. However, the damage to red cell precursors and their progeny in β thalassaemia is not entirely mechanical. The degradation products of excess α -chains, particularly haem and iron, produce a wide range of deleterious effects on red cell membrane proteins and lipids, manifest by marked abnormalities of electrolyte homeostasis and membrane deformability.

The end result is an extremely rigid red cell with a shortened survival.

Thus, the anaemia of β thalassaemia results from a combination of ineffective erythropoiesis and haemolysis. It stimulates erythropoietin production, which causes expansion of the bone marrow and may lead to serious deformities of the skull and long bones. Because the spleen is being constantly bombarded with abnormal red cells, it hypertrophies. The resulting splenomegaly, together with bone marrow expansion, causes a major increase in plasma volume, which also contributes to the anaemia.

As mentioned previously, HbF production almost ceases after birth. However, some adult red cell precursors retain the ability to produce a variable number of γ -chains. Because the latter can combine with excess α -chains to form HbF, cells which make relatively more γ -chains in the bone marrow of β thalassaemics are partly protected against the deleterious effect of α -chain precipitation. These F cells come under selection in the marrow and peripheral blood and thus individuals with β thalassaemia have variable increases in HbF due to selective survival of these F cells. In some cases, there is also a genuine increase in HbF production as well as selection of F cells due to co-inheritance of a genetic determinant, or quantitative trait locus (QTL), for increased HbF production. Because δ -chain synthesis is unaffected, the disorder is characterized by a relative or absolute increase in HbA₂ ($\alpha_2\delta_2$) production.

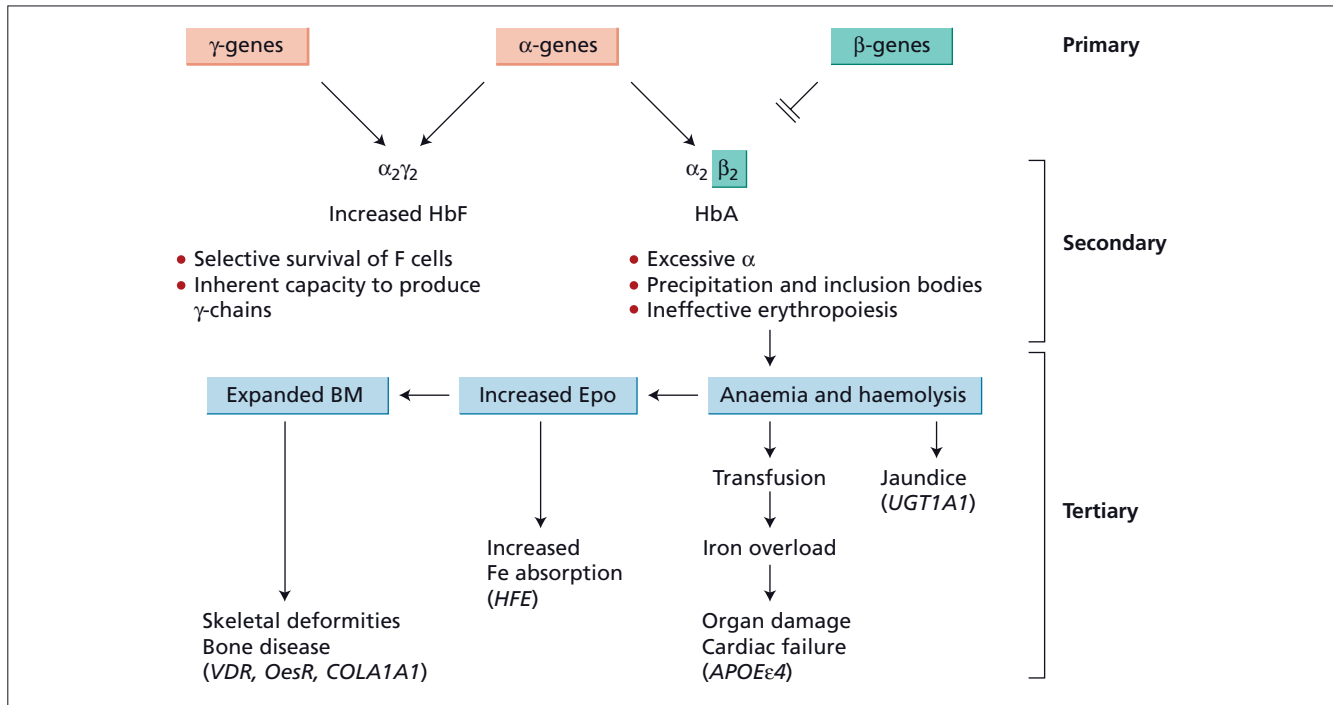

Figure 6.5 The pathophysiology of β thalassaemia. BM, bone marrow; Epo, erythropoietin. (From Thein 2004 with permission.)

It follows therefore that if the anaemia is corrected with blood transfusion, the erythropoietin drive is shut off, growth and development are normal, bone deformities do not occur and splenomegaly is less marked. On the other hand, each unit of blood contains 200–250 mg of iron, and with regular transfusion there is steady accumulation of iron in the liver, endocrine glands and myocardium. Thus, although well-transfused thalassaemic children grow and develop normally, they die of iron overload unless steps are taken to remove iron.

Genotype–phenotype relationships

The β thalassaemias show remarkable phenotypic variability, ranging from severe life-threatening anaemia to an extremely mild condition that may be identified only by chance. The molecular basis for this diversity is at least partly understood.

The genetic modifiers of the β thalassaemia phenotype can be divided into primary, secondary and tertiary (Figure 6.5). Primary modifiers are the different mutations that affect the β -globin gene. These have variable effects on β -globin gene expression that may affect the output of β -globin chains, ranging from zero to a very mild reduction. Secondary modifiers are those that reduce the degree of imbalance of globin chain synthesis. They include the co-inheritance of α thalassaemia and a variety of genetic modifiers of γ -chain production in adult life. Three major QTLs – *Xmn1*- γ site, *HBS1L-MYB* intergenic polymorphisms (*HMIP*) on chromosome 6q, and *BCL11A* gene on chromosome 2 – have recently been mapped, and it seems likely that many remain to be discovered.

While co-inheritance of α thalassaemia reduces chain imbalance and disease severity in individuals who have inherited two copies of β thalassaemia alleles, the increased output of α -globin through co-inheritance of extra α -globin genes in β thalassaemia heterozygotes increases chain imbalance, converting a typically asymptomatic state to that of thalassaemia intermedia. The outcome depends on the number of α -globin genes inherited as one or two copies of triplicated ($/\alpha\alpha\alpha$) or quadruplicated ($/\alpha\alpha\alpha\alpha$) α -globin complexes, and the type of β thalassaemia mutation (β^0 or β^+). More recently, another mechanism of inheriting extra α -globin genes involving segmental duplication of the whole α -globin gene cluster has also been described.

Tertiary modifiers are those that affect the complications of disease; the severity of bone disease, iron loading and jaundice may be affected by polymorphisms of genes involved in the metabolic pathways concerned with these complications. Bone mass, like HbF, is a quantitative trait under strong genetic control involving multiple QTLs, those implicated including estrogen receptor gene, vitamin D receptor (*VDR*) gene, collagen type $\alpha 1$ genes and transforming growth factor $\beta 1$ (*TGFBI*) gene. Studies have shown that the levels of bilirubin and incidence of gallstones are related to a polymorphic variant (seven TA repeats) in the promoter of the uridine diphosphate glucuronosyltransferase 1A (*UGT1A1*) gene, also referred to as Gilbert syndrome. Iron loading in β thalassaemia results not just from blood transfusion but also from increased iron absorption. Variants in the *HFE* gene have a modulating effect

on iron absorption, and as other genes in iron homeostasis become uncovered, it is likely that there will be genetic variants in these loci that influence the different degrees of iron loading in β thalassaemia. Similarly, it seems very likely that the propensity to infection is modified by polymorphisms involving the immune system and its regulation. Finally, it should be remembered that environmental factors, long neglected, may also play an important role in modifying the β thalassaemic phenotype.

Clinical findings in severe β thalassaemia

In many developed countries, neonatal screening programmes will first identify infants with more severe forms of β thalassaemia, before the development of any symptoms; in some cases, antenatal screening of the parents and possibly prenatal diagnosis will have identified the infant to be at high risk of β thalassaemia before birth. Mutations in the β -globin gene almost never cause clinical symptoms *in utero* or neonatally due to the predominance of γ -globin at this stage. In many countries, neonatal screening programmes do not exist and diagnosis in the child will depend on their symptomatic presentation. Severe β thalassaemia usually presents in the first year of life. Typically there is failure to thrive, with poor weight gain and growth with developmental delay. The parents may have noticed that the infant is pale and jaundiced, with a protruding abdomen. There may be a family history of severe anaemia, and typically the family will not be of northern European origin. Examination confirms the pallor and jaundice, with palpable hepatosplenomegaly. There may be evidence of marked erythroid hyperplasia, with signs of the typical 'thalassaemic facies' including expansion of the skull vault and maxillary bones. The symptoms and signs are not specific and differential diagnoses include gastrointestinal or hepatic disease, and malignancy.

Laboratory diagnosis of severe β thalassaemia

The full blood count shows a low haemoglobin, usually less than 5 g/dL. Mean corpuscular haemoglobin (MCH) and mean corpuscular volume (MCV) are low, with a very wide red cell distribution width. The nucleated cell count may be very high due to the presence of large numbers of nucleated red cells. A blood film shows marked anisopoikilocytosis, with basophilic stippling and small red cell fragments (Figure 6.6). The reticulocyte count is elevated but less than expected for the degree of anaemia, in keeping with the ineffective erythropoiesis. Renal function is normal, but liver function tests show elevation of bilirubin, aspartate aminotransferase and lactate dehydrogenase, with a normal alanine aminotransferase. Erythropoietin levels will be high, with soluble transferrin receptor levels up to 30 times greater than normal. White cell and platelet counts should be normal unless there is hypersplenism. A bone marrow aspirate is not essential to make the diagnosis, but if performed shows very marked erythroid hyperplasia, with dyserythropoiesis. Many of the erythroid precursors show inclusions after

Figure 6.6 The peripheral blood appearances in β thalassaemia.

incubation with methyl violet; similar inclusions are found in the peripheral red cells after splenectomy. Immunoelectron microscopy confirms that the inclusions in β thalassaemia consist of precipitated α -globin chains.

Haemoglobin analysis is needed to confirm the diagnosis, typically using either electrophoretic or chromatographic techniques. This will usually show an increased amount of HbA₂, with the vast majority of the remainder consisting of HbF; small amounts of HbA may be present depending on the β -globin mutation, the age of the child and whether the child has been transfused. Absence of HbA confirms a diagnosis of β^0 thalassaemia, while presence of HbA (pre-transfusion sample) confirms β^+ thalassaemia. Testing of the parents should confirm the diagnosis, both typically being carriers of β thalassaemia, with HbA₂ levels greater than 3.5% and MCH below 27 pg. These findings are sufficient to make a diagnosis of severe β thalassaemia, although where DNA analysis is available it is often used to identify the mutations and confirm the diagnosis.

Management of severe β thalassaemia

Any child presenting in the first year of life with the features described above is likely to require regular red cell transfusions to grow and develop normally; this is referred to as thalassaemia major. If such children are not transfused regularly, as happened historically in all countries, and as happens currently in many poorer areas, progressive deterioration occurs. Growth and development continue to be severely impaired. The child often has muscle wasting due to increased metabolic demands, and in particular may become folate deficient. The spleen and liver become progressively enlarged; the spleen can become massive with hypersplenism and resulting cytopenias. There is marked erythroid hyperplasia with bony distortion and extramedullary haemopoiesis. Bones become enlarged, and this is most apparent in the face, with maxillary hyperplasia, dental malocclusion and development of a 'tower' skull. Extramedullary haemopoiesis is typically paraspinous and may

Figure 6.7 Radiograph of a skull of a thalassaemia major patient showing 'hair-on-end' appearance.

cause compression of spinal nerves with resulting symptoms; intracranial haemopoiesis may cause cranial neuropathies and symptoms of raised intracranial pressure. There is an increased tendency to infection, and without transfusion the child typically dies from either infection or high-output cardiac failure. Radiography may show lacey trabecular patterns in long bones and a 'hair-on-end' appearance of the skull (Figure 6.7).

This picture is completely transformed by an appropriate transfusion regimen. Occasional blood transfusions may be necessary because of an acute exacerbation of anaemia, often related to infection. It is a bigger decision to institute a regular transfusion regimen, in that typically transfusions are then continued lifelong. Stopping transfusions in a child or adult who is adapted to a high haemoglobin level inevitably results in a prolonged period of symptomatic anaemia and ill health which may not be tolerated. Regular transfusions should be started if the child is failing to thrive, or if erythroid expansion is causing bony distortion or hypersplenism; abnormal facial appearances, if allowed to progress, may be irreversible without maxillofacial surgery.

Blood transfusions

The aim of regular transfusions is to correct anaemia and suppress the abnormal erythroid hyperplasia. Correcting anaemia improves oxygen delivery to the tissues and facilitates normal growth and development. Suppression of erythropoiesis stops bony distortion, limits excessive iron absorption and reduces extramedullary haemopoiesis. Measurement of soluble transferrin receptor levels, which are proportionate to the size of the erythron, suggest that suppression of erythropoiesis requires trough haemoglobin to be kept above 9.5 g/dL; in practice this means aiming for a pretransfusion haemoglobin of 9–10 g/dL. This can usually be achieved by regular red cell transfusions every 2–4 weeks, with a post-transfusion haemoglobin target of

13–15 g/dL. If venous access is difficult, as is often the case in young children, it is sometimes beneficial to insert a semi-permanent central venous access device, such as a Portacath or Hickman line. The majority of thalassaemia patients are treated with simple top-up transfusions as described. An alternative involves regular exchange transfusion in which blood is both venesected and transfused; this can be performed either manually or automatically using an apheresis machine. The main advantages are that transfusion can be less frequent, at intervals of up to 6 weeks, and iron loading is significantly less as blood is also removed. Disadvantages include increased expense and time, increased donor exposure with risk of infection and alloimmunization, and difficulties with venous access.

Ideally transfusions are with packed red cells. Leucodepleted blood reduces the risk of transfusion reactions and cytomegalovirus infection, and should be used where available. When the ethnicity of the blood donor population differs from that of the recipient thalassaemia population, as occurs in northern Europe, the USA and Australia, the transfused red cells should be matched for an extended range of blood groups to minimize the risk of alloimmunization; typically, full matching for all Rh and Kell groups, in addition to ABO, is of benefit. Before starting transfusions the patient should be vaccinated against hepatitis B, and ideally also hepatitis A.

Iron overload

Iron overload inevitably complicates regular blood transfusions and is the source of many serious complications. Each unit of transfused blood contains about 200–250 mg iron, compared with the 1 mg iron normally absorbed each day. Despite the increased iron, serum hepcidin remains inappropriately low, which further contributes to iron loading through increased intestinal iron absorption. Recent studies show that the low hepcidin is caused by an inhibitory effect of growth differentiation factor (GDF)-15 that is secreted by erythroid precursors and significantly increased in patients with thalassaemia major (see Chapter 4). Iron is initially stored in macrophages within the liver, and is chaperoned around the body bound to transferrin. As transferrin becomes saturated, labile, more toxic forms of iron appear in cells and plasma, referred to as non-transferrin-bound iron (NTBI). It is thought that NTBI is responsible for most of the iron toxicity, including iron loading into cardiac and endocrine tissues. Once in cells, the iron causes oxidative tissue damage, mostly through the generation of free radicals.

Iron overload and chelation is discussed in more detail in Chapter 4. Before iron chelation was available, most regularly transfused thalassaemics died in their late teens, mainly from cardiac iron deposition. Endocrine failure was also inevitable, with diabetes mellitus, hypothyroidism, hypoparathyroidism, hypogonadism and pituitary failure all occurring. With good iron chelation life expectancy is open-ended, and there is an

established link between the efficacy of iron chelation and life expectancy.

The body has no mechanism for excreting iron and iron-chelating drugs are necessary to avoid toxic iron accumulation. Iron chelation is usually started after about 1 year of monthly blood transfusions. Ideally, children delay starting chelation until they are 3 years old, as drug toxicity is thought to be highest in the young; it is usually necessary to start chelation earlier in children who start transfusions in the first year of life, although in general low doses are used.

Currently, three drugs are used for iron chelation: desferrioxamine, deferiprone and deferasirox. Desferrioxamine has been in clinical use since the 1970s and is known to be safe and effective; side-effects seem only to occur when the drug is used in high doses or iron stores are low. Important side-effects include ocular and retinal toxicity, growth impairment and cartilaginous dysplasia. *Yersinia enterocolitica* infection is increased in iron overload, particularly if desferrioxamine is also in use. Regular use of desferrioxamine has been found to prolong survival in several observational studies. The main problem is that it has to be given by injection; the most commonly used regimen involves subcutaneous infusions given over 8 hours using a syringe driver or balloon-pump. To achieve negative iron balance in a regularly transfused person requires a dose of 40 mg/kg five times a week, and this is usually given overnight. The subcutaneous route is inevitably a cause of poor adherence to treatment regimens because of the pain and inconvenience. Historically, therefore, many patients have developed life-threatening iron overload despite the availability of desferrioxamine, with median age of death being 30–40 years. Deferiprone was developed in the UK about 30 years ago and was licensed in Europe in 1999. Initial trials demonstrated its efficacy, although subsequent studies suggested that there may be individual variation in response requiring higher dosage up to 100 µg/kg instead of 75 µg/kg. Arthropathy and agranulocytosis are potentially serious side-effects and it is currently recommended that people taking the drug have full blood counts every week. Despite concerns about its safety and efficacy, deferiprone seems to be particularly effective at removing cardiac iron, which is possibly linked to improved cardiac function and reduced cardiac mortality. It is increasingly used in combination with desferrioxamine. Deferasirox is a rationally designed oral iron chelator that has been approved in the USA and Europe since the mid-2000s. Large clinical trials have demonstrated its efficacy in thalassaemia. It effectively removes hepatic iron, with increasing evidence that it also removes cardiac iron to some extent.

It is important to monitor iron stores regularly in transfusion-dependent patients who are receiving iron chelation. Monitoring the volume of transfused blood allows the iron input to be calculated, which can guide what dose of iron chelator to use. Serum ferritin is proportional to the amount of

stored iron in the liver and can be used to effectively monitor iron overload, particularly if serial measurements are used. Ferritin is artificially elevated by any inflammatory process, which can cause misleading results. Liver iron can be accurately assessed using liver biopsy, but this is invasive with a risk of complications. Increasingly, magnetic resonance imaging (MRI) is used to quantitate liver iron, with the R2 method being approved by both European and North American authorities. Cardiac MRI is also emerging as an important way of identifying those thalassaemics with significant cardiac iron, which allows chelation to be targeted to that organ, using either continuous intravenous desferrioxamine or one of the oral iron chelators. Iron monitoring and chelation is very expensive and not available to most patients in the world with thalassaemia major.

Monitoring and annual review of patients with thalassaemia major

The aim of regular transfusions is to allow the child to grow and develop normally, and for the quality and quantity of life to be as close to normal as possible. This requires the child to be closely monitored, and this is ideally done in a centre with expertise in the condition, often in the form of an annual review. Each year the volume of transfused blood (expressed as mL/kg) should be recorded; if the transfusion requirement is high, exceeding 200–250 mL/kg, this suggests the possibility of hypersplenism, and if the spleen is enlarged splenectomy may significantly reduce the rate of transfusion and iron loading. Splenectomy would not normally be considered before the age of 6 years, and there is emerging concern that it may increase the risk of pulmonary hypertension and other vascular complications in later life.

Growth should be carefully monitored in children, including annual measurement of sitting height to assess spinal growth; desferrioxamine toxicity has been specifically linked to impaired spinal growth. Blood tests should be performed each year to look for endocrinopathy, including fasting glucose, thyroid-stimulating hormone, parathyroid hormone, insulin-like growth factor 1 and sex hormone levels. Hepatic and renal function should be monitored regularly, together with hepatitis serology. Cardiac assessment should include an ECG, echocardiogram and increasingly MRI, which can assess both ejection fraction and iron loading; MRI is not tolerated by children under the age of 7 years without general anaesthesia or sedation, and is not usually justified at this age unless there is strong suspicion of cardiac or other problems. Osteopenia is more common in children and adults with thalassaemia major, and vitamin D levels should be measured, with bone densitometry from the age of about 10. There is evidence that osteopenia with falling bone density may benefit from treatment with bisphosphonates. All patients on iron chelation should also be monitored regularly for audiometric, ocular and retinal toxicity.

Dietary and psychological support are also often beneficial. In general, the organization and provision of all this care requires a multidisciplinary team, including paediatricians, haematologists, cardiologists, endocrinologists, nurse specialists and psychologists.

Bone marrow transplantation in severe thalassaemia

Bone marrow transplantation is generally seen as the treatment of choice if there is an HLA-identical sibling and it is clear that the child is transfusion dependent. The success of bone marrow transplantation is generally reduced as children get older, iron overload increases and iron-related organ damage increases. In optimal circumstances the transplant is successful in more than 90% of cases. The main complications are severe infection during the period of transplantation and either acute or chronic graft-versus-host disease. Significantly reduced fertility is also almost inevitable. Recent improvements in the outcome of medical treatment, related to oral iron chelation and better cardiac monitoring, have possibly shifted the balance away from transplantation. One limitation of transplantation is the availability of suitable donors; cord blood transplants are potentially important in this respect. In a small number of cases preimplantation genetic diagnosis has allowed the selection of HLA-matched embryos to produce siblings who can act as bone marrow donors. Efforts are also being made to develop mini- and micro-transplants, which may be less toxic, preserve fertility and potentially allow the use of alternative donors, such as haploidentical or matched unrelated donors.

Prognosis in severe thalassaemia

In theory, with adequate transfusion and effective chelation, survival in thalassaemia major should approach that of the normal population, although historically this has never been the case because of the difficulties patients encounter in adhering to subcutaneous chelation regimens. In Europe and North America, median survival has improved with each decade since the introduction of desferrioxamine in the 1970s. Most deaths are related to cardiac iron overload and improved survival is primarily related to earlier and more rational use of chelation. Recent studies suggest that death of cardiac origin has become much less common in the last 5–10 years, probably related to improved treatment of iron-related cardiomyopathy with intravenous desferrioxamine and combination therapy with both desferrioxamine and deferiprone. Earlier detection, using cardiac T2* MRI, and prevention of cardiac iron loading, with oral chelation, seem likely to improve prognosis further.

Heterozygous β thalassaemia

Carriers for β thalassaemia are usually symptom-free except in periods of stress such as pregnancy, when they may become more anaemic. Transfusion is sometimes necessary during pregnancy but no other treatment or follow-up is necessary.

Palpable splenomegaly is rare. Carriers may have mild anaemia; haemoglobin values are in the range 9–12 g/dL. The red cells show hypochromia and microcytosis with characteristically low values. The reticulocyte count is normal. The bone marrow shows moderate erythroid hyperplasia with corresponding increase in soluble transferrin receptor levels. The characteristic finding is an elevated HbA₂ level, usually greater than 3.5%. There is a slight elevation of HbF in the 1–3% range in about 50% of cases. Silent or near-silent carriers of β thalassaemia occur fairly rarely, in which the HbA₂ level is normal with only slight hypochromia; this is typically associated with mildly thalassaemic mutations in the promoter region of the gene. Failure to identify this state antenatally can result in significant and unexpected thalassaemia in the offspring, if the partner also carries β thalassaemia.

β Thalassaemia in association with haemoglobin variants

In many populations, because there is a high incidence of both β thalassaemia and various haemoglobin variants, it is quite common for an individual to inherit a β thalassaemia allele from one parent and a gene for a structural haemoglobin variant from the other. Although numerous interactions of this type have been described, only three are common: HbS/ β thalassaemia, HbC/ β thalassaemia and HbE/ β thalassaemia.

HbS/ β thalassaemia

HbS/ β thalassaemia causes sickle cell disease, with the severity varying from very mild to severe. This interaction does not result in the thalassaemia phenotype. The principal determinant of the severity of sickle cell disease is the nature of the β thalassaemia mutation, and to what extent β^A is reduced compared with normal. HbS/ β^0 thalassaemia is broadly similar in severity to HbSS, with no HbA present and an average haemoglobin of 7–8 g/dL. It differs in that red cells are markedly hypochromic and contain excess α -globin chains. Clinically marked splenomegaly is more common than in HbSS, affecting up to 30% of adults. The severity of HbS/ β^+ thalassaemia varies from severe to very mild, depending on how much HbA is produced. Some β^+ thalassaemia alleles produce less than 10% of the normal HbA output and result in a clinical picture identical to HbS/ β^0 thalassaemia. At the other end of the spectrum, promoter mutations typically reduce HbA output by only 10% and result in a condition which is only marginally more symptomatic than sickle cell carriers. These mild forms of HbS/ β^+ thalassaemia occur most often in populations of African origin, whereas the more severe forms are most often found in Mediterranean countries and India.

HbC/ β thalassaemia

This is restricted to West Africans and some North African and southern Mediterranean populations. It is largely asymptomatic and characterized by a mild haemolytic anaemia associated with

splenomegaly. The peripheral blood film shows numerous target cells and thalassaemic red cell changes with a moderately elevated reticulocyte count. Haemoglobin electrophoresis shows a preponderance of HbC. The diagnosis is confirmed by finding the HbC trait in one parent and the β thalassaemia trait in the other.

HbE/ β thalassaemia

This is the commonest severe form of thalassaemia in Southeast Asia and parts of the Indian subcontinent. The β^E allele is mildly thalassaemic due to the activation of a cryptic splice site, and when it is inherited together with β^0 thalassaemia, there is a marked deficiency of β -chain production. HbE is slightly unstable *in vitro*, although it is not clear that this has any clinical significance. The clinical and haematological changes are variable. There is nearly always anaemia and splenomegaly, with typical thalassaemic bone changes. Haemoglobin values are in the range 4–9 g/dL, with an average of 6–7 g/dL; in developed countries about half of the patients with this condition are regularly transfused. There are thalassaemic red cell changes and the bone marrow shows marked erythroid hyperplasia.

Although little is known about the natural history of this disorder, it is clear that in many parts of Southeast Asia and India it causes a very high mortality in early life. Clinically it is indistinguishable from other forms of β thalassaemia, although the link between genotype and phenotype is less predictable, with some patients having thalassaemia major and others growing and developing with few complications.

The diagnosis is confirmed by finding only HbE and HbF on haemoglobin electrophoresis and by demonstrating HbE trait in one parent and β thalassaemia trait in the other. In other cases of HbE/ β^+ thalassaemia, variable quantities of HbA are present and the condition is milder.

Variant forms of β thalassaemia

Despite the vast heterogeneity of mutations, the increased levels of HbA₂ in β thalassaemia heterozygotes is remarkably uniform, in the range 3.5–5.5%, and rarely exceeds 6%. Unusually high HbA₂ levels in excess of 6.5% seem to characterize the subgroup caused by lesions (point mutations or small deletions) that affect the regulatory elements in the promoter region of the β -globin gene (see Figure 6.4). The unusually high HbA₂ levels are usually accompanied by higher than usual increases in HbF, resulting in a milder thalassaemia phenotype despite the absence of HbA₂ in some cases. Otherwise, the haematological picture is identical to the common forms of β thalassaemia. Some β thalassaemia heterozygotes have normal HbA₂ levels despite the typical hypochromic microcytosis. In most cases, this is due to the co-inheritance of δ thalassaemia. Other cases of normal HbA₂ β thalassaemia are extremely mild forms of β thalassaemia that is completely silent in heterozygotes and is only identified when it is co-inherited with a common form of β

thalassaemia. Heterozygotes do not have any evident haematological phenotype, the only abnormality being a mild imbalance of globin chain synthesis.

β Thalassaemia occasionally follows a dominant pattern of inheritance, whereby it is symptomatic in heterozygotes (see Figure 6.3). The clinical picture is characterized by a moderate degree of anaemia and splenomegaly with marked thalassaemic changes of the red cells, and ineffective erythropoiesis with intracellular inclusion bodies. Although not usually transfusion dependent, such individuals develop iron overload from hyperabsorption due to ineffective erythropoiesis and may develop liver or endocrine damage. The common denominator of these dominantly inherited β thalassaemias is the synthesis of hyperunstable β -chain variants, caused by a spectrum of mutations; those resulting from PTCs are typically found in exon 3 of the β -globin gene. Unlike the recessive forms that are prevalent in malarious regions, dominantly inherited β thalassaemias are rare, occurring in dispersed geographical regions. Most of the dominant β thalassaemia alleles have been described in single families, many as *de novo* mutations. Dominantly inherited β thalassaemia should be suspected in any patient with a thalassaemia intermedia phenotype, even if both parents are haematologically normal, and the patient is from an ethnic background where β thalassaemia is rare. The diagnosis is confirmed by DNA sequence analysis of the β -globin genes.

$\delta\beta$ Thalassaemia and hereditary persistence of fetal haemoglobin

HPFH and $\delta\beta$ thalassaemia are much less common than β thalassaemia and manifest as a range of disorders characterized by decreased or absent HbA production and a variable compensatory increase in HbF synthesis. The distinction between them is subtle and originally made on what appeared to be clear-cut clinical and haematological grounds. However, as more cases became recognized and their underlying mutations delineated, it became evident that there is considerable overlap between the two groups of disorders.

The level of compensatory increase is higher in HPFH compared with $\delta\beta$ thalassaemias. HPFH heterozygotes have essentially normal red cell indices, normal HbA₂ levels and HbF levels of 10–35%, whereas heterozygotes for $\delta\beta$ thalassaemia have hypochromic microcytic erythrocytes and normal HbA₂ levels and the HbF increases are lower (5–15%). A distinguishing feature is the heterocellular distribution of HbF in $\delta\beta$ thalassaemia compared with a pancellular (or homogeneous) distribution in HPFH, although the intercellular distribution of HbF may be a reflection of the magnitude of increase and the sensitivity of the technique used to stain F cells. Clinically, HPFH homozygotes are asymptomatic with slightly reduced MCV and MCH, and compound heterozygotes with β thalassaemia have very mild disease. Compound heterozygotes of $\delta\beta$ thalassaemia

with β thalassaemia, and $\delta\beta$ thalassaemia homozygotes have disease severity that ranges from mild anaemia to transfusion dependence.

Two types of mutations underlie this group of disorders: deletions that remove substantial regions of the β -globin cluster, including the β -globin gene (Figure 6.8), and point mutations in the promoters of either of the γ -globin genes ($^G\gamma$ or $^A\gamma$) (Figure 6.9). Six deletion forms of HPFH have been described in Africans, Mediterraneans, Indians and Southeast Asians, with deletions ranging from 13 to 86kb in size. The commonest forms are Black HPFH-1 and HPFH-2, the latter also referred to as Ghanaian HPFH. Included within the HPFH conditions is Hb Kenya, a rare condition found largely in East Africa and

characterized by production of a hybrid $^A\gamma\beta$ -globin chain and increased $^G\gamma$ -chain (Figures 6.8 and 6.10). The first type of $\delta\beta$ thalassaemia to be described was Hb Lepore, which consists of hybrid $\delta\beta$ -globin chains produced by misaligned crossing-over between the δ and β globin genes (Figures 6.8 and 6.10). Heterozygotes for Hb Lepore have hypochromic microcytic red cells, normal HbA₂ and variably increased HbF. The more common forms of $\delta\beta$ thalassaemia result from different length deletions of the β -globin gene cluster (Figure 6.8). Deletions that leave both the γ -globin genes intact are called $^G\gamma^A\gamma$ ($\delta\beta$)⁰ thalassaemias, and they all include parts or all of the δ and β globin genes. $^G\gamma$ ($^A\gamma\delta\beta$)⁰ thalassaemia deletions include part or all of the $^A\gamma$ -globin gene and hence produce HbF containing

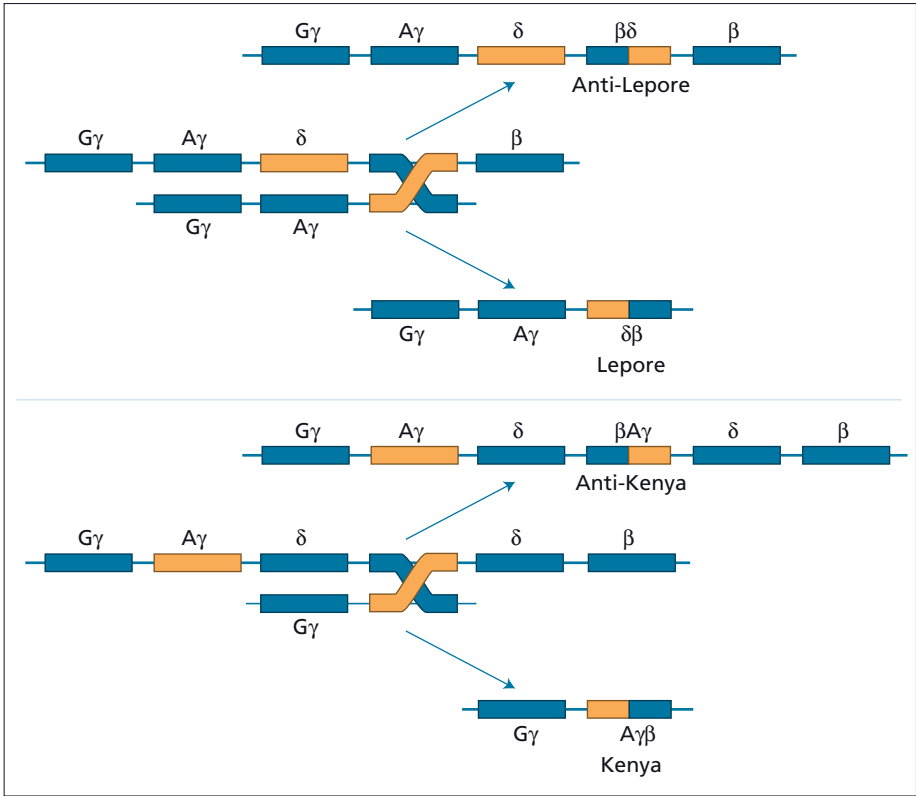

Figure 6.10 The mechanisms for the production of haemoglobin Lepore and related variants.

only $\epsilon\gamma$ -chains. A couple of the $(\delta\beta)^0$ thalassaemias include two deletions separated by an inverted region.

Non-deletion HPFH is caused by mutations within the promoters of either of the γ -globin genes, and lead to variably increased HbF with a preponderance of only one of the γ -chains (Figure 6.9). The mutations (single-base substitutions or minor deletions) are clustered in three regions of the promoters, around positions -114 , -175 and -200 . These regions contain binding sites for ubiquitous and erythroid-specific factors. Altered binding pattern of the transcription factors due to the point mutations are thought to be the cause of the elevated HbF levels, which vary from 5 to 35% in heterozygotes. Deletion and non-deletion HPFH and $\delta\beta$ thalassaemias are clearly inherited in a Mendelian pattern as alleles of the β -globin gene complex. Heterozygotes have significant elevations of HbF ranging from 10 to 40%.

Inherited increases in HbF have also been reported in families with β thalassaemia and sickle cell disease; these increases had a modulating effect on the severity of disease and the inheritance appeared to segregate independently of the β -globin gene cluster. Healthy members of the families may also have slight increases in HbF, and historically these individuals were said to have co-inherited heterocellular HPFH. Heterocellular HPFH was originally recognized in a group of Swiss army recruits; the HbF elevation was modest and unevenly distributed among the erythrocytes, the distinct HbF-carrying red blood cells being termed F cells. Hence Swiss HPFH was also referred to descriptively as heterocellular HPFH. It is now clear that HbF is a highly variable quantitative trait, and that heterocellular HPFH represents the upper tail of the natural continuous distribution that includes approximately 10% of the population with HbF levels between 0.8 and 5%. Unlike the Mendelian forms caused by major deletions or point mutations in the γ -globin promoters, the inheritance of heterocellular HPFH is complex with an overwhelming genetic contribution. The sequence variant (C \rightarrow T) at position -158 of the $\epsilon\gamma$ -globin gene, also referred to as the *Xmn1*- $\epsilon\gamma$ site (or rs74821440), was the first QTL to be implicated through family studies. Subsequent genetic association studies have confirmed *Xmn1*- $\epsilon\gamma$ as one of the three major QTLs modulating HbF production in adults, the other two being the *HBS1L-MYB* intergenic region on chromosome 6q and *BCL11A* on chromosome 2p. These three QTLs account for a relatively large proportion (20–50%) of the common variation in HbF levels, not only in healthy adults but also in patients from diverse ethnic groups with β thalassaemia and sickle cell disease. In African-American patients with sickle cell disease, the three loci contribute more than 20% to the HbF variation with a corresponding reduction in frequency of acute pain. Co-inheritance of the *Xmn1*- $\epsilon\gamma$ site delays transfusion requirements in β thalassaemia. In Sardinia, β thalassaemia patients who have co-inherited certain *BCL11A* variants have higher HbF levels and a milder disease.

$\epsilon\gamma\delta\beta$ Thalassaemia

These are rare conditions and result from large deletions of the β -globin gene cluster that involve the β LCR. The deletions fall into two categories: group I removes all, or a greater part of, the complex including the β -globin gene and the β LCR, and group II removes extensive upstream regions including the β LCR but leaving the β -globin gene itself intact. There is no output from the globin genes of the affected cluster. Clearly, the homozygous state would not be compatible with survival. Heterozygotes have severe haemolytic disease of the newborn, with anaemia and hyperbilirubinaemia. The severity of anaemia and haemolysis is variable, even within a family, and in some cases blood transfusions are necessary during the neonatal period. If they survive the neonatal period, the infants grow and develop normally; in adult life they have the haematological picture of heterozygous β thalassaemia, with mild anaemia, hypochromic microcytic red cells and a haemoglobin pattern of normal HbA₂ β thalassaemia.

The α thalassaemias

Distribution

The α thalassaemias follow a similar distribution to the β thalassaemias, extending throughout sub-Saharan Africa, the Mediterranean region, the Middle East, the Indian subcontinent and Southeast Asia, in a line stretching from southern China through Thailand, the Malay peninsula and Indonesia, to the Pacific Island populations.

In some prevalent areas, carrier frequency for the mild form (α^+) reaches 80% or more. The more severe forms (α^0 thalassaemias) reach their highest frequency in Southeast Asia, where carrier frequency can reach 10%.

Genetic basis of disease: molecular pathology

Normal individuals have four α -globin genes arranged as linked pairs, $\alpha 2$ and $\alpha 1$, at the tip of each chromosome 16, the normal α genotype being represented as $\alpha\alpha/\alpha\alpha$ (Figure 6.11). The α thalassaemias can be classified as α^0 thalassaemia, in which no α -chains are produced from the linked pair, and α^+ thalassaemia, in which production of α -chain from the affected chromosome is reduced.

The α^0 thalassaemias are caused by deletion of both α -globin genes (Figure 6.12). The deletions vary in size and tend to be geographically isolated, with two particularly common ones in Southeast Asia ($/-SE^A$) and the Mediterranean region ($/-MED$). Rarely, α^0 thalassaemia can also arise from deletions of the upstream α -globin regulatory elements (MCS) in which the α -globin genes remain intact but completely inactivated. In other cases, more extensive deletions are associated with monosomy for a segment of the tip of chromosome 16p that result in the syndrome of α thalassaemia and mental retardation

Figure 6.11 The genetics of α thalassaemia.

(ATR-16). The molecular basis of the α^+ thalassaemias is more complicated; the commonest forms result from deletions that remove one of the linked pairs of α -globin genes, leaving the other intact ($-\alpha/\alpha\alpha$). The linked α -globin genes are embedded in two highly homologous duplicated units of 4 kb within which are three homologous subsegments designated X, Y and Z (Figure 6.13). Misalignment and recombination between the Z segments, which are 3.7 kb apart, produces chromosomes with one α -globin gene ($-\alpha^{3.7}$ or *rightward* deletion) and others with three α -globin genes ($/\alpha\alpha\alpha^{\text{anti-3.7}}$). Similarly, crossover between the X boxes, which are 4.2 kb apart, produces the *leftward* deletion $-\alpha^{4.2}$ and the $/\alpha\alpha\alpha^{\text{anti-4.2}}$ allele.

Less commonly, both the α -globin genes are intact and α^+ thalassaemia results from a point mutation that partially or completely inactivates one of them ($\alpha^T\alpha/\alpha\alpha$). In contrast to the β thalassaemias, non-deletional mutations are much less common causes of α thalassaemia but like those that cause β thalassaemia, the non-deletional α thalassaemia variants act at

different stages of gene regulation and expression. Almost 70 types of non-deletional α thalassaemia have been described; more than two-thirds of these are found on the dominant $\alpha 2$ gene, less than one-third on the $\alpha 1$ gene, and the others on an $-\alpha$ chromosome ($-\alpha^T$). In general, the non-deletional α^+ thalassaemia variants ($/\alpha^T\alpha$) give rise to a more severe reduction in α -chain output than the single α gene deletion ($-\alpha$) due to the lack of compensatory increase in α output from the linked $\alpha 1$ gene as observed in deleted cases. One particularly common form of non-deletional α thalassaemia found in Southeast Asia is Hb Constant Spring ($/\alpha^{\text{CS}}\alpha$), which is due to a single-base substitution (TAA→CAA) in the α_2 -globin termination codon. Instead of terminating at the stop codon, mRNA is read through the 3'-UTR until another in-phase termination codon is encountered 31 codons later. This results in an elongated α -globin chain of 172 residues, 31 amino acids from the natural arginine at codon 141. Of the six predicted α_2 -chain termination variants, five have been described: Hb Constant Spring ($\alpha 142$ Gln), Hb Icaria ($\alpha 142$ Lys), Hb Koya Dora ($\alpha 142$ Ser), Hb Seal Rock ($\alpha 142$ Glu) and Hb Pakse ($\alpha 142$ Tyr). Hb Constant Spring is by far the most common of these variants, reaching frequencies of up to 4% in Thailand.

Non-deletional α thalassaemia can also arise from single-base substitutions causing structural α -globin variants that are highly unstable, for example Hb Quong Sze $\alpha 125$ Leu→Pro ($/\alpha^{\text{QS}}\alpha$).

Unusual causes of α thalassaemia

This includes a single case report of α^0 thalassaemia arising from a deletion involving the $\alpha 1$ gene that also inactivated the intact linked $\alpha 2$ gene. Subsequent studies showed that the deletion results in juxtaposition of a downstream gene (*LUC7L*) next to the structurally normal upstream $\alpha 2$ gene. Transcription of antisense mRNA from *LUC7L* led to silencing of the linked $\alpha 2$ gene. Another novel form of non-deletional α thalassaemia results from a single nucleotide substitution in a non-genic region between the α -globin genes and their upstream regulatory elements. The single-base substitution leads to the creation of a new promoter-like element that interferes with normal activation of all the downstream α -like globin genes, resulting in α^0 thalassaemia.

Pathophysiology

The pathophysiology of α thalassaemia is different to that of β thalassaemia. A deficiency of α -chains leads to the production of excess γ or β chains, which form Hb Bart's (γ_4) and HbH (β_4), respectively. These soluble tetramers do not precipitate extensively in the bone marrow and hence erythropoiesis is more effective than in β thalassaemia. However, HbH is unstable and precipitates in red cells as they age. The inclusion bodies cause red cell membrane damage and obstruction in the spleen leading to shortened red cell survival. Furthermore, both Hb

Figure 6.13 The molecular mechanisms that underlie the deletion forms of α thalassaemia: (a) normal cluster showing X, Y and Z homology boxes; (b) 3.7-kb deletion; (c) 4.2-kb deletion. (From Weatherall & Clegg 2001 with permission.)

Bart's and HbH have a very high oxygen affinity and their oxygen dissociation curves resemble myoglobin. Thus, the severe forms of α thalassaemia are due to defective haemoglobin production, the synthesis of homotetramers that are physiologically useless and a haemolytic component.

Genotype–phenotype relationship

Loss of one functioning α gene ($\alpha\alpha/-\alpha$) is almost completely silent, with normal or only slightly hypochromic red cells. Loss of two α genes ($- -/\alpha\alpha$ or $-\alpha/-\alpha$) produces a mild hypochromic microcytic anaemia, the α thalassaemia trait. Homozygotes

for α^0 thalassaemia ($-/-$) have a lethal condition with intrauterine haemolytic anaemia called Hb Bart's hydrops fetalis syndrome (see Figure 6.11). As Hb Bart's hydrops fetalis syndrome follows the homozygous inheritance of α^0 thalassaemia, this condition occurs only in populations in which α^0 thalassaemia is common, notably those of Southeast Asia and the Mediterranean islands. Deficiency of α -chains gives rise to an excess of γ -chains (in fetal life) or β -chains (in adult life), which form γ_4 tetramers (Hb Bart's) or β_4 tetramers (HbH). The presence of Hb Bart's or HbH is thus diagnostic of α thalassaemia. Due to their very high oxygen affinity, Hb Bart's and HbH are not functional haemoglobins; HbH is unstable and precipitates in older red cells forming H inclusions.

HbH disease lies between the two ends of the clinical spectrum, the asymptomatic α thalassaemia trait and Hb Bart's hydrops fetalis. As in β thalassaemia intermedia, HbH disease spans a wide range of clinical and haematological phenotypes, with equally heterogeneous genotypes, varying with the geographic distribution of the different α thalassaemia variants. HbH disease most commonly results from the interaction of α^0 and α^+ thalassaemia ($-/-\alpha$) and thus, similar to Hb Bart's hydrops syndrome, is also restricted to populations where α^0 thalassaemia is common. Less often, it can result from the interaction of α^0 thalassaemia with non-deletional forms of α thalassaemia ($/\alpha^T\alpha$) or from homozygous non-deletional α thalassaemia ($\alpha^T\alpha/\alpha^T\alpha$). HbH disease in Southeast Asia commonly arises from homozygosity or compound heterozygosity for Hb Constant Spring ($\alpha^{CS}\alpha/\alpha^{CS}\alpha$ or $\alpha^{CS}\alpha/-$).

As the non-deletional forms of α^+ thalassaemia tend to have a more severe phenotype than the deletional forms, in some cases the homozygous state ($\alpha^T\alpha/\alpha^T\alpha$) may be associated with the phenotype of HbH disease. In a small number of cases, Hb Bart's hydrops syndrome can arise from the genotype $-/-\alpha^T\alpha$.

Haemoglobin Bart's hydrops syndrome

This is a common cause of fetal loss throughout Southeast Asia and is also encountered in the eastern Mediterranean. There is no production of α -chains and hence neither fetal nor adult haemoglobin. The fetus is usually stillborn between 28 and 40 weeks or, if liveborn, takes a few gasping respirations and then expires within the first hour after birth. Affected neonates show the typical picture of hydrops fetalis, with gross pallor, generalized oedema and massive hepatosplenomegaly. There is an increased frequency of congenital abnormalities and a very large friable placenta. All these findings are due to severe intrauterine anaemia. The haemoglobin is in the range 6–8 g/dL and there are gross thalassaemic changes of the red cells, with many nucleated forms in the blood. The haemoglobin consists of approximately 80% Hb Bart's and 20% Hb Portland ($\zeta_2\gamma_2$). It is believed that these infants survive to term because they continue to produce embryonic haemoglobin. Apart from fetal death, this syndrome is characterized by a high incidence of toxemia of

pregnancy and obstetric complications due to the large placenta.

Haemoglobin H disease

This condition is characterized by a variable degree of anaemia and splenomegaly but it is unusual to find severe thalassaemic bone changes or growth retardation. Patients usually survive into adult life, although the course may be interspersed with severe episodes of haemolysis associated with infection or worsening of the anaemia due to progressive hypersplenism. In addition, oxidant drugs may increase the rate of precipitation of HbH and exacerbate the anaemia. Haemoglobin values range from 7 to 10 g/dL and the blood film shows typical thalassaemic changes. There is a moderate reticulocytosis and, on incubation of the red cells with brilliant cresyl blue, numerous inclusion bodies are generated by precipitation of HbH under the redox action of the dye. After splenectomy large preformed inclusions can be demonstrated on incubation of blood with methyl violet. Haemoglobin analysis reveals 5–40% HbH, together with HbA and a normal or reduced level of HbA₂.

α Thalassaemia traits

α^0 Thalassaemia trait is characterized by very mild hypochromic anaemia with red cell indices similar to those of β thalassaemia trait; the MCH is less than 25 pg and the HbA₂ level is normal. Occasional HbH bodies may be present in the red cell on supravital staining. There are no diagnostic tests with which to identify this condition with certainty except DNA analysis. Deletional α^+ thalassaemia carriers have near-normal haematological findings. The heterozygous states for the non-deletional forms of α^+ thalassaemia are sometimes associated with very mild hypochromic anaemia; the type associated with Hb Constant Spring can be identified by the presence of trace amounts of the variant on haemoglobin electrophoresis at an alkaline pH.

α^0 Thalassaemia carriers can be identified with more certainty in the neonatal period, when they have 5–10% Hb Bart's, which disappears over the first few months of life and is not replaced by HbH. Some α^+ thalassaemia carriers have slightly increased levels of Hb Bart's, in the 1–3% range, but its absence does not exclude the diagnosis.

Other forms of α thalassaemia

There are several other forms of α thalassaemia that are completely unrelated in their pathogenesis and distribution to the conditions described in the previous sections. They comprise the α thalassaemia mental retardation syndromes and the association of α thalassaemia with myelodysplasia.

α Thalassaemia with mental retardation syndromes

There are two forms of α thalassaemia associated with mental retardation, one encoded on chromosome 16 (ATR-16), the other on the X chromosome (ATR-X). ATR-16 results from

large chromosomal rearrangements and extensive deletion of 1–2 Mb from the subtelomeric end of the short arm of chromosome 16. Affected children usually have a relatively mild degree of mental retardation and no dysmorphic features. On the other hand, ATR-X, which because of its mode of inheritance affects boys, is associated with widespread dysmorphic features and severe mental retardation. It results from many different mutations of the *ATR-X* gene, which is located on the X chromosome. The ATRX protein has many features in common with DNA helicases, transcription factors that are involved in the modelling of chromatin and gene regulation. ATRX also appears to play an important role in the transcription of the α -globin genes and undoubtedly many other genes during early development. The *ATR-X* gene has also been reported to be involved in a considerable number of X-linked mental retardation syndromes without an α thalassaemia phenotype.

α Thalassaemia associated with myelodysplasia

An α thalassaemic phenotype is also found in association with forms of myelodysplasia in elderly patients. The blood films of such patients show dimorphic features, with populations of red cells containing HbH inclusion bodies and a variable level of HbH in peripheral blood. Acquired mutations in the *ATR-X* gene have been identified in the blood cells of patients with this syndrome. The relationship of the mutations in *ATR-X* to the neoplastic phenotype remains to be determined.

Thalassaemia intermedia

Definition and molecular pathology

The term *thalassaemia intermedia* is used to describe patients with the clinical picture of thalassaemia which, although not transfusion dependent, is associated with a much more severe degree of anaemia than is found in carriers for α or β thalassaemia. Whether a patient is classified as having thalassaemia intermedia or thalassaemia major depends on a doctor deciding that the patient would benefit from regular blood transfusions; this decision is based not only on the clinical factors mentioned in the section on thalassaemia major, but also on non-clinical factors such as the availability of blood transfusions, the experience of the clinician and the wishes of the patient. Many different genotypes may underlie thalassaemia intermedia, as mentioned earlier, with HbE/ β thalassaemia perhaps being the commonest (Table 6.2). HbH disease is sometimes considered as a type of thalassaemia intermedia, but its pathophysiology is quite different to that caused by β thalassaemia.

Clinical and haematological changes

At one end of the spectrum are individuals who, except for mild anaemia, are symptom-free. At the other, there are patients who have haemoglobin values of 5–7 g/dL and who develop marked splenomegaly, osteopenia and skeletal deformities due to expansion of bone marrow; the severity may change with

increasing age, due to iron loading because of increased intestinal absorption and decreased tolerance of anaemia because of reduced cardiovascular fitness. A wide range of other problems are particularly associated with thalassaemia intermedia, including pulmonary hypertension, hypercoagulability, pseudoxanthoma elasticum and other connective tissue disorders, hypersplenism, leg ulceration, folate deficiency, extramedullary haemopoietic tumour masses in the chest and skull, gallstones and a marked proneness to infection. Because of the heterogeneity of these disorders, management is highly dependent on the course that evolves in an individual patient; all patients should be followed up very carefully from early childhood. The haemoglobin constitution of the intermediate forms of β thalassaemia depends on the contributing genotypes, and in many cases is similar to that found in the major forms.

Treatment

Intermittent blood transfusions are often necessary due to falls in haemoglobin caused by fever and infection, particularly with parvovirus B19, which causes reticulocytopenia. It can be difficult to decide who would benefit from more regular blood transfusions and when to start them. In countries with a ready supply of safe blood, there is an increasing tendency to start

regular transfusions even in children, maintaining the haemoglobin at greater than 8g/dL in order to avoid the emerging complications of skeletal deformities, pulmonary hypertension and osteopenia. There is also some evidence that this improves the quality of life, particularly with emerging options for oral iron chelation. This is not possible in much of the world and management consists of reserving transfusion for severe symptomatic anaemia.

Pharmacological treatment to increase HbF and total haemoglobin levels is potentially applicable to thalassaemia intermedia, in that relatively small increases in haemoglobin levels with a corresponding reduction in ineffective erythropoiesis could help a patient thrive who would otherwise require regular transfusions. Hydroxycarbamide (hydroxyurea) is the most widely used drug in this context, and while some patients undoubtedly benefit, in general results are disappointing. Butyrate and other short-chain fatty acids also promote HbF synthesis and have been used with limited clinical success in thalassaemia intermedia. A number of newer drugs are being developed which may boost HbF to a greater extent, most notably the new generation of short-chain fatty acid derivatives and immunomodulatory drugs such as pomalidomide and lenalidomide.

Screening for thalassaemias

Pre-conception, antenatal and neonatal screening programmes are important in the clinical care and public health management of haemoglobinopathies. Thalassaemia is prevalent in many developing and poorer countries, where either treatment is not available or the cost of regular blood transfusions and chelation is a major drain on limited medical resources. In other countries, including parts of Europe, Australia and North America, it is important to identify the antenatal risk of having a baby with thalassaemia to provide informed parental choice. Apart from bone marrow transplantation, there is no definitive treatment, and many countries in which the disease is common are putting a major effort into programmes for its prevention.

Premarital and pre-conception screening

Ideally, individuals know their thalassaemia status before they decide to have children, and potentially use this information to choose a suitable partner. Some areas therefore concentrate on screening teenagers at school. Other countries insist that a couple are screened for thalassaemia status before they can get married; this latter approach has been successful in Cyprus, where social pressures have reduced the number of at-risk marriages.

Antenatal screening, prenatal diagnosis and preimplantation genetic diagnosis

Many screening programmes concentrate on identifying pregnant women who are thalassaemia carriers in the first trimester

of pregnancy. This is done by varying combinations of blood tests and identifying women at high risk of carrying thalassaemia based on their ethnic origin; this latter approach is particularly effective in areas with a low prevalence of thalassaemia in the native population, such as northern Europe. If a woman is found to be a carrier, screening is then offered to her partner, and if both are carriers, they are counselled about the risk of the fetus inheriting a severe form of thalassaemia and offered prenatal diagnosis (PND).

PND of the thalassaemias was first carried out by fetal blood sampling, typically for β thalassaemia, between 18 and 20 weeks' gestation. At about 20 weeks in the normal fetus, β -globin synthesis constitutes about 10% of the total haemoglobin, giving a β/γ ratio of 0.1. A fetus heterozygous for β thalassaemia has a β/γ ratio of about 0.05, while one with β thalassaemia major produces either none or traces of β -globin with a β/γ ratio of less than 0.025. Fetal blood sampling has now been replaced by fetal DNA analysis. DNA analysis was applied to PND of the haemoglobinopathies in the late 1970s and early 1980s. Fetal DNA is obtained at 11–12 weeks' gestation by chorionic villus sampling or amniocentesis. Initially, detection of the mutations was indirect, relying on linkage analysis of restriction fragment length polymorphisms (RFLPs) and Southern blot hybridization, which required relatively large amounts of DNA and the whole procedure took 7–10 days. The development of polymerase chain reaction (PCR) for specific amplification of DNA has revolutionized the molecular diagnostic field, and mutations can now be detected directly using PCR-based techniques in 1 day, enabling PND to be carried out rapidly within 3 days.

Couples can then make an informed choice as to whether to terminate the pregnancy if the fetus is affected. Some couples find PND helpful in preparing for the birth of a potentially ill child, even though they would not contemplate termination. The main complication of invasive PND is the increased risk of miscarriage of about 1%. This has led to research to develop non-invasive methods of PND based on maternal blood sampling. Maternal blood contains small numbers of fetal cells and also cell-free fetal DNA, both of which could potentially be used to diagnose fetal thalassaemia. The low concentration of fetal material relative to maternal has made this technically very difficult, although advances in methods of DNA analysis seem likely to make this feasible in the near future.

Some couples want to avoid having a fetus without thalassaemia but find PND and selective termination unacceptable. Preimplantation genetic diagnosis involves the use of *in vitro* fertilization techniques to generate 5–15 embryos; at the eight-cell stage, one embryonic cell can be removed and tested for thalassaemia alleles; it is then possible to only implant embryos without thalassaemia. While appealing, it is currently a difficult, stressful and expensive procedure, with only 10–20% of couples taking home a baby. Again, advances in reproductive biology and DNA technology seem likely to make this more applicable in the future.

Neonatal screening

It is possible to detect the majority of babies with severe thalassaemia by neonatal testing, either as cord blood or more commonly from the neonatal blood spot, which is taken up on a piece of blotting paper and also screened for other conditions such as phenylketonuria. If haemoglobin analysis shows HbF only, with no HbA or other haemoglobin variants, it is likely that the baby has inherited a severe form of β thalassaemia and may be transfusion dependent; less severe possibilities include thalassaemia intermedia and homozygosity for HPFH. Babies identified in this way can then be followed up closely rather than waiting until they present following a period of prolonged illness. Parents can also be tested and given advice concerning the risk to future pregnancies.

Structural haemoglobin variants related to thalassaemia (Table 6.3)

The unstable haemoglobin disorders

The unstable haemoglobin disorders are a rare group of inherited haemolytic anaemias that result from structural changes in the haemoglobin molecule, which cause its intracellular precipi-

tation with the formation of Heinz bodies. Their true incidence is not known and there have been several well-documented instances in which patients with one of these variants have had no affected relatives, suggesting that they have arisen by a new mutation.

Molecular pathology and pathogenesis

Most of the unstable haemoglobins result from single amino acid substitutions or small deletions. For example, substitutions in or around the haem pocket can disrupt its anatomy and allow in water, with subsequent oxidative damage to haem, leading to precipitation of haemoglobin. Some substitutions, such as those involving proline residues, cause a marked disturbance of the secondary structure of globin chains. A few variants result from deletions of either single amino acids or several residues. For example, in Hb Gun Hill, five amino acids are missing, including the haem-binding site. As the unstable haemoglobins precipitate in the red cells or their precursors, they produce intracellular inclusions (Heinz bodies) which, together with oxidant damage to their membranes, make the cells more rigid and hence cause their premature destruction in the microcirculation.

Clinical features

All these conditions are characterized by a haemolytic anaemia and splenomegaly. Like all chronic haemolytic anaemias, there is an increased incidence of pigment gallstones with their associated complications; the risk is particularly high if there is co-inheritance of Gilbert syndrome (polymorphic variant in the promoter of the *UGT1A1* gene). The condition may become worse during periods of infection and, in the more severe forms, such episodes are associated with life-threatening anaemia that requires blood transfusion. Some oxidant drugs may increase the rate of haemolysis, and parvovirus B19 infection may cause temporary reticulocytopenia. Apart from icterus and splenomegaly, there are no characteristic physical findings.

Laboratory diagnosis

The peripheral blood film shows typical features of haemolysis but the red cell morphology may be normal. Occasionally, there is mild hypochromia and microcytosis. Heinz bodies are present in the peripheral blood after splenectomy. The most characteristic feature of the unstable haemoglobins is their heat instability. If a dilute haemoglobin solution is heated at 50°C for 15 min, the unstable haemoglobins precipitate as a dense cloud. A similar effect can be induced by isopropanol at lower temperatures. Some of these variants can be seen on haemoglobin electrophoresis but others, because they result from a neutral amino acid substitution, produce no electrophoretic changes and can be demonstrated only by the heat precipitation test. DNA analysis can provide definitive diagnosis, typically by sequencing of the α or β globin genes.

Treatment

Splenectomy seems to be beneficial in some cases, although experience is inevitably limited. Intermittent blood transfusions may be necessary. If haemolysis is very severe, the patient may benefit from regular blood transfusions and bone marrow transplantation should be considered.

High-oxygen-affinity haemoglobin variants

Some haemoglobin variants cause increased oxygen affinity, which results in varying degrees of polycythaemia.

Molecular pathology

Some high-oxygen-affinity haemoglobin variants result from single amino acid substitutions at critical parts of the haemoglobin molecule that are involved in the configurational changes which underlie haem–haem interaction and the production of a sigmoid oxygen dissociation curve at the junctions between the α and β subunits. Others involve the amino acids concerned with the binding of 2,3-DPG to haemoglobin. Reduced 2,3-DPG binding moves the oxygen dissociation curve to the left, reducing the P_{50} and causing the haemoglobin to hold on to oxygen more avidly than normal. This causes functional anaemia, with tissue hypoxia, which in turn causes an increased output of erythropoietin and an elevated red cell mass.

Clinical features

Most affected persons are completely healthy and are identified only when a routine haematological examination shows an unusually high haemoglobin level or packed cell volume. There is no splenomegaly and, apart from a raised red cell mass, there are no associated haematological findings. Although it might be expected that a high-oxygen-affinity haemoglobin would cause defective oxygenation of the fetus, none of the reported families has a history of such problems.

Diagnosis

The condition should be suspected in any patient with a pure red cell polycythaemia associated with a left-shifted oxygen dissociation curve. The diagnosis can be confirmed by haemoglobin analysis using chromatography, mass spectrometry or DNA analysis.

Treatment

In asymptomatic persons, no treatment is necessary. The difficulty arises if there is associated vascular disease, particularly coronary or cerebral artery insufficiency. As these patients require a high haemoglobin level for oxygen transport, venesection should be carried out with great caution. Venesection is undertaken because of increased risk of vascular complications, and typically the aim is to keep the haematocrit below 0.55, although there is little evidence to support this.

Low-oxygen-affinity haemoglobin variants

More than 50 haemoglobin variants with reduced oxygen affinity have been identified, often associated with other abnormal properties such as instability. The first to be described, Hb Kansas ($\beta 102 \text{ Asn} \rightarrow \text{Thr}$), was found in a mother and son with unexplained cyanosis. The subjects were asymptomatic and had normal haemoglobin levels without any evidence of haemolysis. Like many of the high-affinity variants, the amino acid substitution in this variant was at the interface between the α and β globin chains. For reasons that are not clear, some substitutions in this region give rise to variants with a relatively low oxygen affinity. This condition should be thought of in any patient with unexplained congenital cyanosis.

Congenital methaemoglobinaemia due to haemoglobin variants

Several α and β globin variants associated with methaemoglobinaemia have been discovered. These disorders, unlike the genetic methaemoglobinaemias due to enzyme defects, follow a dominant pattern of inheritance. The patients are blue in colour, and may have mild polycythaemia as methaemoglobin does not carry oxygen. Diagnosis is based on measuring methaemoglobin levels, and analysis of haemoglobin and DNA.

Selected bibliography, 124**Introduction**

Sickle cell disease (SCD) is an inherited chronic haemolytic anaemia whose clinical manifestations arise from the tendency of the haemoglobin (HbS or sickle haemoglobin) to polymerize and deform red blood cells into the characteristic sickle shape. This property is due to a single nucleotide change in the β -globin gene leading to substitution of valine for glutamic acid at position 6 of the β -globin chain ($\beta^{\text{Glu}\rightarrow\text{Val}}$ or β^{S}). The homozygous state (HbSS or sickle cell anaemia) is the most common form of sickle cell disease, but interaction of HbS with thalassaemia and certain variant haemoglobins also leads to sickling. The term 'sickle cell disease' is used to denote all entities associated with sickling of haemoglobin within red cells (Table 7.1).

Geographic distribution of sickle mutation

Several distinct β -globin gene haplotypes are associated with the sickle mutation, and their distribution provides evidence for

origin of the mutation in several locations within Africa (the Senegal, Benin and Bantu haplotypes) and Asia (the Arab-Indian haplotype). The sickle trait bestows survival benefit in areas endemic for falciparum malaria, and the distribution of SCD historically paralleled this disease. The sickle haemoglobin-containing red cells inhibit proliferation of *Plasmodium falciparum*, and are more likely to become deformed and removed from the circulation. In recent times, the dissemination of the sickle mutation in different areas of the world took place from the movement of populations via trade routes and the slave trade (Table 7.2). The prevalence of SCD varies tremendously among ethnic and tribal groups within a geographic area. The disease is observed occasionally among the white population: 10% of patients with HbSS identified by the California newborn screening programme are not of African descent.

Pathophysiology**Molecular basis of sickling**

Deoxygenation of HbS leads to a conformational change that exposes a hydrophobic patch on the surface of the β^{S} -globin chain at the site of β^6 valine (Figure 7.1). Binding of this site to a complementary hydrophobic site on a β -subunit of another haemoglobin tetramer triggers the formation of large polymers. The polymers consist of staggered haemoglobin tetramers that

aggregate into 21-nm diameter helical fibres, with one inner and six peripheral double strands. The polymerization proceeds after a delay, the length of which is extremely sensitive to the intracellular deoxy-HbS concentration. Even a small increase in deoxy-HbS concentration, such as might occur with cellular dehydration, profoundly shortens the delay time and augments sickling. The process of polymerization is highly cooperative and its kinetics are best explained by the double nucleation model. The haemoglobin tetramers first aggregate into a nucleus, which rapidly expands into a fibre (homogeneous

nucleation). The newly formed fibre provides nuclei on its surface for aggregation of haemoglobin tetramers to form several more fibres (heterogeneous nucleation).

The polymerization of HbS in the circulating red cells is influenced by the oxygenation status, the intracellular haemoglobin concentration and the presence of non-sickle haemoglobins. Acidosis and elevated level of 2,3-diphosphoglycerate (2,3-DPG) promote polymer formation by reducing the oxygen affinity of haemoglobin. The presence of HbA within the red cells, as in sickle trait, inhibits polymerization by diluting HbS. The inhibitory effect of HbF on polymerization of HbS is more profound owing to the greater amino acid disparity between the β^s- and γ-globin chains.

Effect on erythrocytes

Red cells acquire the sickle or elongated shape upon deoxygenation as a result of intracellular polymerization of HbS, a phenomenon that is reversible on reoxygenation. Even in the normally shaped red cells, however, the presence of HbS polymer reduces deformability, with consequent increase in blood viscosity. Repeated or prolonged sickling progressively damages the red cell membrane, which is a phenomenon of primary importance in the pathophysiology of SCD. Membrane damage causes movement of potassium ions and water out of the cell by the Gardos pathway and potassium–chloride cotransport, leading to dehydration of red cells. The intracellular haemoglobin concentration rises (producing dense cells), which shortens the delay time to sickle polymer formation. A second key consequence of membrane damage is alteration of the chemistry of the red cell membrane. Perturbation of lipid organization causes negatively charged phosphatidylserine to

Figure 7.1 Induction of red cell sickling. As red cells traverse the microcirculation, oxygen is released from oxy-HbS (red circles), generating deoxy-HbS (purple circles). Conformational change exposes a hydrophobic patch at the site of the β^6 -valine replacement, shown as a projection (left column), which can bind to a complementary hydrophobic site on a subunit of another haemoglobin tetramer, shown as an indentation. Only one of the two β^6 -valine sites in each HbS tetramer makes this

contact. The middle column shows the assembly of deoxy-HbS into a helical 14-strand fibre, shown as a twisted rope-like structure. The delay time is inversely proportional to the intracellular haemoglobin concentration raised to the 15th power. As deoxy-HbS polymerizes and fibres align, the red cell is distorted into an elongated banana or 'sickle' shape (right column). (From Bunn 1997 with permission.)

appear on the red cell surface instead of its normal location in the inner monolayer. In addition, the red cells become abnormally adherent to the vascular endothelium through vascular cell adhesion molecule (VCAM)-1, thrombospondin and fibronectin.

Vaso-occlusion

Several processes contribute to development of vaso-occlusion in SCD. Slowing of blood flow arises from abnormal regulation of vascular tone as a result of diminished nitric oxide (NO)-induced vasodilatation. This is aggravated by increase in blood viscosity, resulting from less deformable red cells, a phenomenon called abnormal rheology. Vaso-occlusion is initiated by adhesion of young deformable red cells to the vascular endothelium, and is followed by trapping of rigid irreversibly sickled cells (Figure 7.2). Adhesion occurs in the post-capillary venules

and is promoted by leucocytosis, platelet activation and inflammatory cytokines. Genetic influences independent of the sickle mutation probably modulate the tendency for vaso-occlusion in individuals and account for some phenotypic variation seen in this disease.

Haemolysis

SCD is characterized by chronic intravascular and extravascular haemolysis. Sickling-induced membrane fragmentation and complement-mediated lysis cause intravascular destruction of red cells. Membrane damage also leads to extravascular haemolysis through entrapment of poorly deformable cells or uptake by macrophages. The red cell survival measured by ⁵¹Cr assay is 4–25 days, with dense cells surviving for a considerably shorter time than red cells containing some HbF (F cells). Patients have greatly expanded bone marrow space, but the serum erythro-

Figure 7.2 Endothelial red cell adhesion and vaso-occlusion in sickle cell disease. Adhesive sickle reticulocytes initiate vaso-occlusion by becoming attached to the endothelium of vessel walls. Thereafter, poorly deformable red cells begin to accumulate behind the site of adhesion, ultimately resulting in an occluded vascular segment containing many sickled red cells. The inset shows the site of red cell attachment to an endothelial cell and several adhesion mechanisms that could participate in the vaso-occlusive process. On the red cell, the relevant adhesion receptors include CD36, which binds thrombospondin (TSP), and integrin $\alpha_4\beta_1$, which binds both fibronectin (FN) and vascular cell adhesion molecule (VCAM)-1. On the endothelial

cell, the receptors include CD36; integrin $\alpha_v\beta_3$; the complex of glycoproteins Ib, IX and V (gp Ib-IX-V), which binds von Willebrand factor (VWF); and VCAM-1. Adhesive interactions between the red cell and endothelial cells may be direct ($\alpha_4\beta_1$ to VCAM-1) or mediated by a plasma factor (CD36 to TSP to $\alpha_v\beta_3$). The list of molecules identified as involved in mediating adhesion continues to increase and redundancy in the system is likely. Question marks indicate unidentified receptors. (From Hebbel RP (2000) Blockade of adhesion of sickle cells to endothelium by monoclonal antibodies. *New England Journal of Medicine* 342: 1910–12 with permission.)

poietin level is lower than expected for the extent of anaemia because of the decreased oxygen affinity of HbS. Individuals with concomitant deletion of one or two α -globin genes, or the Senegal or Arab-Indian haplotypes, have higher baseline haemoglobin levels. The significance of chronic intravascular haemolysis in SCD extends beyond anaemia, since the release of free haemoglobin causes depletion of NO in the plasma. This is linked to endothelial dysfunction and the development of several complications including pulmonary hypertension.

Clinical manifestations

Clinical symptoms vary tremendously between patients with SCD for several reasons. The disease is more severe in patients

with HbSS or HbS/ β^0 thalassaemia than in those with HbS/ β^+ thalassaemia or HbSC disease. The Arab-Indian haplotype produces a less severe disease than the African haplotypes. The co-inheritance of one or two α -gene deletions also modifies the clinical picture. The high HbF level observed in hereditary persistence of fetal haemoglobin (HPFH) is associated with very mild disease. However, for poorly recognized reasons, the disease severity varies enormously even within the subgroup of patients with HbSS.

In countries with inadequate healthcare, SCD is associated with high mortality in the first 3 years of life as a result of sepsis and splenic sequestration. In the developed world, the typical patient with SCD has moderately severe anaemia, leads a relatively normal life interrupted by 'crises' as a result of vaso-occlusion, and has a life expectancy of over 45 years.

Anaemia

The underlying β -globin genotype primarily determines the baseline haemoglobin value in SCD, but exacerbation of anaemia can occur for numerous reasons. Patients with more severe anaemia at baseline have a greater probability of developing stroke and renal dysfunction. On the other hand, a higher haemoglobin level is associated with a higher incidence of painful episodes, avascular necrosis and acute chest syndrome. Infants with SCD have lower than normal haemoglobin levels after the neonatal period, and the decline continues until it reaches a nadir between 12 and 15 months of age. Boys are slightly more anaemic than girls in the first decade, whereas adult men have higher haemoglobin values than women. Gradual exacerbation of anaemia is observed in both sexes beginning in the fifth decade.

A gradual decrease in haemoglobin level from the baseline value may indicate an underlying folate or iron deficiency. In older patients, however, inadequate erythropoietin production due to chronic renal insufficiency is the most important aetiology of worsening anaemia. Many such patients will become transfusion dependent, although recombinant human erythropoietin therapy can improve the anaemia.

Acute exacerbations of anaemia are observed with aplastic crises and splenic sequestration. The transient arrest of erythropoiesis and the resultant reticulocytopenia in aplastic crisis is most often due to parvovirus B19 infection. Severe anaemia is the consequence of the shortened lifespan of red cells and the course is similar to other chronic haemolytic anaemias. Aplastic crisis is typically preceded by fever and upper respiratory or gastrointestinal symptoms, and several family members may fall ill over a period of days. The reticulocytopenia begins 5 days after exposure, lasts for 7–10 days and is followed by recovery with reticulocytosis and normoblasts in peripheral blood. Blood transfusion is often required in the short term. Parvovirus B19 infection is followed by development of lifelong protective immunity.

Splenic sequestration is a serious complication in young children whose spleen has not yet undergone fibrosis due to recurrent vaso-occlusion. The peak incidence of first episode of sequestration is between 6 and 12 months of age and it affects 30% of all patients. Approximately 15% of patients die during the acute episode and the condition recurs in half of the survivors. Episodes may be triggered by a viral illness and the rapid acute enlargement of the spleen traps a significant proportion of the blood volume. Clinically, the child presents with acutely worsening anaemia (> 2 g/dL fall in haemoglobin), reticulocytosis, enlarging spleen and hypovolaemic shock. Prompt restoration of the blood volume and correction of anaemia is required. Splenectomy is recommended following a sequestration crisis due to the risk of recurrences. Chronic transfusion therapy or partial splenectomy is sometimes used in infants

with life-threatening anaemic episodes. Parent education to detect splenic enlargement and seek early medical attention significantly reduces the risk of death from sequestration crisis.

Acute painful episode

Acute episode of pain due to vaso-occlusion is the most frequent symptom for which patients with SCD seek medical attention. More frequent painful episodes are observed in patients with HbSS, low HbF level, α thalassaemia and higher baseline haemoglobin levels. Painful episodes are more common in young adults and tend to diminish in older patients. One-third of the patients with SCD rarely experience pain, whereas a small subgroup of patients suffer from recurrent episodes. When patients maintain a pain diary, painful events are noted on up to half of the days but are not severe enough to require visit to a physician. Painful episodes vary in intensity and generally last for a few days. The majority of the episodes have no identifiable cause, although some attacks are precipitated by cold, dehydration, infection, stress or menses.

In young children, the initial pain episode typically presents as dactylitis or hand–foot syndrome, with swelling over the dorsal surface of hands and feet. It arises from bone infarction affecting the small bones and the swelling subsides over 1–2 weeks. The radiographs show thinning of cortex and destructive changes of the affected small bones several weeks after onset. In older children and adults, the common sites of pain are the back, chest, extremities and abdomen. Chest pain is of special significance as it can precede development of acute chest syndrome. Frequent incapacitating painful episodes that are inadequately managed have adverse psychosocial consequences and stress the physician–patient relationship.

Growth and development

Children with SCD are born with normal weight but fall behind other children by the end of the first year. The weight deficit persists through adulthood and imparts a thin habitus to the typical patient, although obesity is seen in some cases. The rate of growth is lower than normal in SCD patients, and the pubertal growth spurt is delayed by 1–2 years, but the final adult height is normal. Delays also occur in skeletal maturation and onset of puberty, and female patients achieve menarche 1–2 years later than their peers.

Infections

Early loss of splenic function from recurrent vaso-occlusion and the inability to make specific IgG antibodies to polysaccharide antigens increases the risk of fulminant sepsis. Pneumococcal infection is a serious problem in SCD, particularly in children

under 3 years (Figure 7.3). Meningitis can accompany pneumococcal sepsis, and the overall mortality rate is 20–50%. Patients who have had previous pneumococcal sepsis are at increased risk for recurrent episodes and must remain on lifelong penicillin prophylaxis. *Haemophilus influenzae* type B is the next most common organism and affects older children. There is considerable variation in the relative incidence of bacterial organisms causing sepsis in young children with SCD in various regions of the world. In Africa, *Salmonella* spp., *Klebsiella* spp., *Escherichia coli* and *Staphylococcus* spp. are more commonly isolated from the blood of febrile children than *Streptococcus pneumoniae*. Pneumococcal infections are particularly infrequent in the eastern province of Saudi Arabia and Nigeria. Furthermore, the incidence of pneumococcal and *H. influenzae* sepsis has declined as a result of penicillin prophylaxis and vaccination of infants. The risk of death during septic episodes has decreased considerably owing to empirical use of antibiotics to treat fever in SCD.

Of the other infections, pneumonia is particularly common in SCD and can be difficult to differentiate from non-infective causes of acute chest syndrome. The most frequent organisms responsible for pneumonia are *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *S. pneumoniae* and *H. influenzae*. Lung infections can also arise due to respiratory viruses. In adults, bacteraemia and urinary tract infections due to *E. coli* and other Gram-negative organisms are more frequent. Patients with SCD are susceptible to osteomyelitis caused by bone infarction resulting from vaso-occlusion. The infection is typically due to *Salmonella* spp. or *Staphylococcus aureus*.

Neurological complications

Neurological complications are an important cause of morbidity in SCD. Transient ischaemic attacks or stroke due to cerebral infarction or haemorrhage occur in 25% of patients with SCD (Figure 7.4a). The risk of stroke is increased with lower baseline haemoglobin, low HbF level, high leucocyte count or high systolic blood pressure. Vascular damage results from elevated cerebral blood flow velocities and interaction of rigid or adherent sickle cells with the vessel wall. Angiography demonstrates stenosis or occlusion of vessels in the circle of Willis and internal carotid arteries, sometimes with aneurysm formation or development of moya moya disease (Figure 7.4b). Increased blood flow velocity due to stenosis can be detected by transcranial Doppler ultrasonography in asymptomatic patients, and flow rates in excess of 200 cm/s correlate with a high risk of stroke.

(d)

(e)

Figure 7.4 Complications of sickle cell disease: (a) stroke; (b) moyamoya transformation; (c) acute chest syndrome; (d) avascular necrosis of hip joint; (e) chronic leg ulcer.

Stroke due to infarction is more frequent in younger children and those over 30 years of age, whereas haemorrhage is more common between 20 and 30 years. Stroke is rare in infants, increases to 1 in 100 patients per year between 2 and 9 years, and then diminishes to half that incidence in older patients. The incidence of stroke is 5–10 times greater in HbSS compared with HbSC, HbS/ β^+ thalassaemia or HbS/ β^0 thalassaemia. Focal seizures or transient ischaemic attacks are common presenting symptoms of stroke, followed by hemiparesis, coma and speech or visual disturbances. The site of bleeding in haemorrhagic stroke is frequently subarachnoid, and these patients present with severe headache, vomiting and coma. Death can occur during the acute event, particularly with haemorrhagic stroke. Patients with neurological symptoms should be evaluated by computed tomography (CT) or magnetic resonance imaging (MRI) to distinguish thrombosis from haemorrhage. Immediate exchange transfusion to lower HbS level to less than 30% is required. Patients with haemorrhage may require surgical intervention to ligate accessible aneurysms. Surgical vascular bypass procedure with extracranial arteries (encephalodural synangi-osis) should be considered in children with moyamoya disease.

As stroke recurs in two-thirds of the survivors within 3 years, all such patients should be maintained on regular transfusions to lower HbS level for several years. Development of first stroke in children at risk, who are identified by elevated cerebral Doppler blood flow velocity, can be prevented effectively through regular transfusions. As an alternative to transfusions, hydroxycarbamide (hydroxyurea) treatment can also reduce the high cerebral blood flow velocity, and its use for primary or secondary prevention of stroke is being explored. Even in the absence of overt stroke, silent cerebral infarcts are commonly observed on MRI in SCD and are linked to progressive neuropsychiatric and neurological damage, and poor school performance. Early detection and treatment is important in preventing further neurocognitive impairment.

Pulmonary complications

Acute and chronic pulmonary complications are the leading cause of death in older patients. The acute chest syndrome is characterized by hypoxia, tachypnoea, fever, chest pain and pulmonary infiltrate on chest radiography (Figure 7.4c). Acute chest syndrome often follows a painful event, particularly in adults (Table 7.3). The pathogenesis of acute chest syndrome involves vaso-occlusion, infection or embolization of bone marrow fat. Infections due to *Mycoplasma*, *Chlamydia*, *Legionella*, pneumococcus, *H. influenzae* and viruses are more likely in children. Fat-laden pulmonary macrophages in the airways due to fat embolization from the bone marrow are present in half of the cases. Hypoxia due to acute chest syndrome can result in widespread sickling and vaso-occlusion, with risk of multiorgan failure. Patients should receive supplemental oxygen, incentive spirometry and antibiotic therapy

Table 7.3 Presenting symptoms of acute chest syndrome.

Symptom	Children (%)	Adults (%)
Fever	86	70
Shortness of breath	31	58
Chest pain	27	55
Extremity pain	22	58
Rib pain	14	30

Adults are more likely than children to have pain preceding the onset of pulmonary symptoms.

directed towards the common organisms. One commonly used regimen consists of cefuroxime and erythromycin, although antibiotics should be guided by local experience. Most patients have a bronchoreactive component and should receive bronchodilator therapy. Patients require close monitoring for persistent hypoxia or worsening lung consolidation for which blood transfusion should be provided. Partial exchange transfusion and mechanical ventilation is sometimes needed in rapidly progressive cases. NO and steroids may be beneficial in life-threatening cases.

Chronic pulmonary problems seen in SCD are restrictive and obstructive lung disease, hypoxaemia and pulmonary hypertension. Chronic complications are more frequent in patients with a history of acute chest syndrome. Echocardiography can detect elevated pulmonary artery systolic pressure (>35 mmHg), which is observed in 20% of patients. Pulmonary hypertension is more frequent among patients with high rates of chronic haemolysis, reflected by marked elevation in plasma lactate dehydrogenase (LDH). The diagnosis of pulmonary hypertension is associated with a 10-fold increase in relative risk of dying compared with patients who have normal pulmonary artery systolic pressure, although most deaths are not from cardiac failure. Hydroxycarbamide therapy should be strongly considered in SCD patients with pulmonary hypertension. Severely affected patients have been treated with regular transfusions, vasodilators, anticoagulation and oxygen inhalation.

Hepatobiliary complications

The liver can be affected by intrahepatic trapping of sickle cells, transfusion-acquired infection and transfusional haemosiderosis. Episodes of cholestasis due to intrahepatic sickling can lead to liver failure in rare instances. Pigmented gallstones are seen in two-thirds of patients, particularly those with HbSS, and can occur in young children. Patients with abdominal symptoms attributable to gallstones should undergo cholecystectomy, although the management of asymptomatic gallstones is less clear. Laparoscopic cholecystectomy can be safely performed, but associated common duct bile stones first require endoscopic retrograde cholangiopancreatography.

Pregnancy

The steady-state haemoglobin level falls in SCD during pregnancy, similar to the decline in haemoglobin observed in normal pregnant women. Folate deficiency can exacerbate the anaemia and supplements should be provided throughout pregnancy. Painful episodes become more common in the last trimester. The incidence of pre-eclampsia is higher than normal in SCD patients and there is a slight increase in maternal mortality. Risk to the fetus from abortion, stillbirth, low birth weight and neonatal death is also increased. Prophylactic transfusions during pregnancy or the type of delivery do not alter the outcome for mother or newborn. It is safe to use oral contraceptives for birth control in SCD.

Renal complications

The hypoxic, acidotic and hypertonic renal medulla favours vaso-occlusion, leading to destruction of the vasa recta and hyposthenuria in the first year of life. It presents clinically as enuresis or nocturia, and patients are susceptible to dehydration in hot weather. Haematuria as a result of papillary necrosis usually originates from the left kidney. Management is generally by bed rest and hydration, although sometimes blood transfusion and ϵ -aminocaproic acid are required. The prevalence of essential hypertension in SCD is lower than in the general population, although elevated systolic blood pressure is a risk factor for stroke. Proteinuria due to glomerular injury precedes development of nephrotic syndrome and eventual chronic renal insufficiency in one-quarter of adults. The progression to renal failure can be delayed by angiotensin-converting enzyme inhibitors. Careful control of blood pressure, avoidance of non-steroidal anti-inflammatory drugs (NSAIDs) and aggressive treatment of urinary tract infection and anaemia are important objectives for patients with chronic renal insufficiency. Patients with end-stage renal disease are treated with dialysis and renal transplantation. Some renal complications, such as hyposthenuria and haematuria, are also observed in individuals with sickle trait, as is the rare renal medullary carcinoma.

Priapism

Priapism occurs in two-thirds of males with SCD, with a peak incidence in the second and third decades. It is caused by vaso-occlusion leading to obstruction of venous drainage from the penis. It typically affects the corpora cavernosa alone, resulting in a hard penis with a soft glans. Episodes can be brief (stuttering) or prolonged, when they last for longer than 3 hours. Recurrent priapism leads to fibrosis and eventual impotence. Young boys require explanation of symptoms and the need to seek early help for priapism. At the onset of priapism, patients should drink extra fluids and attempt to urinate. An oral dose of pseudoephedrine or terbutaline can be given. Persistent pria-

pism requires intravenous hydration and opioid analgesia. If priapism persists for more than 2–3 hours, aspiration and irrigation of the corpora with dilute phenylephrine or etilefrine solution should be performed. A simple intracavernosal injection with these agents tried early may induce detumescence and avoid the need for aspiration and irrigation.

Ocular complications

Vaso-occlusion of retinal and other vascular beds in the eye can lead to grave complications. Patients with SCD can develop abnormal (comma-shaped) conjunctival vessels, iris atrophy, retinal pigmentary changes and retinal haemorrhages. However, much more serious is neovascularization causing proliferative retinopathy, appearing as a 'sea fan', with its potential for vitreous haemorrhage and retinal detachment. Such patients are treated with laser photocoagulation or vitrectomy. The incidence of proliferative changes is substantially higher in HbSC and HbS/ β^+ thalassaemia patients than in HbSS. All patients with SCD should have annual ophthalmological evaluation, beginning in the second decade.

Sudden change in vision in a patient with SCD is an ocular emergency. Central retinal artery occlusion requires immediate treatment with hyperoxygenation and reduction of intraocular pressure, but the prognosis for vision is poor. Hyphaema, which can arise after minor trauma, leads to glaucoma due to sickling of blood in the anterior chamber. The elevated intraocular pressure causes ischaemic optic atrophy and retinal artery occlusion. Individuals with sickle trait are also vulnerable to this complication. Urgent surgical attention is required to wash out blood from the anterior chamber.

Bone complications

The chronic haemolytic process results in expansion of the medullary space, although the resultant bony changes are less pronounced than in thalassaemia. Bone infarction due to vaso-occlusion produces tenderness, warmth and swelling, which can be difficult to distinguish from osteomyelitis. In such cases, cultures from blood and direct aspiration are negative and radiography later shows patchy sclerosis and cortical thickening. Collapse of vertebral end plates due to infarction produces the codfish appearance. Patients are managed with analgesia and hydration until resolution of symptoms.

Avascular necrosis of the femoral head is a serious complication that is difficult to treat and leads to chronic disability and pain (Figure 7.4d). Patients with coexisting α thalassaemia have a higher incidence of osteonecrosis at a younger age. The condition also affects the humeral head but with less functional consequences. The outcome is better in young patients with immature capital epiphysis, who should be treated with analgesics and avoidance of weight-bearing for 3–6 months. In older adolescents and adults the condition is more likely to progress

to degenerative arthritis with conservative management. Aggressive physical therapy or combination of early core decompression followed by physical therapy can postpone the need for additional surgical intervention. Hip arthroplasty may be required for patients with severe symptoms.

Leg ulcers

Chronic leg ulcers are frequent in adult patients with SCD, particularly affecting males with the HbSS genotype (Figure 7.4e). Ulcers arise near the medial or lateral malleolus and may be single or multiple. Occlusion of skin microvasculature from sickle red cells predisposes to ulcers, which are made worse by trauma, infection or warm climate. Ulcers are always colonized with pathogenic bacteria (*Pseudomonas aeruginosa*, *S. aureus* and *Streptococcus* spp.) and acute infection can occur. The ulcers are painful and resistant to healing, and although bed rest and elevation of the leg are efficacious, they may not be practical owing to the chronic nature of the problem. Treatment requires débridement, elastic dressings, zinc sulphate and, in some cases, red cell transfusions and skin grafting.

Variant sickle cell syndromes

Sickle cell trait

Sickle cell trait (HbAS) is a benign condition that has no haematological manifestations and is associated with normal growth and life expectancy. The ratio of HbA to HbS is 60:40, owing to the greater affinity of α -globin chains for β^A -globin chains. Sickle cell trait affects 8–10% of African-Americans and up to 25–30% of the population in West Africa. Sickle trait reduces the risk of severe falciparum malaria, but not the prevalence of parasitaemia. There appears to be no effect on infections with other forms of malaria. Impaired urine-concentrating ability and haematuria can occur, and an increased incidence of urinary tract infection is observed in pregnant women with sickle cell trait. Splenic infarction is possible at very high altitudes, and varies in severity from mild discomfort to occasional splenic rupture. A slight risk of sudden death during exercise has been reported predominantly in two settings. Army recruits with sickle cell trait have a 25-fold higher rate of unexplained death, with greatest risk during basic training or at high altitude. The second risk group is young athletes engaged in intensive exercise that leads to dehydration, hyperthermia and acidosis. Sickling and vaso-occlusion under these extreme circumstances cause rhabdomyolysis, acute renal failure and cardiac arrhythmias. These individuals are advised to gradually increase exercise intensity, avoid dehydration, and to stop physical activity with the onset of muscle cramp or fatigue. Treatment of sudden collapse consists of rapid intravenous hydration and oxygen

supplementation. Genetic counselling should be provided to individuals with sickle cell trait.

HbSC disease

HbC is found among individuals of African descent and the compound heterozygote state HbSC accounts for 25–50% of patients with SCD. The vaso-occlusive complications seen in patients with HbSC resemble those seen in patients with HbSS but are less severe. Splenomegaly and the risk of sequestration can persist into adult life. Of particular note is the higher incidence of proliferative retinopathy in HbSC beginning in the second decade. The haemoglobin level (10–12 g/dL) is higher than in HbSS, and the red cells are relatively microcytic with a higher mean corpuscular haemoglobin concentration (MCHC). Peripheral blood smear reveals frequent target cells, intraerythrocytic crystals and rare sickle cells. The pathogenesis of sickling in HbSC involves membrane damage with resultant water and cation loss and increase in intraerythrocytic concentration of HbS. Equal amounts of HbS and HbC are present in the red cells and the solubility test for sickle haemoglobin is positive. The electrophoretic appearance of HbSC, HbSE and HbSO Arab at pH 8.4 is similar, but a distinction can be made based on ethnicity and by performing isoelectric focusing or agar gel electrophoresis at pH 6.5.

Sickle cell/ β thalassaemia

Sickle cell/ β thalassaemia compound heterozygotes account for less than 10% of patients with sickle syndromes. The majority of these patients have the β^+ phenotype, with the proportion of HbA ranging from 3 to 25%. The clinical phenotype is mild and disease severity correlates with the amount of HbA present. The clinical manifestations of the less frequent HbS/ β^0 genotype are similar in severity to those of HbSS. The red cells are microcytic and hypochromic, and variable numbers of target cells and sickle cells are observed. Reticulocytosis (10–20%) is present and the level of HbA₂ is elevated.

Sickle cell anaemia with coexistent α thalassaemia

Co-inheritance of α thalassaemia ($-\alpha/\alpha\alpha$ or $-\alpha/-\alpha$) with SCD is common, and such patients have less severe anaemia and demonstrate hypochromia and microcytosis. In general, the clinical severity is similar to that seen in HbSS patients with a normal complement of α -globin genes.

Sickle cell/HPFH

Approximately 1 in 100 patients with HbSS has an elevated HbF level due to deletional or non-deletional mutations that maintain γ -globin gene expression after birth. Such individuals have

20–30% HbF and less than 2.5% HbA₂. The haemoglobin level is normal with microcytosis, and target cells are observed in the peripheral smear. The clinical course is benign, and vaso-occlusive complications are rare because of the inhibition of sickling by elevated HbF.

Other sickling syndromes

Sickle cell/Hb Lepore disease

Co-inheritance of Hb Lepore with sickle cell mutation produces a clinical picture similar to that of HbS/β thalassaemia but with a low HbA₂ level.

Sickle cell/HbD disease

Of all the D or G haemoglobins, HbD Punjab (D Los Angeles) alone interacts with HbS to produce moderately severe haemolytic anaemia in compound heterozygotes. Target cells and irreversibly sickled cells (ISCs) are observed in the peripheral smear, and the clinical manifestations resemble mild sickle cell anaemia.

Sickle cell/HbO Arab disease

HbO Arab resembles HbC on alkaline electrophoresis and produces a moderately severe haemolytic anaemia in association with HbS. The disease is more severe than HbSC, and numerous sickled erythrocytes are observed on the peripheral smear.

Sickle cell/HbE disease

HbSE disease causes mild haemolysis and no remarkable abnormality of red blood cell morphology. HbE comprises only 30% of the total haemoglobin because of the thalassaemic nature of the mutation. Patients are generally asymptomatic, although occasionally significant vaso-occlusive complications and anaemia have been observed.

Diagnosis

Peripheral blood findings

The peripheral blood picture depends on the type of sickle cell syndrome. The haemoglobin level is normal in the newborn period, but anaemia develops and sickle or cigar-shaped ISCs can be observed in the peripheral blood by 3–4 months of age as HbF declines. In HbSS disease, the red cells are normocytic and normochromic, with polychromasia, many ISCs and fewer target cells (Figure 7.5a). The average reticulocyte count is 10% (4–20%) and normoblasts may be observed. Red cells are microcytic in the presence of coexisting α thalassaemia or iron deficiency. In HbS/β thalassaemia, ISCs, target cells and hypochromic microcytic red cells are prominent. The red cell morphology in HbSC disease is characterized by predominant target cells and rare ISCs. The occasional Howell–Jolly body, indicative of loss of splenic function in SCD, may be observed.

The white cell count is elevated ($12\text{--}20 \times 10^9/\text{L}$) as a result of an increase in mature neutrophils. The platelet count is also elevated to $300\text{--}500 \times 10^9/\text{L}$ as a result of decreased splenic function.

Other laboratory tests

The measurement of clotting factors in SCD indicates mild ongoing activation of the coagulation system, even in the steady state. The erythrocyte sedimentation rate is consistently low. Serum levels of unconjugated bilirubin and LDH are elevated, and haptoglobin is decreased.

Haemoglobin electrophoresis

HbS can be identified by cellulose acetate electrophoresis at pH 8.4 (Table 7.1 and Figure 7.5b). HbD and HbG have the same electrophoretic mobility with this method, but can be distinguished using citrate agar electrophoresis at pH 6.2 or thin-layer isoelectric focusing. Distinction cannot be made between HbSS and HbS/β⁰ thalassaemia on electrophoresis. The diagnosis of HbS/β⁰ thalassaemia is suggested by microcytosis and elevated HbA₂, and confirmed by finding β thalassaemia trait in one of the parents. HbA and HbS are observed upon electrophoresis in both sickle cell trait and HbS/β⁺ thalassaemia; however, the HbA fraction is greater than 50% in the former, but ranges from 5 to 30% in the latter. The level of HbF is variably elevated, with higher levels observed in patients with the Arab–Indian and Senegal haplotypes.

Other tests to detect sickle haemoglobin

Sickling of red cells can be induced by sealing a drop of blood under a coverslip to exclude oxygen or by adding 2% sodium metabisulphite. The solubility test for HbS utilizes a reducing agent such as sodium dithionite, which is added to the haemolysate. Deoxy-HbS is insoluble and renders the solution turbid (Figure 7.5c). Both these tests are unable to distinguish sickle cell trait from sickle cell anaemia and cannot be used for primary diagnosis. They are useful aids in the identification of an abnormal electrophoretic band as HbS and for identifying sickle cell trait in units of red cells prior to transfusion. High performance liquid chromatography (HPLC) can be used instead of electrophoresis to identify and quantitate HbS and other haemoglobins.

Newborn screening

Universal newborn screening is recommended for identifying SCD in the neonatal period. The efficacy of penicillin prophylaxis in preventing death from early sepsis in SCD provided the rationale for development of screening programmes. Blood samples obtained by heel prick are spotted onto filter paper and

(a)

(c)

(b)

Figure 7.5 (a) Peripheral blood smear from an individual with sickle cell anaemia. (b) Haemoglobin electrophoresis showing standard (lane a), HbSS (lanes b and c), HbSC (lane d) and sickle trait (lane e). (c) Sickle solubility assay is positive (tube a) in all three conditions.

tested by electrophoresis or chromatography. Neonates with HbSS disease and HbS/ β^0 thalassaemia have an FS pattern (the order of haemoglobins indicates their relative abundance in the sample). In sickle cell trait, the haemoglobin pattern is FAS, whereas newborns with HbS/ β^+ thalassaemia have an FSA pattern. Finally, the presence of the FSC pattern suggests HbSC disease. Family studies help to make the definitive diagnosis and, when both parents are unavailable, DNA-based testing is useful.

Prenatal diagnosis

Prenatal diagnosis is available through direct detection of the GAG→GTG mutation responsible for SCD in fetal cells. Genetic counselling is difficult owing to the marked variability in clinical manifestations within the same genotype, and the lack of ability at present to predict individual phenotype. Preimplantation diagnosis and selection of healthy embryos may offer a solution to this ethical problem.

Therapy

This section discusses general issues in the management of sickle cell disease. The treatment of specific complications is addressed in the section Clinical manifestations.

Routine healthcare

The majority of children with SCD can be managed by paediatricians or community physicians in coordination with a haematologist. Adults with SCD should also continue to have routine office visits. Patients who suffer from more severe complications or who need therapy to modify the course of SCD require specialized care at experienced centres.

The level of healthcare available to patients with SCD varies tremendously in different countries. Where resources are limited, the primary focus should be on penicillin prophylaxis, vaccination, education and analgesia for painful episodes. Where comprehensive care is available, both medical and psychosocial needs should receive attention (Figure 7.6). Sickle cell centres should have specialists in several fields who are available to address complications that may affect different organs.

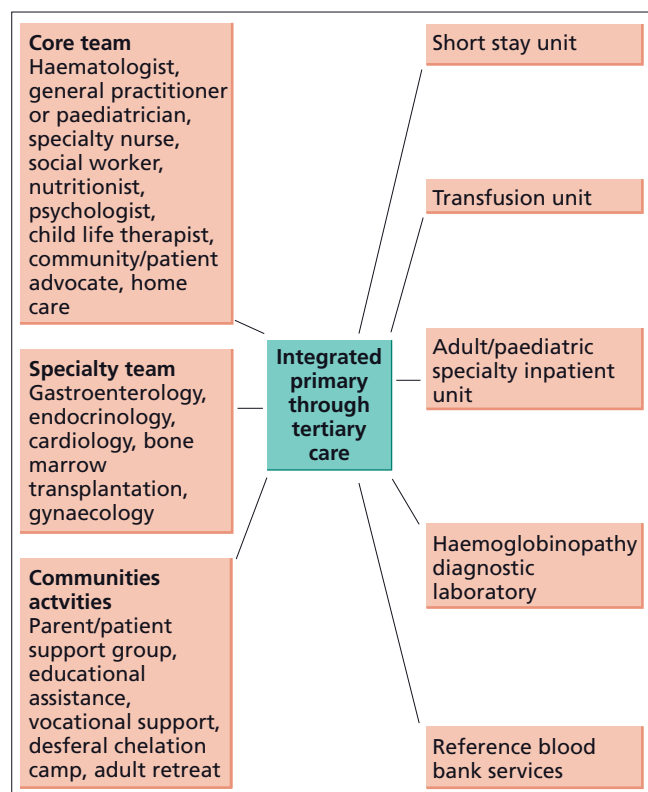

Figure 7.6 Comprehensive care of patients with sickle cell disease.

In cases when diagnosis is made on newborn screening, the infant should be seen within 1–2 months to instruct parents about infections and splenic enlargement. Routine immunization should include pneumococcal, *H. influenzae*, hepatitis B and influenza vaccines. All children receive prophylactic penicillin (phenoxymethylpenicillin orally twice daily or benzathine benzylpenicillin by intramuscular injection once per month), which may be stopped after the age of 5 years in the absence of any episode of pneumococcal sepsis or splenectomy. Folic acid supplementation (1 mg daily) is recommended. Evaluation of cerebral blood flow by transcranial Doppler should be performed on all children after 2 years to identify those at risk for stroke. Annual retinal examination is begun at 10 years. Sexually active women should have routine pelvic examinations and receive instructions about birth control.

Infections

Fever in children with SCD requires urgent attention in the office or emergency room. A complete blood count, blood and urine cultures and chest radiographs should be obtained, and lumbar puncture should be performed if meningitis is suspected. Very young children with fever or older children who appear septic should be hospitalized for intravenous antibiotics. The choice of antibiotics depends on causative agents prevalent locally and the pattern of resistance. In the USA, cefuroxime or ceftriaxone are preferred, whereas high-dose penicillin is used in several other countries. Many patients older than 2 years who do not look septic or seriously ill can be managed at home after receiving ceftriaxone in the emergency department. Antibiotics should continue for 1 week when bacteraemia is documented. In the presence of pneumonia, a macrolide should be added to cover *Mycoplasma* or *Chlamydia*. Antibiotics for osteomyelitis should provide coverage for *Salmonella* and *S. aureus* and are given for a period of 4–6 weeks.

Transfusion therapy

Blood transfusion in SCD is used to treat severe anaemia or to reduce the amount of circulating sickle haemoglobin. Only sickle-negative blood, which can be identified by negative sickle solubility test, is used for transfusions. The blood should also be leucodepleted, and matched for common minor E, C and Kell antigens. A simple transfusion is used to treat severe anaemia that is often associated with aplastic crisis and splenic sequestration. Older patients with renal failure may also need transfusions for declining haemoglobin level.

Dilution of circulating sickle haemoglobin can be accomplished by simple transfusion if the baseline haemoglobin level is low. Exchange transfusion or erythrocytapheresis is required to prevent hyperviscosity from the significant rise in haemoglobin when the patient has high baseline haemoglobin or when

a greater reduction in HbS is desired. The final haemoglobin level should not exceed 12 g/dL after simple or exchange transfusion. Conditions in which a reduction in the proportion of HbS is required include stroke, progressive acute chest syndrome, persistent priapism or preparation for general anaesthesia. Longer-term reduction in HbS through regular transfusions is advocated to prevent recurrence of stroke and sequestration, and in selected patients with leg ulcers or chronic pain. Routine blood transfusion is not needed for pain episodes, infections, minor surgery or uncomplicated pregnancy.

It is possible to eliminate most complications of SCD with the use of chronic transfusions to suppress endogenous sickle haemoglobin production. However, alloimmunization, iron overload and transmission of viruses are significant risks that limit the use of transfusions to the management of severe complications. In addition, because of the limited availability and decreased safety of blood, criteria for transfusion are more stringent in less developed countries. The high incidence of alloimmunization from minor blood group incompatibility (Rh, Kell, Duffy and Kidd) between donors and recipients can be avoided by use of phenotypically matched units. Patients on long-term transfusions develop iron overload, which requires chelation with desferrioxamine or deferasirox. The prevalence of iron-induced organ damage appears to be lower in SCD compared with thalassaemia despite similar amounts of iron burden. Liver biopsies or MRI are usually necessary to measure iron burden because the serum ferritin is unreliable. Because iron accumulation can be reduced or prevented by erythrocytapheresis, this technique is now preferred when venous access is available.

Pain management

Prompt management of pain is essential, given its frequent occurrence and potential adverse psychological consequences. Patients with recurrent pain are best managed in a familiar ambulatory setting rather than the emergency ward. The patient should be evaluated for potential infectious, traumatic or surgical causes of pain. Pain assessment tools are available for young patients and are also helpful in older patients to follow the response to therapy. Adequate hydration should be provided, along with analgesia using narcotics and NSAIDs. Several narcotic agents are available for oral and parenteral use and the choice of medicine depends on local experience as well as the patient's preference. The use of incentive spirometry reduces the potential for developing hypoxia and acute chest syndrome secondary to hypoventilation. Under-treatment of pain can be avoided by using patient-controlled analgesia, which has the added benefit of reducing apparent drug-seeking behaviour. Narcotic addiction is no more frequent in sickle cell patients than in others requiring analgesia. NSAIDs improve pain control with or without narcotics. Providing psychosocial support and reassurance, and allaying anxiety are important

goals. Chronic pain is rare in SCD and may require long-acting narcotics for management.

Hydroxycarbamide

Hydroxycarbamide is a tremendously important drug in the management of patients with SCD who have severe clinical manifestations. Hydroxycarbamide inhibits ribonucleotide reductase, leading to S-phase arrest of replicating cells, and is used in SCD because of its ability to stimulate production of HbF. Hydroxycarbamide increases HbF as a result of stress erythropoiesis induced by its myelosuppressive effect. Patients show variable response in the degree of rise in HbF, and some experience no change from the baseline value. Other biological effects of hydroxycarbamide play an equally significant role in the beneficial clinical effects observed during therapy. Erythrocytes of patients on hydroxycarbamide have increased water content and deformability and decreased adherence to vascular endothelium. There is elevation of the haemoglobin level, mean corpuscular volume (MCV), HbF and F cells, whereas total white cell and neutrophil count, reticulocyte count and the number of dense sickle cells decrease. Patients on hydroxycarbamide experience 50% reduction in the incidence of acute painful episodes and acute chest syndrome. Transfusion needs, frequency of hospital admissions and the risk of death are also decreased. Hydroxycarbamide does not improve leg ulcers, while the effect on priapism is unclear. Hydroxycarbamide may reduce risk of stroke, and its role in children with elevated cerebral blood flow velocities and previous stroke is under intense study.

The efficacy of hydroxycarbamide therapy is now well established in adults and there is growing evidence to support its use in children. Prospective trials are underway to evaluate safety and efficacy in infants, and to specifically examine if end-organ damage to spleen, brain and kidney can be reduced. In young patients with severe disease, stem cell transplantation should also be considered as an alternative to chronic transfusions or long-term hydroxycarbamide therapy. The overall benefit of hydroxycarbamide to the patient is closely related to compliance, for which monitoring in the clinic and psychological support should be provided. Patients should be made aware that 3–6 months may elapse before clinical benefits are realized. Hydroxycarbamide is offered to patients (adults and children over 6 years) with frequent pain episodes or acute chest syndrome. It is started at a dose of 20 mg/kg per day and increased by 5 mg/kg every 2–3 months until the absolute neutrophil count is close to $2.5 \times 10^9/L$. Compliance with prescribed dose should be ascertained before each dose escalation, up to the maximum dose of 35 mg/kg or 2000 mg/day. Patients require frequent monitoring of blood counts, as well as renal and hepatic function. Myelosuppression is the most commonly encountered side-effect and temporary cessation of therapy and dose reduction is required for neutropenia, thrombocytopenia,

reticulocytopenia or fall in haemoglobin. Dose modification is necessary for patients with renal failure. Skin pigmentation affecting the nails, palms and soles is commonly observed. There may be a temporary decline in sperm production among men while on hydroxycarbamide treatment. Despite concerns about the leukaemogenic and teratogenic effects of hydroxycarbamide, no convincing increase has been reported in SCD so far. Men and women should practise contraception while taking hydroxycarbamide, and women who become pregnant should stop the drug. No decrease in growth rate is observed in children over 5 years using hydroxycarbamide, while the growth effects of the drug in younger children are under evaluation. Overall, the risks associated with hydroxycarbamide therapy appear to be low and are certainly tolerable compared with the perils of untreated SCD in the severely affected patient.

New therapeutic modalities

A better appreciation of the pathophysiology of SCD will make it possible to exploit new therapeutic mechanisms (Table 7.4). Agents under development include membrane-active chemicals that improve hydration of sickle cells by blocking Gardos channels and potassium–chloride cotransport, or inhibit red cell adherence to endothelium. Decreased availability of NO has an important role in vaso-occlusion in SCD, and agents that correct NO deficiency may have significant therapeutic benefit. Newer agents to induce HbF synthesis that are being studied include orally effective butyrate compounds and decitabine, an analogue of 5-azacytidine. Decitabine can improve HbF level in patients who do not respond to hydroxycarbamide.

Haemopoietic stem cell transplantation

Allogeneic haemopoietic stem cell transplantation (HSCT) from a matched sibling donor cures 85% of children with SCD less than 16 years of age. Both bone marrow and umbilical cord blood from related donors are suitable sources for the stem cells. Studies are underway to evaluate the use of unrelated donors or reduced intensity conditioning regimens. However, 5% of patients die of complications related to HSCT and another 10% experience graft rejection with the return of SCD (Figure 7.7). Additional long-term risks after HSCT are infertility and second malignancy. Selection of candidates for HSCT is complex owing to the uncertain long-term course of the disease. HSCT should be considered in children (age < 16 years) with SCD (any genotype) who have a human leucocyte antigen (HLA)-identical related donor and evidence of target organ damage involving the brain, lungs, kidneys or eyes. Children who are placed on long-term blood transfusions for any indication should also be evaluated for HSCT. Although it is clear that high-risk patients benefit from this treatment, the role of HSCT in asymptomatic children is not defined. Severe organ dysfunc-

tion increases the risks from the procedure, and hence discussion for HSCT should be started early when eligible indications are identified.

Gene therapy

Correction of SCD by gene therapy requires efficient insertion of a gene into repopulating haemopoietic cells and regulated expression in erythropoietic lineages. An anti-sickling haemoglobin, constituting 20–30% of the total haemoglobin, would be enough to produce clinical response. Mouse models of sickle cell disease have considerably helped in the effort to develop

Figure 7.7 Outcome after transplantation for 59 children with advanced symptomatic sickle cell disease. Kaplan–Meier estimates for survival and event-free survival following marrow transplantation are shown. An event is defined as death, graft rejection or recurrence of sickle cell disease. A cumulative incidence curve for graft rejection and return of sickle cell disease is also depicted. (From Walters MC, Patience M, Leisenring W *et al.* (2001) Stable mixed hematopoietic chimerism after bone marrow transplantation for sickle cell anemia. *Biology of Blood and Marrow Transplantation* 7: 665–73 with permission.)

gene therapy, and correction of the sickling phenotype has been demonstrated in such animals.

Psychosocial issues

Recurrent pain and the unpredictable course of the illness place SCD patients at higher risk of depression and poor family relationships. Despite this, with integrated medical care and social support most patients with SCD are well adjusted. Addiction to narcotics is an uncommon phenomenon and is the result of social influences rather than analgesic therapy. Attention to psychological well-being as well as educational and vocational support are important components of the care provided to SCD patients.

Introduction

This chapter and the next deal with genetically determined disorders of the red cell, other than those of haemoglobin, which cause its premature destruction. In this chapter, genetic changes that affect the structure and function of the red cell membrane are described. Chapter 9 describes the inherited defects in red cell metabolism that shorten red cell survival.

Whereas the primary genetic changes underlying these disorders are quite heterogeneous, many of the manifestations are similar, as they result mainly from the increased rate of red cell destruction and from the consequent hyperactivity of the erythroid component of the bone marrow. Therefore, the description of individual conditions will be prefaced with a brief consideration of the pathophysiology of haemolysis.

Haemolysis

Definitions

Haemolysis indicates that the destruction of red cells is accelerated. Normally, in adults, the bone marrow output is well below its maximal capacity. Red cell production can be increased about sixfold in the adult by increasing the cellularity of existing haemopoietic marrow, as well as by expansion of haemopoietic

marrow into the long bones. In the newborn, and during infancy, marrow expansion depends on expanding the medullary cavity of bones, leading to thinning of cortical bone. These bony changes are most extreme in the β thalassaemia syndromes, but some skeletal changes, usually some bossing of the frontal bones, may be seen in more extreme hereditary haemolytic anaemias of other causes.

Increased red cell destruction is often completely matched by increased production, resulting in compensated haemolysis. When the rate of haemolysis exceeds the maximum erythropoietic capacity of the bone marrow, or when the latter is limited (e.g. because of inadequate supply of iron or folate or by ineffective erythropoiesis), the result is haemolytic anaemia. As in any haemolytic disorder, with or without anaemia, the consequences of haemolysis are always present, and as the same underlying pathogenetic process may cause at different times, even in the same patient, either a compensated haemolytic disorder or haemolytic anaemia, the two terms are often used, somewhat loosely, as though they are interchangeable.

General features of haemolysis

The clinical and laboratory aspects of haemolysis depend on the consequences of increased red cell destruction and production as well as the main process by which destruction takes place. Increased red cell destruction leads to an increase in unconjugated bilirubin from increased haemoglobin turnover. Unconjugated bilirubin does not appear in the urine, although there will be an increase in urinary urobilinogen. The bilirubin level is usually not more than two to three times normal because the normal liver is able to increase excretion to compensate for

at least some of the increased production. Jaundice is usually mild in hereditary haemolytic anaemias although there are important exceptions.

In the neonate, particularly premature infants, liver function is not fully developed and more severe jaundice requiring urgent therapeutic intervention may occur. A rare but potentially confusing problem is the co-inheritance of Gilbert syndrome, which comprises a group of congenital liver enzyme deficiencies that impair bilirubin conjugation. On its own, Gilbert syndrome does not produce clinical jaundice except when there is inadequate calorie intake, but in conjunction with haemolytic anaemia the hyperbilirubinaemia may be considerable. The increased bilirubin of haemolysis does increase the risk of gallstones and cholecystitis, which in turn may lead to an increase in serum bilirubin.

In the degradation of haemoglobin, the molecule is broken down to two $\alpha\beta$ subunits, which are bound to haptoglobin, the complex being rapidly internalized in the hepatocyte after binding to the haptoglobin complex receptor. In the presence of haemolysis, serum haptoglobin levels are greatly reduced or absent. However, haptoglobin is an acute-phase protein and levels will increase in the presence of inflammation. Haemopexin is another haem-binding protein produced by the liver, which is decreased in haemolysis. Chronic haemolytic anaemia may increase the iron content of the body through increased iron absorption as a result of anaemia coupled to the retention of the haem iron following binding to haptoglobin and haemopexin. In rare cases of inherited haemolytic anaemia, this iron overload may be sufficient to produce clinically important effects, particularly if there is co-inheritance of a haemochromatosis gene. In most haemolytic anaemias, owing to membrane defects, the destruction of red cells takes place extravascularly in the reticuloendothelial system and the iron is retained as described. When destruction is intravascular, free haemoglobin will be released into the plasma, producing haemoglobinaemia and methaemalbuminaemia, and will pass through the glomerulus to produce haemoglobinuria and haemosiderinuria. Iron deficiency is thus more likely than overload in intravascular haemolysis.

Increased red cell production leads to expansion of the red cell precursor compartment of the bone marrow as described above. There are also changes in the structure of the marrow as a consequence of the chronic anaemia, which allows the early release of reticulocytes and, in more marked cases of haemolytic anaemia, nucleated red cells and even myelocytes. In the peripheral blood, the polychromasia and macrocytosis of reticulocytosis are the result of this increased throughput and release. The increased cell production requires an increased supply of folate which, at least theoretically, can produce folate deficiency unless supplements are given. It is usual to give folic acid (400 μg daily or 5 mg once weekly) to people with chronic haemolytic anaemia. The main features of haemolytic anaemia are summarized in Table 8.1.

Table 8.1 Main features of haemolytic anaemia.

<i>Increased red cell destruction</i>	
Unconjugated hyperbilirubinaemia	
Mild jaundice	
Increased risk of gallstones	
Increased urinary and faecal urobilinogen	
Decreased serum haptoglobin and haemopexin	
Extravascular changes	
Increased iron stores	
Splenomegaly	
Intravascular changes	
Haemoglobinaemia and haemoglobinuria	
Haemosiderinuria	
Methaemalbuminaemia	
Decreased iron stores	
<i>Increased red cell production</i>	
Marrow expansion: bone changes	
Increased erythropoiesis: \downarrow myeloid/erythroid ratio	
Reticulocytosis: polychromasia	
Increased folate requirements: macrocytosis	

Classification

Because of the unique structural and functional specialization of the mature red cell, the impact on it of a wide range of exogenous or endogenous changes is relatively uniform: the cell will be destroyed prematurely. According to the site of the primary change, haemolytic disorders have been traditionally classified as being due either to intracorporeal or to extracorporeal causes. According to the nature of the primary change, haemolytic disorders have also been classified as inherited or acquired. These two classifications correlate almost completely with each other, in that extracorporeal causes are usually acquired, whereas intracorporeal causes are usually inherited. One notable exception is paroxysmal nocturnal haemoglobinuria, a disease in which an intracorporeal defect is acquired as a result of a somatic mutation (see Chapter 11).

Although in every cell all molecules and organelles are naturally interdependent, it is convenient to consider the red cell as a conveyance for a large amount of haemoglobin contained in a plasma membrane, the stability of which is maintained by an appropriate metabolic machinery. Unfavourable genetic changes in any of these components may cause haemolysis. Accordingly, inherited haemolytic disorders can be classified into three major groups: (i) genetic disorders of haemoglobin (see Chapter 6); (ii) abnormal membrane (including the cytoskeleton); and (iii) abnormal metabolism (enzymopathies) (see Chapter 9).

Red cell metabolism

The details of red cell metabolism are considered in Chapter 9. Suffice to say in this chapter that the red cell membrane requires a supply of both ATP and reducing power to maintain its proper integrity. The way in which energy is supplied to the membrane is intimately related to its structure. The main pathway for metabolizing ATP in the membrane is via Na⁺/K⁺-ATPase. The enzyme glyceraldehyde-3-phosphate dehydrogenase (Ga3PD) is closely associated with the inner layer of the membrane. It catalyses the conversion of glyceraldehyde-3-phosphate (Ga3P) to 1,3-diphosphoglycerate (1,3-DPG), with the production of NADH. ATP is produced in the next step of the glycolytic pathway, the conversion of 1,3-DPG to phosphoglycerate, which occurs in intimate contact with the membrane.

The red cell membrane

The red cell membrane, like all other cell membranes, consists of a lipid bilayer that is stabilized and given specific properties by the proteins, glycolipids and other specialized molecules and structures with which it is associated.

The lipid bilayer consists of approximately equal molar quantities of phospholipids and cholesterol molecules. The charged phosphatidyl groups of the phospholipids are hydrophilic and form the outer and inner surfaces of the bilayer. The interior of the membrane is formed by hydrophobic bonding of the acyl chains and cholesterol, which form the internal parts of the two leaflets (Figure 8.1). The arrangement is energy efficient but the two leaflets are not symmetrical. The outer leaflet consists

Figure 8.1 Arrangement of membrane lipids. The acyl chains of the diacyl phosphatidylglycerides are hydrophobic non-polar domains and they form hydrophobic bonds with the acyl groups of the opposite layer. Cholesterol is present in roughly equimolar amounts and determines the fluidity of the membrane.

mainly of phosphatidylcholine and sphingomyelin, the inner leaflet of phosphatidylethanolamine and phosphatidylserine (Figure 8.2). Maintenance of the asymmetry and the proper function of the membrane requires energy. In mature red cells this is provided by ATP from the glycolytic pathway and reducing power mainly in the form of glutathione.

The normal biconcave shape and function of the red cell membrane are determined by the membrane proteins and their interactions with the lipid bilayer and with each other. There are two main sorts of protein–membrane associations. The integral proteins have strong hydrophobic domains that associate with the hydrophobic part of the bilayer. Many of these integral proteins span the membrane and provide channels between the plasma and cytosolic compartments. The cytosolic inner domains of these proteins interact with each other and with the second main group, the proteins of the cytoskeleton. The integral proteins that provide the links between the plasma surface and the cytoskeleton have conveniently been referred to as ‘vertical connections’, whereas the proteins of the cytoskeleton that comprise the inner network of the cell membrane are characterized as ‘horizontal connections’. Genetic abnormalities that produce spherocytes mainly have mutations affecting the vertical connections. Mutations of the horizontal system usually produce elliptocytosis or more bizarre-shaped changes. The main proteins are listed in Table 8.2, and their arrangement is shown schematically in Figure 8.3.

In addition to the compartments mentioned so far, there are numerous surface proteins that provide the main interface with the plasma, including the blood group systems and other receptors. Many of these molecules are heavily glycosylated, as are

Figure 8.2 Main lipids of the red cell membrane. The outer, plasma, layer contains mostly neutral lipids, sphingomyelin and phosphatidylcholine (lecithin). The inner, cytoplasmic, layer contains mostly acidic groups, phosphatidylserine, phosphatidylethanolamine and phosphatidylinositol. R may be choline, serine, ethanolamine or inositol.

Table 8.2 Proteins of the red cell membrane.

Band*	Protein	Gene location	Function	Associated haemolytic anaemias

Figure 8.3 Arrangement of membrane proteins.

the integral proteins the glycophorins. Sialic acid, which comprises the main side-chain of the glycophorins, contributes the most to the negative surface charge of the erythrocyte. Many of these surface proteins are linked to the membrane by the glycosylphosphatidylinositol (GPI) anchor, which provides the

hydrophobic domain required for association with the inner hydrophobic part of the membrane. Somatic mutations in the gene for phosphatidylinositol glycan A (*PIGA*) leads to a failure to produce the anchor and to paroxysmal nocturnal haemoglobinuria (discussed in Chapter 11).

The integral proteins and vertical interaction

The two major integral proteins that span the lipid bilayer are band 3 (the anion channel protein) and the glycoporphins A, B and C. Band 3 and associated molecules, 4.2 (pallidin) and ankyrin (2.1), form one major vertical interactive pathway with binding to the β -chain of the spectrin tetramer through ankyrin. Glycophorin C and protein 4.1 also provide a vertical interaction but the association with spectrin is through a link with actin, which is a key part of the horizontal network.

The band 3–4.2–ankyrin–spectrin complex is a central part of the organization of the lipid bilayer and loss of part of this complex leads to loss of lipid from the outer leaflet of the bilayer, reducing the surface area to volume ratio of the red cell and leading to the characteristic spherocytes of hereditary spherocytosis.

The main protein of the cytoskeleton is spectrin. Spectrin consists of two subunits, α and β , which associate side by side to produce a heterodimer. The dimers associate head to head to form tetramers about 200 nm long. The tail end of the dimer makes contact with a short actin filament composed of 14 monomers, and the interaction between spectrin and actin is stabilized by protein 4.1. Binding of spectrin dimers to actin filaments produces the more or less hexagonal network of spectrin tetramers on the inner surface of the membrane associated with the lipid bilayer. Spectrin–actin–4.1 interactions provide much of the flexibility of the red cell membrane. Deficiencies of spectrin that affect these horizontal interactions tend to induce a loss of flexibility in the membrane and elliptocytosis.

The clinical phenotypes of hereditary membrane disorders

Mutations in the genes that control the proteins of the membrane and their interaction mainly produce changes in the shape of red cells, which is characteristic in any individual. Many of the conditions are inherited as autosomal dominant disorders, homozygosity for major defects mainly being lethal. Severe, bizarre or unexpected red cell morphology is often produced by double heterozygosity or inheritance of more than one defect of the membrane proteins. The mutations affecting the red cell membrane are many and heterogeneous, but the effect on the phenotype can be classified in five main categories: (i) hereditary spherocytosis; (ii) hereditary elliptocytosis and hereditary pyropoikilocytosis; (iii) Southeast Asian ovalocytosis; (iv) hereditary acanthocytosis; and (v) hereditary stomatocytosis.

Hereditary spherocytosis

As the name implies, hereditary spherocytosis (HS) is a genetically determined haemolytic anaemia characterized by the

Figure 8.4 Hereditary spherocytosis, peripheral blood. Small spherocytic red cells lack area of central pallor. Large polychromatic red cells (reticulocytes) result in normal MCV, although MCHC may be increased.

spherical shape of the affected red cells. The spherical shape produces a characteristic appearance in the stained blood film of round cells with smaller than normal diameter, which lack the area of central pallor of the normal biconcave discs (Figure 8.4). The old name, ‘familial acholuric jaundice’, emphasizes the presence of jaundice in the absence of bile in the urine, distinguishing this jaundice from that caused by hepatobiliary problems. The disorder is generally inherited as a dominant condition with a wide spectrum of severity. The usual clinical picture is of mild to moderate haemolytic anaemia but varies from severe neonatal haemolysis with kernicterus (rare) to clinically silent and asymptomatic (usual) haemolysis. Autosomal recessive inheritance occurs in a few mutations, often producing severe haemolysis.

In white populations, HS is one of the most common haemolytic anaemias due to membrane defects, with a prevalence of clinically apparent disease of 200–300 per million population. The occurrence of clinically silent cases probably means that the overall prevalence is slightly higher.

Clinical features

The commonest forms of HS present as mild anaemia and jaundice, with a modestly enlarged spleen. However, the genetic heterogeneity of HS (see below) is reflected in the clinical presentation. As the main site of increased red cell destruction in HS is the spleen, it is not surprising that the size of the spleen

tends to reflect the severity of the haemolysis, although splenomegaly is rarely marked, enlargement below the umbilicus being very uncommon. When HS presents in adolescence or adult life, it needs to be distinguished from other causes of microspherocytosis, particularly warm autoimmune haemolytic anaemia.

HS may present at birth. The functions of the spleen become mature only after birth, so severe anaemia *in utero* is rare. Erythropoiesis is highly active before birth but enters a phase of reduced activity in the neonatal period. Severe anaemia, developing over 5–30 days post delivery and requiring transfusion, may result from this double physiological development of reduced production and increased destruction, but the anaemia may greatly reduce during the first year of life as compensatory erythropoiesis develops. Decisions about splenectomy do not need to be taken during this time.

Molecular pathology

About 60% of HS cases result from a defect in the ankyrin–spectrin complex, with the genes for the α and β subunits of the spectrin dimer (*SPTA1*, *SPTB*) or for ankyrin (*ANK1*) being implicated in different genetic types (Table 8.2). A further 25% involve deficiency in band 3, the anion channel. In the remainder of the dominantly inherited HS families there is a deficiency of protein 4.2 or no abnormality has yet been identified. Deficiency of protein 4.2 is particularly common in Japanese families with HS (Table 8.2). These defects involving spectrin–ankyrin–band 3 interactions affect the vertical interactions described by Jiri Palek and colleagues.

It will be appreciated that the genetic defect that produces the dominant form of HS affects only one of a pair of genes. The presence of one abnormal protein influences the protein–protein interactions of these complexes, leading to partial deficiency of several proteins, even if they are not genetically disturbed. This is particularly true of spectrin. Complete loss of complex function is probably not viable, so homozygous children are not found. Double heterozygosity or inheritance of separate membrane defects does occur and is associated with usually severe haemolytic anaemia. Other recessive forms of HS are also seen in which the inheritance of one defective gene involving the spectrin subunit produces no clinical effect, whereas homozygosity produces a severe defect and haemolysis.

Laboratory diagnosis

The typical findings of extravascular haemolysis are present in HS (see Table 8.1). The diagnosis is usually made on the basis of morphology of the blood, backed up where possible with a family history. The mean corpuscular haemoglobin concentration (MCHC) is often increased above 35 g/dL in HS, but the presence of macrocytic reticulocytes usually results in a low normal mean corpuscular volume (MCV) rather than true microcytosis. These changes result not only from the reduction

of the surface area to volume ratio but also from the slight dehydration of HS cells. A number of variants of the typical HS features have been described, usually the more severe forms that may have denser and less perfectly round cells in the peripheral blood. In infancy, the morphology may be more difficult to interpret. The effect of immature splenic function and the macrocytosis and anisocytosis of infancy combine with the HS phenotype to produce red cell appearances not typical of the developing HS. Family studies may assist in the diagnosis.

Osmotic fragility test

The osmotic fragility test measures the sensitivity of red cells to lysis *in vitro* to swelling caused by incubation in increasingly hypotonic saline solutions. Red cells are able to swell with increasing volume until the pressure disrupts the unstretchable membrane and lysis occurs. In normal red cells with the biconcave disc shape, 50% lysis occurs when the saline solution reaches about 0.5% sodium chloride. The more rigid HS cells have less ability to swell and so lyse at higher concentrations, producing a right-shifted osmotic fragility curve. One of two patterns may be seen in HS: a generally right-shifted curve, which is the more common finding, and one where there appears to be a ‘tail’ of lysis-sensitive cells. Incubation of blood for 24 hours at 37°C accentuates the fragility (Figure 8.5).

The acidified glycerol lysis test (AGLT) uses glycerol to slow the entry of water into the cells *in vitro*. The time taken for lysis to occur is a function of the osmotic resistance of the cells. HS cells lyse more rapidly than normal cells. The test is easier to perform than the osmotic fragility test.

Autohaemolysis test

The autohaemolysis test examined the ability of red cells to withstand metabolic deprivation by incubation *in vitro* for 24 hours with and without the addition of glucose. It is a crude insensitive test which has generally been abandoned.

Identification of protein abnormalities or gene defects

Methods that identify the defective gene or its product are the most specific for membrane defects but are beyond the scope of most routine haematology laboratories. The original identification of membrane proteins using sodium dodecyl sulphate-solubilized polyacrylamide gel (SDS-PAGE) electrophoresis has led to the classification according to the banding system indicated in Table 8.2. The identification of specific genetic abnormalities may be important in compound haemolytic syndromes but requires specialist laboratories.

One screening test for HS makes use of the binding of eosin-labelled maleimide, in the form of eosin-5-maleimide, to lysine 430 in band 3 and cysteine molecules in surface proteins, particularly rhesus blood groups. In about 25% of HS patients there is a deficiency of band 3 and a loss of surface proteins caused by the instability of the lipid bilayer. HS red cells bind eosin-5-maleimide less than normal cells, by about 25–30%.

Figure 8.5 Osmotic fragility test in hereditary spherocytosis. Osmotic fragility is increased in the microspherocytes (right shift), but there is also a small population of resistant cells due to increased reticulocytes (a). After splenectomy, the microspherocytes remain but the proportion of reticulocytes is reduced to normal values and the resistant cells are not seen (b).

Even when the main defect is not in band 3, there may be sufficient loss of eosin-5-maleimide binding to indicate HS. The screening test has to be used in conjunction with morphology because Southeast Asian ovalocytosis, congenital dyserythropoietic anaemia type II and cryohydrocytosis also give reduced fluorescence.

Clinical course and complications

In most kindred, the course of the disorder is similar in affected members although, as with most inherited defects, there is some variable penetrance and it is not rare to find a very mildly affected parent with more severely affected offspring.

As with all congenital haemolytic anaemias, the anaemia may be aggravated by environmental factors. This may be consequent on an increase in the red cell destruction or a decrease in production. Increased jaundice may occur during viral infections or bacterial sepsis, the anaemia also being aggravated by a decrease in production consequent on the effects of the acute-phase response or the inhibition of erythropoiesis by interferon (IFN)- γ .

Primary infection with parvovirus 19 produces a specific and marked inhibition of erythropoiesis, often characterized as an aplastic crisis. In patients with shortened red cell survival, severe

anaemia may be produced by the inhibition, which lasts for some 4–7 days. In normal individuals with a red cell lifespan of 120 days, such an inhibition produces no clinical effect. The anaemia associated with parvovirus infection in HS may require urgent transfusion. The diagnosis is made by finding absent parvovirus antibodies with subsequent appearance of IgM antibodies. The presence of IgG antibodies at the time of the anaemia excludes the diagnosis.

Acute anaemia due to splenic sequestration is a relatively uncommon complication of HS in childhood. The pathogenesis is probably increased splenic size and activity leading to increased trapping of HS cells within the spleen. This complication may also require urgent transfusion.

Malnutrition may increase anaemia because of folate deficiency but also from increased jaundice through the effect of low-calorie input on unconjugated bilirubin levels in the blood.

The anaemia of pregnancy may aggravate a haemolytic anaemia and hence bring the condition to the attention of clinicians and patients. Classical HS is not a risk to mother or child in pregnancy.

Gallstones are an expected complication in HS as in other chronic haemolytic anaemias. Silent gallstones require no intervention. Recurrent cholecystitis or biliary colic may require cholecystectomy accompanied by splenectomy (see below). Leg ulcers are a rare but well-recognized complication of HS, as with other chronic haemolytic anaemias. Extramedullary haemopoietic masses, usually paravertebral, occur rarely in more severe HS.

Management

Patients with well-compensated haemolysis and no transfusion requirements need no treatment other than reassurance and folic acid supplements (e.g. 400 μ g daily or 5 mg weekly). For people with a well-balanced and adequate diet, folic acid supplements are probably unnecessary, but custom dictates the practice should be continued. Radiolucent gallstones, if detected by chance on ultrasound, are common and need no treatment unless complications arise. Gallstones without recurrent inflammation are not a risk factor for carcinoma of the gallbladder. Recurrent cholecystitis or obstruction would be an indication for cholecystectomy, which would also be an indication for splenectomy.

Splenectomy

For the great majority of patients with autosomal dominant forms of HS, and most patients with *de novo* disease, splenectomy restores the lifespan of the red cells to normal and hence cures the haemolysis and hyperbilirubinaemia. In HS, the spleen is responsible for the removal of the older red cells that have lost the most surface through lipid loss from the outer layer. This removal of damaged but functional cells shortens the lifespan and causes jaundice and reticulocytosis. However, splenectomy carries short- and long-term risks that must be

weighed against the benefits in any individual patient. After splenectomy, the blood film continues to show spherocytosis together with changes of a splenectomy film. The osmotic fragility remains increased.

Risks of splenectomy (see also Chapter 20)

The immediate risks associated with splenectomy include those of any abdominal operation together with an increased risk of thrombosis, associated with a marked rise in platelet count that occurs promptly after splenectomy. In HS, in which the erythropoietic drive returns to normal following splenectomy, the platelet count also returns to normal and the risk diminishes. In conditions where haemolysis persists, the platelet count remains elevated, sometimes markedly, and the increased risk of thrombosis continues. The long-term cardiovascular risks are discussed by Schilling (2008, 2009).

The major hazard of splenectomy is the long-term susceptibility to severe infection, so-called overwhelming post-splenectomy infection (OPSI) (see also Chapter 20). The spleen plays an important role in filtering and phagocytosing bacteria, and removing parasitized red cells from the blood. The spleen is the major source for mounting the rapid, specific IgM response to organisms that enter through the gut. The main organisms of this class are the encapsulated organisms, *Streptococcus pneumoniae*, *Haemophilus influenzae* type B and *Neisseria meningitidis*. Pneumococcal infection is responsible for about 70% of OPSI and has a 60% mortality. Lack of a spleen greatly increases the virulence of the infection, with progression from the first feeling of fever and non-specific flu-like symptoms to irreversible endotoxic shock occurring in a matter of hours. Patients may present with purpura, evidence of disseminated intravascular coagulation, multiorgan failure, hypotension and peripheral limb ischaemia. Diarrhoea and vomiting are common prodromes. It is this speed of progression that makes the prophylaxis of this fortunately uncommon complication so important. Prophylaxis depends on education and awareness for the patient, specific measures to reduce the risk from particular organisms and the provision of information concerning the splenectomy for healthcare workers (Table 8.3). There is no direct evidence that phenoxymethylpenicillin (e.g. 250 mg twice daily) reduces the risk of OPSI in splenectomized patients but good evidence that it does so in homozygous sickle cell patients who have functionally inactive spleens. It is on this evidence that such antibiotic prophylaxis (or erythromycin 250 mg b.d. for those sensitive to penicillin) is recommended (see also Chapter 7). The actual incidence of OPSI is difficult to calculate. The overall risk has been stated as 0.04 per 100 patient-years for patients without added immunosuppression, but considerably higher for those immunocompromised by malignancy or chemotherapy. The risk is greatest in the first 2 years after splenectomy but continues lifelong. Children under the age of 5 years are particularly susceptible and splenectomy should be avoided in this group if at all possible.

Table 8.3 Guidelines for prevention and management of infection in the splenectomized patient.

All patients receive polyvalent pneumococcal immunization, preferably 2 weeks prior to splenectomy, with a booster dose every 5–10 years
Any unimmunized patient should receive <i>Haemophilus influenzae</i> type B vaccine
Meningococcal immunization (types A and C) are not routinely recommended but should be given to travellers to countries where meningitis is possible, and during outbreaks in the UK
Influenza immunization may be beneficial and should be given
Lifelong prophylactic antibiotics (oral phenoxymethylpenicillin or an alternative)
Awareness of risks of malaria and scrupulous prophylaxis if at risk
Animal, particularly dog and tick, bites may be dangerous
Leaflet card for patients to alert health professionals to risk of OPSI
Patients developing infection despite measures should receive systemic antibiotics and be admitted urgently to hospital

Indications for splenectomy

Patients with marked haemolysis producing symptoms or requiring transfusion should be splenectomized, although preferably not before the age of 5 years (later if possible). Recurrent aplastic crises are also an indication. Attacks of cholecystitis or biliary colic warrant cholecystectomy and splenectomy, but symptomless gallstones are not a necessary indication.

Hereditary elliptocytosis and hereditary pyropoikilocytosis

Deficiency of spectrin tetramers, the horizontal links of the cytoskeleton, produces a wide spectrum of disease from fully compensated haemolysis with mildly elliptocytic red cells to severe and life-threatening anaemia with grossly distorted cells. When the morphological characteristic is a relatively uniform elliptical shape, the condition is referred to as hereditary elliptocytosis (HE). Haemolytic anaemia associated with the more distorted forms, which are also heat labile, is called hereditary pyropoikilocytosis (HPP). Recent evidence implies that HPP is a severe form of HE. Within a family, HE and HPP may both be present, the more severely affected individuals having both a total spectrin deficiency as well as a relative deficiency of spectrin tetramers. This may be caused by co-inheritance of a low-expression allele for α -spectrin, compound heterozygosity for two HE alleles or HE homozygosity. A number of families

have been described in which mutations involving the initiation codon of the protein 4.1 gene result in failure to produce the protein. In heterozygotes with this variant, elliptocytosis occurs without haemolysis; in homozygotes, there is a severe haemolysis with extensive cell fragmentation.

Clinical features

As mentioned above, the HE/HPP group of haemolytic anaemias has a heterogeneous clinical presentation and molecular basis. Heterogeneity is amplified by the not uncommon co-inheritance of a mutated gene in *trans* (see below) with the HE gene, usually resulting in a more marked decrease in spectrin tetramer assembly.

Mild common hereditary elliptocytosis

Frequently, HE is discovered by chance from a blood film (Figure 8.6) or the presence of marginally raised bilirubin. Some affected people have no evidence of shortened red cell survival, whereas others have a well-compensated haemolytic anaemia. No treatment is required, although the blood film of partners should be examined if there is consanguinity, making homozygosity in offspring possible. For patients with mild haemolysis, anaemia may increase during infections, in pregnancy, with folate deficiency or with other conditions likely to enhance anaemia.

Figure 8.6 Hereditary elliptocytosis, peripheral blood. Characteristic elliptocytes of mild common hereditary elliptocytosis.

Silent carriers: low-expression genes

Mutations that produce low expression of α -spectrin may lead to no haematological abnormality because of the normal over-expression of α -spectrin in red cells compared with β -spectrin. However, when these defects are inherited in *trans*, on the other allele from an HE gene, HPP may result. Several mutations have been described, particularly commonly in codon 28, which produces low-expression genes. A common polymorphism, intron 45C→T, is spectrin α^{LELY} (LELY denoting 'low-expression allele Lyon').

Hereditary elliptocytosis and poikilocytosis in the neonate

In the neonate, the manifestations of HE may be a more marked poikilocytosis resembling HPP, with more fragmented red cells. These red cells are susceptible to fragmentation above 46°C, whereas normal cells only fragment above 50°C. The morphological changes and haemolysis gradually decrease over the first year until the typical picture of mild HE remains. Treatment of neonatal pyropoikilocytosis is required only if the anaemia is such as to warrant transfusion.

Spherocytic hereditary elliptocytosis

In rare white families with HE, haemolysis with modest splenomegaly is found with a blood film that has a low proportion of abnormally shaped cells, ranging from spherocytes to elliptocytes. Splenectomy is not usually indicated.

Hereditary pyropoikilocytosis

The characteristics of HPP are densely contracted and fragmented cells (Figure 8.7), moderate to severe haemolysis and heterogeneity of manifestations within a family. In general, patients with HPP have spectrin deficiency in addition to the abnormalities of spectrin–spectrin contacts that produce the heterotetramer deficiency of HE. One parent of an HE propositus may have normal haematology but carry a mutation in *trans*, which leads to spectrin deficiency. The affected cells show thermal lability and fragmentation at lower temperatures than normal. HPP is more common in black people.

Hereditary elliptocytosis in Africa

In some parts of West Africa, a high incidence of HE has been found (up to 1.6% of the population). Interestingly, there is considerable molecular heterogeneity for the basis of the condition in this area. *In vitro*, *Plasmodium falciparum* is less able to parasitize HE cells that have mutations in α -spectrin, glycophorin C or protein 4.1. Invasion is reduced in red cells from homozygous patients, and intracellular multiplication reduced, particularly in homozygous 4.1^(-/-) red cells. It seems possible that the varieties of HE offer some protection against the clinical manifestations of falciparum malaria.

Figure 8.7 Hereditary pyropoikilocytosis, peripheral blood. Marked anisocytosis and poikilocytosis from a child with homozygous hereditary elliptocytosis.

Laboratory investigation

The standard approach to the diagnosis of HE/HPP is the identification of haemolysis, coupled to a careful examination of the blood film of the patient and as many first-degree relatives as possible. Examples of blood films are shown in Figures 8.6 and 8.7. Other acquired causes of elliptocytic or fragmented red cells need to be excluded, including iron, folate or vitamin B₁₂ deficiency, and the microangiopathic haemolytic anaemias. Congenital dyserythropoietic anaemia and thalassaemia intermedia also need to be excluded.

As with the investigation of HS, SDS-PAGE may reveal protein abnormalities, although more specific identification requires a sophisticated approach beyond the abilities of most haematology laboratories.

Treatment

Patients with chronic haemolysis should be given folate supplements. Splenectomy is indicated for severe haemolytic anaemia in patients with HPP or homozygous HE. Response in HPP may not be complete, but the anaemia is usually markedly alleviated. There may be a theoretical risk of increased thrombotic tendency due to remaining high platelet count, but the risk is small. The precautions against OPSI are the same as for HS.

Hereditary stomatocytosis and related disorders

Stomatocytes are so called from the mouth-like slit or 'stoma' that appears on blood films (Figure 8.8). The appearance seems

Figure 8.8 Hereditary stomatocytosis, peripheral blood.

to be produced by folding of cells during preparation. Stomatocytes are leaky to cations. There are other variations with Na⁺ or K⁺ leaks that are clinically similar to stomatocytosis without the obvious morphological changes. All these conditions are inherited in autosomal dominant fashion, and mostly produce moderate haemolytic anaemia (haemoglobin 10 g/dL or above) and macrocytosis. There are two main variants: overhydrated hereditary stomatocytosis, in which MCHC is low, and dehydrated hereditary stomatocytosis, with an increased MCHC.

The blood film may show stomatocytosis but more commonly the film is unremarkable, apart from macrocytosis and polychromasia. The group is rare, estimates suggesting that 1 in 10 000 to 1 in 100 000 of the population are affected. However, associated features make the conditions important beyond their rarity (Table 8.4). Pseudohyperkalaemia may occur because K⁺ leaks rapidly from the red cells at room temperature. In some individuals, there is no evidence of haemolysis, only macrocytosis and pseudohyperkalaemia. Unless the cause of the apparent hyperkalaemia is diagnosed, unnecessary, and even dangerous, investigation and treatment may be undertaken. In some families, the K⁺ leak is greatly increased *in vitro* by cold (cryohydrocytosis). In dehydrated hereditary stomatocytosis, there may be marked perinatal ascites that resolves spontaneously over the first year of life, but which again can lead to extensive unnecessary investigation. The third problem with hereditary stomatocytosis, both overhydrated and dehydrated varieties, is that splenectomy is followed by very marked

Table 8.4 Features of hereditary stomatocytosis and related disorders.

Characteristic	Expression	Group affected
Haemolytic anaemia	Mild to moderate	All variants
	Absent	Hereditary pseudohyperkalaemia
Morphology	Macrocytosis	All variants
	Stomatocytosis	Variable
MCHC	Decreased	Overhydrated HSt (hydrocytosis)
	Increased	Dehydrated HSt (hereditary xerocytosis, desiccocytosis)
Serum [K ⁺]	Raised <i>in vitro</i>	Pseudohyperkalaemia Dehydrated HSt Cryohydrocytosis
Thrombotic tendency	Post splenectomy	All variants
Fluid balance	Perinatal oedema	Dehydrated HSt

HSt, hereditary stomatocytosis; MCHC, mean corpuscular haemoglobin concentration.

thrombotic tendencies such that splenectomy should not be performed.

Laboratory investigations

Tests for haemolysis and examination of the blood film of the patient and close relatives are the first steps in diagnosis. The finding of a raised serum potassium, together with macrocytosis, especially with some evidence of haemolysis, indicates the pseudohyperkalaemia of dehydrated hereditary stomatocytosis.

Definitive studies involve the measurement of intracellular [Na⁺] or [K⁺] and their flux through the membrane at different temperatures. Four subgroups have been defined according to the intracellular sodium concentration (normal 5–10 mmol/L). Patients with the pseudohyperkalaemia of dehydrated hereditary stomatocytosis may have normal or slightly high sodium concentrations (12–18 mmol/L); in families with cryohydrocytosis (temperature-sensitive leak) the sodium concentration is 20–50 mmol/L, and in overhydrated hereditary stomatocytosis the sodium concentration is 60 mmol/L or more.

Treatment

There is rarely a need for measures to raise the haemoglobin and splenectomy should be avoided because of the risk of thrombosis, including hepatic and portal vein thrombosis. If splenectomy is necessary, lifelong anticoagulation should be introduced.

Rh_{null} syndrome

The Rh system forms a large complex traversing the lipid bilayer several times, containing extracellular thiol groups. In the Rh_{null} phenotype, the complex is absent. The condition is very rare and is inherited as a recessive disorder. Patients have mild to moderate haemolytic anaemia that may respond to splenectomy, and the blood film shows occasional stomatocytes. The Rh complex involves two genes, one encoding the D polypeptide, the other the Cc and Ee polypeptides, depending on post-translational splicing. Mutation of one or other of the genes encoding these proteins is the molecular basis underlying the Rh_{null} phenotype.

Southeast Asian ovalocytosis

A dominantly inherited ovalocytosis is found in parts of Southeast Asia, where falciparum malaria is common, particularly in Papua New Guinea, Borneo and the Philippines. The red cell morphology is ovalocytic rather than elliptocytic. Stoma-like slits may be present and transverse banding in the red cells is seen (Figure 8.9). Most individuals have no haemolysis but, in a few, mild anaemia may be present. Cells have increased rigidity, unlike HE in which rigidity is decreased. The molecular defect is a deletion of nine amino acids at the transmembrane cytosol junction of band 3, a defect that possibly limits the mobility of band 3 within the membrane. Homozygosity is not found and is presumably lethal *in utero*.

Abnormalities of membrane lipids

Acanthocytosis

Acanthocytes, or spur cells, show prominent, somewhat regular projections on the surface, best demonstrated by scanning electron microscopy. They are formed when the outer lipid layer of the membrane acquires additional lipid. Acanthocytosis is an acquired characteristic of severe liver disease, usually end stage, and the result of interaction of altered plasma lipids.

Abetalipoproteinaemia

Abetalipoproteinaemia is a rare inherited defect with absent β-apolipoprotein, which results in low serum cholesterol but increased sphingomyelin, which enters the cell membrane and produces the acanthocytes. The main clinical features are retinitis pigmentosa, fat malabsorption and hepatic encephalopathy.

McLeod phenotype

In the McLeod phenotype, acanthocytosis occurs (Figure 8.10), together with decreased expression of the Kell antigen. The defective gene is on the X chromosome (Xp21), close to genes

Figure 8.9 Southeast Asian ovalocytosis, peripheral blood films. Mild ovalocytosis and some stomatocytosis. Some cells have apparent transverse ridge.

Figure 8.10 McLeod syndrome, peripheral blood. Note the marked acanthocytosis.

for Duchenne muscular dystrophy and retinitis pigmentosa, conditions with which the phenotype has been linked. The gene codes for the Kx protein that carries the Kell blood group protein. There may be mild anaemia.

Introduction

The main function of the red cell is to carry haemoglobin around the circulation in high concentration and in a functional state so that gas exchange may occur efficiently in the lungs and in the tissue capillaries. Oxygen is thus taken up in the lungs in exchange for carbon dioxide and delivered to the tissues at physiological pH and gas pressure. The structure and function of haemoglobin is discussed in Chapter 6. In order to fulfil its function, the red cell needs a supply of energy in the form of ATP and a source of reducing power.

A mature red cell contains no DNA or RNA and hence is incapable of protein synthesis, and the mitochondria which are present in reticulocytes have been lost during maturation, so that the only source of energy as ATP is derived from anaerobic glycolysis and the linked reducing system of the hexose monophosphate shunt (pentose phosphate pathway) and the glutathione cycle. ATP is required to maintain the membrane in its deformable state, with asymmetric lipid layers, and to regulate ion and water exchange. Reducing power is required to reduce methaemoglobin to its functional state of deoxyhaemoglobin and to counteract the strong oxidative stresses which a cell carrying molecular oxygen around the circulation is likely to encounter. The main process that reduces methaemoglobin utilizes reduced nicotinamide adenine dinucleotide (NADH), produced from nicotinamide adenine dinucleotide (NAD⁺) by the glycolytic pathway. Reduction and detoxification of free oxygen radicals and hydrogen peroxide produced during reactions to

infection is provided by reduced nicotinamide adenine dinucleotide phosphate (NADPH) generated by the first steps of the pentose phosphate pathway, catalysed by glucose-6-phosphate dehydrogenase (G6PD) and the linked enzyme 6-phosphogluconate dehydrogenase. NADPH drives the glutathione cycle, glutathione (GSH) being the major reducing agent within the red cell.

The lack of protein synthesis in the mature red cell means that none of the enzymes in the metabolic pathways can be replaced during the red cell lifespan. Over the 120 days of normal red cell survival, enzyme activities decline at variable but predictable rates. This decline probably contributes to the ageing process of the red cell. Many of the mutations that affect red cell metabolism and provoke haemolytic anaemia cause instability and premature inactivation of the enzyme; other mutations directly affect catalytic activity.

The glycolytic pathway (Embden–Meyerhof pathway)

Glycolysis (or, more correctly, glucolysis) is the process by which glucose is converted to pyruvate through a number of steps, with a net gain of two moles of ATP generated for each mole of glucose metabolized by the pathway. Glucose is derived from the plasma by facilitated transfer through the membrane. Pyruvate and lactic acid are in equilibrium determined by the redox potential of the cell (NAD⁺/NADH) and can diffuse out of the cell. The internal milieu of the cell, with its high K⁺ concentration and presence of other cations such as magnesium necessary for efficient glycolysis, is maintained through the activity of various ion and cation channels in the membrane, with energy linked by appropriate ATPases. The glycolytic

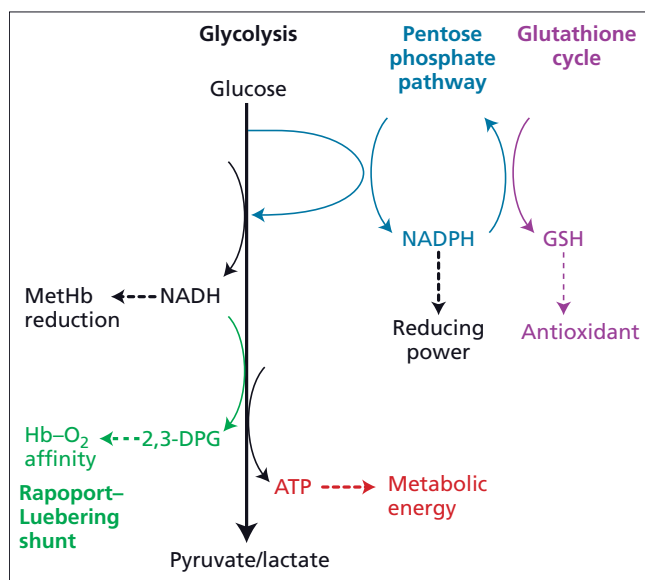

Figure 9.1 Principal pathways of energy production in the mature red cell. The glycolytic pathway provides energy in the form of ATP. Under normal conditions, methaemoglobin (MetHb) is reduced by the coupled reaction with NADH⁺. The Rapoport–Luebering shunt provides 2,3-diphosphoglycerate (2,3-DPG) for control of haemoglobin oxygen affinity. Reducing power is produced by the pentose phosphate pathway and is linked to redox reactions through the glutathione cycle.

pathway also provides the redox reaction to convert methaemoglobin to deoxyhaemoglobin by utilizing NADH in a reaction catalysed by methaemoglobin-NADH reductase (cytochrome *b*₃). The various products and functions of glucose metabolism are shown schematically in Figure 9.1 and in more detail in Figure 9.2.

The Rapoport–Luebering shunt

One of the essential roles of metabolism in the red cell is to provide sufficient 2,3-diphosphoglycerate (2,3-DPG) to regulate the oxygen affinity of haemoglobin. 2,3-DPG is produced from 1,3-DPG under the influence of the enzyme diphosphoglycerate mutase in linked reactions that form the Rapoport–Luebering shunt (Figure 9.2). 2,3-DPG is broken down to 3-phosphoglycerate by a phosphatase and thus re-enters the glycolytic pathway. It should be noted that when metabolism takes place via the Rapoport–Luebering shunt, there is bypass of the stage of ATP production. The shunt thus not only provides the 2,3-DPG for interaction with the haemoglobin tetramer but also acts as an energy control mechanism for glycolysis.

Disorders of the glycolytic pathway

Mutations of most of the enzymes in the glycolytic pathway have been described in association with congenital non-spherocytic haemolytic anaemia (CNSHA). However, deficiency of pyruvate kinase is far and away the most common enzyme to be affected. The haemolysis is the result of a failure to produce sufficient ATP.

Pyruvate kinase

Pyruvate kinase (PK) catalyses the final steps of the glycolytic pathway with the conversion of phosphoenolpyruvate to pyruvate, with the concomitant phosphorylation of ADP to ATP, leading to overall net gain of ATP from this pathway. There are four types of PK in different tissues derived from two separate genes. The *PKM2* gene, on chromosome 15, produces PKM1 and PKM2 through differences in post-transcriptional splicing. PKM1 is present in skeletal muscles, PKM2 in leucocytes, kidneys, adipose tissue and lungs. The *PKLR* gene, on chromosome 1, gives rise to PKL in the liver and PKR in red cells. The isoenzymes are transcribed differently through the influence of tissue-specific promoters. The active enzymes are homotetramers. PKM2, PKR and PKL all demonstrate marked allosteric reactions with several ligands. PKM1, on the other hand, has no allosteric interactions.

The main ligands involved in the allosteric control of PKR in the erythrocyte are shown in Figure 9.3. PK is one of the dominant controlling steps in glucose metabolism (together with hexokinase), exerting its effect through major feedback loops, especially by its requirement for activation by fructose-1,6-diphosphate.

Pyruvate kinase deficiency

PK deficiency leads to chronic non-spherocytic haemolytic anaemia with extravascular haemolysis.

Molecular biology

PK deficiency is the commonest of the enzymopathies of the glycolytic pathway, at least 300 times more common than any other. Best estimates based on gene frequency in the white population suggest a prevalence of about 50 per million. About 200 different mutations have been described in PK deficiency, the majority involving point mutations or deletions in the transcribed gene but a few involving the promoter region. Haemolytic anaemia due to PK deficiency is an autosomal recessive disorder. Many individuals are compound heterozygotes. Not surprisingly, there is enormous genetic heterogeneity between affected individuals, reflected in the multiplicity of quantitative and kinetic defects detected (Figure 9.3). Because PKR is a homotetramer composed of four chains derived from the products of the two alleles, enzyme kinetic variations are many and genotype–phenotype correlates are difficult to predict. First attempts to delineate the genotype–phenotype

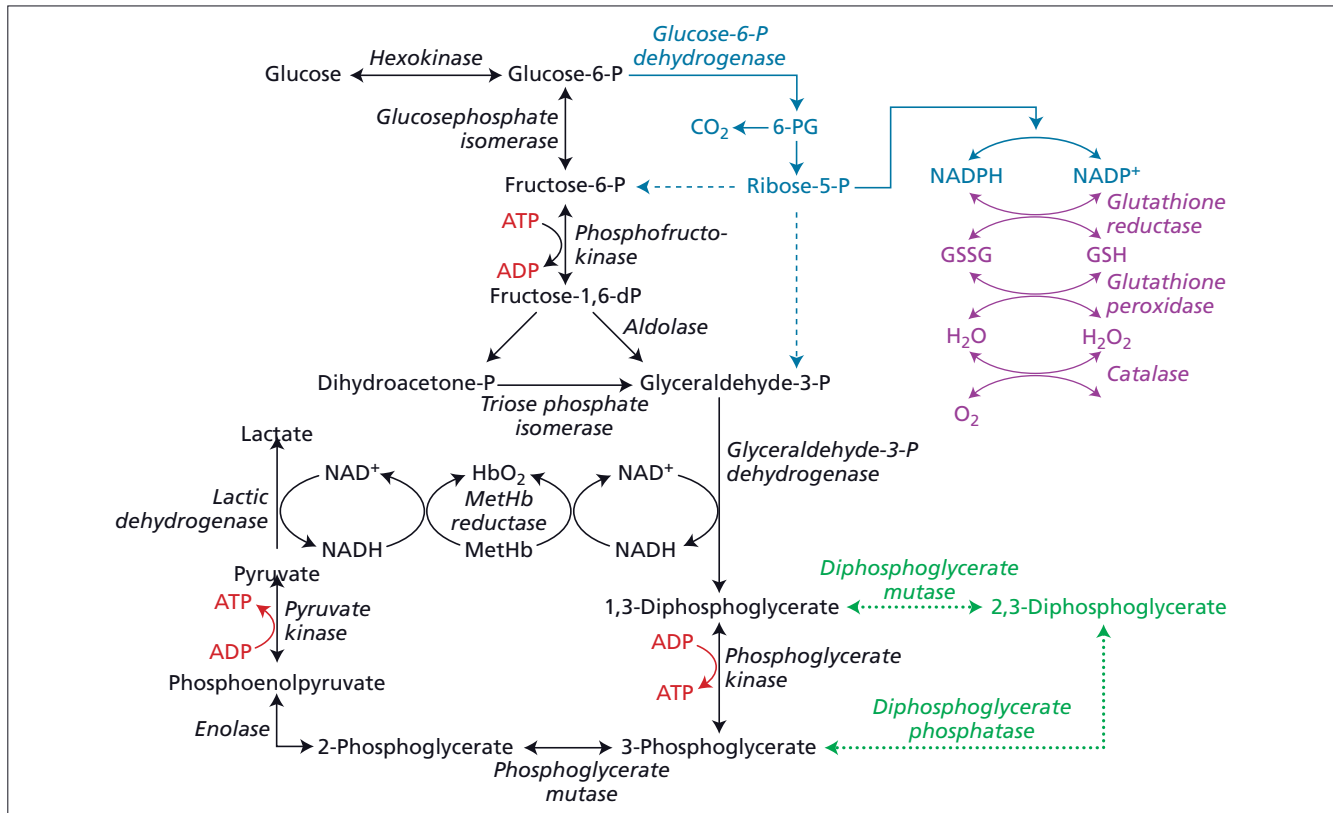

Figure 9.2 The glycolytic pathway and its interactions with the pentose phosphate pathway and the Rapoport–Luebering shunt.

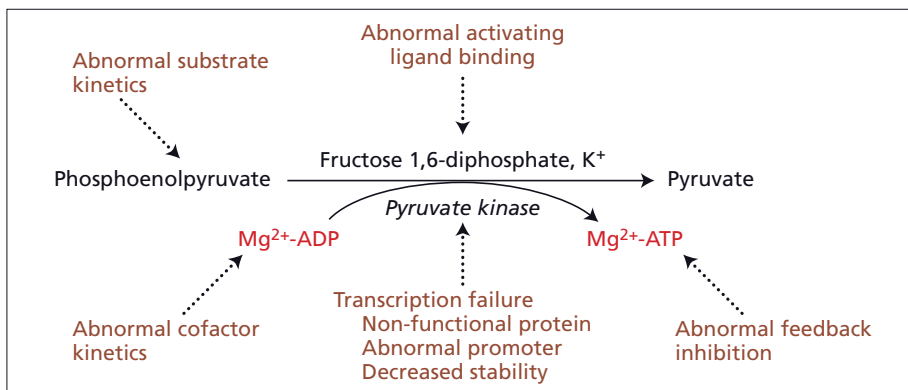

Figure 9.3 The reactions of pyruvate kinase showing the main ligands that influence activity and the sites affected by various mutations encountered in PK deficiency.

association were mainly based on analysis of the enzyme's three-dimensional structure and observation of the few homozygous patients. More recently, comparison of recombinant mutants of human red cell PK with wild-type enzymes has revealed the effect of amino acid replacements on the molecular properties of the enzyme. However, the clinical manifestations of red cell enzyme defects are not merely dependent on the molecular properties of the mutant protein but rather reflect the complex interactions of additional factors,

including genetic background, concomitant functional polymorphisms of other enzymes, post-translational or epigenetic modifications, ineffective erythropoiesis and differences in splenic function.

PK catalyses the ultimate step in the glycolytic pathway. Deficient activity leads to accumulation of substrates further up the pathway, including 2,3-DPG. The increased concentration of 2,3-DPG in PK-deficient red cells shifts the oxygen dissociation curve to the right, indicating low oxygen affinity.

Patients with PK deficiency tolerate apparent anaemia well because the lower haemoglobin content will deliver the same amount of oxygen to the tissues as normal haemoglobin, at least under normal conditions, though oxygen reserve would be limited.

Reticulocytes have alternative means of producing energy in the form of ATP via the oxidative respiratory pathway of the remaining mitochondria. They can also synthesize enzyme in those defects where lack of stability is the major cause of enzyme deficiency in the mature cell. Reticulocytes thus have a metabolic advantage over mature red cells in PK deficiency.

Clinical features

The genetic heterogeneity is reflected by the wide variation in the phenotype. The presenting features may vary from severe neonatal jaundice and anaemia (Figure 9.4), rarely even presenting with hydrops fetalis, severe chronic non-spherocytic haemolytic anaemia requiring repeated transfusions, moderate haemolysis with exacerbation during infections or pregnancy, to symptomless compensated haemolysis with only a minor apparent anaemia. The majority of reported cases have pre-

sented in childhood. PK deficiency does not usually have an adverse effect on the outcome of pregnancy, although occasionally transfusion may be required to compensate the added dilutional anaemia (Figure 9.5).

Jaundice, as with other congenital haemolytic anaemias, may be exacerbated by co-inheritance of other genes, for example Gilbert syndrome. The haemolysis is nearly always extravascular, though rare examples with some intravascular haemolysis have been detected. Gallstones are common in PK deficiency and may lead to bouts of cholecystitis and biliary colic (Figure 9.6). Jaundice may also be increased by administration of drugs that affect bile excretion. As with other cases of congenital haemolytic anaemia with extravascular haemolysis, excess iron accumulation may occasionally develop even in the absence of transfusion or co-inheritance of a haemochromatosis gene.

The spleen is usually palpable in cases where there is significant haemolysis, though in milder cases it may only be evident by ultrasound or other imaging techniques.

PK deficiency is not associated with abnormalities of other tissues, since the deficient enzyme is unique to the red cells, but occasionally individuals are seen with associated

Figure 9.4 Effect of splenectomy in a child with severe CNSHA due to pyruvate kinase deficiency. Splenectomy was delayed until the child was 3 years old. Note the marked reticulocytosis post splenectomy (V, viral infection; Uti, urinary tract infection). The child grew normally despite haemoglobin of around 8 g/dL (see text).

Figure 9.5 Multiple successful pregnancies in a splenectomized patient with pyruvate kinase deficiency. Transfusion was required during pregnancy (p) and before surgery (st, sterilization) and during infection (u, urinary tract infection; s, sepsis).

abnormalities due to deletions within chromosome 1 close to the *PKLR* gene.

Laboratory diagnosis

The blood count reveals a normochromic anaemia with reticulocytosis, sometimes producing a slight macrocytosis. An increased mean corpuscular haemoglobin concentration is occasionally seen in severe cases due to dehydration brought about by ATP deficiency. This dehydration also produces the characteristic spur cells or acanthocytes seen on the blood film (Figure 9.7a,b). Apart from the spur cells (which are not specific) and the very large reticulocytosis post splenectomy (Figure 9.7c), there is nothing to distinguish PK deficiency from other causes of CNSHA.

The autohaemolysis test, involving the incubation of defibrinated red cells with and without glucose for 48 hours at 37°C, has traditionally been used for screening tests. The haemolysis in the unfortified aliquot is uncorrected by the addition of

glucose (type II). The test is not specific and has mainly been abandoned in favour of the enzyme assay.

The definitive diagnosis depends on the analysis of enzyme activity and kinetics, although the finding of an elevated 2,3-

DPG level (two to three times normal) may be a useful pointer. Characterization of the enzyme requires measurement of maximal activation under optimal conditions (V_{\max}), kinetic studies to determine the substrate(s) concentration at which the enzyme shows 50% V_{\max} (K_m), thermal stability, pH optimum and electrophoretic mobility. Meaningful enzyme levels can only be achieved after total removal of leucocytes, which have up to 300 times the PK activity of red cells. The effect of reticulocytes also has to be taken into account. International guidelines for investigation of PK deficiency have been published. Typically, homozygotes have about 25% of normal V_{\max} activity, allowing for the age of the red cells, and heterozygotes 50–60% but the range is great and there is much overlap in V_{\max} between the groups, emphasizing the need for kinetic and other studies (Figure 9.8).

Management

The mainstay of management of patients who have sufficiently severe haemolysis to warrant treatment is splenectomy. Assessment of the need for splenectomy should take into account the symptoms of the patient not the haemoglobin level. The low haemoglobin (even as low as 7.0 g/dL) may be well tolerated because of the right-shifted oxygen dissociation curve. Indications for splenectomy include severe neonatal haemolysis and chronic transfusion requirements. The dangers

Figure 9.8 Pyruvate kinase activity (V_{\max}) measured in patients, obligate heterozygotes and normal control subjects. Note the wide overlap of values between the two groups, indicating the importance of kinetic studies as well as the effect of reticulocytosis.

of splenectomy, particularly the risk of overwhelming sepsis, have been discussed in Chapter 8. Splenectomy raises the effective haemoglobin so that transfusion is not required but does not prevent hyperbilirubinaemia so biliary complications may still arise after splenectomy. Following splenectomy for PK deficiency, there is a huge elevation in the reticulocyte count, which may reach 80% or more of the peripheral blood cells (see Figure 9.4).

Although pregnancy may exacerbate this anaemia, there is no indication that PK deficiency itself has an adverse effect on the pregnancy or outcome, so long as the anaemia is managed as necessary (see Figure 9.5). As with all chronic haemolytic anaemias, folic acid 5 mg per week or 400 µg daily is a sensible supplement.

Other defects of the enzymes of the glycolytic system

Compared with PK deficiency, the other defects of the glycolytic pathway are very rare. The main features of these disorders are summarized in Table 9.1.

Hexokinase

Hexokinase (HK1) catalyses the phosphorylation of glucose to glucose-6-phosphate (G6P), the first step in the glycolytic pathway. The enzyme in the red cell differs from that in nucleated cells, which have oxidative respiration, by lacking a porin-binding domain that links the enzyme to the mitochondrial membrane. The red cell enzyme is derived from alternative splicing of the gene product. The enzyme provides a major rate-limiting step in glycolysis and has extensive allosteric interactions: it is highly pH sensitive and its activity is regulated by its products, G6P, P_i , 2,3-DPG and disulphide compounds. The enzyme activity decays predictably with age of the normal red cell, and may be used as a comparator for other enzyme activities where absolute levels may be difficult to interpret because of the age distribution of the red cells.

Hexokinase deficiency

Hexokinase deficiency has been recorded in only 17 families, but even within this small number there is evidence of molecular and phenotypic heterogeneity. Complete hexokinase deficiency is probably lethal. Most patients have moderately reduced activity for the age of the red cell, and in the majority of cases it is the stability of the enzyme that is affected by the mutation. Combined heterozygosity for complete gene deletion and a nonsense mutation affecting activity has been recorded as a typical example of compound genetic inheritance. In most recorded cases, the activity of the enzyme is reduced to 10–20% of normal. As with other glycolytic enzyme deficiencies, there is variable non-spherocytic haemolytic anaemia, in this case mostly relatively mild. Obligate heterozygotes have reduced levels of the enzyme, but assaying the activity in patients with

Table 9.1 Main features of glycolytic enzyme deficiencies.

Enzyme	Gene (chromosome, inheritance)	Haematology	Other systems affected	Comment
Hexokinase	<i>HK1</i> , 10q22 AR	CNSHA High O ₂ affinity	None directly*	Very rare, occasional AD
Glucose phosphate isomerase	<i>GPI</i> , 19q13.1 AR	CNSHA	None directly*	Most common after PK deficiency
Phosphofruktokinase	<i>PFKL</i> (L subunit), 21q22.3 <i>PFKM</i> (M subunit), 12q13.11 Complex	Erythrocytosis Minimal haemolysis	Dominated by myopathy	Tarui disease, subunit genes
Fructose diphosphate aldolase A	<i>ALDOA</i> , 16p11.2 AR	CNSHA Intermittent HA	Dysmorphism, myopathy	Very rare (three families)
Triose phosphate isomerase	<i>TPI1</i> , 12p13 AR	CNSHA Infections	Neuromuscular, cardiac	Neuromuscular defects dominate, sudden death, splenectomy not helpful
Phosphoglycerate kinase	<i>PGK1</i> , Xq13.3 X-linked	CNSHA	CNS, myopathy, rhabdomyolysis	Rare (28 families), variable systems involved
Diphosphoglycerate mutase	<i>BPGM</i> , 7q31–q34 AR	Erythrocytosis	None	Very rare, low 2,3-DPG
Glyceraldehyde-3-phosphate dehydrogenase	<i>GAPDH</i> , 12p13.31 AD	None	None	Membrane protein band 6, gene syntenic with <i>TPI</i>
Pyruvate kinase	<i>PKLR</i> , 1q22 AR rarely AD	CNSHA	None	Commonest CNSHA

*Neurological signs may be secondary to hypoxia or ischaemia.

AD, autosomal dominant; AR, autosomal recessive; CNSHA, congenital non-spherocytic haemolytic anaemia; HA, haemolytic anaemia.

haemolytic anaemia due to hexokinase deficiency may be difficult to interpret because of the higher activity in reticulocytes and in young cells. Typically, reduced hexokinase activity is associated with a fall in the concentration of 2,3-DPG within the cells. Patients have less exercise tolerance for a given level of haemoglobin than would be expected because of the left shift in the oxygen dissociation curve.

Glucose phosphate isomerase

Glucose phosphate isomerase (GPI) catalyses the second step of the Embden–Meyerhof pathway, the interconversion of G6P to fructose-6-phosphate (F6P). The enzyme is also known as phosphohexose isomerase, phosphoglucose isomerase, autocrine motility factor and neuroleukin. The names ‘autocrine motility factor’ and ‘neuroleukin’ indicate that the protein has other actions in other cells. The interconversion of the hexose phosphates is driven towards F6P by the rapid metabolism of that product along the metabolic pathway so that the concentration of F6P in the red cell is low and drives the reaction towards its formation.

Glucose phosphate isomerase deficiency

Deficiency of GPI is one of the commonest causes of CNSHA after G6PD deficiency and PK deficiency. About 50 families have been described; it is about as common as pyrimidine 5′-nucleotidase deficiency (see later). The mutations that give rise to GPI deficiency are very heterogeneous. About 30 different mutations have been identified but only seven of them have been found in more than one family; 17 of the 27 cases were compound heterozygotes. The clinical picture perhaps reflects this genetic heterogeneity. Most reported cases present with mild to moderate haemolytic anaemia, but in one Indian family stillbirths and hydrops occurred in several sibs before early delivery and exchange transfusion for hydrops allowed survival. The mutations described mainly affect the stability of GPI, which is perhaps why there are no associated anomalies found in nucleated cells. In T lymphocytes, GPI acts as neuroleukin, a lymphokine that induces the formation of antibody-secreting cells. It is also present in neutrophils, but there is no increase in infections in deficient subjects. In some severely deficient patients, neurological retardation has been thought to be related

to hypoxia or ischaemia *in utero* rather than to direct metabolic effects.

Phosphofructokinase

Phosphofructokinase (PFK) catalyses a reaction in which F6P is phosphorylated to fructose-1,6-diphosphate, ATP being the donor of the phosphate group. Under normal physiological conditions this may be the major rate-limiting step in glycolysis in the red cell. PFK is a tetramer, which in the red cell is a heterotetramer composed of M or L subunits. Two separate genes code for the two subunits. PFK is a homotetramer of M subunits (M4) in muscle and of L subunits (L4) in liver. In the red cell, there may be five isoenzymes composed of different numbers of L and M subunits. A third subunit is found in platelets.

Phosphofructokinase deficiency

Deficiency of the M subunit leads to glycogen storage disease type 7 (Tarui disease). It is characterized by muscle cramps and myoglobinuria on exertion. Shortened red cell viability may be a minor component of this disease. Evidence of haemolysis may be accompanied by mild erythrocytosis as a result of decreased production of 2,3-DPG. To date, 15 PFK-deficient *PFKM* alleles from more than 30 families have been characterized.

Fructose diphosphate aldolase A

Fructose-1,6-diphosphate aldolase A (ALDOA) catalyses the conversion of fructose-1,6-diphosphate to Ga3P and dihydroxyacetone phosphate (DHAP). There are three aldolases in human tissues, A, B and C, of which only A is expressed in the red cell. ALDOA is produced in the developing embryo and also forms the bulk of the enzyme in muscle, where it may be as much as 5% of the total cellular protein. In the red cell, the reaction catalysed by the enzyme is virtually irreversible.

Fructose diphosphate aldolase A deficiency

The condition is extremely rare, with only three families having been definitely identified as having ALDOA deficiency. Two families have been described in which the propositus presented with CNSHA, mental retardation and dysmorphic features similar in the two families. In at least one family, the mutation produced an unstable enzyme. In a third patient, symptoms were mainly of myopathy with weakness and premature fatigue. Anaemia and jaundice were intermittent, and rhabdomyolysis occurred. There was severe deficiency of both muscle and red cell enzyme activity.

Triose phosphate isomerase

Triose phosphate isomerase (TPI) catalyses the interconversion of DHAP and Ga3P. In the glycolytic pathway of the red cell, all DHAP is converted to Ga3P, which is then metabolized down the glycolytic pathway, providing the ultimate two molecules of ATP for each molecule of glucose metabolized by that

pathway. The enzyme is a homodimer present in all tissues. In tissues other than the red blood cell, DHAP is an important precursor for the biosynthesis of ether glycerolipids (plasmalogens).

Triose phosphate isomerase deficiency

TPI deficiency produces a severe syndrome present from birth, consisting of CNSHA, a progressive neurological disorder with spasticity and central nervous system (CNS) degeneration. Cardiac failure and sudden death due to arrhythmias are also features. Death occurs usually about 5 years of age. There is, as usual, some variation and haemolysis without neurological degeneration, and the opposite, have been described. Splenectomy does not appear to be effective in modifying the haemolysis and does not influence the neurological complications. The diagnosis is made based on clinical suspicion together with the appropriate enzyme assay. A number of point mutations have been identified that lead to the syndrome, but by far the most predominant is Glu104Asp, a mutation linked by common haplotypes suggesting descent from a common ancestor.

Phosphoglycerate kinase

Phosphoglycerate kinase (PGK) catalyses the reversible conversion of 1,3-DPG to 3-phosphoglycerate, generating one molecule of ATP for each molecule of 1,3-DPG metabolized by this pathway. It should be noted that two molecules of 1,3-DPG are produced for each molecule of glucose metabolized by this pathway. PGKA, the active enzyme in the red blood cell, is the product of a gene (*PGK1*) on the X chromosome. The enzyme is monomeric and is expressed in all tissues (a testis has an additional *PGK2* gene coded on an autosome).

Phosphoglycerate kinase deficiency

A total of 28 families with PGK deficiency have been reported, and sequencing data are available for 17 families. Overall, 17 different mutations in the *PGK1* gene, mostly missense, have been described in association with PGK deficiency. Of the 28 families, CNSHA occurred in 17, CNS disorders in 13 and myopathy with or without rhabdomyolysis in 13. All three systems were involved in only one of the families. Anaemia when present is usually well tolerated because of the increased concentration of 2,3-DPG produced by the increased flow of 1,3-DPG to 2,3-DPG via the Rappaport–Leubering shunt in the presence of the mutated PGK deficiency. Splenectomy has been effective in some cases of severe anaemia, but less so in others.

Defence against oxidative stress: the production of reducing power

As with all cells, but perhaps more urgently, red blood cell needs to be protected against the effects of free radicals, hydrogen

peroxide and other highly oxidative material in order to maintain membrane integrity and functional activity. In addition, haemoglobin has to be maintained in its functional state, and the steady production of methaemoglobin reversed to deoxy-haemoglobin, which is able to combine reversibly with oxygen. The major generator of reducing power within the red cell

is the pentose phosphate pathway (hexose monophosphate shunt), which generates reducing power in the form of NADPH from NADP⁺ coupled to the oxidation of G6P to 6-phosphogluconate (6PG) and the subsequent oxidation of that compound to ribose-5-phosphate, the two reactions catalysed by G6PD and 6-phosphogluconate dehydrogenase (Figure 9.9).

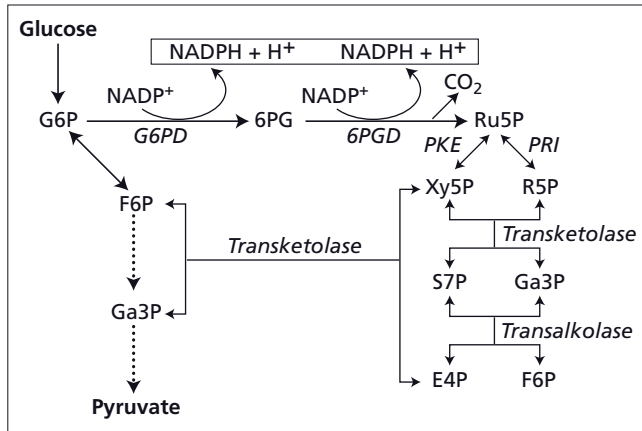

Figure 9.9 The pentose phosphate pathway. Substrates: G6P, glucose-6-phosphate; 6PG, 6-phosphogluconate; Ru5P, ribulose-5-phosphate; R5P, ribose-5-phosphate; Ga3P, glyceraldehyde-3-phosphate; F6P, fructose-6-phosphate; Xy5P, xylose-5-phosphate; S7P, septulose-7-phosphate; E4P, erythrose-4-phosphate. Enzymes: G6PD, glucose-6-phosphate dehydrogenase; 6PGD, 6-phosphogluconate dehydrogenase; PKE, phosphoketoepimerase; PRI, phosphoribose isomerase.

GSH is important for protecting cells from oxidative damage by these free radicals, protecting against the effects of infection, maintaining protein sulphhydryl groups in the reduced state and maintaining membrane transport. A constant supply of GSH is provided by the glutathione cycle linked to the pentose phosphate pathway through the action of glutathione reductase (Figure 9.10).

Oxidative stress that exceeds the reducing power of the red cell leads to intravascular haemolysis following denaturation of haemoglobin and precipitation as Heinz bodies and peroxidation of the red cell membrane. Methaemoglobinaemia may occur. The clinical features that emerge – acute intravascular haemolysis, Heinz body haemolytic anaemia or methaemoglobinaemia – depend on the nature of the oxidative stress and the size of the imbalance between the stress and the redox potential.

Pentose phosphate pathway (hexose monophosphate shunt)

The reactions of the pentose phosphate pathway are shown schematically in Figure 9.2 and in more detail in Figure 9.9. In most cells the pentose phosphate pathway is an essential pathway

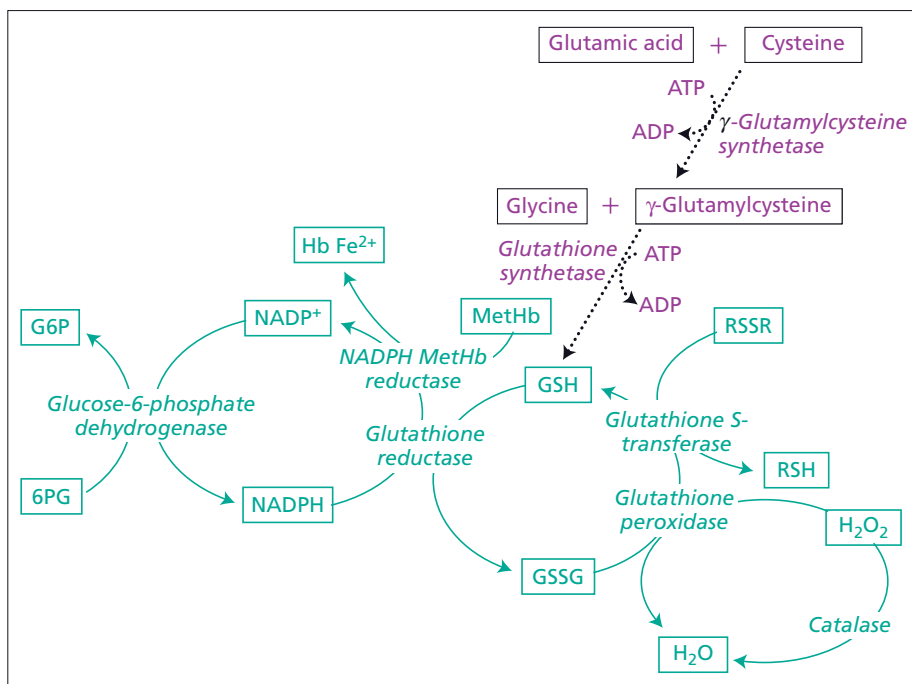

Figure 9.10 The glutathione (GSH) cycle and synthetic pathways. GSH is synthesized in two linked steps. Redox control is exercised by the glutathione cycle linked to the NADPH of the pentose phosphate pathway by glutathione reductase.

for the production of ribose and its incorporation into RNA. In the red cell its only function is the production of reducing power in the form of NADPH. The first step of the pathway, catalysed by G6PD, utilizes G6P as substrate. G6P is also a substrate for the glycolytic pathway. Under normal circumstances, about 10% of glucose is metabolized by the pentose phosphate pathway, the activity of that pathway being determined by the availability of NAD^+ and feedback inhibition by ATP. Under conditions of oxidative stress, the flux through the pentose phosphate pathway can be greatly increased. The products of the pathway re-enter the glycolytic pathway through F6P or Ga3P.

From the point of view of haematological disorders, G6PD deficiency is far and away the most important step in the pathway. However, other enzymes of the pathway can be important in acquired disorders, some steps being inhibited by drugs, including estrogen/progesterone contraceptive pills.

Glucose-6-phosphate dehydrogenase

G6PD catalyses the first step of the pentose phosphate pathway and is the enzyme controlling flux through the pathway. The activity is controlled by the availability of NADP^+ . Conversion of G6P to 6PG is accompanied by the reduction of NADP^+ to NADPH and the second step in the pathway, the oxidation of 6PG to ribose-5-phosphate, produces a second molecule of NADPH.

The gene for G6PD is located on the X chromosome at Xq28. The gene has 13 exons and 12 introns. The gene is transcribed as a monomer of 514 amino acids that assemble to produce an equilibrium of dimers and tetramers (Figure 9.11). Each monomer has an NADP^+ -binding domain and a large domain with the active site between the two. The gene is a household gene, active in all cells, with an essential role in the production of RNA in nucleated cells. Not surprisingly, the gene is highly

conserved in evolutionary history. Complete inactivity of the enzyme in nucleated cells would not be compatible with life. The clinical consequences of G6PD deficiency are virtually confined to the red blood cell, with occasional evidence of leucocyte malfunction in some variants. The majority of mutations affect the stability of the transcribed enzyme so that there is a rapid decline in activity in the mature enucleate red cell as it ages.

In the red cell, G6PD determines the reduction of NADP^+ to NADPH (Figure 9.9); NADP^+ availability is determined by the activity of the glutathione cycle, which is linked to the pentose phosphate pathway through the activity of the enzyme glutathione reductase (Figure 9.10). The availability of NADP^+ is the major rate-limiting step for the pentose phosphate pathway.

Glucose-6-phosphate dehydrogenase deficiency

G6PD deficiency is the commonest genetically determined enzyme deficiency in the world, with an estimated 400 million people being affected. At least 127 different variants associated with deficient enzyme activity have been described, as well as a number of polymorphisms that do not affect enzyme activity. The G6PD variants have been classified into five groups according to their activity relative to the wild-type G6PD type B (Table 9.2). In Africa, the variant G6PD type A^- is the predominant polymorphism, with equivalent activity to G6PD type B.

Epidemiology

G6PD deficiency is widely disseminated throughout Africa, the Mediterranean basin, the Middle East, Southeast Asia and indigenous populations of the Indian subcontinent. G6PD- A^- (with two mutations in the *G6PD* gene; see Figure 9.12) is common in Africa, the Mediterranean variant is common in southern Italy, Sardinia and other places around the Mediterranean basin, and G6PD-Canton is common in southern China. These variants are only the most common among

Figure 9.11 Structure of glucose-6-phosphate dehydrogenase in dimer form showing active sites for glucose-6-phosphate and NADP^+ . Mutations that affect interactions of the monomers lead to CNSHA.

Figure 9.12 Map of glucose-6-phosphate dehydrogenase (*G6PD*) gene showing mutation sites. Numbered boxes refer to the location of *G6PD* exons. Yellow circles, class I and II variants; yellow ellipses, class IV variants; red circles, polymorphic

variants; green circles and squares, class I variants caused by amino acid substitutions and small in-frame deletions, respectively. (Courtesy of Tom Vulliamy, Hammersmith Campus, Imperial College, London.)

Table 9.2 World Health Organization classification of G6PD deficiency (1989).

Class	Enzyme activity (% normal)	Examples	Clinical effects
I	Severe (usually <20)	Santiago de Cuba (Gly447Arg)	CNSHA, acute exacerbations
II	<10	Mediterranean (Ser188Phe) Canton (Arg459Leu) Orissa (Ala44Gly)	Favism, acute intravascular haemolysis (drug induced), neonatal jaundice
III	Moderate (>10, <60)	A ⁻ (Val68Met, Asn126Asp)	Acute intravascular haemolysis (drug induced), neonatal jaundice
IV	100	B (wild type) A (Asn126Asp)	None None

CNSHA, congenital non-spherocytic haemolytic anaemia.

many different mutations in these areas and throughout the rest of the affected world (Figure 9.13). This distribution of the deficiency equates with areas where *Plasmodium falciparum* malaria is common, and this is thought to be the evolutionary drive that has produced such widespread polymorphisms (Figure 9.13). It has subsequently been confirmed that G6PD deficiency does indeed protect against lethal falciparum malaria, particularly in childhood, and this protection, especially in hyperendemic areas, more than outweighs the haematological problems associated with deficiency.

Clinical features

There are four main syndromes associated with G6PD deficiency. In all four, haemolysis is aggravated or promoted by exposure to oxidative stress through infection or ingestion of oxidative foods or drugs, but the clinical presentations differ. Age always modifies the clinical effects, not always as might be expected. The four syndromes are neonatal jaundice, favism,

chronic non-spherocytic haemolytic anaemia and drug-induced haemolytic anaemia. The neonatal jaundice syndrome has been described in class I, II and III variants, favism in mainly, though not exclusively, class II, CNSHA in class I, and the drug-induced haemolytic anaemias mainly class III. While G6PD deficiency is most common in males, the prevalence of the gene in many parts of the world (Figure 9.13) means that female homozygotes are not uncommon and heterozygous females are often susceptible to oxidative stress because of the effects of X-inactivation and marked lyonization in leaving a significant population of deficient red cells.

Neonatal jaundice and G6PD deficiency in infancy

Neonatal jaundice is a severe manifestation of G6PD deficiency and is a major source of potential morbidity from kernicterus. Most common variants have been associated with the syndrome, including the A⁻ and Mediterranean variants. In parts of the world where the mutations are common, the deficiency

Figure 9.13 Global distribution of G6PD gene variants causing G6PD deficiency. Shaded areas indicate the prevalence of G6PD deficiency. The coloured dots depict the distribution of 16 of the most common variants. (From Luzzatto & Notaro 2001 with permission.)

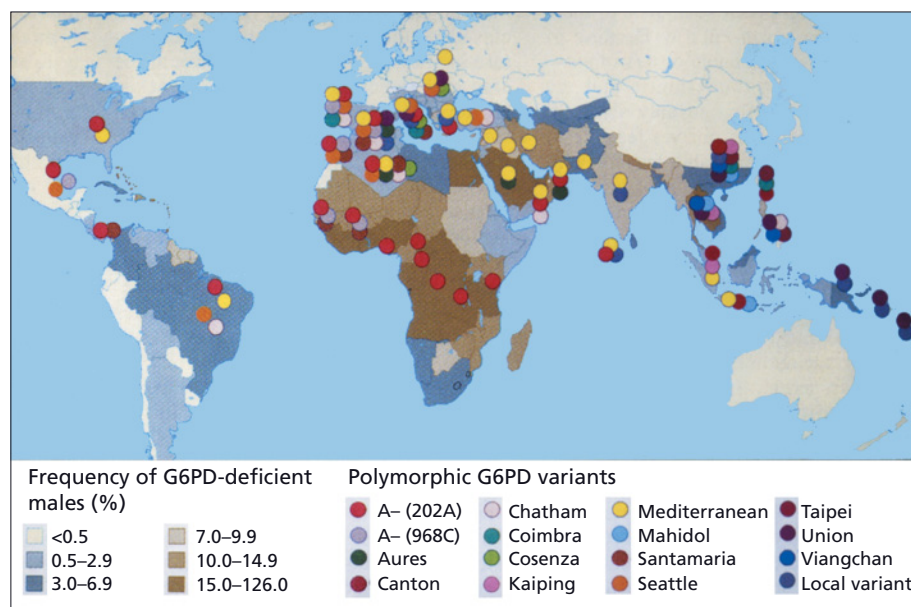

Table 9.3 Association between G6PD deficiency and jaundice in male newborns.*

Groups of newborns	N	G6PD deficiency (%)
Normal	500	22.5
Mild jaundice (bilirubin 150–200 $\mu\text{mol/L}$)	38	45
Severe jaundice (bilirubin > 230 $\mu\text{mol/L}$)	70	60
Admitted with kernicterus	20	78

*Data collected in Ibadan, Nigeria.

is the most prevalent cause of neonatal jaundice (Table 9.3). The jaundice probably starts *in utero* in the perinatal period, but the clinical problem only becomes apparent about the second or third day after birth. Between 10 and 50% of deficient infants are affected. Phototherapy or exchange transfusion may be required to prevent neurological sequelae. Anaemia is not a feature, and it is thought that this is a manifestation of liver enzyme deficiency coupled perhaps to the physiological underdevelopment of neonatal liver function or the co-inheritance of the UDP-glucuronyltransferase 1 deficiency of Gilbert syndrome.

Acute haemolytic crises may occur in G6PD-deficient infants, usually through exposure to oxidative stress, including nitrites or nitrates in water or the ingestion of fava beans by the mother, but in some cases of severe acute haemolysis, even fatal, no cause has been obvious.

Table 9.4 Characteristic features of haemolytic attack in G6PD deficiency.

Phase	Clinical	Laboratory
Acute	Abrupt onset	
	Malaise, prostration	
	Pallor	Anaemia, Heinz bodies, reticulocytosis, G6PD deficient
	(Abdominal pain)	
	Fever	Leucocytosis
	Dark urine	Haemoglobinuria, haptoglobin absent
Recovery	Haemoglobinaemia	
	Methaemalbuminaemia	
	Jaundice	Hyperbilirubinaemia
	(Renal failure)	\uparrow Urea, \uparrow creatinine
	Gradual but rapid cessation of haemolysis	Reticulocytes peak days 5–8
Urine clears in few days	G6PD increases but rarely to normal range	
	Jaundice clears in 1–2 weeks	

Favism

Favism is the term given to the G6PD syndrome where acute intravascular haemolysis may be precipitated by exposure to the broad bean *Vicia faba*, usually about 24 hours after the meal (Table 9.4). Fresh, dried or frozen beans or even exposure to

pollen may precipitate the crisis. The offending agent is divicine, or its aglycone isouramil, which can produce free oxygen radicals on autoxidation. Divicine is not present in peas or beans of other types, which may be eaten without effect. The amount of haemolysis is dose-related, which may explain the marked variation in susceptibility not only between children and adults but also in the same individual at different times. There is variation in divicine content between different cultivars; some fungi can break down the compound and the amount may vary in different seasonal environments. In children acute haemolysis, sometimes life-threatening, is common but renal failure is uncommon, although there may be systemic symptoms of fever and loin pain. Renal failure occurs more often in adults, possibly because of co-morbidity. Favism is usual in class II variants, for example Mediterranean and Canton, but may occur in others, including the African A⁻ variant. Acute haemolysis after eating fava beans has also been described in glutathione reductase deficiency. Although fava beans give the syndrome its name, some other compounds with which affected individuals may come in contact can cause acute haemolysis, including topical henna and some of the pulses used to make local sweetmeats.

Between attacks of favism or exposure to oxidizing substances, the blood count is normal with no evidence of haemolysis. The co-occurrence of infection, which promotes the formation of hydrogen peroxide following the oxygen burst in neutrophils and macrophages, with ingestion of oxidizing substances, even mild ones such as chloramphenicol, may promote haemolysis even though the drug on its own does not.

Chronic non-spherocytic haemolytic anaemia

Sporadic cases in virtually all populations of CNSHA are found with underlying G6PD deficiency. Many of the mutations that cause CNSHA occur on exon 10 and affect the formation of dimers or tetramers (see Figures 9.11 and 9.12). The haemolysis is extravascular, although additional oxidative stress may provoke an acute intravascular episode.

Drug-induced acute haemolysis

The introduction of primaquine and its derivative pamaquine as antimalarials to replace quinine during the Pacific phase of the Second World War and the later Korean War revealed that a proportion of men exposed, particularly in the black population, suffered from severe acute intravascular haemolysis. Intensive studies by Carson and others from the University of Chicago, working at the Statesville Penitentiary Malaria Project, finally identified the problem as G6PD deficiency and identified that young red cells and reticulocytes had sufficient activity to withstand the oxidative stress so that haemolysis lessened as the reticulocyte level rose. It became apparent that many other drugs could also produce haemolysis, but mostly fava beans did not. The common African A⁻ variant is the main example of class III mutations producing this type of haemolysis.

The haemolysis is dose-related and may be self-limiting. Although it is important to recognize which drugs are likely to produce haemolysis (Table 9.5), it is also important to realize that the disease for which the drugs may be needed, for example falciparum malaria, may be fatal and thus the haemolysis is a lesser problem.

Laboratory diagnosis

Acute intravascular haemolysis raises the suspicion of G6PD deficiency. The blood film shows red cells with contracted haemoglobin in 'ghost' membranes (Figure 9.14). Haemoglobinuria may be gross, producing almost black urine without red cells in the centrifuge deposit.

Several screening tests have been devised to identify G6PD deficiency in red blood cells. The most widely used tests have been the brilliant cresyl blue decolorization test, the methaemoglobin reduction test and an ultraviolet spot test. These tests can reliably distinguish between deficient and non-deficient individuals, but are not reliably quantitative. Hemizygous deficient males and homozygous deficient females will be identified, the threshold being a G6PD activity of about 30% of normal.

If a screening test indicates deficiency or is doubtful, the ideal follow-up test for definitive diagnosis is quantitation of G6PD activity by spectrophotometric assay. Standardized methods have been published. There are two clinical situations in which quantitation is especially important. First, during a haemolytic attack, the oldest red cells (with the least G6PD activity) are destroyed selectively and therefore the surviving red cells have a relatively higher (but still deficient) G6PD activity. This increases further as the reticulocyte response sets in over the following days. During this time, a screening test might yield a

Figure 9.14 Glucose-6-phosphate dehydrogenase deficiency. Peripheral blood film following acute oxidant drug-induced haemolysis shows an erythroblast and damaged red cells, including 'blister' and 'bite' cells.

Table 9.5 Drugs to be avoided in G6PD deficiency.**Antimalarials*

Primaquine (can be given at reduced dosage, 15 mg daily or 45 mg twice weekly under surveillance)
Pamaquine

Sulphonamides and sulphones

Sulfanilamide
Sulfapyridine
Sulfadimidine
Sulfacetamide (Albucid)
Sulfasalazine (Salazopyrin)
Dapsone[†]
Sulfoxone[†]
Glucosulfone sodium (Promin)
Septrin

Other antibacterial compounds

Nitrofurans: nitrofurantoin, furazolidone, nitrofurazone, nalidixic acid

Analgesics

Acetylsalicylic acid (aspirin): moderate doses can be used
Acetophenetidin (phenacetin): paracetamol is a safe alternative

Anthelminthics

β-Naphthol
Stibophan
Niridazole

Miscellaneous

Vitamin K analogues (1 mg menadoxime can be given to babies)
Naphthalene (mothballs)[†]
Probenecid
Dimercaprol (BAL)
Methylene blue
Toluidine blue

*This list is compiled on the basis of data available for patients with the A⁻ variant of G6PD deficiency. It can be generally assumed to be applicable to patients from Africa and of African descent. For patients with the Mediterranean type of G6PD deficiency, with an unknown variant, or with CNSHA, the following should also be added: acetanilide, chloramphenicol, chloroquine (may be used under surveillance when required for prophylaxis or treatment of malaria), mepacrine, *p*-aminosalicylic acid and thiazosulfone. Many other drugs may produce haemolysis in particular individuals.

[†]These drugs may cause haemolysis in normal individuals if taken in large doses.

false-normal result and, rarely, even a quantitative test might do so. In such cases, the best counsel is to repeat the test a couple of weeks later. Alternatively, the oldest remaining cells can be isolated by differential centrifugation and they can be shown to have low G6PD activity. The diagnosis of heterozygous females can be especially difficult; in extreme cases, it can only be done by family studies. However, from the practical point of view, it must be borne in mind that the probability of clinically significant haemolysis in a heterozygote roughly correlates with the proportion of G6PD-deficient red cells in her blood. Therefore, if a normal level of G6PD activity is found in a heterozygote, she is unlikely to be at risk of G6PD-related haemolysis. In regions where G6PD has a high prevalence and the main variants are known, DNA analysis is the most effective way of identifying heterozygotes.

Management

Management is mostly dictated by the symptoms and signs in the patient, although education in the avoidance of oxidizing substances is important (Table 9.5). In many populations the condition is well known and the need for avoidance recognized. Neonatal jaundice may need urgent therapy to prevent neurological damage (Table 9.3). Extreme hyperbilirubinaemia can be prevented by administration of Sn-mesoporphyrin if the diagnosis is known at birth. Acute intravascular haemolysis may require transfusion but the anaemia is often self-limiting (Table 9.4). High fluid intake should be encouraged to prevent renal damage. CNSHA may be severe enough to warrant active treatment and splenectomy may be helpful.

Glutathione

GSH is the major intracellular thiol in aerobic cells, and is equally important in the red blood cell. It is thought to have a number of critical functions: protecting cells against oxidative damage, participation in detoxification of foreign compounds, maintenance of protein sulphhydryl groups in a reduced state, and possibly transport of amino acids. In the red cell, its main function is as an antioxidant. GSH is synthesized from glutamate, cysteine and glycine by the link reactions of two enzymes, γ-glutamylcysteine synthetase and glutathione synthetase (see Figure 9.10). GSH exerts its function in preserving thiol groups and reducing hydrogen peroxide and free oxygen radicals through reactions catalysed by the enzymes glutathione-S-transferase and glutathione peroxidase, respectively. Oxidized glutathione (GSSG) is reduced to GSH by the action of glutathione reductase, the hydrogen donor being NADPH (see Figure 9.10). Failure to maintain the GSH level as a result of deficiency in the synthetic pathways or deficiency in the recycling process leads to chronic haemolytic anaemia and increased susceptibility to oxidative stress.

Table 9.6 Enzymopathies of the glutathione cycle and synthetic pathways.

Enzyme	Gene	Haematology	Other systems	Comments
Glutathione synthetase	GSS, 20q11.2 AR	CNSHA, Heinz bodies, oxidative HA	Neurological, metabolic acidosis	5-Oxoprolinaemia/uria, RBC deficiency, may have no neurological disease, nine families
γ -Glutamylcysteine synthetase	GCLC, 6p12 GCLM, 1p21 AR	CNSHA, oxidative HA, basophilic stippling	Neurological	Variable neurological features, five families
Glutathione reductase	GSR, 8p21.1 AR	Favism	None	Most reports due to FAD deficiency, one family
Glutathione peroxidase	GPX1, 3p21.3 AR	HDN, acute intravascular haemolytic anaemia	None	Self-limited neonatal jaundice, one Japanese family

AR, autosomal recessive; CNSHA, congenital non-spherocytic haemolytic anaemia; FAD, flavin adenine dinucleotide; HDN, haemolytic disease of the newborn.

Glutathione deficiency

Complete loss of GSH synthesis is probably lethal. Severe deficiency leads to 5-oxoprolinuria, metabolic acidosis and mental retardation. A milder deficiency limited to red cells is associated with haemolytic anaemia aggravated by oxidative stress. Low levels of GSH caused by γ -glutamylcysteine synthetase or glutathione synthetase deficiency, with CNSHA, have been described. Haemolytic anaemia due to deficiency of glutathione reductase and glutathione peroxidase has also been reported (Table 9.6).

Nucleotide metabolism

Adenosine nucleotides – ATP (85–90%), ADP (10–12%) and AMP (1–3%) – comprise the main nucleotide pool in the mature red cell. The cell has no mechanism for making nucleotides once the RNA of the reticulocytes has been degraded. The cell does have an effective salvage mechanism for maintenance of the adenine pool, with the enzymes adenosine deaminase (ADA) and adenylate kinase involved in regulation. Deficiency of the enzymes in the salvage pathway does not lead to haemolysis. ADA deficiency is associated with severe combined immunodeficiency and excess activity is found in Diamond–Blackfan anaemia. During maturation of reticulocytes the RNA is broken down to pyrimidine and purine nucleotides, which are dephosphorylated to nucleosides that can diffuse out of the cell. The purine nucleotides enter the salvage pathway. Deficiency of pyrimidine 5'-nucleotidase leads to accumulation of pyrimidine nucleotides that interferes with the adenine nucleotide pool, producing haemolysis.

Figure 9.15 Pyrimidine nucleotide catabolism in the reticulocyte. Pyrimidine 5'-nucleotidase converts the nucleotides to monophosphates, which diffuse out of the cell.

Pyrimidine 5'-nucleotidase

Pyrimidine 5'-nucleotidase (P5N), also called pyrimidine 5'-monophosphate hydrolase, catalyses the dephosphorylation of the pyrimidine 5'-monophosphates uridine monophosphate (UMP) and cytidine monophosphate (CMP) to corresponding nucleosides (Figure 9.15). In red blood cells, there are two isoforms of P5N, type 1 (P5N1), which has a high affinity for UMP and CMP, and type 2 (P5N2), which hydrolyses deoxypyrimidine nucleotide monophosphates. It is deficiency of P5N1 that leads to haemolytic anaemia. The gene (*NT5C3*, also named *P5'N1*) is located on chromosome 7p14.3. The gene consists of 10 exons with alternative splicing at exon 2, which gives rise to isoforms with 286 and 297 amino acids. The P5N1 enzyme corresponds to the 286-amino-acid isoform. The enzyme is strongly inhibited by lead.

Pyrimidine 5'-nucleotidase deficiency

P5N1 deficiency is not uncommon: more than 60 patients have been reported worldwide, with presumably large numbers

Figure 9.16 Peripheral blood film from patient deficient for pyrimidine 5'-nucleotidase showing basophilic stippling (a similar appearance is seen in chronic lead poisoning).

undetected. The prevalence of P5N1 deficiency is unknown. It is probably the third most common enzyme deficiency causing haemolytic anaemia, perhaps equal to GPI deficiency. Nearly all reported cases have shown homozygosity for the mutation, and the mutation has been specific for individual families. However, there is a suggestion that certain mutations (del G576 and ins GG743) might be more prevalent in southern Italy or southern Mediterranean regions. One compound heterozygote was found in this region.

Deficiency of P5N1 is associated with a recessively inherited haemolytic anaemia characterized by marked basophilic stippling in the red cells (Figure 9.16) and accumulation of high concentrations of pyrimidine nucleotides. The haemolysis is usually mild to moderate, although more severe cases have been reported. Splenectomy is usually of little value, though benefit has been reported in some cases. The appearance of the blood film is similar to that seen in lead poisoning, and the mechanism of the anaemia in lead poisoning certainly involves the inhibition of P5N.

Introduction

Acquired haemolytic anaemias are usually divided into two main categories depending on the mechanism by which the premature destruction of red blood cells is produced. In the immune haemolytic anaemias, antibodies are the main agents of destruction. The non-immune acquired haemolytic anaemias include diverse causes and mechanisms of haemolysis. In most anaemias, there is some shortening of red cell survival, but in the haemolytic anaemias this shortening of red cell lifespan is the major cause of the anaemia and produces the classical features of haemolysis.

Immune haemolytic anaemias

Antibody-mediated haemolysis is an important cause of acquired haemolytic anaemia. Antibodies may be autoantibodies produced by the patient's own immune system and directed against epitopes of his/her own red cell antigens or they may be alloantibodies. Alloantibodies may be produced by the patient and directed against antigens not present on that person's own red cells, but either introduced as foreign red cell antigens by blood transfusion or secondarily acquired by the patient's red cells, as in drug-induced haemolysis. Alloantibodies directed against the patient's red cell antigens might also be introduced from outside the patient, most notably from the mother in haemolytic disease of the newborn. A simple classification of immune haemolytic anaemias is given in Table 10.1. Typically, the immune haemolytic anaemias are distinguished from the

non-immune by detecting antibody on the surface of red cells by the direct antiglobulin test (DAT), also known as the Coombs test.

Autoimmune haemolytic anaemia

Autoimmune haemolytic anaemia (AIHA) is characterized by a positive Coombs test or DAT, which detects antibody, with or without complement, on the red blood cell surface. AIHA is classified into warm and cold types, depending on whether the antibody reacts more strongly with red blood cells at 37°C or at 4°C and whether IgG (warm) or IgM (cold) autoantibody predominates. Haemolysis is mainly extravascular in AIHA, although complement-mediated intravascular haemolysis may sometimes occur in either type. Red blood cells coated with IgG only are preferentially destroyed in the spleen, but if they are also coated with complement or with complement alone, their main site of destruction is the liver. The site and severity of red cell destruction depend on structural and functional characteristics of the antibody and efficiency of the mechanism of destruction. The degree of anaemia depends on the rate and acuteness of the destruction and the capacity of the bone marrow to compensate.

AIHA may occur without any underlying cause (as primary or idiopathic conditions) or may be associated with other systemic autoimmune disease (such as systemic lupus erythematosus and rheumatoid arthritis), malignancy (lymphoma, thymoma and chronic lymphocytic leukaemia) or drug exposure. In many cases, the pathogenesis involves a disturbance of the immune system in which T-lymphocyte control of autoreactive B lymphocyte clones is reduced.

Antibody characteristics

Antibody characteristics that influence the site and intensity of red cell destruction in AIHA can be evaluated using the DAT.

Table 10.1 Classification of immune haemolytic anaemias.

Antigen type	Antibody	Diseases	Associations
Autoimmune	Warm antibody	Primary Secondary	Idiopathic Autoimmune diseases (SLE, etc.) Lymphoproliferative disorders Infections (EBV) Ovarian cysts Some cancers Drugs
	Cold antibody	Cold haemagglutinin disease Cold antibody syndromes	Infections, lymphoproliferative disorders
	Donath–Landsteiner	Paroxysmal cold haemoglobinuria	Post viral, syphilis
Alloimmune	Induced by red cell antigens	Haemolytic transfusion reactions Haemolytic disease of the newborn Post-stem cell allografts	
	Drug dependent	Antibody/macrophage mediated Antibody/complement mediated Membrane modification	

EBV, Epstein–Barr virus; SLE, systemic lupus erythematosus.

The thermal range of antibody binding also characterizes the antibody.

Immunoglobulin class

Monospecific antihuman globulin reagents for the DAT are routinely available for the detection of IgG, IgM and IgA and for complement components C3c and C3d. Multispecific reagents are also available, as are reagents specific for IgG subclasses, but the latter are difficult to standardize.

Warm-acting antibodies

Warm-acting antibodies are most active *in vitro* at 37°C. The antibodies are polyclonal, and IgG antibodies predominate. Where the specificity of the antibody can be determined, it is most commonly in the rhesus blood group complex. The most frequent patterns detected by the DAT on the red cell surface are as follows: IgG alone; IgG and complement; and complement alone. Antibodies may be detected in the serum at 37°C by the indirect antiglobulin test in about 50–60% of patients; this will rise to more than 90% when the red cell membrane of the reagent cells is modified with papain or another proteolytic enzyme. Antibody may also be eluted from the red cell membrane in a majority of cases and the specificity determined. A subtype of warm AIHA has been defined in which both warm- and cold-type antibodies are found. Both tend to be lytic, and this 'mixed type' AIHA tends to produce a more severe haemolysis with an intravascular component. It is most commonly

associated with systemic lupus erythematosus (SLE) or lymphoproliferative disease.

Cold-acting antibodies

Cold-acting antibodies are predominantly IgM and are most actively bound to antigen in the cold (4°C). Cold antibodies act as both agglutinins and lysins *in vitro*; the two functions may have different thermal ranges. The clinical significance of the antibody depends purely on the thermal range: how the antibody binds to red cells at or near 37°C, not the titre in the cold. IgM antibodies active against I (auto)antigen at 4°C are a normal finding but produce no clinical disturbance if not active above 31°C. The IgM antibodies have specificity mainly for the I antigen, although i specificity may be found in Epstein–Barr virus (EBV)-associated antibodies and some cases of lymphoproliferative disease. Rarely, anti-P activity is found. *In vitro*, the IgM antibodies elute off the red cell membrane, usually leaving bound complement to be detected by anti-C3d in the DAT. In cold haemagglutinin disease (CHAD) and most cases associated with lymphoproliferative disease, the cold antibodies are monoclonal (IgM κ). Those associated with viral infections are polyclonal.

The antibodies in a subtype of cold AIHA, paroxysmal cold haemoglobinuria (PCH), are IgG in type and bind to antigen below 20°C. When the temperature is raised to 37°C in the presence of complement, lysis occurs. This biphasic reaction is the basis of the Donath–Landsteiner reaction.

Complement activation

Autoantibodies against red cell antigens may activate complement on the red cell membrane. Antibody binding to two adjacent sites on the red cell membrane is required to activate the C1 complement component by the classical pathway. IgM molecules are pentameric and a single molecule can bind adjacent sites. IgG molecules will activate complement if they form a 'doublet': IgG1, IgG2 and IgG3 can activate complement, whereas IgG4 and IgA do not. In AIHA, complement activation usually stops at the C3 stage, where C3b is bound to the membrane and further proteolysed to form the inactive component C3d, which is detected by the appropriate DAT. Complement beyond the C3 stage may lead to the formation of the membrane attack complex and intravascular haemolysis. AIHA due to IgG2 alone is very rare, and that due to IgG4 or IgA alone is uncommon. It is interesting that in the rare case of IgA AIHA, complement does become activated on the cell surface. In general, when there is more than one class or subclass of antibody on the cell surface, the haemolysis is more intense and may be intravascular.

Specificity of red cell autoantibodies

Warm-type autoimmune haemolytic anaemia

In most cases, the antibody detected in the patient's serum is pan-reacting with all cells in a routine group O panel. Some 10–15% of antibodies show specificity for rhesus antigens, particularly anti-e, anti-D or anti-c. A greater proportion show specificity by reacting with all cells except –/– Rh^{null} cells. Other rare specificities against high-frequency antigens include anti-En^a, anti-Wr^b or anti-U. Usually, autoantibodies show reactivity against a number of antigens and are not as specific as alloantibodies.

Cold-type autoimmune haemolytic anaemia

In cold agglutinin syndrome, anti-i specificity is usually seen. Occasionally, there is specificity for anti-I, and even more rarely for anti-Pr, anti-P, anti-M or anti-N, and even cold-reacting anti-A or anti-B. In PCH, the specificity is anti-P.

Effector mechanisms for immune red cell destruction

in vivo

Two main effector mechanisms exist *in vivo*: (i) cell-mediated, predominantly extravascular, immune destruction and (ii) complement-mediated intravascular haemolysis.

Cell-mediated immune red cell destruction

Human macrophages and monocytes have cell-surface receptors for the Fc portion of IgG and for antigenic determinants present on activated C3. Cellular immune destruction is mediated through these receptors. Neutrophils and lymphocytes also have these receptors, but macrophages of the reticuloendothelial system within the spleen, liver and bone marrow are the main site of destruction *in vivo*.

Fc receptor mechanism

Macrophages have Fc receptors for IgG1 and IgG3 molecules, but not for IgG2, IgG4, IgM or IgA. Only IgG-coated red cells are destroyed in this way, but this is clinically important in warm AIHA as 70–75% of autoantibodies are IgG. Phagocytosis and antibody-dependent cell-mediated cytotoxicity are the major Fc receptor-dependent modes of antibody-coated cell destruction.

The role of the spleen

The splenic vasculature is adapted to make the spleen an efficient filter for such particles as effete red cells, bacteria and immune complexes. As blood passes through the central arteries towards the red pulp, the branches of these arteries have a plasma-skimming effect that raises the haematocrit of the blood as it passes towards the splenic cords. There, red cells come into close contact with the splenic macrophages. The low plasma content and the relative lack of free plasma IgG molecules allow red cell-bound IgG to interact preferentially with the macrophage Fc receptors, leading to phagocytosis of the coated red cells. When phagocytosis is partial, so that only portions of the cell membrane are removed, the remaining circulating red cell becomes spherocytic, although the somewhat rigid spherocytes may themselves be trapped in the splenic sinusoids and destroyed. The spleen is thus most commonly the major site of red cell destruction when IgG alone is the main Fc-binding protein on the red cell surface (see Chapter 20).

The role of the liver

Kupffer cells are macrophages that are present in the liver sinusoids and which express Fc receptors on their surface. Blood flow through the sinusoids is rapid compared with the spleen and there is no plasma-skimming effect. IgG-coated red cells are not preferentially destroyed in this situation, where there is competition for Fc receptors from circulating IgG. Here, red cell destruction is more dependent on cells being coated with C3.

C3 receptor mechanisms

Two types of C3 receptor have been identified on macrophages, CR1 and CR3. CR1 is specific for an antigenic site in the C3c region of activated C3b that is not exposed on native C3. The breakdown product of C3b (iC3b) is also a major ligand for CR1 and is the only ligand for CR3. Immune adherence of C3b-coated red cells to macrophages occurs mainly through CR1, whereas CR3 binding triggers phagocytosis. The largest concentration of C3b-binding macrophages is found in the liver sinusoids so that the liver becomes the major site for trapping and phagocytosing C3b-coated red cells. There is no competition for complement receptor sites from non-activated C3 in the plasma. If the spleen is very large, this too becomes an important site of cell destruction.

In cold AIHA, IgM agglutinins bind most avidly to red cells in the peripheral circulation, where the temperature may be as low as 10–20°C. Complement activation occurs and leads to C3b and iC3d expression on the red cell membrane. Macrophage destruction of red cells is the main mechanism of haemolysis in IgM cold antibody-coated cells and also occurs in warm AIHA as a result of complement-fixing IgG and IgM antibodies.

Complement-mediated intravascular haemolysis

Intravascular complement-mediated haemolysis is a minor mechanism for red cell destruction in most patients with AIHA. In a small proportion of patients, such a mechanism may predominate and produce severe intravascular haemolysis. Complement-induced intravascular haemolysis in warm AIHA is most likely to occur when more than one class or subclass of immunoglobulin is present on the red cell surface. Intravascular haemolysis has been reported with IgA-coated red cells, although the mechanism is obscure, as IgA does not itself fix complement.

In cold AIHA syndromes, intravascular haemolysis may be precipitated by exposure to cold. In such cases, lytic as well as agglutinating antibodies with a high thermal range may be demonstrated *in vitro*. This pattern is not uncommon in cold AIHA associated with *Mycoplasma pneumoniae*. Acute intravascular haemolysis is the usual presentation in PCH, where the antibody is IgG in type.

Other factors influencing red cell destruction and production

Bone marrow function

The ability of the marrow to increase erythropoiesis may be impaired. Autoantibodies may be produced, which act against reticulocytes and erythroblasts, as well as mature red cells. Red cell production may also be reduced by folate deficiency secondary to the increased demand. Lymphoproliferative diseases may impair production through infiltration of the marrow.

Reticuloendothelial function

The severity of cellular immune red cell destruction depends largely on macrophage function. Reticuloendothelial function may be reduced in SLE by the clearance of immune complexes, a process known as reticuloendothelial blockade. In methyl-dopa-induced AIHA, the drug has been shown to reduce reticuloendothelial clearance of IgG-coated red cells, which might explain why many patients with a strongly positive DAT due to methyl-dopa have little or no haemolysis.

Hypocomplementaemia

Partial protection from complement-mediated lysis may occur in patients with chronic CHAD, in which continuous complement activation may lead to relative complement deficiency. Hypocomplementaemia is common in SLE and may also be caused by chronic activation of the complement pathway. In

addition, there is a strong association between SLE and the occurrence of null alleles for the C2 and C4 genes, which causes a genetically determined complement deficiency.

Warm-type autoimmune haemolytic anaemias

Clinical features

Warm-type AIHA affects all age groups and accounts for up to 70% of AIHA cases. Haemolysis is caused by high-affinity IgG antibodies produced by reactive polyclonal B cells. An underlying or associated disorder can be identified in 50–70% of cases. Presentation is variable and depends on the speed with which anaemia develops, the capacity of the bone marrow to compensate and the effects of any associated disease. Most commonly, the onset is insidious, with the gradual awareness of symptoms of anaemia or the observation of pallor or icterus by friends or relatives. Occasionally, the onset is acute, with rapidly developing anaemia and, in older patients, the risk of heart failure. Rarely, severe cases can occur with fulminating haemolysis, resulting in life-threatening anaemia. Mild jaundice is present. A moderate increase in unconjugated serum bilirubin and excess urinary urobilinogen occurs as a result of extravascular haemolysis. Intravascular haemolysis occurs occasionally, leading to dark urine caused by haemoglobinuria and haemosiderinuria. More marked icterus (bilirubin >90 µmol/L) suggests coexisting liver disease or biliary tract obstruction due to pigment gallstones or biliary sludge. Mild splenomegaly is common, rarely more than 2–3 cm below the costal margin at presentation. Marked splenomegaly suggests the possibility of a lymphoproliferative disease. Reticulocytosis is present, and the peripheral blood film is characterized by polychromasia, spherocytes (Figure 10.1), circulating nucleated red cells and, in some cases, red cell agglutination. Rarely, there may be reticu-

Figure 10.1 Warm autoimmune haemolytic anaemia. Blood film showing spherocytosis, polychromasia and nucleated red blood cell (×40).

lycopenia associated with a positive DAT. There is an increase in lactate dehydrogenase (LDH) due to lysis of red cells, but other liver function tests are normal unless there is associated liver or biliary tract disease. The DAT is positive, most commonly as a result of the presence of red cells coated with IgG alone (mainly IgG1 and IgG3 subclasses) or IgG and complement (the latter pattern commonly seen in SLE). Autoantibody in the serum may show specificity within the rhesus system (e.g. auto-anti-e), but in most cases is pan-reactive with all red blood cells. The autoantibody reacts at 37°C. In very rare cases the amount of antibody remaining on the red cell surface is insufficient to be detected by the conventional DAT.

Idiopathic warm AIHA

In approximately 30% of patients with a DAT-positive haemolytic anaemia, no associated disorder is found. Idiopathic AIHA may occur at any age. There is a peak incidence during infancy and early childhood and a second rise during the third decade, with the majority of cases occurring after the fifth decade. There is a preponderance of female patients in both idiopathic and secondary AIHA. A careful drug history should always be taken to exclude drug-induced AIHA, and chemical exposure at work or in the domestic environment must be assessed. In girls, AIHA may precede clinical or immunological evidence of SLE, so that negative serology for SLE does not exclude the disease at a later date. As mentioned above, the presentation may vary from the gradual onset of anaemia to an acute haemolytic process. Systemic symptoms are rare other than those of anaemia. Pallor, jaundice and mild splenomegaly (usually to between one and a half to five times its normal size) are present. Enlargement of the spleen to the umbilicus or below is not a feature of idiopathic AIHA and suggests a secondary cause.

Evans syndrome

This is defined as the combination of AIHA and immune thrombocytopenia (ITP) in the absence of any underlying disease. The occurrence of thrombocytopenia may coincide with the haemolysis or may arise as separate episodes. The platelet and red cell antibodies are distinct and do not cross-react. Rarely, episodes of immune neutropenia or pancytopenia have also been described in association with a positive DAT.

The diagnosis is important because there appears to be a higher incidence of underlying illness such as immunodeficiency or autoimmune lymphoproliferative disease in children and SLE or T-cell lymphoma in adults. Typically, the disease runs a chronic course characterized by relapses and remissions. Management is as for warm AIHA or ITP (see Chapter 49) but patients with Evans syndrome tend to be more resistant to initial therapy with prednisolone. Options for second-line therapy include immunosuppressive drugs such as vincristine, danazol, ciclosporin and mycophenolate mofetil as single agents

or in combination regimens. Splenectomy is usually considered but responses are inferior to those seen in uncomplicated ITP. More recently, the anti-CD20 antibody rituximab has produced remission of both cytopenias in a high proportion of children and adults with steroid-refractory Evans syndrome. Stem cell transplantation offers the only hope for long-term cure for severe refractory patients but carries a significant risk of transplant-related morbidity and mortality.

Warm AIHA in infancy and childhood

AIHA of unknown cause occurs in infancy and in young children. In infancy, the onset is often acute and anaemia may be profound and difficult to control. The majority of cases in children are transient. It is interesting that in this group the sex difference is reversed, with more boys being affected. In childhood, the haemolytic episode is frequently precipitated by infection. IgG antibodies may be transferred from a mother with AIHA across the placenta to produce haemolysis in the newborn.

Warm AIHA associated with other autoimmune diseases

AIHA is often associated with SLE, especially in young women. Autoantibodies are usually IgG, and both IgG and C3d are found on the red cell surface. Occasionally, the DAT may be positive because of immune complexes adsorbed onto the red cell surface. The spleen is important for clearing such coated cells and splenectomy should be avoided if possible. Otherwise, treatment is as for idiopathic AIHA (see below). This condition is also described with other autoimmune or presumed autoimmune diseases, notably rheumatoid arthritis, Sjögren syndrome and ulcerative colitis; AIHA is also part of the spectrum of autoimmune diseases associated with agammaglobulinaemia.

Warm AIHA in lymphoproliferative diseases

The most common association is with B-cell chronic lymphocytic leukaemia (CLL), low-grade B-cell non-Hodgkin lymphoma or Hodgkin disease. The AIHA may precede the diagnosis of lymphoma, sometimes by months or years. On other occasions, the presentations may be simultaneous or the AIHA may be delayed. The antibodies are polyclonal and have no distinct pattern of antibody type or specificity. The formation of antibodies in this group is thought to be due to immune dysregulation rather than direct production by the malignant clone. Both fludarabine and alemtuzumab, used in the treatment of CLL, are associated with an increased incidence of often somewhat refractory autoimmune cytopenias, probably the result of their powerful effect on the immune system.

Warm AIHA due to drugs

Haemolytic anaemia caused by antibodies directed against self antigens has been described with a number of drugs. Mefenamic acid, levodopa and procainamide have been reported to provoke

this condition. The mechanism by which AIHA is produced by exposure to drugs is not known. Alteration to the red cell membrane or modulation of the immune response by the drug have both been suggested. Treatment of patients with CLL with fludarabine and other purine analogues may provoke a very severe and life-threatening acute AIHA and, less commonly, other autoimmune cytopenias. The mechanism may be related to a decrease in autoregulatory T cells caused by treatment with fludarabine.

Warm AIHA and carcinoma

AIHA has been recorded with a number of malignancies, but it is not clear that there is a true association. It may be associated with ovarian cysts, with the cyst fluid containing the agglutinin. It has been suggested that there is also an association with ovarian carcinoma.

Warm AIHA and viral infections

In children, but rarely in adults, AIHA may follow a viral infection. Haemolysis is usually brisk but self-limiting. It is possible that the virus alters the red cell membrane, which provokes 'auto' antibodies against the altered antigens, or that antiviral antibodies cross-react with membrane antigens. A third possibility is that immune complexes form between the virus and specific antibodies and are secondarily adsorbed onto the red cell surface, leading to immune destruction.

Treatment

Corticosteroids

First-line treatment of warm AIHA is with corticosteroids. The initial dose should be prednisolone 1–2 mg/kg body weight daily. The dose may be given once daily if tolerated and should be continued for 10–14 days, according to response. In patients who respond, the dose should then be reduced steadily, down to half the starting dose over the next 2 weeks and more gradually thereafter. In practice, the reduction in dose is tailored to individual patients and their response. It is important not to stop the steroids too quickly and allow relapse. About 70–80% of patients improve their haemoglobin initially but only 15–20% maintain this response long term. For patients who do not respond or who require unacceptably high doses of prednisolone (>20 mg/day) to maintain a reasonable haemoglobin, other measures should be tried as they are at risk of serious steroid side-effects such as avascular necrosis, osteoporosis, infections and diabetes mellitus. A proton pump inhibitor or histamine H₂ antagonist should be given at the same time as the steroids to reduce the risk of gastric erosions. Folic acid supplements should be given to patients with chronic haemolysis.

Cytotoxic immunosuppressive drugs

These agents are used for patients who are refractory to steroids or those who relapse following steroid withdrawal. On its own,

azathioprine is largely ineffective and is used for its steroid-sparing action at a dose of 1.5–2.0 mg/kg daily. Cyclophosphamide 1.5–2.0 mg/kg daily or ciclosporin, starting at 5 mg/kg daily in two divided doses to achieve trough plasma levels of 100–200 mg/L, can also be used. There has been recent interest in the use of mycophenolate mofetil as an alternative immunosuppressive agent for severe refractory AIHA. Response to these drugs is not usually seen for 4–6 weeks and they should be continued for at least 3 months before being deemed ineffective. The mechanism of action of these agents is relatively non-selective, resulting in significant systemic toxicity including bone marrow suppression, renal toxicity and the potential long-term risk of malignancy. It should be emphasized that there are no controlled trials to prove the worth of cytotoxic drugs in AIHA but there are small case reports of success with each agent.

Intravenous immunoglobulin

Intravenous immunoglobulin has been used in AIHA, particularly when IgG is the main component on the red cell surface. The dose used is the same as for ITP, 0.4 mg/kg daily for 5 days. AIHA responds less frequently to intravenous immunoglobulin than does ITP. Side-effects include headache, fever-chill reactions and a small but present risk of viral transmission.

Splenectomy

The spleen is the primary site of clearance of antibody-coated red cells and splenectomy is considered if there is no response to corticosteroids after 3 months' trial. Patients with predominantly IgG on the red cell surface respond best, and those with complement often respond poorly. Splenectomy may be performed laparoscopically; of selected patients, about 30% achieve a complete remission and do not require steroids, 30% have a significantly reduced steroid requirement and the remainder show no or only transient response. There is no certain way to determine who will respond to splenectomy. There is an increased risk of overwhelming sepsis after splenectomy and all patients should receive pneumococcal, meningococcal and *Haemophilus influenzae* B vaccination at least 2 weeks before the procedure, and prophylactic penicillin indefinitely. The complications of splenectomy are dealt with in more detail in Chapter 8. Because of the emergence of monoclonal antibody therapy as an effective alternative treatment for AIHA, there is a trend towards delaying splenectomy as an option for more resistant/refractory cases.

Monoclonal antibody therapy

Recently, rituximab, a chimeric murine–human monoclonal antibody that binds to the CD20 antigen on B cells and immature plasma cells and largely used in the treatment of CD20-positive B-cell non-Hodgkin lymphoma, has been shown to be effective in idiopathic and secondary warm AIHA as well as in cold agglutinin disease. The standard dose and treatment

schedule used in follicular lymphoma (375 mg/m² i.v. weekly for 4 weeks) is used for autoimmune cytopenias, although more recent studies in ITP suggest that lower doses may be as effective. Response has been shown in patients who are steroid-refractory and who have received multiple treatment modalities, and some patients who relapse after rituximab have been found to respond to retreatment. Overall response rates of 45–75% have been reported, with durable responses of up to 3 years in patients of all ages. Side-effects are minimal and mainly infusion related, such as fever, chills and hypotension. There are concerns about the long-term effects of the profound B-cell depletion that occurs immediately following rituximab therapy. However, naive and memory B cells can be detected by 4–6 months after therapy and the incidence of viral infections remains low in treated patients. In contrast, the results with alemtuzumab (Campath 1H), the anti-CD52 antibody, have been disappointing in AIHA and ITP.

Blood transfusion

Blood transfusion must be given if the clinical situation demands it, if the haemoglobin continues to fall or heart failure develops, despite the impossibility of achieving a satisfactory cross-match in the presence of a positive DAT. The least incompatible grouped blood should be used and transfused slowly. Some authors recommend the use of blood lacking antigens to which the autoantibodies react, but others point out that specificity is rarely absolute and that there is a risk of provoking an alloantibody response.

Prognosis

The prognosis in warm AIHA depends on a number of variables, including age, associated diseases and severity of haemolysis. In all patients, AIHA should be considered a serious and potentially life-threatening disease. Estimates of mortality of idiopathic AIHA in adults vary from 10% at 5 years to 40% at 7 years. The higher figures are mainly in patients aged over 50 years. Most deaths occur in the first 2 years after diagnosis and are related to associated disease. In children, mortality is much

lower, probably about 5%, with the majority of patients recovering completely. AIHA may carry considerable morbidity, often from prolonged high-dose steroid therapy.

Cold-type autoimmune haemolytic anaemias

The clinical features of the cold haemagglutinin syndromes vary with the pathogenesis of the disorder. Serological tests are useful in identifying the cause and in determining treatment. The serological characteristics of the antibodies found in these syndromes are shown in Table 10.2.

Clinical features

Idiopathic cold haemagglutinin disease

Primary CHAD, a relatively uncommon disorder accounting for only 15% of AIHA, is mainly seen in older people and runs a chronic course. Although the condition is mostly benign, the clinical features may be very distressing and disabling. Purplish skin discoloration, maximal over the extremities (acrocyanosis), may be present in cold weather. Acrocyanosis is due to stasis in the peripheral circulation secondary to red cell agglutination. On warming the skin, the colour returns to normal or there is transient erythema. This sequence distinguishes acrocyanosis from Raynaud syndrome. Haemolysis resulting in anaemia is usually present and the patient may be mildly icteric. Occasionally, haemolysis dominates the clinical picture, depending on the ability of the antibody to activate complement on the red cell surface. The cold agglutinins are monoclonal IgM κ, with heavy chain variable regions encoded by the IGHV4–34 gene segment but serum electrophoresis may not reveal a monoclonal band because the concentration of the protein is too low. CHAD may be thought of as a premalignant B-cell disorder, which only presents clinically because of the specificity of the antibody for red cell surface antigens. This is highlighted by the fact that although, traditionally, CHAD has been defined by the absence of an underlying disorder, recent studies using sensitive flow cytometric and immunohistochemical assessments have demonstrated a monoclonal CD20-positive κ-positive B-lymphocyte population in the bone

Table 10.2 Serological characteristics of cold-acting antibodies in the cold agglutinin syndromes.

Disorder	Specificity		
	Anti-I	Anti-i	Anti-P, -Pr
Idiopathic (CHAD)	Monoclonal IgM κ		Monoclonal (rare)
Secondary to			
Lymphoproliferative disease	Monoclonal IgM κ/λ (IgG)		Monoclonal (rare)
<i>Mycoplasma pneumoniae</i>	Polyclonal		
Infectious mononucleosis	Polyclonal		Polyclonal
Paroxysmal cold haemoglobinuria	Donath–Landsteiner (biphasic)		Polyclonal (anti-P)

CHAD, cold haemagglutinin disease; mono.

Figure 10.2 Cold haemagglutinin disease. Blood film showing gross haemagglutination ($\times 20$).

marrow of 90% of patients and lymphoplasmacytic lymphoma is a frequent finding.

In the laboratory, spontaneous agglutination of red cells is frequently observed, both macroscopically and on the peripheral blood film if made at room temperature (Figure 10.2). Automated blood cell counters detect the agglutinates and record erroneously high mean corpuscular volume and low haemoglobin values, unless the sample is tested at 37°C. The DAT shows only C3d on the red cell surface; IgM cold agglutinins are not detected because they elute from the cell surface *in vitro*. They are usually anti-I, although anti-Pr, anti-P and other rarer specificities have been described.

Cold agglutinin syndromes and lymphoproliferative disorders

Occasionally, the cold agglutinin syndrome accompanies or precedes a B-cell lymphoma or CLL. In these cases, the antibody is monoclonal and is a product of the malignant clone. The serological specificity is either anti-I or anti-i. Haemolysis is often more troublesome than symptoms of agglutination. The prognosis is usually that of the underlying lymphoproliferative disease.

Cold agglutinin syndromes and infections

Haemolysis due to cold agglutinins may follow infections, almost always due to *M. pneumoniae*, or infectious mononucleosis. Rare cases following *Listeria* or *Toxoplasma* infections have been reported. The antibodies are mostly polyclonal IgM in type but occasional IgG cold antibodies are found. The antibodies develop in response to the infecting organism and cross-react with the red cell antigens. Haemolysis appears 2–3 weeks after the infection and is usually mild and self-limiting. Occasionally, very severe and even fatal acute intravascular haemolysis develops after *M. pneumoniae* infection. Blood transfusion through a blood warmer may be urgently required.

Treatment

General

Management of cold haemagglutinin syndromes is difficult. All patients should avoid exposure to cold, and electrically heated gloves and socks are available for use in winter. Wintering in a warm climate is a pleasant alternative. Folic acid supplements should be given to patients with chronic haemolysis.

Alkylating agents

Chlorambucil may be effective in reducing antibody production when there is an underlying B-cell neoplasm such as in CLL. Intermittent regimens such as 10 mg/day for 14 days every 4 weeks or continuous treatment of 2–4 mg/day are both effective. Long-term treatment carries the risk of bone marrow suppression and the development of myelodysplasia and acute myeloid leukaemia. Alkylating agents including chlorambucil, purine analogues such as cladribine and interferon alfa are usually ineffective in idiopathic CHAD.

Corticosteroids

Corticosteroids are rarely of use. They should be used only in exceptional circumstances when the antibodies are present in low titres and have a high thermal range. Their use should be avoided in other cases.

Splenectomy

Removal of the spleen is rarely of any use. The cells are coated with C3b and destruction occurs mainly in the liver.

Blood transfusion

Blood transfusions should be given with due regard to the difficulty in cross-matching in the presence of cold haemagglutinins. Blood should be given through an in-line blood warmer. The patient should be nursed in a warm environment, preferably at 37°C. Special precautions are needed for surgical procedures to keep the patient warm.

Plasma exchange

The titre of cold agglutinin may be lowered temporarily by plasma exchange. The procedure may be useful in the control of severe symptoms but has no effect on the underlying disease.

Monoclonal antibody therapy

The anti-CD20 monoclonal antibody rituximab has been shown to be an effective therapeutic option for both idiopathic CHAD and cold agglutinin syndromes with associated B-lymphoproliferative disorders. Response rates of up to 50% have been reported in Phase II studies but with relatively short response duration of only 11 months.

Paroxysmal cold haemoglobinuria

This rare syndrome usually occurs in children following acute viral infections. The original cases were described by Donath,

Landsteiner and Ehrlich in congenital and tertiary syphilis but such cases are no longer encountered. A history of cold exposure is not always present and presentation is with sudden intravascular haemolysis resulting in pallor, dark urine (haemoglobinuria), abdominal pain and sometimes collapse. The cold antibody is a biphasic polyclonal IgG antibody (Donath–Landsteiner antibody) that reacts with red cells below 20°C in the peripheral circulation, causing lysis by complement activation as the red cells are warmed to 37°C in the central vessels. The antibody has specificity for the P antigen.

Treatment depends on keeping the patient warm, preferably at an ambient temperature of 37°C. Haemolysis is usually self-limiting but blood transfusion is often required. The rare pp cells are not usually available and transfusion of ABO- and rhesus-compatible P-positive blood should be given through a blood warmer.

Alloimmune haemolytic anaemia

Drug-induced immune haemolytic anaemia

Antibody-induced haemolytic anaemia caused by drugs is rare but in some cases may be acute, severe and even life-threatening. Four main mechanisms have been proposed for antibody-dependent drug-induced haemolytic anaemias: drug adsorption, immune complex and membrane modification mechanisms that lead to antibodies reacting with novel epitopes, and true autoantibody-induced haemolytic anaemia (see above). The same drug at different doses or repeated usage may activate different mechanisms and there are recent suggestions that membrane modification may underlie most of the mechanisms. The diagnosis of drug-induced immune haemolytic anaemia should be made in three stages: (i) diagnosis of a DAT-positive haemolytic anaemia; (ii) careful drug history; and (iii) serological demonstration of drug-specific antibody, which interacts with red cells.

Pathogenesis

Drug adsorption mechanism: IgG antibodies and extravascular haemolysis

Penicillin is the prototype drug, although cephalosporins and other penicillin derivatives have also been implicated. Drugs in this group readily form hapten–carrier complexes with plasma proteins, which enhance drug-specific antibody production. It has been estimated that 90% of individuals receiving penicillin produce clinically insignificant IgM anti-penicillin antibodies. When high-dose intravenous penicillin is administered, the drug is adsorbed onto the red cell surface, where it becomes non-specifically attached to red cell surface proteins. A minority of patients on high-dose intravenous penicillin therapy (>1 million units daily) develop high-titre IgG anti-penicillin antibodies that attach to the drug bound to the red cell surface and cause predominantly extravascular haemolysis. The clinical picture is usually of mild to moderate haemolysis but if unrec-

ognized, so that large doses of the drug are continued in the presence of increasing antibody levels, complement fixation and acute intravascular haemolysis may occur. The DAT becomes positive after some weeks of treatment and is due to IgG only on the red cell surface. When the drug is stopped, the DAT rapidly becomes negative and haemolysis stops. Antibody in the patient's serum or eluate from the red cells will react with normal red cells only in the presence of the drug. The clinical and serological features are shown in Table 10.3.

Immune complex mechanism: complement-activated acute intravascular haemolysis

Several drugs have been reported to cause immune haemolytic anaemia by this mechanism. Those most frequently reported are rifampicin, phenacetin, quinine, quinidine, hydrochlorothiazide and chlorpropamide and, more recently, intravenous cephalosporins and diclofenac (see below). Hapten–carrier complexes are formed between these drugs and plasma proteins, leading to the production of drug-specific antibodies. Once drug antibodies are present, reintroduction of the drug causes immune complexes to form, which are adsorbed onto the red cell membrane and complement is activated.

Classically, haemolysis occurs on the second or subsequent exposure to the drug and may develop within minutes or hours of drug ingestion. Severe intravascular haemolysis may occur with fever, rigors or nausea and, in extreme cases, acute renal failure. Several groups have reported fatal immune haemolysis with the third-generation cephalosporin ceftriaxone, and cefotaxime and ceftazidime have also been reported to cause immune haemolytic anaemia. Second-generation cephalosporins have also been implicated, although there are fewer reports with them than with third-generation antibiotics. Diclofenac can also cause an immune haemolytic anaemia with intravascular haemolysis, and this is thought to be mediated by both immune complex and drug adsorption mechanisms.

Membrane modification mechanism

Cephalosporin, in addition to the drug adsorption mechanism, can cause a positive DAT by modifying red cell membrane components. Cisplatin and carboplatin have also been reported to cause immune haemolytic anaemia by this mechanism. As a result, a variety of plasma proteins, including immunoglobulin and complement, may attach via a non-immune mechanism to the red cell membrane. This may result in the finding of a positive DAT but rarely causes immune haemolytic anaemia.

Ribavirin in combination with interferon alfa or peginterferon alfa is the treatment for chronic hepatitis C infection. The main dose-limiting toxicity is haemolytic anaemia. Ribavirin enters cells and is phosphorylated to ribavirin triphosphate. In nucleated cells the triphosphate is hydrolysed back to ribavirin, which leaves the cells as the serum level declines. Red cells lack the hydrolysing enzymes: the triphosphate accumulates and alters the deformability of the membrane and extravascular

Table 10.3 Drug-induced immune haemolytic anaemias: clinical and serological features.

	<i>Drug adsorption mechanism</i>	<i>Immune complex mechanism</i>	<i>Autoimmune mechanism</i>	<i>Membrane modification mechanism</i>
Examples	Penicillin Cephalosporins	IV third-generation cephalosporins Quinidine Diclofenac	Methyldopa Procainamide Mefenamic acid Fludarabine* Cladribine*	Cephalosporins Cisplatin Carboplatin
Dose/duration	Large therapeutic doses/prolonged	Very low dose on second or subsequent exposure/short	Therapeutic About 6 weeks	Therapeutic
Haemolysis	Extravascular Subacute	Intravascular Acute	Extravascular Mild/subacute	Rare
DAT	IgG ± C'3	C'3 only	IgG only	IgG
Serum reaction	To drug-treated cells	Only in presence of drug or metabolite	To normal cells	To drug-treated cells
Eluate reaction	To drug-treated cells	Non-reactive	To normal cells	To drug-treated cells

*May change T-cell regulation.

haemolysis occurs. With ribavirin monotherapy the haemolysis may be compensated by increased marrow activity but the marrow suppression caused by interferon alfa inhibits the response and severe anaemia may result. Occasionally, autoantibodies have been detected, presumably generated to antigens in the altered membrane. Haemolytic anaemia may require dose reduction (<800 mg/day) or erythropoietin in 10–30% of patients.

Autoimmune mechanism

Methyldopa was the paradigmatic drug in drug-induced AIHA. There was a delay of some 6 weeks before the DAT became strongly positive due to IgG on the red cell surface. Haemolysis was absent or trivial, although this is not true with some other drugs that produce haemolysis by this route, notably mefenamic acid (Ponstan). The antibodies usually show no Rh specificity when tested against Rh_{null} cells. It should be noted that some drugs may produce haemolysis by both the immune complex and autoimmune mechanisms, depending on the circumstances.

Serological diagnosis of drug-induced haemolytic anaemia

Drug adsorption and membrane modification mechanisms

The DAT is usually positive with IgG1, or IgG and C3 on the red cell surface. The red cell eluate and serum do not react against normal or enzyme-modified red cells. Warm-reacting drug-specific antibody in the eluate and serum is only detected after preincubation of the test red cells with the appropriate drug.

Immune complex mechanism

The DAT is usually positive but may be negative if performed immediately after a brisk episode of haemolysis. The red cell eluate is not reactive even in the presence of the drug. The drug-specific antibody is best detected by preincubating the patient's serum with the drug in solution to allow immune complexes to form. The preincubated serum is then tested against normal and enzyme-modified groups of cells in the presence of fresh complement. In some cases the antibodies may be specific for metabolites rather than for the parent drug. Drug metabolite antibodies may be detected by preincubating drug metabolite obtained from the serum or urine of a volunteer (who has taken the drug) with the patient's serum. A simplified summary of the serological investigation of a patient with suspected drug-induced immune haemolysis is shown in Table 10.3.

Alloimmune haemolytic anaemia with anti-D

Intravenous anti-D immunoglobulin (WinRho) is licensed for the treatment of ITP in unsplenectomized RhD-positive patients. Some intravenous anti-D immunoglobulin preparations have been licensed for treatment of ITP in unsplenectomized RhD-positive patients. Higher doses than those used in prevention of haemolytic disease of the newborn are indicated by the manufacturers. The mechanism of action is thought to be inhibition of platelet destruction by the spleen due to phagocytosis of coated red cells. In some patients, severe acute intravascular haemolysis may occur 1–24 hours after treatment. The onset is with loin pain, fever, prostration and dark red or black urine. Oliguria and disseminated intravascular coagulation (DIC) may ensue with renal failure. A number of deaths have

been reported. The reaction is similar to that seen in acute intravascular haemolytic reaction in mismatched transfusion reactions (see Chapter 16), but so far no culpable antibodies other than anti-D have been detected in different batches of the anti-D preparations tested. The reaction does not happen at the doses used with any of the preparations given to prevent rhesus sensitization in pregnancy.

Non-immune acquired haemolytic anaemias

Haemolysis and haemolytic anaemia may be the consequence of a wide variety of acquired conditions that do not lend themselves to a precise and logical classification. Classification tends to be based on causes rather than mechanisms, although there are some common pathogenetic mechanisms that lead to red cell destruction. The main groups of agents causing haemolysis are infections, vascular disorders (mechanical disorders) and chemical and physical agents, and disorders affecting the red cell membrane. A classification is shown in Table 10.4.

Infections causing haemolytic anaemia

A variety of infections may produce haemolysis through several different pathways. Haemolysis may be a consequence of direct invasion of the red cell by a microorganism or may arise from alterations in the microcirculation, leading to mechanical haemolysis. The intracellular organisms tend to produce the more severe haemolysis.

Malaria

Some degree of haemolysis is seen in all types of malarial infection, but the most severe abnormalities are found in *Plasmodium falciparum* infection. *Plasmodium falciparum* infection is one of the most common causes of anaemia in the world. Many factors may contribute to the anaemia, including marrow suppression, dyserythropoiesis, folate deficiency, hypersplenism and red cell sequestration, as well as haemolysis. The condition has two main components: extravascular destruction of parasitized cells in the reticuloendothelial system, particularly the spleen, and intravascular lysis when the sporozoites break out of the red cells in the circulation. In most patients, the systemic symptoms of malaria dominate the clinical picture but, occasionally, acute intravascular haemolysis is the presenting emergency problem. Haemolysis in malaria is often associated with a positive DAT.

Blackwater fever

Acute intravascular haemolysis leading to the passing of black or dark-red urine is an uncommon but well-described and feared complication of falciparum malaria. The syndrome usually occurs after a few days of typical malaria fever. The appearance of black urine is usually accompanied by further

Table 10.4 Non-immune acquired haemolytic anaemias.

Cause	Examples	Mechanisms
Infections	Falciparum malaria	Intracellular organisms
	Babesiosis

	Perivalvular leak	
	Microangiopathic haemolytic anaemia	Vasculitis, endothelial cell swelling, fibrin shear
Acquired membrane disorders	March haemoglobinuria	
	Liver disease	Lipid/cholesterol changes
	Paroxysmal nocturnal haemoglobinuria	Somatic mutation

DIC, disseminated intravascular coagulation.

fever and often back pain in the renal angle. Oliguric renal failure may ensue, particularly if the patient becomes hypotensive and hypovolaemic from dehydration. Pulmonary and cerebral symptoms may develop. The condition was first described

in white people, most of whom had been treated with quinine, and the importance of this association was stressed. However, the condition is seen in all populations in endemic areas and certainly does not seem to be confined to non-immune individuals. In indigenous populations, glucose-6-phosphate dehydrogenase (G6PD) deficiency may play a part in the pathogenesis as well as quinine exposure. The spread of chloroquine-resistant malaria in the Far East has led to increased use of quinine and an increase in the incidence of blackwater fever.

The degree of parasitaemia is very variable. In about half of the cases the parasite count may be high, whereas in others the count may be low, perhaps because of the intense intravascular haemolysis. The red cell count may fall to $1 \times 10^{12}/L$ within 24 hours of the start of the haemoglobinuria. There is usually a rise in fibrin degradation products in the serum, but this rise is not often marked and is compatible with a degree of renal failure. Intravascular coagulation does not seem to play a major role in pathogenesis.

Immediate treatment is directed towards correction of the fluid and electrolyte loss, counteracting the anaemia and eradication of the parasite. Renal dialysis may be required and may have to be continued for 1 month or more before renal function returns. Subsequent attacks of falciparum malaria are likely to produce further episodes of blackwater fever in susceptible individuals, so scrupulous prophylaxis should be followed.

Babesiosis

Infection with the intracellular protozoan *Babesia* is uncommon and symptomatic disease is mostly confined to splenectomized patients, at least in the European variety. *Babesia* is a tick-borne organism, the tick in Europe being *Ixodes ricinus*, associated with cattle, and in North America, *Ixodes dammini*, carried by rodents and deer. It may be transmitted by blood transfusion.

In splenectomized patients, the disease has an acute onset and is often fatal. There is a 1–3 day period of malaise, sometimes with vomiting and diarrhoea, followed by high fever, rigors, jaundice, acute intravascular haemolysis, haemoglobinuria, renal failure and death. In North America, unsplenectomized patients may experience a milder self-limiting disease, although intravascular haemolysis does occur. The diagnosis is made from the peripheral blood film, where the parasites, looking very similar to *P. falciparum*, are seen in the red cells. There may be a history of tick bite or of exposure to potential vectors. Treatment is difficult. Clindamycin and quinine are the standard therapy for severe infection; exchange transfusion and renal support may be required in severely affected patients.

Bartonella (Oroya fever)

Infection with *Bartonella bacilliformis* is an arthropod-transmitted infection found only in the western Andes of Peru and neighbouring countries. The diagnosis is made from the peripheral blood film. The organism is an intracellular Gram-negative rod during the acute attack, becoming coccoid in

recovery. In non-immune individuals, there may be splenomegaly and haemolytic anaemia, partly intravascular, partly through erythrophagocytosis. The organism is rapidly killed by chloramphenicol, tetracyclines, penicillin and aminoglycosides.

Clostridium perfringens

Clostridium perfringens septicaemia causes an intense intravascular haemolysis with prominent microspherocytosis and ghost cells in the peripheral blood film. The spherocytosis is the result of membrane destruction by lipases and proteases produced by the organism. Although the organism is sensitive to a variety of antibiotics, the appearance of intravascular haemolysis is usually a harbinger of death because of the toxemia.

Toxoplasmosis

Infection with *Toxoplasma gondii* acquired *in utero* may produce haemolysis and a syndrome similar to haemolytic disease of the newborn. In adults, toxoplasmosis is not associated with haemolysis, except perhaps in the immunocompromised host.

Bacterial infections

Intravascular coagulation produced by bacterial infection may be accompanied by some degree of intravascular haemolysis with fragmentation of red cells. Septicaemia from meningococcal or pneumococcal infection may show evidence of haemolysis, but such features are not clinically significant compared with the other effects of the septicaemia.

Haemorrhagic fevers

Haemorrhagic fevers may be accompanied by haemolysis. Dengue fever is widespread in many parts of the world and may cause intravascular haemolysis. Other haemorrhagic fevers, for example yellow fever and West African haemorrhagic fevers, may also produce haemolysis.

Haemophagocytic syndrome

The haemophagocytic syndrome (HPS) is characterized by proliferation of macrophages in the bone marrow, spleen, liver and lymph nodes, with inappropriate phagocytosis of erythroid precursors, granulocytes and platelets. In some variations, the skin may be involved. It may occur in severe systemic infections, such as cytomegalovirus, fungal infection and tuberculosis. Clinically, the patient presents with persistent fever, pancytopenia, jaundice and evidence of liver dysfunction, often with a coagulopathy. The manifestations may be acute or subacute, with the patient exhibiting severe malaise, weight loss and rapidly developing pancytopenia. The jaundice is partly the result of the destruction of red cells and their precursors in the marrow, spleen or liver, usually associated with a marked rise in LDH. There is an acute-phase response, with greatly elevated serum ferritin levels ($>20\,000\ \mu\text{g}/L$) and increases in interferon (IFN)- γ and tumour necrosis factor (TNF)- α with variable changes in other cytokines. The syndrome is associated with abnormal T-cell activation, which triggers the macrophage

response and which may be the consequence of a T-cell lymphoma or may be unmasked by a variety of infections. The two main subdivisions of the syndrome are infection-associated HPS and malignant HPS. Clinically, the distinction may be very difficult because in the lymphomas the proliferation may be trivial, the syndrome being derived from the release of cytokines, and because in malignant HPS superadded infection is common. Likewise, in infection-associated HPS it may be impossible to identify the underlying infection. In children, infection-associated HPS seems to be more common, whereas in adults the majority of cases are associated with lymphoma.

Fragmentation haemolysis: mechanical haemolytic anaemias

The relationship between the vascular endothelium, the cellular elements of the blood and the mechanisms of haemostasis and fibrinolysis is clearly intricate and complex. The integrity of the red blood cell may be destroyed by contact with abnormal endothelial surfaces, although not all abnormalities of vessels cause haemolysis. It may be that some adherence between the red cell and the abnormal vessel wall is necessary for fragmentation of the red cell to occur, and that this usually happens in the context of abnormal flow as well as an altered endothelium. The situations in which fragmentation haemolysis may occur are the presence of prosthetic material and altered flow following cardiovascular surgery, the trapping or adherence of red cells in arteriovenous malformations, and the destruction of red cells in pathologically altered small blood vessels (microangiopathic haemolytic anaemia).

The characteristic features of fragmentation haemolysis are the appearance of the blood film (Figure 10.3) and the presence of intravascular haemolysis. Depending on the underlying vascular pathology, there may be a reduction in the platelet count and evidence of DIC. The rate of red cell destruction also varies

according to the pathogenesis, so the signs of intravascular haemolysis vary from absence of haptoglobin, elevated LDH and minimal haemosiderinuria to acute intravascular destruction with haemoglobinaemia and haemoglobinuria. The major causes of fragmentation haemolysis are shown in Table 10.5.

Cardiac haemolytic anaemia

This syndrome was so called because it mainly occurred after cardiac surgery in which prosthetic valves, patches or grafts were inserted. Haemolysis usually becomes significant only when there is turbulent flow that brings the circulating red cells into intimate contact with the prosthetic material. There are certain situations in which the haemolysis may be of considerable clinical importance.

Figure 10.3 Microangiopathic haemolytic anaemia. Blood film from a patient with carcinoma and bone marrow metastases. Note fragmentation of red cells, leucoerythroblastic changes with nucleated red cell and metamyelocyte and low platelets suggesting possible disseminated intravascular coagulation (×40).

<i>Vascular origin</i>	<i>Pathogenesis</i>	<i>Platelets</i>
Cardiac haemolysis	Prosthetic heart valves Patches, grafts Paraprosthetic or perivalvular leaks	Normal
Arteriovenous malformations	Kasabach–Merritt syndrome Malignant haemangioendotheliomas	Very low
Microangiopathic	TTP/HUS Malignant disease Vasculitis Pre-eclampsia, HELLP Renal vascular disorders Disseminated intravascular coagulation	Low Normal/low Normal/low Low Normal/low Low

Table 10.5 Classification of mechanical anaemias caused by fragmentation haemolysis.

HELLP, haemolysis with elevated liver function tests and low platelets; HUS, haemolytic–uraemic syndrome; TTP, thrombotic thrombocytopenic purpura.

Periprosthetic or perivalvular leaks

If after insertion of a prosthesis or repair of a heart valve a leak occurs around the valve or through a suture track, there may be severe intravascular haemolysis without evidence of haemodynamic distress. A difficulty may be that fragmentation of red cells is not always prominent, although spherocytes may be present. However, once autoimmune haemolysis is ruled out, the diagnosis can scarcely be anything other than cardiac haemolysis in a patient who has had cardiac surgery. The haemolysis can be cured only by further surgery.

Ambulatory haemolysis

A patient who has undergone valve replacement may show only slight evidence of haemolysis while in hospital but experience significant anaemia after discharge. This is thought to occur because the higher cardiac output associated with the greater exercise as an outpatient produces more turbulence and hence greater opportunity for red cell fragmentation. A similar mechanism is thought to operate if the patient becomes iron deficient as a result of chronic intravascular haemolysis. Iron replacement and advice about the level of exercise may prevent or delay the need for further surgery.

Cardiopulmonary post-perfusion syndrome

Acute intravascular haemolysis may occur in patients who have undergone cardiopulmonary bypass surgery. The haemolysis may be accompanied by neutropenia and pulmonary distress. The syndrome does not strictly belong in this section as the haemolysis seems to be caused by complement activation and binding of the membrane attack complex to the red cell surface. The blood film shows ghost red cells rather than fragmentation. The condition is self-limiting and the patient requires only supportive care.

Arteriovenous malformation

Fragmentation of red cells may be seen in Kasabach–Merritt syndrome, in which platelets are trapped in the vascular network of giant arteriovenous malformations, sometimes with evidence of a consumption coagulopathy. The bleeding disorder is of greater significance than the haemolysis in these patients. A similar picture, usually with clear evidence of a consumptive coagulopathy with evidence of DIC, may be seen in malignant haemangio-endothelioma, in which the tumour tends to invade and grow along veins.

Microangiopathic haemolytic anaemias

Microangiopathic haemolytic anaemia (MAHA) is a condition in which intravascular haemolysis with fragmentation of red cells is caused by their destruction in an abnormal microcirculation. Proof of microangiopathy may be lacking in those not subjected to a post-mortem, and MAHA should be considered a clinical syndrome. The three main pathological lesions that give rise to MAHA are deposition of fibrin strands, often associ-

Table 10.6 Causes of microangiopathic haemolytic anaemia.

<i>Disease</i>	<i>Microangiopathy</i>
Haemolytic–uraemic syndrome	Endothelial cell swelling, microthrombi in renal vessels
Thrombotic thrombocytopenic purpura	Platelet plugs, microaneurysms, small-vessel thrombi
Renal cortical necrosis	Necrotizing arteritis

Carcinomatosis	Abnormal tumour vessels, intravascular coagulation (disseminated or localized)
Primary pulmonary hypertension	Abnormal vasculature
Cavernous haemangioma (Kasabach–Merritt)	Local vascular changes, thrombosis

HELLP, haemolysis with elevated liver function tests and low platelets.

ated with DIC; platelet adherence and aggregation; and vasculitis. The vessel abnormalities may be generalized or confined to particular sites or organs. In most cases, the haemolysis is of less consequence than the underlying cause of the microangiopathy, but the fragmentation of red cells may be important in pointing to the diagnosis. Some of the disorders producing MAHA are given in Table 10.6. Only well-defined clinical syndromes are described in detail here.

Microangiopathic haemolytic anaemia and malignant disease

Fragmentation of red cells with chronic intravascular haemolysis may occur in malignant disease. Clinically significant anaemia may occur, especially when there is invasion of the tumour into a large blood vessel (as in haemangiopericytoma), but more commonly the haemolysis is trivial or well compensated. The fragmentation may simply be noted on the blood film. A blood film that shows evidence of MAHA together with leucoerythroblastic changes is virtually diagnostic of malignant disease with secondary deposits in the bone marrow (Figure

10.3). Mucin-secreting tumours are most likely to produce MAHA.

In acute leukaemia, particularly but not exclusively promyelocytic (M3), there may be intense intravascular coagulation that may be accompanied by MAHA. The coagulation changes dominate the clinical picture.

Microangiopathic haemolytic anaemia and infection

Infections, particularly septicaemia, may provoke intravascular coagulation and MAHA. Generally, the coagulation changes and septic shock overshadow the mild fragmentation but, occasionally, infections produce a chronic state of partially compensated intravascular haemolysis and marked red cell fragmentation. Haemolytic-uraemic syndrome may be precipitated by infection, particularly *Escherichia coli* 0157. Haemolytic-uraemic syndrome is discussed in Chapter 44.

Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura is an acute syndrome characterized by fever, neurological signs, haemolytic anaemia with fragmented red cells and thrombocytopenia. The diagnosis is made on the basis of the clinical presentation and evidence for haemolytic anaemia with fragmented red cells and thrombocytopenia. Bilirubin is elevated, as is serum LDH, indicating intravascular haemolysis. LDH is a useful marker for measuring the activity of the microangiopathic process, as is the persistence of red cell fragments in the blood film. It may take up to 1 week for all fragments to be removed from the circulation after the haemolytic process stops. The destruction of red cells occurs at the site of intravascular occlusions; at post-mortem, platelet and fibrin plugs are found in capillaries (Figure 10.4). The condition, including the pathophysiology, is discussed in detail in Chapter 44.

March haemoglobinuria

Haemoglobinuria following running has been documented for about 100 years. Its origin is mechanical, with destruction of red cells occurring in the feet. It can be cured by wearing soft shoes or running on soft ground. The disorder may arise in joggers and is benign except that it may lead to extensive invasive investigations unless recognized. The blood film does not show any red cell fragmentation or consistent abnormality. Occasionally, haemoglobinuria after running is accompanied by nausea, abdominal cramps and aching legs, and enthusiastic athletes with this condition may exhibit mild splenomegaly and jaundice.

Chemical and physical agents

Oxidative haemolysis

Oxidative substances may cause haemolysis in people with normal red cell metabolism and normal HbA if the oxidative stimulus is large enough. The major causes of oxidative haemo-

(a)

(b)

Figure 10.4 Thrombotic thrombocytopenic purpura. Microthrombi in capillaries: (a) section from the myocardium; (b) thrombus in a bone marrow capillary (haematoxylin and eosin, $\times 100$). (Courtesy of Dr Margaret Burke.)

lysis in normal subjects are shown in Table 10.7. The clinical features of this condition are dependent on the main sites of oxidative attack, whether on the membrane of the red cell (intravascular haemolysis), the globin chains (Heinz body formation) or the haem group (methaemoglobin accumulation).

Chronic intravascular haemolysis with Heinz bodies

Dapsone and sulfasalazine (Salazopyrin) will cause oxidative intravascular haemolysis in normal subjects if taken in sufficiently high dosage. Red cells show the 'bite' abnormality of the chemically damaged cell (Figure 10.5). Heinz bodies may be absent or scanty in patients with an intact spleen. Dapsone may be used in the treatment of G6PD-deficient subjects with leprosy and in the treatment of dermatitis herpetiformis, in which functional hyposplenism occurs; Heinz bodies appear in the latter case, acute intravascular haemolysis in the former. Haemosiderinuria may be detected in patients taking these

Table 10.7 Substances causing oxidative haemolysis and/or methaemoglobinaemia in normal people.

Substance	Use	Remarks
Dapsone	Leprosy, dermatitis herpetiformis	Chronic haemolysis; slow acetylators more susceptible
Maloprim	Antimalarial	Methaemoglobinaemia in NADH methaemoglobin reductase-depleted subjects
Sulfasalazine	Ulcerative colitis	Chronic intravascular haemolysis
Phenazopyridine	Analgesic in urinary tract infections	Methaemoglobinaemia
Menadiol	Water-soluble vitamin K analogue	Haemolysis/kernicterus in infants
Nitrites	Fertilizer; present in well water, some vegetable juices	Methaemoglobinaemia in infants
Nitrates	Amyl nitrate, butyryl nitrite; abused recreationally	Methaemoglobinaemia/haemolysis
Chlorate	Weed killer	Acute i.v. haemolysis; renal failure; >30 g fatal
Arsine	Gas produced in smelting and other industrial processes	Acute i.v. haemolysis; renal failure

Figure 10.5 Oxidative haemolysis caused by drug (phenacetin). Note red cells with contracted haemoglobin.

drugs, and there may be polychromasia and macrocytosis. Haemolysis is usually well compensated and there is no need to stop the treatment unless the anaemia is severe. A dose reduction may sometimes be needed. Methaemoglobinaemia is uncommon unless the patient is partially deficient in NADH methaemoglobin reductase. The gene for this abnormality may not be very uncommon, and it may account for some people becoming cyanosed after taking dapsone-containing antimalarial preparations.

Methaemoglobinaemia with or without haemolysis

Nitrites in water or vegetable juices may cause methaemoglobinaemia in infants who have a physiological impairment of the reducing systems. Well-water that comes from land with an excess of nitrites and which is used to reconstitute artificial feeds has produced cyanosis in infants. Cases have also been described following the enthusiastic feeding of juice from carrots grown

on organically fertilized land and of spinach juice (spinach has a high concentration of nitrogen-fixing bacteria on its leaves). Nitrate drugs, for example amyl nitrate, also produce methaemoglobinaemia and have proved fatal when taken in sufficiently high dosage for 'recreational' purposes. Water-soluble analogues of vitamin K (menadiol sodium diphosphate) cause haemolysis with or without methaemoglobinaemia in infants and *in utero* if given to the mother during the third trimester. Fat-soluble vitamin K preparations must be used if required in these situations. Methaemoglobinaemia due to oxidative drugs rarely causes problems with oxygen delivery but severe cases (>40% methaemoglobin) may be treated with intravenous methylene blue 1–2 mg/kg. Ascorbic acid by mouth may also be used. These measures are ineffective in G6PD-deficient patients and when very strong oxidant substances are implicated. In these circumstances, methylene blue should be avoided because it acts as an oxidant and makes the condition worse.

Acute intravascular haemolysis, methaemoglobinaemia and renal failure

These conditions occur following exposure to strong oxidizing substances found mainly in industrial or horticultural settings, for example sodium chlorate is a popular weedkiller and arsine is a gas produced in various industrial situations, including dross removal in smelting procedures and drain clearances where arsenic is a contaminant. Acute intravascular haemolysis and haemoglobinuria develop 1–24 hours after exposure depending on the dose. The serum becomes brown, often very dark, so that blood cells cannot be seen in anticoagulated preparations, due to the presence of methaemalbumin, methaemoglobin and free haemoglobin. Vomiting, abdominal pain and oliguric renal failure usually develop over about 24 hours. The blood film shows microspherocytosis, ghost cells and bizarre forms. Plasma exchange and renal dialysis are the mainstays of treatment, methylene blue being ineffective. Poisoning with

arsine is usually reversible with these measures. Chlorate poisoning is more difficult, 30g being a generally fatal dose. It is mostly ingested deliberately in suicide attempts.

Thermal injury

Normal red cells when heated *in vitro* show no changes when heated to 46°C for 1 hour but show temperature- and duration-dependent changes above 47–50°C. Some hereditary membrane defects produce red cells that have increased thermal fragility (see Chapter 8).

Haemolysis following burns

Severe burns may be accompanied by intravascular haemolysis with haemoglobinuria. The intravascular haemolysis is related to the extent and severity of the burns. The gross haemoglobinuria occurs over the first 24 hours after the burns and ceases thereafter. The blood film shows spherocytosis and schistocytes, the morphological abnormalities reflecting the thermal damage and the amount of lysis. Prolonged anaemia after burning is related to inflammation, occult blood loss and infection rather than haemolysis.

Lead poisoning

Haemolysis is an important contributor to the anaemia associated with excessive lead exposure. Lead is a potent inhibitor of pyrimidine 5'-nucleotidase 1 (P5N1). This is the prime mechanism of lead-induced haemolysis, producing the same gross basophilic stippling of the red cells as seen in the inherited deficiency of the enzyme (see Chapter 9). P5N1 activity is a good surrogate marker for lead exposure.

Acquired disorders of the red cell membrane

The most common acquired disorder is paroxysmal nocturnal haemoglobinuria, caused by somatic mutation of the phosphatidylinositol glycan A (*PIGA*) gene on the X chromosome, which leads to failure to produce the glycosylphosphatidylinositol (GPI) anchor needed to transport and attach many proteins to the red cell membrane. Intravascular haemolysis occurs through the unchecked action of activated complement. Paroxysmal nocturnal haemoglobinuria is described in detail in Chapter 11.

The mature red cell does not have the capacity to repair its membrane. The lipids of the membrane are in equilibrium with the lipids of the plasma and changes in the ratio of free cholesterol to phospholipids in plasma may affect red cell shape and, in some instances, lead to haemolysis. This is most commonly seen in liver disease, but other inherited lipid disorders may affect the red cell secondarily.

Liver disease

Some degree of shortening of red cell survival occurs in most cases of acute hepatitis, cirrhosis and Gilbert disease, but

anaemia is not present and there is only a slight rise in reticulocytes, which may not be detectable. Biliary obstruction is associated with the appearance of target cells and fulminant hepatitis with acanthocytosis, both consequent on changes in the plasma lipid composition.

Zieve syndrome is an uncommon disorder seen mainly in alcoholics. It comprises intravascular haemolysis and acute abdominal pain. These patients usually have cirrhosis and jaundice. The cause is unknown but is probably related to lipid changes in the blood. Spherocytes are seen in the peripheral blood.

Wilson disease may present as acute intravascular haemolysis. This is probably not a membrane disorder but is consequent on the high levels of copper ions in the blood. The haemolysis may antedate the development of hepatic or neurological features, but Kayser–Fleischer rings are usually present. The blood film may show spherocytosis. The diagnosis is made once the condition is suspected. Apart from caeruloplasmin deficiency, patients have a specific aminoaciduria.

Hereditary acanthocytosis (abetalipoproteinaemia)

This rare inherited deficiency of low-density lipoproteins is characterized by retinitis pigmentosa, steatorrhoea, ataxia and mental retardation. The haemolysis that occurs is of minor importance to such patients, but the blood film may indicate the diagnosis, with the red cells showing marked acanthocytosis.

Vitamin E deficiency

Deficiency of vitamin E may occur in infants who are fed a diet rich in polyunsaturated fatty acids. There is haemolysis with contracted cells and a thrombocytosis. Oedema may be present. Vitamin E is an antioxidant, and oxidative damage to the red cell membrane is thought to be the cause of the haemolysis.

Paroxysmal nocturnal haemoglobinuria (PNH) has fascinated haematologists since its first definitive description in 1882 by Paul Strübbing. PNH is unique as an acquired haemolytic disorder in which the defect is intrinsic to the red cell. Patients have a propensity to develop thromboses that are frequently life-threatening. PNH is also associated with bone marrow failure and indeed may provide a unique insight into the pathophysiology of a variety of bone marrow failure syndromes.

Recently, the development of the terminal complement inhibitor eculizumab has revolutionized the treatment of PNH but in turn has revealed further insights into the pathophysiology of the disease and into normal physiology. The treatment of PNH with eculizumab is not without problems in that a minority of patients have suboptimal responses and require modifications to maximize the benefits of therapy.

Pathophysiology**Glycosylphosphatidylinositol defect**

PNH results from the expansion of an abnormal haemopoietic clone that arises following an acquired mutation in a gene critical for the biosynthesis of glycosylphosphatidylinositol (GPI) structures. These GPI anchors are highly conserved

throughout evolution from yeast to humans, having an identical core structure. GPI anchors are glycolipid structures through which a large number of cell surface antigens are attached to the cell membrane. All patients with PNH have the same biosynthetic defect in one of the early steps of the pathway, namely the transfer of *N*-acetylglucosamine from UDP-*N*-acetylglucosamine to phosphatidylinositol. In 1993, Miyata and colleagues reported the cloning of the phosphatidylinositol glycan complementation class A (*PIGA*) gene, which is part of the enzyme complex involved in this step of the pathway and which has subsequently been shown to be mutated in all cases of acquired PNH reported to date.

Mutations of the *PIGA* gene are different between patients as they are acquired somatic mutations not inherited. It appears that the mutation rate of *PIGA* is similar to that of other genes and in fact populations of PNH-like GPI-deficient cells can be observed at extremely low levels (1–10 per million cells) in most normal individuals, indicating that occasional haemopoietic stem cells by chance acquire *PIGA* mutations. Since the *PIGA* gene is located on the X chromosome (Xp22.1), each somatic cell, male or female, only has a single active copy and therefore a somatic mutation of this active gene leads to deficiency of GPI biosynthesis. GPI-deficient clones only expand if there is an additional factor that encourages their selection. The mechanism of this selective growth advantage of PNH clones is of key importance in understanding the pathophysiology of PNH. This could involve a second genetic event intrinsic to the PNH clone, as described in two separate cases where a chromosomal translocation of the *HMGA2* gene has been reported. However, *HMGA2* abnormalities have not been discovered in the analysis of a large number of cases of PNH. A much more likely explanation is indicated by the association between PNH and other bone marrow failure syndromes.

Association with bone marrow failure

PNH clones frequently occur at very low levels in normal individuals but very rarely expand to become routinely detectable let alone replace virtually all haemopoiesis, as is frequently observed in haemolytic PNH. In addition, PNH clones are detectable in up to 50% of patients with aplastic anaemia and in a smaller proportion of patients with myelodysplastic syndrome. This suggests that such bone marrow failure syndromes are permissive for the expansion of PNH clones. There is overwhelming evidence that aplastic anaemia is an autoimmune disorder in which there is an aberrant immune attack, probably by CD8 cytotoxic T cells directed against the haemopoietic stem cell. It would therefore appear likely that PNH stem cells, presumably due to GPI deficiency, evade this immune attack. This implies that the immune attack in bone marrow failure syndrome is, at least in part, directed through a GPI-linked structure. Understanding PNH may well provide an insight into the mechanism of a variety of bone marrow failure syndromes and provide a unique therapeutic target for these conditions.

Epidemiology

If PNH is defined as the presence of a PNH clone identified during the investigation of bone marrow failure, haemolysis or thrombosis, then the incidence of PNH in a series from the UK was found to be 1.3 newly diagnosed patients per million per year and the prevalence 15.9 patients per million population. However, of these patients, 57% have less than 10% PNH neutrophils, indicating that they are unlikely to have clinically significant haemolysis and only one-third reported macroscopic haemoglobinuria. Thus in the region of 5 patients per million population have haemolytic PNH, and of these only a proportion will be severely affected with symptoms requiring transfusion.

Clinical features

Clinical triad

The clinical picture in PNH depends on the balance between three components: intravascular haemolysis, bone marrow failure and thrombotic complications.

Haemolysis

PNH, the disorder with perhaps the most intense chronic intravascular haemolysis, is characterized by episodes of haemoglobinuria, during which the patient's urine is often black and which, for unknown reasons, is worse in the morning. This episodic haemoglobinuria is frequently associated with dis-

abling symptoms including profound lethargy out of keeping with the patient's anaemia, abdominal pain sometimes requiring opiates, dysphagia that can be temporarily absolute, and erectile dysfunction. The degree of haemolysis is associated with the size of the PNH clone and particularly the proportion of PNH type III (completely deficient) red cells. Macroscopic haemoglobinuria is rarely seen unless there are at least 10% type III red cells. However, patients with apparently identical PNH clones can have a wide range of disease severity, from very occasional attacks of haemoglobinuria without anaemia to severe recurrent or even continuous haemoglobinuria and transfusion dependence, suggesting that other important factors influence the severity of the symptoms. It is possible that this variation is due to the severity of underlying bone marrow failure, to an inherent variation in complement activity or to some other unidentified factor.

Many of the symptoms and complications of PNH result directly from intravascular haemolysis. The presence of extracellular haemoglobin is deleterious as is suggested by the elaborate mechanisms to remove even the smallest quantity. Free plasma haemoglobin is immediately bound to haptoglobin and removed, explaining why haptoglobin is depleted in every patient. Free haemoglobin binds to and removes other gases such as nitric oxide (NO). This depletion of NO in PNH results in smooth muscle dysfunction, vasoconstriction and pulmonary and systemic hypertension. This leads to dysphagia, abdominal discomfort, possibly due to intestinal spasm, erectile dysfunction, severe lethargy, pulmonary hypertension and possibly thrombosis, all classic symptoms of PNH. This syndrome of NO consumption has only become clear since the development of eculizumab (see below), which stops intravascular haemolysis in almost all patients and abrogates the clinical features of PNH.

Bone marrow failure

The degree of anaemia and other cytopenias is a composite of the activity of intravascular haemolysis and the degree of persisting bone marrow failure. The platelet count in many patients is a suitable surrogate for marrow function but in some patients, for example those with previous intra-abdominal thrombosis and subsequent hypersplenism, there may be other causes for a low platelet count. The presence of a PNH clone in patients with bone marrow failure probably indicates that there is a significant immune component to the marrow failure and may suggest that immune suppression is a reasonable therapeutic option. The degree of bone marrow failure will also impact on the efficacy of eculizumab as this will only treat the component due to complement activity, such as intravascular haemolysis and thrombosis.

Thrombosis

The precise cause of thrombosis in PNH is not entirely clear and is probably multifactorial. The activation of PNH platelets

Table 11.1 Sites of thrombotic events in haemolytic PNH.

<i>Venous thrombosis</i>	
Deep vein thrombosis	41 (33.1%)
Lower extremity	23 (18.5%)
Other	18 (14.5%)
Mesenteric/splenic vein thrombosis	23 (18.5%)
Hepatic/portal vein thrombosis	21 (16.9%)

by complement is at least part of the cause. Also, intravascular haemolysis and NO consumption may lead to endothelial damage and thrombosis. Recent data indicate that the thrombotic tendency in PNH is in arterial as well as venous sites, with several patients reported as having cerebrovascular accidents and myocardial infarctions at an early age. Thrombosis occurs in 40–50% of patients with haemolytic PNH, with a predilection for certain veins such as the hepatic veins (Budd–Chiari syndrome), other intra-abdominal veins or the cerebral veins (Table 11.1). Approximately 10% of patients present with a thrombosis as their initial clinical manifestation of PNH. After the first thrombosis, patients have a 7.8-fold increased risk of dying compared with those patients who have not had a thrombosis. A classical clinical scenario is that of downward spiralling thrombotic events: after a first thrombosis, patients continue to experience further apparently discrete thromboses despite what would be considered adequate anticoagulation with warfarin and/or heparin until they eventually succumb. Eculizumab has a marked effect on thrombosis in PNH and can interrupt this spiral of thrombosis.

Other clinical sequelae

Consequences of haemolysis

Even before the development of targeted therapy for PNH, patients usually survived for prolonged periods, with a median survival in the region of 20 years. A minority of patients experienced spontaneous remissions and therefore the majority of patients had decades of life in which they experienced a con-

tinuous high level of intravascular haemolysis. This leads to several complications of the disease.

Renal disease

All patients with haemolytic PNH develop heavy renal tubular iron loading due to the continuous filtration of haemoglobin. This is evident on both magnetic resonance imaging (MRI) and post-mortem studies. The majority of patients will eventually develop chronic renal disease, with a minority progressing to established chronic renal failure requiring dialysis. In addition, during times of very intense intravascular haemolysis and haemoglobinuria, patients can rarely develop acute renal failure, which is potentially fully reversible even though it may require dialysis. Some patients may develop repeated episodes of acute renal dysfunction. The use of nephrotoxic therapies, such as ciclosporin, adds to the renal insult, as do rare complications such as renal vein thrombosis.

Cholelithiasis

Patients with PNH have both intravascular and extravascular haemolysis, which increases the risk of developing gallstones. In patients who develop abdominal pain, a common symptom in PNH, and particularly if there is any additional change in liver function tests, then the presence of gallstones should be considered.

Leukaemic transformation

There have been a number of case reports of myelodysplastic syndrome and acute myeloid leukaemia (AML) in patients with PNH. These have led to the suspicion that PNH may be pre-leukaemic. However, this is almost certainly not the case for two principal reasons. Firstly, in patients with PNH who develop AML, GPI-linked antigens on myeloid blasts have been reported to be deficient in some but normal in others, indicating that the leukaemia can develop in either the residual normal or the GPI-deficient haemopoietic cells. Secondly, less than 5% of PNH patients in the larger series develop AML. This is similar to the incidence of AML in aplastic anaemia and since it seems the majority, if not all, patients with PNH have an underlying aplasia, then the rate of AML is no higher than would be expected if GPI deficiency has no impact on leukaemogenesis. Therefore it is aplastic anaemia that predisposes to both AML and PNH, and the development of PNH does not increase the development of AML.

Spontaneous remission

PNH often develops in young adults between 20 and 40 years old. Historically, most patients with PNH have either died as a direct or indirect result of their disease or have suffered from the disease for the remainder of their life. In a series of 80 haemolytic PNH patients reported in 1995, initially diagnosed between 1940 and 1970, median survival was 10 years and 12 of the 35 patients surviving at least 10 years experienced spontaneous remission. Analysis of GPI-linked antigens on blood

Figure 11.1 Identification of PNH red cells by flow cytometry. (a) GPI anchor protein (e.g. CD59) expression on normal red cells (type I). (b) A total of 46% of red cells are completely GPI anchor-deficient (type III). (c) A mixture of all three types of red

cells are shown: type III, 10%; type II (partial GPI anchor expression), 54%; normal type I cells, 36%. (Figure courtesy of S.J. Richards.)

cells up to 20 years after spontaneous clinical remission demonstrated that the myeloid series was entirely normal with no residual PNH cells, whereas there was a small PNH clone in the lymphoid compartment (presumably these are long-lived memory cells). Early reports suggest that a proportion of patients treated with eculizumab have a progressive decrease in the size of their PNH clone, perhaps suggesting that remission may occur.

Nitric oxide consumption

Intravascular haemolysis leads to the release of cell-free haemoglobin into the plasma. There is now a growing body of evidence in other haemolytic disorders, such as sickle cell anaemia, that many of the symptoms and complications are due to the deleterious effects of free haemoglobin. Free haemoglobin absorbs NO, which is a key mediator in homeostasis and smooth muscle function. Since PNH has extremely high and chronic levels of intravascular haemolysis, it is perhaps not surprising that many of the symptoms of the disease – severe lethargy out of keeping with the level of haemoglobin, dysphagia, abdominal pain, erectile dysfunction, pulmonary hypertension – are most probably due to intravascular haemolysis and NO consumption.

Investigation

The diagnosis of PNH was historically made by demonstrating the sensitivity of red cells to lysis by activated complement. The method used to activate complement varied, for example by acidification in the Ham test or by low ionic solutions in the sucrose lysis test. However, these tests only give an indirect assessment of the proportion of PNH red cells and do not assess the type of PNH red cells (complete versus partial GPI

deficiency) nor do they provide information about the proportion of PNH leucocytes. The proportion of PNH neutrophils and monocytes probably gives a more accurate assessment of the true size of the PNH clone as they are not influenced by the intensity of intravascular haemolysis or by transfusions. The modern diagnosis of PNH depends on the flow cytometric analysis of at least two cell lineages (e.g. neutrophils and red cells), with a transmembrane marker to positively identify the cell type and at least two separate GPI-linked antigens to clearly separate PNH cells from their normal counterparts (Figures 11.1 and 11.2). In most patients there is a population of red cells with complete deficiency of GPI-linked molecules (PNH type III cells, the most complement-sensitive cells) and in some an additional population with partial GPI deficiency (PNH type II cells, intermediate complement sensitivity). Type II and III are usually not evident in the neutrophils. The size of the PNH clone correlates with the risk of complications, such as thrombosis, and the severity of haemolysis. In addition, the evolution of the clone – either its expansion, leading to more haemolytic disease, or its reduction, ultimately leading to spontaneous remission – can be tracked. Flow cytometry has superseded the complement sensitivity tests in the diagnosis of PNH.

Treatment

Supportive care

Conventional management in PNH has been supportive. The severity of haemolysis varies greatly between patients, in part dependent on the size of the PNH clone and the degree of underlying bone marrow failure. However, even patients with no evidence of clinically apparent marrow failure and large

Figure 11.2 Identification of PNH granulocytes by multicolour flow cytometry. (a) Granulocytes identified based on CD15 expression and side scatter. (b) Analysis of CD16 and CD24 (both GPI-linked proteins) reveals a small population of PNH granulocytes (10%) that are deficient in both proteins. (Figure courtesy of S.J. Richards.)

PNH clones can have highly variable levels of haemolysis: some patients experience recurrent, even continuous, haemoglobinuria and are transfusion dependent, whereas others experience haemoglobinuria only rarely, or not at all, do not require any transfusions and have a well-compensated haemolytic anaemia. Patients with a significant degree of haemolysis should receive folic acid supplementation. The constant haemosiderinuria means that patients, even those who require regular transfusions, have a tendency to become iron deficient. This iron deficiency can result in failure of the marrow to compensate for the increased red cell destruction and therefore increasing anaemia. Iron supplementation has been reported to precipitate episodes of intravascular haemolysis but usually patients tolerate oral iron supplements well and should be treated where iron deficiency is present.

Patients should be transfused according to their symptoms. In most patients the severity of haemoglobinuria lessens immediately after a transfusion but then increases, with a progressive fall in haemoglobin level until the patient requires a further transfusion. Incidental infections lead to an increase in haemolysis, presumably due to activation of the complement system, and frequent sudden drops in the level of haemoglobin. These episodes are often associated with severe symptoms of abdominal pain, dysphagia and debilitating lethargy.

Corticosteroids have been widely used in the treatment of haemolysis in PNH. At high doses steroids do appear to have an effect of reducing the activity of complement and some patients report an improvement in symptoms. However, high doses are required to have a clinically useful effect and as the haemolysis in PNH is chronic, the required dose is too high. Steroids are therefore not generally recommended in PNH as the long-term side-effects outweigh the potential benefits.

Thrombosis

The major cause of morbidity and mortality in PNH is thrombosis, which usually affects the venous system, particularly

the intra-abdominal and cerebral vessels, but also appears to result in arterial thrombosis (Table 11.1). The chance of developing a thrombosis depends on the size of the PNH clone and the severity of haemolysis, two variables that are closely related; half of patients with over 50% PNH neutrophils will develop a thrombosis at some point in their disease course. In most series, approximately one-third of patients will eventually die as a result of thrombosis. In a series reported by Hall and colleagues, 39 patients with PNH who had not previously experienced a thrombosis were treated with warfarin to maintain an International Normalized Ratio (INR) of 2.0–3.0. None of these 39 patients developed a thrombosis compared with a 36.5% chance of thrombosis at 10 years for the 56 patients with large PNH clones who elected not to have warfarin prophylaxis. However, two patients on warfarin experienced intracranial haemorrhage and one of these died as a result. Therefore it appears that primary prophylaxis with warfarin is effective in preventing thrombosis but carries a significant risk in this patient group. Aspirin does not appear to be protective against thrombosis and has no effect on the symptoms of PNH such as abdominal pain (Peter Hillmen, unpublished observation). It seems very likely that primary prophylaxis with warfarin is unnecessary for patients receiving the anti-complement monoclonal antibody eculizumab, as this agent significantly reduces the risk of thrombosis in PNH (see below).

The treatment of established thrombosis is similar to the management of thrombosis in patients without PNH. However, in view of the risk of recurrent thrombosis, patients should remain on lifelong anticoagulation after their first episode of thrombosis. Hepatic vein thrombosis (Budd–Chiari syndrome) is one of the more common thromboses seen in PNH and there have been reports of the successful lysis of such thromboses using tissue plasminogen activator; this should be considered even in patients who present with a relatively long history suggesting that their thrombosis occurred days or even weeks before.

Allogeneic bone marrow transplantation

The only curative strategy for PNH is allogeneic stem cell transplantation but this carries a considerable risk of mortality. From the reported series and in view of the fact that a proportion of patients will eventually experience a spontaneous remission of PNH and with the advent of potentially effective novel therapies such as eculizumab, transplantation should only be considered in selected cases, such as those with a syngeneic donor or with associated bone marrow failure. In these patients the indications for transplantation are similar to those for aplastic anaemia.

Complement blockade

The development of eculizumab (Soliris), a humanized monoclonal antibody that blocks the activation of terminal complement, has dramatically altered the management and almost certainly the prognosis in PNH. The complement cascade can be activated by the classical pathway (antibody dependent), the alternative pathway (directly through microbial membranes) or the lecithin pathway, which all converge at the fifth component of complement (C5). C5 is cleaved and releases C5a (a potent anaphylatoxin) and C5b, to which C6, C7, C8 and numerous C9 molecules bind to form a pore (the membrane attack complex) that punches holes in the membrane of the target. Eculizumab binds to C5 and stops it being cleaved and, as long as trough plasma levels remain above 35 mg/L, prevents any activation of terminal complement. Individuals with inherited terminal complement deficiency are either asymptomatic or present with recurrent *Neisseria meningitidis* (meningococcus) infections and this highlights the main concern with eculizumab. The clinical features of PNH are due largely to the absence of CD59 from haemopoietic cells and therefore the uncontrolled activity of terminal complement on PNH cells, making eculizumab an ideal candidate for the targeted therapy of PNH. In the initial study, 11 patients with transfusion-dependent haemolytic PNH were treated with eculizumab using a schedule designed to maintain trough levels to ensure that complement was completely blocked. The responses were dramatic, with an immediate resolution of the symptoms of intravascular haemolysis. This study was followed by a randomized placebo-controlled Phase III trial (TRIUMPH) and a non-randomized trial (SHEPHERD). In total, 195 patients were included in these three trials, which led to the licensing of eculizumab in the USA and Europe in 2007. The results of these trials are summarized below.

Efficacy of eculizumab

Intravascular haemolysis

Eculizumab has a profound and immediate effect on intravascular haemolysis in PNH. The lactate dehydrogenase (LDH)

concentration, which is typically as much as 10–20 times normal in PNH, falls immediately in all patients treated with eculizumab to normal or just above normal. Other markers of haemolysis, such as aspartate aminotransferase, fall to normal and in some patients the haptoglobins become detectable, at least temporarily. In general this results in increasing haemoglobin level which, depending on the degree of coexistent bone marrow failure as well as the extent of extravascular haemolysis (see below), will reach a plateau usually between 9 and 12 g/dL. The most dramatic effect of eculizumab is on the symptoms, with resolution of the abdominal pain and dysphagia and improvement in the severe lethargy and the other features of haemolysis. In the vast majority of patients transfusion requirements improve, with over half of patients becoming transfusion independent. The dramatic improvement in PNH-related symptoms is due to a marked reduction in NO consumption during therapy as a result of the improvement in intravascular haemolysis and thereby the reduction in free haemoglobin. This probably explains many of these benefits of the drug and provides insights into the pathophysiology of the symptoms of PNH. There is a dramatic and clinically significant improvement in the quality of life of patients as measured by validated questionnaires. There is now evidence that the adverse consequences of intravascular haemolysis, such as renal damage and pulmonary hypertension, are ameliorated by eculizumab.

Thrombosis

Eculizumab also protects patients from thrombosis. Compared with thrombosis before patients commencing eculizumab (effectively using patients as their own controls), the thrombotic rate reduces by fivefold to tenfold. In patients who have had a previous thrombosis and who are on anticoagulation, there is still a high recurrent thrombosis rate prior to starting eculizumab. However, since eculizumab became available, such recurrent thromboses are extremely uncommon. Patients who commence eculizumab during a 'spiral' of thrombotic events stop having further thromboses, indicating that eculizumab specifically targets the mechanism of thrombosis in PNH and that this is a more effective strategy than conventional anticoagulation alone. There is now increasing confidence that the catastrophic thrombotic complications of PNH can be much more successfully managed with a combination of eculizumab and anticoagulation. This observation will have an impact on the decision to use warfarin prophylaxis: in cases where there are concerns over the safety or requirement for warfarin prophylaxis, such as those with low platelets or with borderline PNH clone sizes, it is clearly safer to withhold anticoagulation as long as the use of eculizumab is an option for the patient should a thrombosis occur.

Renal dysfunction

In the 195 patients entering the eculizumab trials, renal dysfunction or damage was observed in 65% of patients before they

were treated with eculizumab. In this series, 27% of patients had developed major clinical kidney disease within 10 years from their initial diagnosis of PNH and 21% of patients developed late-stage chronic kidney disease (stage 3 or 4 as defined by the Kidney Disease Outcomes Quality Initiative) or kidney failure (stage 5). The early analysis of patients treated with eculizumab suggests that many of the patients with early renal dysfunction (stages 1 and 2) will improve, and the deterioration in renal function in patients with advanced renal dysfunction (stages 3–5) is frequently stabilized. Thus eculizumab appears to have a beneficial effect on renal function in PNH and this is presumably due to the marked reduction in intravascular haemolysis and therefore in haemoglobinaemia and haemoglobinuria.

Extravascular haemolysis with eculizumab

Despite the impressive impact on intravascular haemolysis, most patients remain somewhat anaemic, maintaining their haemoglobin between 9 and 12 g/dL. Virtually all have a persisting reticulocytosis and many continue to have a raised bilirubin. These features are suggestive of ongoing extravascular haemolysis, which has previously been unreported in PNH. On further investigation it transpires that approximately two-thirds of PNH patients on eculizumab develop a positive direct antiglobulin test to complement only. Flow cytometry demonstrates that the PNH red cells are coated by early complement components (C3b and C3d), possibly because PNH red cells, as well as being deficient in the principal controller of terminal complement, namely CD59, do not express the inhibitor of C3 convertase decay-accelerating factor (DAF). It appears that preventing terminal complement activation leads to a build-up of the early complement components, which accumulate on PNH red cells due to their deficiency of DAF. If intense, this extravascular haemolysis results in a poor increase in haemoglobin and a minority of patients continuing to require transfusions. If the transfusions are due to poor marrow reserves and a lack of compensation, particularly in patients with evidence of renal dysfunction, then treatment with erythropoietin can lead to a clinically meaningful increase in haemoglobin. If this fails, then it does not appear that steroids have a major role. When patients become generally unwell, particularly with coexistent infections, there can be an increase in the level of extravascular haemolysis and/or a decrease in marrow compensation, leading to a fall in the level of haemoglobin. When patients recover from infection, they usually goes back to their steady state.

Eculizumab administration and dosing

Eculizumab is given as a 30-min intravenous infusion. The aim is to rapidly block complement and to maintain complement blockade continuously. The standard dosage schedule for eculizumab comprises a loading dose of 600 mg every week for 4 weeks, followed by 900 mg the next week and then 900 mg every 2 weeks indefinitely. In the majority of patients this is adequate to maintain trough levels of eculizumab above 35 mg/L and

therefore to block complement completely. In approximately 5% of patients this dose is inadequate and patients break through complement blockade. Patients appear well with no signs of haemolysis until immediately before a dose of eculizumab but then develop dark urine often with abdominal pain, sometimes with dysphagia, and a sudden deterioration in the laboratory measures of haemolysis, such as LDH and bilirubin, and a fall in the level of haemoglobin. In this situation the maintenance dose of eculizumab is too low and an increase, either by reducing the interval or more conveniently by increasing the dose (from 900 mg every 2 weeks to 1200 mg every 2 weeks is usually effective), will raise trough levels of eculizumab above 35 mg/L and re-establish continuous control of haemolysis (Figures 11.3 and 11.4).

Infectious risk with eculizumab

Eculizumab is generally very well tolerated with few infusion-related reactions. However, as noted above, blocking terminal complement activity would be expected to increase the risk of infection with *Nisseria meningitidis* (meningococcus). All patients commencing eculizumab should be vaccinated with a wide-spectrum meningococcal vaccine (ACWY Vax). Unfortunately, the current vaccines do not cover serotype B, which is common in the UK. Although the risk of meningococcal infection is a concern, the observed risk is less than 0.5 cases of meningococcal infection per 100 patient-years on eculizumab. However, when these infections occur they can be life-threatening and it is vitally important to impress on patients that they should seek medical help if they suffer any symptoms suggestive of infection, and these are usually of septicaemia rather than meningitis. The role of antibiotic prophylaxis with penicillin is currently being explored. There is no convincing evidence as yet of an increased risk to any other organism except for *N. meningitidis*.

Pregnancy in PNH

It is difficult to estimate the true risk of pregnancy in PNH but there is undoubtedly an increased risk of maternal morbidity and mortality. The reported maternal mortality, mainly from thrombosis, is between 12 and 21%, although this is likely an overestimate due to biased reporting. In addition, an increased fetal loss rate has been reported, although again this is difficult to substantiate and is probably due to maternal factors. There have now been a number of successful pregnancies in women receiving eculizumab either later in pregnancy or throughout the pregnancy from conception to delivery. The reports to date are positive with little or no eculizumab crossing the placenta into the fetus. It does appear that the metabolism of eculizumab may be altered in pregnancy and women seem more likely to break through complement blockade and may need higher doses in the latter part of pregnancy.

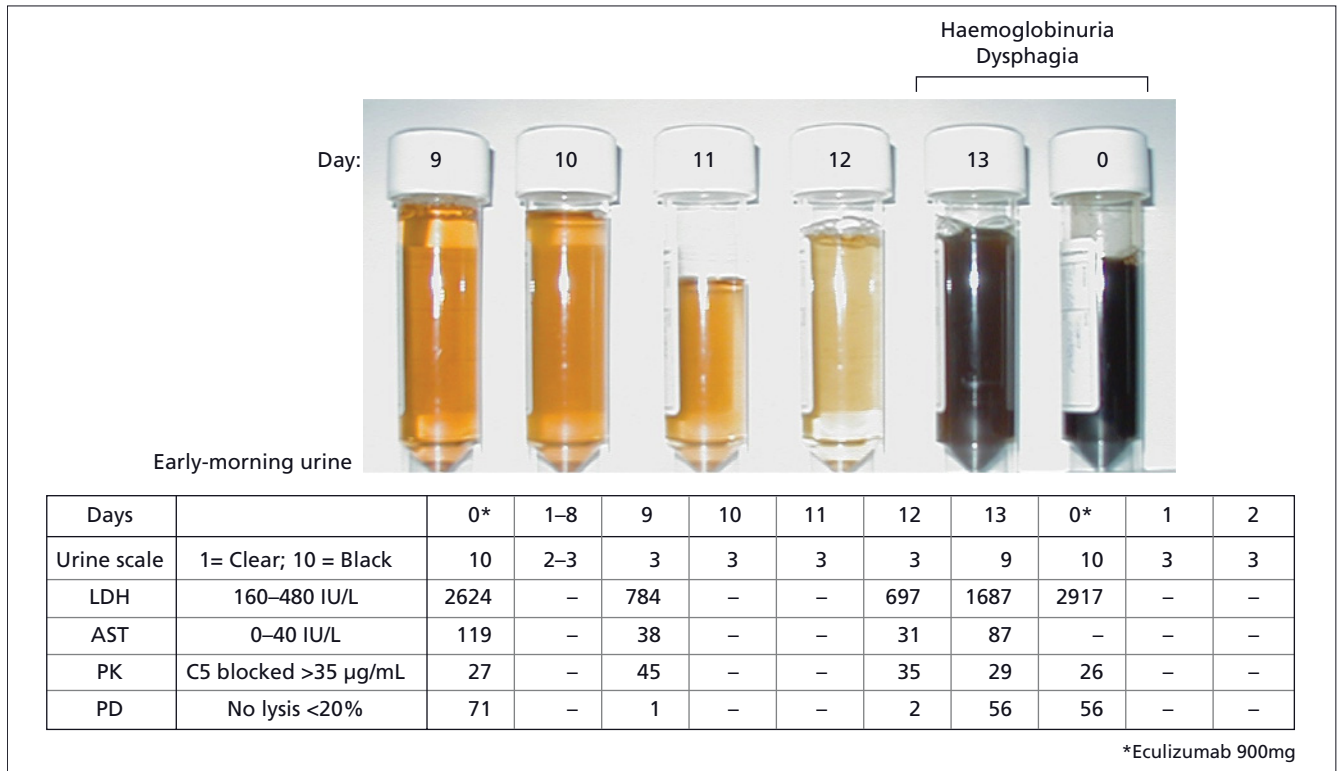

Figure 11.3 Breakthrough from complement blockade by eculizumab due to inadequate dose level. The urine is clear with lactate dehydrogenase (LDH) just above normal and no haemolytic activity in the patient’s serum at day 12 after a 900-mg dose of eculizumab. On day 13, the patient suddenly begins to haemolyse as the level of eculizumab falls below 35 mg/L (the level at which complement is blocked). Immediately

after the next dose (day 0), the haemolysis stops. Urine scale: patient assesses urine colour first thing in the morning (red or black urine at 6+). AST, aspartate aminotransferase; PK, pharmacokinetics (serum level of eculizumab); PD, pharmacodynamics (haemolytic potential of the patient’s serum *in vitro*).

Figure 11.4 Urine colour with increasing eculizumab dose. Patient records early-morning urine colour according to scale on y-axis. He is breaking through from complement blockade for 2 days when receiving 900 mg eculizumab every 14 days. When the

frequency of eculizumab 900 mg is increased to every 12 days, his breakthroughs cease. He is now maintained on 1200 mg eculizumab every 14 days.

Prognosis

A series of 80 patients with haemolytic PNH diagnosed between 1940 and 1970 were reported in 1995 to reveal a median survival of approximately 10 years from initial diagnosis of PNH. In this series, spontaneous remissions of PNH were reported in 12 of the 34 patients who survived over 10 years from diagnosis. A more recent series of 465 patients reported from France, including patients with small PNH clones as well as haemolytic PNH, reported a median survival of 22 years. The major causes of death in haemolytic PNH are thrombotic and since these are virtually abolished by eculizumab therapy, it is anticipated that treatment will have a major impact on survival in PNH.

Future challenges and developments

The development of targeted therapy for PNH promises to alter the natural history of the disease. Recently, a global PNH registry has been established to document the changes in the natural history of the disease as well as to record any unexpected complications of the newer therapeutic interventions. The current therapy of PNH controls rather than cures the disease. It is hoped that with more detailed understanding of the pathophysiology of PNH a curative strategy may be developed.

Introduction

A number of inherited (constitutional/genetic) disorders are characterized by aplastic anaemia (AA)/bone marrow failure, usually in association with one or more somatic abnormalities (Table 12.1). The features of some of these are summarized in Table 12.2. The precise incidence/prevalence of these remains unclear but, collectively, they represent approximately 10–20% of patients presenting with AA and constitute a significant clinical burden, as many are associated with premature mortality. The bone marrow failure may present at birth or at a variable time thereafter, including in adulthood in some cases. The bone marrow failure may involve all lineages or a single lineage; in some cases it may initially be associated with a single cytopenia and then progress to pancytopenia. Scientifically, they constitute an important group of diseases as recent advances in understanding the genetics of some of these are not only beginning to unravel their pathophysiology but are also providing important insights into normal haemopoiesis.

The two syndromes that are frequently associated with generalized bone marrow failure/AA are Fanconi anaemia (FA) and dyskeratosis congenita (DC). These two syndromes are now also two of the best characterized and are discussed in some detail in this chapter (followed by sections on Shwachman–Diamond syndrome, Diamond–Blackfan anaemia, congenital

dyserythropoietic anaemia, congenital neutropenia, thrombocytopenia with absent radii and congenital amegakaryocytic thrombocytopenia) to demonstrate their clinical and genetic heterogeneity, management and possible impact on our understanding of the pathophysiology of the more common ‘idiopathic aplastic anaemia’. Indeed, patients with both FA and DC can sometimes present with AA alone as their initial manifestation and can thus pose a diagnostic/management challenge.

Fanconi anaemia

Clinical features

Since the first description by Guido Fanconi in 1927, FA has become to be recognized as an autosomal recessive disorder (X-linked in a rare subset) in which there is progressive bone marrow failure and an increased predisposition to malignancy, especially acute myeloid leukaemia (AML). Most, but not all, affected individuals also have one or more somatic abnormalities, including skin (café-au-lait spots), skeletal (absent thumbs, radial hypoplasia, scoliosis), genitourinary (underdeveloped gonads, horseshoe kidneys), gastrointestinal, cardiac and neurological anomalies (Table 12.3). Some of these somatic abnormalities are shown in Figure 12.1. The course of the disease and the pattern of somatic abnormalities show considerable variation, with approximately one-third of patients having no physical abnormalities. This makes diagnosis based on clinical criteria alone difficult and unreliable.

Table 12.1 The inherited bone marrow failure syndromes.

<i>Pancytopenia (usually associated with a global haemopoietic defect)</i>
Fanconi anaemia
Dyskeratosis congenita
Shwachman–Diamond syndrome
Reticular dysgenesis
Pearson syndrome
Familial aplastic anaemia (autosomal and X-linked forms)
Myelodysplasia
Non-haematological syndromes (Down, Dubowitz syndromes)
<i>Single cytopenia (usually)</i>
Anaemia
Diamond–Blackfan anaemia
Congenital dyserythropoietic anaemia
Neutropenia
Severe congenital neutropenia including Kostmann syndrome
Thrombocytopenia
Congenital amegakaryocytic thrombocytopenia
Amegakaryocytic thrombocytopenia with absent radii

Table 12.3 Somatic abnormalities in FA.

Abnormality	Percentage of patients
Skeletal (radial ray, hip, vertebral, scoliosis, rib)	71
Skin pigmentation (café-au-lait, hyper- and hypo-pigmentation)	64
Short stature	63
Eyes (microphthalmia)	38
Renal and urinary tract	34
Male genital	20
Mental retardation	16
Gastrointestinal (e.g. anorectal, duodenal atresia)	14
Heart	13
Hearing	11
Central nervous system (e.g. hydrocephalus, septum pellucidum)	8
No abnormalities	30

Malignancy	Yes	Yes	Yes	Yes	?No	?No	Yes	Yes
Chromosome instability	Yes	Yes	Yes	?	?	?	?	Yes
Genes identified	13	6	1	7	1	No	3	*

*Heterozygous mutations in TERC and TERT are risk factors for some cases of AA.

AA, aplastic anaemia; AD, autosomal dominant; AR, autosomal recessive; CDA, congenital dyserythropoietic anaemia; DBA, Diamond–Blackfan anaemia; DC, dyskeratosis congenita; FA, Fanconi anaemia; IAA, idiopathic aplastic anaemia; Eryth, ineffective erythropoiesis; Megs, low megakaryocytes; RCA, red cell aplasia; SCN, severe congenital neutropenia; SDS, Shwachman–Diamond syndrome; TAR, thrombocytopenia with absent radii; XLR, X-linked recessive.

The cumulative incidence of bone marrow failure by the age of 40 years is estimated to be around 90%. At birth the blood count is usually normal. Pancytopenia develops insidiously and presents in most cases between the ages of 5 and 10 years (median age 7 years). However, in some cases the pancytopenia develops in adolescence or even in adult life. The haemoglobin and platelet count are usually first to fall; the granulocytes are usually well preserved in the early stages. As the pancytopenia develops, the bone marrow becomes progressively hypocellular. There is often a marked increase in macrophage activity with evidence of haemophagocytosis. Bone marrow failure leading to fatal haemorrhage or infection is the main cause of death in

FA patients. In an analysis from the International Fanconi Anaemia Registry (IFAR), the median survival time was 24 years; this is changing with improvements in clinical care.

FA is associated with an increased risk of leukaemia and other malignancies. The leukaemias are usually of the acute myeloid type, particularly FAB types M4 (myelomonocytic) and M5 (monocytic). In some cases, leukaemia may be the initial event leading to the diagnosis of FA. The cumulative incidence of haematological malignancy by the age of 40 years is 33%. Besides these haematological malignancies, there is a significant risk of hepatic tumours and squamous cell carcinoma, including squamous cell carcinomas of the vulva, oesophagus, head

Figure 12.1 Fanconi anaemia. (a) Photographs of patients with FA (A1–A3) with small mouth and chin ('Fanconi facies'). (b) Abnormalities of pigmentation (hyper- and hypopigmentation) on the abdomen (B1) with a close-up (B2) of a café-au-lait spot and a hypopigmented patch. The bottom

photograph (B3) shows the back of an FA patient demonstrating lumbar scoliosis. (c) Hands/forearms of FA children showing hypoplastic thumbs (C1), rudimentary ('dangling') thumbs (C2) and a radiograph (C3) showing rudimentary thumb (skeletal) development.

and neck. The cumulative incidence of solid tumours is calculated to be 28% by the age of 40 years. The impression is that malignancies occur mainly in patients with late-onset bone marrow failure and longer survival, with a median age of 13 years for leukaemia and 25 years for solid tumours. Recent analysis from the German FA registry largely concurs with these earlier observations. Furthermore, long-term follow-up in FA patients who have been treated by haemopoietic stem cell transplantation (HSCT) is showing a higher incidence of non-haematological malignancies in patients with FA than patients with other types of bone marrow failure who underwent HSCT, again emphasizing the predisposition to malignancy.

Cell and molecular biology

Over the last three decades many advances have been made in our understanding of the pathophysiology of FA. FA cells characteristically display a high frequency of spontaneous chromosomal breakage and hypersensitivity to DNA cross-linking agents such as diepoxybutane (DEB) and mitomycin C (MMC). This genomic instability (Figure 12.2) led to the development of a diagnostic test (i.e. increased chromosomal breakage in FA cells compared with normal controls after exposure to DEB/MMC) over two decades ago and this remains a useful FA screening test today. This 'FA cell phenotype' has also facilitated many advances in our understanding of FA, including elucidation of the complex genetics of this disease, with 13 subtypes/complementation groups currently characterized. The genes responsible for these subtypes have all been identified and are designated *FANCA*, *FANCB*, *FANCC*, *FANCD1*, *FANCD2*,

FANCE, *FANCF*, *FANCG*, *FANCI*, *FANCL*, *FANCM* and *FANCN* (Table 12.4).

Studies from several research groups around the world have demonstrated that the proteins encoded by the FA genes participate in a complicated network important in DNA repair. Specifically, eight of the FA proteins (*FANCA*, *FANCB*, *FANCC*, *FANCE*, *FANCF*, *FANCG*, *FANCL* and *FANCM*) interact with each other and form a nuclear complex called the FA core complex (Figure 12.3). The FA core complex is required for activation of the *FANCD2* protein to a monoubiquitinated isoform (*FANCD2-Ub*). In normal (non-FA) cells, *FANCD2* is monoubiquitinated in response to DNA damage and is targeted to chromatin containing the DNA damage (e.g. DNA cross-link). *FANCD2-Ub* then interacts with DNA repair proteins (including *BRCA2* and *RAD51*) leading to repair of the DNA damage. In cells from FA-A, FA-B, FA-C, FA-E, FA-F, FA-G, FA-L or FA-M patients, *FANCD2* monoubiquitination is not observed. It has been recently observed that *FANCI* (the protein mutated in the FA-I subtype) is a paralogue of *FANCD2*. *FANCI* associates with *FANCD2* as the *FANCI-FANCD2* (I-D2) complex. Like *FANCD2*, *FANCI* is also monoubiquitinated. FA-D1 patients have biallelic mutations in *BRCA2*. These observations have linked the FA proteins (*FANCA*, *FANCB*, *FANCC*, *FANCD2*, *FANCE*, *FANCF*, *FANCG*, *FANCI*, *FANCL* and *FANCM*) with *BRCA1* and *BRCA2* (*FANCD1*) in a DNA damage response pathway called the FA-BRCA pathway. The *BRCA2* protein is important in the repair of DNA damage by homologous recombination. Cells lacking *BRCA2* inaccurately repair damaged DNA and are hypersensitive to DNA cross-linking agents. It has also been established that *FANCI* is *BRIP1*

Table 12.4 FA complementation groups/genetic subtypes.

Complementation group/gene	Approximate percentage of FA patients	Chromosome location	Protein (amino acids)	Exons
A (<i>FANCA</i>)	65	16q24.3	1455	43
B (<i>FANCB</i>)*	< 1	Xp22.2	859	10
C (<i>FANCC</i>)	12	9q22.3	558	14
D1 (<i>FANCD1</i>) [†]	< 1	13q12.3	3418	27
D2 (<i>FANCD2</i>)	< 1	3p25.3	1451	44
E (<i>FANCE</i>)	4	6p21.3	536	10
F (<i>FANCF</i>)	4	11p15	374	1
G (<i>FANCG</i>)	12	9p13	622	14
I (<i>FANCI</i>)	< 1	15q26.1	1328	35
J (<i>FANCI/BRIP1</i>) [‡]	< 5	17q23.2	1249	20
L (<i>FANCL</i>)	< 1	2p16.1	375	14
M (<i>FANCM</i>)	< 1	14q21.3	2048	23
N (<i>FANCN/PALB2</i>) [§]	< 1	16p12.1	1186	13

**FANCB* is on the X chromosome.

[†]*FANCD1* is *BRCA2*.

[‡]*FANCI* is *BRIP1* (*BRCA1* interacting protein).

[§]*FANCN* is *PALB2* (partner and localizer of *BRCA2*).

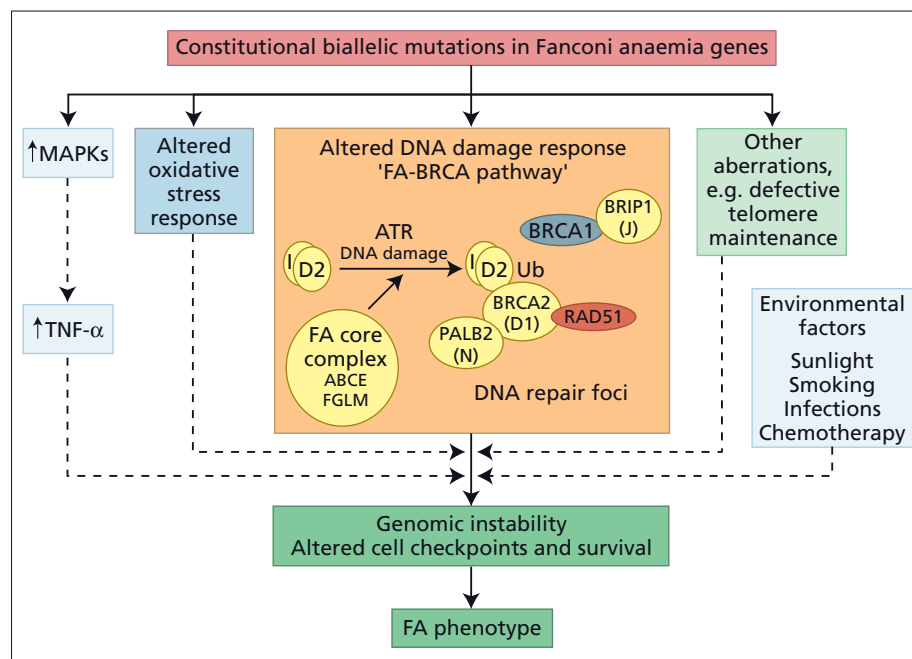

Figure 12.3 Schematic representation of the FA–BRCA pathway and related networks. The diagram shows that the constitutional mutations in FA cells lead to aberration of the FA–BRCA pathway, abnormal handling of oxidative stress, aberrant activation of mitogen-activated protein kinases (MAPKs), defective telomere maintenance as well as possibly other biological aberrations. The net impact of these is increased genomic instability and altered cell survival/checkpoints. The diagram also highlights the potential role of environmental factors such as smoking and sunlight in adding to the effect of

the FA mutations. Within the FA–BRCA pathway, the proteins shown in yellow are those mutated in different FA patients. The FA core complex consists of eight FA proteins (A, B, C, E, F, G, L and M) and this, together with ATR (ataxia telangiectasia and RAD3-related protein), is essential for activation (ubiquitination) of the I–D2 complex after DNA damage. Activated I–D2–Ub translocates to DNA repair foci where it associates with other DNA damage response proteins including BRCA2 and RAD51 and participates in DNA repair. TNF, tumour necrosis factor; Ub, ubiquitination.

(partner of BRCA1) and that FANCN is PALB2 (partner of BRCA2). These findings further strengthen the connection between the FA and BRCA proteins and DNA repair.

The FA–BRCA pathway is activated in response to DNA damage (e.g. replication fork arrest) and involves ATR (ataxia telangiectasia and RAD3-related protein) (Figure 12.3). The pathway is inactivated by the de-ubiquitinating enzyme USP1. ATR appears to directly regulate the FA pathway as it is required for the monoubiquitination of FANCD2 and FANCI. ATR is mutated in a subset of patients with Seckel syndrome, a disease exhibiting some clinical similarity to FA. ATR and ATM (ataxia telangiectasia mutated) are known to phosphorylate FANCD2 and FANCI. Interestingly, ATR–Seckel cells also exhibit defects in FANCD2 monoubiquitination. Furthermore, Nijmegen breakage syndrome (NBS) cells (mutated in *NBN*) show defects in FANCD2 monoubiquitination. This suggests that as well as clinical overlap between patients with FA, NBS and Seckel syndrome, there is also overlap in the biological defects observed in cells from these patients. This highlights the complexity of physical interactions between the different molecules involved in this matrix of pathways. Equally it is clear that FA cells also display other abnormalities in addition to DNA repair (Figure 12.3). This includes hypersensitivity to oxygen, accelerated telomere shortening, abnormal cell cycle kinetics, and overactivation of the mitogen-activated protein kinase (MAPK) pathways leading to overproduction of tumour necrosis factor (TNF)- α . These observations suggest that our understanding of the molecular events responsible for all the FA pathology is currently incomplete.

It is noteworthy that the phenotypes associated with biallelic *BRCA2* (FA-D1) and *PALB2* (FA-N) mutations are markedly similar to each other but different from the other FA genes. Specifically, FA-D1 and FA-N are associated with high risks of solid childhood malignancies (e.g. Wilms tumour and medulloblastoma) which are not usually seen in the other FA subtypes. Furthermore, heterozygous mutations in *BRCA2* (FA-D1), *PALB2* (FA-N) and *BRIP1* (FA-J) confer an elevated risk of breast cancer yet this is not the case for the other FA genes. These differences highlight that the relationship between the FA proteins and their interactions with other molecules is complex at both the clinical and molecular levels.

In vitro gene transfer studies have demonstrated that introduction of the appropriate wild-type FA gene into FA human lymphoid and haemopoietic cells markedly enhances their growth and normalizes their response to MMC; in lymphoid lines, cell kinetics (G_2 phase) and chromosomal breakage are normalized. Thus the transfer of the wild-type FA genes corrects the extreme sensitivity to DNA cross-linking agents, the hallmark of the FA cell phenotype. These studies provide the rationale for haemopoietic gene therapy (discussed below).

Murine mouse models of FA have shown that haemopoietic progenitors are hypersensitive to TNF- α and interferon (IFN)- γ . This differential hypersensitivity to IFN- γ is thought to be

mediated by *fas*-induced apoptosis and may turn out to be an important mechanism in the development of progressive bone marrow failure in FA. It is noteworthy that patients with idiopathic AA usually have raised IFN- γ levels, thus providing a possible link in the pathophysiology of bone marrow failure in both idiopathic and FA-associated AA. The presence of short telomeres in cells from patients with both FA and idiopathic AA can also be expected to be important in the pathophysiology of bone marrow failure in both diseases. This feature is discussed further in relation to DC.

Treatment

The major cause of premature mortality in FA patients is the development of bone marrow failure. Until the advent of HSCT, treatment consisted largely of supportive care and attempts to stabilize and improve haemopoietic function by administering androgens (oxymetholone) and corticosteroids (prednisolone). Oxymetholone treatment can produce useful trilineage haematological responses in 50–70% of patients but many will become refractory after a variable time. Oxymetholone is associated with side-effects, including liver dysfunction and increased risk of hepatic tumours. It is a very good holding treatment until more definitive treatment can be planned using HSCT, which has now become the treatment of choice. From the *in vitro* and *in vivo* studies it has become clear that cells from FA patients are hypersensitive to agents such as cyclophosphamide and high-dose irradiation compared with non-FA patients. Therefore, HSCT conditioning regimens have been modified by reducing the dose of cyclophosphamide and radiation. Initially, using low-dose cyclophosphamide (20 mg/kg) and 4.5–6 Gy of thoracoabdominal irradiation, the actuarial survival for patients transplanted using HLA-identical sibling donors was found to be around 70% at 2 years. The results using unrelated donors were less good, with 2-year survival between 20 and 40%. More recently, the use of fludarabine is being explored in conditioning protocols. Additionally, long-term follow-up of patients who have survived after HSCT shows a much higher incidence of malignancies, particularly of the head and neck, usually 8–10 years after the transplant. This partly relates to the inherent predisposition of FA patients to malignancy (which can perhaps now be explained given the link to defects in DNA repair) and partly to factors such as the use of radiotherapy in the conditioning. Transplant groups are therefore exploring low-dose cyclophosphamide (20–40 mg/kg) HSCT protocols that avoid the use of radiotherapy. Preliminary results using fludarabine (120–150 mg/m²) in association with low-dose cyclophosphamide are very encouraging for both sibling and unrelated HSCT. Longer follow-up is necessary to determine if such protocols will be associated with a lower risk of malignancy.

In addition to HSCT, alternative treatment strategies are being explored. The identification of the FA genes, combined

with the *in vitro* gene transfer data which show that FA haemopoietic stem cells rescued by gene therapy should have a selective growth advantage within the hypoplastic bone marrow environment, has resulted in clinical studies of retroviral-mediated gene therapy for FA patients. The pilot study on FA-C patients was associated with no serious side-effects but efficacy was limited. Further studies on this approach are being undertaken but none have yet shown significant efficacy in the clinic.

The identification of FA *mosaic* patients strengthens the case for future trials of gene therapy. In such cases, the DEB/MMC test may be negative or only demonstrate chromosomal instability in a subgroup of cells. Somatic mosaicism is due to reversion of a pathogenic allele to 'wild' type in a single haemopoietic (somatic) cell. The mechanism of how this occurs can vary, but in each case it generates one 'normal' FA allele and the resulting cell effectively becomes a 'heterozygous cell', which would be expected to have a growth/survival advantage in the background of FA cells. These mosaic patients can have an improvement in their haematological profile, suggesting that a single pluripotent stem cell may be sufficient to restore adequate haemopoiesis. FA patients with somatic mosaicism can thus be regarded as having undergone natural haemopoietic gene therapy.

Over the last 20 years there has been significant progress in treating the bone marrow failure associated with FA. For the future the major challenge will relate to the treatment of malignancies and in the management of patients with atypical presentations.

Dyskeratosis congenita

Clinical features

Classical DC is an inherited disease characterized by the mucocutaneous triad of abnormal skin pigmentation, nail dystrophy and mucosal leucoplakia (Figure 12.4). Since its first description by Jacobi in 1906 and Zinsser in 1910, a variety of non-cutaneous (dental, gastrointestinal, genitourinary, neurological, ophthalmic, pulmonary and skeletal) abnormalities have also been reported (Table 12.5). Bone marrow failure is the principal cause of early mortality, with an additional predisposition to malignancy (haematological and non-haematological) and fatal pulmonary complications. X-linked recessive, autosomal dominant and autosomal recessive forms of the disease are recognized. It is therefore now acknowledged that DC is a very heterogeneous disorder, both clinically and genetically.

Clinical manifestations in DC often appear during childhood. The skin pigmentation and nail changes typically appear first, usually by the age of 10 years. Bone marrow failure usually develops below the age of 20 years; 80–90% of patients will have developed bone marrow abnormalities by the age of 30 years. In some cases, the bone marrow abnormalities may appear before the mucocutaneous manifestations and the patients may be categorized as having 'idiopathic aplastic anaemia'. The main causes of death are bone marrow failure/immunodeficiency

Figure 12.4 Photographs of patients with dyskeratosis congenita showing abnormal skin pigmentation (A, B, C), nail dystrophy (D, E) and leucoplakia of tongue (F).

Table 12.5 Somatic abnormalities in dyskeratosis congenita.

Abnormality	Percentage of patients
Abnormal skin pigmentation	89
Nail dystrophy	88
Bone marrow failure	85.5
Leucoplakia	78
Epiphora	30.5
Learning difficulties/developmental delay/mental retardation	25.4
Pulmonary disease	20.3
Short stature	19.5
Extensive dental caries/loss	16.9
Oesophageal stricture	16.9
Premature hair loss/ greying/sparse eyelashes	16.1
Hyperhidrosis	15.3
Malignancy	9.8
Intrauterine growth retardation	7.6
Liver disease/peptic ulceration/enteropathy	7.3
Ataxia/cerebellar hypoplasia	6.8

Microcephaly	5.9
Urethral stricture/phimosis	5.1
Osteoporosis/aseptic necrosis/scoliosis	5.1
Deafness	0.8

(about 60–70%), pulmonary complications (about 10–15%) and malignancy (about 10%).

Cell and molecular biology

DC has many features in common with FA, in which cells display hypersensitivity to clastogenic agents such as MMC. Although the occasional DC patient may show some evidence of chromosome breakage, in general there is no significant difference in chromosomal breakage between DC and normal lymphocytes with or without the use of bleomycin, DEB, MMC and γ -irradiation. This observation enables DC patients to be distinguished from FA.

Primary DC skin fibroblasts are abnormal in both morphology and growth rate. Furthermore, they show unbalanced chromosomal rearrangements (dicentrics, tracentrics, translocations, end-to-end fusions) in the absence of any clastogenic agents. In addition, peripheral blood and bone marrow metaphases from some patients show unbalanced chromosomal rearrangements in the absence of any clastogenic agents. These studies provide evidence for a defect that predisposes DC cells to developing

chromosomal rearrangements. DC, like FA, may thus be regarded as a chromosome/genomic instability disorder but with a predisposition principally to chromosomal rearrangements rather than the gaps and breaks seen in FA.

Haemopoietic progenitor studies have shown reduced numbers of all progenitors compared with control subjects and there is usually a downwards decline with time. The degree to which the progenitors are reduced can vary from patient to patient and they can be reduced even when the peripheral blood count is normal. The demonstration of abnormalities of growth and chromosomal rearrangements in fibroblasts suggests that the bone marrow failure is likely to be a consequence of abnormalities in both haemopoietic stem cells and stromal cells.

X-chromosome inactivation patterns (XCIPs) have been studied in peripheral blood cells of women from X-linked DC families by investigating a methylation-sensitive restriction enzyme site in the polymorphic human androgen receptor locus (*HUMARA*) at Xq11.2–q12. All carriers of X-linked DC showed complete skewing in XCIP. The presence of the extremely skewed pattern of X-inactivation in peripheral blood cells suggests that cells expressing the defective gene have a growth/survival disadvantage over those expressing the normal allele. Furthermore, a skewed XCIP provides important information about carrier status for use in the counselling of families at risk of DC. In addition, XCIP allow us to distinguish an inherited mutation from a *de novo* event in sporadic male DC cases, as well as autosomal from X-linked forms of the disease.

The majority of DC patients recruited to the Dyskeratosis Congenita Registry in London are male. This observation suggests that the X-linked recessive form of DC represents a major subset of cases. Initially, through linkage analysis in one large family with only affected males, it was possible to map the gene for the X-linked form to Xq28. The availability of polymorphic genetic markers from the Xq28 and additional X-linked families facilitated positional cloning of the gene (*DKC1*) that is mutated in X-linked DC. Identification of the *DKC1* gene in 1998 made available a genetic test that can be used to confirm diagnosis in suspected cases and provide antenatal diagnosis in X-linked families. It also led to the demonstration that another rare syndrome, Hoyeraal–Hreidarsson (HH) syndrome, is due to mutations in the *DKC1* gene. HH syndrome is a severe multisystem disorder characterized by severe growth failure, abnormalities of brain development (particularly cerebellar hypoplasia), aplastic anaemia and immunodeficiency ($T^+ B^- NK^-$ severe combined immunodeficiency). The recognition that HH syndrome is a severe variant of DC has further highlighted the considerable variability of the DC phenotype.

In addition to providing an accurate diagnostic test, this genetic advance has provided insights into the pathogenesis of DC. The *DKC1* gene is expressed in all tissues of the body, indicating that it has a vital housekeeping function in the

human cell. This correlates well with the multisystem phenotype of DC. The *DKC1* gene and its encoded protein, dyskerin, are highly conserved throughout evolution. Dyskerin is a nucleolar protein associated with the H/ACA class of small nucleolar RNAs (snoRNAs) and is involved in pseudo-uridylation of specific residues of ribosomal RNA (rRNA). This step is essential for ribosome biogenesis and therefore initially suggested that DC arises largely because of defective ribosome production.

Subsequent studies have shown that dyskerin also associates with the RNA component of telomerase (TERC), which also contains an H/ACA consensus sequence. Telomerase is an enzyme complex that is important in maintaining chromosomal telomere length after cell division. The precise composition of the telomerase complex is unknown, but two essential components, the RNA component (TERC) and the catalytic reverse transcriptase (TERT), have been well characterized. Telomerase activity can be reconstituted *in vitro* using just

TERC and TERT. In patients with X-linked DC, it was initially demonstrated that the level of TERC was reduced and that telomere lengths were much shorter than in age-matched normal controls. Subsequently, it was found that telomeres are also shorter in cells from patients with autosomal forms of DC. This therefore suggested that DC might principally be a disease of defective telomere maintenance rather than of ribosome biogenesis. Further clarification came from linkage analysis in one large DC family, which showed that the gene for autosomal dominant DC is on chromosome 3q, in the same area where the gene for TERC had been previously mapped. This led to *TERC* mutation analysis in this and other DC families and the demonstration that autosomal dominant DC is due to mutations in the *TERC* gene.

As the *DKC1*-encoded protein dyskerin and TERC are both components of the telomerase complex (Figure 12.5), it now appears that DC arises principally from an abnormality in tel-

Figure 12.5 A schematic representation of the telomerase complex (dyskerin, GAR1, NHP2, NOP10, TERC and TERT), the shelterin complex and their association with different categories of dyskeratosis congenita and related diseases. The telomerase complex is an RNA–protein complex since TERC is a 451-base RNA molecule that is never translated. The other molecules (dyskerin, GAR1, NHP2, NOP10 and TERT) are proteins. Recent studies suggest that the minimal active telomerase enzyme is composed of two molecules each of TERT, TERC and dyskerin.

Dyskerin, GAR1, NHP2 and NOP10 are believed to be important for the stability of the telomerase complex. The shelterin complex is made up of six proteins (TIN2, POT1, TPP1, TRF1, TRF2 and RAP1) and is important in protecting the telomere. Mutations in components of the telomerase complex or the shelterin complex, as occurs in different subtypes of DC, result in telomere shortening. AA, aplastic anaemia; DC, dyskeratosis congenita; HH, Hoyeraal–Hreidarsson syndrome; MDS, myelodysplastic syndrome; RS, Revesz syndrome.

Table 12.6 Genetic subtypes of dyskeratosis congenita (DC).

<i>DC subtype</i>	<i>Approximate percentage of DC patients</i>	<i>Chromosome location</i>	<i>RNA/protein product</i>	<i>Exons</i>
X-linked recessive	30	Xq28	Dyskerin	15
Autosomal dominant	< 5	3q26.2	TERC	1
	< 5	5p15.33	TERT	16
	10	14q12	TIN2	6
Autosomal recessive	< 1	15q14–q15	NOP10	2
	< 1	5p15.33	TERT	16
	< 1	5q35.3	NHP2	4
Uncharacterized*	40–50	?	?	?

*These are likely to represent more than one genetic locus and include the genetically heterogeneous autosomal recessive DC.

omerase activity. Affected tissues are those that need constant renewal, consistent with a basic deficiency in stem cell activity due to defective telomerase activity. The demonstration of *DKC1* and *TERC* mutations in DC families provides an accurate diagnostic test, including antenatal diagnosis, in a significant subset of cases (Table 12.6). For DC patients, this now also provides the basis for designing new treatments. For the wider community it provided the first direct genetic link between a human disease characterized by features of premature ageing (premature grey hair/hair loss, early dental loss, abnormalities of skin pigmentation, nail dystrophy, bone marrow failure, increased predisposition to malignancy) and short telomeres. Therefore, unravelling the biology of this rare disease has had important implications not only for patients with DC but also for the more common disorders, such as ageing, cancer and AA, that are also associated with abnormal telomeres.

Recently, heterozygous *TERC* mutations have been observed in a subset of patients with AA and myelodysplastic syndrome (MDS) but who lacked classical features of DC. Furthermore, AA patients associated with *TERC* mutations had significantly shorter telomeres than age-matched controls. These data indicate that, in a subset of patients with AA and MDS, the disorder is associated with a genetic defect in the telomere maintenance pathway. They also highlight the diverse manifestations of DC: its severe variant form (HH syndrome), its classical form and its 'cryptic' form (AA or MDS). The similarities between DC and AA are given in Table 12.2.

These findings also suggest that treatments aimed at restoration of telomere length might be useful in this group of patients. Heterozygous mutations in *TERT* have also recently been found in some patients with bone marrow failure and autosomal dominant DC. These findings further support the model that DC is principally a disorder of telomere maintenance. Additionally, telomerase dysfunction (heterozygous mutations in *TERT* or *TERC*) has also been identified as the likely cause of a subset of familial idiopathic pulmonary fibrosis, a disease

in which fibrotic tissue forms in the lungs, eventually leading to respiratory failure. More recently, a subset of DC patients have been found to have heterozygous mutations in a component of the shelterin complex TIN2. Patients with *TIN2* mutations also have very short telomeres, providing further evidence that DC is principally a disorder of defective telomere maintenance.

Recently, the genetic basis of some cases of autosomal recessive DC has been elucidated. In one large family with autosomal recessive DC, the disease has been found to be due to homozygous mutations in the telomerase-associated protein NOP10. Patients with homozygous *NOP10* mutations, like patients with *DKC1* and *TERC* mutations, were also found to have very short telomeres, further highlighting that DC is principally a disease of defective telomere maintenance. In some autosomal recessive families it has been found that the disease is due to biallelic mutations in *TERT*, suggesting that a pure but severe deficiency in telomerase can produce a phenotype of classical autosomal recessive DC and its severe variant, HH syndrome. Very recently, in two autosomal recessive families biallelic mutations have been found in the telomerase component NHP2 and these patients also had very short telomeres.

Treatment

Transient successful responses to granulocyte/macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF) and erythropoietin have been reported. As in FA, the anabolic steroid oxymetholone (0.5–2.0 mg/kg daily) can produce an improvement in haemopoietic function in many (> 50%) patients for a variable period of time. The use of oxymetholone and growth factors may be synergistic in some patients. However, the main treatment for severe bone marrow failure is allogeneic HSCT, and there is some experience using both sibling and alternative stem cell donors. Unfortunately, because of early and late fatal pulmonary/

vascular complications after HSCT, the results of conventional transplants have been less successful than in FA. The presence of pulmonary disease in a significant proportion of DC patients perhaps now explains the high incidence of fatal pulmonary complications in the setting of HSCT. It also highlights the need to avoid therapies (such as busulfan and radiotherapy) associated with pulmonary toxicity. As bone marrow failure is the main cause of premature death in DC patients and HSCT is the only curative option for bone marrow failure at present, HSCT should continue to be performed on carefully selected patients. Perhaps the best candidates for HSCT are patients with no pre-existing pulmonary disease and who have sibling donors. HSCT using fludarabine-based protocols that avoid radiotherapy and busulfan appears to be giving encouraging preliminary results.

DC is theoretically a good candidate for haemopoietic gene therapy. In any given patient, DC is a single-gene disorder and the cells that need to be targeted (haemopoietic stem cells) are accessible. Furthermore, there is evidence from fibroblast culture studies and from skewed XCIPs in X-linked DC carriers that cells transfected with the normal gene would have a growth/survival advantage compared with uncorrected cells. Such an advantage would also be predicted from the role of the DC genes in telomere maintenance. It remains to be seen whether treatments aimed at restoration of telomere length will prove to be of clinical benefit in DC and related disorders.

Shwachman–Diamond syndrome

Clinical features

Shwachman and Bodian and their colleagues first reported this disease independently in 1964. Shwachman–Diamond syndrome (SDS) is now recognized as an autosomal recessive disorder characterized by exocrine pancreatic insufficiency (100%), bone marrow dysfunction (100%) and other somatic abnormalities (particularly involving the skeletal system). Signs of pancreatic insufficiency (malabsorption, failure to thrive) are apparent early in infancy (note that pancreatic function can improve in a subset of patients with SDS by 5 years of age). Other common somatic abnormalities include short stature (~ 70%), protuberant abdomen and an ichthyotic skin rash (~ 60%). Metaphyseal dysostosis is seen on radiographs in about 75% of patients. Other abnormalities include hepatome-

galy, rib/thoracic cage abnormalities, hypertelorism, syndactyly, cleft palate, dental dysplasia, ptosis and skin pigmentation.

The spectrum of haematological abnormalities includes neutropenia (~ 60%), other cytopenias (~ 20% have pancytopenia), myelodysplasia and leukaemic transformation (~ 25%). The age at which leukaemia develops varies widely, from 1 to 43 years. AML is the commonest category and there is an unexplained preponderance of cases of leukaemia in males (male to female ratio approximately 3:1).

Exocrine pancreatic insufficiency and haematological abnormalities are also seen in Pearson syndrome (PS), and this is therefore an important differential diagnosis. In PS, the anaemia is usually more prominent than neutropenia and the marrow usually shows ringed sideroblasts along with vacuolation of myeloid and erythroid precursors. In addition, acidosis, abnormalities of liver function and mitochondrial DNA rearrangements are seen in PS. PS has a worse prognosis than SDS, with many patients dying before the age of 5 years from liver or marrow failure. Other differential diagnoses to be excluded are cartilage hair syndrome and cystic fibrosis.

Cell and molecular biology

The SDS gene (*SBDS*) on 7q11.22 was identified in 2003. The majority (> 90%) of SDS patients have been found to have mutations in this gene (Table 12.7). Its precise function is unknown but, based on the function of its homologues, it is predicted to have an important role in RNA metabolism and/or ribosome biogenesis. Recent data from yeast studies provide compelling evidence that the SBDS protein has an important role in the maturation of the 60S ribosomal subunit (Figure 12.6). Several abnormalities in SDS cells have been observed, including haemopoietic stem and stromal defects, increased rates of apoptosis and short telomeres. It will be interesting to see how mutations in the *SBDS* gene lead to all these cell defects, the increased frequency of isochromosome 7q and the clinical abnormalities characteristic of SDS. More immediately, this advance provides a genetic test that will facilitate diagnosis in difficult cases. It will also enable researchers to determine the role of the *SBDS* gene in AA, MDS and leukaemia in general. In this regard it has recently been shown that the SBDS protein can act to stabilize the mitotic spindle, preventing genomic instability, and that cells from SDS patients exhibit an increased incidence of abnormal mitoses.

Table 12.7 Genetic subtypes of Shwachman–Diamond syndrome (SDS).

<i>SDS subtype</i>	<i>Approximate percentage of SDS patients</i>	<i>Chromosome location</i>	<i>Protein product</i>	<i>Exons</i>
Autosomal recessive	> 90	7q11.22	SBDS	5
Uncharacterized	< 10	?	?	?

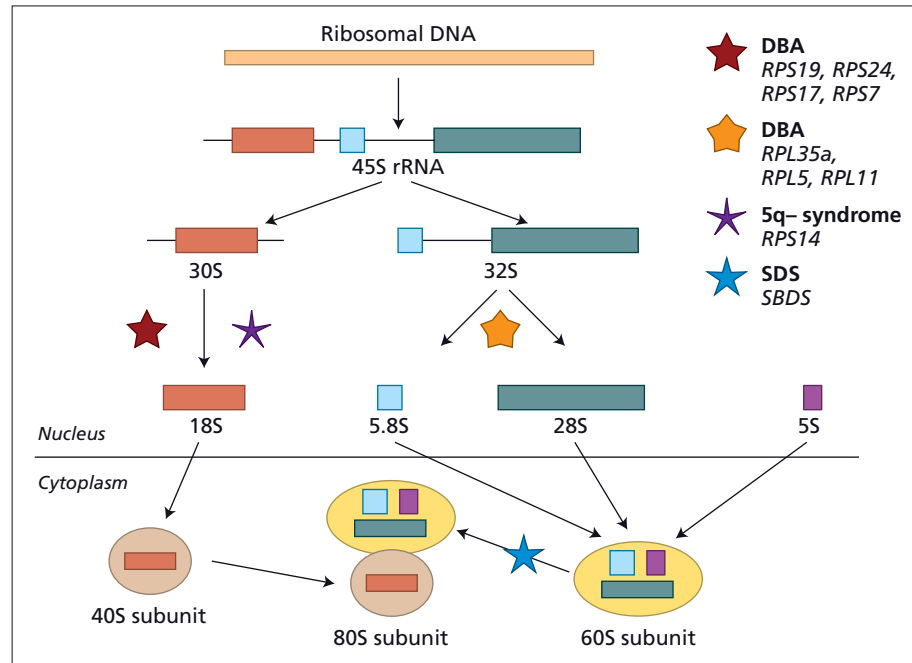

Figure 12.6 Schematic diagram showing scheme of ribosomal (r) RNA processing in human cells and the points at which this is possibly disrupted in the different bone marrow failure syndromes. The rRNAs are transcribed by RNA polymerase I as a single precursor transcript (45S rRNA). The 45S rRNA is then processed to 18S, 5.8S and 28S rRNAs. The 18S is a component of the 40S ribosomal subunit. The 5.8S and 28S together with 5S (synthesized independently) are components of the 60S

ribosomal subunit. The 40S and 60S subunits are assembled to form the 80S ribosomes. The processing steps affected in Diamond–Blackfan anaemia (due to heterozygous mutations in *RPS19*, *RPS17*, *RPS24*, *RPS7*, *RPL35a*, *RPL5* and *RPL11*), 5q– syndrome (haploinsufficiency of *RPS14*) and Shwachman–Diamond syndrome (biallelic mutations in *SBDS*) are indicated by the different coloured stars. DBA, Diamond–Blackfan anaemia; SDS, Shwachman–Diamond syndrome.

Treatment

The malabsorption in SDS responds to treatment with oral pancreatic enzymes. For those with neutropenia, G-CSF may produce an improvement in the neutrophil count. Some patients with anaemia and/or thrombocytopenia may achieve haematological responses with oxymetholone treatment. As in other cases of bone marrow failure, supportive treatment with red cell and platelet transfusions and antibiotics is very important. The main cause of death is infection or bleeding.

Recent analysis of SDS patients has showed that the incidence of myelodysplasia and transformation to AML (about 15–25%) is higher than reported previously. The development of leukaemia, often with features of myelodysplasia, usually has a poor prognosis. SDS patients with leukaemia treated with conventional courses of chemotherapy usually fail to regenerate normal haemopoiesis. As this is a constitutional disorder all somatic cells, including haemopoietic stem cells, are abnormal. In addition, the haemopoietic stem cells may have accumulated secondary abnormalities as suggested by complex karyotypes (especially involving chromosome 7) often observed in the

bone marrow from such patients. Therefore, for those who develop leukaemia, the only approach likely to be successful is allogeneic HSCT, perhaps in the future using low-intensity conditioning regimens that include fludarabine. The similarities between SDS and the other common inherited bone marrow failure syndromes emphasize that SDS should be regarded as a disorder with high propensity to develop both AA and leukaemic transformation, particularly AML with erythroid differentiation (AML-M6). As these complications may not develop until adult life, it is important to continue close haematological follow-up throughout life. It is noteworthy that non-haematological malignancies have not been observed in SDS patients.

Diamond–Blackfan anaemia

Clinical features

Red cell aplasia was first reported in 1936 by Josephs. In 1938, Diamond reported on four children with hypoplastic anaemia

and this has now come to be recognized as Diamond–Blackfan anaemia (DBA) or congenital pure red cell aplasia. DBA usually presents in early infancy, with features of anaemia such as pallor or failure to thrive. The hallmark of classical DBA is a selective decrease in erythroid precursors and normochromic macrocytic anaemia associated with a variable number of somatic abnormalities such as craniofacial, thumb, cardiac and urogenital malformations. Hitherto the diagnostic criteria for DBA have comprised (i) normochromic, usually macrocytic, but occasionally normocytic anaemia developing in early childhood; (ii) reticulocytopenia; (iii) normocellular bone marrow with selective deficiency of erythroid precursors (erythroblasts < 5%); (iv) normal or slightly decreased leucocyte counts; and (v) normal or often increased platelet counts. More recently, elevated erythrocyte deaminase activity, macrocytosis and elevated fetal haemoglobin have been added to the list of supportive features of DBA. It has also been recognized that in a subset of cases the presentation may be in adulthood.

There is considerable heterogeneity in the associated somatic abnormalities, pattern of inheritance and response to therapy. Analysis of 420 cases recruited to the DBA Registry of North America (DBAR) has confirmed previous findings as well as highlighting new features. The annual incidence of DBA is about 5 per million live births. The median age at presentation was 8 weeks and 93% of patients presented in the first year of life. In total, 79% were initially responsive to steroids, 17% were non-responsive and 4% were never treated with steroids; 31% of patients were receiving transfusions at analysis. The actuarial survival rates at older than 40 years were 100% for those in sustained remission, 87% for steroid-maintained patients and 57% for transfusion-dependent patients. Of the 36 deaths reported to the DBAR, 25 were treatment related: five from infections, five from complications of iron overload, one related to vascular access and 14 from transplant-related complications.

In the DBAR, 8.8% of families had more than one affected individual. Most of the familial cases displayed an autosomal dominant pattern of inheritance. Somatic anomalies, excluding short stature, were found in 47% of patients. Of these, 50% were craniofacial (high-arched palate, cleft lip, hypertelorism and flat nasal bridge), 38% were upper limb and hand (flat thenar eminence, triphalangeal thumb), 39% genitourinary and 30% cardiac. Height was below the third centile for age in about 30%.

MDS and AML have been reported in a few patients with DBA, suggesting an increased predisposition to haematological malignancies. There are also cases that have evolved into AA; neutropenia and thrombocytopenia are relatively common after the first decade. Giri and colleagues reported on moderate to severe bone marrow hypocellularity in 21 of 28 (75%) patients with steroid-refractory DBA; marrow hypoplasia correlated with the development of neutropenia (9 of 21, 43%) and/or thrombocytopenia (6 of 21, 29%). Furthermore, using

in vitro long-term culture-initiating cell assay, they provided evidence for a trilineage haemopoietic defect in patients with refractory DBA. Thus, although DBA has been regarded classically as a pure red cell aplasia, a more global haemopoietic defect is likely to be present, and this may be seen more frequently in the future as patients are surviving longer due to improved medical care.

Cell and molecular biology

The classical haematological profile in DBA patients consists of normochromic macrocytic anaemia, reticulocytopenia and a normocellular marrow with selective deficiency of red cell precursors. A number of different defects of *in vitro* erythroid progenitor proliferation, differentiation and cytokine responsiveness have been reported but have not clarified the mechanism of *in vivo* erythroid failure. For many years, based on the typical selective deficiency in red cell precursors, many researchers believed that DBA was due to an intrinsic problem with erythroid proliferation/differentiation. On the other hand, the observation of a wide range of somatic abnormalities in a significant proportion of patients and case reports of thrombocytopenia, neutropenia and AA, together with the recent evidence for a trilineage haemopoietic defect, suggest that the primary problem in DBA is not confined to the erythroid lineage.

The establishment of DBA registries, advances in genetics and the identification of a female with a balanced X;19 translocation has facilitated a change in research strategy in DBA. Genetic mapping studies localized a gene responsible for DBA to a 1-Mb region on 19q13 on the basis of (i) the identification of a *de novo* balanced reciprocal X;19 translocation breakpoint in a girl with DBA; (ii) linkage analysis in multiplex DBA families; and (iii) *de novo* microdeletions associated with the disease. Cloning of the chromosome 19q13 breakpoint demonstrated that this breakpoint interrupts the gene encoding ribosomal protein S19 (*RPS19*). The subsequent finding of *RPS19* mutations in about 25% of DBA patients led to the first genetic characterization of DBA and has paved the way for subsequent studies. Interestingly, mutations in the *RPS19* gene were also found in some apparently unaffected individuals from DBA families presenting only with an isolated elevation of erythrocyte adenosine deaminase activity. The lack of a genotype–phenotype correlation implies that other factors modulate the phenotypic expression of the primary genetic defect in families with *RPS19* mutations.

Over the last 10 years, heterozygous mutations in other genes encoding ribosomal proteins of the small (RPS214, RPS17, RPS7) and large (RPL5, RPL11 and RPL35a) ribosomal subunits have also been reported (Table 12.8); collectively the genetic basis of approximately 50% of DBA patients can now be substantiated at the genetic level. It has also been demonstrated that mutations in these genes are associated with diverse defects in the maturation of rRNAs in the large or the small ribosomal

Table 12.8 Genetic subtypes of Diamond–Blackfan anaemia (DBA).

DBA subtype	Approximate percentage of DBA patients	Chromosome location	Protein product	Exons
Autosomal dominant	25	19q13.2	RPS19	6
	2	10q22–23	RPS24	7
	< 1	15q25.2	RPS17	5
	7	1p22.1	RPL5	8
	5	1p36.1–p35	RPL11	6
	3	3q29–qter	RPL35a	5
	< 1	2p25	RPS7	7
Uncharacterized*	~ 50	?	?	?

*These are likely to represent more than one genetic locus.

subunit production pathway (see Figure 12.6). These studies therefore suggest that the primary defect in DBA is defective ribosome biogenesis, which then leads to other biological defects including increased apoptosis and alterations in molecules such as c-Myc and p53. It will now be important to establish how precisely mutations in these ribosomal protein genes lead to altered cell growth (and anaemia), developmental anomalies and increased susceptibility to cancer. Review of clinical and genetic data has shown that patients with mutations in the *RPL5* gene tend to have multiple physical abnormalities, including craniofacial, thumb and heart anomalies, whereas isolated thumb malformations are predominantly seen in patients with heterozygous *RPL11* mutations. Some genotype–phenotype correlations are therefore beginning to emerge.

In summary, it is noteworthy that the recent advances in the genetics of DBA have demonstrated that (i) DBA is caused by mutations in genes important in the biogenesis of the small (*RPS19*, *RPS24*, *RPS17* and *RPS7*) and large (*RPL11*, *RPL5* and *RPL35a*) ribosomal units; (ii) the *SBDS* gene mutated in SDS (see above) is required for the maturation of the large ribosomal unit; and (iii) the 5q– syndrome (a recognized subtype of acquired myelodysplasia) is associated with haploinsufficiency of the gene encoding the ribosomal protein RPS14. These advances have thus provided a very interesting connection between DBA, SDS, MDS and defective ribosome biogenesis (see Figure 12.6). They also highlight the importance of studies on rare syndromes, as often they can provide significant insights into the pathology of more common diseases.

Treatment

The first line of treatment for DBA remains corticosteroids. Once a maximal haemoglobin response has been achieved, the dose of prednisolone should be tapered slowly until the patient is on the lowest dose possible on an alternate-day regimen. The dose required to achieve this can vary considerably from patient

to patient. For those patients who fail to respond or become refractory to steroids, blood transfusion is the mainstay of treatment. As in thalassaemia, the major complication from transfusions is iron overload, and chelation of iron with desferrioxamine should therefore be commenced as soon as patients have increased iron stores. The promising results with the new oral iron chelator deferasirox are likely to have a positive impact in the management of this group of DBA patients. Splenectomy may be indicated in the event of an increased transfusion requirement secondary to hypersplenism. For patients who are transfusion dependent and who have a compatible sibling donor, HSCT may be appropriate and is potentially curative.

Congenital dyserythropoietic anaemia

Congenital dyserythropoietic anaemia (CDA) comprises a heterogeneous group of inherited disorders of erythropoiesis characterized by anaemia, increased ineffective erythropoiesis and frequently morphological evidence of dyserythropoiesis. The first description of this group of disorders was in 1966 by Crookston and colleagues. In 1968 Wendt and Heimpel classified CDA into three types (I, II and III) (Table 12.9). Over the years many additional subtypes (IV, V, VI and VII) have been added to the list, often based on case report studies. Much of the work of establishing diagnostic features and criteria for classification of CDA has been done by Wickramasinghe and colleagues. With the emerging genetics it will be interesting to see how this classification will evolve.

CDA type I

Over 150 cases have been published. The majority of patients present with splenomegaly and mild to moderate anaemia. In some cases non-haematological features (e.g. skeletal abnormalities, abnormal skin pigmentation) have been observed. In

Table 12.9 Characteristics of common subtypes of congenital dyserythropoietic anaemia.

Feature	Type I	Type II	Type III
Inheritance	AR	AR	AD, AR
Erythrocytes	Macrocytic	Normocytic	Macrocytic
Erythroblasts			
Light microscopy	Megaloblastic, internuclear chromatin bridges	Normoblastic, binuclearity	Megaloblastic, up to 12 nuclei/cell
Electron microscopy	'Swiss-cheese' appearance	Peripheral double membranes	Non-specific
Serology			
Ham test	Negative	Usually positive	Negative
Anti-i-agglutinability	Normal/strong	Strong	Normal/strong
SDS-PAGE	Normal	Band 3 thinner and migrates faster than normal	Band 3 migrates faster than normal
Gene location	15q15.2	20q11.2	15q21–q25
Genes identified*	<i>CDANI</i>	?	?

*It is not known how many genes are mutated in each CDA subtype.

Source: modified from Wickramasinghe & Wood (2005) with permission.

Figure 12.7 Congenital dyserythropoietic anaemia type I. Bone marrow aspirate showing internuclear bridging in normoblasts.

a review by Wickramasinghe and colleagues, the steady-state haemoglobin varied between 6.6 and 11.6 g/dL and approximately 70% had macrocytosis. Ineffective erythropoiesis was evidenced by morphological abnormalities in the peripheral blood (anisocytosis) and in the marrow (megaloblastic erythroid precursors, internuclear chromatin bridging, binuclearity affecting 3–7% of erythroblasts; Figure 12.7), as well as by increased markers of haemolysis (elevated lactate dehydrogenase and bilirubin). The defining ultrastructural feature is a spongy ('Swiss cheese') appearance of the heterochromatin in the majority of erythroblasts on electron microscopy.

Recognized to be an autosomal recessive disorder, the gene responsible for CDA type 1 (*CDANI*) was identified in 2002 and is located on chromosome 15q15.2. Subsequent studies

have shown that not all patients previously classified as CDA type 1 have mutations in this gene, suggesting that there is genetic heterogeneity within this subtype. The precise function of this gene (and its encoded protein, codanin-1) remains unknown.

CDA type II

This is the most common subtype of CDA (over 300 reported cases) and was initially described as hereditary erythroblastic multinuclearity with a positive acidified serum lysis test (HEMPAS) in 1969. It is inherited as an autosomal recessive trait and has been described in several ethnic groups. The anaemia is variable (haemoglobin 8–11 g/dL). It is important to recognize that about 10% of cases require regular transfusions and that some cases present with anaemia at birth. The clinical presentations include a variable degree of jaundice, hepatomegaly and splenomegaly and cirrhosis. Mental retardation has been reported in some cases.

Peripheral blood morphology shows moderate to marked red cell anisocytosis. Bone marrow features include normoblastic erythroid hyperplasia with usually more than 10% binucleate erythroblasts (Figure 12.8). At the electron microscope level, the erythroid cells have a characteristic peripheral arrangement of the endoplasmic reticulum giving the appearance of a 'double membrane' (Figure 12.9). Red cells from patients with CDA type II are haemolysed by some acidified sera but not by the patient's own serum. The primary defect in CDA type II remains unknown. There is some evidence to suggest that CDA type II is associated with defects in the synthesis of complex N-linked oligosaccharides. The gene for CDA type II has been mapped to chromosome 20q11.2.

CDA type III

This subtype is rare, with three large families having been described as well as some sporadic cases. In one of the largest (Swedish) families investigated the disease was characterized by giant multinucleated erythroblasts in the marrow (Figure 12.10). There appears to be an increased prevalence of lymphoproliferative disorders in CDA type III. The disease in the Swedish family appears to be autosomal dominant and the gene has been mapped to chromosome 15q21–q25.

Treatment

Those with mild anaemia require no major intervention. Folate supplementation should be given to prevent folate deficiency. If regular transfusions are necessary, early attention to iron chelation is essential. Splenectomy may be of benefit in some patients (CDA type II) and there are rare case reports of successful HSCT. In CDA type I there are also case reports of improvement in the haemoglobin after treatment with interferon alfa. The mechanism of this therapeutic benefit remains unclear.

Figure 12.9 Congenital dyserythropoietic anaemia type II. Electron micrographs of erythroblast showing peripheral arrangement of endoplasmic reticulum with 'double membrane' appearance.

Congenital and cyclical neutropenias

Congenital neutropenia is a heterogeneous disorder (Table 12.10). It includes Kostmann syndrome, which was first described in 1954. Although the original description by Kostmann was of an autosomal recessive disorder, other congenital neutropenia subtypes (both sporadic and autosomal dominant) have subsequently been included in this category. The neutropenia is usually recognized at birth and the neutrophil count is often below $0.2 \times 10^9/L$. The haemoglobin and platelet count are usually normal and the bone marrow shows maturation arrest of myelopoiesis at the level of the promyelocyte/myelocyte (with abundant promyelocytes but with selective reduction in myelocytes, metamyelocytes and neutrophils).

The neutropenias are associated with severe infections and early death. No patient has developed AA but myeloid leukaemias (~ 25% by 25 years) can occur. The availability of G-CSF has revolutionized the outcome of these children. However, somatic mutations in the gene that encodes the G-CSF receptor have been documented during the evolution to leukaemia in patients receiving G-CSF. The precise contribution of G-CSF therapy to the development of G-CSF receptor mutations remains unclear. For patients who become refractory to G-CSF or who develop leukaemia, HSCT may be appropriate and curative.

Cyclical neutropenia is characterized by a neutrophil count that usually reaches a nadir with a 21-day periodicity. Around the nadir, patients may develop fever and mouth ulcers. In cyclical neutropenia, the pattern of inheritance is usually autosomal dominant. Linkage analysis in affected families resulted in the localization of the disease gene to 19p13.3. Subsequent studies identified mutations in the gene (*ELA2*) encoding neutrophil elastase. An extraordinary twist to the story was the identification of *ELA2* mutations in many patients with congenital neutropenia as well. In cyclical neutropenia, the mutations are usually clustered around the active site of the molecule, whereas the opposite face of the molecule tends to be mutated in congenital neutropenia. Neutrophil elastase is a serine pro-

tease that is synthesized predominantly at the promyelocytic stage and can be expected to be important in neutrophil development. Recent studies suggest that *ELA2* mutations lead to accumulation of the non-functional protein, which in turn triggers an unfolded protein response leading to maturational arrest. The precise mechanism leading to maturation arrest of promyelocytes remains unclear. The original family described by Kostmann had autosomal recessive severe congenital neutropenia, and has recently been shown to be associated with biallelic mutations in the *HAX1* gene, predicted to lead to defects in cell death. Biallelic mutations in *HAX1* account for approximately 10% of congenital neutropenia. The *HAX1* protein is a critical regulator of the mitochondrial membrane potential and cellular viability. While there are data which suggest that *HAX1* is important in controlling apoptosis, it is unclear why premature death of neutrophils is consistently associated with *HAX1* deficiency. Mutations in other genes (*GF11*, *WASP*) are also known to be rarely associated with severe congenital neutropenia, demonstrating genetic heterogeneity.

Thrombocytopenia with absent radii

Thrombocytopenia with absent radii (TAR) is an autosomal recessive disorder characterized by hypomegakaryocytic thrombocytopenia and bilateral radial aplasia. Babies with TAR often have haemorrhagic manifestations at birth, when the diagnosis is usually made because of the characteristic physical appearance combined with thrombocytopenia. Additional skeletal abnormalities (absent ulnae, absent humeri, clinodactyly) and other somatic abnormalities (microcephaly, hypertelorism, strabismus, heart defects) may be seen in some patients.

The platelet count is usually below $50 \times 10^9/L$. The leucocyte count can be normal or raised, sometimes up to $100 \times 10^9/L$ ('leukaemoid reaction'). Bone marrow cellularity is normal and myeloid and erythroid lineages are normal or increased. Megakaryocytes are absent or decreased. Most patients bleed in infancy and then improve after the first year. The mainstay of management is prophylactic and therapeutic use of platelet

Table 12.10 Genetic subtypes of neutropenia.

Subtype	Approximate percentage of patients	Chromosome location	Gene/protein product	Exons
Autosomal dominant	50–60	19p13.3	<i>ELA2</i> /neutrophil elastase	5
Autosomal recessive	10–15	1q21.3	<i>HAX1</i>	7
Autosomal dominant	< 1	1p22	<i>GF11</i>	
Uncharacterized*	30–40	?	?	?

*This is likely to be a heterogeneous group. Furthermore, some patients initially presenting as isolated neutropenia may turn out to be cryptic presentations of other syndromes, such as Wiskott–Aldrich and Shwachman–Diamond syndromes.

Table 12.11 Genetic subtypes of congenital amegakaryocytic thrombocytopenia (CAMT).

<i>CAMT subtype</i>	<i>Approximate percentage of CAMT patients</i>	<i>Chromosome location</i>	<i>Gene/protein product</i>	<i>Exons</i>

Table 12.12 Laboratory tests useful in the investigation of patients with bone marrow failure.

<i>Test</i>	<i>Diagnostic value</i>
<i>Peripheral blood</i>	
Fetal haemoglobin	High level suggestive of generalized bone marrow failure
DEB/MMC chromosomal breakage	Increased in FA
Mutation analysis of specific genes	
<i>FANCA–FANCN</i>	Mutated in FA
<i>DKC1, TERC, TERT, NOP10, NHP2, TINF2</i>	Mutated in DC
<i>SBDS</i>	Mutated in SDS
<i>RPS19, RPS24, RPS17, RPL5, RPL11, RPL35a, RPS7</i>	Mutated in DBA
<i>CDANI</i>	Mutated in CDA type I
<i>ELA2, HAX1, GFI1</i>	Mutated in congenital and cyclic neutropenia
<i>MPL</i>	Mutated in CAMT
Mitochondrial DNA analysis	Deletions seen in PS
X-chromosome inactivation patterns	Skewed in carriers of X-linked DC
Ham test (CD59 analysis)	Abnormal in paroxysmal nocturnal haemoglobinuria
Telomere length	Short in AA, very short in DC
Constitutional karyotype	Abnormality suggestive of constitutional AA
<i>Other investigations</i>	
To identify somatic abnormalities	
Skeletal survey	Presence of somatic abnormalities in association with AA is suggestive of constitutional/inherited AA
Ultrasound of abdomen	
Pulmonary function tests	
Echocardiogram	
Exocrine pancreatic function	Abnormal in SDS and PS
Neutrophil chemotaxis	Abnormal in SDS
Fibroblast cultures	Abnormalities seen in DC

AA, aplastic anaemia; CAMT, congenital amegakaryocytic thrombocytopenia; CDA, congenital dyserythropoietic anaemia; DBA, Diamond–Blackfan anaemia; DC, dyskeratosis congenita; DEB/MMC, diepoxybutane/mitomycin C; FA, Fanconi anaemia; PS, Pearson syndrome; SDS, Shwachman–Diamond syndrome.

transfusions. Patients with TAR have a very good prognosis after infancy. There have been no reports of AA or leukaemia.

The pathophysiology of TAR is unknown. Thrombopoietin levels are usually elevated and thrombopoietin receptor expression on the surface of TAR platelets is normal. Therefore, defec-

tive megakaryocytopoiesis/thrombocytopoiesis does not appear to be caused by a defect in thrombopoietin production. There is some evidence that it may be due to a lack of response to thrombopoietin in the signal transduction pathway of the thrombopoietin receptor (c-mpl).

Congenital amegakaryocytic thrombocytopenia

Congenital amegakaryocytic thrombocytopenia (CAMT) is a rare disorder that usually presents in infancy and is characterized by isolated thrombocytopenia and reduction/absence of megakaryocytes in the bone marrow, usually with no somatic abnormalities. It is genetically heterogeneous with autosomal recessive and X-linked subtypes. Approximately 50% of patients will develop AA, usually by the age of 5 years. For patients with severe thrombocytopenia or AA, the treatment of choice is HSCT if a compatible donor is available.

In a subgroup of patients with CAMT, mutations in the gene encoding the thrombopoietin receptor (*MPL*) have been identified (Table 12.11). As patients with *MPL* mutations can also have abnormalities in the leucocyte count and haemoglobin level and central nervous system (CNS) abnormalities (e.g. cerebral and cerebellar hypoplasia), this study highlights the important role of the thrombopoietin receptor in haemopoiesis in general and in CNS development. It also substantiates the genetic heterogeneity of CAMT.

Conclusion

Since the identification of the first FA gene (*FANCC*) in 1992, there have been significant advances in our understanding of FA, DC and other bone marrow failure syndromes. This is already facilitating diagnosis, as highlighted in Table 12.12. It can be anticipated that further studies of the pathophysiology of these disorders is likely to lead to a better understanding of normal haemopoiesis and how this becomes defective in many patients presenting with the more common forms of AA and MDS. Indeed, recent studies have already established a link between DC and AA and, in turn, to defective telomere maintenance. Equally, a link between DBA, SDS and MDS and, in turn, defective ribosome biogenesis has been recognized. These advances also suggest that new treatment strategies, based on correction of the primary defect in each syndrome, may now emerge.

Acknowledgements

I would like to thank all my research colleagues past (Stuart Knight, Anna Marrone, David Stevens and Philip Mason) and present (Richard Beswick, Upal Hossain, Michael Kirwan, Amanda Walne and Tom Vulliamy) and all the patients and clinicians on whom research in our laboratory depends. The research work is supported by funding from the Wellcome Trust and the Medical Research Council UK.

Characterization and definition

Aplastic anaemia (AA) is defined by pancytopenia with a hypocellular bone marrow in the absence of an abnormal infiltrate and with no increase in reticulin. The term 'aplastic anaemia' encompasses different entities, but here we discuss acquired idiosyncratic AA, most often idiopathic though sometimes a drug or chemical or a virus infection is implicated. 'Inevitable' AA/myelosuppression occurs after treatment with cytotoxic drugs or radiation; it is dose dependent and recovery is usually predictable, and is discussed no further here.

AA is a bone marrow failure disorder and shows considerable overlap with clonal disorders of bone marrow failure, including myelodysplastic syndrome (MDS), acute myeloid leukaemia (AML), paroxysmal nocturnal haemoglobinuria (PNH) and T-large granular lymphocyte leukaemia/lymphoproliferative disorder (T-LGL), and a tendency itself to later evolve to MDS/AML (Figure 13.1). The inherited forms of AA, such as Fanconi anaemia (FA), dyskeratosis congenita (DC) and Shwachmann–Diamond syndrome (SDS), are rarer than acquired AA and are discussed in detail in Chapter 12. However, the importance of excluding an inherited form of AA and the increasing proportion of adults with apparent acquired AA with related genetic lesions is highlighted in this chapter.

In AA there must be at least two of the following: (i) haemoglobin below 10 g/dL; (ii) platelet count below $50 \times 10^9/L$; and

(iii) neutrophil count below $1.5 \times 10^9/L$. The severity of the disease is graded into very severe, severe and non-severe AA, according to the blood count parameters and bone marrow findings as summarized in Table 13.1. However, it is important to remember that routine use of the more accurate automated counting of reticulocytes overestimates the reticulocyte count used in the historical Camitta criteria for defining disease severity. The assessment of disease severity is important in treatment decisions but has less prognostic significance today in terms of correlation with response to antithymocyte globulin (ATG) (see section Predictors of response to ATG). Patients with bilineage or trilineage cytopenias that are less severe than this are not classified as AA. However, they should have their blood counts monitored to determine whether they will develop AA later.

Epidemiology

Incidence

Because AA is a rare disease, only large national and international prospective studies, with appropriate diagnostic criteria, will provide meaningful data on the aetiology of this condition. Studies indicate an incidence of AA in the West of 2 per million per year. There is a twofold to threefold higher incidence rate in Asia. In a large prospective study from Thailand, an incidence of 3.9 per million was reported from the metropolitan area of Bangkok compared with 5 per million in the northeast region of Khonkaen. An incidence of 7.4 per million was reported from a prospective study from China, although this may represent an

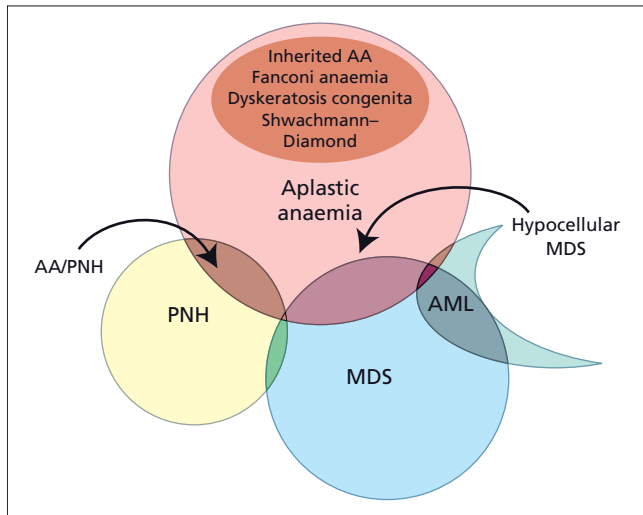

Figure 13.1 The overlap of acquired and inherited aplastic anaemia (AA) with the clonal disorders of myelodysplastic syndrome (MDS), acute myeloid leukaemia (AML) and paroxysmal nocturnal haemoglobinuria (PNH).

Table 13.1 Definition of disease severity of aplastic anaemia (AA).

Severe AA

Bone marrow cellularity < 25%, or 25–50% with < 30% residual haemopoietic cells

Two out of three of the following:

Neutrophils < $0.5 \times 10^9/L$

Platelets < $20 \times 10^9/L$

Reticulocytes < $20 \times 10^9/L$

Very severe AA

As for severe AA but neutrophils < $0.2 \times 10^9/L$

Non-severe AA

Patients not fulfilling the criteria for severe or very severe AA

The definition of severe AA is based on the so-called Camitta criteria (Camitta *et al.* 1975). The reticulocyte count threshold was based on manual reticulocyte counts, but today automated reticulocyte counts are routinely estimated and these correlate poorly with manual counts. These criteria are still useful for management planning but are not predictive of response to immunosuppressive therapy.

overestimate as a bone marrow trephine was not required for the diagnosis of AA. There is a biphasic age distribution, with peaks at 10–25 years and over 60 years; it is possible that some cases diagnosed in older patients represent hypocellular MDS rather than AA. There is no significant difference in incidence between males and females.

Aetiology

The reasons for the differences in incidence are not known but may include environmental and genetic factors. The relative importance of genetic factors was examined in a hospital-based study of children with AA in Canada. A higher incidence was reported among Asian children who had emigrated to Canada, and an association with human leucocyte antigen (HLA) type demonstrated.

Post-hepatic AA accounts for around 5–10% of cases; invariably such cases are negative for the known hepatic viruses. AA may follow liver transplantation for severe hepatitis (also non-A, non-B, non-C hepatitis). Post-hepatic AA is usually severe but responds well to immunosuppressive therapy, and similar oligoclonal expansion of activated cytotoxic T cells is observed as in idiopathic AA, suggesting a common pathogenesis for the hepatitis and bone marrow failure. However, the same therapeutic algorithm should be used for all cases of AA, with first-line allogeneic haemopoietic stem cell transplantation (HSCT) if the patient is young and has an HLA-matched sibling donor. Rarely, AA may be a sequela of infectious mononucleosis.

AA occurs in association with other systemic autoimmune disorders, especially eosinophilic fasciitis but also systemic lupus erythematosus (SLE), Sjögren syndrome and coeliac disease. There have been anecdotal reports of SLE-associated AA responsive to high-dose cyclophosphamide or ATG. SLE can also produce pancytopenia with a cellular bone marrow or it may occasionally be associated with myelofibrosis. A positive family history of rheumatoid arthritis occurs more frequently in patients with AA. AA may be associated with thymoma. Fatal AA is almost invariably the outcome of transfusion-associated graft-versus-host disease (GVHD); it is well documented clinically and can be reproduced *in vivo* in a mouse model (see next section on pathogenesis).

AA can rarely occur in pregnancy, although this may be due to chance and other possible causes should always be sought. A retrospective review from Leiden over a 24-year period of the frequency of pregnancy in 35 women of childbearing age and with a new diagnosis of AA found a similar frequency of pregnancy to that in the general population. However, due to the rarity of AA, this may not exclude a possible association in a larger number of patients. The disease may remit spontaneously after termination, whether spontaneous or therapeutic, and after delivery, but not in all cases. There is a risk of relapse in pregnancy in patients who have previously responded to immunosuppressive therapy. In contrast, after successful allogeneic HSCT, pregnancy does not trigger relapse.

In rural areas of Thailand, the use of non-bottled water, agricultural pesticides, non-medical needle exposures and exposure of farmers to ducks and geese are significant environmental risk factors for developing AA. There is good evidence for an association between benzene exposure and AA, but for

other solvents, such as hair dyes and glycol ethers, the data are not strong. Occupational exposure to pesticides such as organophosphates, lindane, DDT, paraquat and carbamates has also been implicated. A wide variety of chemicals including cutting oils and lubricating agents were identified in a large British case-control study. However, confounding factors may complicate this picture, for example exposure to an infectious agent in the environment in individuals exposed to a pesticide. For these reasons, blacklists of implicated drugs and chemicals need to be interpreted cautiously in assigning causation in an individual case, including for legal purposes.

Many drugs and chemicals have been implicated in the aetiology of AA, but for only a few is there strong evidence for an association, and even then it is usually impossible to prove causality (Table 13.2). In most studies, drug exposure accounts for around 5–10% of cases of acquired AA, although in a recent epidemiological study from Spain AA was associated with drug exposure in 20.8% of cases. Confounding factors include exposure to viruses and systemic diseases such as rheumatoid arthritis, which may themselves contribute to an increased risk of AA. For these reasons, the proportion of cases attributed to drugs

Table 13.2 Drugs and occupational and environmental exposures reported to be associated with aplastic anaemia.

Drugs

Antibiotics: chloramphenicol, sulphonamides, co-trimoxazole, linezolid

Anti-inflammatory agents: phenylbutazone, indomethacin, diclofenac, naproxen, piroxicam, gold, penicillamine

Anticonvulsants: phenytoin, carbamazepine

Antithyroid agents: carbimazole, thiouracil

Antidepressants: dothiepin, phenothiazides

Antidiabetic agents: chlorpropamide, tolbutamide

Antimalarial agents: chloroquine

Others: mebendazole, thiazides, allopurinol, ticlopidine

Occupational and environmental exposures

Benzene: evidence base includes large industrial studies, case-control study from Thailand

Pesticides (organochlorines such as lindane; organophosphates; pentachlorophenol): evidence base includes literature review of case reports and UK case-control study

Cutting oils and lubricating agents: evidence base includes UK case-control study

Recreational drugs (e.g. methylenedioxymethamphetamine, Ecstasy): evidence base includes case reports

Source: Marsh JCW, Gordon-Smith EC (2009) Aplastic anaemia and other causes of bone marrow failure. In: *Oxford Textbook of Medicine* (DA Warrel, eds). Oxford University Press, Oxford, with permission.

may be declining in the literature as investigators become more sceptical of assigning aetiology based on putative association. Nevertheless, a careful drug history, including occupational exposures, should be obtained. Drug exposure in the year preceding presentation should be detailed. Earlier exposures should be recorded but are not likely to be relevant unless the particular drug or drug group has been readministered during the presumed critical period. If the patient is taking several drugs that may have been implicated in AA, even if the evidence is based on case reports alone, then all the putative drugs should be discontinued and the patient should not be rechallenged with the drugs after recovery of the blood count.

Since the 1950s chloramphenicol has been reported to be strongly associated with AA. It is likely that the risk has been overestimated, and more recent epidemiological studies, including the study from Thailand where chloramphenicol is still used, have failed to demonstrate an association. Drugs commonly associated with AA are listed in Table 13.2. European case-control epidemiological studies have reported relative risks for sulphonamides, gold, penicillamine, non-steroidal anti-inflammatory drugs, anticonvulsants, allopurinol, ticlopidine and sulphonylureas; a similarly designed study from Thailand incriminated sulphonamides, thiazide diuretics and mebendazole. More recently, the antibiotic linezolid has been implicated in bone marrow suppression but this has not been evaluated in population-based studies.

Pathogenesis and its clinical relevance

The haemopoietic defect in AA

AA is characterized by both a quantitative and qualitative defect in the haemopoietic stem cell compartment. The primitive long-term culture-initiating cells and more mature haemopoietic progenitors in the bone marrow (colony-forming cells) of all cell lineages are reduced or absent. The long-term bone marrow culture (LTBMC) system was modified using crossover experiments, in which AA CD34⁺ cells were inoculated onto irradiated preformed LTBMC stromas; this demonstrated a lack of generation of CFU-GM over time, consistent with impaired marrow repopulating ability of AA bone marrow CD34⁺ cells. There is a reduction in the percentage of CD34⁺ bone marrow cells, and the CD34⁺ cells are more apoptotic than normal CD34⁺ cells. About 10–15% of patients with AA have shortened telomeres, as measured in blood leucocytes. This was initially presumed to reflect 'stressed' haemopoiesis, but subsequently mutations in the telomerase gene complex have been demonstrated in such patients with apparent acquired AA.

The bone marrow stromal cell microenvironment functions normally in most patients, as assessed by crossover LTBMC in

which normal bone marrow CD34⁺ cells are inoculated onto irradiated AA stromal layers. Such an *in vitro* system does not examine individual cellular components of the stromal cell microenvironment and thus defects in particular cells cannot be excluded. The frequencies of fibroblast colonies (CFU-F) are normal in AA, and mesenchymal stem cells showed normal phenotype as defined by CD34⁻CD45⁻CD44⁺CD29⁺CD90⁺CD105⁺CD106⁺. The differentiation capacity of AA mesenchymal stem cells has not yet been formally evaluated. Cultured AA mesenchymal stem cells support *in vitro* haemopoiesis after addition of normal bone marrow mononuclear cells.

AA is not due to a deficiency of any known haemopoietic growth factor (HGF). Long-term marrow culture studies have shown normal mRNA expression and/or secretion of granulocyte/macrophage colony-stimulating factor, granulocyte colony-stimulating factor (G-CSF), interleukin (IL)-6, stem cell factor and thrombopoietin from stromal cells. Serum levels of most HGFs, including the above and recombinant human erythropoietin, are markedly elevated. These observations explain the lack of striking effects of HGFs in most AA patients.

The immune-mediated nature of acquired AA

In acquired AA, it is proposed that an inciting event, such as a virus or drug, provokes an aberrant immune response, triggering oligoclonal expansion of cytotoxic T cells that destroy haemopoietic stem cells (Figure 13.2). Bone marrow transplantation (BMT) or immunosuppressive therapy leads to complete or partial response by eradicating or suppressing pathogenic T-cell clones (Figure 13.2a, middle panel). Relapse occurs with recurrence of the immune response, and the immunologically stressed and depleted stem-cell compartment also allows selection of abnormal haemopoietic clones that manifest as MDS and occasionally AML.

There is strong evidence that AA has an autoimmune nature in many patients based on the following observations.

- 1 Haematological recovery after immunosuppressive therapy with ATG and ciclosporin (CSA) occurs in the majority of patients.
- 2 There are activated autoreactive oligoclonal CD8⁺ T cells present in blood and bone marrow that release interferon (IFN)- γ and tumour necrosis factor (TNF)- α , cytokines that inhibit haemopoiesis.
- 3 Intracellular IFN- γ levels in T cells correlate with response to immunosuppressive therapy.
- 4 Increased Fas expression on bone marrow CD34⁺ cells indicates increased apoptosis.
- 5 T-cell repertoire analysis shows oligoclonal expansion of CD8⁺ T cells in AA, MDS and PNH.
- 6 Transcription factor T-bet is upregulated and binds to the IFN- γ promoter, resulting in increased expression of IFN- γ .
- 7 CD4⁺CD25⁺FOXP3⁺ regulatory T cells are reduced in AA patients.

Gene expression profiling in AA CD34⁺ cells has shown that more than half the upregulated genes are related to the immune response, including genes for cytokines and cytokine receptors, signal transduction genes, as well as other immune response genes. Many apoptosis and cell death genes are upregulated and some anti-apoptotic genes downregulated.

It is unclear why T cells are activated in AA. HLA-DR2 and its split HLA-DR15 and DRB1*1501 and 1502 alleles are over-represented in AA, as a class I HLA-B*4002 and HLA-A*0206, indicating a possible role for antigen recognition. There is correlation between ATG response and DRB1*1501, but most of these HLA data come from studies of Japanese patients. Studies of cytokine gene polymorphisms that may reflect a heightened immune response in AA are limited; polymorphisms in the TNF- α promoter, IL-6 and IFN- γ genes have been reported, but a systematic assessment of all potentially relevant cytokine genes has not been reported.

The specific cytotoxic T-cell targets on haemopoietic stem and progenitor cells in AA have not been identified. Potential candidates, identified by screening antibodies in patients' serum against a peptide library using leukaemia cell lines, include kinectin, DRS-1 (diazepam-binding inhibitor-related protein-1), PMS1 (postmeiotic segregation increased 1), moesin and hnRNPK (heterogeneous nuclear ribonucleoprotein K). However, the relevance of these findings is unclear, and they may represent epiphenomena rather than primary targets of cytotoxic T-cell attack.

Alternatively, a defect in the glycosylphosphatidylinositol (GPI) anchor may be the trigger for the immune response against normal progenitor cells through aberrant expression of intracellular GPI-protein(s) while at the same time providing a protective mechanism for GPI-defective cells. The expansion of PNH clones in a subset of patients with AA and hypoplastic MDS is also a well-established finding but the mechanism(s) that leads to this expansion is poorly understood. PNH cells may show a selective clonal advantage because (i) GPI-negative haemopoietic stem cells are spared from autoimmune attack because the absent GPI anchor is the target of the immune attack; (ii) GPI-negative cells acquire a second mutation that confers a survival advantage; or (iii) *PIGA* mutation confers an intrinsic resistance to apoptosis. *PIGA* mutations are present in the blood of most healthy individuals but do not result in disease. They may also appear following treatment with the monoclonal antibody alemtuzumab, which recognizes the GPI-linked antigen CD52. ATG contains high levels of antibodies to the GPI-deficient proteins CD52 and CD48 and low levels of antibodies to CD16, which may contribute to the emergence of PNH clones after treatment of AA.

Mouse models

There is currently no ideal animal model of AA. An early mouse model was produced by high-dose chronic administration of

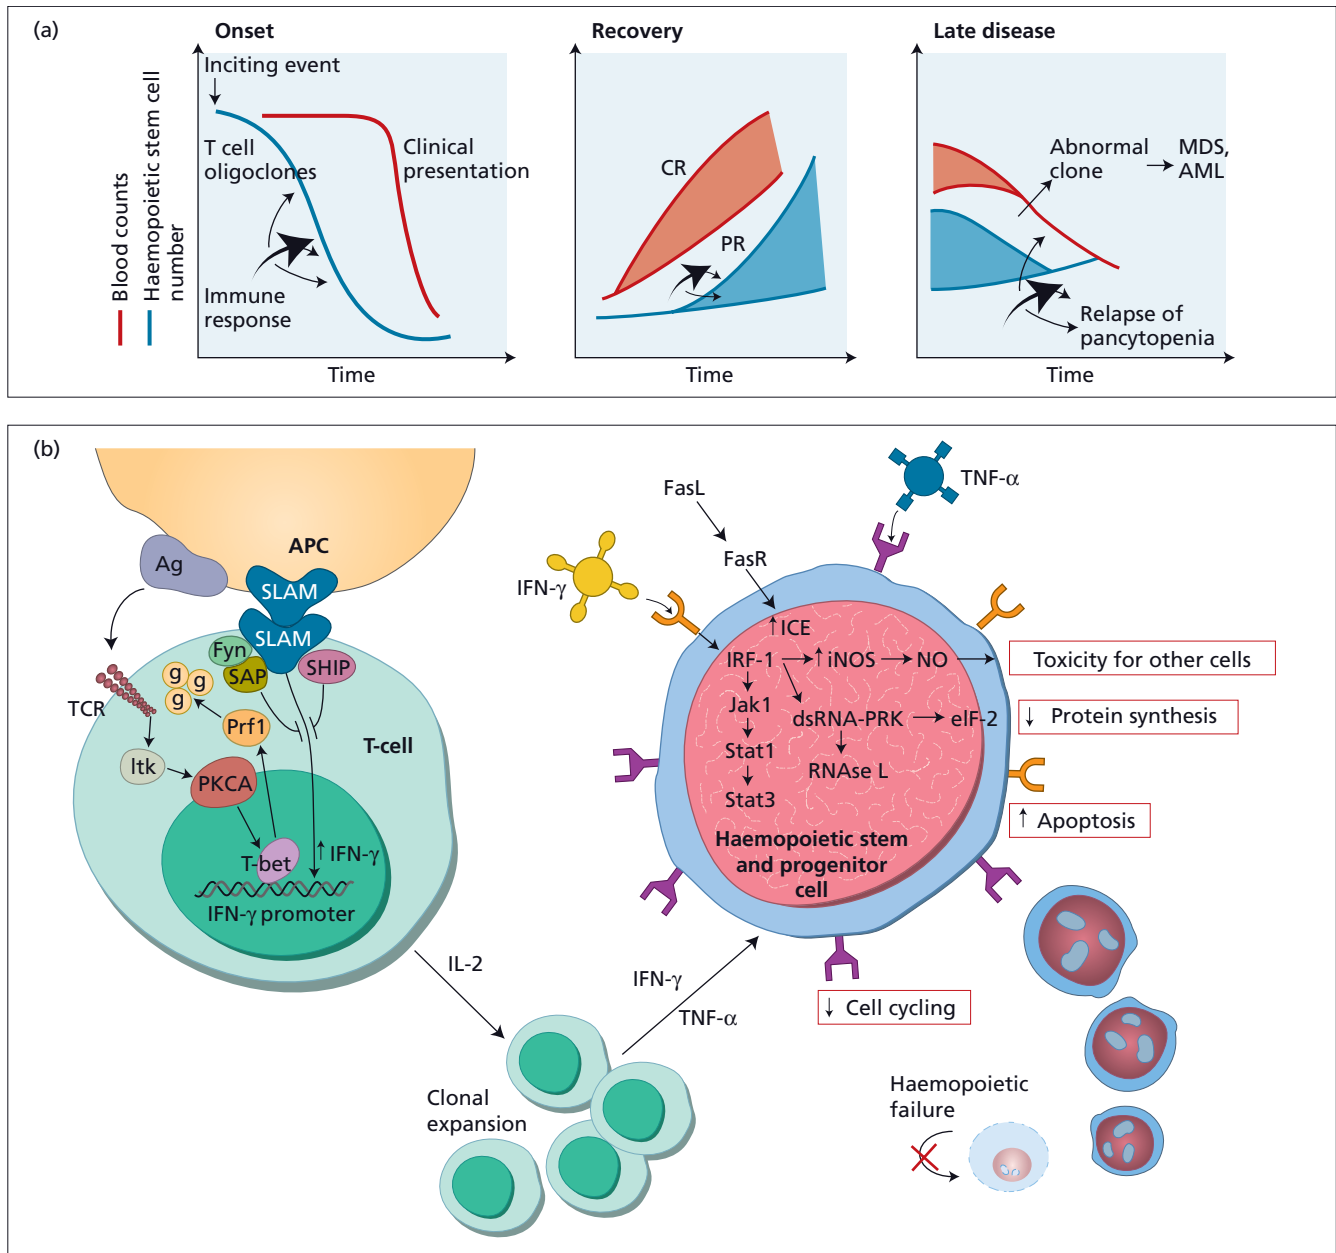

Figure 13.2 (a) Pathophysiology of acquired aplastic anaemia (AA). In acquired AA, it is proposed that an inciting event, such as a virus or drug, provokes an aberrant immune response, triggering oligoclonal expansion of cytotoxic T cells that destroy haemopoietic stem cells (left-hand panel, Onset). Bone marrow transplantation or immunosuppressive therapy leads to complete response (CR) or partial response (PR) by eradicating or suppressing pathogenic T-cell clones (middle panel, Recovery). Relapse occurs with recurrence of the immune response, and the immunologically stressed and depleted stem-cell compartment also allows selection of abnormal haemopoietic clones that manifest as myelodysplastic syndrome (MDS) and occasionally as acute myeloid leukaemia (AML) (right-hand panel, Late disease). (b) Immune destruction of haemopoiesis. Antigens are presented to T lymphocytes by antigen-presenting cells (APCs), which trigger T cells to activate and proliferate. T-bet, a transcription factor, binds to the interferon (IFN)- γ promoter region and induces gene expression. SAP binds to Fyn and modulates SLAM

activity on IFN- γ expression, diminishing gene transcription. Patients with AA show constitutive T-bet expression and low SAP levels. IFN- γ and tumour necrosis factor (TNF)- α upregulate cellular receptors on other T cells and also the Fas receptor. Increased production of interleukin (IL)-2 leads to polyclonal expansion of T cells. Activation of Fas receptor by the Fas ligand leads to apoptosis of target cells. Some effects of IFN- γ are mediated through interferon regulatory factor (IRF)-1, which inhibits the transcription of cellular genes and entry into the cell cycle. IFN- γ is a potent inducer of many cellular genes, including inducible nitric oxide synthase (NOS), and production of the toxic gas nitric oxide (NO) may further diffuse toxic effects. These events ultimately lead to reduced cell cycling and cell death by apoptosis. Ag, antigen; TCR, T-cell receptor. (This research originally published in *Blood*. Young NS, Calado RT, Scheinberg P. Current concepts in the pathophysiology and treatment of aplastic anaemia. *Blood* 2006;108:2509–19. © American Society of Haematology.)

the cytotoxic drug busulfan. After a year, mice developed pancytopenia, aplasia and very low CFU-S frequency. This model is used for studying chemotherapy-induced myelosuppression and is consequently not a model of immune-mediated AA.

Workers at the National Institutes of Health (NIH) have infused parent lymph node cells into F₁ hybrid mice to induce a model based on transfusion-induced GVHD. Allogeneic lymphocytes present in the infused cells attacked and destroyed host cells in a graft-versus-host response, resulting in pancytopenia, hypocellular bone marrow, increased serum IFN- γ levels, a 35-fold increase in bone marrow CD4⁺ cells, a 400-fold increase in bone marrow CD8⁺ cells, and increased bone marrow CD95 expression. However, the nature of the effector cells was unclear and mice did not show a response to CSA. Using a similar model, but without sublethal irradiation, the same group also demonstrated oligoclonal T-cell expansion, recovery of blood counts and improved survival after administration of ATG or CSA, and improved survival after anti-IFN- γ or anti-TNF- α . This model involves transplanting cells that differ in major and minor histocompatibility antigens. Mismatch for minor histocompatibility antigens in the setting of HLA-identical sibling BMT is responsible for severe immune responses against host cells. Chen has recently shown that a single mismatch for the H60 minor histocompatibility antigen results in generation of H60-specific cytotoxic T lymphocytes that can trigger AA in this mouse model, which is prevented by administration of CSA or CD4⁺CD25⁺ T cells. Mice were engineered with a germline deletion of T-bet (T-bet^{-/-}). Whereas T-bet^{+/+} lymph node cells induced severe aplasia, infusion of T-bet^{-/-} cells into sublethally irradiated F₁ hybrids did not result in severe aplasia, CD4⁺ and CD8⁺ cells were diminished, bone marrow IFN- γ was reduced but IL-4 and IL-7 were increased, indicating that the reduced Th1 response due to T-bet deficiency was partially compensated by increased Th2 and Th17 responses.

Genetic predisposition to AA

Inherited forms of AA have long been regarded as very rare causes of acquired AA, these including FA, DC and SDS (see Chapter 12). More recent awareness of these syndromes, with characterization of the genetic mutations in these and other bone marrow failure syndromes and the finding of very short telomeres in some patients with AA, indicate (i) a more common occurrence than previously realized, (ii) a shared defect in ribosomal biogenesis for SDS and Diamond–Blackfan anaemia (DBA), and (iii) a shared pathophysiology in DC and AA based on accelerated telomere attrition.

DC is due to mutations in the telomerase gene complex, a protein–RNA molecular machine for telomere repair, and also in the shelterin family, proteins that directly bind to and protect telomeres (Figure 13.3). The clinical features and gene mutations are discussed in further detail in Chapter 12. The DC

genes are involved in telomere maintenance, and all DC patients invariably have very short telomeres. About 10% of patients with apparent acquired AA have inherited mutations in *TERC*, *TERT* or one of the two shelterin genes, *TERF1* and *TERF2*, with none or very mild mucocutaneous abnormalities. Families of affected individuals often show an increase in pulmonary fibrosis and cirrhosis.

SDS is an autosomal recessive inherited form of bone marrow failure, and another example of disordered ribosomal biogenesis and RNA processing. SDS usually occurs in childhood with neutropenia, but can present in adult life. The molecular and clinical features of SDS are discussed in Chapter 12.

In addition to mutations in the DC genes, other factors such as ‘stressed’ haemopoiesis as a result of reduced stem cell numbers in AA, and environmental factors such as smoking, contribute to the shortened telomeres. Telomeres are assumed to be short in all organs, but they are only measured in blood leucocytes (the tissue for which there are sufficient age-matched controls). The consequences of telomere shortening include genomic instability resulting in increased risk of malignant transformation (MDS, AML), bone marrow failure, and defects in repair and regeneration (pulmonary fibrosis, cirrhosis). The clinical consequences of missing an inherited form of AA include likely mortality after allogeneic HSCT using standard conditioning regimens and failure to screen potential family bone marrow donors for inherited bone marrow failure.

That not all patients with acquired AA respond to immunosuppressive therapy could be explained in pathogenetic terms by (i) complete stem cell depletion due to a severe autoimmune attack, (ii) insufficient degree of clinical immunosuppressive therapy, or (iii) a non-immune basis for the bone marrow failure, of which one mechanism may be a genetic predisposition resulting in genomic instability. The presence of shortened telomeres in AA does not preclude initial response to immunosuppressive therapy, but there are insufficient data in patients with *TERC* or *TERT* mutations on response to immunosuppressive therapy (see also section Predictors of response to ATG).

Clinical features

Patients with AA most commonly present with symptoms of anaemia and skin or mucosal haemorrhage (ecchymoses or petechiae), including buccal haemorrhages, or visual disturbance due to retinal haemorrhage. Infection, particularly sore throat or failure of minor infections to clear, may be a presenting feature but is less common. There is no lymphadenopathy or hepatosplenomegaly in the absence of infection. An important careful history and clinical examination help to exclude an inherited form of AA, especially in children and young adults. This also applies to older patients as it has more recently been

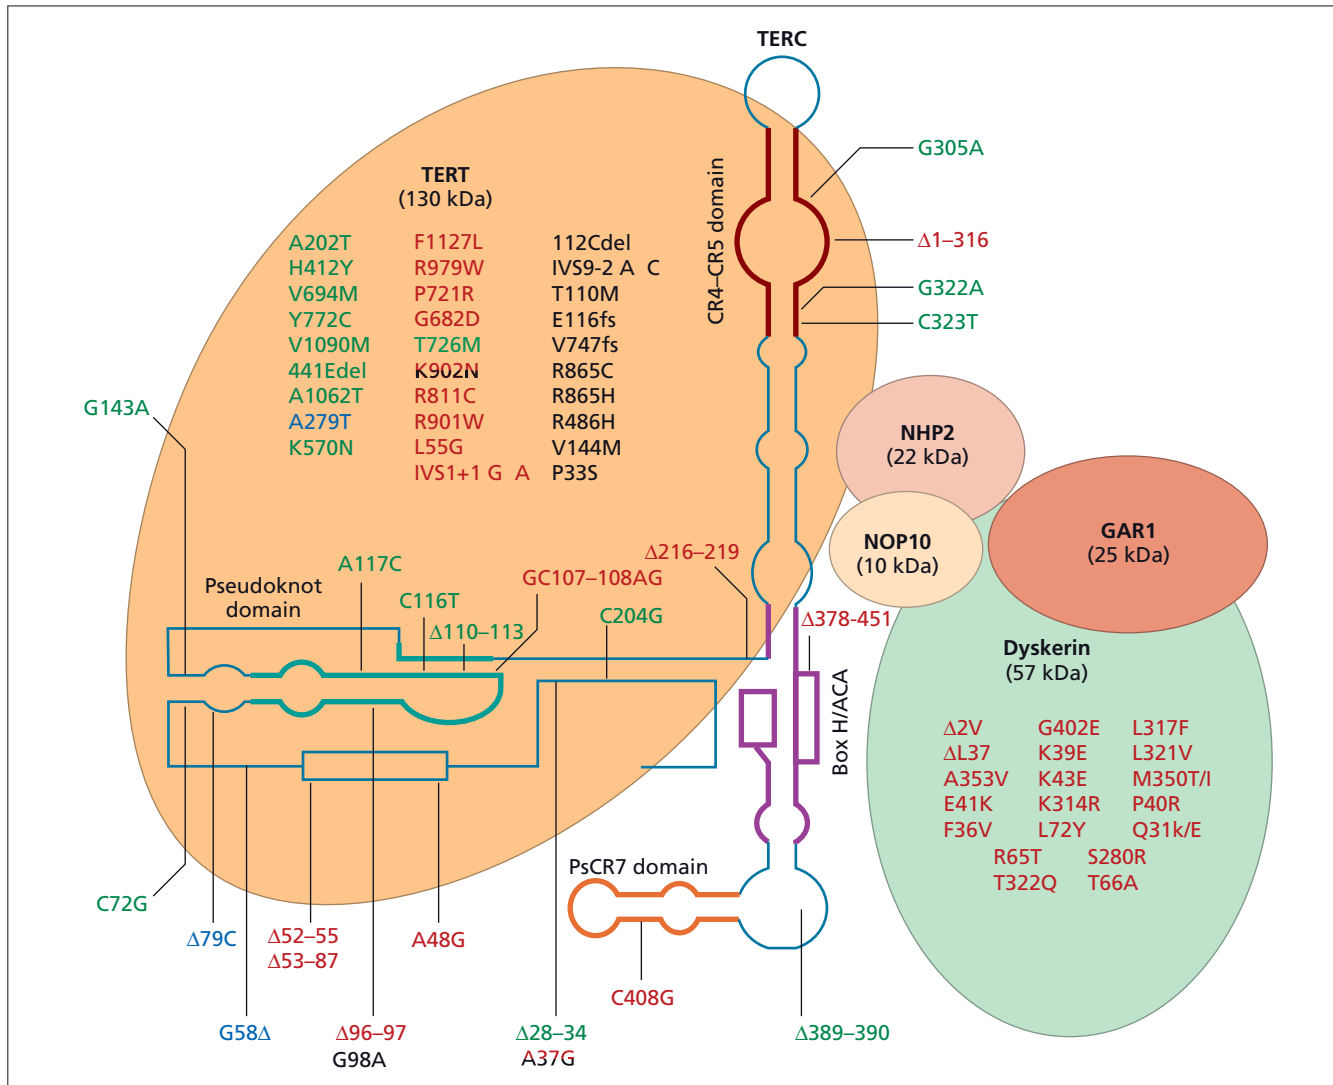

Figure 13.3 The components of the telomerase gene complex: TERT (reverse transcriptase), TERC (RNA template for TERT) and the nucleolar protein dyskerin, which forms a protein complex with the other proteins NHP2, NOP10, GAR1, that associates with TERC. Shown in red are the mutations found in dyskeratosis congenita, in green the mutations found in patients

with AA, and in black mutations the mutations found in ‘idiopathic’ pulmonary fibrosis. The mutations shown in blue represent polymorphisms. (This research originally published in *Blood*. Calado RT, Young NS. Telomere maintenance and human bone marrow failure. *Blood* 2008;111:4446-55. © American Society of Hematology.)

realized that typical features of inherited bone marrow failure syndromes may be absent and/or other features may be present in older patients. The findings of short stature, abnormal thumbs and forearms, café-au-lait spots and skeletal anomalies would raise the possibility of an inherited form of AA, specifically FA, although FA can present in adults without physical anomalies. Patients with FA most commonly present between the ages of 3 and 14 years but can occasionally present later in

their thirties or forties and very rarely early fifties. The findings of leucoplakia, nail dystrophy and pigmentation of the skin are characteristic of DC, with a median age at presentation of 7 years (range 6 months to 26 years). Some affected patients may have none of these clinical features and the diagnosis is made later after failure to respond to immunosuppressive therapy. For patients with AA and an inherited *TERC/TERT* mutation, the family history is very important as the pedigree may reveal

pulmonary fibrosis, cirrhosis, osteoporosis or avascular necrosis of bone. A previous history of malabsorption or neutropenia may underlie a diagnosis of SDS in children or young adults, especially as the malabsorption often resolves in later life. A preceding history of jaundice, usually 2–3 months, may indicate a post-hepatitic AA.

Diagnostic investigations and differential diagnosis

To diagnose AA with certainty, it is important to consider other possible causes of pancytopenia with a hypocellular bone marrow and to exclude an inherited form of AA, as this will have important implications for treatment options, the choice of conditioning regimen for BMT, genetic screening and counselling of family members and the choice of donor for HSCT. All patients should be screened by cytogenetics and for a PNH clone.

The full blood count shows pancytopenia, although usually the lymphocyte count is preserved. In most cases the haemoglobin level and neutrophil and platelet counts are all uniformly depressed, but in the early stages isolated cytopenia, particularly thrombocytopenia, may occur. Such patients may be misdiagnosed as having immune thrombocytopenic purpura. There is anaemia with reticulocytopenia, and macrocytosis is common. The blood film should be examined to exclude the presence of dysplastic neutrophils and abnormal platelets, blasts and other abnormal cells such as hairy cells. In AA, anisopoikilocytosis is common and neutrophils may show toxic granulation. Platelets are reduced in number and are mostly of small size.

Both a bone marrow aspirate and trephine biopsy are required. Fragments should be readily obtained from the aspirate. A 'dry tap' should raise the suspicion of a diagnosis other than AA, such as primary myeloid metaplasia or myelofibrosis secondary to a malignancy. The bone marrow is hypocellular with prominent fat and variable amounts of residual haemopoietic cells. Erythropoiesis is reduced or absent; dyserythropoiesis is very common and often marked, and on its own does not indicate MDS. Megakaryocytes and granulocytic cells are reduced or absent; dysplastic megakaryocytes and granulocytic cells are not seen in AA. Lymphocytes, macrophages, plasma cells and mast cells appear prominent. In the early stages of the disease, one may also see prominent haemophagocytosis by macrophages, as well as background eosinophilic staining representing interstitial oedema. The trephine is needed to assess overall cellularity, the morphology of residual haemopoietic cells and to exclude an abnormal infiltrate. The trephine is hypocellular throughout but is sometimes patchy, with hypocellular and cellular areas. A 'hotspot' in a patchy area may explain why sometimes the aspirate is normocellular. Reticulin is not

increased and abnormal cells are not present. Increased blasts are not seen in AA.

Liver function tests should be performed to detect antecedent hepatitis, but in post-hepatitic AA the serology is invariably negative for all the known hepatitis viruses. The onset of AA occurs 2–3 months after an acute episode of hepatitis and is more common in young males. Blood should be examined for hepatitis A antibody, hepatitis B surface antigen, hepatitis C antibody and Epstein–Barr virus (EBV). Cytomegalovirus (CMV) and other viral serology should be assessed if HSCT is being considered. HIV is not a recognized cause of AA but can cause isolated cytopenias. Appropriate investigations to exclude alternative aetiologies of cytopenias (vitamin B₁₂, red cell folate and HIV) should be performed, although bone marrow aplasia secondary to vitamin deficiency is exceedingly rare. Blood should be sent for antinuclear antibody to exclude SLE as another rare cause of AA.

The presence of a PNH clone is diagnosed by performing flow cytometry. Analysis of GPI-anchored proteins, such as CD55, CD59 and CD66b, is a sensitive and quantitative test for PNH that enables the detection of small PNH clones, which occur in up to 50% of patients with AA. Small clones are most easily identified in the neutrophil and monocyte lineages in AA and will be detected by flow cytometry and not by the Ham test. A recent blood transfusion does not prevent the diagnosis of a PNH clone, as flow cytometry will detect a GPI-deficient population of neutrophils and monocytes; a population of GPI-deficient red cells can be demonstrated in the presence of the transfused red cells. The clinical significance of a small PNH clone in AA as detected by flow cytometry remains uncertain. Such clones can remain stable, diminish in size, disappear or increase. A large PNH clone may be seen with clinical or laboratory evidence of haemolysis.

Cytogenetic analysis of the bone marrow should be attempted, although this may be difficult in a very hypocellular bone marrow and often insufficient metaphases are obtained. In this situation, fluorescence *in situ* hybridization analysis of chromosomes 5 and 7 can be attempted. The relevance of an abnormal cytogenetic clone in patients with no morphological features of MDS or AML remains controversial. Abnormal cytogenetic clones may be present in up to 12% of patients with otherwise typical AA at diagnosis. Common cytogenetic abnormalities include trisomy 6, trisomy 8, trisomy 15 and monosomy 7/del 7q. Monosomy 7 is associated with a high risk of MDS and poor response to immunosuppressive therapy. In contrast, trisomy 8 is associated with a good response to ATG and excellent survival. Abnormal cytogenetic clones may also arise during the course of the disease. If there is a lymphocytosis or prominent large granular lymphocytes on the blood film, immunophenotyping and analysis of T-cell receptor gene rearrangement should be performed to detect a clonal T-cell disorder such as T-LGL.

The diagnosis of FA is made by culturing peripheral blood lymphocytes for spontaneous and diepoxybutane (DEB)- or mitomycin C (MMC)-induced chromosomal breakages. This test should be performed in younger patients and is mandatory before stem cell transplantation. Rarely, FA has been diagnosed in the fifth decade of life. DC may be excluded by identifying a known mutation but there are probably other mutations yet to be identified. Along with measuring telomere lengths, this is not currently available as a routine clinical service in the UK, and at present remains a research investigation. Rarely, the chromosomal breakage test performed on peripheral blood may be falsely negative in patients with FA who have haemopoietic mosaicism due to genetic reversion in one allele. In this situation, skin fibroblast cultures will demonstrate hypersensitivity to DEB or MMC.

Chest radiography is useful at presentation to exclude infection and for comparison with subsequent films. Radiographs of the radii are not routinely indicated but may be helpful in inherited AA, especially FA. An abdominal ultrasound may be performed if an enlarged spleen and/or enlarged lymph nodes and a malignant haematological disorder are suspected. Abnormal anatomically displaced kidneys or a single kidney are features of FA.

Differential diagnosis

The following disorders may sometimes present with pancytopenia and a hypocellular bone marrow.

- Hypocellular MDS/AML, featuring dysplastic megakaryocytes and dysplastic granulocytic cells, increased reticulin fibrosis, blasts, ALIPs (abnormal localization of abnormal precursors), the presence of any ringed sideroblasts and an increase in CD34⁺ cells.
- Aleukaemic leukaemia describes cases of hypocellular acute lymphoblastic leukaemia, or less often hypocellular AML, in children. It presents initially with pancytopenia and a hypocellular bone marrow but later evolves to overt leukaemia.
- Hairy cell leukaemia classically presents with pancytopenia, monocytopenia, an interstitial infiltrate of hairy cells and increased bone marrow reticulin. Splenomegaly is common.
- Lymphomas, either Hodgkin disease or non-Hodgkin lymphoma, and myelofibrosis. Myelofibrosis is usually accompanied by splenomegaly.
- Mycobacterial infections, especially atypical infection. Other bone marrow abnormalities include granulomas, fibrosis, marrow necrosis, haemophagocytosis and demonstrable acid alcohol-fast bacilli.
- Anorexia nervosa or prolonged starvation. The bone marrow may show hypocellularity and gelatinous transformation (serous degeneration/atrophy) with loss of fat cells as well as haemopoietic cells, and increased ground substance.

Management

Supportive care

Transfusions

Support with red cell and platelet transfusions is essential for patients with AA to maintain a safe blood count. Current practice in both the UK and USA is to give prophylactic platelets when the platelet count is below $10 \times 10^9/L$ (or $< 20 \times 10^9/L$ in the presence of fever, sepsis or bleeding). A trial to evaluate the use of prophylactic platelets in thrombocytopenic patients is currently ongoing in the UK (TRAP, Trial to Reduce Alloimmunization to Platelets). Predicting bleeding is difficult in an individual patient. Fatal haemorrhage, usually cerebral, is more common in patients who have less than $10 \times 10^9/L$ platelets, extensive retinal haemorrhages, buccal haemorrhages or rapidly spreading purpura.

A common problem in multitransfused patients with AA, compared with leukaemia patients, is that they may develop alloimmunization to leucocytes present in red cell and platelet transfusions by generating HLA or non-HLA (minor histocompatibility) antibodies. In AA, rates of alloimmunization obtained prior to universal leucodepletion are around 30–50%. Leucodepletion, which has been universally applied to cellular blood components in the UK since November 1999, has probably reduced the incidence of alloimmunization. Alloimmunization can result in platelet refractoriness, as well as an increased risk of graft rejection after allogeneic BMT. Patients who become refractory to platelet transfusions should be screened for HLA antibodies, once other causes of platelet refractoriness have been excluded. If a patient does become sensitized to random donor platelets, HLA-matched platelets should be used. Current matching strategies in the UK and USA are based on counting the number of HLA-A and -B mismatches between patient and donor. This procedure requires the availability of a large HLA-typed donor panel and even then sometimes no suitable matches can be found. Novel approaches, including the use of HLA epitope-matched platelets, merit further evaluation.

Red cell and platelet transfusions should be given to maintain a safe haemoglobin level and platelet count and not be withheld for fear of sensitizing the patient. Directed blood and platelet donations from family members are not permitted within the National Blood Service, and not looked on favourably in the USA either; the recipient may become sensitized to minor histocompatibility antigens from the potential bone marrow donor, resulting in a high risk of graft rejection. In exceptional circumstances, a family donor may provide the most compatible platelets if a patient has developed multispecific HLA antibodies and requires platelets urgently.

If a patient is a candidate for early or later BMT, it is recommended that the patient is transfused with CMV-negative blood

products until the patient's CMV status is known. CMV-negative blood products should then be continued only if both the patient and donor are CMV negative.

It is currently unclear whether red cell and platelet transfusions should be routinely irradiated in all AA patients who are potential HSCT candidates and in all patients undergoing treatment with ATG. The rationale for considering the use of irradiated blood products is twofold. Firstly, animal data demonstrate that irradiation of all red cell and platelet transfusions before HSCT further reduces the risk of sensitization to minor histocompatibility antigens (and hence reduced risk of graft rejection after allogeneic HSCT). Leucodepletion of blood products is likely to have reduced alloimmunization in AA patients. Secondly, irradiated blood products would abolish the potential risk of transfusion-associated GVHD associated with ATG therapy. Transfusion-associated GVHD has very rarely been reported after ATG. Rabbit ATG is more immunosuppressive than is horse ATG. Rabbit ATG also results in a more prolonged period of lymphopenia and has a longer half-life and higher-affinity IgG subtype to human lymphocytes than does horse ATG. For these reasons, even though there is no evidence base, the British Committee for Standards in Haematology now recommends empirically the use of irradiated blood components for all AA patients receiving ATG.

The use of granulocyte transfusions is being re-evaluated as supportive therapy in patients with life-threatening neutropenia. Adverse events, such as febrile reactions, HLA alloimmunization and transfusion-related acute lung injury, are well-recognized complications following granulocyte transfusions. Irradiated granulocyte transfusions are used at specialized centres to support patients with fungal/mould disease or bacterial sepsis who are severely neutropenic and not adequately responding to maximal antibiotics, when the possible benefits outweigh the hazards.

Iron chelation therapy

Many AA patients require multiple red cell transfusions leading to transfusion haemosiderosis. Iron overload impacts adversely on outcome after allogeneic BMT. Iron chelation therapy should commence when the serum ferritin is above 1000 µg/L, although the evidence base for this is lacking. It may be difficult to deliver subcutaneous desferrioxamine to AA patients on account of local haemorrhage and infection from subcutaneous injections. If not tolerated, intravenous desferrioxamine through a central line may be considered. Alternative oral agents include deferiprone and deferasirox (Exjade). Because of a high incidence of agranulocytosis with deferiprone, it is not used routinely in patients with AA. In the USA, deferasirox is now widely prescribed in the marrow failure syndromes. There were initial concerns about cytopenias in patients treated with deferasirox, so its safety in AA patients was unclear. Results of a recent prospective study of deferasirox in 166 iron-over-

loaded AA patients showed that after 1 year there was a median fall in serum ferritin of 946 µg/L from a baseline median of 3254 µg/L. There were no cases of myelosuppression due to deferasirox.

Infections

Patients with AA are at risk of bacterial and fungal infections, depending in part on the degree of neutropenia. Very severe neutropenia (neutrophils $< 0.2 \times 10^9/L$) carries a high risk of systemic bacterial and fungal infections. At neutrophil counts between 0.2 and $0.5 \times 10^9/L$, the risk of infection is less but acquired infection cannot be readily counteracted. If there is severe neutropenia, non-absorbable antibiotics are sometimes administered to reduce the potential pathogenic load from the gastrointestinal tract. An alternative option is an oral quinolone, although neither is standard practice in the USA. Oral hygiene is important. Entry sites for venous access are potential sources of systemic infection. Patients with AA are at high risk of fungal infection, including *Aspergillus*. Fluconazole provides no protection against *Aspergillus* species, for which the drugs of choice are itraconazole, which has clinically significant but manageable or avoidable interactions with other drugs, and posaconazole, which has not yet been shown to be superior in efficacy to itraconazole.

Fever should be treated with broad-spectrum antibiotics without waiting for laboratory isolation of organisms, and with early introduction of systemic antifungal therapy if fever fails to respond to antibiotics. Chest radiography should be part of the investigation of new or persistent fever, along with computed tomography of the chest. G-CSF is usually ineffective in severe AA due to a marked reduction or absence of myeloid progenitor cells, although it is reasonable to consider giving a short course to assess for a temporary increase in the neutrophil count.

General comments relating to the management of AA

Because AA is a rare disease, the haematologist responsible for the patient should contact a centre/specialist with expertise in AA soon after presentation to discuss a management plan for the patient. Patients should be offered the opportunity to be reviewed in a specialist centre. Whenever possible, patients should be enrolled into prospective national or international trials.

Prior to administration of specific treatment for the disease, the patient should be stabilized clinically in terms of controlling bleeding and treating infection. The presence of infection is an adverse factor for outcome after HSCT, although it may sometimes be necessary to proceed with HSCT in the presence of active infection, particularly fungal infection. In this setting, transplantation may offer the best chance of early neutrophil

recovery, and delaying the transplant may risk progression of the fungal infection.

Indications for treatment of AA

The two main treatment options for AA are allogeneic HSCT or immunosuppressive therapy with ATG and CSA, based on disease severity, age of the patient, availability of a matched sibling donor, and patient choice. Young patients with a low neutrophil count have a significant advantage if treated with first-line HSCT. Older patients with a higher neutrophil count do better if given immunosuppressive therapy as first-line therapy. For patients with severe AA who are under 40 years of age, the first-line treatment is matched sibling donor HSCT. For all other patients who require treatment, namely those with non-severe AA or those older than 40 years, immunosuppressive therapy is the first option. An exception to this is children with non-severe AA who are transfusion dependent, where first-line treatment is matched sibling donor HSCT. Unrelated donor HSCT is indicated after failure to respond to one course of immunosuppressive therapy, for those patients who lack a matched sibling donor, and who are under 50 years of age, or older if of good performance status.

The currently recommended regimen for immunosuppressive therapy comprises the combination of ATG and CSA. There is no role for HGFs as specific therapy for AA. Corticosteroids should not be given to treat AA as they are ineffective and encourage fungal and bacterial infections. Figure 13.4 illustrates current treatment algorithms for severe and non-severe AA.

Immunosuppressive therapy

Antithymocyte globulin: properties, mechanism of action and administration

ATG is a polyclonal IgG antibody preparation produced by immunizing horses or rabbits with human thymocytes obtained at the time of cardiac surgery in children. It binds to T cells, B cells, monocyte/macrophages, dendritic cells and endothelial cells, and also reacts with molecules involved in the immune response, cell migration and adhesion and signal transduction. Its mechanism of action in AA is not entirely clear. Furthermore, the mode of action of rabbit and horse ATG preparations may differ. Possible mechanisms include the following:

- 1 T-cell depletion by complement-mediated lysis;
- 2 destruction of activated cytotoxic T lymphocytes by Fas-mediated apoptosis and antibody-dependent cellular cytotoxicity;
- 3 reduced apoptosis and Fas expression on AA CD34⁺ bone marrow cells;

4 direct stimulation of normal and AA CD34⁺ bone marrow cells and a mitogenic effect in the absence of complement resulting in release of HGFs;

5 direct stimulation of T-regulatory cells has been demonstrated when normal bone marrow mononuclear cells are incubated with rabbit ATG.

In the UK, most of Europe and many other countries, the standard preparation of ATG has until recently been horse ATG (Lymphoglobuline, Genzyme). In the USA, horse ATG (Atgam) is still widely used. The rabbit preparation (Thymoglobuline, Genzyme) was usually reserved for second or subsequent courses. From June 2007, horse ATG was withdrawn due to manufacturing difficulties in maintaining quality control.

ATG is a powerful immunosuppressive drug and its use in severely neutropenic patients requires very careful monitoring, the prophylaxis and treatment of fevers and infections, as well as adequate (and sometimes intensive) platelet transfusion support. Rabbit ATG is given for 5 days as a daily intravenous infusion over 12–18 hours through a central venous catheter. The daily dose of rabbit ATG is 1.5 vials per 10 kg body weight (1 vial of rabbit ATG contains 25 mg protein, so the daily dose is 3.75 mg/kg). A test dose must be given beforehand and if a severe systemic reaction or anaphylaxis occurs, further doses of that preparation of ATG must not be given. Instead of giving a separate test dose, some centres give the first 100 mL of the first infusion very slowly over 1 hour. Allergists maintain that this is inadequate to prevent anaphylaxis as the amounts delivered are relatively large. In the USA, a skin test for horse ATG sensitivity is routinely given but by custom not for rabbit ATG in the absence of published data. Horse ATG (Atgam) dosage is 40 mg/kg daily for 4 days.

Immediate side-effects are allergic and occur commonly, including fever, rigors, rash, hypertension or hypotension and fluid retention. Each daily dose should be preceded by intravenous methylprednisolone and chlorpheniramine. In the USA, patients are pretreated with diphenhydramine and pethidine if fever and chills have occurred. Platelet transfusions should be given to maintain a safe platelet count (ideally $> 30 \times 10^9/L$; in the USA, a threshold of $> 20 \times 10^9/L$ is used). Prior to starting ATG, patients should be assessed to ensure adequate platelet increments with random donor platelets. Poor platelet increments should be investigated beforehand. Patients are often in isolation with reverse barrier nursing, but this is not standard practice in the USA. Fevers are treated with broad-spectrum antibiotics. Intravenous methylprednisolone (or oral prednisolone) and paracetamol are given at least 30 min before each daily dose of rabbit ATG 1–2 mg/kg, with reduction of the prednisolone dose by half every 5 days. Prednisolone is given to help prevent serum sickness. Serum sickness typically occurs between 7 and 14 days from the start of ATG treatment. The common symptoms of serum sickness include arthralgia, myalgia, rash,

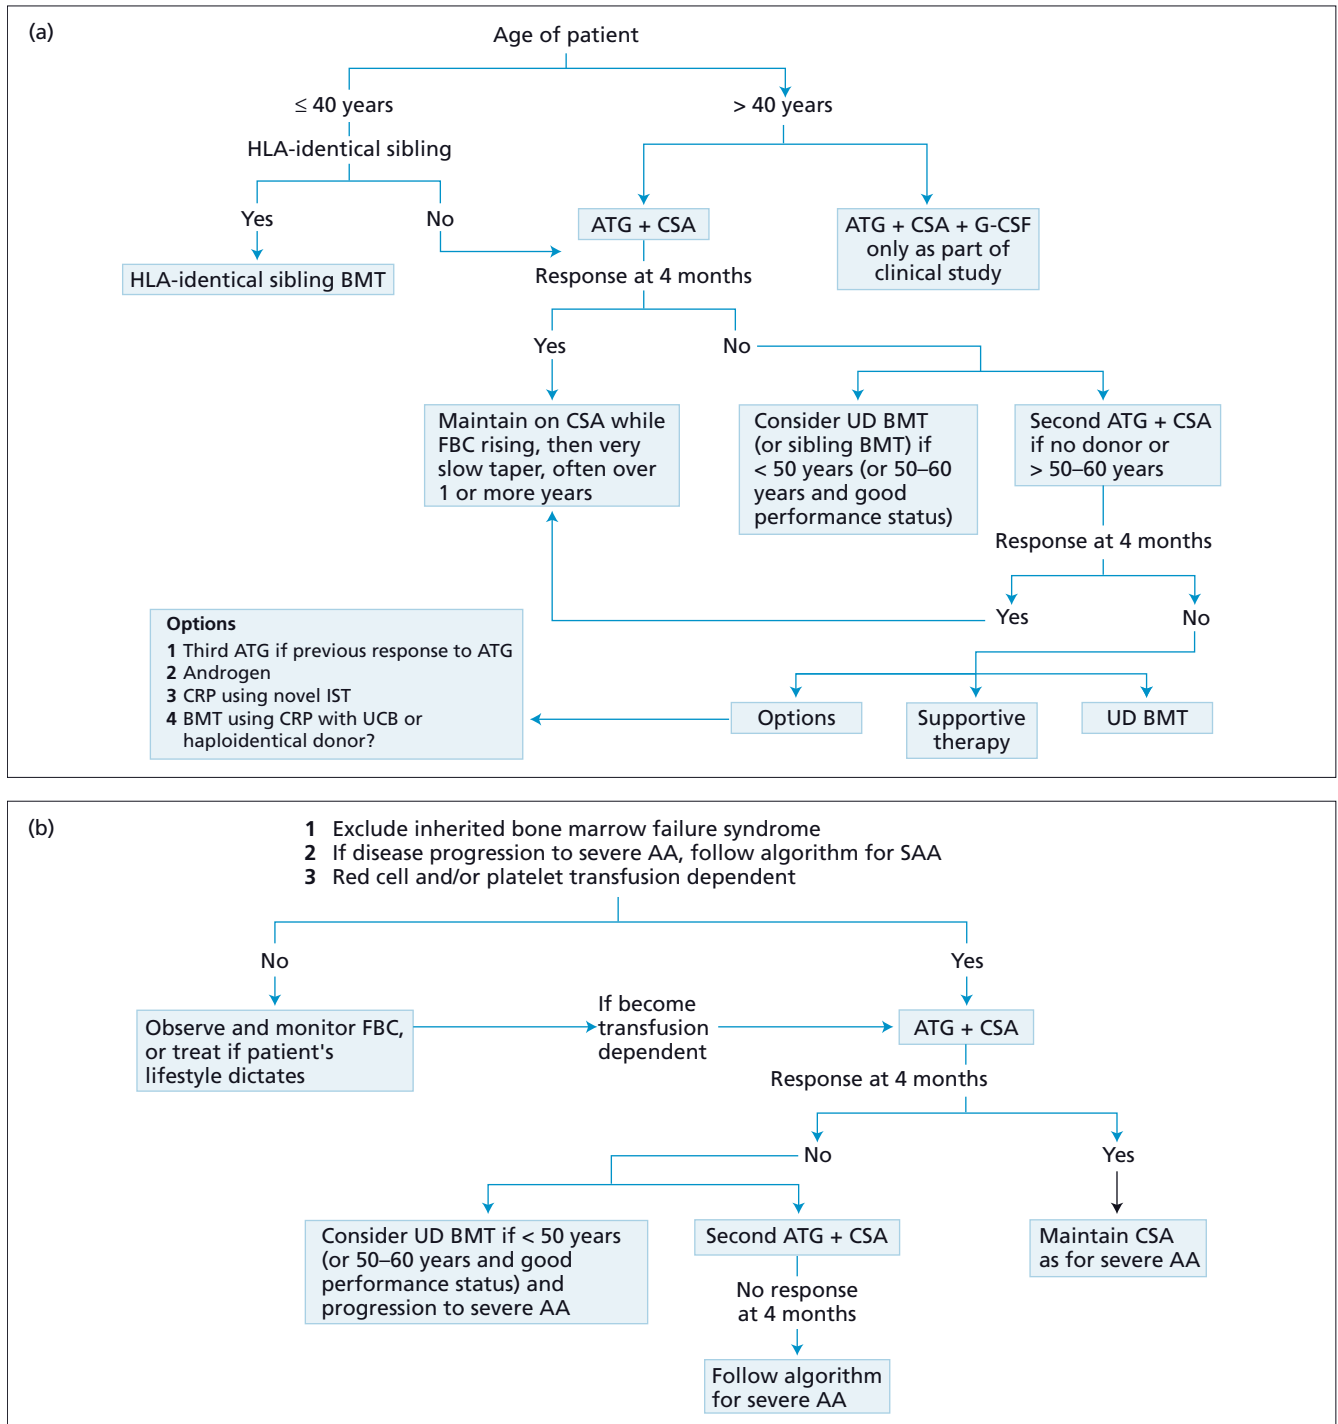

Figure 13.4 Algorithms for treatment of (a) severe acquired aplastic anaemia and (b) non-severe aplastic anaemia. AA, aplastic anaemia; ATG, antithymocyte globulin; BMT, bone marrow transplantation; CSA, ciclosporin; FBC, full blood count; IST, immunosuppressive therapy; UD, unrelated donor; HLA id

sib BMT, HLA-identical sibling BMT; CRP, clinical research protocol; UCB, umbilical cord blood. (Modified from Marsh *et al.* (2009) *British Journal of Haematology* 147: 43–70, with permission of Wiley Publishers.)

fever, mild proteinuria and platelet consumption often necessitating increased platelet transfusion support.

Evolution of ATG-based immunosuppression

ATG was first used in the treatment of AA by George Mathé, who observed autologous recovery after haploidentical BMT with ATG. Subsequent work confirmed that the responses seen were due to ATG and not the haploidentical bone marrow. During the late 1970s and early 1980s, ATG was given with high-dose methylprednisolone, on the (incorrect) assumption that high-dose methylprednisolone contributed to response. The addition of androgens (in most cases oxymetholone) to ATG and high-dose methylprednisolone during the early to mid 1980s failed to significantly improve response rates or survival after ATG. ATG in combination with CSA during the mid/late 1980s resulted in a significant improvement in response rates and survival. For non-severe AA, the combined use of ATG and CSA resulted in 75% response compared with 45% for CSA alone. For severe AA, significantly better responses were seen with the combination of ATG and CSA compared with ATG alone.

The rationale for using daily G-CSF (administered for 3 months) with ATG and CSA was to help reduce infection and to improve response. There were concerns about an increase in later clonal disorders with G-CSF, particularly from studies in Japan; transformation could only be fully appreciated with follow-up of at least 10 years. Two prospective randomized studies comparing ATG, CSA and G-CSF with ATG and CSA alone demonstrated no difference in response and survival between the two groups. A further prospective study from Europe is awaiting analysis. A large retrospective study from the European Group for Blood and Marrow Transplantation (EBMT) of patients treated with ATG and CSA, of whom 43% also received G-CSF, reported an incidence of MDS/AML of 10.9% with G-CSF and 5.8% without G-CSF. *In vitro* studies have shown that incubation of AA CD34⁺ bone marrow cells with G-CSF selected cells in which there was upregulation of the class IV mRNA isoform of G-CSFR, which is defective in cellular differentiation signalling. Incubation of bone marrow cells from AA patients with monosomy 7 with high doses of G-CSF increased the proportion of monosomy 7 cells. These studies showed that high doses of G-CSF did not induce monosomy 7 in AA but caused expansion of pre-existing monosomy 7 cells. Because of the above observations, and the continued need for longer follow-up in these studies, the routine use of G-CSF with ATG and CSA is not currently recommended.

There is a good rationale for considering the use of additional immunosuppressive drugs with ATG and CSA, as some non-responders may not have received adequate immunosuppression. Two separate studies from NIH evaluated the addition of mycophenolate mofetil (MMF) and sirolimus to ATG and CSA. There was no improvement in response or reduction in relapse

using MMF in combination with ATG and CSA compared to therapy without MMF. The second study examined the addition of sirolimus in a prospective randomized study. Sirolimus was chosen because it has a different pathway of action to CSA, and in solid transplantation it is synergistic with CSA. Sirolimus blocks mTOR (mammalian target of rapamycin), a serine/threonine kinase, and so may target those autoreactive T cells that escape inhibition through calcium-independent or CSA-resistant pathways. However, no significant difference in response was demonstrated to ATG and CSA with or without sirolimus (37% at 3 months and 51% at 6 months in the arm with sirolimus; 57% at 3 months and 62% at 6 months without sirolimus).

Survival after ATG

Data from EBMT and large single centres confirm that over the last three decades overall survival after ATG therapy has improved steadily, with 5-year survival of 70–80% reported (Figure 13.5). The reasons for improved survival have been difficult to assess formally, but likely factors include (i) improved supportive care for prevention and treatment of infections, especially superior antifungals and better availability and quality of blood products, (ii) the use of CSA with ATG and (iii) successful second-line therapies including another round of ATG, unrelated donor BMT (UDBMT) in younger patients and allogeneic HSCT in older adults. A summary of large studies reporting outcomes after immunosuppressive therapy with ATG and CSA is shown in Table 13.3.

Predictors of response to ATG

Although disease severity does not impact on overall survival, patients with non-severe AA are more likely to respond than

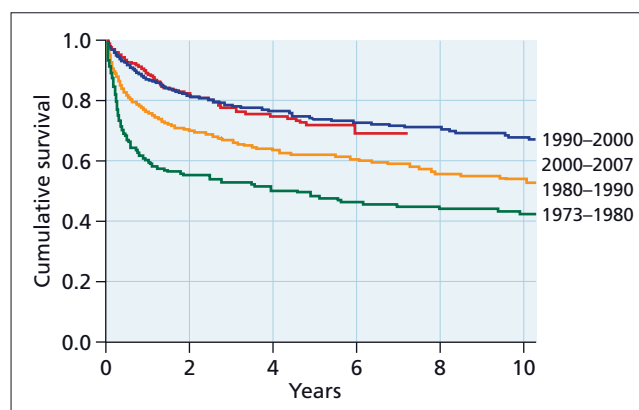

Figure 13.5 Survival of patients with severe aplastic anaemia: overall survival of 2400 patients reported to the EBMT database according to year of treatment with ATG with or without ciclosporin. (From Passweg JR, Tichelli A (2009) Immunosuppressive treatment for aplastic anaemia: are we hitting the ceiling? *Haematologica* 94: 310–12 with permission.)

Table 13.3 Immunosuppressive therapy using ATG and CSA.

Study	N	Median age (years)	Response (%)	Relapse (%)	Clonal evolution (%)	Survival (%)
1	84	32	66	19	8	59 at 11 years
2	100	16	77	12	11	85 at 5 years
3	122	35	61	35	11	55 at 7 years
4	119	9	68	22	6	89 at 3 years
5	104	30	62	37	9	80 at 4 years

Only studies with more than 20 enrolled patients are shown. Responses to immunosuppressive therapy are usually partial; blood counts may not normalize but patients become transfusion independent and recovery of neutrophil count is sufficient to prevent infection. Study 4 included androgens with or without G-CSF; study 5 included mycophenolate mofetil.

are patients with severe or very severe AA. However, the classical Camitta criteria (see Table 13.1) were not designed to predict response to ATG. Furthermore, automated reticulocyte counting tends to overestimate at low levels and correlates poorly with manual counts.

In a recent multivariate analysis from NIH of response at 6 months, only younger age, absolute reticulocyte count (ARC) and absolute lymphocyte count (ALC) correlate with response to ATG. The lack of association with the absolute neutrophil count reflected a high number of early deaths in patients with very severe neutropenia. For patients with ARC $25 \times 10^9/L$ or more and ALC $1.0 \times 10^9/L$ or more, the response was 83% compared with 41% for those with lower counts. The better prognostic group also showed significantly better survival.

Several studies have examined whether the presence of a PNH clone is associated with response to ATG, with conflicting results. This may reflect differences in sensitivity of the test used to detect a PNH clone. Those using very sensitive tests to detect GPI-deficient clones of less than 0.003 cells show a strong correlation with response.

HLA type may also correlate with response to immunosuppressive therapy. A Japanese study showed that HLA-DRB1*1501 associated with response to CSA. Although HLA-DR15 or DRB1*1501 predicts response to ATG in white patients with MDS, no association was seen in AA patients. More recently, the same Japanese group demonstrated that of the 30 different DRB1 alleles, only DRB1*1501 and DRB1*1502 occurred more frequently in AA than in controls, and that response to ATG and CSA was only associated with DRB1*1501 in the presence of a PNH clone. Thus specific HLA haplotypes correlate with response to immunosuppressive therapy in Japanese patients, but similar studies in white Europeans are lacking.

Recent studies from NIH indicate that shortened telomere length does not preclude initial response to immunosuppressive therapy, but predicts relapse after ATG and is a risk factor for

later cytogenetic abnormalities and evolution to MDS and AML. Thus telomere length at diagnosis may reflect depleted stem cell reserve so that prolonged stem cell division is not possible, resulting in later relapse; later clonal evolution reflects genomic instability of the critically shortened telomeres. In patients with *TERC* or *TERT* gene mutations, there are insufficient data on their response to immunosuppressive therapy.

Repeat courses of ATG

A second course of rabbit ATG may be administered if there is relapse after the first course or no response to the first course by 3–4 months. The response rate following a second course of horse ATG for relapse was 61%, and 64% in patients who did not respond to the first course. When rabbit ATG is given for the second course following an initial course of horse ATG, the response rate was only 30% for non-responders and 65% for relapsing patients. A recent study from Japan has examined prospectively the outcome of 52 children who failed one course of horse ATG, and who went on to receive either a second course of horse ATG or an unrelated donor HSCT. The response to a second course of ATG was only 11%, with a 5-year failure-free survival of only 9.5%; three children had anaphylaxis to the second course of ATG. Another study has assessed the value of giving three courses of ATG. Among those patients who showed no response to the first or second courses, there were no sustained responses, but for those who had relapsed after two previous courses, all responded to a third. Those patients treated with more than two courses of ATG had received various combinations of horse and rabbit ATG. Following the withdrawal of horse ATG (Lymphoglobuline), there are currently no data on using rabbit ATG more than twice in the same patient. For patients receiving more than one course of ATG, the risk of anaphylaxis may be higher. Serum sickness is still unpredictable though it may occur earlier following a second course of the same animal preparation of ATG.

Late complications after ATG

Relapse occurs in up to 30–35% of patients when CSA is withdrawn at 6 months. A more prolonged course of CSA with a later slow tapering of the drug reduces the relapse risk to around 13–16%. About one-third of patients are CSA dependent and require a small dose long term. CSA can be continued for at least 12 months after a maximal response before starting to taper the drug, followed by a very slow taper, for example by 25 mg every 3 months.

Patients treated with ATG are also at risk of developing clonal disorders, such as PNH, MDS and AML. A survey in 1993 from EBMT reported a 10-year incidence of developing MDS of 10%; the corresponding 10-year incidence for AML was 5%. Long-term follow-up of the prospective German national study of 84 patients treated with either the combination of ATG and CSA or ATG alone, between 1986 and 1989, reported overall survival of 58% and 54%, respectively, at 11 years. The actuarial probability of developing haemolytic PNH at 11 years was 10%, MDS or AML 8% and a solid tumour 11%. Risk factors for developing MDS/AML include repeated courses of ATG, older age, and high doses, prolonged duration of G-CSF with ATG and CSA, and shortened telomeres. Long-term follow-up from a large NIH cohort showed a 55% 7-year overall survival, 35% relapse at 5 years, and 10% risk of PNH and 15% risk of clonal evolution excluding PNH at 10 years.

ATG treatment in older patients and children

For older patients, the response rate and survival rate are lower compared with younger patients, with a higher risk of bacterial and fungal infections, bleeding and serious cardiac events after ATG. Although there is no upper age limit for ATG treatment, consideration for treatment should be preceded by medical assessment to exclude significant comorbidities and bone marrow examination to exclude hypocellular MDS. For older patients who are not candidates for ATG, CSA may be considered, but there is increased risk of renal toxicity and hypertension.

Excellent response to ATG is seen in children. Current response rates are around 75%, with 90% long-term survival. Hence, for children with severe AA who lack an HLA-identical sibling donor, first-line therapy should be ATG with CSA. If there is no response to a single course of immunosuppressive therapy, unrelated donor HSCT should be explored.

Other immunosuppressive drugs used in AA

Cyclophosphamide

High-dose cyclophosphamide (HDC) administered at 200 mg/kg has been used to treat AA in the absence of stem cell support, following the observation that complete autologous haematological recovery occurs in a small number of patients undergoing allogeneic sibling BMT using HDC. Although durable responses were seen, the predictable and markedly prolonged

cytopenias exposed patients to a high risk of fatal fungal infections and a significant increase in use of blood and platelet transfusions, days of intravenous antibiotics and amphotericin, and inpatient days in hospital. In addition, HDC treatment did not eliminate the risk of clonal events. Consequently, the use of HDC in the treatment of AA has not been met with much enthusiasm.

Alemtuzumab

The anti-CD52 monoclonal antibody alemtuzumab (Campath-1H) is effective in other autoimmune disorders such as multiple sclerosis, autoimmune cytopenias and the vasculitides. It is currently being evaluated in the treatment of AA. It produces profound lymphocyte depletion by antibody-dependent cell-mediated cytotoxicity and complement-mediated lysis. A small prospective study combined with a retrospective review of cases reported to EBMT on the use of a single course of alemtuzumab (100 mg over 5 days) and CSA in AA showed response in 9 of 18 patients, although relapses were common. At the NIH, preliminary data from ongoing studies (but with a larger number of patients) suggest that alemtuzumab (100 mg over 10 days) is effective for patients refractory to horse ATG or who have relapsed.

Haemopoietic stem cell transplantation

Outcomes following allogeneic HSCT for acquired AA, whether from a matched sibling donor or a matched unrelated donor, have steadily improved over time. Matched sibling donor transplantation for severe AA results in a 75–90% chance of long-term cure in young patients, but is less successful in older patients (Figure 13.6). More recently, significant improvements have been observed for matched unrelated donor HSCT for AA patients failing immunosuppressive therapy, with 60–80% survival and the best results seen in younger patients. Major difficulties remain for older patients in general and for patients who have failed immunosuppressive therapy and who have no suitable bone marrow donor. For these patients, new transplantation approaches are needed.

Pretransplant assessment of the patient

A reassessment bone marrow examination with cytogenetics and flow cytometry for GPI-deficient cells should be performed to exclude a malignant, premalignant or PNH clone, along with a careful re-evaluation to ensure that a constitutional form of aplasia has been excluded, since this would influence the choice of transplant conditioning regimen. Patients with FA need a much reduced intensity conditioning regimen compared with that used for acquired AA. A repeat HLA antibody screen should be performed to exclude HLA alloimmunization.

Pretransplant comorbidities impact adversely on non-relapse mortality after HSCT, including iron overload. Iron status is

Figure 13.6 Survival of patients transplanted for severe aplastic anaemia according to (a) year of transplant and (b) patient age. (Data obtained from EBMT database, JR Passweg, 2007.)

especially relevant to patients with AA who have often been multiply transfused prior to HSCT. Efforts should be made to reduce the serum ferritin before transplantation, although there is no clear guidance on the target level to achieve. The issues relating to pre-existing comorbidities are of importance in older patients with AA, because their transplant-related mortality is higher than in younger patients.

HLA-matched sibling donor transplantation

Conditioning regimens

The standard conditioning regimen for younger patients is HDC 200 mg/kg, which results in survival of at least 80% in younger patients (< 30 years). HDC is relatively free of long-term side-effects, and fertility is usually preserved. The dose needs to be carefully calculated because it is close to a cardiotoxic dose. The commonly used transplant regimens for AA patients are non-myeloablative. Older patients may need modified conditioning, as discussed later.

ATG is widely used with HDC to reduce graft rejection, although a prospective randomized study from the Centre

for International Blood and Marrow Transplant Research (CIBMTR) registry failed to show a significant difference in graft rejection, GVHD or survival when HDC alone was compared with HDC and ATG. Standard GVHD prophylaxis is with CSA and methotrexate. Alemtuzumab has also been used with CSA; one small single-centre study confirmed a significant reduction in GVHD compared with ATG-based conditioning regimens in AA. Because AA patients are at risk of late graft failure, CSA is usually continued for 12 months after HSCT.

Dose and source of haemopoietic stem cells

It is important to give at least 3×10^8 nucleated marrow cells/kg because at lower doses the risk of graft rejection increases significantly higher. Infusion of less than 2×10^6 CD34⁺ cells/kg is associated with delay in neutrophil engraftment and increased risk of graft failure and bacterial infections.

There is thus a good theoretical rationale for considering using G-CSF mobilized peripheral blood stem cells in HSCT for AA as a means of obtaining a high stem-cell dose and early engraftment, although a retrospective study showed more chronic GVHD in younger patients after peripheral blood stem cell transplantation in younger patients, worse survival and graft rejection the same, compared with BMT. At present, routine use of peripheral blood stem cell transplantation for AA is not recommended, although data from the EBMT Registry show that its use in AA continues to increase.

Graft rejection

Historical data indicate that AA patients have a higher rate of graft rejection compared with patients transplanted for haematological malignancies, although this has not been re-evaluated in the light of now routine practice of giving only leucodepleted blood products. Graft rejection occurred in 5–15% of matched sibling donor and 10–30% of matched unrelated donor HSCT. Early (or primary) graft rejection results in either no evidence of engraftment following the transplantation, with persistent pancytopenia, or early engraftment with neutrophils and monocytes but followed by pancytopenia. Late (or secondary) graft rejection occurs after a period of established engraftment.

Factors associated with graft rejection in AA include:

- 1 Multiple blood transfusions, in most series classified as more than 50 transfusions prior to HSCT, can result in alloimmunization to HLA and minor histocompatibility antigens present on donor cells but lacking in recipients.
- 2 Pretransplant and post-transplant immunosuppression affect graft rejection, namely the use of CSA or irradiation.
- 3 A low dose of donor haemopoietic stem cells.
- 4 T-cell depletion of donor marrow.
- 5 Sex-mismatched HSCT when male donors used for female recipients.
- 6 Progressive mixed chimerism.

Chimerism

Using polymerase chain reaction for short tandem repeats on unfractionated bone marrow or peripheral blood mononuclear cells, the Dublin group in collaboration with EBMT reported mixed chimerism in 25% of HSCTs for AA. Full donor chimerism occurs in 75%. Patients with mixed chimerism may have either stable or progressive mixed chimerism. All the cases of graft failure occurred in the progressive mixed chimerism group, of whom 50% rejected their grafts. Patients with stable mixed chimerism had excellent survival and no chronic GVHD, suggesting a state of tolerance may be achieved. Regular monitoring of chimerism is especially important at the time of CSA withdrawal. Increasing recipient chimerism would indicate the need for continued CSA.

Treatment of graft rejection

If graft rejection occurs, a second HSCT may be indicated. If there is residual host haemopoiesis, reconditioning of the recipient is necessary. Graft rejection associated with inadequate donor haemopoiesis may benefit from 'booster' donor stem cells without the need for further immunosuppression. Late graft failure may respond to reintroduction of therapeutic doses of CSA if the rejection occurred after discontinuation or withdrawal of CSA. Outcome after second HSCT depends on performance status and timing of the second transplant, with better outcome if the patient is transplanted more than 3 months after the first HSCT. There have been anecdotal reports of using donor lymphocyte infusion in cases of late graft failure, but there have been no formal clinical trials to fully evaluate its effectiveness and safety. The major concern with this approach is the induction of chronic GVHD. Complete autologous recovery may occur after graft rejection, and is defined as normalization of the blood count with restoration of host haemopoiesis; it results in excellent long-term survival.

Adverse factors for outcome

The effect of age on matched sibling donor HSCT is an important factor determining outcome. An EBMT study showed actuarial survival of patients aged 16 years or less, 17–40 years and over 40 years to be 77%, 68% and 54%, respectively. Other adverse prognostic factors are prior failed immunosuppressive therapy, long interval between diagnosis and HSCT, heavy transfusion burden and active infection before HSCT. For patients transplanted for haematological malignancies, iron overload is an adverse factor for outcome.

The outcome of patients above 40 years of age undergoing HSCT with conventional intensity protocols is significantly inferior compared with younger patients. A recent CIBMTR study has compared outcomes in patients over 40 years of age. Older patients showed worse survival, more GVHD and slower platelet recovery. Factors impacting on survival in older patients included poor performance status, multiple blood transfusions and more than 6 months from diagnosis to transplant. Because

of worse outcomes in older patients transplanted for AA, new approaches are needed. There are encouraging preliminary results using minimal-intensity conditioning with fludarabine, low-dose cyclophosphamide and ATG, with improved survival.

Graft-versus-host disease

GVHD (especially chronic) is one of the most serious complications, as it adversely impacts on performance status, quality of life and survival after marrow transplantation, especially in a disease like AA where there is no advantage in having a graft-versus-disease effect. It is seen mainly in patients with complete donor chimerism. Using ATG-based conditioning regimens, the incidence of acute GVHD is 12–30% and of chronic GVHD 30–40%. Chronic GVHD remains one of the most important challenges in HSCT for AA.

The risk factors for chronic GVHD include (i) history of prior acute GVHD, (ii) infusion of unirradiated donor buffy coat cells (this manoeuvre was used previously to overcome the problem of graft rejection but abandoned because of the high incidence of chronic GVHD), (iii) older patient age, (iv) the use of peripheral blood stem cells and (v) the use of ATG compared with alemtuzumab-based conditioning regimens.

Long-term complications of HSCT

Infertility

Fertility is usually well preserved when irradiation is not used in the conditioning regimen, and the chances of pregnancy or fathering a child are much higher in patients who receive a marrow transplant for AA than for haematological malignancies. Pregnancies in patients transplanted for AA usually have a successful outcome. Fludarabine-based conditioning regimens in AA use much lower doses of cyclophosphamide and may therefore have a theoretical advantage over conventional intensity protocols in preserving fertility, but data are lacking.

Secondary malignancies

There is an increased frequency of solid tumour malignancies after marrow transplantation for AA, but the risk is lower than in patients transplanted for haematological malignancies when irradiation is avoided. A combined study from Seattle and Paris of 700 patients, of whom 79 had FA, reported an estimated risk of developing a secondary tumour at 20 years for AA patients (excluding FA) of 14% and a median time for developing a second tumour of 9 years. Significant risk factors were treatment of chronic GVHD with azathioprine, irradiation and age.

Risk factors for EBV post-transplant lymphoproliferative disease after allogeneic HSCT for acute and chronic leukaemia and AA include unrelated donor HSCT, mismatched related donor transplantation, T-cell depletion of donor marrow, use of ATG, older age (> 50 years) and patients receiving second

transplants. For AA patients, immunosuppressive therapy with ATG prior to HSCT is also a risk factor. The use of alemtuzumab in the conditioning regimen instead of ATG is associated with a lower risk as it depletes not only T cells but also B cells (including EBV-infected B cells).

Unrelated donor HSCT for AA

Indications and timing

Unrelated donor HSCT is considered for young adults and children with severe or very severe AA who have failed one course of ATG and CSA. In older patients a second course of ATG may be preferred before proceeding to matched unrelated donor BMT. They should ideally have a fully matched (at DNA level for both class I and II antigens) donor and be under 50 years old, although patients aged 50–60 years may be considered if they have a good performance status.

Improvements in outcome after unrelated donor HSCT for AA

Up until the late 1990s, the outcome after unrelated donor HSCT for severe AA was dismal, with only 30–40% long-term survival. Subsequently, the EBMT identified a significant improvement in 5-year survival, from 32% for patients transplanted before 1998 to 57% after 1998. Improved outcome may be due to better donor matching with high-resolution DNA typing and better supportive care. Because of improved outcomes, unrelated donor HSCT is now considered earlier, after one failed course of immunosuppressive therapy as compared with the previous practice of deferring unrelated donor HSCT until patients had failed at least two courses of immunosuppressive therapy. Earlier HSCT is likely to be more successful as there would be less chance of allosensitization from multiple transfusions, reduced iron overload and less risk of exposure to infections.

Two approaches have been used to improve outcome after unrelated donor HSCT, involving modification of the condition regimen using (i) irradiation-based conditioning and (ii) non-irradiation, fludarabine-based conditioning. Deeg and colleagues used a de-escalating dose of total body irradiation (TBI), from 6 Gy to 2 Gy, in combination with cyclophosphamide 200 mg/kg and ATG. Graft rejection was low (5%) and 7-year survival was 61% for matched unrelated donor HSCT. The risk of GVHD was high, 69% for grade II–IV acute GVHD and 52% for chronic GVHD. The optimal dose of TBI was 2 Gy: survival in patients under 20 years of age using this regimen was 80%. The Japan Marrow Donor Programme has reported 154 patients exposed to varying doses of TBI/limited field irradiation and cyclophosphamide 120–200 mg/kg, with or without ATG; survival at 5 years was 56% and graft failure 11%.

The European approach has been to use a radiation-free regimen, at least in younger patients. The initial regimen comprises fludarabine 30 mg/m² daily for 4 days, cyclophosphamide

300 mg/m² daily for 4 days and ATG 15 mg/kg. Survival is 73% at 2 years, and graft rejection 18%. For children (< 14 years) survival is excellent at 84% with only 5% graft rejection, but for older patients survival is 61% and rejection 32%. Acute GVHD occurs in 11% and chronic GVHD in 27%. For older patients, EBMT now recommend the addition of 2-Gy TBI and a reduction in ATG to 7.5 mg in order to reduce the risk of EBV post-transplant lymphoproliferative disorder. With this modification, graft rejection is 12% in older patients.

The exact degree of mismatch that can be tolerated is not clear. The Japanese study identified mismatching for HLA-A or HLA-B as important, but not HLA-DR. The importance of HLA matching was examined further in a French national study. 10/10 allelic matching for HLA-A, -B, -C, -DRB1 and -DQB1 was associated with better survival and less graft rejection and GVHD, but this was not the case for HLA-A, -B, -DRB1 and -DQB1 matched grafts, suggesting that mismatching for HLA-C could be particularly important. The current viewpoint is that (i) better outcomes follow high-resolution matching that approximates a matched sibling donor and (ii) the use of more aggressive conditioning regimens for mismatched UDBMT will likely increase the rate of late complications.

Alternative forms of HSCT

Umbilical cord blood transplantation

Experience in acquired AA is still limited. Recent studies show encouraging results, although graft rejection is the major issue. In a study of nine adult patients from China who received cyclophosphamide 60 mg/kg and ATG with CSA and methotrexate, seven survived, six with stable mixed chimerism and normal or near-normal blood counts, and one with complete donor chimerism. The incidence of GVHD was low. The Japan Cord Blood Network reported 31 patients undergoing single umbilical cord blood transplantation, with a median age of 27.9 years (range 0.8–72.7). Most patients received fludarabine, TBI and melphalan, with or without ATG. Sustained engraftment was seen in only 17 patients. Median time to absolute neutrophil count above $0.5 \times 10^9/L$ was 19 days (range 12–35) and median time to platelet count above $50 \times 10^9/L$ was 59 days (range 39–145). Cumulative incidence of greater than grade II acute GVHD was 17%, and 19.7% for chronic GVHD. Survival at 2 years was 41%, but 20% for patients aged over 40 years. Favourable outcome factors were conditioning with fludarabine, cyclophosphamide and TBI, and the absence of ATG. A study of nine children from Texas, using most often fludarabine, cyclophosphamide, TBI and ATG, reported graft rejection in three patients, two of whom received a second umbilical cord blood transplantation using alemtuzumab. Actuarial survival was 78% at 3 years, there were three cases of extensive chronic GVHD, a high incidence of bacterial and viral infections, and three cases of EBV post-transplant lymphoproliferative disorder.

Haploidentical HSCT

There are only anecdotal reports during the last 5 years, mostly in children, using very immunosuppressive conditioning and CD34⁺-selected stem cells. These data show that some selected patients might benefit from this approach, but there are no large studies at present to evaluate its role further in AA.

Introduction

The primary purpose of transfusion medicine is to provide 'safe' blood when the clinician requires it. However, blood groups and immunohaematological problems of blood transfusion and transplantation are extremely interesting in their own right and their solutions have much to offer to haematology in general.

Blood group serology or immunohaematology includes the study of antigenic molecules present on the various cellular and soluble components of whole blood, together with study of the antibodies and lectins that recognize them and their interactions. However, in practice the term 'blood group serology' is generally restricted to red cell surface antigens and their interactions with specific antibodies. In this narrower sense, the complexities of human leucocyte antigen (HLA), granulocyte, platelet and plasma protein determinants do not normally fall within the blood group serologist's realm, even though all are likewise genetically polymorphic and play a role in blood transfusion.

The narrower definition of blood group serology encompasses (i) determination of the phenotype of red cells using

antibodies and reagents of known specificity; (ii) the search for and identification of antibodies using red cells of known phenotype; and (iii) compatibility testing of patients' sera against cell samples from donor units. At present, more than 2 million units of red cells are transfused to patients each year in the UK alone.

The aim of this chapter is to provide an introduction to blood group serology and to include aspects of immunology, biochemistry and molecular genetics that contribute to our understanding of blood group antigens, antibodies and antigen–antibody reactions.

The red cell membrane and chemistry of blood group antigens

The red cell membrane is composed of about 40% (w/w) lipids and up to 10% carbohydrates, the remainder being proteins. The exact arrangement of its components is still unresolved, but a rough model is shown in Figure 14.1.

The lipids of the red cell membrane can be subdivided into 60% (w/w) phospholipids, 30% (w/w) neutral lipids (mainly cholesterol) and 10% (w/w) glycolipids. The phospholipids and glycolipids play a role in the structure of the membrane and are important in the maintenance of red cell shape. These lipids have a molecular arrangement reminiscent of a tuning fork,

Figure 14.1 Diagrammatic representation of some integral red cell membrane proteins, including the band 3/Rh macrocomplex and components of the membrane cytoskeleton.

with the hydrophobic fatty acids forming the 'prongs' and the polar group the 'handle'. They are arranged in a bilayer with the 'prongs' pointing inwards and the hydrophilic 'handle' pointing out towards the plasma or towards the cytoplasmic surface of the membrane. Cholesterol is inserted between the other lipids. This arrangement allows the interior of the membrane to be in a semi-fluid state and the whole membrane to be very flexible. The lipid bilayer does not allow the passive transfer of ions. The carbohydrates are attached to the lipids and proteins, and occur only on the external surface of the membrane. They are composed of chains of monosaccharides, the majority of which are hexoses.

About 60–80% of the proteins of the membrane are released only after drastic treatment with detergents. These are the integral proteins that penetrate the lipid bilayer and, in some cases, are bound to the membrane skeleton or cytoskeleton. Cell surface proteins are not necessarily discrete units within the cell membrane. They may congregate together in lipid rafts or might be part of complexes of proteins in which the components contribute to the function of the whole. There are four types of integral proteins in the red cell membrane (Figure 14.1). Type 1 glycoproteins, typified by the glycoporphins, cross the membrane once, with the amino-terminal domain on the outside and the carboxy-terminal domain in the cytosol. The Kell glycoprotein is a type 2 structure. It also crosses the membrane once, but has the carboxy-terminal domain on the outside and the amino-terminal domain in the cytosol. Type 3 glycoproteins are polytopic: they cross the membrane several times giving rise to a series of extracellular loops, one of which is usually glycosylated. These N-glycans express ABO, H and Ii blood group activity. In most of these type 3 proteins both terminal domains are cytosolic (e.g. Rh proteins, band 3, Kidd

glycoprotein), but the Duffy glycoprotein has an extracellular amino-terminal domain. Type 5 membrane glycoproteins, which include the Dombrock and Cromer glycoproteins, reside in membrane microdomains rich in cholesterol known as lipid rafts and are attached to the lipid bilayer by a glycolipid, the glycosylphosphatidylinositol (GPI) anchor.

On the inside of the lipid bilayer is a network of glycoproteins that comprise the membrane skeleton, often called the cytoskeleton, which is responsible for maintenance of the shape and integrity of the red cell as it squeezes through the tiniest capillaries. The main components of the membrane skeleton are the α and β subunits of spectrin, which form long flexible rods, plus actin, ankyrin, proteins 4.1R and 4.2, and several other glycoproteins. Band 3, the anion exchanger and Diego blood group antigen, has an extended N-terminal domain attached to the membrane skeleton through ankyrin and proteins 4.2 and 4.1R. Glycophorin (GP)C and GPD, the Gerbich glycoproteins, have C-terminal domains attached to the membrane skeleton through protein 4.1R and p55. In addition there is evidence that several other integral membrane proteins interact with components of the membrane skeleton. Absence or reduced levels of these integral membrane proteins that interact with the membrane skeleton often result in some degree of abnormal red cell morphology.

Blood group antigens have been found in the polypeptide and carbohydrate moieties of membrane glycoproteins and in the carbohydrate moieties of glycolipids (Table 14.1). Most blood groups represent amino acid sequence changes in glycoproteins, although the Rh antigens are non-glycosylated proteins containing two or three molecules of palmitic acid. ABH and Ii antigens are found predominantly on the carbohydrate moieties of the major red cell glycoproteins band 3 (anion

exchanger) and on the glucose transporter, although they are also present on some other minor glycoproteins and on the carbohydrate portions of membrane glycolipids. P, P^I and P^K antigens are expressed on the carbohydrate of glycolipids. The M and N antigens arise from interactions between the carbohydrate and polypeptide in the glycoprotein GPA. In addition to the antigens on integral membrane components, the Lewis and Chido/Rogers antigens are not of erythroid origin and are adsorbed from the plasma. Structural details of selected antigens are given in Chapter 15.

Antigens

Originally, an antigen was defined as the part of a molecule that is bound by a specific antibody. More recently, it has become

customary to define an antigen as a substance that can stimulate an immune response (immunogenicity). Immune responses can be either positive or negative. Positive responses lead to the production of antibodies (humoral immunity) and/or proliferation of immunocompetent cells (cellular immunity) that can bind and eliminate their stimulatory antigen. In negative responses, the cells that mediate humoral and cellular immune responses are rendered non-responsive. This state is described as acquired immunological tolerance and is important in preventing autoimmune disease, as well as in establishing the ‘take’ or acceptance of transplanted syngeneic and allogeneic tissues.

The hallmark of the adaptive immune response is its specificity: specific immunocompetent cells and/or antibodies are produced, which can distinguish molecules that differ only by two or three atoms (e.g. trinitrophenol versus dinitrophenol).

As described later, even the difference between the A and B antigens is minimal. However, antibodies can often react with antigens similar, but not identical, to the stimulatory antigen (cross-reactivity). As far as is known, specific immune responses to human red cells are mediated by antibodies only; *specific* cell-mediated immunity to red cell alloantigens or autoantigens has not been described.

The parts of an antigen that bind antibodies or cellular receptors are called epitopes, and those parts of the antibodies that bind to them are called paratopes. Most antigens that occur naturally are of high molecular weight, and each antigenic molecule may have several different or several identical epitopes. As antibodies are specific for the individual epitopes and not for the antigen as a whole, antisera will usually be a collection of antibodies specific for different regions of the antigen in question, arising from different clones of immunocompetent cells (polyclonal antibodies); such antibodies can sometimes be distinguished serologically by anti-idiotypic reagents (see below).

The biological significance of blood group antigens

The functions of many red cell membrane protein structures bearing blood group antigenic determinants are known, or can be deduced from their structure (Table 14.1). Some are membrane transporters, facilitating the transport of biologically important molecules through the lipid bilayer: band 3 membrane glycoprotein, the Diego antigen, provides an anion exchange channel for HCO_3^- and Cl^- ions; the Kidd glycoprotein is a urea transporter; the Colton glycoprotein is aquaporin 1, a water channel; and the GIL antigen is aquaporin 3, a glycerol transporter. The Rh proteins and the Rh-associated glycoprotein (RhAG) together with band 3 and other proteins form a protein macrocomplex. RhAG probably functions as a channel for rapid CO_2 transfer in and out of the cell. CO_2 in the red cell is converted to bicarbonate ions by carbonic anhydrase II and then transported rapidly out of the cell to the plasma by band 3, where it is carried rapidly to the lungs.

The Lutheran, LW and Indian (CD44) glycoproteins are adhesion molecules, possibly serving their functions during erythropoiesis. The Duffy glycoprotein is a chemokine receptor and might function as a 'sink' or scavenger for unwanted chemokines. The Cromer and Knops antigens are markers for decay accelerating factor and complement receptor 1, respectively, which protect the cells from destruction by autologous complement. Some blood group glycoproteins have enzyme activity: the Yt antigen is acetylcholinesterase and the Kell antigen is an endopeptidase with the ability to cleave a biologically inactive peptide to produce the vasoconstrictor endothelin-3. The C-terminal domains of the Gerbich antigens, GPC and GPD, and the N-terminal domain of the Diego glycoprotein, band 3, are attached to components of the cytoskeleton and function to

anchor the membrane to its skeleton. The carbohydrate moieties of the membrane glycoproteins and glycolipids, especially those of the most abundant glycoproteins, band 3 and GPA, constitute the glycocalyx, an extracellular coat that protects the cell from mechanical damage and microbial attack.

The difference between red cell antigens that represent the products of alleles (e.g. A and B, K and k, Fy^a and Fy^b) is small, often being just one monosaccharide or one amino acid. The biological importance of these differences is unknown and there is little evidence to suggest that one antigen confers any significant advantage over another. Most blood group systems have a null phenotype in which the whole blood group protein is absent from the red cells or any other cells. These usually result from homozygosity for gene deletions or inactivating mutations within the genes. In most cases, individuals with these null phenotypes are apparently healthy, suggesting that whatever the precise function of the missing structure may be, some other structure must be able to substitute in its absence. However, there are exceptions; 15% of whites lack the D protein of the Rh system with no ill effect, but those rare Rh_{null} individuals who lack D and CcEe Rh proteins, as well as RhAG, have chronic haemolysis, which may be compensated by increased red cell production, but may require splenectomy for stabilization. Absence of the Xk protein causes weakness of expression of all Kell system antigens, as a result of linkage between the two proteins in the membrane, but is also associated with acanthocytosis and neurological and muscular disorders. Very rare patients lacking the RAPH glycoprotein, CD151, have disruption of basement membranes causing hereditary nephritis, epidermolysis bullosa and neurosensory deafness. A patient lacking the Diego antigen, the anion transporter, only survived with extreme medical intervention, and no person with the Yt_{null} phenotype and thus absence of neurotransmitter acetylcholinesterase has been found. On the other hand, people with the rare Bombay phenotype lack ABH antigens from all cells and tissues, with no apparent ill effect or red cell abnormality.

Some blood group antigens are exploited by pathological microorganisms as receptors for attaching and entering cells. Consequently, in some cases absence of antigens can be beneficial. The Duffy glycoprotein, expressing Fy^a or Fy^b , is used by *Plasmodium vivax* to penetrate red cells. The $\text{Fy}(a-b-)$ phenotype is common in Africans and confers resistance to *P. vivax* malaria. $\text{Fy}(a-b-)$ in Africans results from homozygosity for a mutation in an erythroid-specific transcription factor binding site, leading to absence of the Duffy glycoprotein from red cells but expression in other tissues. *Plasmodium falciparum* malaria appears to have played a part in the establishment of the ABO polymorphism. The geographic distribution of group O is consistent with selection pressure by *P. falciparum* in favour of group O individuals in malaria endemic regions and there is evidence that blood group O protects against severe *P. falciparum* malaria through reduced rosetting.

[§]Human IgE has been reported to bind to macrophages.

Antibodies

Antibodies are immunoglobulins produced by the B lymphocytes of the adaptive immune system in response to an antigen for which they exhibit specific binding. Depending on the origin of the antigenic stimulus, antibodies can be termed (i) alloantibodies, when produced by an individual against epitopes present in another individual of the same species; (ii) autoantibodies, when reactive with determinants present on the individual's own antigens; and (iii) xenoantibodies (or heteroantibodies), when produced against antigenic determinants present on the cells of another species. The first two are the antibodies encountered routinely in the blood bank; xenoantibodies can be used as antiglobulin sera or typing reagents when raised in animals against human antigens and are often present in reagents as monoclonal antibodies.

There are five classes of immunoglobulins: IgM, IgG, IgA, IgD and IgE. Antibodies with specificity for blood group antigens are found only in the IgG, IgM and, rarely, IgA classes. IgA antibodies play a minor role in blood group serology as they only appear as alloantibodies together with IgM and/or IgG. Some of the biochemical and biophysical differences between IgG, IgM and IgA are listed in Table 14.2.

Biochemistry and genetics of immunoglobulins

Figure 14.2 shows a diagram of the basic immunoglobulin molecule. This consists of four polypeptide chains arranged as two light (L) chains and two identical heavy (H) chains. The light and heavy chains are held together by disulphide (S-S) bonds. IgG and serum IgA molecules are mainly monomers of this basic immunoglobulin structure; secretory IgA is mainly dimeric. IgM molecules are pentamers, with the basic immu-

Figure 14.2 Structure of the basic immunoglobulin molecule.

noglobulin molecules held together by S-S bonds and a joining (J) chain (Figure 14.3).

There are two distinct types of light chain, kappa (κ) and lambda (λ). These are common to all immunoglobulins. Either of these chains may combine with any heavy chain, but in any one immunoglobulin molecule both light chains are of the same type and are identical; κ chains occur in about 65% and λ chains in about 35% of the normal immunoglobulins in each class. Each class has an immunologically distinct heavy chain: γ for IgG, μ for IgM, α for IgA, δ for IgD and ϵ for IgE (Figure 14.3).

Figure 14.3 Structure of IgG, IgM and IgA molecules.

There are four subclasses of human IgG (IgG1, IgG2, IgG3 and IgG4, with $\gamma 1$, $\gamma 2$, $\gamma 3$ and $\gamma 4$ heavy chains), and two IgA subclasses (IgA1 and IgA2, with $\alpha 1$ and $\alpha 2$ heavy chains).

Analyses of various light chains from different sources show that the amino acid sequence differs in half of the chain (variable region), whereas in the other half the sequence remains remarkably constant (constant region) between light chains of the appropriate κ or λ groups. Similarly, in the corresponding heavy chain, there is a variable region and a constant region when different chains are analysed.

Papain can split the basic immunoglobulin molecule into three fragments at a site near the S–S bonds that hold the heavy chains together (Figure 14.2). One fragment contains the C-termini of the heavy chains and is called the Fc fragment. The other two are called Fab fragments, each of which consists of the N-terminus of the heavy chain (Fd portion) and the whole of the light chain, and contains the antigen-binding site of the molecule.

Repetition of amino acid sequences within the heavy chain constant regions indicates that there are either three (for IgG and IgA) or four (for IgM, IgD and IgE) constant region domains for H chains. These are designated C_{H1} , C_{H2} , C_{H3} and

C_{H4} . In contrast, there is only one constant region domain for light chains and only one variable region domain for heavy and light chains. The segment between C_{H1} and C_{H2} is called the *hinge region*. This area imparts flexibility to the immunoglobulin molecule so that antigen-binding sites can span varying distances.

The vast majority of the differences between antibodies of various specificities occurs in three or four short amino acid sequences in the L- and H-chain variable regions. These hypervariable sequences contact the antigen on binding and provide the basis of antibody specificity. The remaining sequences within the variable region are known as the framework determinants. These are believed to provide the general skeleton of the antigen-recognizing region, within which variations in and between hypervariable sequences generate specificity for the different epitopes bound by different antibodies.

Amino acid sequences within framework and hypervariable segments can sometimes be recognized by specific antisera, usually from another species, raised by deliberate immunization with a particular antibody. The sequences recognized are referred to as idiotopes, and the sera that define them are called anti-idiotypes. The idiootype of the particular immunoglobulin

molecule represents the sum of all the idiotopes of all its framework and hypervariable sequences.

The binding of anti-idiotypic sera that recognize idiotopes within hypervariable sequences of the immunizing immunoglobulin can be inhibited by the specific hapten recognized by that immunizing antibody. This is because contact between the hapten and the hypervariable sequences blocks access of the idiotype-specific antibody. In contrast, binding of anti-idiotypes to framework determinants of the immunizing antibody is usually not blocked by binding of the hapten recognized by that antibody.

The great diversity in the repertoire of antibodies generated by the immune system in response to the immense variety of antigens that it encounters is a direct reflection of the immune system's ability to generate variations within the three hypervariable sequences. This ability is partly genetic in origin and arises from the random selection and joining of several separate genetic elements that produce a single intact variable region gene coding for the final variable region amino acid sequence.

The variable region genes comprise (i) genes coding for a large number of V-region sequences, with approximately 150 κ -chain, 125 λ -chain and 500 or so H-chain variable region genes; each of these genes is arranged in three exons, the random joining of which provides the variations that generate the first and second hypervariable sequences; (ii) in H chains only, approximately 10–20 D (diversity) genes; and (iii) in both H and L chains, five or six J (joining) genes.

The random joining of numerous choices, in a variety of combinations of V–J genes in L chains and V–D–J genes in H chains, during ontogeny of the immune response, generates the third hypervariable sequence and provides an additional somatic contribution for increasing the repertoire of the immune system. Following V–J/V–D–J joining, which is achieved by splicing together of certain DNA sequences and deletion of others during B-cell maturation, a further increase in antibody diversity is achieved by mutation in the spliced V gene DNA of mature B cells, during their proliferation in an ongoing immune response.

Biological and physical properties of immunoglobulins

Immunoglobulins are essentially multifunctional; not only do they bind antigen, but they also perform various other functions depending on the class. Most of these additional functions reside in the Fc fragment and are listed in Table 14.2. The most important include the following.

- 1 Complement fixation (IgM > IgG3 > IgG1 > IgG2); IgA does not bind complement in the classical pathway.
- 2 Binding to Fc receptors of mononuclear phagocytic cells, particularly monocytes and macrophages (IgG3 >> IgG1). After IgG-coated cells bind to Fc receptors on mononuclear phago-

cytic cells, they are destroyed by phagocytosis or cytotoxicity (see Chapter 16).

3 Transplacental passage: there is preferential active transport of IgG1 relative to the other IgG subclasses.

Some functions can be ascribed to particular domains, for example C_H2 or C_H2/C_H3 for complement (C1q) binding and control of catabolic rate; the hinge region for binding to the Fc receptors of macrophages and monocytes; C_H2 and C_H3 for binding to staphylococcal protein A (IgG3 does not bind) and to the Fc receptors on placental syncytial trophoblasts and lymphocytes.

For blood group-specific antibodies, these class-dependent biological functions contribute to their clinical significance. In the majority of cases, antigen–antibody binding does not cause red cell destruction per se; immune-mediated red cell destruction is usually a consequence of these secondary effector functions.

As only IgG passes the placental barrier, only IgG blood group antibodies can cause haemolytic disease of the fetus and newborn (HDFN) and only IgG1 and IgG3 will mediate significant immune red cell destruction. The IgG level in cord blood will be much the same as the level in the mother. Passively transferred maternal IgG gradually disappears from the infant after birth and is almost gone by 3 months of age. The serum of newborn infants contains a small amount of IgM of fetal origin and almost no IgA; the production of IgA and IgG starts at about 1–2 months of age.

There are many ways of separating IgG and IgM molecules by physical methods (e.g. gel filtration and affinity chromatography). In routine serology, IgG is easily distinguishable from IgM by treating sera with mild reducing agents such as 2-mercaptoethanol or dithiothreitol at low concentrations. These agents split the S–S bonds of the J chains, which link the IgM subunits, thereby rendering them non-agglutinating; IgA is either slightly affected or not affected by such reducing agents.

Blood group antibodies

Several terms have been used in the past and are still sometimes used to describe different types of blood group antibodies, including 'naturally occurring' and 'immune' antibodies, 'cold' and 'warm' antibodies, and 'complete' (or 'saline') and 'incomplete' antibodies. They are described below and an attempt is made to correlate these terms with the class of immunoglobulin involved.

Naturally occurring and immune antibodies

Antibodies are naturally occurring when they are produced without any obvious immunizing stimulus, such as during pregnancy, transfusion or injection of blood. These antibodies

are not present at birth and, in the case of anti-A and anti-B, start to appear in the serum at about 3–6 months of age. ABO antibodies are probably produced in response to antigens of bacteria, viruses and other substances that are inhaled or ingested; many Gram-negative organisms have antigens that are structurally similar to the A and B antigens. Despite this probable antigenic stimulus, the term ‘naturally occurring’ is retained for these ‘non-red cell-induced’ antibodies. ‘Immune’ blood group antibodies are only produced after pregnancy or following transfusion or injection of blood or blood group substances.

Cold and warm antibodies

Cold antibodies give higher agglutination titres at low temperatures (0–4°C) and many of them will not agglutinate red cells at 37°C. Most naturally occurring antibodies are cold reacting. Some, such as naturally occurring anti-A,B, have a wide thermal range and will still react at 37°C, at which temperature they will activate complement and lyse red cells, but the titre will be much higher at 0–4°C. Cold antibodies that fail to react above 30°C are of no clinical significance and can be ignored for blood transfusion purposes.

The thermal optimum of warm antibodies is 37°C and this implies that higher titres are obtained at this temperature. Immune antibodies are warm reacting. Any red cell antibody reacting above 30°C should be considered potentially capable of destroying red cells *in vivo*.

IgM and IgG antibodies

IgM or ‘complete’ antibodies agglutinate red cells when they are suspended in saline. They are often called saline or directly agglutinating antibodies in laboratory parlance. Conversely, ‘incomplete’ IgG antibodies will not agglutinate saline-suspended red cells. However, lack of agglutination does not mean that the antibodies have not bound to their antigen, and it can be shown that they have reacted by using antiglobulin reagents, which facilitate agglutination of antibody-coated cells (see below). Most naturally occurring antibodies are cold reacting, complete and IgM. Immune antibodies are always warm reacting; most are partly IgG, but some may be IgM. Exceptionally, and when very potent, IgG complete antibodies are found.

Monoclonal antibodies

Animal sera have generally been a poor source of blood grouping reagents. Deliberate immunization of laboratory animals to produce blood group-specific xenoantibodies has had limited success as only a few polyclonal specificities have been made in rabbits, goats and chickens. The most useful reagents have been anti-A, -B, -M, -N, -P₁, -Le^a, -Le^b and -LW.

The advent of monoclonal antibody technologies has increased the repertoire of blood grouping reagents. By fusing the spleen cells of immunized mice or rats with drug-sensitive myeloma cells and selecting for drug-resistant hybrids, it has been possible to establish permanently growing cloned cell lines in tissue culture that secrete antibodies of desired specificities. Several murine hybrids secreting human blood group-specific monoclonal antibodies have now been established, many of which were raised using immunogens other than intact red cells (e.g. anti-A, -B, -Le^a, -Le^b, -M and -N). Unfortunately, rodents have proved remarkably resistant to efforts to produce antibodies to the human D antigen.

Attempts to produce human monoclonal antibodies by the cell fusion approach have been of limited success owing to the lack of suitable human myelomas. Nevertheless, human monoclonal antibodies specific for D, other Rh antigens, Jk^a and Jk^b, and several other antigens, have been obtained by alternative approaches involving transformation of isolated peripheral blood lymphocytes from immunized individuals with Epstein–Barr virus or by fusion of human lymphocytes with mouse myelomas to form heteromyelomas. Monoclonal antibodies of murine and human origin have widely replaced polyclonal blood grouping reagents in everyday ABO and D grouping.

The future of antibody reagent production may lie in recombinant DNA technology, but a useful blood grouping reagent is still to be produced by these methods.

Lectins

Lectins are sugar-binding proteins, mostly extracted from plants and lower vertebrate animals. They are useful tools for routine and experimental blood group serology. They combine with simple sugars (e.g. fucose, galactose, *N*-acetylgalactosamine) present on the glycolipids and glycoproteins of cell membranes and body fluids. Most lectins agglutinate red cells irrespective of target cell phenotype; hence only a handful are used with any regularity in blood group serology. The three most commonly used blood group-specific lectins are extracts from *Dolichos biflorus*, *Vicia graminea* and *Ulex europaeus*, which have anti-A₁, anti-N and anti-H specificities, respectively. Several other lectins have proven valuable in investigating red cell polyagglutinability (see Chapter 15). In addition to blood grouping, lectins are also used for determining ABH secretor status and for partially purifying and identifying blood group-active membrane glycoproteins.

Complement

Complement consists of a series of proteins, mainly enzymes present in fresh plasma as inactive precursors, which react sequentially with each other to form products that are important in the immune destruction of cells, including bacteria. In

complement activation there are two stages of relevance. The first stage is the generation of the active form of the third component, C3b, which leads to the coating, or opsonization, of the cell with a large amount of protein. There are two pathways by which active C3b may be generated: the classical and alternative pathways (Figure 14.4). The second stage is the lytic stage: activation of the proteins of the membrane attack complex, comprising components C5 through C9, leads to the destruction of red cells in the circulation.

In general terms, the complement cascade is analogous to the clotting sequence. Activation of one component or group of components leads to the generation of enzyme activity for activation of the next components. To lead to haemolysis, however, the activated components in the plasma must bind to the red cell membrane (except C1, which binds only to a specific binding site on the antibody), which they do with varying degrees of efficiency. Moreover, some activated components, for example C1, C4 and C3, have specific inactivators in the plasma as well as (for C3b and C4b) in the red cell membrane itself; even though these components bind to the red cell membrane, their active life may be very short (half-life 2–25 min). As a consequence, and as happens with several IgG blood group antibodies such as anti-Jk^a and -Fy^a, the whole sequence is not completed and there is no intravascular haemolysis. In these cases, early components can be detected on the red cell surface with suitable antiglobulin reagents.

Complement components in the classical pathway are designated C1 to C9 in their native form. Apart from C4, which is activated before C2 and C3, the components are activated

sequentially according to their numerical order. Complement components in the alternative pathway include factor B, factor D and properdin. During activation of the ‘classical’ components, small-molecular-weight fragments (C4a, C3a, C5a) are released, which have important chemotactic and anaphylactic activity. Release of C3a and C5a, as well as vasoactive amines and cytokines, leads to most of the signs and symptoms observed in severe haemolytic transfusion reactions and also in febrile non-haemolytic transfusion reactions caused by white cell antibodies.

The opsonization phase of the complement sequence (Figure 14.4)

The classical pathway

The classical pathway can be activated by many factors, including antigen–antibody complexes, enzymes (trypsin, plasmin, lysosomal enzymes), endotoxins and low-ionic-strength media. Only one molecule of IgM on a cell membrane is necessary to activate the complement system, although at least two of the five IgM subunits must attach to the cell membrane, in close proximity, for activation to occur. At least two IgG molecules must combine with antigen sites very close together on the cell membrane to bring about complement activation.

The first component of complement is a complex of three protein molecules, C1q, C1r and C1s. After complement-fixing antibodies have bound to their red cell antigens (EA is often used to denote the resulting erythrocyte–antibody complex), C1 binding sites are exposed on the Fc fragments. If two such sites

Figure 14.4 The complement cascade. Component C3b plays a central role in the classical and alternative pathways.

are sufficiently close together (approximately 25–40 nm), the C1 complex is fixed through its C1q subunits. C1q is a complex molecule with six immunoglobulin-binding sites. Binding of C1q activates C1r, which in turn cleaves the third molecule, C1s, yielding the active enzyme form of the C1 complex, which is held together by calcium. In the presence of EDTA or other chelating agents, the complex falls apart and the whole process of complement fixation will not occur.

C1s can now activate sequentially C4 and C2 in the presence of magnesium, generating a second enzyme, C4b2b, called C3 convertase.

The cell-bound C4b2b can optimally activate several thousand C3 molecules by splitting them into C3a and C3b. As C3 is present in large amounts (100–150 mg/dL) in the serum, the fixation of C3b can considerably increase the globulin coating of the red cells. While C3b is still intact, opsonized red cells will adhere to monocytes and macrophages through their C3b receptors and may then be phagocytosed. C3b has a short half-life and there is no free C3b in plasma. Hence, C3b coating of IgG-sensitized cells neutralizes the inhibitory effect of free plasma IgG on immune adherence to macrophage Fc receptors and amplifies erythrophagocytosis and antibody-mediated cytotoxicity 100-fold. Thus, C3b-coated IgG-sensitized cells are destroyed mainly in the liver, where there are numerous phagocytic cells with receptors able to bind cells coated with IgG and C3b. On the other hand, cells coated with non-complement-fixing IgG antibodies can only be destroyed in the spleen where there is haemoconcentration and less competition of IgG-coated cells for Fc receptors with fresh IgG in plasma. The active phase of C3 is transient because C3b is rapidly degraded by an enzyme (C3b inactivator, C3bINA or factor I) and its accelerator (β IIH or factor H) so that only C3dg remains on the red cell surface. C3dg is an end product of the complement sequence and, by occupying the C3 sites, can prevent further binding of C3b and therefore haemolysis of the red cell. C3dg, unlike C3b, is not capable of adhering to receptors on macrophages and monocytes, so that cells coated with C3dg may return to the circulation and will be resistant to further lysis. This explains the existence of a population of C3dg-coated cells refractory to lysis in chronic cold haemagglutinin disease. C3dg-coated cells can be detected by anti-complement in the antiglobulin test.

C4b2b3b will 'trigger' the fixation of C5, C6, C7, C8 and C9, leading to the formation of the membrane attack complex on normal red cells and bringing about their lysis.

The alternative pathway

The alternative pathway does not necessarily involve antibody and represents non-specific 'innate' immunity. The proteins of the alternative pathway form a feedback loop for the conversion of C3 to C3b; the latter is both a product and reactant of this loop.

The alternative pathway can be activated by aggregated IgA, zymosan, bacterial cells or lipopolysaccharides. Initiation of the

alternative pathway is a two-step process: (i) binding of C3b to an activator and (ii) interaction of bound C3b with neighbouring surface structures. Initially, spontaneously generated fluid-phase C3b interacts with factor B to form a complex. Factor B is activated through cleavage by the protease factor D, releasing a fragment Ba into the plasma and yielding a transient alternative C3 convertase, C3bBb. The latter can be stabilized by properdin, which is essential for preventing the dissociation of C3bBb by factor H.

The alternative C3 convertase splits serum C3 into C3a and C3b. C3b attaches to the cell surface and can then combine with more factor B and D, thereby restarting the feedback loop. The amount of C3b deposited by the alternative pathway is low owing to the small amount of convertase generated and to the inefficient deposition of C3b from plasma. This contrasts with the vast numbers of C3b molecules generated by the classical pathway. The two sources of C3b are indistinguishable; both act on C5 to start the lytic phase.

The classical and alternative pathways cannot be separated from each other *in vivo*. The alternative pathway amplifies the classical pathway because, when C3b is generated, factors B and D may be activated and complexed with it to generate further C3b.

The lytic phase of the complement sequence (Figure 14.4)

The lytic phase starts with the activation of C5 by C3b, yielding membrane-bound C5b and fluid-phase C5a. This step is followed by non-enzymatic interaction of C5b with C6, C7, C8 and C9. These molecules adhere to each other to form the membrane attack complex and insert themselves into the lipid bilayer of the red cell membrane. C8 catalysed by C9 produces protein-lined cylinders in the red cell membrane that are about 10 nm in diameter. They form pores through which ions and water can enter. The osmotic pressure exerted by haemoglobin draws water into the cell until it swells and bursts.

Optimum temperature and pH for complement lysis

Many of the active complement components are enzymes and as such are very sensitive to changes in pH and temperature. The optimum pH for haemolysis to occur is 6.8 and the optimum temperature is 32–37°C. At temperatures below 15°C, the red cell cannot be haemolysed by complement and it is assumed that the last stages of complement fixation do not occur. However, the early stages of complement fixation can occur at 15°C and the components can be detected on the red cell surface with anti-complement reagents.

Ability of the antibody to bind complement

Why some antibody molecules bind complement easily and others do not is not fully understood, but several factors seem to be important.

1 The immunoglobulin class and subclass of the antibody, as discussed later.

2 At least two C1q-binding sites properly aligned and close together are necessary for complement fixation. One molecule of IgM antibody carries several C1q-binding sites, whereas one molecule of IgG carries only one and will therefore need another molecule of IgG alongside it (IgG doublet) in order to fix C1q. Therefore, for IgG antibodies to cause lysis by complement, there must be many more molecules available. It has been shown that only one molecule of IgM anti-sheep red cell antibody is needed to lyse a sheep red cell, but at least 700–1000 molecules of IgG antibody are needed to ensure that two IgG molecules are aligned in order to start the whole complement cascade.

3 If the antigen site density is low or moderate, it may be difficult for two IgG molecules to be properly aligned regardless of quantity of antibody available. This may partly explain the poor performance of IgG antibody molecules in complement fixation compared with IgM.

4 Flexibility at the hinge region is important; the wider the angle at this junction, the greater the ability of the IgG antibody to fix complement.

In red cell destruction caused by complement-fixing lytic antibodies, the number of red cells that can be rapidly destroyed is limited only by the amount of antibody and complement available. In ABO-incompatible transfusions, there may be no surviving A or B red cells in the circulation within 1 hour of transfusion. If antibodies are partially able to fix complement up to C3b (most anti-Jk^a, -K and -Fy^a), red cell destruction will be extravascular and will proceed more slowly.

Clinical significance of red cell antibodies

The clinical significance of different red cell antibodies depends partly on their destructive capacity and partly on their frequency. For example, anti-PP₁P^K (anti-Tj^a) is a very potent haemolysin, but it is of minimal importance in blood transfusion practice owing to its rarity. Conversely, ABO and D antibodies are by far the most significant, owing to their prevalence and destructive capacity.

Several factors influence immune red cell destruction *in vivo*.

1 *Plasma concentration and avidity of the antibody.*

2 *Thermal amplitude of the antibody.*

3 *Immunoglobulin class and subclass.* The complement-fixing ability of most warm-reacting IgM antibodies makes them clinically significant. Of the IgG subclasses, IgG1 and IgG3 have clinical importance because of the ability of some to fix complement up to C3b and their capacity to bind to the Fc receptors of mononuclear phagocytic cells, the effector cells of extravascular immune red cell destruction.

4 *Antibody specificity.* Several warm-reacting antibodies are incapable of causing *in vivo* red cell destruction (e.g. anti-Ch, -Rg, -Cs^a, -Kn^a, -Xg^a and most examples of anti-Yt^a).

5 *Antigen density on the red cell membrane.* The likelihood and degree of sensitization of a red cell with antibody and complement increases with the number of antigen sites on the surface.

6 *Volume of incompatible red cells transfused.* A small volume of incompatible red cells will be destroyed more rapidly than a large volume from the same donor. Larger volumes of cells may exhaust the circulating antibody available and saturate the mononuclear phagocytic system.

7 *Presence of antigen in donor plasma.* Lewis antigens (Le^a and Le^b) and the Chido and Rogers antigens are primarily in plasma and are only secondarily adsorbed onto red cells. The free antigen in plasma can react with the antibody and inhibit its binding to red cells. Also, the amount of Lewis antigen on red cells depends on the ABO group. Hence, cross-match-compatible blood, of the same ABO group, unscreened for Lewis phenotype is transfused to patients with Lewis antibodies. Furthermore, when Lewis-positive blood is transfused to patients with antibodies, the cells lose their Lewis antigens and become Le(a–b–). For this reason, Lewis antibodies are unable to cause delayed haemolytic transfusion reactions.

8 *Activity of cells of the mononuclear phagocyte system.* The ability of macrophages to remove sensitized red cells varies between individuals. Splenectomy and drugs such as corticosteroids will decrease the clearance of IgG-sensitized cells.

9 *Sensitivity of red cells to complement.* Because of the absence of cell-bound complement regulators, patients with paroxysmal nocturnal haemoglobinuria have red cells that are highly sensitive to lysis by complement activation.

10 *Extent of complement activation.* Some antibodies regularly bind complement and others do so rarely or not at all. Of the complement-binding antibodies, IgM (e.g. anti-A, -B, -PP₁P^K) will activate the complement cascade through to C9, resulting in intravascular destruction, but IgG antibodies, such as anti-Fy^a, -Jk^a and -K, the cascade is interrupted at the C3 stage. Red cells coated with IgG and C3b will be destroyed extravascularly in the liver. As a rule, Rh antibodies do not fix complement.

Blood group antigen–antibody reactions

In blood group serology, the interaction between the antigen sites on the cells and the corresponding antibody is normally detected by observing agglutination of the cells concerned. Agglutination is the result of the cross-linking of individual red cells by antibody molecules and can be thought of as occurring in two stages. The first stage is the fundamental reaction, i.e. the combination of the antibody molecules with their specific

antigen sites. The second stage is the actual linkage of the individual antibody-coated red cells.

First stage of agglutination: combination of antibody with antigen

The combination of antigen with antibody cannot be observed directly; it arises from the fit of the antigen into a structurally complementary site within the antibody molecule. The resulting complex is then stabilized by various short-range forces between the chemical groups of the antigen-binding site in the antibody and the antigenic determinant itself. These weak short-range forces include ionic attraction, hydrogen bonding, van der Waals forces and hydrophobic interactions. Individually, these forces are weak; however, when in close apposition, the simultaneous formation of a large number of bonds stabilizes antigen binding. The greater the interface between antigen and antibody, the stronger the binding forces generated and the greater the affinity of the antibody for its specific antigen.

The association of antigen (Ag) with antibody (Ab) is reversible and obeys the law of mass action, so that at equilibrium:

where k_1 and k_2 are rate constants of association and dissociation respectively. Hence, at equilibrium:

$$K = k_1/k_2 = \frac{(\text{AgAb})}{(\text{Ag})(\text{Ab})}$$

where K is the equilibrium constant for the reaction and reflects the strength of association between antigen and antibody. The greater the value of K , the greater the amount of antigen-antibody complex formed.

Factors affecting the first stage of agglutination

Factors that affect the equilibrium constant include pH, ionic strength and temperature.

pH

Most antibodies are not affected by changes in pH within the range 5.5–8.5. Below pH 4 and above pH 9, antigen-antibody complexes are largely dissociated and the antibody can be recovered in the supernatant. This is the basis of some techniques for eluting antibodies from red cells.

Ionic strength of the medium

In saline of normal ionic strength, the ionized groups of both antigen and antibody are partially neutralized by oppositely charged ions in the medium. By lowering the ionic strength while maintaining tonicity, the ions become exposed and theoretically there should be an increase in attraction. Decreasing

the ionic strength increases the rate of association (k_1) of antigen with antibody but has little effect on their rate of dissociation (k_2). Low-ionic-strength saline (LISS) solutions have been used routinely in some blood banks to increase the speed and sensitivity of pretransfusion tests. Regrettably, LISS can lead to failure to detect some clinically important antibodies, in particular anti-K.

LISS solutions are also used to coat red cells with complement components via the alternative pathway. For this reason, the use of LISS under uncontrolled conditions can lead to unwanted positive direct and indirect antiglobulin tests.

Temperature of the reaction

The effect of temperature on antigen-antibody reactions includes (i) an alteration in the equilibrium constant and (ii) an alteration of the rate of encounter. With warm antibodies, the equilibrium constant is not changed by variations in temperature, but decreasing the temperature from 37°C to 4°C slows the rate of reaction 20-fold. With cold antibodies, there is an increase in the equilibrium constant with decreasing temperature and, even though the encounter rate is reduced, stronger reactions and higher titres are found at lower temperatures.

Second, or 'visual', stage of agglutination

Factors that affect the second stage of agglutination

These include the degree of contact of the antibody-coated red cells with each other, the span of the antibody molecules, the electrical charge of the red cells, the location and density of the antigen sites on the red cells, and the capacity of the antibody to bind complement after reacting with the antigen.

Degree of contact of antibody-coated cells

This contact can be achieved by allowing the cells to settle by gravity, although full settling does not occur in a saline serum medium until 1–2 hours have elapsed. Settling can be accelerated by centrifugation, but as red cell drifts mimicking agglutination may be formed, it is best to centrifuge at quite low speeds for not more than 1 min.

Electrical charge of the red cells

Red cells suspended in 9 g/L of NaCl are negatively charged; because of this charge and the repulsive force that it generates, there is always a gap between individual red cells. The minimum distance of approach of unsensitized cells is approximately 18 nm between their membranes. This is considerably greater than the maximum distance between the two arms of an IgG molecule (12 nm). IgM molecules, with a greater distance (~ 30 nm) between the antigen-combining sites, are able to bridge this gap and thus cause agglutination of appropriate cells suspended in saline. For this reason IgM antibodies are called

'complete'. Conversely, cells coated with IgG (e.g. anti-D) approach each other to within 6 nm between the Fc ends of the coating IgG. Agglutination of IgG-coated cells can then be brought about by various agents that bring them closer together or by molecules that cross-link coating IgG, such as proteases or neuraminidase, or antiglobulin reagents.

Span of the antibody molecule

The span of an IgG molecule can be increased by mild reduction and alkylation, which opens up the hinge region by cleaving S–S bonds. Antibodies treated in this way can be used as direct agglutinins.

Location and density of antigen sites

IgG anti-A, -B, -M and -N may agglutinate the appropriate red cells in saline. This could be due to the comparatively high number of the corresponding antigen sites (see Chapter 15 and Table 14.1). For those antigens that protrude from the cell surface (e.g. ABO, MN, I, i), agglutination by the corresponding antibodies will occur more readily than for antigens embedded in the membrane (e.g. Rh).

The number of antigen sites is, for some blood group systems, a reflection of the genotype; *MM* cells will carry twice the number of M antigens as *MN* cells and will be more readily agglutinated by the appropriate antibody (dosage effect). In other systems (e.g. ABO), zygosity dosage is not apparent.

Capacity of the antibody to bind complement

If an antibody binds complement, there might be no agglutination. The simplest explanation of this absence of agglutination is that the added presence of complement molecules, close to the antibody, prevents the antibody molecules from linking up individual cells. This lack of agglutination can be dangerous. In grouping or compatibility tests, for instance, anti-A,B in a patient's fresh serum may cause partial lysis of the red cells and no agglutination of the unlysed cells. If this lysis is not noticed, the test may be read as negative and grossly incompatible blood might be regarded as compatible.

Use of enzyme-treated red cells

Several proteases (papain from papaya, trypsin from calf spleen, bromelain from pineapple, ficin from figs) are used to treat red cells and potentiate agglutination. Whether enzyme treatment of the red cells enhances agglutination by an antibody depends on the nature of the appropriate antigen. Agglutination by Rh, Lewis, P₁, Kidd, I and i antibodies is enhanced regardless of whether the antibodies are IgM or IgG. Agglutination by most examples of anti-K is not enhanced with enzyme-treated cells. Several protein antigens are destroyed by protease treatment of intact red cells. These include M, N, S, Fy^a, Fy^b, Xg^a, In^a, In^b, Yt^a, Ch, Rg, Pr and Tn (see Chapter 15).

Detection of red cell antigen–antibody reactions

Principles of agglutination techniques

There are various ways of detecting antigen–antibody reactions *in vitro*. In manual methods, tubes, microplates or gels can be used. The most widely used methods employ the following techniques.

Direct agglutination

Most IgM antibodies will directly agglutinate the appropriate red cells suspended in saline. This method is used routinely for ABO and RhD grouping using monoclonal antibodies.

Indirect agglutination

Apart from ABO, antibodies against most blood group antigens are IgG and generally will not produce direct agglutination of red cells. Such antibodies can be detected with the aid of agents that enhance agglutination, for example proteases, albumin and other colloids, and aggregating agents such as polybrene.

Antiglobulin or Coombs test

The antiglobulin test is used to detect IgG antibodies that do not cause direct agglutination of red cells carrying the corresponding antigen when suspended in saline. The technique can be used to test directly, with an antiglobulin reagent, for the presence of antibodies or complement components that are bound to the red cells *in vivo*, as in autoimmune haemolytic anaemias or haemolytic transfusion reactions; this is the so-called direct antiglobulin test (DAT). Alternatively, the test can be used before transfusion to detect IgG antibodies in a patient's serum by adding the appropriate screening test red cells and then, after incubation and thorough washing of the cells, adding an antiglobulin reagent that will agglutinate cells coated *in vitro* with antibody or complement components; this is the so-called indirect antiglobulin test (IAT).

IATs are also used with many reagent antibodies for determining blood group phenotypes. If an IAT is undertaken with red cells suspended in normal-ionic-strength saline (NISS) solution, maximum antibody uptake, and hence maximum sensitivity, is achieved within a 60–90 min incubation period. The incubation phase for IATs can be reduced to 10–15 min by using LISS solutions. LISS IATs may be performed by either suspending the test red cells in LISS before adding the patient's serum or by adding LISS to the red cell–serum mixture. LISS IAT is less sensitive than NISS IAT for the detection of some examples of anti-K if the incubation time is reduced below 15 min. A further disadvantage of LISS IAT is that, if used in the cold, clinically insignificant antibodies such as anti-P₁ and anti-Le^a may be detected more readily because of their increased uptake under low ionic strength conditions. In view of the many

LISS preparations available, it is important that the manufacturer's instructions are followed strictly.

When the DAT and IAT are performed in tubes or microplates, it is essential that the red cells are washed three or four times with a large volume of saline before adding the antiglobulin reagent, as any free IgG or complement will neutralize the anti-IgG or anti-complement reagent and lead to false-negative reactions. This test was previously mainly carried out in tubes, but the use of microplates and microcolumns containing a matrix of either a gel or glass beads is becoming increasingly popular. With columns, the wash phase, as described below, has been eliminated.

Anti-human globulin (AHG) serum was originally made by injecting animals, usually rabbits, sheep or goats, with human serum. Of particular relevance to the antiglobulin test are antibodies against IgG and complement, which should always be present in polyspecific AHG reagents. The anti-IgG component is essential for pretransfusion antibody screening and cross-matching, as the vast majority of clinically significant antibodies, apart from anti-A and -B, are IgG. The anti-complement component is needed for the detection of occasional examples of weak complement-binding antibodies (e.g. some anti-Jk^a) and for the detection of *in vivo* complement coating of red cells (i.e. in the DAT). Antiglobulin reagents are now generally produced from monoclonal antibodies to C3d and polyclonal antibodies to IgG, made in animals.

The basic composition of a polyspecific reagent is a blend of anti-IgG and anti-C3d. Anti-C4d should be avoided and antibodies against IgA and IgM are not necessarily always present in polyspecific reagents. Pure anti-IgG, anti-IgA and anti-IgM serum can be made in animals by injecting the appropriate purified immunoglobulin and removing any antibody against L chains by absorption.

Most IgM blood group antibodies can be detected readily by direct agglutination. On those occasions when it is desirable to detect subagglutinating amounts of IgM active at 37°C, the lack of anti-IgM in polyspecific reagents can be offset by the ability of most IgM antibodies to fix complement in the presence of fresh serum. Moreover, as only a few molecules of IgM are needed to start the complement sequence and lead to the binding of many hundreds of molecules of C3, the agglutination of complement-coated cells by anti-complement sera can be a very sensitive method of detecting IgM antibodies. Complement-fixing IgG antibodies will also be detected with anti-complement sera but, in most cases, they can be detected effectively by anti-IgG. However, there are exceptional examples of complement-fixing IgG red cell alloantibodies (e.g. anti-Jk^b) that are not detectable with anti-IgG, and anti-complement is essential for their identification.

Polyspecific antiglobulin reagents composed of anti-IgG and anti-C3d are perfectly suitable for pretransfusion testing, including the cross-match. For those rare cases of autoimmune haemolytic anaemia in which the test with polyspecific AHG is

negative, it is necessary to test with anti-IgA and anti-IgM, which are now available ready for use in gel microcolumns. Polyclonal and monoclonal reagents against the four human IgG subclasses are commercially available and are generally used in research for characterizing clinically significant red cell alloantibodies.

Standardization of AHG reagents

All antiglobulin reagents available at present, monospecific or polyspecific, are standardized by the producer and issued pre-diluted for immediate use or within the gel or bead matrix of a microcolumn.

When new batches of an AHG reagent or IAT microcolumns are acquired by a laboratory, they should be subjected to a minimum *verification* with several IgG antibodies of different specificities to ensure that all are detectable. Laboratories should confirm that, on each day of use, the AHG reagent is reacting according to the manufacturer's specifications, with control red cells coated weakly with IgG. The control IgG-coated cells are the same cells as those used to check the validity of negative antiglobulin tests when a washing step is part of the process; the weakly coated cells are added to each tube that has given a negative result, followed by repeat centrifugation and reading. Agglutination of these cells confirms that the AHG reagent in the tube had not been neutralized by residual unbound IgG that was not removed during washing of the original test cells.

Agents that enhance agglutination

Various agents may be added to serological mixtures to enhance the agglutinability of red cells. These include albumin and LISS, as described above, as well as polybrene and polyethylene glycol.

Inhibition of agglutination

Expected agglutination reactions with known antigens and antibodies can be neutralized by soluble antigens of the appropriate specificity. For example, the saliva of group A secretors inhibits the agglutination of group A cells by anti-A. Hydatid cyst fluid with P₁P^K activity can be used to confirm the presence of anti-P₁ in sera. Soluble antigens produced by recombinant DNA technology will become useful in reference laboratories as aids to sorting out complex serological problems.

Haemolysis

Red cell lysis indicates a positive antigen-antibody reaction mediated by IgM complement-fixing antibodies. A pink or red coloured supernatant after settling or centrifugation of red cell-antibody mixtures is an indication of red cell lysis.

Adsorption and elution tests

Specific antibodies can be removed from serum by adsorption on red cells carrying the corresponding antigen. Bound antibodies can be subsequently recovered from the washed

Figure 14.5 Enzyme-linked immunosorbent assay (ELISA) for cell-bound antibodies. Enzyme substrate is represented by open and closed stars, for colourless and coloured derivatives respectively.

sensitized red cells by elution with heat treatment, freeze-thawing, low pH or chloroquine treatment.

Specialized serological methods

Flow cytometry and enzyme-linked immunosorbent assays (ELISAs) are used for the estimation of the number of antigen sites on red cells and when more sensitive antiglobulin techniques are required. The essence of these approaches is the use of a labelled antiglobulin: in flow cytometry, fluorescent anti-IgG is used (or antibodies can be directly coupled with a fluorescent dye); in the case of ELISA, enzymes are attached covalently (i.e. conjugated) to the antiglobulin.

The execution of these assays requires antibody-coated cells or particles to be incubated with the labelled antiglobulin reagent. After incubation, excess unbound antiglobulin is washed away and bound labelled antiglobulin is then measured. For flow cytometry, a cytofluorimeter is used to measure fluorescence of each cell. For ELISA, the bound enzyme conjugate is detected through the enzyme's ability to modify, and usually effect a colour change, in its substrate (Figure 14.5). The colour intensity of the modified substrate can then be measured with a spectrophotometer.

Microcolumn tests (gel and beads)

The principle of microcolumn tests is the separation of agglutinated from non-agglutinated red cells by centrifugation through a miniature filtration column. For blood grouping, red cells are layered on microcolumns impregnated with blood grouping sera; for antibody screening and identification, phenotyped panel red cells are mixed with patients' sera within the incubation chamber of the microcolumn. After centrifugation, agglutinated red cells are retained towards the top of the microcolumn because the agglutinates are trapped by the column matrix, whereas unagglutinated red cells form a button at the bottom of the column (Figure 14.6).

Positive and negative results are discriminated by the appearance of cells trapped within the matrix or at the bottom of the microcolumn respectively. Antiglobulin tests can be accomplished by centrifuging the preincubated mixture of red cells and patient's serum through a column impregnated with

Figure 14.6 Results of a gel microcolumn test. The subject is group B D-negative. Red cells remaining at the top of the gel represent a positive result; red cells collected at the bottom of the tube represent a negative result.

anti-IgG or polyspecific AHG. Any red cells coated with IgG will be agglutinated by the free anti-IgG in the matrix of the column, giving a positive result. No washing of sensitized cells is required as IgG in the serum does not penetrate the column and so does not neutralize the anti-IgG in the column. The advantages of microcolumn techniques are the ease of reading and reproducibility, and the fact that the tests can be stored for later examination, checking, photocopying or photographing. In the Diamed ID system, Sephadex gels are used. The Ortho Biovue system uses glass beads rather than gels. Both systems can be automated and the agglutination results evaluated by image analysis.

Microplate techniques

Semi-automated blood grouping and antibody screening can be performed in microtitre plates, which can also be used for extended phenotyping of red cells, antibody identification and large-scale screening for rare red cells and antibodies. A single microplate is equivalent to 96 short test tubes and the same

basic principles of discrete analysis of agglutination apply. The advantages of these techniques include enhanced sensitivity, speed of performance, reduced reagent requirements, simplicity and reduced requirements for laboratory space and expensive equipment. Several commercial microplate-based blood grouping systems are now available that incorporate the use of bar codes to identify samples, automated liquid handling of samples and reagents, and plate readers linked to computers for easy and accurate record-keeping.

Solid-phase systems, involving microplates containing red cells adhered to the surface of the plastic, help to reduce the variability between tests that is inherent in liquid-phase systems when undertaken by different operators, and easily lend themselves to automated reading of results. Blood grouping (e.g. for ABO and D groups) by solid phase can be accomplished by the use of U-shaped microplate wells coated with the relevant antibody (e.g. anti-A, -B, -D); suspensions of patients' or donors' red cells are added to the wells and then centrifuged. Positive results appear as a carpet of cells coated over the bottom of the well. Negative results appear as a tight pinhead of unattached cells in the centre of the well.

Antibody screening and identification by a solid-phase technique can be achieved with microplates coated with a panel of phenotyped red cell ghosts. The wells are incubated with patient serum and LISS, washed and then anti-IgG is added. Anti-IgG will bind to those wells where the patient's IgG red cell antibody has bound to the relevant red cell ghost; bound anti-IgG is then easily detected by adding indicator red cells coated with IgG (e.g. D-positive cells coated with anti-D), followed by brief centrifugation, as described above.

Automated techniques

Fully automated blood grouping and antibody screening, using microcolumn techniques or microplates, are carried out in transfusion centres, where large numbers of donor samples are tested daily, and increasingly in hospital transfusion laboratories. In automated systems such as the Olympus PK, test samples are mixed with typing sera or screening cells in individual wells of a special microplate that are constructed to have a terraced surface at the bottom of the well. After incubation and settling of the red cells in the reaction mixtures, agglutination patterns are distinguished either on the basis of light transmission or by image analysis with the aid of a computer-controlled CCD camera.

Other automated systems are available for use with microcolumns, for example ID-GelStation (Diamed) and AutoVue systems (Ortho). These are fully automated walk-away systems using bar codes to identify samples, reagents and test cards. Each has a pipetting (liquid handling) station, incubator, centrifuge and reader linked to a computer to maintain the identity of the sample being tested throughout the entire testing process. Similar walk-away systems are available for use with solid-phase

microplate systems, for example Tango (Biotest), Galileo (Immucor). The Qwalys system (Diagast) applies magnetized red cells for antigen typing and antibody detection, in order to avoid centrifugation.

A continuous-flow autoanalyser is commonly used for quantification of anti-D or anti-c, especially in antenatal patients and immunized volunteers, as well as in plasma pools used for the manufacture of anti-D immunoglobulin. Manual titration is simple, but provides only a fairly crude semi-quantitative estimate of the concentration of anti-D.

Quantitative haemagglutination methods using continuous-flow automated analysers and appropriate anti-D or anti-c international standards are sensitive (e.g. as low as 0.02 IU/mL for anti-D), relatively simple, objective, rapid, of acceptable reproducibility, and amenable to routine use and standardization. The method involves the agglutination of D-positive red cells by the anti-D to be quantified, in the presence of an agglutination enhancer, while being pumped through a series of coils at set temperatures to allow the desired incubation of the segments of reactants. The agglutinates are sedimented and removed, whereas the remaining unagglutinated red cells are haemolysed by a detergent. The absorbance of the haemolysate is proportional to the amount of haemoglobin and is thus inversely proportional to the number of agglutinated cells removed. This reflects the antibody concentration, which can be calculated (in IU/mL) using the values obtained from the standard, run in parallel.

Flow cytometry can also be used for antibody quantitation, but is probably less reliable than the autoanalyser technology described above.

Blood grouping reagents

To avoid potential fatalities resulting from errors in ABO and D grouping, it is essential that the chosen ABO and RhD typing reagents have suitable potency and comply with the European Directive on *in vitro* diagnostic devices and the associated Common Technical Specifications and carry the 'CE' mark to show they are in conformance.

Blood grouping reagents prepared from polyclonal antisera should be free of unwanted antibodies and should have been exhaustively tested with an extensive panel of cells to exclude common and rare specificities before they are issued for routine use. Unwanted contaminating antibodies are generally not a problem with monoclonal reagents as they have to be extensively tested before being placed on the market. IgM monoclonal reagents are generally used for ABO, Rh and K typing.

Strict adherence to the manufacturer's instructions for each reagent is essential. Standard operating procedures should include completing the worksheet prior to testing, labelling all tubes, microplates or gels, recording results immediately after reading, repeating discrepancies and using adequate controls. Any other equipment used in an investigation (centrifuge,

incubator) must be calibrated and in range at the time that the test is undertaken.

ABO grouping has an in-built control in the reverse grouping (serum check; see Chapter 15). Controls for D typing must always be used in order to prevent a D-negative patient being mistyped as D-positive. At least two potent anti-D reagents should be used in Rh typing and these reagents must be selected to detect or not detect variants of D, as appropriate (see Chapter 15).

Antibody screening and identification

With plenty of anticipation prior to transfusion, patients' sera should be screened against unpooled group O cells from selected individuals known to carry the following antigens between them: D, C, E, c, e, M, N, S, s, P₁, Le^a, Le^b, K, k, Fy^a, Fy^b, Jk^a and Jk^b. Ideally, one cell sample should be R₁R₁ (DCe/DCe) and the other R₂R₂ (DcE/DcE), so that the Rh antigens are all in double dose. A minimum homozygous expression (i.e. double dose) of Fy^a and Jk^a should be present on one of the red cell samples. It is generally possible to meet these requirements with two cells but if more antigens are required with homozygous expression, it might be necessary to use three cells. Zygosity can be checked by molecular genetic methods.

The techniques employed for antibody screening of patient's sera need only include a well-controlled sensitive IAT, commonly using microcolumn techniques. If the antibody screening is positive, antibody identification with a second sensitive technique (e.g. enzyme-treated cells or the polyethylene glycol or manual polybrene test), in addition to the IAT, should be used against a panel of fully phenotyped red cells. Saline tests are not essential for antibody screening or identification and all incubations should be performed at 37°C; antibodies reacting at lower temperatures are of no clinical importance.

It is recommended that an autologous control be used by incubating the patient's serum with the patient's cells, by the methods used for antibody identification. All tests must follow a written standard operating procedure. Immunohaematologists should not forget that the main aim of blood group serology is to provide hazard-free transfusions.

Molecular techniques for blood grouping

Almost all the genes for human blood groups have now been cloned and the molecular bases for all the clinically important blood group polymorphisms have been determined. Consequently, it is now possible to predict blood group phenotypes from DNA with a high degree of accuracy. This is usually performed when a blood group phenotype is required but a suitable red cell sample is not available. The most important application is the determination of fetal blood groups. When a pregnant woman has a blood group antibody with the potential

to cause HDFN (see Chapter 16), it is beneficial to be able to determine whether her fetus has the corresponding antigen and consequently whether it is at risk from HDFN. Such tests usually involve RhD typing, but may also involve typing for Rhc and K antigens, and rarely other blood group antigens. The usual source of fetal DNA used to be amniocytes, obtained by amniocentesis, an invasive procedure with a small risk of spontaneous abortion and a 20% risk of transplacental haemorrhage, which could boost the mother's antibody. Non-invasive testing for D and other antigens is now used routinely in some countries, in which fetal blood group phenotype is predicted from the small quantity of free fetal DNA present in the maternal plasma. Such testing will also be useful for unsensitized RhD-negative pregnant women in order to genotype the fetus they are carrying and thus avoid giving antenatal Rh immunoglobulin prophylaxis when the fetus is shown to be D negative.

Another use of molecular methods for blood grouping is for transfusion-dependent patients, where serological methods are not possible because of the presence of transfused red cells that are always present in the patient's blood. If genotypes can be determined for all clinically important blood group polymorphisms in transfusion-dependent patients, then matched blood can be provided to prevent the patient from making multiple antibodies to blood group antigens. Tests are carried out on DNA that is isolated from whole blood from the transfused patient. Another application is blood grouping of patients with autoimmune haemolytic anaemia, whose red cells are coated with immunoglobulin, making serological typing difficult.

Several types of tests are commonly used in blood group genotyping.

1 Amplification of a portion of a blood group gene to determine whether it is present. This only applies to *RHD* of the Rh system. Presence of the amplified product can be detected by gel electrophoresis, although monitoring of the amplification by the use of a fluorescent probe in a 'real-time' system is the usual method for detecting fetal *RHD* in maternal plasma.

2 Amplification of a portion of a gene followed by detection of the polymorphism with restriction endonucleases (see Chapter 15). Kits for blood group testing by this technology are available commercially.

3 Selective amplification of a specific allele by the use of an allele-specific primer (see Chapter 15).

4 Amplification of a portion of a gene followed by direct sequence of the amplified product.

5 Allelic discrimination by polymerase chain reaction (PCR) incorporating allele-specific fluorescently labelled probes, in which relative quantities of a pair of alleles are measured.

6 Application of some sort of microarray technology in which numerous polymorphisms can be tested from a relatively small quantity of DNA.

It is unlikely that molecular genetics will be used for routine ABO and Rh typing of donors and patients, at least in the near future. However, there may be other roles for molecular blood

grouping in the future. One such function could be genotyping large numbers of blood donors for multiple blood groups in order to establish a database of donors typed for all clinically significant blood groups. This would be valuable for the treatment of transfusion-dependent patients, as it would facilitate the provision of compatible blood for those patients who have made blood group antibodies and matched blood for those who have not. To perform such testing, high-throughput methods will be required. High-throughput techniques for detecting DNA polymorphisms are available, and some are being developed for blood group testing.

The main topic of this chapter is red cell antigens and their antibodies. However, in human blood there are many other antigenic structures that stimulate the production of antibodies in recipients of blood transfusions. Leucocyte antibodies are an important cause of febrile transfusion reactions in patients who have had previous transfusions or pregnancies. Lymphocytotoxic antibodies and, rarely, platelet antibodies may be a cause of failure of the platelet count to rise after platelet transfusions. Thus, a description of granulocyte and platelet antigens and antibodies is also included. The human leucocyte antigen (HLA) system is covered in Chapter 37. Antibodies against proteins present in plasma may lead to urticarial or anaphylactic transfusion reactions; these are considered briefly.

The International Society of Blood Transfusion recognizes 308 red cell surface antigens, 270 of which belong to one of 30 blood group systems (Table 15.1). Each system represents either a single gene locus or two or three very closely linked loci of homologous genes. Each system is genetically discrete from all the others. In addition, there are 38 antigens that have not been

included in systems. Most blood groups are inherited as Mendelian characters, although environmental factors may occasionally affect blood group expression. The 35 genes representing the 30 systems have been located on a specific chromosome (Table 15.1). All are autosomal except XG and XK, which are on the X chromosome, and CD99, which is located on both the X and Y chromosomes. All the genes have been cloned.

Blood group antigens may be integral proteins or glycoproteins of the red cell membrane, or they may be membrane glycolipids. In proteins and glycoproteins, blood group polymorphisms and variants may represent differences in the amino acid sequence (e.g. Rh and Kell antigens). In glycoproteins and glycolipids, the blood group activity may reside in the carbohydrate moiety and polymorphism is associated with differences in the oligosaccharide sequence (e.g. ABO). In some glycoproteins, blood group polymorphism may be caused by amino acid substitutions, but antigen expression is also dependent on glycosylation of the polypeptide.

The ABO system

The clinical importance of a blood group system in blood transfusion lies in the frequency of its antibodies and in the possibility that such antibodies will destroy incompatible cells *in vivo*.

ABO was the first system to be recognized and remains the most important in transfusion and transplantation (histo-blood group system). Almost everybody over the age of about 6 months has clinically significant anti-A and/or anti-B in their serum if they lack the corresponding antigens on their red cells. Thus, if we consider the incidence of ABO blood groups in the UK (Table 15.2), transfusions given without regard to ABO would result in a major incompatibility (patient has the antibody and the antigen is on the transfused red cells) about once in every three cases.

Antigens of the ABO system

The vast majority of human bloods can be grouped into six main ABO phenotypes (Table 15.3), although several other rare weak variants can be distinguished serologically. The incidence of ABO groups varies very markedly in different parts of the

Table 15.2 Incidence of ABO groups in southern England.

Phenotype	Frequency (%)
O	44.9
A ₁	30.8
A ₂	10.3
B	10.1
A ₁ B	2.7
A ₂ B	1.2

world and in different races. Even in the UK, there is some variation between north and south, and in some cities the frequencies will reflect racial differences. In such areas, the blood groups of the patient population do not reflect those of the predominantly white blood donors.

Table 15.3 ABO grouping.

Agglutination of test cells with				Agglutination by test serum of			ABO group of test sample	Possible genotype
Anti-A	Anti-A ₁	Anti-B	Anti-A,B*	A cells	B cells	O cells		
–	–	–	–	+	+	–	O	O/O
+	+	–	+ [†]	–	+	– [†]	A ₁	A ¹ /A ¹ , A ¹ /O, A ¹ /A ²
+	–	–	+	–/+ [‡]	+	–	A ₂	A ² /A ² , A ² /O
–	–	+	+	+	–	–	B	B/B, B/O
+	+	+	+	–	–	– [†]	A ₁ B	A ¹ /B
+	–	+	+	–/+ [‡]	–	–	A ₂ B	A ² /B

*Anti-A,B (group O serum) is not generally used in routine laboratories.

[†]Some group A₁ and A₁B individuals may have weak anti-H in their plasma.

[‡]Serum from a proportion of A₂ (1–8%) and A₂B (22–35%) individuals contain anti-A₁.

A₁ and A₂ subgroups

The distinction between the A₁ and A₂ subgroups is usually made by using anti-A₁, which will agglutinate A₁, but not A₂, red cells. Anti-A₁ can be obtained in several ways: (i) it can be made by absorbing anti-A (from group B people) with A₂ red cells; (ii) it is found in the serum of some A₂ and A₂B persons (Table 15.3); (iii) it can be made from a saline extract of the seeds of the hyacinth bean *Dolichos biflorus*; and (iv) mouse monoclonal anti-A₁. Anti-A₁ is not used routinely as it is not necessary to distinguish group A₁ from group A₂ blood for most transfusion recipients. There is no specific antibody for A₂ red cells; if anti-A is absorbed with A₁ cells, all the antibody is removed. Group B serum can therefore be thought of as containing two antibodies: anti-A, which agglutinates both A₁ and A₂ red cells, and anti-A₁, which agglutinates only A₁ red cells. The anti-A component of group O serum also has both antibodies.

The presence of the A² allele in the presence of A¹ cannot be determined by serology. Among people who are genotypically A/O or A/B, approximately three possess the A¹ gene for every one who possesses A² (Table 15.2).

The difference between the A₁ and A₂ subgroups is partly quantitative: the red cells of A₁ and A₁B subjects have more A antigen sites than A₂ and A₂B subjects, respectively. For practical purposes, A₂ can be regarded as a weaker form of A. Table 15.4 shows quantitative differences in the number of A antigen sites on A₁ and A₂ red cells. When both the A and B antigens are present, there are less sites for each than when either is present alone. The practical importance of this lies in the fact that the A antigen of A₂B red cells may give an extremely weak reaction with anti-A, which could be missed in routine grouping tests if reagents of inadequate potency are used. Moreover, if the same person's serum contains anti-A₁ and is tested in the reverse grouping only with A₁ and not A₂ red cells, they will be grouped as B. For this reason, potent anti-A reagents reacting with A₂B cells must be used in routine blood grouping.

Table 15.4 Numbers of A and B antigen sites on red cells of various ABO groups.

Blood group of red cell	Approximate no. of A antigen sites	Approximate no. of B antigen sites
A ₁ adult	1 000 000	–
A ₁ cord	300 000	–
A ₁ B adult	500 000	–
A ₁ B cord	220 000	–
A ₂ adult	250 000	–
A ₂ cord	140 000	–
A ₂ B adult	120 000	400 000
B adult	–	700 000

There is also a qualitative difference between A₁ and A₂, but this must be very subtle because A₂ red cells can absorb all the anti-A from group B serum if the absorption is carried out at 0–4°C for sufficient time. The chemical basis is unresolved, but A-active oligosaccharide structures called type 3A and type 4A (see p. 249) might represent A₁; they are of relatively low abundance on A₁ cells, but may be absent from A₂ red cells.

H antigen

Group O cells have no antigens of the ABO system (Table 15.3) but do possess H antigen, the precursor upon which the products of the ABO genes act. The H gene (called *FUT1*) segregates independently from ABO and is on a different chromosome: ABO on chromosome 9, *FUT1* on chromosome 19. The H antigen is present to some extent on almost all red cells, regardless of the ABO group, but the amount of H antigen varies with the ABO group as follows: O > A₂ > A₂B > B > A₁ > A₁B.

Individuals with the rare Bombay phenotype are homozygous for inactive *FUT1* alleles (*h/h*). Their red cells are not agglutinated by anti-A or anti-B, regardless of ABO genotype, but are

not group O as they are also not agglutinated by anti-H. The serum of Bombay subjects contains potent anti-H, anti-A and/or anti-B that will only allow them to be transfused with the scarce Bombay blood. Parents and offspring of Bombay individuals, who are heterozygous for the inactive *FUT1* allele (*H/h*), have H and red cells of normal ABO phenotype.

Development of the A, B and H antigens

The A and B antigens can be detected on the red cells of very young fetuses, but their reactions are weaker than those of adults. Table 15.4 shows that there are fewer A and B antigen sites on cord than on adult red cells. Similarly, the H antigen is less well developed at birth than in adult life. After birth, the expression of the A, B and H antigens increases until about 3 years of age, and thereafter, in health, remains stable throughout life.

Distribution of the A, B and H antigens

ABH antigens are often referred to as histo-blood group antigens because they are widely distributed in the body. They are therefore very important in transplantation. They are present on white cells, platelets and epidermal and other tissue cells. They are also present in the plasma, whether individuals are secretors or non-secretors of A, B or H, and in the saliva and other secretions of ABH secretors (see later).

Rare ABO variants

Rare ABO variants are usually disclosed because an expected ABO antibody is missing. A sample typed as group O that has anti-B but no anti-A will usually prove to be a weak A variant. The presence of weak A or B antigens can be demonstrated either by using potent antisera or by adsorption and elution. Rare ABO variants can arise as follows.

1 Rare ABO genes. These include A_3 , A_x , A_{end} , A_m and A_{el} variants. All are extremely rare and are usually recognized by their variable reactions with anti-A and/or anti-A,B sera. Similarly, subgroups of B have been described; all are very rare.

2 Genes segregating independently of ABO. These rare variants are the H-deficiency or Bombay phenotypes described on p. 250.

3 Environmental effects. Weakening of the A antigen can occur in various types of leukaemia (usually acute myeloid). The A antigen may revert to almost normal in remission. Similar weakening of B, H and I has been described. B-like antigens may be acquired by group A individuals who are suffering from bowel infections, usually associated with carcinoma or strictures of the large bowel. Red cells with an acquired B antigen are agglutinated by some anti-B, including some monoclonal anti-B, but not by the patient's own anti-B. Bacterial deacetylases convert *N*-acetylgalactosamine, the immunodominant sugar of the A antigen, into galactosamine, a structure similar to galactose, the immunodominant sugar of the B antigen (see p. 248). In some cases, acquired B may also be associated with polyagglutination (see p. 261).

Antibodies of the ABO system

Anti-A, anti-B and anti-A,B

Sera taken from people over the age of about 6 months that do not contain the expected A and B antibodies (Table 15.3) are very rare. They should always be investigated thoroughly; often, some interesting explanation will be found, for example a rare subgroup of A, a blood group chimera or congenital absence of IgM.

It is likely that ABO antibodies arise in response to A- and B-like antigens present on bacterial, viral or animal molecules. Titres of ABO antibodies vary considerably with age, reaching a peak in young adults and then declining in old age. Titres vary depending on the techniques used: normal adult sera can have anti-A titres, by direct agglutination in saline medium, in the range 16–1024 and anti-B titres in the range 4–256, but most have saline titres below 100. The anti-A and anti-B titres of group O subjects are much higher than in group B or A subjects.

Naturally occurring anti-A and anti-B have a wide thermal range. Although they are active at 37°C, they react better at lower temperatures. The antibodies always have some IgM component and, in group A and B persons, they are almost entirely IgM. Antibodies from group O individuals, even before immunization, usually have some IgG anti-A,B, an antibody that cross-reacts with both A and B structures.

Following immunization with red cells or blood group substances, the thermal characteristics of the antibodies change, but group A and B subjects continue to produce antibodies that are mainly IgM. Most group O persons, however, will produce IgG as readily as IgM anti-A,B. Consequently, mothers of children with ABO haemolytic disease of the fetus and newborn (HDFN) are almost always group O. Immune anti-A,B are mainly IgG2, which does not cause HDFN because there are no Fc receptors for IgG2 on the cells of the mononuclear phagocyte system. When the maternal serum contains potent IgG1 and/or IgG3 ABO antibodies, HDFN may occur, although this is usually mild compared with Rh HDFN. Some IgA anti-A or anti-B is produced following immunization with A or B substances. Some differences in the serological properties of immune and naturally occurring anti-A and anti-B are shown in Table 15.5, which also indicates ways of detecting IgG anti-A or anti-B in the presence of IgM anti-A or anti-B, which has relevance to ABO HDFN, as discussed in Chapter 17.

Dangerous 'universal' donors

Good practice in pretransfusion testing requires compatibility testing, which consists of incubating the patient's serum with donor red cells. Group O red cells can be given to A, B or AB recipients and group O donors were formerly, and inappropriately, called 'universal donors'. Group O donors have anti-A, anti-B and anti-A,B in their plasma, which will react with the recipient's A or B cells. Normally, if group A, B or AB recipients

Table 15.5 Some properties of immune and naturally occurring anti-A and anti-B.

	Naturally occurring IgM	Immune IgM	IgG
Complement binding (at 37°C)	++/+++	+++	++
Agglutination of appropriate cells	+++	+++	+++
Cross the placenta	–	–	+++
Detection enhanced by anti-IgG	–	–	+++
Inhibited by soluble A or B substances (e.g. saliva)	+++	+++	–*
2-ME or DTT sensitive	+++	+++	–

*IgG ABO antibodies are usually inhibited only by large amounts of specific substance.

2-ME, 2-mercaptoethanol; DTT, dithiothreitol.

are transfused with a relatively small number of group O units of whole blood, the anti-A or anti-B that is transfused will be diluted out and neutralized by the plasma of the adult recipient, especially if plasma-reduced blood, or red cells in additive solution are used. However, if the transfused units of red cells contain potent immune haemolytic antibodies, this neutralization and dilution effect could be insufficient and the antibodies may cause marked destruction of the A or B red cells of the recipient, leading to a severe acute haemolytic transfusion reaction (HTR). For this reason, the practice of transfusing group O whole blood, or even plasma-reduced red cells, to non-O recipients should be strongly discouraged.

There is usually a shortage of group O blood, and not infrequently a surplus of group A blood. In the vast majority of cases, including emergencies, there is enough time to perform a rapid ABO group on the patient's cells, which will allow the transfusion of group-specific blood. If there is no time to do an ABO group before transfusion, red cells in optimal additive solution, devoid of plasma, should be given until the patient's blood group is known. The practice of transfusing group O platelets to non-O patients should be discouraged as the dose of adult platelets will contain at least 300 mL of plasma, unless part of it has been replaced by platelet-additive solution. Group O fresh-frozen plasma and cryoprecipitate should only be given to group O recipients. This matter is discussed again in Chapter 17.

Anti-A₁

Anti-A₁, reactive at room temperature (18–22°C), can be found in the serum of 1–8% of group A₂ and 22–35% of group A₂B

persons. Most of these antibodies are more of a nuisance in compatibility tests than of clinical importance because they often do not agglutinate A₁ red cells at 30°C and above, and so are unable to cause increased *in vivo* red cell destruction. Very rarely, anti-A₁ able to agglutinate A₁ red cells at 37°C may lead to significant destruction of A₁ red cells *in vivo*. The appropriate group A₂ or A₂B red cells should be cross-matched in these rare instances.

Anti-H

Several forms of anti-H exist.

1 Clinically significant 'true' anti-H occurs in the serum of the very rare persons with Bombay phenotype. When it does occur, it is active at 37°C and only Bombay phenotype blood may be transfused.

2 Anti-H and anti-HI, commonly found in the serum of group A₁, B and A₁B persons, react much more strongly with adult than with cord red cells. Anti-H is inhibited by secretor saliva; anti-HI is not. Although these antibodies agglutinate O red cells at 20°C, they do not usually agglutinate them at temperatures above 30°C. Very occasionally, anti-H/anti-HI may cause rapid destruction of at least some of the transfused O red cells *in vivo*. However, these antibodies will not interfere with the survival of transfused cells if ABO identical units, i.e. A₁, B or A₁B donor units, are chosen for A₁, B or A₁B recipients respectively.

ABH secretor status

About 80% of the UK population are ABH secretors as they have H antigen, plus A or B according to their ABO genotype, in a water-soluble form in their body secretions. The remaining 20% are non-secretors and have no secreted ABH antigens, regardless of ABO genotype.

Biochemistry and biosynthesis of ABH antigens

ABH antigens

A, B and H antigens on red cells are predominantly glycoproteins, the majority being on the N-glycans of the anion exchanger (band 3) and the glucose transporter. ABH antigens on red cells are also expressed on glycosphingolipids, which include paraglobosides (Table 15.6). Soluble ABH antigens are glycoproteins. Differences in the terminal sugars of the glycoproteins and glycolipids determine the specificity of these antigens: L-fucose (Fuc) for H; L-fucose plus N-acetyl-D-galactosamine (GalNAc) for A; and L-fucose plus D-galactose (Gal) for B.

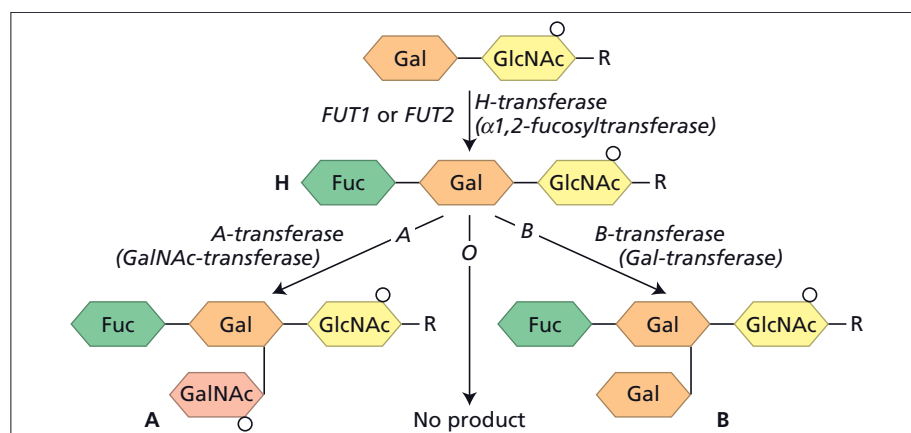

Two major types of carbohydrate chain endings serve as acceptors for the fucosyltransferases that synthesize H antigen: type 1 and type 2 chains have Gal joined to N-acetylglucosamine (GlcNAc) through 1→3 and 1→4 linkages, respectively. A- and B-transferases synthesize the transfer of GalNAc and Gal, respectively, from their donor substrates UDP-GalNAc and

Cer, ceramide; Fuc, fucose; Gal, galactose; GalNAc, *N*-acetylgalactosamine; Glc, glucose; GlcNAc, *N*-acetylglucosamine.

Figure 15.1 Biosynthetic pathway of H antigen from its precursor, and of A and B antigens from H. H remains unconverted in the absence of *A* or *B* gene products. R, remainder of molecule.

UDP-Gal to the terminal galactosyl residue of type 1 H and type 2 H, creating A and B epitopes and masking H specificity (Figure 15.1).

Secretory glycoproteins possess both type 1 and type 2 linkages, whereas red cells synthesize type 2 chains only. Plasma glycolipids, passively adsorbed onto the red cells, have only type 1 chains; these also carry Lewis antigens (see p. 250). Other chains, called type 3 and 4, are also present in low numbers on red cells, but probably only on glycolipids.

ABO genes

The *ABO* gene is located on the long arm of chromosome 9, comprises seven exons and encodes proteins with a structure characteristic of glycosyltransferases. Products of the *A* and *B* alleles differ by four amino acids encoded by exon 7, two of which determine whether the enzyme product has GalNAc-transferase (*A*) or Gal-transferase (*B*) activity.

The majority of *O* alleles (called *O*ⁱ) resemble *A*, but have a single-base deletion in exon 6, which creates a shift in the

reading frame and scrambles the amino acid sequence after the first quarter of the transferase polypeptide; introduction of a premature stop codon truncates any putative polypeptide. About 3% of *O* alleles (called *O*²) have a single-nucleotide polymorphism (SNP) that changes one of the vital amino acids in the catalytic site, inactivating the enzyme.

The *A*² allele has a single-base deletion immediately before the usual termination codon, creating a reading frameshift and abolition of this stop codon. This creates an *A*-transferase with an extraneous 21 amino acids on its C-terminus, which accounts for its reduced efficiency as a GalNAc-transferase.

Gene sequences for many variants of *A*, *B* and *O* alleles have been determined and in most cases there is heterogeneity, with more than one mutation accounting for similar phenotypes.

H genes

At least two genes, *FUT1* and *FUT2*, are responsible for production of H antigen. Both encode α 1,2-fucosyltransferases that catalyse the transfer of fucose to the terminal galactose residue of the H precursor chain (Figure 15.1). *FUT1* is active in mesodermally derived tissues, including haemopoietic tissues, and is responsible for H expression on red cells. Homozygosity for inactivating mutations in *FUT1* gives rise to Bombay and related phenotypes. *FUT2* is responsible for the expression of H antigen in endodermally derived tissues, including those responsible for secretions, and hence is the gene responsible for ABH secretion. Secretors are homozygous or heterozygous for an active allele (*Se*) at *FUT2*; non-secretors are homozygous for an inactive allele (*se*) usually containing a nonsense mutation.

The Lewis system

Antigens of the Lewis system and their biosynthesis

The Lewis system differs from all other blood group systems in that it is primarily a system of soluble antigens present in secretions and in plasma. The Lewis antigens on red cells are adsorbed passively from the plasma, and a constant presence of plasma is needed to maintain Lewis antigen on the red cells. There are two basic Lewis antigens: Le^a and Le^b. Expression of either requires the presence of an active Lewis gene, but Lewis phenotypes are also governed by the gene controlling H secretion (*FUT2*). Lewis antigens in saliva and plasma are glycoproteins and glycolipids, respectively.

The Lewis gene, *FUT3*, encodes an α 1,4-fucosyltransferase that catalyses the addition of L-fucose in 1→4 linkage to the subterminal GlcNAc of type 1 chains (Figure 15.2). If the type 1 core structure has been unmodified, Le^a antigen is produced. If the secretor α 1,2-fucosyltransferase has already modified the type 1 chains to produce type 1H, the action of the Le-transferase

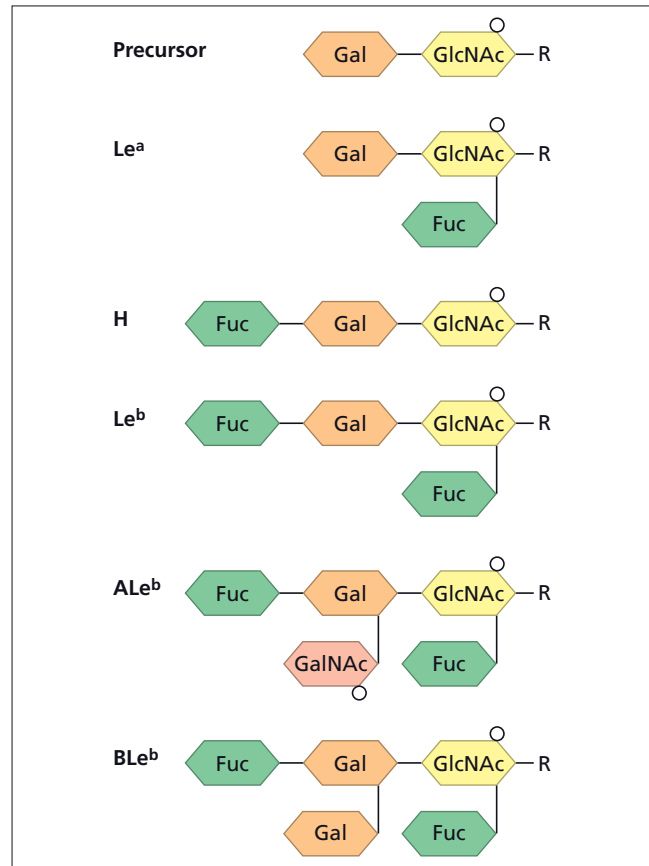

Figure 15.2 Diagrammatic representation of H and Lewis antigens. Le^a requires the action of the Lewis α 1,4-fucosyltransferase, H the action of the H α 1,2-fucosyltransferase, Le^b the action of both Lewis and H fucosyltransferases, and ALe^b and BLe^b the action of Lewis and H fucosyltransferases and the A or B glycosyltransferases.

leads to the formation of Le^b. In a white population, 75% have active Lewis and secretor genes and hence Le(a-b+) red cells; 20% have an active Lewis gene but are H non-secretors and have Le(a+b-) red cells; and 5% are homozygous for Lewis genes with inactivating mutations and are Le(a-b-) (Table 15.7). In Oriental populations there is a low incidence of non-secretors, but a high incidence of a weak secretor allele of *FUT2*. Competition between the Lewis and weak-secretor transferases leads to the Le(a+b+) red cell phenotype.

Adsorption of the Lewis substances by red cells

Le(a+b-) and Le(a-b+) red cells incubated in Le(a-b-) plasma lose their Lewis antigens into the plasma. Similarly, if Le(a+b-) or Le(a-b+) red cells are transfused into an Le(a-b-) person, the transfused cells will gradually lose their Lewis antigens and will group as Le(a-b-) within 1 week of transfusion. So, if the patient has clinically significant anti-Le^a or anti-Le^b, the red cells

that were not destroyed in the first few days will not be haemolysed once they become Le(a-b-).

Development of Lewis antigens on red cells

The Lewis antigens are poorly developed at birth and red cells from cord blood are usually Le(a-b-). Thereafter, *Le^a* develops first, followed by *Le^b* if the relevant Lewis and secretor genes are present. The cells of children between the ages of 6 months to 4 years often type as Le(a+b+) if they are destined to become Le(a-b+). The definitive adult Lewis phenotype may not be reached until the age of 4-5 years.

Antibodies of the Lewis system

Lewis antibodies are generally made only by individuals with the Le(a-b-) red cell phenotype. Anti-*Le^a* occurs fairly frequently. The incidence of Le(a-b-) is much higher in people of African and Southeast Asian origin than in whites and Lewis antibodies detectable at 22°C or above may be found in up to 10% of random serum samples from black people.

Anti-*Le^b* commonly accompanies anti-*Le^a*. Pure anti-*Le^b* is uncommon and is made by people who are non-secretors and whose red cells are Le(a-b-). Very rarely, anti-*Le^b* can be made by Le(a+b-) individuals.

Serological characteristics of Lewis antibodies

Lewis antibodies are predominantly IgM, even after deliberate stimulation. They usually agglutinate the appropriate cells at 20°C. All Lewis antibodies that react at 37°C will bind complement and may lyse antigen-positive cells. Usually, Lewis antibodies do not agglutinate red cells in saline at 37°C, but can be detected with anti-complement in an indirect antiglobulin test (IAT).

Clinical significance of Lewis antibodies

Some patients may have Lewis antibodies reacting at 37°C. Anti-*Le^a* is usually more haemolytic than anti-*Le^b*, and there are

some anti-*Le^{a+b}* that can be very potent, leading to increased intravascular red cell destruction in the initial stages of transfusion. However, all Lewis antibodies lead to two-component survival curves of transfused incompatible red cells, i.e. the first cells are destroyed at an accelerated rate and the remainder, which have been stripped of their adsorbed Lewis antigens, will have a normal survival.

For patients with Lewis antibodies reacting at 37°C, it is recommended that ABO-identical red cells, compatible in an IAT cross-match at 37°C, should be transfused. It is important to choose ABO-identical cells as group A, B and AB cells carry less Lewis antigens than group O cells routinely used in antibody screening. This is because the A- and B-transferases compete with the Lewis transferase for the same precursor substrate. The provision of pretyped Le(a-b-) blood for patients with Lewis antibodies is not necessary, as it is always easy to find cross-match-compatible red cells at 37°C.

Lewis antibodies do not cause HDFN as they are almost always IgM and newborn infants have Le(a-b-) red cells.

P blood groups

P₁ was discovered by Landsteiner and Levine, who used suitably adsorbed sera of rabbits injected with human red cells. About 75% of subjects tested were positive for *P₁*, which is inherited as a Mendelian dominant character. *P₁* frequency varies in different populations and the *P₁*-negative phenotype is called *P₂*. *P₁* is weakly expressed at birth and its strength varies considerably in adults. For this reason, identification of anti-*P₁* can be difficult, as panel cells will have varying expression of the antigen.

Anti-*P₁* is a naturally occurring antibody commonly found in the serum of *P₂* individuals. Unlike anti-A and anti-B, anti-*P₁* rarely causes transfusion reactions because it is usually a cold-reacting IgM antibody, often not reactive above 30°C.

P_1 is a structure in the paragloboside series of glycolipids. The *PI* gene is an α 1,4-galactosyltransferase that adds galactose to the P_1 precursor, paragloboside (see Table 15.6). A precursor of paragloboside is lactosylceramide, which is converted to the P^K antigen by α 1,4-galactosyltransferase-1. In most people, almost all P^K is further converted to P antigen (globoside) by β 1,3-*N*-acetylgalactosaminyltransferase-1. The very rare 'p' phenotype results from deficiency of α 1,4-galactosyltransferase-1 and leads not only to absence of P^K and P, but also P_1 because α 1,4-galactosyltransferase-1 is also the enzyme responsible for P_1 synthesis. Deficiency of β 1,3-*N*-acetylgalactosaminyltransferase-1 causes the P^K phenotype, in which the red cells express P^K antigen strongly, but no P (globoside). P^K red cells may be P_1 or P_2 .

Anti- PP_1P^K and anti-P invariably occur in the sera of the very rare individuals with p and P^K phenotypes, respectively. Anti- PP_1P^K react with all red cells except those of the p phenotype; anti-P react with all red cells except those of the P^K and p phenotypes. They are usually strong IgM antibodies, often lytic at 37°C, and can cause severe transfusion reactions if incompatible red cells are transfused. Occasionally, IgG anti-P or anti- PP_1P^K are found and have been associated with spontaneous early abortion.

The biphasic Donath–Landsteiner autoantibody is found in the sera of patients suffering from paroxysmal cold haemoglobinuria. It is always IgG and usually has anti-P specificity.

I and i antigens

The antigens I and i are not controlled by alleles: i is the biosynthetic precursor of I. I and i antigens are carbohydrates and are on the interior structures of the complex oligosaccharides that carry ABO, H and Lewis antigens. The i antigen represents linear structures that are converted to I-active branched structures by the product of the I gene (*GCNT2*), a β 1,6-*N*-acetylglucosaminyltransferase. This enzyme is not active in neonates. Consequently, red cells of most adults are agglutinated strongly by anti-I and only weakly by anti-i, whereas red cells from cord blood give the opposite result. The agglutinability of an infant's red cells with anti-I increases, and with anti-i decreases, with maturity; at about 18 months of age the red cells give the reactions of adult cells. Adults who are homozygous for rare inactivating mutations in *GCNT2* have the adult i phenotype; their red cells react weakly with anti-I and strongly with anti-i, and their serum contains anti-I.

In haematological disorders such as thalassaemia, megaloblastic anaemia, sideroblastic anaemia, hereditary spherocytosis, paroxysmal nocturnal haemoglobinuria and some aplastic and dyserythropoietic anaemias, agglutinability by anti-i is increased without a reciprocal decrease in the agglutinability by anti-I.

Anti-I

Autoanti-I that agglutinates the patient's own and other adult ABO-compatible red cells at 20°C, but not at 30°C, occurs in a variety of disorders and after blood transfusions. These patients' red cells give a negative direct antiglobulin test (DAT). A transient increase in strength, titre and thermal range of anti-I regularly occurs after infections with *Mycoplasma pneumoniae* and occasionally leads to acute haemolysis; red cells of such patients give a positive DAT, as do those of patients suffering from chronic cold haemagglutinin disease (CHAD). In CHAD, the autoantibody is nearly always monoclonal and usually has anti-I specificity. All anti-I in CHAD are IgM and complement binding.

Anti-i

Autoanti-i is found transitorily in many patients suffering from infectious mononucleosis. Very occasionally, the titre and thermal range of this antibody may lead to acute haemolysis, particularly if the patient's red cells are more agglutinable than normal with anti-i. Red cells of these patients give a positive DAT. Autoanti-i may occasionally be the antibody specificity in chronic CHAD. Such patients often have an underlying lymphoma.

The Rh system

The Rh blood group system, the fourth to be discovered, is the second most important in blood transfusion. This is not because Rh antibodies are usually present when the Rh antigen is absent, but because anti-RhD is formed readily when RhD-positive blood is transfused to an RhD-negative person. Moreover, as these immune antibodies are normally IgG, they are able to cross the placenta and cause HDFN. The Rh system now contains a total of 50 antigens, but D (RH1), because of its high immunogenicity, is by far the most important because of its ability to cause severe HDFN and HTRs.

Rh antigens

The D antigen (RH1)

In 1939, Levine and Stetson described a patient who had an antibody that agglutinated the red cells of 85% of ABO-compatible donors. She had delivered a stillborn infant and then suffered a severe reaction to transfusion of her husband's blood. In 1940, Landsteiner and Wiener found that guinea pigs and rabbits injected with rhesus monkey red cells made an antibody that not only agglutinated rhesus monkey red cells, but also the red cells of 85% of people of European origin. The human and animal antibodies were originally thought to be the same and the human antibody was called anti-Rhesus.

Results of testing with anti-D, -C, -c, -E and -e red cells from 2000 English donors, 274 Yoruba of Nigeria and 4648 Cantonese from Hong Kong.

Many years later, it was realized that the human antibody (now called anti-D of the Rh system) does not identify the same antigen as the rabbit and guinea pig rhesus antibody, the error arising out of a phenotypic association between the antigens. As it was now too late to change the name of the whole system, Levine suggested that the antigen defined by the original rhesus antibody should be called LW in honour of Landsteiner and Wiener. The blood group system originally identified by the human antibody is now called the Rh system.

For clinical purposes, individuals can be classified as Rh-positive (have the D antigen) and Rh-negative (lack the D antigen).

The expansion to include C, E, c and e (RH2–RH5)

By the end of 1943, four antisera detecting genetically related antigens were available to Fisher and Race, who noticed that two of them appeared to give antithetical results. They proposed that the antigens recognized by these two antisera were allelic and called them C and c. They gave further letters, D (the original Rh antigen) and E, to the antigens recognized by the other two antisera and postulated that each had an alternative, which they called d and e. Anti-e was found in 1945. Anti-d has never been found as no d antigen exists. Fisher and Race proposed that the Rh antigens were controlled by three closely linked genes, giving rise to eight gene complexes or haplotypes: *CDe*, *cDE*, *cDe*, *CDE*, *cde*, *Cde*, *cdE* and *CdE*. At about the same time, Wiener proposed that there was only one Rh gene, controlling a number of blood factors, equivalent to C, c, D, E and e.

Molecular genetics has shown that there are two Rh genes, one encoding D, the other encoding the Cc and Ee antigens. As the Cc and Ee polymorphisms are determined by separate regions of a single gene, the CDE terminology of Fisher and Race is still suitable for understanding Rh at most levels (although the Wiener terminology is often used as a shorthand; Table 15.8). The approximate frequencies of the Rh gene complexes in three populations are shown in Table 15.8. In a white

Table 15.9 The most common Rh genotypes in the UK population.

Genotype		Frequency (%)
<i>DCE/dce</i>	R^1r	31
<i>DCE/DCE</i>	R^1R^1	16
<i>dce/dce</i>	rr	15
<i>DCE/DcE</i>	R^1R^2	13
<i>DcE/dce</i>	R^2r	13
<i>DcE/DcE</i>	R^2R^2	3

population, the first three complexes form 94% of the total and combinations of these three will give the most common genotypes (Table 15.9). Genotype frequencies vary considerably in different parts of the world. For instance, *dce/dce* varies from about 35% in Basques to 0.3% in Japanese and Chinese.

Probable Rh genotype

When a person's Rh phenotype is known, the probable genotype can be discerned and its likelihood calculated from known genotype frequencies within the same population (Table 15.10). When probable genotype determinations are carried out, it is very important that the ethnic origin of the person is known; figures for one population will not apply to people of other populations. For example, in white populations, *dce* is 15 times more common than *Dce*, whereas in African populations *Dce* has a slightly higher frequency than *dce*. Consequently, the phenotype D+ C+ c+ E- e+ represents a probable genotype of *DCE/dce* in a white person, but of *DCE/Dce* in a black person.

Levels of D antigen expression are affected by the presence of other Rh antigens on the red cells. Table 15.10 shows the

Table 15.10 Determining probable Rh genotype in the UK population and the number of D antigen sites on red cells of those phenotypes.

Reactions with anti-					Common genotypes	Genotype incidence (%) for each phenotype		No. of D antigen sites

*Probable genotype.

number of D antigen sites on red cells of different phenotypes as estimated by the use of ¹²⁵I-labelled anti-IgG to quantify bound IgG anti-D. The *DcE* haplotype produces high levels of D expression and, for reasons still to be explained, *C* causes depression of D antigen produced by the Rh haplotype on the opposite chromosome.

Molecular genetics of Rh

Rh genes and proteins

Rh antigens are encoded by two closely linked genes with 92% sequence homology. *RHD* encodes the D antigen and *RHCE* the Cc and Ee antigens. Each consists of 10 exons and, unusually for homologous genes, the two genes are in opposite orientation on the chromosome (Figure 15.3). Each gene encodes a 416-amino-acid polypeptide of 30–32 kDa that is palmitoylated but not glycosylated. The polypeptides encoded by *RHD* and *RHCE* differ by 31–35 amino acids, depending on the *RHCE* genotype.

There is substantial evidence that the Rh polypeptides traverse the lipid bilayer 12 times, with both termini in the cytoplasm and six extracellular loops that provide the putative sites for antigenic activity (Figure 15.3). Rh antigen activity is very dependent on the conformation of the proteins within the membrane and may involve interactions between two or more of the extracellular loops. Removal of the proteins from the membrane generally ablates all antigenic activity.

Figure 15.3 Rh and related genes and the polypeptides they encode, showing the 10 exons of *RHD* and *RHCE* in reverse orientation on chromosome 1 and of *RHAG* on chromosome 6, and the RhD and RhCcEe polypeptides and RhAG glycoprotein crossing the membrane 12 times.

D, C/c and E/e polymorphisms

In white people, the D-negative phenotype almost always results from homozygosity for a complete deletion of the *RHD* gene. Consequently, D-negative represents the absence of the whole RhD protein from the membrane. Anti-D can detect epitopes on any of the external loops of the RhD protein. D-positive people may be homozygous or hemizygous for the presence of *RHD*. However, most D-negative black Africans have an inac-

tive *RHD*, called the *RHD* pseudogene (*RHD* ψ), that contains a 37-bp duplication in exon 4 and a translation stop codon in exon 6.

The Cc polymorphism is associated with three or four amino acid substitutions encoded by exons 1 and 2 of *RHCE*, although the definitive change is Ser103 for C and Pro103 for c in the second extracellular loop of the RhCcEe protein. E and e are associated with Pro226 and Ala226, respectively, in the fourth extracellular loop.

The Band 3/Rh molecular macrocomplex

The two Rh proteins are closely associated in the red cell membrane with a glycoprotein, the Rh-associated glycoprotein (RhAG). RhAG is homologous to the Rh proteins and has a similar conformation in the membrane, spanning the membrane 12 times, but is glycosylated on the first extracellular loop (Figure 15.3). Unlike *RHD* and *RHCE*, which are on chromosome 1, the gene encoding RhAG is on chromosome 6. The complex of Rh proteins and RhAG is part of a membrane macrocomplex or metabolon, with band 3 (the anion exchanger and Diego blood group antigen) at its core and also containing the LW glycoprotein (ICAM-4), CD47 and glycophorin (GP)A and GPB. This macrocomplex is attached to the membrane skeleton (see Chapter 14), primarily through ankyrin and protein 4.2.

The function of the Rh/RhAG complex is unknown, although evidence exists that RhAG might function as a gas channel for CO₂ and possibly O₂. The Rh proteins are only present on erythroid cells, but RhAG and non-erythroid related proteins (RhBG, RhCG) are more widely distributed and homologues are found throughout the animal and plant kingdoms where they often function as ammonium transporters.

Variants of D

Most D-negative individuals lack the whole RhD protein from their red cells and, when immunized by D-positive red cells, can make antibodies to an array of epitopes on the external loops of the RhD protein. About 30 D epitopes have been defined using monoclonal antibodies. There are numerous variants of D, which have, for convenience, been divided into two types, weak D (formerly D^u) and partial D, though in reality the boundaries have been blurred and the situation is more complex than that. Numerous variants of e are known, generally found only in people of African origin.

Weak D

By definition, weak D red cells express all epitopes of D at a low level and individuals with weak D phenotype cannot make anti-D. Red cells that have the weak D phenotype should, for most transfusion purposes, be regarded as D-positive. Weak D red cells have fewer D sites per cell than normal D-positive red cells. In a white population, the gene for weak D is commonly accom-

panied by *RHCE* encoding either a C or E antigen (*D*^{weak}*Ce* or *D*^{weak}*cE*); *D*^{weak}*ce* is rare. Weak D is more common in Africans and is usually produced by *D*^{weak}*ce*. It is important that anti-D typing reagents should detect most weak D phenotypes, especially in blood donors, although very weak forms of D will be typed as D-negative. The weakest form of weak D, named DEL, can only be detected serologically by absorption and elution tests.

In the UK, the recommended method for D typing of patients requires direct agglutination tests, in duplicate, with potent IgM monoclonal anti-D reagents. An antiglobulin test is not required. This means that very weak D red cells will be typed as D-negative. This is not considered important, as the patient will be harmlessly transfused with D-negative red cells. Donors are not typed any longer for D by an antiglobulin test, as this is not necessary because it is unlikely that transfusion of very weak D red cells to a D-negative patient will result in immunization of the patient.

Partial D

Partial D antigens have some or many of the D epitopes missing; those that are present may be expressed normally or weakly. If immunized with normal D-positive red cells, individuals with partial D can make antibody to the D epitopes they lack. This antibody will not react with the subject's own cells, or with partial D red cells of the same type, but will behave as anti-D when tested with red cells of common Rh phenotypes. Over 40 different types of partial D have been recognized and the classification of these D variants can only be made by serological methods in a few specialized reference laboratories.

The most important partial D antigen, from a transfusion perspective, is called DVI ('D six'). It is not the most common, but lacks most of the D epitopes and is the most commonly encountered partial D associated with the production of anti-D. In the UK it is recommended that anti-D reagents for typing patients should not detect DVI. Consequently, DVI patients will be transfused with D-negative red cells and DVI pregnant women will be given anti-D prophylaxis. Ideally, one of the anti-D reagents used for typing donor red cells should detect DVI. Consequently, DVI individuals should be considered D-negative patients but D-positive donors.

Molecular basis of D variants

Partial D antigens result either from missense mutations in *RHD*, encoding single amino acid changes, or from *RHD* in which a segment has been replaced by the equivalent segment of an *RHCE* gene. For example, the most common form of DVI is produced by an *RHD-CE-D* hybrid gene in which exons 4–6 have the nucleotide sequence of *RHCE*, and external loops 3 and 4 of the encoded hybrid protein have the amino acid sequence of an RhCe protein. Hence, a protein is produced with a sequence similar enough to *RHD* to be stable in the membrane, but different enough to lack many epitopes of D. A

variety of names have been used to denote the different types of partial D, for example DIII1, DVI, DFR, DAR, DBT. These can mostly be distinguished by sophisticated serological techniques.

Weak D results from missense mutations in *RHD* that encode amino acid changes that are predicted to be in the cytoplasmic or membrane-spanning domains of the D protein, but not in any of the loops exposed to the exterior of the cells. Based on molecular genotyping, at least 60 different types of weak D have been identified, and these have been numbered. They cannot be distinguished serologically. The three most common weak D types are weak D type 1 (70%, Val270Gly), type 2 (18%, Gly385Ala) and type 3 (5%, Ser3Cys).

Unfortunately, some D variants, for example weak D type 4.2 and weak D type 15, have been given weak D numbers based on their molecular background, but have subsequently been found in a number of cases to be associated with anti-D production and so are really partial D. Clearly a new terminology is needed and care must be taken in making transfusion decisions based on the terminology derived from molecular testing.

Other Rh antigens

Table 15.11 lists the antigens of the Rh system recognized by the International Society of Blood Transfusion. A few of these are described below.

C^w and C^x antigens (RH8 and RH9)

C^w and C^x occur in about 2% and 0.2% of white people, respectively, although substantially higher frequencies are found in Finns. They appear to have an allelic relationship, although C^w and C^x represent Gln41Arg and Ala36Thr substitutions in an RhCcEe protein, respectively. Anti-C^w and anti-C^x have caused HDFN but on the rare occasions on which this has occurred, it has usually been mild.

G antigen (RH12)

With only rare exceptions, G is expressed when either D or C, or both, are present. Anti-G recognizes a determinant common to the products of *RHD* and the C allele of *RHCE*. Anti-G usually occurs with anti-D (see p. 257).

Table 15.11 Antigens of the Rh system.

Number	Alternative names	Frequency*	Number	Alternative names	Frequency*
RH1	D	Polymorphic	RH32	R ^N	Low
RH2	C	Polymorphic	RH33	Har	Low
RH3	E	Polymorphic	RH34	Hr ^B	High
RH4	c	Polymorphic	RH35	R ^N -like	Low
RH5	e	Polymorphic	RH36	Be ^a	Low
RH6	ce, f	Polymorphic	RH37	Evans	Low
RH7	Ce	Polymorphic	RH39	C-like	Polymorphic
RH8	C ^w	Polymorphic	RH40	Tar	Low
RH9	C ^x	Low	RH41	Ce-like	Polymorphic
RH10	V	Polymorphic [†]	RH42	Cce ^s	Polymorphic [†]
RH11	E ^w	Low	RH43	Crawford	Low
RH12	G	Polymorphic	RH44	Nou	High
RH17	Hr _o	High	RH45	Riv	Low
RH18	Hr	High	RH46	Sec	High
RH19	hr ^s	Polymorphic	RH47	Dav	High
RH20	VS	Polymorphic [†]	RH48	JAL	Low
RH21	C ^G	Polymorphic	RH49	STEM	Low
RH22	CE	Low	RH50	FPTT	Low
RH23	D ^w	Low	RH51	MAR	High
RH26	c-like	Polymorphic	RH52	BARC	Low
RH27	cE	Polymorphic	RH53	JAHK	Low
RH28	hr ^H	Polymorphic [†]	RH54	DAK	Low
RH29	Total Rh	High	RH55	LOCR	Low
RH30	Go ^a	Low	RH56	CENR	Low
RH31	hr ^B	Polymorphic	RH57	CEST	High

*Polymorphic indicates > 1%, < 99% in at least one major population.

[†]Only polymorphic in black people, low in other populations.

VS and V antigens (RH20 and RH10)

VS and V have frequencies of about 40% and 10%, respectively, in Africans, but are rare in other ethnic groups. Both are associated with an *RHCE* mutation encoding Leu245Val, but only VS is expressed when a Gly336Cys mutation is also present. Neither anti-VS nor anti-V have caused HDFN or an HTR.

Compound antigens

Antibodies to the compound antigens, anti-ce (-f, -RH6), anti-Ce (-RH7), anti-cE (-RH27) and anti-CE (-RH22), define pairs of CcEe antigens present only when they are encoded by the same *RHCE* gene. For example, anti-Ce and anti-cE will react with D+ C+ c+ E+ e+ cells of *DCe/DcE* genotype, but not *DCE/dce*, whereas the reverse applies to anti-ce and anti-CE.

Rh_{null}, Rh_{mod} and D--**Rh_{null} and Rh_{mod}**

Rh_{null} red cells lack all antigens of the Rh system and people with this rare phenotype can make an antibody, anti-RH29, that reacts with all red cells except those of the Rh_{null} phenotype. They also lack RhAG, LW, and Fy5 of the Duffy system, and have weakened expression of CD47 and of S, s and U antigens on GPB. Rh_{null} subjects have a chronic haemolytic stomatocytic anaemia, which is usually compensated but may require splenectomy.

There are two modes of inheritance of the Rh_{null} phenotype.

1 Homozygosity for a deletion of *RHD* (characteristic of most D-negatives) plus homozygosity for an inactivating mutation in *RHCE*. Consequently, neither Rh protein is produced. Both parents are heterozygous for the mutations and possess only half of the usual quantity of Rh antigens. This is the rarer of the two types.

2 Homozygosity for inactivating mutations (frameshift, splice site, missense) in *RHAG*, the gene encoding RhAG. In the absence of RhAG, no Rh antigens are expressed, despite the presence of normal Rh genes. Consequently, individuals with this type of Rh_{null} inherit normal Rh genes from their parents and pass them on to their offspring. These parents and offspring are heterozygous for the *RHAG* mutation and have apparently normal Rh antigens, although there may be some weakening of expression. The parents of both types of Rh_{null} individuals are usually consanguineous.

Rh_{mod} arises from partial inactivation of *RHAG*, caused by mutations encoding single amino acid substitutions. This results in weakened expression of all Rh antigens. Rh_{mod} individuals cannot make anti-RH29.

D-- and related phenotypes

Homozygosity for a rearranged *RHCE* gene, together with an active *RHD*, results in a series of phenotypes, called D--, D**, Dc- and DC^w-, in which no E or e antigens and, in the case of D-- and D**, no C or c is produced. These phenotypes are very

rare and have enhanced expression of D. If transfused, individuals with these phenotypes produce anti-Hr_o (-RH17), an antibody that reacts with all red cells except for Rh_{null} cells and cells with D-- and related phenotypes.

Antibodies of the Rh system**Naturally occurring antibodies**

Generally, Rh antibodies are only produced following immunization with red cells. However, anti-E is often naturally occurring; about half may occur without a history of pregnancy or transfusion. Rarely, naturally occurring anti-D and anti-C^w are found. All such naturally occurring Rh antibodies react optimally with enzyme-treated cells.

Immune antibodies

The clinical importance of the Rh system lies in the readiness with which anti-D arises in D-negative subjects after stimulation with D-positive red cells by pregnancy or transfusion. Prophylaxis against D immunization with anti-D immunoglobulin has led to a significant decrease in the incidence of anti-D, but it still remains the most common immune antibody of clinical relevance detected in a routine blood transfusion laboratory. D is considerably more immunogenic than the other Rh antigens, which have the following order of immunogenicity: c > E > e > C.

About 20–30% of anti-D sera also appear to contain anti-C. Usually, this anti-C is not a separable antibody and is probably more correctly called anti-G (see p. 256). About 1–2% of anti-D sera also contain anti-E. Anti-C (and anti-G) in the absence of anti-D is very uncommon.

The incidence of other Rh antibodies is much lower, but together they are more common than anti-K (Kell), which is the most immunogenic antigen after D. In routine screening, pure anti-E is the most common, followed by anti-c, although anti-c is a more common cause of HDFN, which can be severe. This is probably because about half of the examples of anti-E are weak, naturally occurring antibodies. Anti-e, like anti-C, is very rare.

The vast majority of Rh antibodies are IgG and do not fix complement. Anti-D may occasionally be partly IgA. IgM anti-D is very rare.

D immunization

The realization that D-negative women without anti-D who had just delivered a D-positive child could be protected from forming anti-D by the injection of IgG anti-D soon after delivery has been a powerful stimulus for experimental work on D-negative volunteers. About 90% of D-negative people will make anti-D after the transfusion of a large volume of D-positive cells, and 70% will respond to repeated small volumes.

It has been shown that 20 µg (100 IU) of anti-D immunoglobulin given intramuscularly will give complete protection

from 1 mL of concentrated D-positive red cells (approximately 2 mL of blood). This figure is the basis for the standard dose of 100 µg (500 IU) anti-D immunoglobulin given post partum in the UK, as it will cover the vast majority of cases of transplacental haemorrhage (TPH). A dose of 3.2–4.0 mg of anti-D immunoglobulin given intravenously will protect a D-negative recipient against the consequences of inadvertently transfusing a unit of D-positive whole blood (c. 200 mL of red cells). If D-positive platelets need to be given to D-negative girls and women of childbearing age, they should be protected with a dose of intravenous anti-D immunoglobulin.

The mechanism of protection by anti-D immunoglobulin is not really known. Two explanations have been suggested. The first is that the passively administered antibody leads to phagocytosis of antibody-coated red cells and their rapid destruction by mononuclear phagocytic cells in the spleen before they can combine with receptors of immunologically competent cells. The second is a central mechanism by which the Fc fragment of the antibody combined to antigen might give a suppressive or inactivating signal to the immunocompetent cells. It has been calculated that the amount of passive antibody needed to protect the recipient from antibody formation is less than that needed to cover all the D antigen sites on the injected Rh-positive cells.

Prior to the advent of Rh immunoprophylaxis, the first ABO-compatible, D-positive baby resulted in the primary immunization of about 17% of D-negative women. In about half of these women, the antibodies appeared within 6 months of delivery; in the other half, the antibodies became detectable by the end of the second pregnancy.

Source of anti-D for immunoprophylaxis

Anti-D is usually obtained from immunized D-negative volunteer men and from women unable to bear children from the USA. Those with low levels of anti-D are deliberately restimulated with D-positive red cells. Plasma from these donors is harvested by apheresis and sent to a fractionation plant for processing. It is unlikely that the use of human monoclonal anti-D for prophylaxis will become a reality in the near future, since clinical trials have been fraught with difficulty.

Detection of fetal red cells in the maternal circulation

Fetal red cells can be detected in a sample of maternal blood by the acid elution method of Kleihauer, which depends on the fact that fetal haemoglobin is more resistant to elution in an acid medium than adult haemoglobin. Thus, fetal haemoglobin is retained in the cell and the fetal red cell stains darkly with the counterstain, whereas adult haemoglobin elutes and the mother's red cells appear as ghosts. Fetal D-positive cells can also be quantified in the maternal circulation by flow cytometry after fluorescent staining with anti-D, with as few as 0.05% of fetal cells being detected.

Fetal red cells can frequently be detected in the mother's circulation, particularly during the last trimester of pregnancy and after delivery. In about 85% of blood samples taken soon after delivery, the proportion of fetal cells to adult cells is less than 1 in 20 000 (equivalent to a TPH of less than 0.5 mL). In two to three samples per 1000 deliveries, the TPH will be of the order of 10 mL of whole blood (5 mL of red cells) or more. Such women, if D-negative and delivering a D-positive infant, will not be protected by the standard UK anti-D immunoglobulin dose of 100 µg and additional protection should be given. All laboratories should standardize the conditions of the acid elution technique (or any other quantitative technique) in order to estimate the absolute amount of fetal red cells present in the maternal circulation.

Immunization by abortion, miscarriage and obstetric intervention

Abortion and miscarriage can induce the immunization of D-negative women; the incidence is greater if the abortion is therapeutic and if it occurs in the second trimester rather than in the first. Amniocentesis, chorionic villus sampling, fetal blood sampling and other obstetric manoeuvres can also lead to immunization of D-negative women carrying a D-positive fetus.

Prediction of fetal Rh genotype by molecular methods

Knowledge of the molecular basis for D-negative phenotypes has made it possible to devise tests for predicting fetal D type from fetal DNA. This is valuable in determining whether the fetus of a woman with anti-D is at risk from HDFN. Most methods involve polymerase chain reaction (PCR)-based tests that detect the presence or absence of *RHD*, but it is also important to test for more than one region of *RHD*, so that hybrid genes responsible for partial D antigens do not give a false result, and to test for the *RHD* pseudogene (*RHDψ*), so that this does not give rise to a false-positive result.

Although fetal DNA can be obtained by amniocentesis, this procedure is associated with a significant risk of fetal loss and fetomaternal haemorrhage. An alternative source of fetal DNA for determining fetal D type in D-negative pregnant women is the small quantities of free fetal DNA present in maternal plasma. This non-invasive form of fetal D typing is now provided for pregnant women with significant levels of anti-D as a reference service in the UK and some other parts of Europe.

It is a common practice to offer all D-negative pregnant women one or two doses of anti-D immunoglobulin at around 28–30 weeks' and 34 weeks' gestation to prevent antenatal immunization. However, in a predominantly white population about 40% of these women will have a D-negative fetus and receive the treatment unnecessarily. Several successful trials have been carried out on high-throughput methods for deter-

mining fetal D type from DNA in maternal plasma, and it is likely that fetal D testing of all D-negative pregnant women will be available in some countries within the next few years. The testing will make it possible to discern which women are in need of routine antenatal prophylaxis because they are carrying a D-positive fetus.

The MNS system

MNS was discovered by Landsteiner and his colleagues in 1927 and the MNS genes were the first blood group genes to be cloned, in 1986 and 1987. The MNS system now contains 46 antigens.

Antigens of the MNS system

M and N are inherited as codominant Mendelian traits, giving rise to three common genotypes *M/M*, *M/N* and *N/N*. The *Ss* locus, which is closely linked to *MN*, also consists of two codominant alleles, at least in Europeans and Asians, producing S or s antigens. In northern Europeans, haplotype frequencies are as follows: *MS*, 25%; *Ms*, 28%; *NS*, 8%; *Ns*, 39%. The system also contains many variants. About 2% of black West Africans and 1.5% of African-Americans are S- s- and most of these lack the U antigen that is present when either S or s is expressed.

The MN antigens are carried on GPA, which is encoded by the *GYP A* gene on chromosome 4. M and N differ by amino acids at positions 1 and 5 of the external N-terminus of GPA. There are about 1 million molecules of GPA per cell, yet their absence in the rare En(a-) phenotype does not affect red cell function or survival. The negative charge of the red cells is mainly due to the ionized COOH groups of sialic acid (neuraminic acid), which is mostly carried on the oligosaccharides of GPA and can be removed with neuraminidase. En(a-) cells therefore have a reduced negative charge and behave serologically as if they have been treated with neuraminidase. GPB carries the S and s determinants, which represent an amino acid substitution at position 29. GPB is encoded by *GYP B*, which is closely linked and homologous to *GYP A*. S- s- U- red cells lack GPB. The sequence of the N-terminal amino acids of GPB is identical to that of N-specific GPA and accounts for the weak 'N' reactivity of *M/M* cells, provided they are S+ or s+. The numerous MNS variants mostly result from amino acid substitutions in GPA and GPB and from the formation of hybrid GPA-GPB molecules, formed by intergenic recombination between *GYP A* and *GYP B*. GPA and GPB are exploited as receptors by the malaria parasite *Plasmodium falciparum*.

Antibodies of the MNS system

Anti-M is uncommon and reacts with about 80% of random samples. It is usually naturally occurring, but can be immune and, very rarely, causes HDFN.

Anti-N is also rare and reacts with about 70% of random samples. It is nearly always a cold-reactive IgM antibody. Because of the 'N' activity of GPB at low temperatures, anti-N reacts with, and can be completely absorbed by, *M/M* cells, except those of the M+ N- S- s- phenotype. Useful anti-N lectin can be prepared from the seeds of *Vicia graminea*.

Anti-S, the rarer anti-s and anti-U are usually immune, IgG and can cause HDFN. They have also been implicated in HTRs. Anti-U only occurs in S- s- black people and reacts with all cells that have the S or s antigens and up to 50% of cells that are S- s-. Finding compatible blood for a patient with anti-U can prove difficult.

The Lutheran blood group system

Lutheran is a complex system comprising four pairs of allelic antigens: Lu^a and Lu^b, Au^a and Au^b, Lu⁶ and Lu⁹, Lu⁸ and Lu¹⁴. These represent single amino acid substitutions in the Lutheran glycoproteins. There are another 11 antigens of very high frequency in this system. The incidence of Lu^a/Lu^b phenotypes in the UK population is as follows: Lu(a+b-), 0.1%; Lu(a+b+), 7.5%; Lu(a-b+), 92.4%. The extremely rare Lu_{null} phenotype, in which no Lutheran antigens are expressed, results from homozygosity for an inactive Lutheran gene; anti-Lu³ may be produced. Individuals heterozygous for a dominant suppressor gene, *In(Lu)*, have very low levels of Lutheran antigens and reduced levels of some other blood group antigens, including P₁ and In^b. *In(Lu)* represents mutations in the erythroid transcription factor gene *EKLF*.

Lutheran antibodies are uncommon and are not generally considered clinically significant, although anti-Lu^b may have caused mild delayed HTRs. Lu^a may be omitted from antibody screening cells.

The Lutheran glycoproteins bind the extracellular matrix glycoprotein laminin and might function as adhesion molecules with a role in erythropoiesis.

The Kell blood group system

The Kell system consists of one triplet and four pairs of allelic antigens – K and k; Kp^a, Kp^b and Kp^c; Js^a and Js^b; K11 and K17; K14 and K24 – all of which represent amino acid substitutions in the Kell glycoprotein, plus 15 high-frequency and five low-frequency antigens.

In European whites, the incidence of the K/k phenotypes, the most important clinically, is as follows: K+ k-, 0.2%; K+ k+, 8.7%; K- k+, 91.1%. K is rare in populations other than those of white people. Js^a is present in about 20% of black people, but is extremely rare in other ethnic groups. The very rare null

phenotype of the Kell system, in which no Kell system antigens are expressed, is called K_0 , and results from homozygosity for a variety of inactivating mutations in the *KEL* gene.

The Kell antigens are located on a glycoprotein of 93 kDa, which crosses the cell membrane once and has a large glycosylated C-terminal extracellular domain, maintained in a folded conformation by multiple disulphide bonds. Reduction of these bonds by 2-aminoethylisothiuronium bromide (AET) results in loss of expression of all Kell system antigens. The Kell glycoprotein has sequence and structural homology with a family of neutral endopeptidases that processes biologically important peptides. The Kell glycoprotein cleaves the biologically inactive peptide big endothelin-3 to produce endothelin-3, an active vasoconstrictor. Whether Kell performs this function *in vivo* is not known.

The Kell glycoprotein is linked by a single disulphide bond to the Xk protein, which is produced by an X-linked gene, *XK*. Absence of Xk protein, resulting from hemizyosity in males of a deletion of *XK* or *XK* inactivating mutations, gives rise to the McLeod phenotype, in which there is no expression of Kx antigen and weak expression of all Kell system antigens. This rare phenotype is also associated with McLeod syndrome, a neuroacanthocytosis that is usually characterized by late-onset muscular, neurological and, occasionally, psychiatric disorders, and abnormally shaped red cells. In some cases, an X chromosome deletion is large enough to encompass *XK* and *CYBB*, a gene for a subunit of flavocytochrome b_{558} , which leads to McLeod syndrome and chronic granulomatous disease (CGD). If boys with McLeod syndrome and CGD are transfused, they are liable to make anti-Kx, which can cause severe HTRs and makes compatible blood very difficult to find.

Anti-K is an important antibody in white populations; it is nearly always immune, IgG and complement-binding. It causes severe HTRs and HDFN. K antigen stimulates the formation of anti-K in about 10% of K-negative people who are given one unit of K-positive blood. About 0.1% of all cases of HDFN are caused by anti-K; most of the mothers will have had previous blood transfusions. HDFN caused by anti-K differs from Rh HDFN in that anti-K appears to cause fetal anaemia by suppression of erythropoiesis, rather than immune destruction of mature fetal erythrocytes. Kell antigen is expressed by erythroid cells at a very early stage of erythropoiesis and anti-K probably facilitates immune destruction of early erythroid progenitors, before they become haemoglobinized. Anti-K is best detected by the IAT; anti-K does not always agglutinate red cells treated with enzymes or suspended in low-ionic-strength solution.

Anti-k is a very rare antibody, which reacts with 99.8% of random blood samples. It is always immune and has been incriminated in HDFN. Most other Kell system antibodies are rare and best detected by the IAT.

The Duffy blood group system

Fy^a and Fy^b antigens represent a single amino acid substitution in the extracellular N-terminal domain of the Duffy glycoprotein. Their incidence in the UK is as follows: $Fy(a+b-)$, 20%; $Fy(a+b+)$, 46%; $Fy(a-b+)$, 34%. About 70% of African-Americans and close to 100% of West Africans are $Fy(a-b-)$. They are homozygous for an Fy^b allele containing a mutation in a binding site for the erythroid-specific GATA-1 transcription factor, which means that Duffy glycoprotein is not expressed in red cells, although it is present in other tissues. The Duffy glycoprotein is the receptor essential for penetration of *Plasmodium vivax* merozoites into erythroid cells and the $Fy(a-b-)$ phenotype confers resistance to *P. vivax* malaria. An identical GATA mutation is found in an Fy^b allele in Papua New Guinea and in Brazil.

The Duffy glycoprotein (also called Duffy-antigen chemokine receptor, DARC) is a red cell receptor for a variety of chemokines, including interleukin 8. It might function as a 'sink' or scavenger for the removal of unwanted chemokines.

Anti- Fy^a is not infrequent and is found in previously transfused patients who have usually already made other antibodies. It is IgG, often complement-fixing and can cause HTRs, but seldom HDFN. It is best detected by IAT and does not react with red cells treated with the proteases papain and ficin. Anti- Fy^b is very rare and is always immune.

The Kidd blood group system

Kidd has two alleles, Jk^a and Jk^b , which represent a single amino acid change in the Kidd glycoprotein. Phenotype frequencies in the UK population are as follows: $Jk(a+b-)$, 25%; $Jk(a+b+)$, 50%; $Jk(a-b+)$, 25%. A Kidd null phenotype, $Jk(a-b-)$, results from homozygosity for inactivating mutations in the Kidd gene, *SLC14A1*. It is very rare in most populations, but reaches an incidence of greater than 1% in Polynesians. The Kidd glycoprotein is a urea transporter in red cells and in renal endothelial cells.

Anti- Jk^a is uncommon and anti- Jk^b is very rare, but they may both cause severe transfusion reactions and, to a lesser extent, HDFN. Kidd antibodies have often been implicated in delayed HTRs; they are IgG and predominantly complement-fixing up to C3b, but may be difficult to detect because they tend to disappear and then reappear promptly in an anamnestic response. The antiglobulin test is the best method for detection; reactions will be enhanced if the cells have been protease-treated or if fresh serum is added as a source of complement. Patients who have made Kidd antibodies should always be given an antibody card.

The Diego blood group system

Diego is a large system of 21 antigens: two pairs of allelic antigens – Di^a and Di^b , Wr^a and Wr^b – plus 17 antigens of very low frequency. All represent single amino acid substitutions in band 3, the red cell anion exchanger. The original Diego antigen, Di^a , is very rare in white and black people, but relatively common in Mongoloid people, with frequencies varying between 1% in Japanese and 50% in some native South Americans. Anti- Di^a and anti- Di^b are immune and rare, but can cause HDFN. Wr^a has a frequency of about 0.1%. Its high-frequency antithetical antigen, Wr^b , is dependent on an interaction between GPA and band 3 for its expression. Naturally occurring anti- Wr^a is present in approximately 1% of blood donors. Anti- Wr^a is often found in the serum of patients who have made other antibodies or who are suffering from autoimmune haemolytic anaemia. Very rarely, anti- Wr^a causes HDFN.

The Dombrock blood group system

Do^a and Do^b antigens represent a single amino acid substitution on the Dombrock glycoprotein, a member of the ADP-ribosyltransferase family, which also expresses the high-incidence antigens Gy^a , Hy , Jo^a and $DOYA$. Approximately 67% of northern Europeans are $Do(a+)$ and 82% $Do(b+)$. $Gy(a-)$ red cells are $Do(a-b-)$ $Hy-$ $Jo(a-)$. Dombrock antibodies are extremely rare, immune and are best detected by IAT; they have been implicated in severe acute and delayed HTRs. Anti- Do^a and anti- Do^b reagents are rare and unreliable, so Dombrock typing is best achieved by molecular methods.

The Colton blood group system

Co^a and Co^b represent a single amino acid substitution in the water channel aquaporin-1. Colton phenotype frequencies in white people are as follows: $Co(a+b-)$, 90.5%; $Co(a+b+)$, 9.0%; $Co(a-b+)$, 0.5%. The extremely rare Colton null phenotype, $Co(a-b-)$, results from homozygosity for inactivating mutations in the Colton gene, *AQPI*. Colton antibodies are very uncommon. Anti- Co^a has caused severe HDFN, and has been implicated in acute and delayed HTRs.

Some other blood group systems

Yt^a and Yt^b of the Yt system represent a single amino acid change in red cell membrane acetylcholinesterase. Yt^a and Yt^b have frequencies of about 99.8% and 8% respectively. Anti- Yt^a

and anti- Yt^b are exceptional and most are of no clinical significance.

The Scianna system consists of seven antigens, including the allelic antigens $Sc1$ and $Sc2$ of high and low frequency, respectively. They are located on the adhesion protein ERMAP. Scianna antibodies are very rare and little is known of their clinical significance.

The Xg system comprises two antigens, Xg^a and $CD99$, encoded by separate but homologous genes on the X chromosome; *CD99* is also expressed on the Y chromosome. The corresponding antibodies are rare and of no clinical significance.

The eight antigens of the Gerbich system, three of high frequency and five of low frequency, are located on GPC and GPD, which are encoded by a single gene, *GYPC*. The 15 antigens of the Cromer system and nine antigens of the Knops system are carried on the complement regulatory glycoproteins decay accelerating factor (*CD55*) and complement receptor 1 (*CD35*), respectively. Antibodies of these three systems are not generally considered clinically significant, although antibodies of the Knops system are relatively common and may obscure identification of other, clinically important antibodies in the same serum. Once identified, Knops antibodies can be ignored from a clinical point of view.

Antigens with high or low frequency

There are many other antigens, of either very high or very low incidence, that have not been assigned to blood group systems. Anti- Vel , $-Lan$, $-At^a$, $-AnWj$ and $-MAM$ are examples of antibodies to high-frequency antigens that have caused HDFN and/or HTRs. For those rare individuals who have formed antibodies to high-frequency antigens, the provision of compatible blood can be a problem; it is often necessary to approach the national or international panels of rare donors for compatible units.

Antibodies to low-frequency antigens are usually naturally occurring; they may occasionally give rise to unexpected incompatible cross-matches. Some antibodies to low-frequency antigens have caused HDFN.

Polyagglutinable red cells

Erythrocyte polyagglutination is the agglutination of red cells irrespective of blood group by many sera from normal adults. Polyagglutinable red cells are not agglutinated by the patient's own serum. The abnormality is a property of the red cells, not of the sera, in contrast to panagglutination, which is the agglutination of most red cells by one serum.

There are two main categories of polyagglutination, acquired and inherited. The acquired forms can be subdivided into

Table 15.12 Some characteristics of T, Tk, Tn and Cad polyagglutinable red cells.

	<i>T</i>	<i>Tk</i>	<i>Tn</i>	<i>Cad</i>
MN antigens	↓	Normal	↓	Normal
ABH antigens	Normal	↓	Normal	Normal
Most normal sera	+	+	+	+
<i>Glycine soja</i> lectin	+	–	+	+
<i>Arachis hypogaea</i> lectin	++	+	–	–
<i>Bandeiraea simplicifolia</i> lectin	–	+	–	–
<i>Salvia sclarea</i> lectin	–	–	+	–
<i>Dolichos biflorus</i> lectin (other than group A ₁)	–	–	+	+
Polybrene* solution	–	+	+mf	+

*Polybrene is a positively charged polymer that agglutinates cells with a negative charge and fails to aggregate sialic acid-deficient cells.

↓, reduced reactivity of MN or ABH antigens; mf, mixed field.

(i) microbial polyagglutination, which results either from the passive coating of red cells with bacteria or their products or from the action of microbial enzymes on red cell surface oligosaccharides (T, Tk, acquired B); and (ii) non-microbial polyagglutination, which is caused by somatic mutation (Tn). There are four types of inherited polyagglutination: Cad (strong expression of Sd^a), congenital dyserythropoietic anaemia type II (CDAIL or HEMPAS), NOR and Hyde Park. Lectins are required for the identification of the different types of polyagglutination (Table 15.12).

T activation

T activation occurs transiently in some patients with an obvious microbial infection, especially *Vibrio cholerae*, *Clostridium perfringens*, *Streptococcus pneumoniae*, various other streptococci and the influenza virus. These microbes produce sialidases, which remove sialic acid (*N*-acetylneuraminic acid) from the oligosaccharides of membrane sialoglycoproteins (Table 15.13) to expose the hidden T antigen (galactose linked to *N*-acetylgalactosamine), with an accompanying loss of negative surface charge.

Most adult sera contain naturally occurring, cold-reacting, complement-fixing, IgM anti-T. Most cases of T activation and other forms of polyagglutination were detected by the discrepancy in results of cell and serum ABO grouping, but with the introduction of monoclonal antibody reagents polyagglutination is found much less often.

Table 15.13 Structure of T, Tn and Tk antigens.

O-linked oligosaccharide of GPA and GPB	
NeuNAcα2→3Galβ1→3GalNAc–Ser/Thr	Normal
	6
	↑
	2
NeuNAc	T
Galβ1→3GalNAc–Ser/Thr	Tn
GalNAc–Ser/Thr	
A-, B- or H-active chains modified by endo-β-galactosidase	
GlcNAcβ1→3Galβ1→4GlcNAc–R	Tk

Gal, galactose; GalNAc, *N*-acetylgalactosamine; GlcNAc, *N*-acetylglucosamine; NeuNAc, *N*-acetylneuraminic acid (sialic acid); R, remainder of molecule; Ser/Thr, serine or threonine.

T polyagglutination may be associated with (i) haemolytic anaemia, (ii) HTRs (especially in children) caused by anti-T in transfused plasma, although this is still questionable, (iii) haemolytic–uraemic syndrome and (iv) neonatal necrotizing enterocolitis.

Peanut (*Arachis hypogaea*) lectin is the most effective tool for identification of T-activated cells (Table 15.12).

Tk activation

Tk activation, like T activation, is transient and associated with infection. Endo-β-galactosidases produced by *Bacteroides fragilis*, various clostridia or *Candida albicans* remove β-galactose from ABH polysaccharide chains, exposing *N*-acetylglucosamine (see Tables 15.7 and 15.13), with the consequent depression of ABH expression, without affecting the quantity of sialic acid on the red cell. Tk cells are specifically agglutinated by BSII lectin, an extract from *Bandeiraea simplicifolia* (see Table 15.12). These cells are also agglutinated by peanut lectin, probably owing to the exposure of galactose, the next sugar in the chain.

Tn activation

Tn activation, unlike T and Tk, is a persistent abnormality caused by an abnormal clone of stem cells arising by somatic mutation. Tn is often associated with other haematological abnormalities, such as chronic haemolytic anaemia, leucopenia or thrombocytopenia, but may be present in healthy individuals. Somatic mutation in a gene encoding a molecular chaperone leads to a deficiency of T-synthase, the galactosyl-transferase that elongates the O-linked oligosaccharides on GPA. Consequently, many of the O-glycans consist of only *N*-acetylgalactosamine, the immunodominant sugar of Tn (see Table 15.13). This loss results in a depression of M and N anti-

gens, a loss of sialic acid and a negative charge similar to that found in T activation. Only some of the red cells are agglutinated by the anti-Tn present in all normal adult sera, giving a mixed field appearance in agglutination tests. Platelets also show two populations. *Salvia sclarea* lectin specifically agglutinates Tn-activated cells, and the exposed *N*-acetylgalactosamine molecules can be detected with *D. biflorus* lectin (but only in people who are not group A₁).

White cell and platelet antigens and antibodies

HLA and transfusion

The HLA system is covered in Chapter 37. Leucocyte-reactive antibodies have in the past been reported, albeit transiently, in up to 96% of massively transfused patients. Complement-fixing lymphocytotoxic antibodies have been found in as many as 50% of patients receiving multiple transfusions of platelet concentrates over a 4-week period. This frequency is lower in immunosuppressed patients. In contrast, some patients never become HLA immunized, despite repeated transfusions, and are considered to be non-responders to HLA. Pregnancy can lead to HLA antibodies in approximately 15%, 25% and 35% of women after a first, second or third pregnancy, respectively. Such antibodies are generally of class I specificity, with anti-HLA-B being approximately twice as prevalent as anti-HLA-A.

HLA antibodies stimulated by pregnancy or transfusion are usually IgG and complement-fixing; naturally occurring IgM antibodies produced without a known stimulus, usually HLA-B8 specific, can be found in about 1% of individuals. The clinical importance of HLA antibodies relates to their ability to mediate graft rejection. In pregnant women, IgG antibodies may cross the placenta but are not considered to be a cause of neonatal leucopenia or thrombocytopenia. HLA antibodies are the usual cause of immunological refractoriness to random donor platelet transfusions, but not all patients with HLA antibodies are refractory to platelet transfusions, because platelets carry HLA

class I antigens, and a small proportion of immunologically refractory patients have no detectable lymphocytotoxic antibodies. Currently, the most sensitive and specific technique for detecting and identifying cytotoxic and non-cytotoxic HLA antibodies is Luminex. In this technique the relevant recombinant or purified proteins (antigens) are bound to coloured polystyrene beads of uniform size. These beads are then incubated with the patient's serum. The reaction is visualized using a phycoerythrin-conjugated anti-human IgG; following washing, the beads are run on a LabScan 100 flow-based machine to detect the reactions against the different beads. Two laser beams are used: one laser discriminates between different coloured beads and the other quantifies the fluorescent reporter molecule. The management of patients who become immunologically refractory to platelet transfusions is described in Chapter 16.

Residual HLA antigens, often referred to as Bg antigens, are also present on red cells of some individuals and HLA antibodies have been implicated in rare cases of delayed and acute HTRs.

Neutrophil-specific antigens and antibodies

Neutrophils carry not only HLA class I antigens but also neutrophil-specific antigens, now termed the HNA system (Table 15.14). Antibodies showing specificity to the following antigens are clinically important.

- 1 Alloimmune neonatal neutropenia (HNA-1a, HNA-1b, HNA-1c, HNA-2, HNA-3a, HNA-4a).
- 2 Febrile transfusion reactions (HNA-1a, HNA-1b, HNA-2, and other unidentified antigens on FcγRIIIb and CD18).
- 3 Transfusion-related acute lung injury, caused by the passive transfer of mainly HLA antibodies, but also HNA antibodies in donor plasma (HNA-1a, HNA-1b, HNA-2, HNA-3a, NB2).
- 4 Autoimmune neutropenia, in adults or in infancy.

The antigens of the HNA-1 system are expressed on FcγRIIIb; those of HNA-4 and HNA-5 on the integrins $\alpha_M\beta_2$ (MAC-1) and $\alpha_L\beta_2$ (LFA-1), respectively. In addition, neutrophils express polymorphic antigens that also occur on endothelial cells (EM

antigens), monocytes (HMA antigens), monocytes plus lymphocytes (HNA-4, HNA-5), and granulocytes and lymphocytes (SL).

Working with granulocytes is cumbersome and typing, as well as antibody screening, should be left to specialized laboratories. The techniques most widely used to detect neutrophil antigens and antibodies are the granulocyte agglutination test (GAT), the granulocyte immunofluorescence test (GIFT) and the monoclonal antibody immobilization of granulocyte antigens (MAIGA) assay. GAT and GIFT will detect HLA antibodies, including non-complement fixing ones that are not detectable by the lymphocytotoxicity test (LCT). Genotyping is also used for determining phenotype, but is not applicable to HNA-2, because the HNA-2 null phenotype results from a transcription defect.

The discrimination of granulocyte-specific antibodies from granulocyte-reactive antibodies such as anti-HLA, which also react with other leucocyte subsets, requires access to large panels of HLA-typed granulocytes and lymphocytes and the application of tests that detect non-complement-fixing lymphocyte-binding antibodies (e.g. GIFT and MAIGA). More recently, the Luminex technique (see above) LABScreen^R has been described, using recombinant antigens for HNA-1a, HNA-1b, HNA-1c and HNA-2a and purified HNA antigens for HNA-4a and HNA-5a.

Neutrophil antibodies can be found in as many as 3% of pregnant women, especially if their serum is tested against their partner's neutrophils. However, neonatal alloimmune neutropenia is very rare and, as expected, associated with the presence of potent IgG antibodies. Neutrophil autoantibodies are usually IgG, although some cold-reacting IgM antibodies have also been reported; some may be cytotoxic. Soluble IgG-containing immune complexes, rather than granulocyte-binding (auto) antibodies, may cause the neutropenia associated with Felty syndrome. Autoimmune neutropenia may also be caused by antibodies that prevent neutrophil precursor maturation rather than by destroying mature neutrophils, and some drug-dependent antibodies may also act by binding to neutrophil precursors.

Platelet-specific antigens and antibodies

Platelets carry ABH, Lewis, Ii and P antigens, as well as HLA class I antigens and the platelet-specific human platelet antigens (HPA). The HLA class I antigens are predominantly HLA-A and HLA-B; HLA-C is only weakly expressed on platelets. In some individuals, HLA-A and HLA-B are barely detectable, or undetectable, on the platelet surface. HLA antibodies are the single most important cause of immunological refractoriness to random donor platelet transfusions, although platelet-specific antibodies occur in 3–9% of cases, usually in association with HLA antibodies. HPA antibodies are also responsible for post-transfusion purpura (PTP) and neonatal alloimmune thrombo-

cytopenia (NAIT) and, very occasionally, febrile transfusion reactions.

Over 20 antigens have been described as platelet-specific (Table 15.15). These include the antigens of the various HPA systems, most of which are composed of a high-incidence 'a' allele (e.g. *HPA-1a*) and a low-incidence 'b' allele (*HPA-1b*). However, some of the HPA antigens are not truly platelet specific; the HPA-1 antigens are also found on endothelial cells, which might contribute to the severity of NAIT and PTP caused by anti-HPA-1a. The HPA-5 antigens have been described on activated T cells and probably also on endothelial cells, on the VLA-2 (very late antigen-2) membrane protein. The genetic basis of the HPA alleles is known for all HPA systems. Almost all represent SNPs encoding amino acid substitutions at different positions on platelet glycoproteins (Table 15.15).

The platelet antibody specificity that most frequently causes PTP is anti-HPA-1a, found in 85% of cases; anti-HPA-1b has been reported in 5% and anti-HPA-3a in 7% of cases in Europe. Similarly, anti-HPA-1a is the most common cause of NAIT, having been reported in 80% of HPA-1a-negative mothers at the time of birth of an affected infant. Anti-HPA-5b has been found in 15% of NAIT cases, as have occasional examples of anti-HPA-1b and anti-HPA-3a, in HPA-1a-positive mothers in Europe.

Serological methods for platelet typing and antibody detection

Typing for platelet antigens by serology is difficult: sera with appropriate specificity are rare, usually contaminated by HLA antibodies, and generally lack the adequate potency required for reliable typing. Serology is now often replaced by PCR-based DNA typing methods.

Serological techniques for platelet antibody detection in patients' sera include the platelet suspension immunofluorescence test (PIFT), a solid-phase technology and an antigen-capture ELISA technique known by the acronym MAIPA (monoclonal antibody immobilization of platelet antigens). In the PIFT, HPA-typed platelets are incubated with the patient's serum, washed, and any bound immunoglobulin detected with a fluorescent anti-immunoglobulin conjugate is visualized by ultraviolet microscopy or flow cytometry. In the solid-phase method, platelets are anchored onto the bottom of U-well microtitre plates by a polyclonal rabbit/anti-human platelet serum. Following incubation with the patient's serum, platelet-bound IgG is subsequently detected using anti-human IgG-coated indicator red cells. In the MAIPA assay, donor platelets are incubated successively with the patient's serum and a mouse monoclonal antibody that recognizes a specific platelet membrane glycoprotein complex (e.g. anti-GPIIb/IIIa, anti-GPIa/IIa or anti-GPIb/IX), and are then solubilized in a mild detergent such as Triton X-100. Immune complexes in the resulting supernatant are captured into the wells of an ELISA plate coated with goat-anti-mouse IgG. Any human antibody present in a

captured monoclonal antibody–platelet glycoprotein trimolecular complex is detected with an anti-human immunoglobulin ELISA conjugate. Other techniques that have been used for platelet serology, although much less frequently, include platelet agglutination, the platelet radioactive antiglobulin test, ELISA, ⁵¹Cr release, monocyte chemiluminescence and complement fixation.

A new Luminex-based approach, similar to one described for HLA antibodies, is currently being developed for the detection of HPA antibodies.

Molecular methods for platelet typing

Two alternative strategies for PCR typing have been widely used. In the first (PCR-RFLP), the relevant HPA genes are

amplified with appropriate primers and the alleles encoded subsequently discriminated with allele-specific restriction enzymes. The length of the DNA fragments produced on cleavage by the enzymes are analysed by gel electrophoresis. In PCR-SSP, allele sequence-specific primers are used to amplify individual alleles and the PCR product is visualized after electrophoresis through agarose and staining with ethidium bromide. In these PCR-based typing methods, DNA extracted from lymphocytes is used because platelets, being anucleate, lack DNA. Amplification of genomic DNA by PCR-SSP can be used to type donors and patients, even when the latter are thrombocytopenic. Alternatively, platelet mRNA can be converted to cDNA with reverse transcriptase before PCR amplification by a 5'-nuclease (Taqman) assay.

Platelet provision and matching for immunologically refractory patients

The major cause of immunological refractoriness to platelet transfusion is the presence of HLA-A and/or HLA-B antibodies in multitransfused patients. Quite often, such antibodies are found to react with the lymphocytes from the majority (and sometimes all) of the donors included in the panel. Platelet-specific antibodies may occur in 3–9% or less of refractory patients. Implicated specificities have included anti-HPA-1a and anti-HPA-1b, as well as anti-HPA-3a, anti-HPA-2b and anti-HPA-15b, and in this setting platelet-specific antibodies are usually accompanied by HLA antibodies.

Management of immunological refractoriness can often be accomplished by transfusion of platelets obtained by apheresis from HLA-typed donors that match the HLA type of the immunologically refractory patient. The best matched platelets are theoretically from 'A-matched' donors which do not express HLA-A or HLA-B antigens that are not present on the recipient's lymphocytes. Some degree of mismatching of donor-recipient phenotypes may be permissible. 'HLA-B-matched' platelets, which differ by one or more antigens (B1 to B4 matches) within a serologically cross-reactive group of HLA-A or HLA-B antigens, can often provide satisfactory increments in platelet counts, for example by transfusing platelets from an HLA-A1-A11-B8-B27 donor to an A1-A11-B8-B7 patient (B7 and B27 are cross-reactive). Donors with apparently 'homozygous' HLA phenotypes (e.g. A1-X-B8-X) can often provide 'A-matched' platelets for a variety of recipients (e.g. A1-A2-B8-B44) who have an HLA haplotype in common with the homozygous donor. All matched donor platelets must be gamma-irradiated before transfusion to prevent potentially fatal transfusion-associated graft-versus-host disease.

The provision of HLA-matched platelets is an extremely expensive service, so it is strongly recommended that their use is properly justified by taking post-transfusion platelet counts 1 or 24 hours after transfusion. In immunological refractoriness to platelet transfusions, the provision of HLA-matched platelets may not be sufficient per se for obtaining satisfactory post-transfusion platelet increments; it could be that a previously unrecognized HLA specificity, detectable by cross-matching the donor's lymphocytes by LCT, might be present, or that platelet-specific antibodies might be involved. If a patient does not show good increments when transfused with HLA-matched platelets that gave negative LCT cross-matches, then cross-matching the donor's platelets by a method such as the solid-phase technique could prove valuable in selecting compatible donors.

If HLA-matched or cross-match (by LCT or solid phase) compatible platelets still do not provoke satisfactory increments and the presence of platelet-specific antibodies has been excluded, then it is recommended to revert to the transfusion of platelets from random donors. Larger than normal doses of platelet concentrates may be needed.

Plasma protein antigens and antibodies

Many components of human plasma can be antigenic when whole blood or plasma is transfused. Problems associated with such antibodies represent one of the less well investigated areas in blood transfusion. Urticarial reactions following the transfusion of blood or plasma components are not infrequent, although the culprit proteins are only rarely disclosed and are most likely to consist of haptens present in donor plasma derived from food ingested recently (e.g. chocolate, prawns, drugs). Quite often the antibodies causing the reactions are IgE, present in atopic recipients. Antibodies to factor VIII are not known to cause transfusion reactions, although they will cause inhibition of the activity of transfused factor VIII. Antibodies to IgA can lead to serious anaphylactic reactions. Antibodies to IgG determinants may cause problems in blood grouping, but their role in transfusion reactions is debatable.

This chapter describes pretransfusion testing of the recipient's blood, complications and adverse effects of blood transfusion, appropriate use of components and, finally, a description of the features of haemolytic disease of the newborn. The first section deals with aspects of blood donation and collection, and the preparation and storage of blood components.

The blood donor (Tables 16.1 and 16.2)

Blood donation shall in all circumstances be voluntary.

Financial profit must never be a motive for the donor or for those collecting the donation.

These statements sum up the attitude of the World Health Organization (WHO) and the International Society of Blood Transfusion towards the principle of blood donation. However, in a number of countries worldwide, whole blood donation and apheresis plasma donation are remunerated. There are data showing that the microbiological safety of donations from paid

donors is inferior, and stringent post-donation testing and viral inactivation, when possible, are required to enhance blood safety.

In general, blood donors should be healthy adults between the ages of 17–18 and 65–70 years. These age limits vary slightly worldwide, but a lower limit is set to take account of the high iron requirements of adolescence. An upper limit is necessary because with age there is an increase in medical conditions that might make blood donation more hazardous and which increase the probability that coincidental accidents may be attributed to the act of giving blood. Pregnant and lactating women are not accepted as donors of allogeneic blood, again because of high iron requirements.

Because donors should be fit healthy individuals, no donations should be accepted from those who have ever suffered from cancer, diabetes, or heart or kidney disease. Those with severe allergic disorders should not give blood because recipients may develop temporary hypersensitivity reactions due to passively transfused antibodies.

Minor red cell abnormalities

Donors with minor red cell abnormalities, such as thalassaemia trait, sickle cell trait and hereditary spherocytosis, are perfectly acceptable, providing that the haemoglobin (Hb) screening test excludes anaemia. Red cells containing HbS have limited sur-

Table 16.1 Measures to protect the donor.

Age 17–70 years (60 at first donation)
Weight above 50 kg (7 st 12 lb)
Haemoglobin > 13 g/dL for men, 12 g/dL for women
Minimum donation interval of 12 weeks (16 weeks advised) and three donations per year maximum
Pregnant and lactating women excluded because of high iron requirements
Exclusion of those with:
Known cardiovascular disease, including hypertension
Significant respiratory disorders
Epilepsy and other CNS disorders
Gastrointestinal disorders with impaired absorption
Insulin-dependent diabetes
Chronic renal disease
Ongoing medical investigation or clinical trials
Exclusion of any donor returning to occupations such as driving bus, plane or train, heavy machine or crane operator, mining, scaffolding, etc. because delayed faint would be hazardous

vival under conditions of reduced oxygen tension and so should not be transfused to newborn infants and patients with hypoxia or sickle cell disease. Red cells with HbS obstruct leucodepletion filters and it is therefore advisable, in the UK, to defer such people from blood donation. Blood from donors with glucose-6-phosphate dehydrogenase deficiency survives normally, unless the recipient is given oxidant drugs.

Volume of blood taken

Modern blood collection packs are designed to hold 450 ± 45 mL of blood, mixed with 63 mL of citrate-phosphate-dextrose-adenine (CPD-A) anticoagulant. The ratio of anticoagulant to blood must be maintained at the optimal level, and donations of less than 405 mL or more than 495 mL of blood should not be issued for clinical use. Healthy donors can generally withstand the loss of 450 mL of blood without any ill effect, but vasovagal reactions become more common in those who weigh less than 50.0 kg, as the standard donation represents a greater proportion of their total blood volume. The allowable donation frequency is generally 16 weeks in the UK, with a minimum of 12 weeks. In some countries, such as China and Japan, ‘underweight’, otherwise healthy, donors may donate smaller volumes (250 mL) of blood into specially designed packs containing the appropriate volume of anticoagulant. In several countries, including the UK, double doses of red cells are collected by apheresis from suitable large donors; such units are very useful for decreasing donor exposure in multitransfused patients such as those with β -thalassaemia major.

Table 16.2 Conditions in the donor that lead to deferral.

All potential donors provided with information, so those at risk of HIV through lifestyle will refrain from donation (sexual practices, piercing, tattooing)
Donors with history of hepatitis deferred until 12 months after recovery
Exclusion of all potential donors who have themselves received a blood component transfusion since 1980 (due to risk of third party vCJD transmission)
Exclusion of those who have received pituitary-derived hormones or cadaveric dura mater or corneal grafts, and those with family history of CJD
Exclusion of those whose travel history places them at risk of malaria, Chagas disease (unless antibody test available) and SARS
Permanent exclusion of any donor who has had filariasis, bilharzia, yaws or Q fever
Exclusion for varying time periods following vaccinations
Exclusion after known exposure to infectious illnesses such as varicella
Exclusion of anyone with a malignant condition except fully excised BCC of skin
Exclusion of those with diseases of unknown origin, e.g. Crohn’s disease
Donor deferral for most drugs based on the underlying illness, e.g. cardiovascular, diabetes, malignancy, anaemia
Exclusion of those taking teratogenic drugs or those that accumulate in the tissues

BCC, basal cell carcinoma; SARS, severe acute respiratory syndrome; vCJD, variant Creutzfeldt–Jakob disease.

Haemoglobin estimation

A test to exclude anaemia is performed before donation. A convenient and widely used method depends on the specific gravity of a drop of blood, obtained by means of a fingerprick. An estimate of the haemoglobin value can be made, depending on whether the drop of capillary blood sinks in a copper sulphate solution of known specific gravity. According to the EU Blood Directive, the haemoglobin standard for male donors is 13.4 g/dL and for female donors is 12.4 g/dL, although lower limits have been introduced in some countries. The copper sulphate method tends to underestimate the haemoglobin value and may lead to unnecessary rejection of donors. On the other hand, the specific gravity of whole blood does not depend solely on the haemoglobin content of red cells and a pathological rise in plasma protein level or total white cell count (e.g. myeloma, chronic myeloid leukaemia) can lead to an anaemic donor passing the haemoglobin test. An alternative rapid simple colorimetric test using filter paper has been tried by WHO and is used in some countries. Many transfusion services use portable

haemoglobinometers on donors who fail the copper sulphate test, or as an alternative screening test. A relatively inexpensive portable haemoglobinometer can significantly reduce the number of unnecessary rejections.

Donation intervals

A donation of 450 mL of blood contains approximately 200 mg of iron, which is lost to the body. Studies have shown depletion of iron stores in those who give three or four blood donations per year, but overt iron deficiency anaemia is uncommon except in female donors of childbearing age. In general, donors are given the opportunity to donate two or three times per year in the UK (minimum interval 16 weeks), but some donors are able to donate more frequently without any significant iron depletion. When it is standard practice to take donations at shorter intervals, appropriate monitoring and/or iron supplements are recommended.

Hazards of blood donation

The most common hazard of blood donation is fainting, reported in 2–5% of all donors, but being especially common in young people and in those donating for the first time, particularly if they are nervous or apprehensive. A sympathetic approach by blood collection staff, provision of a drink prior to donation, enforcement of an adequate rest period, and constant vigilance to detect warning signs of an impending vasovagal attack can help avert this problem. Once a faint occurs, the standard treatment of rest in a horizontal position and elevation of the legs is usually sufficient. Delayed faints occurring after a donor has left the clinic are potentially hazardous and a contraindication to further donation. For this reason, those donors who are drivers, machine operators, scaffolders and so on should not return to work on the day of donation. Infection of the venepuncture site should be avoided by meticulous attention to skin cleansing and aseptic techniques.

All blood collection packs are manufactured as integral sets; each needle is sterile, to be used only once. No pack should be reused (even on the same donor) if the initial venepuncture attempt fails. Bruising of the arm may occur, particularly when venous access has been difficult; firm pressure over the site for 2–3 min and an explanation to the donor are usually sufficient. In the very rare event of arterial puncture, elevation of the limb and firm pressure over the site for 10–15 min should be combined with prolonged rest if a whole donation has been taken, as the rate of blood donation under such circumstances is usually very rapid. Very occasionally, attempted venepuncture may result in trauma to the nerves in the arm, resulting in pain, paraesthesiae and numbness. Such symptoms generally resolve in a few days, but very rarely may take several months of recovery. Even rarer complications are aneurysms and arteriovenous fistulae, following arterial punctures.

Hazards of allogeneic blood transfusion

A number of diseases have the potential to be transmitted by transfusion of blood or its components. Donor selection criteria and subsequent testing of all donations are designed to prevent such transmission (Table 16.3).

The viruses that pose the greatest potential risk for transmission by transfusion are those that have long incubation periods (often causing subclinical infection), and especially those that may be carried by asymptomatic individuals for many years, or even lifelong. Alternatively, some viruses that are transfusion transmissible exhibit cell-associated latency. If the virus is latent in white blood cells, recrudescence of that virus, stimulated by allogeneic transfusion, can cause infection of the recipient.

More rarely, a few viruses causing acute infection can be transmitted in the short presymptomatic viraemic phase if this coincides with the time of blood donation. Such agents pose a risk only if recipients have not been previously infected and donors have become infected during an epidemic period (e.g. parvovirus B19) or after visiting endemic countries (e.g. hepatitis A). Theoretically, respiratory infections such as influenza and severe acute respiratory syndrome (SARS) may also pose a potential risk.

Bacteria, especially skin contaminants and blood-borne parasites, are also potentially transmissible by blood transfusion. The key transfusion-transmissible agents are summarized in Table 16.4.

Table 16.3 Measures to protect the recipient.

<i>Measure</i>	<i>UK currently</i>
Donor selection	Yes
Donor deferral/exclusion	Yes
Stringent arm cleansing	Yes
Diversion of the first 20–30 mL of blood collected	Yes
Microbiological testing of donations	Yes
Immunohaematological testing of donations	Yes
Leucodepletion of cellular blood components	Yes
Post-collection viral inactivation of FFP (e.g. MB or SD treatment)	For at-risk patients
Safest possible sources of donors for plasma-based products	For at-risk patients
Monitoring and testing for bacterial contamination	Under evaluation
Pathogen inactivation of cellular components (e.g. psoralens)	No
Prion filtration	No

MB, methylene blue; SD, solvent-detergent.

Table 16.4 Transfusion-transmissible agents.

Agents		Characteristics related to transfusion
Viruses		
Hepatotropic	HAV	Very rarely transfusion transmitted during incubation; no carrier state; faecal–oral transmission
	HEV	As above but person-to-person spread is rare
	HBV	2–6 month incubation period; carrier state; readily transmissible by blood
	HCV	Majority of cases asymptomatic; carrier state; readily transmissible by blood
Retroviruses	HIV-1 and HIV-2	Carrier state and latent in WBCs; readily transmissible by blood
	HTLV-I and HTLV-II	Latent in WBCs
Herpesviruses	CMV	50% of UK adults have been infected; latent in WBCs
	EBV	Most UK adults have been infected (therefore already exposed pre transfusion); latent in WBCs
Others	Parvovirus B19	Generally mild or asymptomatic, posing no transfusion risk except for non-immune aplastic anaemia patients and fetuses Approximately two-thirds of UK adults have been infected Seasonal variation (and epidemic years) in incidence rate
	West Nile virus	Recently exhibiting epidemic rates of transmission in summer months in North America
	Dengue virus	Transfusion transmission has been reported in Asia
Bacteria		
Endogenous	<i>Treponema pallidum</i>	Inactivated by storage at 4°C No transfusion transmissions reported in the past 15 years
	<i>Yersinia enterocolitica</i>	Very occasional transmissions, usually contaminated red cells transfused late in the storage period
Exogenous	For example <i>Staphylococcus epidermidis</i> , <i>Micrococcus</i> , <i>Sarcina</i>	Mainly skin commensals or contaminants Most common cause of platelet contamination
Parasites		
	Malaria	Only five verified transfusion cases reported in UK in 25 years (all <i>Plasmodium falciparum</i>)
	Chagas disease	No transmission of <i>Trypanosoma cruzi</i> by transfusion has been reported in UK; many cases in Latin America
Prions		
	Abnormal PrP	Transfusion risk from vCJD. Only five possible cases of transmission in 12 years (three with disease)

WBCs, white blood cells.

Hepatitis viruses

Donors with a history of hepatitis are deferred for 12 months. The hepatitis viruses can be transmitted in cellular and plasma components, as well as plasma products.

When serum from an individual with hepatitis B virus (HBV) is ultracentrifuged and examined with the electron microscope, three types of particle may be seen. The large (42-nm diameter) Dane particle is the actual virus with its central nucleocapsid core, which has its own antigenic constituent HBc. The core contains partially double-stranded DNA and DNA polymerase,

and is surrounded by a lipoprotein coat carrying the hepatitis B surface antigen (HBsAg). The other two types of particles are 18–22 nm rods and spheres and represent overproduction of surface antigen material. HBsAg can be detected for a few months only in cases of acute HBV infection, or for years in chronic carriers. The HBe antigen is in soluble form and is present in the incubation period, during acute infection and during the first years of the carrier phase. HBeAg is a marker of high infectivity. Dane particles are very rare in the plasma of low-infectivity carriers. When HBc disappears, anti-HBc

appears, persisting for a long time, in the presence or absence of HBsAg. All donations are tested for the presence of HBsAg by sensitive enzyme-linked immunosorbent assays (ELISAs) that can detect at least 0.2 IU/mL of HBsAg.

Hepatitis C virus (HCV) is recognized as the cause of the majority of cases of what was previously known as non-A non-B (NANB) hepatitis. Although electron microscopic visualization of HCV has not been verified, its genome has been cloned and ELISAs have been developed in which cloned and/or synthetic peptides can react with antibody to HCV. Combined antigen plus antibody detection tests are also available.

Individuals with a history of jaundice may be accepted as donors, provided that they have been shown to be negative for markers of HBV and HCV. Clinical jaundice may be due to causes other than HBV and HCV, including non-viral causes; also, the majority of donors who are positive for HBsAg have no such history, so there is no sense in rejecting all people who give a history of clinical jaundice. In the UK, the incidence of HBsAg in first-time blood donors is approximately 1 in 2000 and in established donors (i.e. new infections) less than 1 in 100 000. HBsAg-positive subjects are permanently excluded from donation, and should be under specialist follow-up, as they have an increased risk of developing chronic liver disease and hepatocellular carcinoma.

Although the transmission of HBV by blood and blood components has been virtually eliminated, HBsAg testing will not exclude all donors capable of transmitting HBV, as the sensitivity of presently available serological techniques may allow as many as 10^4 – 10^6 HBV genome copies per millilitre of plasma to remain undetected. The introduction of screening for anti-HBc and/or HBV DNA would reduce the very low risk of transmission of HBV yet further. Although reports of clinically apparent post-transfusion hepatitis are very rare in the UK, HBV DNA testing (as part of a 'triple' assay that also detects HIV and HCV RNA) has been introduced in the UK in line with several other countries.

In the USA, before screening for anti-HCV was introduced, about 10% of transfusions caused significant increases in transaminase activity in recipients, the so-called NANB hepatitis. There were also occasional cases of symptomatic hepatitis. Acute HCV infection is usually mild, but a proportion of patients do develop chronic liver disease, with a risk of hepatocellular carcinoma. Confirmed rates of HCV positivity in the UK are 1 in 2000 for new donors and less than 1 in 100 000 for repeat donors. Methods of heat inactivation and solvent-detergent treatment of factors VIII and IX prevent transmission of HCV. Haemophiliacs who have received effectively inactivated factor VIII have proved negative for anti-HCV, in contrast with those who received untreated concentrate.

Hepatitis A virus is rarely transmitted by transfusion. Any donor who has been in close contact with a case (e.g. household contact) or developed hepatitis A is deferred for 12 months.

Hepatitis E virus is similarly rarely transmitted by transfusion. Like hepatitis A virus, hepatitis E has a short incubation period and no carrier state. Unlike hepatitis A it is rarely transmitted from person to person.

The so-called 'hepatitis G' virus (more correctly classified as GB virus-C) is not hepatotropic. Although transmissible by transfusion, it is asymptomatic and has not been associated with any pathology.

Human immunodeficiency virus (HIV-1 and HIV-2)

The classical descriptions and the vast majority of the literature on AIDS refer to HIV-1; a second retrovirus capable of causing AIDS, HIV-2, mainly occurs in West Africa.

Human immunodeficiency virus (HIV) can be transmitted in both cellular and plasma components (platelets, white cells, single donor plasma, fresh-frozen plasma and cryoprecipitate). Most of the patients infected by the transfusion of blood components were transfused before the introduction of screening of blood donations for HIV antibodies. Moreover, the majority of recipients of blood products who were infected in the past were transfused before 1985 with unheated non-pasteurized pooled plasma products, mainly factor VIII and factor IX concentrates. Thus, HIV infection became an important sequel to transfusion of factor VIII concentrates to haemophiliacs in the early 1980s, before the introduction of heat treatment and other viral inactivation methods. HIV is more heat labile than HBV, especially when in solution. Prolonged heat treatment and other viral inactivation methods of plasma products are effective means of protecting haemophiliacs from infection.

Albumin solutions are pasteurized, and carry no risk of HIV transmission. Similarly, intramuscular immunoglobulin preparations are rendered safe from HIV infectivity by their manufacturing processes.

Certain behaviour patterns place individuals at greater risk of HIV infection. Accordingly, male homosexuals and bisexuals, intravenous drug users and prostitutes are permanently deferred from blood donation. The sexual partners of such individuals and of haemophiliacs treated with blood products are also excluded. In addition, large areas of sub-Saharan Africa and Southeast Asia have a high incidence of HIV seropositivity in the general population. Inhabitants of these areas and their partners are also considered to be at greater risk of HIV infection than heterosexual non-drug users in other areas of the world. Donor education and encouragement of those whose behaviour may have exposed them to HIV to exclude themselves from blood donation are highly cost-effective methods for the prevention of transmission of HIV infection by blood transfusion. Systems for donor selection and deferral should continue to be in place, even in the presence of sensitive assays for the detection of infectious donors.

In most HIV-infected subjects, antibody develops within 3–4 weeks and coexists with the virus thereafter. Hence, HIV sero-

positivity is an indicator of infectivity. The tests that lend themselves most readily to the rapid mass screening required in blood transfusion are all ELISA or chemiluminescence based. As many of the commercially available kits have some false-positive reactions, mainly due to cross-reactivity, confirmatory tests using alternative methodologies are carried out before a positive result is reported.

Routine screening, combined with the well-established donor education and self-deferral schemes, have reduced even further the already small risk of the transfusion of a contaminated donation. There have been only four documented cases of HIV transmission by transfusion in the UK since screening began in 1985. The small residual number of HIV transmissions through screened blood will arise through donations given in the 'window period' of infectivity, i.e. soon after the donor has been infected but before anti-HIV has become detectable (as in the four UK documented cases referred to), or potentially through system errors. With current combined antigen-antibody screening techniques, the window period has been estimated to be less than 2 weeks on average. With the recently introduced nucleic acid test (NAT) for HIV RNA, the window period has decreased to approximately 7 days. The prevalence of HIV antibodies in repeat UK blood donors is less than 1 in 100 000, and is 1 in 25 000 in new donors; there is no doubt that energetic donor education has contributed to this very low rate by excluding high-risk individuals. In areas of low HIV incidence, the number of extra donors detected by NAT screening will be extremely small. In the UK, combined antigen-antibody serological testing has proved extremely effective, although NAT for HIV has been introduced as part of a triplex assay for HCV, HIV and HBV (see above).

In England and Wales in 2008, it was estimated that the residual risk of HIV infection by transfusion, per donation, was approximately 1 in 5.4 million. Although small, the risk of HIV transmission by transfusion is greater in the USA (approximately 1 per million donations) than in the UK.

Human T-cell leukaemia viruses

Human T-cell leukaemia viruses (HTLV-I and HTLV-II) are related retroviruses. The importance of HTLV-II is not clear; it appears to be associated with intravenous drug use in the Western world and has no known association with any clinical condition. However, HTLV-I is endemic in the Caribbean, parts of Africa and in Japan, where 3–6% of the population are seropositive. The virus is transmitted from mother to child through breast-feeding. Infection with HTLV-I is associated with at least two distinct clinical conditions; it can occasionally lead to adult T-cell leukaemia, with an incubation period of approximately 20 years, and, on even rarer occasions, to tropical spastic paraparesis (also known as HTLV I-associated myelopathy), with a shorter incubation period. Only about 1% of patients who are seropositive develop T-cell leukaemia. Both

HTLV-I and HTLV-II are cell associated and not transmitted in plasma. In highly endemic areas, transmission of HTLV-I by transfusion was relatively common before mandatory screening was introduced. Both tropical spastic paraparesis and adult T-cell leukaemia have been associated with transfusion-transmitted HTLV-I.

In areas of low prevalence of HTLV-I and HTLV-II infection, the cost benefit of mandatory screening of blood donations has been a matter for debate. Routine serological screening is by ELISA, but confirmation of positive results can still cause difficulties because other retroviruses may cross-react. In certain cases, it may also be difficult to differentiate between HTLV-I and HTLV-II in the laboratory. The prevalence of anti-HTLV in previously untested UK blood donors is roughly 1 in 50 000. Screening using a sensitive ELISA for anti-HTLV-I/II on pooled plasma samples became mandatory in 2002. In the UK the residual risk of transmission of HTLV by transfusion is estimated to be approximately 1 in 24 million donations (figures for UK residual risk 2006–2008 courtesy of Lisa Brant).

Cytomegalovirus

Although most cases of post-transfusion cytomegalovirus (CMV) infection are subclinical, the syndrome of post-transfusion infectious mononucleosis-like illness is well recognized, especially after the transfusion of large amounts of blood. The infection is characterized by fever, splenomegaly and atypical lymphoid cells in the peripheral blood, with a negative Paul Bunnell test. The usually benign course of CMV infection in recipients and the high prevalence of CMV antibodies in the general population have meant that there has been no necessity to screen all donors for evidence of past infection. However, immunosuppressed individuals are at great risk from potentially fatal pneumonitis or disseminated CMV infection, and these recipients require special measures to prevent CMV transmission.

The groups at particular risk include premature babies weighing less than 1500 g, bone marrow and other organ transplant recipients, and pregnant women (the fetus is at risk). In such cases, if the patient (and the organ/cell donor) or the mother (in the case of neonates) lacks evidence of past CMV infection, then anti-CMV-free blood and blood components should be provided. This may cause logistical problems, especially with platelet supplies, as the prevalence of anti-CMV in the UK adult population is 50–60%. Although only a small number of antibody-positive donors may be capable of transmitting the infection, there is no test for infectivity. Thus, all antibody-positive donors should be considered as having the potential to transmit CMV. As CMV is cell associated, effective leucodepletion should provide similar levels of safety as serological testing. This has not been demonstrated by prospective parallel studies, although observational studies are supportive.

Syphilis

According to WHO data, the global incidence of syphilis has increased in recent years. Each donation is tested by a serological test for syphilis. Although *Treponema pallidum* does not survive well at 4°C and red cell preparations are likely to be non-infective after 4 days' refrigeration, passive transmission of the antibody to a recipient could cause diagnostic confusion. The organism is more likely to be transmitted in platelet concentrates, due to their room temperature storage and short shelf-life. Any donation from an individual giving a positive result is discarded, and subjects with positive tests are permanently debarred from donation, even after effective therapy. In the past, syphilis testing was believed valuable as a surrogate marker for lifestyles known to be associated with high risk of HIV infection. Sensitive HIV assays have reduced this usefulness.

Malaria

Malarial parasites remain viable in blood stored at 4°C and are readily transmissible by blood transfusion. In some endemic areas, all recipients are treated with antimalarial drugs. In non-endemic areas, there is a real risk of failure to recognize post-transfusion malaria owing to the rarity and unexpectedness of the infection. This fact, combined with increasing travel to tropical areas, necessitates the careful vetting of blood donors by direct questioning and, in some centres, by tests for malarial antibodies. In the UK, donors with a history of possible malaria exposure (provided it was more than 6 months previously and they are free of symptoms) can be accepted if they are negative by ELISA for malarial antibodies.

Other infections

There are no other protozoal or microbiological diseases (for which tests are available) that pose a significant problem in the context of blood transfusion in the UK. However, diseases such as Chagas disease cause significant problems for the blood transfusion services in Latin America, and potential exposure of UK donors necessitates stringent donor selection criteria and specific serological testing of those individuals to exclude the possibility of infection.

Babesia microti, the agent of Nantucket fever, still poses a risk in certain areas of the USA. There are very few reports of possible transmission of *Leishmania donovani*, all outside Europe. Subjects giving a history of brucellosis are not accepted as donors in the UK due to the risk of transmission of this agent.

Other viral risks of transfusion

Acute infections, although associated with short phases of viraemia, can pose transmission risk by transfusion especially if their incidence is high. This has been amply demonstrated by West Nile virus (WNV) in North America. WNV is an arthropod-borne infection of birds, with humans and horses as incidental

hosts. The annual outbreaks in recent years in the USA and Canada have resulted in several transmissions by transfusion, with severe morbidity and mortality in immunosuppressed and elderly patients. This has necessitated the introduction of NAT screening of donors in these countries and the temporary exclusion, in non-endemic countries such as the UK, of donors who have visited North America. A similar situation pertains with two other arboviruses, dengue virus (which has caused two reported instances of transfusion transmission to date) and Chikungunya fever virus in French departments.

Hepatitis A and hepatitis E viruses, both acute infections with short periods of viraemia and no carrier state, have also occasionally been transmitted by transfusion. The possible risk from respiratory viruses with transient viraemia such as SARS and influenza viruses is being monitored internationally. No transmissions by transfusion have been reported.

Bacteria

Although rare in absolute terms (approximately three to four cases are reported and confirmed per year in the UK), bacterial transmissions by transfusion constitute two-thirds of all reported microbial transmissions by this route in the UK and often prove fatal. The vast majority of such cases are due to contaminated platelet preparations that are more than 3 days old, because bacteria (mostly skin commensals) proliferate easily at room temperature. This risk is now far greater than that posed by viruses because of the introduction of viral screening of blood donations by sensitive ELISAs and NAT. UK blood services have introduced enhanced methods of donor arm cleansing, and 'diversion' of the first 20 mL of the donation to reduce the risk from skin contaminants. Routine bacterial screening of platelet preparations is in place in Scotland and Wales. In England, a proportion of platelet concentrates undergo bacterial screening during long weekends, in order to extend the shelf-life from 5 to 7 days. The UK Serious Hazards of Transfusion (SHOT) 2008 report cites four (platelet) units transmitting bacteria. These resulted in one fatality directly caused by the transfusion, one fatality in which the transfusion was implicated and one case of major morbidity. Three other 'possible' bacterial transmission complications were noted.

Prions

Variant Creutzfeldt-Jakob disease (vCJD), the human form of bovine spongiform encephalopathy (BSE), is considered a potential threat to blood safety. This risk remains mainly applicable to the UK, where nearly 170 cases of vCJD had been reported by 2009. Therefore, plasma for fractionation (and fresh-frozen plasma for infants and children not exposed to the risk of BSE in food) is obtained from the USA. Appropriate donor exclusions and the introduction of leucodepletion of all blood components are other precautionary interventions. It has been shown experimentally that BSE acquired in sheep, by eating contaminated beef, can be transmitted by blood transfu-

sion to other sheep. As it is not known how many people could be infected with vCJD and because of the reports of at least three possible transfusion-associated cases of vCJD transmission, recipients of blood and blood products have been excluded as blood donors in the UK. In addition, vCJD prion has been detected in spleen and/or lymph nodes in two recipients of blood and blood products from donors diagnosed with vCJD subsequent to donation. Both recipients died of unrelated causes, with no clinical manifestations of vCJD. Interestingly, one was a haemophilia patient. The implicated blood donations were all made prior to the introduction of leucodepletion. As yet no screening tests are available for testing blood donations, although several companies are claiming to have made progress. In addition, two companies have reported success with a special filter to remove abnormal prions from red cell units; these claims are under investigation.

Laboratory tests on blood donations (Table 16.5)

Samples for laboratory testing are taken at the time of donation in order to avoid later entry into the sterile blood pack. The routine tests are automated if large numbers of donor samples are tested daily, as is the case in blood centres in the UK.

All blood donors in the UK are tested at each donation for syphilis, HBsAg, anti-HIV-1 and anti-HIV-2 and HIV antigen, anti-HCV, HCV and HIV RNA, HBV DNA, and anti-HTLV. ABO and RhD grouping are determined routinely on each occasion. Typing for other Rh antigens (C, E, c and e) and K is now routinely performed on all blood donations in the UK. Phenotyping for antigens other than ABO, Rh and K is only performed on a restricted number of units in order to match blood for special cases, such as alloimmunized patients and

sickle cell disease patients. Ideally, girls and women of child-bearing age should be matched for c and K, as anti-c and anti-K are, after anti-D, the major causes of severe haemolytic disease of the newborn (HDN) in the UK.

All donations are also screened for the presence of atypical red cell alloantibodies by testing against group O red cells that are selected to bear the most common blood group antigens, ideally in double dose. The incidence of clinically significant red cell alloantibodies in blood donors is very low (0.3%) compared with the incidence in potential recipients (1–2%). Donations with potent clinically significant alloantibodies are not issued to hospitals. Group O blood for emergency or ‘flying squad’ use, which in exceptional circumstances may be given to ungrouped recipients, should be given as red cells in additive solution such as saline-adenine-glucose-mannitol (SAGM) in order to avoid problems that might be caused by high-titre anti-A,B in donor plasma. As soon as the patient’s group is known, group-specific blood should be given. If group O platelets have to be given to non-O recipients, donors with high-titre anti-A,B should be excluded as the providers of the plasma used to suspend the platelets; alternatively, platelet-additive solutions can be used to replace most of the plasma.

Some donations are screened for CMV antibodies for patients in need of CMV-negative blood. Units from donors at risk are screened for malaria antibodies, Chagas disease antibodies and for HbS (sickle trait).

Residual microbial risk of allogeneic blood transfusion

The residual risks of microbial transmission are now so low in the UK that the prospective studies to determine them would be too large to be practical. Risk is therefore calculated from the length of the window period (prior to laboratory detectability of the infection) and the rate of new infections (incidence) for specific viruses. The calculated residual risks per donation in England and Wales for HIV, HBV and HCV are approximately 1 in 5.4 million, 1 in 0.9 million and 1 in 72 million respectively (figures for UK residual risk 2006–2008 courtesy of Lisa Brant). These calculations are consistent with ‘haemovigilance’ reports in the UK SHOT scheme. Indeed, acute microbial transmissions in 2008 constituted less than 1% of all reported hazards, with ‘incorrect blood component transfused’ being the major reported risk. The low microbial risk is a result of a series of incremental safety interventions becoming ever more complex and costly. Bacterial transmissions continue to pose the major microbial risk of blood transfusion.

In this context, reduction in pathogen-inactivation techniques is likely to prove cost-*ineffective*, unless a safe single treatment becomes available for blood prior to component separation, existing safety interventions can be reduced or discontinued, or ‘emerging’ microbial risks are considered to pose a sufficient threat. In any case, if pathogen-inactivation

Table 16.5 Microbial testing in England and North Wales.

HIV	ELISA (combined HIV-1 antigen plus anti-HIV-1 and anti-HIV-2); NAT for RNA
HBV	HBsAg ELISA; NAT for DNA
HCV	Anti-HCV ELISA plus NAT for RNA
HTLV	Anti-HTLV ELISA (on pools of samples)
CMV	Anti-CMV for immunosuppressed recipients only
Malaria	Antibody screening of potentially exposed donors
Chagas disease	Antibody screening of potentially exposed donors
Bacteria	All donations are tested for antibody to syphilis; the option to test platelet preparations by culture methods is under review

techniques such as photochemical inactivation are introduced, we need to ensure that the blood component is not affected in its immunogenicity or efficacy, and that the benefits of their introduction outweigh the risks.

In the UK, because of the risk of vCJD, fresh-frozen plasma (FFP) for paediatric use is imported from the USA. It has recently been recommended that all FFP for use in the UK should be imported. However, because the residual risk of viral transmission by transfusion is greater in the USA than in the UK, all imported plasma is subjected to pathogen inactivation with methylene blue.

Storage of blood

When blood is stored in a liquid state there is a progressive loss of viability of the red cells, and of red cell ATP, and depletion of 2,3-diphosphoglycerate (2,3-DPG). The purpose of modern anticoagulants used for the collection of blood, and additive solutions used to store red cells and platelets, is to reduce these changes to a minimum.

Anticoagulants

The vast majority of whole blood donations are collected into CPD (citrate-phosphate-dextrose) anticoagulant. The addition of 'rejuvenating' agents or purine nucleosides such as adenine to standard anticoagulant solutions (e.g. CPD-AI) has been shown to improve significantly the viability of red cells by restoring their ATP or 2,3-DPG content. However, for some clinical indications, such as neonatal or intrauterine transfusion, there have been theoretical concerns regarding toxicity of additives such as adenine and mannitol. In the UK, the majority of blood for neonatal or intrauterine transfusion is now prepared from CPD whole blood. Heparinized blood for neonatal cardiac surgery and exchange transfusion has been replaced by CPD or CPD-AI blood, less than 5 days old, with no untoward effects. Platelet preparations from apheresis are usually collected into acid-citrate-dextrose. CPD is used to collect both double-dose red cells and plasma from apheresis donors.

Optimal additive solutions (e.g. SAGM)

Optimal additive plasma replacement solutions have been developed to improve the viability of plasma-depleted red cells on storage, by maintaining both ATP and 2,3-DPG levels. SAGM (as well as ADSOL and Nutricel) medium provides good red cell storage conditions and is now the most usual preservative solution for red cells in the UK. The majority of red cells for transfusion are stored in additive solutions rather than autologous plasma. There are few clinical indications for red cells stored in plasma and but include red cells for neonatal exchange transfusion and those for intrauterine transfusion. Red cells in SAGM are now usually used for top-up and large-

volume transfusions to neonates (e.g. cardiac surgery). Currently in the UK, platelets are normally stored in CPD-plasma either from one of the four pooled donations, in the case of 'buffy coat' platelets (see below), or as part of the apheresis collection. Alternatively they can be resuspended in 70% platelet additive solution and 30% plasma, especially for patients in whom exposure to plasma is contraindicated or when the potency of anti-A,B in group O platelets needs to be reduced for non-O recipients. For patients with severe allergic reactions to plasma proteins, platelets can be suspended in 100% additive solution, but this limits the shelf-life to 24 hours due to the lack of plasma to maintain platelet function.

Blood components

Preparation and storage of blood components

There are no specific clinical indications for the transfusion of whole blood, and the vast majority of blood that is transfused is therefore separated into its component parts. This is achieved by the collection and separation of whole blood donations, or by collection of specific components from donors by apheresis. A multiple 'bottom and top' blood collection pack is used (Figure 16.1) if the donation will be used to make platelets; otherwise, a simpler 'top and top' system is used to make red cells and plasma. The blood donation is taken into the main pack, which contains standard CPD anticoagulant. In the bottom and top system, after centrifugation, whole blood is separated into plasma at the top, a buffy coat in the middle and red cells at the bottom (Figure 16.1). Fresh plasma is expressed from the top and red cells from the bottom of the pack, leaving the buffy coat in the original pack. The red cells are transferred to a pack containing an optimal additive solution to preserve red cell function during storage. The resulting red cells have a shelf-life of 35–42 days (35 days in the UK).

The plasma is then kept to resuspend the platelets, or frozen either for clinical use as FFP or it can be subjected to a fractionation process for the manufacture of intravenous immunoglobulin, albumin, anti-D, specific antiviral immunoglobulins and coagulation factors. However, at present it is not permitted to use UK plasma for fractionation because of concerns over the possible transmission of vCJD by blood products.

The buffy coat layer contains most of the platelets, over 80% of the white cells and 5–10% of the red cells. This is pooled with three other buffy coats and more than 200 mL of plasma from one of the donations, preferably from a male donor, using a sterile connecting device (Figure 16.2). The pool undergoes a second gentle centrifugation step and the supernatant is used to produce a platelet preparation. The residue from the buffy coat pool, containing mainly white cells and red cells, is then discarded.

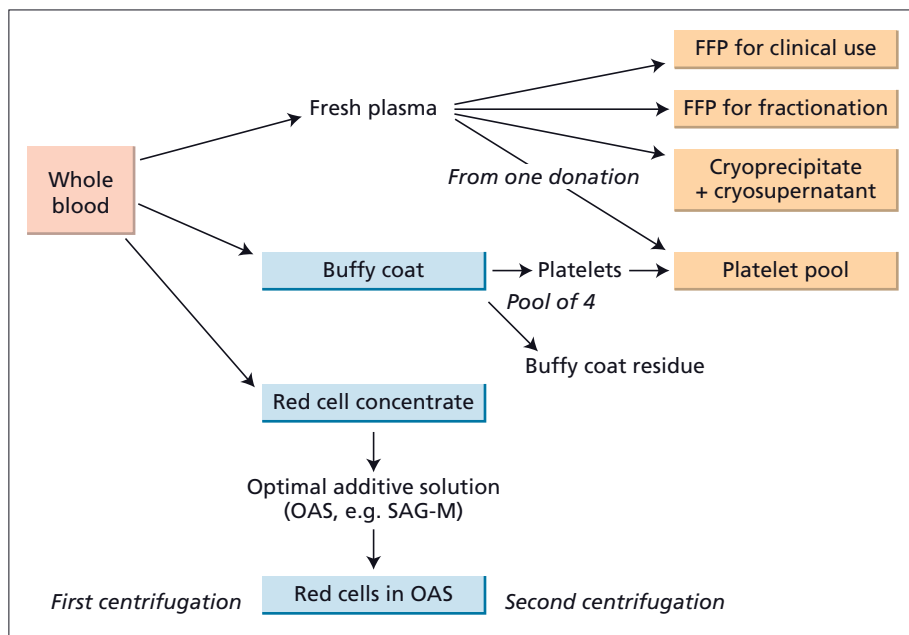

Figure 16.1 Diagrammatic representation of the preparation of components from whole blood by the ‘top and bottom’ or ‘buffy coat’ method. Items in boxes represent final components. FFP, fresh-frozen plasma.

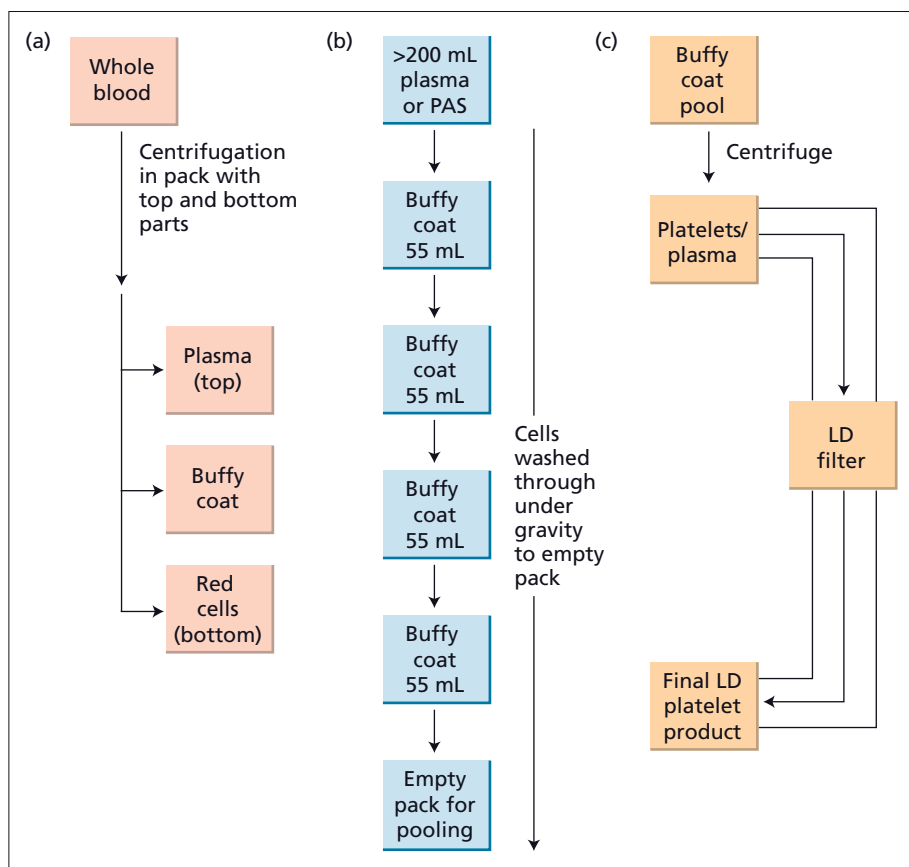

Figure 16.2 Preparation of leucodepleted pooled, buffy coat-derived platelet preparations. PAS, platelet additive solution; LD, leucodepletion.

The systems that enable the separation of buffy coats in a semi-automated manner are called blood separators, examples of which include Optipress and Compomat (Figure 16.2). Cellular components (red cells and platelets) and plasma may, at this stage, be individually filtered to leucodeplete to a level below 5×10^6 white cells per unit. The alternative is to use leucodepletion filters at the initial stage on whole blood, before separation of components. These two alternative methods are necessary because most whole blood filters also remove a significant number of platelets, making production of platelet concentrates from filtered whole blood impossible. In the UK, leucodepletion of all blood components has been mandatory since 1999, as a measure which might decrease the risk of vCJD transmission by transfusion. Added benefits of leucodepletion include a significant decrease in the incidence of febrile non-haemolytic transfusion reactions, in the risk of human leucocyte antigen (HLA) alloimmunization and in the risk of transmission of intracellular viruses such as CMV and HTLV.

Platelet preparations

Unlike red cells, platelets must be stored at 20–22°C, since storage at 4°C results in poor survival of platelets following transfusion. Platelets have a shelf-life of 5 days, and are stored in permeable bags that allow the diffusion of oxygen into the pack, which, with constant gentle agitation, maintains aerobic metabolism and reduces the rate of fall of pH. The shelf-life of platelet preparations can be extended to 7 days provided that systems are in place to monitor bacterial contamination or to inactivate pathogens in platelet concentrates (e.g. photochemical inactivation with psoralens).

Platelet pools provide an adequate adult dose of platelets and contain, on average, 3×10^{11} platelets, usually from four donations suspended in the plasma from one donation, preferably from a male donor, in order to avoid the risk of transfusion of donor white cell antibodies that might cause transfusion-related acute lung injury (TRALI) (Figure 16.2).

In the USA, platelets are prepared from individual donations by a method which leaves the platelet-rich plasma as a supernatant. Each platelet concentrate contains a minimum of 5.5×10^{10} platelets, suspended in 50 mL of plasma. An adult dose of platelets prepared in this way contains significantly more leucocytes than the platelet concentrates prepared by 'top and bottom' systems and which are considered to be leucocyte poor, even before leucodepletion.

The equivalent of two or even three adult doses of platelets (minimum 2.4×10^{11} each) may be obtained from one donor, with adequate platelet counts, by an apheresis procedure lasting approximately 90 min. At present, in the UK, approximately 80% of platelets are produced by this method. These preparations reduce donor exposure and are invaluable for the treatment of immunologically refractory thrombocytopenic patients requiring HLA-matched platelets. However, they are expensive

to produce and demanding on both staff and donors. A large HLA-typed donor panel is available in England to provide HLA-matched platelets for immunologically refractory patients. Most apheresis platelet donors are also human platelet antigen (HPA) typed in order to provide HPA-1a-negative platelets for newborns affected with neonatal alloimmune thrombocytopenia and also for some of the HPA-1a-negative patients who have become immunologically refractory to platelet transfusions.

Frozen platelets can be preserved in dimethyl sulphoxide (DMSO) or glycerol. The platelet recovery is significantly lower than with fresh preparations, but the post-transfusion survival is normal. Frozen platelets are very seldom used and are not available in the UK, due to the remaining concerns about their safety and loss of efficacy.

Systems to kill pathogens that may be present in platelet preparations are now available, but none are yet in routine use in the UK or the USA.

Granulocyte concentrates

With the increase in intensive chemotherapy regimens, demand for granulocytes has risen in order to prevent or treat fungal or other serious infections in severely neutropenic patients.

Granulocytes are extremely labile; they must be separated from whole blood immediately after collection and transfused within hours of preparation. Granulocytes prepared from routine blood donations (buffy coats) are heavily contaminated with red cells and platelets. Buffy coats from at least 10 donors are required to produce a therapeutic dose for an adult (at least 1×10^{10} granulocytes). Ten buffy coats also contain the equivalent of two units of red cells and 2.5 pools of platelets. Venesection of the recipient may therefore be required if daily buffy coats are indicated. A new pooled granulocyte component produced from whole blood donations that has reduced volume and red cell contamination is under clinical assessment in the UK. However, due to the heavy red cell contamination of available buffy coats, they should be ABO and RhD compatible with the recipient and cross-matched against the recipient's serum. Granulocyte concentrates prepared by apheresis are the only satisfactory means of achieving a therapeutic dose for an adult neutropenic patient. Sedimenting agents (gelatin, hydroxyethyl starch) must be added to the blood or given to the donor in order to obtain an adequate yield, unless the donor has chronic granulocytic leukaemia.

A directed donation from a suitable relative may sometimes be possible. Consent may then be obtained for the donors to have their counts boosted using steroids and granulocyte colony-stimulating factor (G-CSF), resulting in an excellent yield of granulocytes. In the UK, it is not permitted for non-directed volunteer donors to receive this medication. Average yields from unstimulated apheresis collections are 0.7×10^{10} ; with the use of G-CSF and steroids, this can be increased to $5\text{--}10 \times 10^{10}$.

All granulocyte concentrates should be cross-matched against the recipient's serum by lymphocytotoxicity, as white cell anti-

bodies may cause severe transfusion reactions, with respiratory distress.

Fresh-frozen plasma

This plasma has been separated from whole blood (Figure 16.1) or obtained by apheresis, and frozen within 24 hours to a temperature that will maintain the activity of the labile factors V and VIII. FFP contains all coagulation factors and should be stored at -30°C or below for up to 24 months or even longer. When needed, the plasma is thawed rapidly at 37°C and then transfused without delay. A dose of 15 mL/kg is appropriate to correct abnormal coagulation in acquired coagulopathies when no concentrate is available. The main use of FFP is for multiple acquired coagulation factor deficiency, but it is also used to treat inherited single coagulation factor deficiencies if the appropriate factor concentrates are not available. Evidence is gathering in favour of the early and more liberal use of FFP, together with red cells and platelets, in the massive haemorrhage of trauma (see below).

Single units of FFP can be treated with photosensitizing chemicals such as methylene blue (MB), riboflavin or amotosalen and exposed to visible or ultraviolet light to inactivate pathogens that may be present in the plasma. If required, the residual chemicals can be removed before the plasma is rapidly frozen to -30°C . Alternatively, FFP can be pooled with around 1500 other units and treated with solvent-detergent (SD) in order to inactivate pathogens. All methods of viral inactivation reduce the levels of labile clotting factors in FFP. The current recommendation from the UK Department of Health is that the treatment of choice for children is MB-FFP and that SD-FFP should be used for plasma exchanges in the treatment of thrombotic thrombocytopenic purpura (TTP). Both types of FFP are produced from plasma collected outside the UK in order to reduce the risk of vCJD.

In recent years in the UK, every effort is made to prepare FFP only from male donors in order to minimize the risk of passive transfer of donor white cell antibodies that can give rise to TRALI.

Cryoprecipitate

Cryoprecipitate is prepared from FFP that is allowed to thaw slowly (classically at 4°C overnight). After removal of the supernatant, factor VIII:C, von Willebrand factor (VWF), fibrinogen, fibronectin and factor XIII are left as a precipitate, which is then refrozen in approximately 30 mL of plasma and stored at -30°C or below for up to 24 months. Each unit should contain a minimum of 70 IU of factor VIII:C and 140 mg of fibrinogen. Cryoprecipitate is now used mainly as a source of fibrinogen in cases of disseminated intravascular coagulation (DIC), hepatic failure and hypofibrinogenaemia. A standard adult dose of cryoprecipitate is 10 units, which are thawed at 37°C in about 10 min and should be used immediately. Pools of 5 single units are available in the UK. Fibrinogen concentrate,

a safer low-volume alternative to cryoprecipitate, is now available in the UK.

Cryoprecipitate-poor plasma (cryosupernatant)

This term is used for the remaining plasma after the removal of cryoprecipitate. It is stored frozen at -30°C or below for up to 24 months. The only specific indication for cryosupernatant is for plasma exchange in TTP. This is an immune-mediated condition in which there is an autoantibody directed against a VWF-cleaving metalloproteinase. The resulting accumulation of high-molecular-weight VWF multimers contributes to the pathophysiology of the condition, with thrombosis in the microvasculature. Although cryosupernatant has reduced levels of high-molecular-weight multimers compared with FFP, there is no evidence that plasma exchange for TTP with cryosupernatant is any more effective. FFP or cryosupernatant are therefore alternatives to the current product of choice (SD-FFP); however, they are derived from UK donors, who might have been exposed to vCJD.

Storage changes of blood components

Loss of red cell and platelet viability are the most important practical considerations. Progressive loss of viability varies according to the combination of anticoagulant used, how blood is stored prior to component separation, what storage medium the components are stored in, and the pack systems used. The time limit for storage of blood or its component parts is set taking all these into consideration. After transfusion of stored red cells or platelets, a proportion is removed from the circulation within the first 24 hours. The remainder appear to survive normally. There are various changes in the *in vitro* characteristics of red cells during storage (the so-called storage lesion), including depletion of metabolic substrates such as ATP and 2,3-DPG, leakage of potassium and changes in red cell morphology. Some of these changes can be partially reversed *ex vivo* by incubation with purine nucleosides, or following transfusion *in vivo*. ATP seems to be an important determinant of red cell viability, although not the only one. 2,3-DPG is almost completely depleted in red cells after 14–21 days storage. Red cell 2,3-DPG is restored to normal by approximately 24–48 hours after transfusion. The clinical significance of the low 2,3-DPG level of stored red cells is only likely to be an important consideration in recipients with severe anaemia or coronary artery insufficiency.

During storage of red cells, potassium gradually leaks out through the cell membrane once active transport has been halted by the cooling of blood to 4°C . There is rapid restoration of electrolyte levels after transfusion. The pH of blood decreases with storage, but most recipients can handle the acid load during transfusion without ill effect.

Likewise there are a number of changes in platelet function that occur during platelet storage, including increased platelet

activation and decreased responsiveness to agonists such as ADP. For both red cells and platelets, the relationship between these changes *in vitro* and the function of the cells following transfusion is complex, and it is notoriously difficult to predict post-transfusion viability from the results of laboratory testing.

As the storage time of either red cells or platelets increases, the viability decreases. Acceptable limits for the recovery of red cells and platelets following transfusion are as follows: greater than 75% of red cells 24 hours following transfusion, and greater than 66% of platelets (compared with that of fresh platelets).

Frozen red cells

Red cells can be stored for a prolonged period (up to 30 years) without damage if glycerol is added before freezing. Thawed red cells must be washed free of glycerol before transfusion. This method of storage is expensive and time-consuming but is invaluable as a means of storing red cells with rare phenotypes. National banks for frozen rare cells have been established for this purpose. Freezing, thawing and washing is also an efficient way of removing plasma, platelets and leucocytes from red cells.

The recipient

Preoperative assessment (Table 16.6)

The need to correct anaemia with haematinics preoperatively and avoid unnecessary transfusions, in addition to the growing pressure on hospital beds and increasing use of day surgery, suggest that a preoperative assessment should be performed before admission. This allows for efficient use of hospital resources and limits the number of cancelled operations. The key aims are to assess a patient's fitness to undergo surgery and anaesthesia (including haemoglobin optimization), anticipate complications, arrange for supportive therapy to be available perioperatively and to liaise with the appropriate specialists regarding non-surgical management. This assessment needs to take place at a presurgical clinic at least 1 month before the planned date of surgery. After the clinic, it is imperative that the results are evaluated so that the necessary action, such as the treatment of ferropenic anaemia, can be taken for each patient.

Only a small proportion (1–2%) of potential recipients will have red cell alloantibodies other than anti-D; however, a sample taken at the pre-assessment clinic for pretransfusion antibody screening will allow blood bank staff to identify those samples that need detailed investigation, well in advance of the planned transfusion, so that antigen-negative blood can be available as required.

Table 16.6 Preoperative assessment.

Take a full history and examination, including previous surgical episodes and bleeding history, transfusion and obstetric history
Arrange full blood count (FBC), group and antibody screen, routine chemistry, coagulation screen (if indicated) and tube for haematinics assessment (ferritin level for iron stores, vitamin B ₁₂ and folic acid), which can be put on hold pending FBC results
Make cell salvage available if there is a likelihood of significant blood loss requiring transfusion and a 'clean' surgical procedure
Consider using recombinant erythropoietin (600 IU/kg weekly for 4 weeks preoperatively) and/or intravenous iron preparations in order to optimize haemoglobin even when within normal range
Prescribe iron and folic acid supplement if any suspicion of iron deficiency
Establish whether patient is taking regular aspirin, clopidogrel, non-steroidal anti-inflammatory drugs or warfarin and, whenever possible, make necessary arrangements to stop this drug 7 days preoperatively

Laboratory tests

Pretransfusion group and screen

The ABO and RhD groups of all potential recipients should be determined before transfusion. No other blood groups are routinely tested or matched when selecting blood for transfusion. The need for blood is rarely so urgent that there is insufficient time to perform the ABO and RhD groups before transfusion, as rapid testing need take only 5–10 min. The patient's serum should also be screened for the presence of atypical red cell antibodies using a sensitive indirect antiglobulin test (IAT), with two or three individual (not pooled) group O red cells selected to express, between them, all the common red cell antigens, ideally in double dose. If a positive result is obtained, further investigation using a red cell panel of 8–10 cells is required to identify the antibody.

For patients who have preformed antibodies, because they are already good responders, an antibody screen using a panel of cells that are negative for the pertinent antigen(s) should be used (i.e. panel of rr cells in the case of preformed anti-D). Only 1–2% of patients have clinically significant red cell alloantibodies other than anti-D. About 75% of these antibodies have Rh and/or K specificity. Therefore, patients with haematological diseases (e.g. sickle cell anaemia, β -thalassaemia) who are likely to need repeated transfusion over many years should ideally be phenotyped for the major red cells antigens; if this is not possible, at least RhD, C, c, E, e and K typing should be performed.

Blood that is compatible with the patient's Rh and K type should be transfused, as this reduces the probability that they will produce alloantibodies. It is not difficult to implement this policy in England, as all red cell units are typed for all Rh antigens and for K. Because, after RhD, the K and Rhc antigens are the most immunogenic and the antibodies that can lead to severe HDN, ideally girls and women of childbearing age should be transfused with K-negative red cells, although K typing is not necessary as only 9% will be positive. On the other hand, girls and women of childbearing age should be typed for the Rhc antigen and those found to be negative should be given c-negative blood.

Red cells for transfusion are selected to be of the same ABO and RhD group as the recipient. If clinically significant red cell alloantibodies are present in the recipient, units of blood lacking the relevant antigens are selected for compatibility testing, even if the maximum (or standard) surgical blood ordering schedule (SBOS, see below) only requires group and screen for that surgical procedure.

Compatibility testing (cross-match)

The donor red cells are routinely tested against the recipient serum or plasma in order to detect any potential incompatibilities, i.e. identify any antibodies in the recipient that are reactive with antigens on the red cells of the selected donor. This test will provide a means of checking the ABO compatibility of donor and recipient. If the antibody screen is negative, then the cross-match should be as simple as possible, for example an immediate spin or IAT at 37°C. This will detect ABO incompatibilities resulting from clerical or technical errors such as sample switching or erroneous group in the bag, as well as the presence of antibodies missed in the screening. The antiglobulin test can be performed in low-ionic-strength saline (LISS) solution in tubes or using gel (column) techniques (see Chapter 14) that decrease the incubation time and increase the sensitivity for the detection of most antibodies. Tests should be carried out at 37°C, not at room temperature, otherwise clinically insignificant cold antibodies will be detected, especially when LISS is used. This may cause confusion and inconvenience to the recipient (e.g. cancellation of planned surgery). Any clinically significant antibody will react at 37°C (see Chapter 14), and the techniques chosen should take this into account.

A group and screen policy used in combination with a maximum (or standard) surgical blood ordering schedule (MSBOS, SBOS) can reduce the number of compatibility tests performed and avoid the reservation of red cell units unlikely to be transfused. Each hospital should agree its own SBOS among the blood bank, surgeons and anaesthetists, through the hospital transfusion committee. The SBOS is based on a retrospective comparison of the number of units of blood cross-matched and the number actually transfused for each elective surgical procedure. Procedures that are likely to require blood

have a ratio of cross-matched to transfused blood below 2.5:1. All patients awaiting surgery have blood samples taken for grouping and antibody screening. As long as no atypical alloantibodies are detected, cross-matching is reserved for those in whom the need for blood is fairly certain. Operations for which blood is not usually required (such as hysterectomy and cholecystectomy) are not covered by cross-matched blood. If blood is unexpectedly needed, an abbreviated cross-match (using an immediate spin technique to ensure ABO compatibility) may be used safely, with minimal risk to the recipient. If atypical antibodies are detected, antigen-negative blood should be cross-matched before surgery if there is any minimal likelihood of blood being required, regardless of the SBOS.

Electronic cross-match

An increasing number of hospitals with suitable blood bank computing systems now use a so-called electronic cross-match or 'electronic issue'. A patient has group and screen performed on two separate occasions. If both screen results on the laboratory's computer system are negative and if no blood has been transfused during this period, ABO and Rh compatible blood is issued directly via the computer with no further wet testing being performed. This makes it possible to reduce the number of operations for which blood is issued in advance even further, as the electronic cross-match is very quick. It also saves laboratory time, which can then be dedicated to more complex problems.

Antenatal testing

All women should have blood samples taken at antenatal booking for blood grouping and antibody screening. If no clinically significant antibody is detected, further samples should be tested at 28 weeks' gestation (see p. 294) before routine antenatal prophylaxis is given to RhD-negative women. Much of the emergency compatibility testing for possible Caesarean sections can be avoided by performing another antibody screen and group at admission, using either an abbreviated or electronic cross-match, should blood be required.

Repeated transfusions

Patients who require repeat transfusion after an interval of more than 72 hours must have a new sample screened before the next transfusion to detect any clinically significant antibody that may have been stimulated in an anamnestic response by the recent transfusion. Severe haemolytic transfusion reactions (HTRs) still occur due to failure to observe this simple rule; many could be avoided. In the case of an HTR, in addition to the antibody screen, a direct antiglobulin test (DAT) should be performed on the red cells of the new sample to detect, in mixed field agglutination, any alloantibodies attached to donor red cells but not free in the serum.

Massive transfusion

If the total blood volume has been replaced within less than 24 hours, compatibility testing becomes academic. In such patients, inter-donor incompatibility is a possible problem, but all donor sera should have been screened at the transfusion centre for the presence of potent atypical antibodies. When a pretransfusion alloantibody screen on the recipient has not detected any atypical antibodies and blood has been cross-matched without a problem, then continued compatibility testing may be omitted. If a pretransfusion screen reveals the presence of an atypical antibody, the blood selected should be negative for the relevant antigen. Once transfusion has commenced, the antibody will be 'diluted out' and compatibility testing may no longer be reliable, unless the original serum sample is used for all testing. In practice, once 10 units have been transfused there is no need to continue to cross-match red cells for further transfusions, or to select antigen-negative red cells, if these are scarce. If unimmunized RhD-negative men or postmenopausal women are likely to need massive transfusion, RhD-positive red cells should be transfused from the start.

Transfusion in autoimmune haemolytic anaemia

Ideally, patients with this condition should not be transfused. However, if transfusion is imperative, special serological techniques such as elution and absorption should be used to exclude the presence of alloantibodies, which may be masked by autoantibodies. Blood should then be selected that is compatible with the alloantibody, if present, even though transfused red cells will be destroyed by the autoantibody at the same rate as the patient's own blood. Whenever possible, red cells should also be Rh and K compatible to reduce the possibility of further alloimmunization. Blood that does not express the antigen to which the autoantibody is directed should be issued only when the autoantibody has restricted specificity and mimics an alloantibody such as anti-e. However, if the patient is a female of childbearing age and is RhD-negative, with an autoantibody mimicking anti-e, then R₂R₂ (cDE/cDE) cells should not be given because of the high risk of RhD immunization.

Neonatal 'top-up' transfusion

Premature infants are among the most widely transfused patients, with 'top-up' transfusions being very frequent. Only the first pretransfusion sample needs to be tested, with no further sample testing until 4 months of age, as infants are not capable of making clinically significant antibodies in the first months of life. Ideally, the unit of red cells used for the first transfusion should be aliquoted into several (six to eight) satellite (or 'paedi') packs and used for the same infant until expiry in order to decrease exposure to multiple donors. Measures

should be in place in all neonatal units and their supporting laboratories to minimize the quantities of blood required for testing, by use of microsampling techniques and near-patient testing. Anaemia in this group is largely due to 'bleeding into the laboratory'. Erythropoietin has been extensively studied as an alternative to transfusion in the anaemia of prematurity but it does not consistently reduce the need for transfusion in this patient group.

Complications of blood transfusion

The frequency of the complications of blood transfusion will vary inversely with the care exercised in preparation for, and especially in supervision of, the transfusion.

Although the majority of side-effects are mild, the overall incidence of complications is estimated at 2–5%. Immediate fatalities, although difficult to quantify accurately, are of the order of 1 in 100 000 to 1 in 500 000 patients transfused; 50% of these are caused by ABO incompatibilities, mainly due to failure to correctly identify the donor or recipient at the time of sampling or at the time of transfusion. The wrong pack of blood, i.e. one intended for a different recipient, is reported to be given in 1 in 6000 to 1 in 30 000 transfusions. This is likely to be an underestimate due to underdetection and non-reporting of incidents. It follows that transfusions of blood and blood components should only be prescribed when there is a definite and appropriate clinical indication, when there are no feasible alternatives and when the benefits of transfusion are judged by the prescribing clinician to outweigh its short- and longer-term risks.

The complications of blood transfusion can be conveniently divided into acute and delayed, immunological and non-immunological categories (Table 16.7).

Immunological complications

Sensitization to red cell antigens

As only the ABO and RhD antigens are routinely matched in blood transfusion, there is a constant possibility of sensitization to other red cell antigens, although all red cell antigens are significantly less immunogenic than D. Alloimmunization is more likely in multitransfused patients. The consequences may be negligible but can lead to difficulty with compatibility testing, HDN and HTRs.

Haemolytic transfusion reactions

This is premature destruction of transfused red cells reacting with antibodies in the recipient. Naturally occurring antibodies, such as ABO antibodies, are IgM and, if warm-reacting, can destroy red cells *in vivo* by complement fixation. Red cell alloantibodies are usually IgG and form in response to exposure, through previous transfusions or pregnancies. HTRs may occur

Table 16.7 Hazards of transfusion.**Immediate (hours)***Non-immune complications*

immediately after the transfusion or may be delayed for anything up to 2–3 weeks.

Immediate or acute haemolytic transfusion reactions

These may be intravascular or extravascular.

Immediate intravascular red cell destruction is the most dangerous type of HTR; it is associated with activation of the full complement cascade by IgM antibodies and is practically always due to ABO-incompatible blood transfusions (haemolytic anti-A,B, anti-A or anti-B present mainly in the recipient or, rarely, in the donor plasma). Most of these ABO-incompatible transfusions are due to errors, and occur with an approximate frequency of 1 in 100 000 patients transfused. The mortality rate in such ABO-incompatible cases is 5–10%. In a further 10–15% of cases there is major morbidity.

In the 20–25% of recipients of ABO-incompatible blood with serious reactions, the symptoms are usually dramatic and severe; most are due to the anaphylatoxins C3a and C5a that are liberated during complement activation, releasing vasoactive amines and hydrolases from mast cells and granulocytes (see Chapter 14). The cytokines interleukin (IL)-1, IL-8 and

tumour necrosis factor (TNF) also play an important role, causing inflammation, smooth muscle contraction, platelet aggregation, increased capillary permeability, and hypotension. Typically, within less than 1 hour of the start of the transfusion, when the reaction is symptomatic, the patient complains of heat or pain in the cannulated vein, throbbing in the head, flushing of the face, chest tightness, nausea and lumbar pain. These symptoms are usually accompanied by tachycardia and hypotension. In severe cases, there is profound hypotension, leading to shock and renal failure. Rigors and pyrexia usually follow. Intravascular destruction of red cells brings about liberation of thromboplastin-like substances that activate coagulation and lead to DIC. The bleeding diathesis and increased destruction of red cells (which may eventually involve the recipient's cells) further exacerbates the problem. Intravascular destruction of red cells liberates haemoglobin into the circulation. Once haptoglobins are saturated, haemoglobin will also appear in the urine. If haemoglobinuria is very severe, haemosiderinuria may be seen. Renal complications consist of acute renal failure with oliguria and anuria, possibly the result of hypotension and/or the action of activated complement. The initial symptoms may of course be modified or abolished in anaesthetized or heavily sedated patients, in whom evidence of DIC, hypotension or the presence of haemoglobinuria may be the first signs.

Immediate intravascular destruction of recipient red cells should be avoidable. In practice, the main cause is error, when the incorrect blood component is transfused. The most severe reactions occur in major incompatibility, when a group O recipient with high-titre anti-A,B is transfused with group A, B or AB red cells. Less severe intravascular haemolysis occurs when group A red cells are transfused to a group B recipient, or vice versa, because group B and A subjects have less potent ABO antibodies than those of group O. More rarely, intravascular red cell destruction may occur when group O plasma is transfused by mistake to A, B or AB recipients. For this reason, group O red cells, even in additive solution, should not routinely be used for non-O recipients; furthermore, this practice leads to unnecessary shortages of group O blood. If unavoidable, the group O blood must first be screened for the presence of high-titre haemolysins or be devoid of plasma. In the UK, screening for high-titre ABO antibodies is routinely carried out at the blood centre and marked on the bag. ABO-compatible cryoprecipitate, FFP and platelet transfusions should be selected for all recipients, especially for children because of their smaller blood volume. Group A, B or AB plasma components are safe for group O recipients.

Occasionally, there is a laboratory error when tubes are transposed or there are transcription errors or misrecording of results, or there is insufficient time to complete an antibody screen or compatibility test. In the UK haemovigilance (SHOT) system, approximately 30% of cases of incorrect blood component transfusion reported in the last 12 years have been primarily due to clerical or technical errors that originated in the

hospital laboratory. Obviously, not all the errors led to ABO-incompatible transfusions; in fact 10% of errors led to ABO incompatibilities. The remainder of reports (70%) relate to clerical or administrative errors in the ward, collection of the blood from the blood bank, failure to confirm the identity of the patient when taking samples, mislabelling of the sample of blood or failure to perform proper checks before removing the units from the refrigerator or transfusing the blood. The potentially serious consequences of failures resulting in ABO-incompatible transfusions emphasize the need for set protocols with meticulous checking at all stages. If an identification mistake has been made, it is important to check, as a matter of urgency, that the units intended for the patient under investigation have not also been misdirected to another recipient.

Haemoglobinaemia and haemoglobinuria may also be seen in severe extravascular HTRs (see below) and, occasionally, after the transfusion of lysed red cells. This may occur in the following circumstances: inappropriate warming and overheating of blood; exposure to extreme cold due to faulty storage conditions; lysis due to mechanical problems during administration; or due to the injection of 5% dextrose with the transfused red cells. Severe fulminant toxic symptoms leading to death, similar to those of intravascular HTRs, can be seen after the transfusion of bacterially infected blood, especially if it contains endotoxin-producing organisms (e.g. *Staphylococcus* and *Yersinia* species). Haemoglobinaemia and haemoglobinuria may also follow transfusion of blood to a patient with severe autoimmune haemolytic anaemia, due to an increase in the number of red cells in the circulation which will be subject to immune lysis.

Extravascular red cell destruction is mediated by IgG antibodies (Table 16.8). Mononuclear phagocytic cells have receptors for the Fc fragment of IgG1 and IgG3; the binding of IgG-coated cells to these receptors is inhibited by free IgG in plasma. There are no receptors for IgM on macrophages. Red cells sensitized with IgG1 and/or IgG3 antibodies may or may not activate complement up to C3b only. If they do not, they are removed extravascularly (by phagocytosis or cytotoxicity) by mononuclear phagocytic cells, predominantly in the red pulp of the spleen, where the plasma is largely excluded and the IgG on the red cells can compete with free IgG in the plasma. However, cells coated with IgG antibodies, which activate complement up to C3b, adhere to the C3b receptor on macrophages and monocytes. The presence of C3b on red cells greatly enhances the extravascular destruction of IgG-coated cells. This is because the binding to C3b receptors is not inhibited as there is no native C3b in plasma and consequently IgG/C3b-coated cells are destroyed by phagocytosis or cytotoxicity, predominantly in the liver, where there are abundant macrophages (Kupffer cells) and a generous blood flow. As C3b is rapidly inactivated and converted into C3dg by the action of factors H and I and proteases, a proportion of the cells re-enter the circulation, coated with C3dg, and are resistant to further lysis (Figure 16.3). Red

Figure 16.3 Mechanisms of extravascular destruction of red cells coated with IgG1 or IgG3 (± C3b). ADCC, antibody-dependent cell-mediated cytotoxicity.

cells coated with potent IgG antibodies, especially if they are C3b-binding, are destroyed mainly by cytotoxicity. Red cells coated with less potent antibodies are mostly destroyed by phagocytosis. Very rarely, red cell alloantibodies too weak to be detectable by routine pretransfusion testing may destroy donor red blood cells carrying the corresponding antigen.

The features of an immediate HTR vary according to a number of factors: whether the red cells are destroyed within the circulation or in the mononuclear phagocytic system; the strength, class and subclass of the antibody; the nature of the antigen; the number of incompatible red cells transfused; and the clinical state of the patient. When antibodies are present in the circulation in low titres and a large volume of incompatible blood is given, all circulating antibody will bind to the incompatible red cells, coating them weakly, without destroying them. There will then be no antibody detectable in the serum for a number of days until secondary antibody production is stimulated by the immune challenge. On the other hand, in the presence of an overloaded or poorly functioning mononuclear phagocytic system, large volumes of IgG-sensitized incompatible red cells can be present in the circulation with minimal or no premature removal, so the haemoglobin level may be stable with little evidence of haemolysis. The DAT will be positive, but as there is no free antibody, elution techniques will be necessary for antibody identification.

Immediate extravascular destruction of red cells may be accompanied by hyperbilirubinaemia, occasionally haemoglobinuria due to antibody-dependent cytotoxicity (in severe cases), fever and failure to achieve the expected rise in haemoglobin level. The signs and symptoms are less severe and dramatic than in intravascular haemolysis and usually appear more than 1 hour after the start of transfusion (Table 16.8). There may be no signs or symptoms at all. Renal failure is very rare,

even when the antibody binds the earlier components of the complement cascade. Symptoms are attributed in large degree to liberation of cytokines from mononuclear phagocytic cells after binding to IgG-coated red cells and to liberation of C3a when complement is bound up to C3b. The mortality is extremely low, but in an already sick patient the added complication of destruction of transfused red cells may contribute to death.

The management of immediate HTRs should be to terminate the transfusion immediately the patient develops the appropriate signs or symptoms. The identity of the patient and the units transfused should be checked against the appropriate documentation. Blood samples must be taken for investigation (Table 16.9). The circulating blood volume should be restored and blood pressure and urinary flow maintained using fluid challenges and furosemide (frusemide) infusion. Monitoring on a high-dependency unit may be required. The renal team should be involved early if urine output is poor (< 1 mL/kg per hour) and haemofiltration may be necessary. Appropriate blood component therapy will be required if there is DIC.

All packs of transfused units should be returned to the blood bank. Pretransfusion samples should be tested in parallel. If no identification mistake is discovered immediately, a sample should be sent for bacteriological testing and all urine passed during the first 24 hours should be measured and examined for haemoglobin. Subsequent management depends upon awareness of the possible complications and prompt therapy if these occur. If the patient develops only a rise in temperature, unaccompanied by other symptoms, red cell incompatibility is unlikely and the transfusion should be slowed, under strict monitoring, but need not be stopped.

New technologies to prevent patient identification errors are being evaluated in a number of countries. These generally

Table 16.9 Investigation of suspected acute haemolytic transfusion reaction.

<i>Blood test</i>	<i>Rationale/findings</i>
Full blood count	Baseline parameters, red cell agglutinates on film
Plasma/urinary Hb, haptoglobin, bilirubin	Evidence of intravascular or extravascular haemolysis
Blood group of patient and units transfused	Compare with retested pretransfusion sample, to detect ABO error Unexpected ABO antibodies may arise from transfusion of incompatible plasma. Rechecking labels is often sufficient
DAT	Positive in majority. Compare with retested pretransfusion sample. May be negative if all incompatible cells destroyed
Compatibility testing	Repeat antibody screen and compatibility testing on pre- and post-transfusion samples. Elution of antibody from post-transfusion cells may aid antibody identification or confirm specificities in plasma in cases of non-ABO incompatibility
Urea, electrolytes and creatinine	Baseline renal function
Coagulation screen	Detection and monitoring of DIC
Blood cultures of patient and units	In event of possible septic reaction caused by bacterial contamination of unit

involve bar-coded patient identification details on the patient's wristband and the use, both on the wards and in the laboratory, of a hand-held bar-code reader with all data collated by the transfusion computer system. These systems are likely to be developed in tandem with similar arrangements for pharmacy and drug prescriptions, as well as ordering of blood tests and other investigations for patients.

Delayed haemolytic transfusion reactions

Such reactions are neither predictable nor preventable. They are always caused by IgG antibodies. In the majority of cases, an individual has been previously sensitized to one (or more) red cell antigen(s) by previous transfusion or pregnancy. Antibody is not detectable in routine pretransfusion testing, but the transfusion of blood containing the antigens to which the recipient has been sensitized previously provokes a brisk anamnestic response that is characteristic of the secondary immune response. Within days, the antibody level rises and the transfused cells are removed from the circulation. The effects of the secondary immunization are usually seen about 5–10 days after the transfusion, when the recipient may already have left hospital.

Most of these reactions are asymptomatic, but when manifest the clinical features include the triad of fever, hyperbilirubinaemia and anaemia. The degree of reduction in haemoglobin level will of course depend on the number of incompatible units transfused.

The possibility of delayed HTRs underlines the importance of always taking fresh serum samples for antibody screening, DAT and compatibility testing if a transfusion has been given more than 72 hours previously. Awareness of this complication may avoid unnecessary investigations to exclude infection when fever develops a few days after a transfusion. Most importantly, it will detect any alloantibody that will have been boosted by the transfusion, thus enabling the provision of compatible blood.

Reactions due to white cell and platelet antibodies

Non-haemolytic febrile transfusion reactions

Febrile reactions are most frequently due to the transfusion of blood components containing white cells to patients sensitized to white cell antigens and, more rarely, to platelet antigens. Together with urticaria, these are the most common types of immunological reactions to blood transfusion. Antibodies are directed usually against HLA antigens, or sometimes against granulocyte and platelet-specific antigens; they are stimulated by previous transfusions or pregnancies. Cytokines released from white cells during storage may also be pyrogenic. Characteristically, the onset of the reaction is delayed until 30–90 min after the start of the transfusion (depending on the strength of antibody and the speed of transfusion). A rise in temperature may be the sole symptom, but the recipient may

suffer chills, headache or rigors. There is no associated hypotension, lumbar pain or chest discomfort. These reactions are usually only troublesome rather than dangerous, except in very sick patients or when caused by very potent lymphocytotoxic HLA antibodies.

The management of a simple mild febrile transfusion reaction is to slow the rate of transfusion and treat the patient with an antipyretic such as paracetamol. Antihistamines are of no benefit. It is usually not necessary to discontinue the transfusion: more blood is probably wasted by premature termination of a unit due to a simple febrile reaction than for any other reason.

When a patient requiring repeated transfusions has a history of simple febrile reactions, the rate of transfusion should be kept slow and antipyretics should be prescribed prophylactically. If severe symptoms persist, tests for HLA antibodies (lymphocytotoxicity) should be carried out. If these are negative, platelet antibodies should be sought. In the UK, the incidence of febrile transfusion reactions has decreased significantly since the introduction, first, of buffy-coat removal (leucoreduction) and, since 1999, of universal leucodepletion of blood components. Modern pre-storage leucodepletion filters are highly efficient and can remove more than 98% of the white cells; the specification is that 99% of leucodepleted components should have less than 5×10^6 leucocytes. Red cells and platelets should be filtered as soon as possible after collection in the transfusion centre. In countries where there is no universal leucodepletion policy, there is no need to administer white cell-depleted blood prophylactically, except in cases where prevention of sensitization to HLA and leucocyte/platelet antigens is essential (i.e. possible future consideration for bone marrow transplantation, especially in patients with aplastic anaemia). In such countries, the provision of buffy coat-poor red cell and platelets will prevent most non-haemolytic febrile transfusion reactions.

Transfusion-related acute lung injury

TRALI consists of non-cardiogenic pulmonary oedema with bilateral pulmonary infiltrates on chest radiography, accompanied by chills, fever, cough and dyspnoea with low oxygen saturation and low or normal central venous pressure. The clinical picture, depending on the severity, will be the same as acute lung injury or acute respiratory distress syndrome (ARDS) due to other causes, and a differential diagnosis is essential. Symptoms develop very rapidly, usually within 1–2 hours, or up to 6 hours after infusion of a plasma-containing component.

Management is essentially supportive, requiring care in a high-dependency unit, and careful attention to fluid balance. The reaction is due in most cases to passive transfer of leucoagglutinins (mostly anti-HLA class I or class II or granulocyte antibodies, i.e. anti-HNA) in donor plasma, leading to endothelial and epithelial injury, alveolar damage and inflammatory changes, mediated by cytokines and other inflammatory media-

tors. The donors are usually multiparous women. Once identified as the source of a reaction, such donors should be removed from the panel, even though it is known that their plasma does not always lead to TRALI in recipients with the pertinent antigens. The incidence is unclear but may be in the region of 1 in 5000 transfusions. There appears to be a significant mortality rate from this condition, but not as high as from other causes of ARDS.

In the UK, the incidence of TRALI has been declining in recent years since the introduction of the policy to produce FFP and use plasma to suspend platelet pools mainly from male donors.

Post-transfusion purpura

Post-transfusion purpura is a rare complication of blood transfusion, characterized by sudden onset of severe thrombocytopenia 7–10 days after the transfusion of platelet-containing blood components, usually red cells. The patient always has a history of previous blood transfusions or pregnancies (thus it is far more common in women). The most frequent cause is the presence in the recipient of an antibody (anti-HPA-1a) against the platelet-specific antigen HPA-1a (PI^{A1}); next in frequency is anti-HPA-5b. It appears that the antigen–antibody reaction between the recipient's antibody and the donor platelets causes both transfused and autologous platelets to be prematurely destroyed, either by the formation of immune complexes (in a manner similar to the 'innocent bystander' mechanism) or by cross-reaction of the causative antibody with the patient's own platelets. The disease is self-limiting, but in severe cases or if bleeding occurs, prompt therapy with intravenous immunoglobulin or plasma exchange is indicated. Platelet transfusion is not recommended, as this may exacerbate the disease process.

Transfusion-associated graft-versus-host disease

Transfusion-associated graft-versus-host disease is a very rare but usually fatal complication of blood transfusion, caused by the engraftment and clonal expansion of HLA-compatible donor lymphocytes in the recipient. It is characterized by fever, skin rash, diarrhoea, hepatitis and pancytopenia. The diagnosis is made by detecting donor-derived cells or DNA in the peripheral blood or affected tissues of the patient. The first SHOT (haemovigilance) reports included 13 cases of transfusion-associated graft-versus-host disease, all fatal, in patients for whom gamma-irradiated blood components were not indicated at the time. In recent years there have been no reports of this condition.

Reactions due to plasma protein antibodies

Mild urticarial reactions without other symptoms are not uncommon during blood transfusion; they occur with an approximate incidence of 1% and are mediated by IgE antibodies, usually against plasma proteins or other allergens present

in donor plasma. Mild urticarial reactions may be treated effectively with antihistamines, and do not always recur. There is no necessity to avoid transfusion of standard 'bank blood' unless symptoms are recurrent and severe. On the other hand, anaphylactic reactions accompanied by dyspnoea, wheezing, collapse and shock are rare and potentially fatal. Such severe reactions are associated with the presence of anti-IgA in an IgA-deficient recipient. These antibodies react with IgA in the transfused plasma and complement is activated, with the consequent liberation of anaphylatoxins C3a and C5a, leukotrienes and cytokines. Milder anaphylactoid reactions may be associated with anti-IgA of limited specificity.

If an anaphylactic reaction occurs, the recipient should be treated promptly with adrenaline and tested for the presence of plasma protein antibodies. If anti-IgA is detected, plasma from IgA-deficient donors should be used in future, as well as well-washed red cells and platelets. Occasionally, washed cells may be indicated for patients with serious urticarial or severe hypersensitivity reactions due to non-IgA antibodies.

Non-immunological complications

Disease transmission

See p. 270.

Reactions due to bacterial pyrogens and bacteria

The presence of bacteria in transfused blood may lead either to febrile reactions in the recipient (due to pyrogens) or to the far more serious manifestations of septic or endotoxic shock. Bacterial-transmitted infections are considerably more frequent than serious acute manifestations of virus-transmitted infections in countries such as the UK (see p. 274).

Bacterial pyrogens are rarely the cause of reactions with present-day methods of manufacture and the sterilization of fluids and disposable equipment. Infection of stored blood is also rare, but has a very high mortality in recipients. Skin contaminants are sometimes present in freshly donated blood but many (e.g. staphylococci) do not survive storage at 4°C. However, they will grow profusely in platelet concentrates stored at 22°C. A number of Gram-negative, psychrophilic, endotoxin-producing contaminants found in dirt, soil and faeces (pseudomonads, coliforms) may very rarely enter a unit and grow readily under the storage conditions of blood (and even more rapidly at room temperature).

Healthy individuals who are bacteraemic at the time of donation may also act as a source of infection. The majority of such cases relate to transmission of *Yersinia enterocolitica*, which grows well in red cell components due to its dependence on citrate and iron.

Transfusion of heavily contaminated blood will usually lead to sudden dramatic symptoms, with collapse, high fever, shock and DIC with haemorrhagic phenomena. These symptoms resemble, and may be more severe than, those of ABO

incompatibility. Prompt recognition of the cause and administration of broad-spectrum intravenous antibiotics, in conjunction with the treatment of shock, are vital. The diagnosis should be confirmed by direct microscopic examination of the blood, and blood cultures from both the recipient and the blood bag.

Prevention of this potentially disastrous complication of blood transfusion rests on stringent observation of procedures for aseptic technique during arm cleansing prior to blood collection and for the manufacture of anticoagulant solutions and packs. Diversion of the first 20–30 mL of blood into a satellite pouch further reduces the contamination of units of blood with skin bacteria. Packs should never be opened for sampling, and the unit should be transfused within 24 hours if any open method of preparation has been used (e.g. washed red cells, frozen–thawed blood). Blood should always be kept in accurately controlled refrigerators (with alarms), maintained strictly at 2–6°C, and a unit of blood should never be removed and taken to the ward or theatre until it is required. The practice of ordering multiple units of blood for the same patient and leaving unused units at room temperature (or in uncontrolled ward refrigerators) until needed must not be tolerated. Handling and storage errors are increasingly reported to SHOT and comprised 13% of all reports in 2008. Bacteria may cause haemolysis or clotting of blood and all units should be inspected for these before transfusion. Platelets should be inspected for discoloration, foaming and absence of swirling.

Baseline observations and regular monitoring of patients undergoing transfusion, with repeat observations at 15–30 min after commencement, are essential so that reactions are detected and acted upon at the earliest opportunity.

Transfusion-associated circulatory overload

All patients, except those who are actively bleeding or fluid depleted, will experience a temporary rise in blood volume and venous pressure after the transfusion of blood and/or plasma. In young people with normal cardiovascular function, this will not cause any embarrassment, providing the total volume given and the transfusion rate are not excessive. In contrast, pregnant women, patients with severe anaemia, and the elderly with compromised cardiovascular function will not tolerate the increase in plasma volume, and acute pulmonary oedema may develop. In view of this possibility, concentrated red cells should be given to these patients slowly over 4 hours. Patients with severe chronic anaemia and cardiac failure may require partial exchange transfusion. In less severe cases, diuretics (oral or intravenous furosemide) should be given at the start of the transfusion and only one or two units of concentrated red cells should be transfused in any 24-hour period. Faster correction of anaemia is rarely required in a non-bleeding patient. The patient should be observed carefully for early signs of cardiac failure (raised jugular venous pressure, crepitations at the lung bases, and symptoms of pulmonary oedema, cough and breath-

lessness). For this reason alone, transfusions should be given during the day, when staff are able to monitor the patient closely. Overnight transfusions should be avoided for the patient's safety and comfort. If circulatory overload occurs, transfusion should be discontinued, the patient propped upright and intravenous diuretics given. Emergency venesection for fluid overload should not be necessary if all precautions have been taken.

Thrombophlebitis

Thrombophlebitis is a complication of indwelling venous cannulae, and not specifically related to blood transfusion.

Air embolism

This is now practically unknown, as blood and blood components are administered from plastic bags.

Transfusion haemosiderosis

Haemosiderosis is a very real complication of repeated blood transfusions, and is being seen more commonly as long-term blood transfusion therapy improves the survival of patients suffering from some chronic anaemias. It is most commonly seen in thalassaemic individuals, who commence transfusions in early childhood. Each unit of blood contains approximately 200 mg of iron, whereas the daily excretion rate is about 1 mg, and the body has no way of excreting the excess. Unless a patient is actively bleeding, and therefore losing iron, iron accumulation is inevitable. Significant iron overload is generally present after approximately 50 units of blood have been transfused to an average-sized adult. It is routine practice to give thalassaemic patients the parenteral iron-chelating agent desferrioxamine or the oral iron chelator deferiprone when available, or a combination of both or deferasirox orally. This does not completely overcome the iron load administered with blood, but has substantially delayed the onset of problems due to haemosiderosis (see Chapters 4 and 6).

Patients who are transfusion dependent should receive blood which is less than 1 week old, which may help to increase the transfusion interval and therefore reduce the overall number of units required. Transfusion of neocytes, or young red cells, looked promising as a means of decreasing the frequency of transfusions and of reducing the iron load. However, this practice is expensive and time-consuming and the trial results were not as favourable as expected.

Complications of massive transfusion

Massive transfusion is usually defined as the replacement of the total blood volume within a 24-hour period. Although a number of different problems may result from changes that occur in stored blood, it should not be forgotten that any patient who needs a massive blood transfusion is by definition already seriously ill. Too much attention may be paid to the theoretical problems caused by metabolic changes in stored blood and not

enough to the underlying clinical condition. The coagulopathy problems derived from massive transfusion are different in trauma from those in elective surgery.

Although the transfusion problems encountered in cardiac surgery were in the past similar to those of massive transfusion, the volume of blood transfused to such patients is now insufficient to merit the routine administration of fresh blood or FFP. When postoperative bleeding occurs, this is usually due to platelet dysfunction and/or reduced numbers. Platelet transfusion is then indicated. Whenever possible, antiplatelet and antithrombotic drugs should be suspended 5–7 days prior to elective surgery.

Replacement of the total blood volume will inevitably lead to some dilution of platelets. Blood effectively has no functional platelets after 48 hours of storage and once 8–10 units of blood have been given to an adult, thrombocytopenia will usually be seen. Regular monitoring of the platelet count in these situations is essential, preferably employing reliable point-of-care testing techniques for rapidly available results; platelet administration may then be judged on the clinical condition and the platelet count. As a guide, platelet transfusion is indicated if the platelet count falls below $80 \times 10^9/L$ in the face of continued bleeding or surgical intervention. Red cell transfusion contributes to normal haemostasis by helping with the margination of platelets and responsiveness of activated platelets, so it is recommended to aim for haemoglobin levels around 10 g/dL if possible.

Coagulation factors will also be diluted as stored blood is administered. Whole blood that has been stored for less than 14 days has adequate levels of most coagulation factors for haemostasis (whole blood is not available in the UK). Factors V and VIII are the most labile but, in conditions of patient 'stress', factor VIII is released from endothelial cells; deficiency of factor VIII sufficient to cause bleeding does not usually occur in these circumstances. If stored blood more than 14 days old is given, or if plasma-reduced blood or red cells in optimal additive solution have been used, replacement of coagulation factors may become necessary. Treatment should be monitored by coagulation studies and DIC screen; FFP and cryoprecipitate, as a source of fibrinogen, should be prescribed on the basis of results from the laboratory or point-of-care testing, such as the thromboelastograph. DIC associated with massive transfusion is most usually due to the underlying condition, such as trauma and/or prolonged shock, and not due to transfused blood per se.

Recent evidence, especially from military practice, has suggested that in cases of major trauma with massive haemorrhage, aggressive early platelet and FFP transfusion reduces overall component usage and improves outcome, especially in patients with High Injury Severity Score. Although further good-quality data are still required, some practitioners in this area favour the issue of a 'shock pack' from the blood bank in these circumstances, so that platelets and FFP as well as red cells are available for immediate transfusion. Fibrinogen concentrate, pro-

thrombin complex concentrate and recombinant FVIIa are increasingly used to aid the control of massive haemorrhage. Well-designed randomized controlled studies are difficult in this area, but case series show encouraging results.

Metabolic changes in stored blood include low pH, hypocalcaemia and hyperkalaemia. The reduced oxygen-carrying capacity of stored blood becomes significant only after 21 days' storage (for CPD-AI blood) and is due to low 2,3-DPG levels (see Chapter 20, p. 376). Although excess citrate in transfused blood could cause toxicity theoretically, its metabolism in the liver is usually rapid. In practice, the only situations when citrate toxicity is a real problem is with extremely rapid transfusion (1 unit every 5 min), or in infants, especially if premature, having exchange transfusion with blood stored in citrate for longer than 5 days. Hypocalcaemia and hyperkalaemia are usually transient and rapidly corrected once the transfused blood is circulating. Acidosis is not generally significant, as citrate metabolism leads to an alkalosis. However, if a patient is severely shocked and under-transfused, acidosis may be a clinical problem. All these changes due to stored blood are exacerbated by hypothermia. Cardiac irregularities, in particular ventricular fibrillation, may result from transfusion of large quantities of cold blood. The optimal functioning of coagulation factors and of platelets is also temperature dependent and effectiveness is reduced by hypothermia. Thus, the use of a blood warmer and keeping the patient warm may be the most important measures to prevent the complications of massive transfusion. Unfortunately, this inevitably reduces the speed at which blood can be transfused, which may be a serious disadvantage when rapid transfusion is needed. When replacement therapy has failed, recombinant activated factor VII (rFVIIa) has been reported as successful in treating the coagulopathy of massive transfusion. However, more evidence is needed. The utilization of prothrombin complex concentrates in this setting also requires evaluation. Tranexamic acid is also being tried in a controlled trial.

The most important consideration in massive blood transfusion is to replace blood loss quickly and adequately with maintenance of normal tissue perfusion, and to prevent development of coagulopathy or thrombocytopenia by aggressive early replacement. Too little blood too late has far more serious consequences than massive blood transfusion itself.

Haemovigilance and SHOT

The interest in transfusion-transmitted infections (TTIs) has meant that transfusion medicine has developed significantly in the last two to three decades and great emphasis has been put on quality, audit and good manufacturing practice. However, there were no surveillance systems in place to assess the incidence and prevalence of transfusion risks. France instituted the first system of national haemovigilance in 1994. Haemovigilance is defined by the International Haemovigilance Network as 'a

set of surveillance procedures organized from the collection of blood and its components to the follow-up of its recipients, with the purpose of collecting and evaluating information on the undesirable and unexpected effects resulting from the therapeutic use of labile blood components and of preventing their occurrence or recurrence’.

The UK’s professionally led haemovigilance system, SHOT, was introduced in 1996 (Figure 16.4). SHOT receives reports of adverse incidents surrounding the transfusion of single or small pool blood components supplied by the UK National Blood Services (red cells, platelets, FFP including MB and SD treated, cryoprecipitate and cryodepleted plasma). The vast majority of incidents reported are from hospitals, with at least 50% arising from clinical areas. SHOT does not comprehensively cover complications of fractionated plasma products but does report on incidents related to anti-D immunoglobulin administration. In the past, reporting to SHOT has been voluntary. In recent years a number of quality, inspection and accreditation bodies within the UK have made reporting to SHOT a requirement. These include Clinical Pathology Accreditation UK, the National Patient Safety Agency and the Department of Health (via HSC 30/2007).

There is now a statutory requirement to report serious adverse reactions and serious adverse events arising in blood establishments or hospital blood banks to the European Commission under Directive 2005/61. In the UK, reporting to both SHOT and the regulatory authority, the Medicines and Healthcare Products Regulatory Agency, is completed online via a shared portal called SABRE (Serious Adverse Blood

Reactions and Events). Hospitals report incidents to SHOT in the following categories.

- 1 Error-related incidents
 - (a) Incorrect blood component transfused, regardless of harm to recipients.
 - (b) Handling and storage errors.
 - (c) Inappropriate and unnecessary transfusion.
- 2 Physiological reactions
 - (a) Acute transfusion reaction within 24 hours.
 - (b) Delayed transfusion reaction beyond 24 hours.
 - (c) Transfusion-associated graft-versus-host disease.
 - (d) TRALI.
 - (e) Transfusion-associated circulatory overload.
 - (f) Transfusion-associated dyspnoea.
 - (g) Post-transfusion purpura.
- 3 Transfusion-transmitted infection
 - (a) Bacterial contamination.
 - (b) Post-transfusion viral infection.
 - (c) Other post-transfusion infection (e.g. malaria, vCJD).
- 4 ‘Near-miss’ events (this has been introduced more recently).
- 5 Anti-D-related events.

Since 1996, SHOT has collected data on serious transfusion complications in the UK and has used these to make firm recommendations for improvements in transfusion safety. The four UK Blood Services currently issue approximately 3 million blood components each year. Since 1996 there has been a year-on-year increase in the number of reports, with over 400 eligible hospitals registered on the scheme. Participation in the scheme continues to increase, and a greater number of hospitals are

Figure 16.4 Cumulative numbers of cases reviewed 1996–2008. ATR, acute transfusion reaction; HSE, handling and storage errors; HTR, haemolytic transfusion reaction; I&U, inappropriate and unnecessary transfusion; IBCT, incorrect blood component transfused; PTP, post-transfusion purpura; TACO, transfusion-

associated circulatory overload; TAD, transfusion-associated dyspnoea; TA-GvHD, transfusion-associated graft-versus-host disease; TRALI, transfusion-related acute lung injury; TTI, transfusion-transmitted infection.

sending in more than one report. There has been a consistent increase in reporting every year, with most recently an 85% increase between 2007 and 2008, affecting all categories except transfusion-transmitted infection.

Of 5374 fully analysed reports between 1996 and 2008, 2355 (44%) were 'wrong blood' incidents (excluding handling and storage errors and inappropriate and unnecessary transfusion, which were previously included in the category 'Incorrect blood component transfused'; see Figure 16.4). Of these, 233 were ABO-incompatible red cell transfusions. Immune complications constituted 28% of reports, with 236 cases of possible TRALI.

Over the 12 years of reporting, the trends observed by SHOT have borne the hallmarks of an effective vigilance system. The number of incidents reported overall has risen, while the frequency of the most serious events has fallen (Figure 16.5). There has been a decrease in the number of ABO-incompatible transfusions and a reduction in the number of cases of TRALI. These trends follow changes in national policies on training and competency for staff involved in blood transfusion, and a switch to male-only FFP, both instigated as a result of SHOT data. Overall mortality directly attributable to transfusion has decreased (Figure 16.6). TTI constituted just 1.2% of reports. There were 64 confirmed TTIs, of which the majority (38 cases)

Figure 16.5 Incorrect blood component transfused (IBCT) and ABO-incompatible red cell cases reported to SHOT 1996–2008. HSE, handling and storage errors; I&U, inappropriate and unnecessary transfusion.

Figure 16.6 Decline in mortality definitely related to transfusion, SHOT 1996–2008.

were of bacterial contamination, 32 from platelets and six from red cells. In 2008 there were four incidents involving bacterially contaminated platelets affecting six patients, two of whom died.

The SHOT data demonstrate that in high-resource countries, virological safety of the blood supply is advanced. Efforts should now be concentrated on preventing bacterial contamination and in other areas of transfusion medicine, such as the encouragement of appropriate use of blood, safe administration of blood components, and accurate patient and sample identification.

Appropriate use of blood and alternatives to allogeneic blood transfusion

In view of the inherent risks of blood transfusion and difficulties with donor recruitment due to escalating stringent donor selection criteria, blood components should only be transfused when the benefits outweigh the risks.

There are several reasons for aiming to reduce unnecessary allogeneic blood transfusion:

- 1 safety of the patient, by avoiding errors, as well as microbiological and immunological risks;
- 2 shortages of blood and increasing difficulties in the recruitment of blood donors;
- 3 cost containment;
- 4 high anxiety levels in patients that are disproportionate to the real residual infectious risk of transfusion.

There are several alternatives to allogeneic blood transfusion, and these can be classified as operational, biological and pharmacological.

Operational alternatives

- Treatment of preoperative anaemia with haematinics, if appropriate, in a timely way through pre-assessment clinics for elective surgery. Optimization of preoperative haemoglobin using haematinics (including intravenous iron) and erythropoietin.
- Autologous transfusion. Cell salvage is most cost-effective if applied to patients undergoing surgical procedures with a high risk of requirement for blood transfusion. Preoperative autologous deposit is becoming less favoured as evidence of efficacy is patchy and contradictory. European regulation (Directive 2002/98, UK Blood Safety and Quality Regulations 2005) mandates that this process can only be carried out at a blood establishment. The value of preoperative haemodilution needs further assessment.
- Re-evaluation of transfusion triggers and algorithms for estimation of acceptable blood loss in surgery. Adherence to guidelines.

- Alternative fluid replacement, i.e. replace use of FFP or albumin with crystalloids or colloids when appropriate.
- Anaesthetic methods to reduce blood loss (e.g. hypotension, patient warming).
- Enhancement of surgical haemostasis and new surgical technologies (e.g. harmonic scalpels, laser, water jets).
- Non-invasive surgery (e.g. angioplasty, laparoscopic surgery).
- Stopping aspirin, non-steroidal anti-inflammatory drugs, clopidogrel and anticoagulants preoperatively.
- Postoperative haematinics.
- Point-of-care testing in theatre.
- Miniaturizing blood sampling in intensive care units for premature babies and adults.
- Stem cell transplantation for transfusion-dependent patients (e.g. thalassaemia).

Biological alternatives

- Recombinant erythropoietin.
- G-CSF.
- Recombinant clotting factors.
- Recombinant activated factor VII (rFVIIa).
- Fibrin glue in surgery.
- In the future: haemoglobin solutions and platelet substitutes?

Pharmacological alternatives

- Tranexamic acid infusion intraoperatively or postoperatively.
- DDAVP preoperatively in mild haemophiliacs.
- Intravenous iron, with or without recombinant erythropoietin preoperatively, especially in patients intolerant or unresponsive to oral iron.
- In the future: oxygen carriers such as fluorocarbons?

Haemolytic disease of the fetus and newborn

Haemolytic disease of the fetus and newborn is a condition in which the lifespan of the fetal/neonatal red cells is shortened due to maternal alloantibodies against red cell antigens inherited from the father. Maternal IgG can cross the placenta, and thus IgG1 and IgG3 red cell alloantibodies can gain access to the fetus. If the fetal red cells contain the corresponding antigen, then binding of antibody to red cells will occur. When the antibody is of clinical significance (e.g. anti-D, -c, -E, -K, -Jk^a), and of sufficient potency, the coated cells will be prematurely removed by the fetal mononuclear phagocytic system. The effects on the fetus/newborn infant may vary according to the characteristics of the maternal alloantibody.

The antibodies giving rise to HDN most commonly belong to the Rh or ABO blood group systems. The morbidity of Rh HDN is explained by the great immunogenicity of the D antigen; HDN due to anti-c is also important and its incidence comes second among the cases of severe HDN, closely followed by the non-Rh antibody, anti-K. (The disease caused by anti-K is more properly called *alloimmune anaemia of the fetus and newborn* as it is due to direct inhibition of erythropoiesis by the antibody and haemolysis is not a feature.) Antibodies against antigens in almost all the blood group systems (e.g. Duffy, Kidd), and against the so-called 'public' and 'private' antigens, have also been occasionally responsible for HDN. However, IgM cannot cross the placenta and Lewis and P₁ antibodies, which occur frequently during pregnancy, are usually IgM and do not lead to HDN. Furthermore, the Lewis antigens are not red cell antigens per se and are not fully developed at birth.

All women who have had previous pregnancies or blood transfusions may become immunized against 'foreign' red cell antigens. However, red cell antibodies may be found in those with no such history, either because the antibodies are 'naturally occurring' or because a spontaneous abortion early in a previous pregnancy was unrecognized as such. Blood samples from all pregnant women must be tested early for the presence of atypical red cell antibodies (usually at 12–16 weeks, during the booking visit), and again at 28 weeks' gestation, even if no antibody was found at booking.

When anti-D, anti-c or anti-K are detected at booking, the strength of the antibody and the rate of rise (if any) in titre, or level in micrograms, during pregnancy must be carefully monitored by regular monthly blood sampling during the second trimester and fortnightly thereafter. If the level of any other clinically significant antibody is moderately high or high at 28 weeks, it should be monitored fortnightly until term. If the level of anti-D is greater than 10 IU/mL (2 µg/mL) or anti-c greater than 20 IU/mL, or if other antibodies have an IAT titre of 32 or greater, the fetus should be monitored by ultrasound/Doppler for evidence of anaemia and cardiac decompensation. At these levels, in the case of anti-D, anti-c or anti-K, referral to a fetomaternal unit is advised. It should be noted that, in the case of potent anti-K, severe anaemia may occur relatively early during gestation.

Fetal and neonatal anaemia due to anti-D and anti-K tends to be more severe than that due to any other alloantibody. The next important, in terms of severity, is that due to anti-c. Anti-A,B is a common cause of HDN in group O mothers delivering group A or B infants (1 in 150 births), but the disease is usually mild; death *in utero* is unknown though exchange transfusion after birth may occasionally be required.

There are many significant differences between HDN due to ABO and Rh incompatibilities. The low incidence of infants requiring treatment for ABO HDN contrasts with the situation in Rh HDN. Furthermore, ABO HDN is found as frequently in the first pregnancy as in later pregnancies; subsequent infants

may not be affected. In Rh HDN, a first pregnancy is usually unaffected (unless there has been prior immunization by abortion or transfusion), and subsequent Rh-incompatible infants are affected to an equal degree or more severely. The majority of neonates affected with Rh HDN require some form of therapy.

Clinical features

In its least severe form, HDN manifests itself as mild haemolytic anaemia. The infant's red cells, coated with maternal IgG alloantibody, are removed prematurely from the circulation, causing slight jaundice (maximum on the second to third days of life) and mild anaemia during the second week of life. More severely affected infants show severe hyperbilirubinaemia in the neonatal period, a condition that was called *icterus gravis neonatorum*. Prompt treatment with exchange transfusion is necessary to prevent bilirubin impregnation of the basal ganglia and neurological damage, a condition known as *kernicterus*. This condition may be fatal, or lead to serious neurological deficit, with deafness, mental retardation, choreoathetosis and spasticity.

In the most severely affected cases, profound anaemia develops *in utero*, and intrauterine death may occur at any time from the 18th week of gestation. Affected fetuses are pale and oedematous, with marked ascites. The placenta is bulky, swollen and friable. This condition is known as *hydrops fetalis*, and had a high mortality rate until ultrasound-guided intravascular transfusions and improved intensive care facilities for very premature babies were introduced. The pathophysiology of hydrops is not fully understood, but extravascular haemolysis with fetal anaemia seems to play a major role by stimulating extramedullary erythropoiesis in the liver, with distortion of the hepatic circulation, leading to portal hypertension and impaired albumin production. Hypoalbuminaemia leads to ascites, oedema and pleural/pericardial effusions. In addition, the severe anaemia leads to cardiac failure and tissue hypoxia, which damages the endothelium, leading to fluid extravasation into the extravascular space.

The blood film of a fetus affected by HDN shows polychromasia and increased numbers of nucleated red cells (Figure 16.7). In most cases (except a few due to ABO antibodies), the DAT (Coombs test) on the infant's cells is positive owing to IgG coating.

Rh haemolytic disease of the newborn

Until the early 1970s (when Rh immunoprophylaxis was introduced), 0.5–0.75% of all births gave rise to infants affected by Rh HDN. Anti-D accounted for over 90% of all cases. Although anti-D HDN has decreased significantly as a cause, it remains the most important. Of all infants affected by Rh HDN, 10–20% died *in utero* or in the early neonatal period before effective

Figure 16.7 Blood film of a fetus affected by HDN showing polychromasia and increased numbers of normoblasts.

therapy was possible. The disease due to anti-D is more severe than that due to most other alloantibodies (e.g. anti-c, -E) except for some cases of anti-K. Early detection of maternal alloantibodies, regular fetal monitoring and assessment of rises in antibody titres are prerequisites to a successful outcome.

Antenatal assessment of maternal blood

Rarely, anti-D may develop in a first pregnancy in a woman who has had no previous transfusions. However, it is not common for the antibody to reach high levels, and it is not usually detectable before 28 weeks; most of such cases become apparent after delivery. Conversely, in women who have had previous pregnancies or transfusions with Rh-positive red cells, anti-D may be detected early in pregnancy; regular monitoring of the level is necessary in order to plan the best type and timing of intervention. At present, the most objective means of quantifying anti-D levels routinely is with an automated analyser or, rarely, by flow cytometry and not by manual titration. More important than the anti-D levels in determining the severity of HDN is the obstetric assessment of the fetus.

The ABO, Rh groups and antibody screen should be performed in all pregnant women at booking (usually around 16 weeks' gestation). All women should have the testing repeated once more at about 28 weeks to confirm the Rh group and to detect the presence of atypical antibodies. If clinically significant antibodies are detected, more frequent testing will be required (see below). If the mother is RhD negative with no anti-D by 28 weeks, routine antenatal prophylaxis should be given (see below). Following delivery, all RhD-negative women who are unsensitized for RhD should be given prophylactic anti-RhD immunoglobulin if the infant is RhD positive (Figure 16.8).

The level of anti-D in the serum correlates approximately with the clinical severity of the HDN, but this is also affected by factors such as IgG subclass, rate of rise of antibody, past history and presence of maternal blocking antibodies. As a

rough guide, levels below 4.0 IU/mL (0.8 µg/mL) require no action, whereas a level above 4 and up to 10 IU/mL (2.0 µg/mL) indicates moderate risk; 10–20 IU/mL indicates high risk of HDN and levels greater than 20 IU/mL indicate a high risk of hydrops. Anti-D, anti-c and anti-K should be monitored monthly to 28 weeks and 2-weekly thereafter. Other red cell antibodies reacting by IAT should be retested at 28 weeks, titrated and the maternal serum should be tested for the presence of Kell alloantibodies. If the anti-D level is above 10 IU/mL, anti-c above 20 IU/mL or for other antibodies the IAT titre is above 32, the fetus should be monitored by the fetal medicine specialist for evidence of anaemia. The strength and trend in titre of other maternal alloantibodies should be reported to the obstetrician, for fetal monitoring as appropriate.

Antenatal assessment of disease severity and treatment of haemolytic disease

The severity of the haemolytic process may be assessed by fetal medicine specialists using clinical and ultrasound monitoring, including Doppler flow velocity. The systolic velocity of the fetal middle cerebral artery is a reliable indicator of fetal anaemia (Figure 16.9). Measurement of bile pigments in the amniotic fluid by spectrophotometry from week 28 onwards is less commonly used now in the UK. The absorbance of normal amniotic fluid over the range of wavelengths 400–600 nm forms a smooth curve when plotted on semi-logarithmic graph paper. When there is an excess of bilirubin, the curve shows a greatly increased absorbance, with a peak at about 450 nm. The increase in density at this wavelength over the normal absorbance is the measurement of severity.

If the non-invasive parameters of severity indicate a severely affected infant, the fetal medicine specialist can perform ultrasound-guided fetal blood sampling from 18–20 weeks onwards. The fetal haemoglobin deficit is measured (Figure 16.10) and, if necessary, an intravascular transfusion with fresh (< 5 days old) group O, RhD-negative, CMV-negative, irradiated blood of the desired packed cell volume (PCV) can be administered. Such transfusions will be performed subsequently throughout pregnancy, with a frequency determined by the severity of the disease. Fetal blood sampling and amniocentesis carry a risk of immunizing a previously unsensitized RhD-negative woman carrying an RhD-positive fetus, due to leakage of fetal blood into the maternal circulation. Similarly, pre-existing low antibody levels may be 'boosted' by a new stimulus. Immunization to, or boosting of, other clinically significant red cell alloantibodies is not a rare occurrence. Although the risks of fetal blood sampling are small in experienced hands, there are possible adverse effects on the fetus (e.g. bleeding through puncture of fetal vessels).

Intraperitoneal transfusion involves injection of antigen-negative donor red cells into the peritoneal cavity of the fetus (now rarely used). Blood with the same specification as for intravascular transfusions is used from 24 weeks of gestation. If

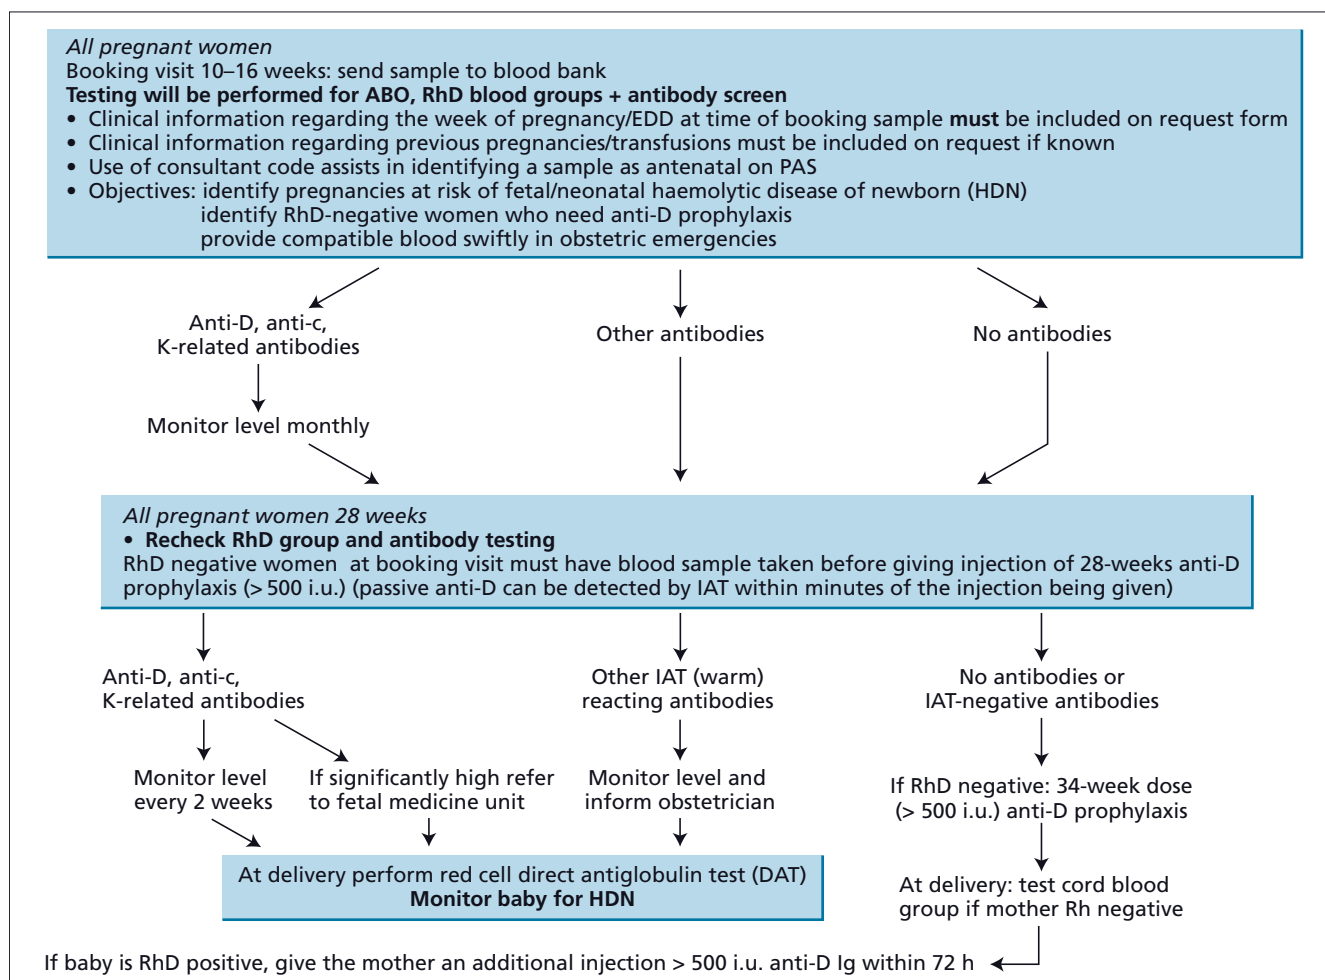

Figure 16.8 Blood group and antibody testing in pregnancy. (From British Committee for Standards in Haematology (1996) *Guidelines for Blood Grouping and Antibody Testing During Pregnancy*, with permission).

ascites is already present, absorption of the red cells into the fetal circulation is slow and intravascular transfusion will continue to be the treatment of choice.

It is possible to determine the Rh genotype of the fetus from amniotic cells through DNA typing, thus avoiding further manipulations when the fetus is RhD negative. Fetal RhD genotyping is now possible by DNA extraction from maternal plasma from 16–18 weeks' gestation; this non-invasive technique is replacing amniocyte typing (see Chapter 15). If the partner is available, he too may be tested for the presence of the relevant antigen.

Premature delivery

Modern neonatal intensive care has dramatically increased survival rates of very premature infants born at 24–30 weeks' gestation. Nevertheless, morbidity is high and premature delivery is now, due to the success of intrauterine transfusions, rarely performed. It is sometimes considered at 36 weeks for fetuses suf-

fering from haemolytic disease due to antibodies other than anti-D, anti-c or anti-K. When the previous obstetric history is poor, the mother starts with a high level of anti-D and the partner is homozygous for D, or the fetus is known to be D positive, intravenous immunoglobulin is given to carry the pregnancy to 20 weeks, when intrauterine transfusions can be started. In several countries, intravenous immunoglobulin is the mainstay of therapy throughout pregnancy.

Assessment of severity in the newborn

Cord blood samples should be taken at delivery. The DAT may be positive but is not a useful indication of severity or need for therapy. The best simple criterion of severity is the cord haemoglobin level; this is much more useful than a sample taken a few hours after birth, when rapid haemodynamic changes are occurring. The normal range of cord haemoglobin levels is 13.6–19.6 g/dL. Most infants with levels in this range do not require therapy; more than 50% of affected babies have a level

Figure 16.9 Middle cerebral artery Doppler. Peak velocity of systolic blood flow in the middle cerebral artery in 111 fetuses at risk for anaemia due to maternal red cell alloimmunization. Open circles indicate fetuses with either no anaemia or mild anaemia (≥ 0.65 multiples of the median Hb concentration). Triangles indicate fetuses with moderate or severe anaemia

(< 0.65 multiples of the median Hb concentration). Solid circles indicate the fetuses with hydrops. Solid curve indicates the median peak systolic velocity in the middle cerebral artery and the dotted curve indicates 1.5 multiples of the median. (Courtesy of Professor Charles Rodeck.)

Figure 16.10 Fetal haemoglobin (Hb) concentration of 48 hydropic (open circles) and 106 non-hydropic (closed circles) fetuses from red cell isoimmunized pregnancies at time of first blood sampling. Values are plotted on the reference range of fetal Hb for gestation. The individual 95% confidence intervals of the

normal Hb for gestation define zone I and the individual 95% confidence intervals of the Hb for gestation of the hydropic fetuses define zone III. Zone II indicates moderate anaemia. (Courtesy of Professor Charles Rodeck.)

in the normal range. Where the cord haemoglobin is below 12 g/dL, exchange transfusion will be necessary. It may also be indicated for a rising bilirubin level after birth, depending on the rate of rise and the maturity of the infant. Phototherapy may be given to reduce the rise in bilirubin levels but it is not a substitute for transfusion. Less severely affected infants may

require small-volume transfusions of red cells at 2–3 weeks of age. In both these instances, careful follow-up arrangements must be made as haemolysis may continue, causing further rises in bilirubin or need for additional top-up transfusion.

The infant's RhD group should be determined on the cord blood sample of all infants born to D-negative mothers with no

performed anti-D in order to give anti-D immunoglobulin prophylaxis if they type as D-positive. A DAT is only performed on cord bloods of mothers who have made anti-D; the cord bloods of women given antenatal Rh prophylaxis should not undergo DAT as it may be positive due to the passive anti-D given. If intrauterine transfusions have been given, the ABO and Rh groups may be those of the donor, and the DAT may be negative. A DAT should be performed on the cord blood of all women who have IAT-reactive antibodies. If the DAT is positive, the cord haemoglobin should be checked and the clinical state, haemoglobin and bilirubin of the infant monitored for signs of HDN for 1 month.

Exchange transfusion

Exchange transfusion is effective therapy for HDN, removing from the infant's circulation sensitized red cells and plasma containing both maternal antibody and bilirubin. It also treats the anaemia.

An exchange transfusion of one blood volume will replace approximately 75% of the infant's red cells. It is usual to exchange relatively large volumes of blood (e.g. 160 mL/kg) slowly, via an umbilical vein catheter. The donor blood should be ABO compatible with mother and infant, and lack the antigen against which the maternal antibody is directed. A compatibility test should be performed against maternal serum. Blood in CPD-AI of less than 5 days old with a PCV of 0.5–0.6 is suitable for exchange transfusions, regardless of the ABO group of the infant. If group O blood is used in all exchange transfusions, it should be devoid of high-titre ABO antibodies. CMV antibody-negative donations should be used for infants less than 1200 g in weight. If possible, the blood should be irradiated, but there should be no delay to the exchange on account of this. Irradiated blood must be given to infants who have been transfused *in utero*, because they are at greater risk of transfusion-associated graft-versus-host disease.

ABO haemolytic disease of the newborn

In 20% of births, the mother is ABO incompatible with her fetus. In A and B subjects, the anti-B and anti-A are predominantly IgM and do not enter the fetus. ABO HDN is usually restricted to group O mothers possessing IgG anti-A,B, in addition to IgM antibodies. In 15% of all pregnancies of white mothers, a group O mother carries a group A or B fetus, but the overall incidence of ABO HDN requiring treatment is extremely low. In absolute terms, however, exchange transfusion may be required in up to 1 in 3000 infants.

The lack of severity of ABO HDN can be accounted for by the widespread occurrence of A and B antigens, not only on red cells but also in plasma and on other cells, which will partially neutralize maternally derived ABO antibodies. Furthermore, the A and B antigens are not fully developed in the infant and the number of ABO sites is much smaller than in adults (see

Chapter 15, p. 247). Thus, only small amounts of the maternal antibody bind to infant red cells, and clinical sequelae are usually mild.

Serological findings

The mother is usually blood group O; IgG anti-A,B, anti-A and anti-B can be demonstrated in her plasma after inactivating or inhibiting the IgM component with a reducing agent (2-mercaptoethanol or dithiothreitol, ZZAP). When infants are affected and require therapy, the maternal IgG anti-A or anti-B is almost always present in a titre greater than 64.

The infant will be group A or B and the DAT may be positive, only weakly positive or negative. In most cases, spontaneous agglutination will be observed if a drop of whole blood from the cord is rocked gently on a tile, especially if the cells are suspended in ABO-compatible plasma. Testing eluates from the red cells by IAT will reveal anti-A or anti-B specificity. Examination of the infant's blood film may show spontaneous agglutination of red cells, spherocytosis (not seen with Rh HDN), reticulocytosis, polychromasia and increased numbers of nucleated red cells.

Treatment

Severe anaemia is uncommon. Hyperbilirubinaemia is more often a problem and often subsides with phototherapy, but may occasionally be serious enough to warrant exchange transfusion to prevent brain damage. Group O donor blood with low-titre anti-A,B should be used.

Haemolytic disease of the newborn due to other antibodies

After anti-D, the antibodies encountered most commonly as a cause of HDN are anti-c and anti-K (the former usually due to previous pregnancy and the latter to previous maternal blood transfusions). The disease is generally less severe than that caused by anti-D, but may sometimes be serious enough to warrant early delivery and/or exchange transfusion, and occasionally requires treatment of the fetus. Anti-K of high titre may cause severe fetal anaemia, because the K antigen is present in early red cell precursors. Assessment and treatment of the fetus and infant should be along the same lines as for anti-D. Blood that lacks the appropriate antigen should be given if intrauterine or exchange transfusion is required.

Although uncommon, practically all other red cell alloantibodies have been implicated in HDN, requiring no therapy, small-volume transfusion or, very rarely, exchange transfusions.

Prevention of haemolytic disease of the newborn

The major success in HDN in the last 15 years is because of the decrease in cases due to anti-D, so that other antibodies now

account for a higher proportion of cases. This reduction has been achieved by the routine administration of a minimum dose of 500 IU (100 µg) anti-RhD immunoglobulin to all RhD-negative mothers within 72 hours following delivery of a RhD-positive infant. Extra doses of 50–75 IU (20–25 µg) per additional millilitre of red cells may be required for the small number of women (< 1%) who have a transplacental bleed greater than that covered by the standard dose (which covers 4 mL of packed cells). Anti-RhD immunoglobulin is also indicated after spontaneous or therapeutic abortion or threatened miscarriage and all procedures that might lead to a fetomaternal bleed (amniocentesis, external version, abdominal injury, chorionic villus sampling); the dose is 250 IU (50 µg) up to 20 weeks' gestation and 500 IU thereafter. It is critical that a Kleihauer acid elution test for detection and quantification of fetal red cells is performed on a maternal blood sample taken shortly after (within 1 hour of) delivery and after each sensitizing event after 20 weeks. If the test shows more than 4 mL of fetal cells, flow cytometry should be used to check the volume and give additional doses of anti-D as required. In several countries, and parts of the UK, the standard dose of anti-D immunoglobulin is 1250–1500 IU (250–300 µg). Where routine antenatal anti-D prophylaxis (see below) is being used, some lesser sensitizing events will be adequately covered. However, a Kleihauer test must still be performed.

Despite prophylaxis, new cases of sensitization to the D antigen still occur. Some may be due to an early unrecognized abortion and some to clerical and administrative errors (e.g. incorrect grouping of mother or child, or errors in the recording of groups). Failure of protection after delivery may result from omission of anti-D immunoglobulin (e.g. early discharge), an insufficient dose, or where primary immunization has already occurred during the pregnancy, now the most common cause of failure of conventional postnatal prophylaxis. Approximately 0.8–1.5% of Rh-negative women carrying a Rh-positive fetus become immunized during pregnancy.

To further reduce Rh immunization significantly, anti-RhD immunoglobulin should be given routinely during pregnancy to all RhD-negative women. A minimum of 500 IU (100 µg) should be administered intramuscularly at 28 and 34 weeks, with some centres administering up to 1250 IU. A single dose of 1500 IU (300 µg) at 28 weeks has also been recommended, although there are insufficient data regarding efficacy and the risk to mother and fetus if this single dose is missed is much more significant. Data from Canada suggest that a second dose of 300 µg may be needed for many women at 34 weeks, despite the larger dose at 28 weeks. The UK national policy is to offer routine antenatal prophylaxis to all pregnant RhD-negative women, as it significantly reduces the incidence of RhD sensitization in pregnant women. It is expected to offer D typing of the fetus from DNA extracted from maternal plasma before 28 weeks' gestation (see Chapter 15). This will avoid giving unne-

cessary routine antenatal Rh prophylaxis to women carrying RhD-negative fetuses.

The next most common causes of HDN requiring therapy are anti-c and anti-K. Any reduction in the cases due to anti-K could only be achieved by prevention of sensitization through transfusion of all women of childbearing potential with K-negative blood.

Neonatal alloimmune thrombocytopenia

This is a condition in which the platelets of the fetus and newborn are destroyed by maternal platelet-specific alloantibodies against platelet antigens inherited from the father. It is analogous to HDN, but for platelets. Although more than 15 human platelet antigen (HPA) systems have been described, most cases are due to anti-HPA-1a in alloimmunized HPA-1b mothers. The difference with neonatal alloimmune thrombocytopenia is that the offspring of the first pregnancy can be affected and that the potency of the platelet antibodies is often not correlated with the severity of the fetal or neonatal thrombocytopenia. The most serious complication is intracranial haemorrhage, which may lead to death or severe neurological sequelae. Treatment consists of intravenous immunoglobulin and/or transfusion of HPA-1a-negative platelets, available from stock throughout the National Blood Service.

Selected bibliography, 327**Introduction**

White blood cells have fundamental roles in defence against invading microorganisms and the recognition and destruction of neoplastic cells as well as their role in acute inflammatory reactions. Furthermore, through their phagocytic function, white blood cells are influential in clearing senescent and apoptotic cells, hence allowing tissue repair and remodelling. Production of various cytokines by white blood cells influences the functions of other cells and affects processes such as cellular and humoral immunity, and allergic phenomena. The phagocytic actions of white blood cells can cause damage to the host tissue, leading to inflammation. This occurs either as a by-product of their microbial killing actions or as a direct attack on the host in autoimmune disorders.

Normal haemopoiesis, including generation of appropriate white blood cell number and constellation, is dependent upon intricately regulated signalling cascades that are mediated by cytokines and their receptors. Orderly function of these pathways leads to the generation of the normal constellation of haemopoietic cells, and their abnormal activation results in impaired apoptosis, uncontrolled proliferation and neoplastic transformation. Cytokines function in a redundant and pleiotropic manner; different cytokines can exert similar effects on the same cell type and any particular cytokine can have several differing biological functions. This complexity of function is a result of shared receptor subunits as well as overlapping downstream pathways, culminating in transcription of similar genes. Increased understanding of the role of cytokines and other

growth factors in the control of normal haemopoiesis has led to better delineation of the pathogenetic events that affect the function and number of these cells.

In this chapter, we consider the normal production and function of white blood cells involved in phagocytosis and describe various disorders causing their altered number and activity.

Mechanisms of phagocyte function**Locomotion**

Phagocytes are an important part of the innate host defence system, performing their function either as resident cells in tissues (e.g. macrophages) or as circulating defenders (e.g. neutrophils, eosinophils and monocytes). Phagocytosis of invading microorganisms by both types of defenders involves the synthesis of highly toxic derivatives of molecular oxygen by the respiratory burst NADPH oxidases and the delivery of stored antimicrobial proteases into the vacuoles containing microbes.

Circulating phagocytes such as neutrophils respond to spatial gradients of chemotaxins and move by alternating the extrusion and retraction of broad frontal lamellipodia that determine the direction of movement. As a result, the body of the cell elongates along the axis defined by the lamellar protrusion. As little as a 2% change in the concentration of the chemoattractant can be recognized by neutrophils. The signals generated by such gradients activate the cytoplasm of the cell leading to propulsive and retractive events. The movement of neutrophils is achieved by the contraction of an actin filamentous network in the cortical gel at the leading front. This dynamic network provides strength for the forming protrusions and serves as an anchor for adhesion molecules. ATP provides the energy for the movement of the cell.

Phagocytic cells possess a number of cell–cell adhesion receptors and ligands, which mediate their recruitment, migration and interaction with other immune cells (Table 17.1). These include members of the integrins, the immunoglobulin superfamily and the selectins. Migration of macrophages involves their adhesion to endothelial surfaces and their extravasation to the extravascular space. This process is mediated by cytokine-regulated expression of intercellular adhesion molecules (ICAMs) on the surface of both phagocytes and endothelial cell. ICAMs share similar structure to the immunoglobulin family and other immunoglobulin-like adhesion molecules such as vascular cell adhesion molecule (VCAM)-1, and serve as ligands for the β_2 integrins. The distribution and regulation of the three members of the ICAM family is different. ICAM-1 is expressed at a low level on endothelial cells; its expression is enhanced by the inflammatory cytokines such as interleukin (IL)-1, interferon (IFN)- α and IFN- γ . ICAM-2 is constitutively expressed on endothelial cells, with no response to the inflammatory cytokines. ICAM-3 is expressed by neutrophils, monocytes and lymphocytes. Another member of the endothelial immunoglobulin superfamily, PECAM-1 (CD31), serves an important role in transmigration of neutrophils into mucosal or other body tissues.

The β_2 integrin family consists of three leucocyte restricted integrins, LFA-1 (CD11a/CD18), CR3 (MAC-1, CD11b/CD18) and p150/95 (CD11c/CD18). They share a common β -subunit, CD18, and three unique α -subunits, CD11a, CD11b and CD11c. LFA-1 and ICAM-1 are both present on monocytes and mediate their attachment to endothelial cells and to lymphocytes bearing the corresponding receptor/ligand, thereby facilitating antigen presentation. Leucocyte adhesion deficiency type I, described later in the chapter, is caused by the genetic deficiency of all three CD18 integrins, and neutrophils in this condition bind poorly to IL-1-stimulated endothelial cells and do not undergo transendothelial migration.

Selectins are expressed on all leucocytes (L-selectins) as well as post-capillary endothelial surfaces (E-selectins) and in platelet α -granules and endothelial cell Weibel–Palade bodies (P-selectins). Neutrophils, eosinophils, monocytes and macrophages constitutively express L-selectin. E- and P-selectins recognize oligosaccharide ligands on macrophages. Selectins are implicated in the early interactions of phagocytes and endothelium. The interaction of E- and P-selectins on cytokine-activated endothelial cells, and L-selectins on macrophages with their appropriate ligands, targets phagocytic cells to the endothelium at sites of vascular injury and initiates the rolling movement of leucocytes along the vessel wall. The ligands for selectins have a similar structure, containing carbohydrate groups typically as terminal structures of glycoproteins and glycolipids. A major selectin ligand, a sialylated and fucosylated tetrasaccharide related to the sialylated Lewis X blood group, is heavily expressed on quiescent neutrophils and monocytes.

Paracellular diapedesis is the purposeful coordinated movement of leucocytes through the endothelial lining towards sites of inflammation. Neutrophil chemotaxis requires a series of sequential steps resulting in the recruitment of these cells at tissue sites away from the vessel lumen. Selectin-mediated leucocyte tethering and rolling across endothelial surfaces is followed by integrin-mediated firm adhesion and leucocyte polarization at endothelial cell junctions. CD157, a glycosylphosphatidylinositol (GPI)-anchored surface protein, is crucial to this process of locomotion and is expressed on the surface of neutrophils and vascular interendothelial junctions. As would be expected, neutrophils from patients with paroxysmal nocturnal haemoglobinuria, in which there is loss of GPI-linked proteins, demonstrate defective chemotaxis with impaired transendothelial migration.

Phagocyte receptors

Phagocytes express a number of surface receptors that are able to recognize microbial surfaces as well as altered tissue components and apoptotic bodies (Table 17.2). Furthermore, non-specific components of the innate immune response, such as the components of the complement cascade, can tag and thereby identify invading microorganisms, thus allowing their opsonization via another family of receptors, leading to the uptake of complement-coated microorganisms. This complement fixation can occur either via the classical pathway, which is activated by the prior binding of immune IgG or IgM to the organism or particle, or by antibody-independent activation of the alternative pathway. Similarly, other molecules such as matrix proteins (i.e. fibronectin and vitronectin) can act as opsonins allowing recognition and uptake by the phagocytic cells. Interestingly, in order to evade phagocytes, pathogenic bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Neisseria meningitidis* have developed strategies such as production of polysaccharide capsules, which provide a shield against complement binding and activation, and recognition by scavenger receptors.

Two types of complement receptors, CR1 (CD35) and CR3 (CD11b/CD18), have been described. CR1 is a glycosylated protein of 160–250 kDa and can be identified as CD35. CR1 is present on all phagocytes as well as some T lymphocytes. CR1 mediates phagocytosis of particles opsonized by C3b and regulates complement activation. CR3 is a member of the β_2 integrin family and is designated CD11b/CD18. It is composed of two polypeptide chains, an α -subunit of 185 kDa and a β -subunit of 95 kDa. CR3 is expressed on all phagocytes as well as natural killer cells and some $\gamma\delta$ T cells. Monocytes and macrophages express high levels of CR3; neutrophils have lower-level expression that can increase rapidly through release from intracellular stores. CR3 can bind particles opsonized with C3bi as well as determinants on unopsonized microbes. The avidity of CR3 is enhanced by an amphipathic anion lipid called integrin-

Table 17.1 Phagocytic cell adhesion molecules.

<i>Adhesion molecule</i>	<i>CD number</i>	<i>Cellular distribution</i>	<i>Ligand</i>	<i>Function</i>
Integrin family				
<i>Very late-acting antigens</i>				
$\alpha_1\beta_1$ (VLA-1)	CD49a/29	Mo, EC	Collagen I, IV, laminin	Cell adherence to ECM

$\alpha_6\beta_1$ (VLA-6)	CD49f/29	Mo	Laminin	Cell adherence to ECM
<i>Leucocyte integrins (LFA-1 family)</i>				
$\alpha_D\beta_2$	–/18	Ma	?	
$\alpha_L\beta_2$ (LFA-1)	CD11a/18	Mo, Ma, granulocytes	ICAM-1, ICAM-2, ICAM-3	Cell–cell adhesion and cell–matrix adhesion
$\alpha_M\beta_2$ (CR3, Mac-1)	CD11b/18	Mo, Ma, granulocytes	ICAM-1, C3bi, fibronectin, factor X, microbial antigens	Endothelium adherence/extravasation
$\alpha_X\beta_2$ (p150,95)	CD11c/18	Mo, Ma, granulocytes	C3bi, fibronectin	Adhesion during inflammatory response
<i>Cytoadhesins</i>				
$\alpha_V\beta_3$ (vitronectin receptor)	CD51/61	Mo, EC	Vitronectin, fibronectin, collagen, thrombospondin, vWF	Cell adherence to ECM
$\alpha_R\beta_3$ (leucocyte response integrin)		Mo, granulocytes	Vitronectin, fibronectin, collagen, thrombospondin, vWF	Cell adherence to ECM
$\alpha_V\beta_5$	CD51/–	Mo	Vitronectin, fibronectin	Cell adherence to ECM
$\alpha_V\beta_7$	CD51/–	Ma	?	
Immunoglobulin superfamily				
ICAM-1	CD54	Mo, EC	$\alpha_L\beta_2, \alpha_M\beta_2$	Cell–cell adhesion
ICAM-2	CD102	Mo, EC	$\alpha_L\beta_2$	Cell–cell adhesion
ICAM-3	CD50	Mo, granulocytes	$\alpha_L\beta_2$	Cell–cell adhesion
VCAM-1	CD106	Ma, EC, dendritic cells	$\alpha_4\beta_1$	Recruitment
PECAM-1	CD31	Mo, EC, platelets	CD31, $\alpha_V\beta_3$	Transmigration
HCAM	CD44	Ubiquitous	Collagen I, IV, fibronectin	Extravasation
Selectin family				
L-selectin	CD62L	Mo, granulocytes	Carbohydrate determinants on EC	Migration, rolling on vessel wall
E-selectin	CD62E	Neutrophil, EC	Mo, neut, eos	Migration, rolling on vessel wall
P-selectin	CD62P	EC, platelets	Mo, neut, eos	Adhesion to activated platelets and EC

Bas, basophil; CD, cluster of differentiation; EC, endothelial cell; eos, eosinophil; ICAM, intercellular adhesion molecule; Mo, monocyte; Ma, macrophage; neut, neutrophil.

Table 17.2 Opsonic receptors mediating phagocytosis.

Receptor	Marker	Opsonic ligand	Binding affinity (K_d)	Cell type	Function
Fc γ RI	CD64	IgG1	High (50 nmol/L)	Monocytes, macrophages, neutrophils (after IFN- γ exposure)	Phagocytosis, respiratory burst
Fc γ RII	CD32	IgG1 = IgG3 \geq IgG4 = IgG2	Low (1 μ mol/L)	Neutrophils, monocytes, macrophages	Phagocytosis, respiratory burst
Fc γ RIII		IgG1 = IgG3	Low (110 nmol/L)	Neutrophils, monocytes, macrophages	IIIB: phagocytosis (requires CR1 or Fc γ RII)
IIIA	CD16a, 1 allotype NA1		Low (470 nmol/L)		
IIIB	CD16b, two allotypes NA1 and NA2				
Fc α R	CD89 My43 IgM	IgA1, IgA2, secretory IgA1 and IgA2		Neutrophils, monocytes, macrophages, T and B cell subsets, NK cells, erythrocytes	Phagocytosis, respiratory burst, bacterial killing
CR1	CD35, four alleles	C3b and C4b dimers	High (0.5 nmol/L)	All phagocytes, some T lymphocytes	Phagocytosis
CR3	CD11b/CD18 Mac1	C3bi	High (0.5 nmol/L)	All phagocytes, NK cells, $\gamma\delta$ T cells	Phagocytosis, respiratory burst

CR, complement receptor; NK, natural killer.

modulating factor (IMF-1) as well as by bacterial peptide fragments, C5a, leukotriene (LT) B_4 , and cytokines such as tumour necrosis factor (TNF), granulocyte colony-stimulating factor (G-CSF) and granulocyte/macrophage colony-stimulating factor (GM-CSF). However, IFN- γ transiently decreases the binding capacity of both CR1 and CR3. Simultaneous cross-linking between two different receptor types also increases binding by CR3. For example, macrophages adhered to collagen ingest complement-coated particles less efficiently than macrophages adhered to fibronectin, which cross-links other integrin receptors. CR3 also plays a critical role in adherence-dependent potentiation of the respiratory burst and secretory responses of neutrophils.

Phagocytes also express a number of receptors for the Fc portion of immunoglobulin molecules IgA, IgE and IgG. They mediate opsonization of particles and microorganisms, enhancing their phagocytic uptake. The antigen-binding site (Fab) of IgG binds to bacteria exposing the Fc-binding site, which is in turn recognized by one of three classes of receptor, Fc γ RI, Fc γ RII or Fc γ RIII. Fc γ RIII is constitutively expressed by neutrophils, with 100 000–300 000 copies per cell, and is identified as CD16. Two isoforms, A and B, exist, which differ only with respect to their transmembrane and cytoplasmic domains. Fc γ RIIIB lacks both of these domains and is anchored by a GPI protein and is therefore absent in patients with paroxysmal

nocturnal haemoglobinuria. Fc γ RIIIB can trigger granule release but no associated respiratory burst. However, Fc γ RIIIB and CR3, together with Fc γ RII, act synergistically to activate the respiratory burst. Fc γ RII (identified as CD32) is a constitutive low-affinity receptor with low expression (1000–4000 copies per cell) requiring dimeric IgG for binding. Cross-linking Fc γ RII stimulates oxygen radical production. Fc γ RI, identified as CD64, is not expressed on quiescent neutrophils but its expression is highly increased after exposure to IFN- γ and a number of inflammatory mediators. It binds IgG1 and IgG2 with high affinity and promotes phagocytosis of bacteria opsonized by them. Polymeric IgA antibody can also function as an opsonin and is recognized by a specific IgA receptor (Fc α R), which is widely distributed on the circulating haemopoietic cells but is more highly expressed in phagocytes found in secretions of the gut and the lung.

A number of miscellaneous receptors involved in phagocytosis have been described. The mannosyl/fucosyl receptors, otherwise known as the macrophage mannose receptors (MMR), are lectin-like molecules that bind mannose and fucose residues on the surfaces of yeast, bacteria and parasites. These receptors are present only on the surface of macrophages and their expression is increased by IFN- γ . Their activation mediates endocytosis, phagocytosis and cytotoxicity by reactive oxygen intermediates. The receptors described to date are composed of

eight and ten contiguous C-type lectin domains. In addition to recognizing the haemoglobin–haptoglobin complex, the macrophage scavenger receptor CD163 has also been shown to bind Gram-positive and Gram-negative bacteria and elicit an inflammatory cytokine response as part of the innate immune response. CD14 is the receptor for complexes of lipopolysaccharide (LPS)-binding protein with LPS, which coat Gram-negative bacteria and enhance phagocytosis. CD14 is constitutively expressed on monocytes and macrophages but its expression is modulated by cytokines. TNF, IL-1 and IL-6 increase its expression, whereas IFN- γ and IL-4 decrease it. CD14 expression can also be induced on neutrophils by various cytokines. CD14 is also a GPI-linked protein and is shed by monocytes.

Several receptors have also been implicated in the recognition and phagocytosis of apoptotic cells. Defective clearance of apoptotic cells is believed to promote inflammatory responses leading to the development of autoimmunity and efficient removal of apoptotic cells maintains peripheral immunological tolerance. Epithelial cells, fibroblasts, mesangial cells and both professional and non-professional phagocytes contribute to the effective identification and removal of apoptotic bodies before their intracellular contents are released. Different subsets of dendritic cells and macrophages likely play distinct roles in the clearance of cells at different stages of apoptosis. IL-10-producing anti-inflammatory macrophages are the professional phagocytes involved in the recognition and clearance of early apoptotic cells. Morphological changes in the apoptotic cells, such as formation of characteristic membrane protuberances (blebs), lead to the exposure of phosphatidylserine and changes on surface sugars, which are recognized by phagocytic receptors. These include integrins of the $\alpha_v\beta_3$ or $\alpha_x\beta_5$ classes and the lipid scavenger receptors of both A and B classes. The membrane of apoptotic cells binds increased amounts of thrombospondin, a macrophage secretory product that is recognized by both CD36 (thrombospondin receptor) and integrin $\alpha_v\beta_3$ (vitronectin receptor). Similarly, phagocytic lectin receptors bind carbohydrate determinants exposed on the surface of apoptotic cells. A specific receptor for phosphatidylserine has also been described, which acts alone or in association with CD36 to recognize the exposed phosphatidylserine. CD14 has also been reported to be involved in tethering of apoptotic lymphocytes via interaction with ICAMs. Apoptotic cell-associated molecular patterns (ACAMPs) are highly conserved molecular changes expressed in cells undergoing apoptosis that are recognized by innate immune system receptors such as CD14, CD91, C1q, C3bi, collectins and pentraxins. ACAMPs can be visualized as a topological change in grouping of molecules in the apoptotic cell plasma membrane that form a pattern that is then recognized by phagocytic cells.

Neutrophils also recognize chemoattractant signals through receptors expressed on their cell surface. *N*-formyl-methionyl

tripeptide receptors such as f-Met-Leu-Phe (FMLP) are similar to naturally occurring bacteria-derived factors. Each demonstrates time-dependent saturable binding kinetics and a high-affinity dissociation constant (K_D) for the specific chemoattractant. Approximately 50 000 FMLP receptors per cell with a K_D of 20 nmol/L have been demonstrated on human neutrophils. Thrombospondin also has chemotactic activity and binds neutrophils via specific receptors linked to G_{i2} proteins, a subpopulation of which is also associated with the FMLP receptors. Neutrophils also have a specific receptor for the chemotactic cleavage product of C5a, with receptor expression of approximately 50 000–100 000 per cell and a binding affinity of 2 nmol/L.

Chemokines are a family of proinflammatory cytokines with potent chemotactic activity. They are small proteins (8–10 kDa, characterized by a pattern of conserved cysteine residues. CXC chemokines such as IL-8 are specific to neutrophils and are distinguished by having their first two cysteine residues separated by an amino acid. CC chemokines, including macrophage inflammatory protein (MIP)-1 α , have the first two cysteine residues adjacent, are inactive for neutrophils, but attract monocytes, basophils, eosinophils and T lymphocytes. Monocyte migration is also directed by monocyte chemotactic proteins. Eosinophil migration is directed by MIP-1 α and RANTES (regulation on activation normal T-cell expressed and secreted protein), in addition to the CC chemokine eotaxin. Phagocytic cells in general have high expression of the receptors for these chemokines, enabling them to recognize and respond to the appropriate chemoattractants.

Phagocytic signalling

The complex process of phagocytosis is regulated by events related to the activation of various receptors such as the Fc γ Rs. Such receptor activation results in initiation of downstream signalling events through immunoreceptor tyrosine-based activation motifs (ITAMs). As a result of cross-linking of these receptors under appropriate conditions, downstream effector functions are activated, resulting in phagocytosis, stimulation of the respiratory burst, degranulation of bactericidal proteins and activation of transcription factors, in turn leading to enhanced expression of genes encoding cytokines and other inducible proteins.

Members of the Src family of tyrosine kinases (e.g. Lyn, Fgr and Hk) associate with Fc γ Rs and are probably responsible for their tyrosine phosphorylation. The tyrosine-phosphorylated ITAMs then serve as binding sites for downstream kinases such as Syk, which propagate signals important for phagocytosis. Downmodulation of Syk in monocytes using antisense oligonucleotides results in decreased ability of these cells to ingest IgG-coated particles. Furthermore, macrophages that lack Syk demonstrate a profound reduction in Fc γ R-mediated tyrosine

phosphorylation of p85 subunit of phosphatidylinositol 3-kinase (PI3K), SHIP, Shc and other important signalling proteins.

Phosphorylation and activation of members of the Rho/Rac family of GTPases as well as the ARF6 family are probably involved in cytoskeletal remodelling necessary to trigger phagocytosis. For example, inhibition of Rac1 or Cdc42 in murine macrophage models leads to impaired focal actin assembly beneath bound IgG-coated particles and blocks subsequent ingestion without affecting particle binding. Cdc42 and Rac1 appear to control different steps in the phagocytic process, namely pseudopod formation for the former and phagosome closure for the latter. The role of phospholipase C γ and protein kinase C (PKC) isoforms in actin assembly and the role of PI3K pathways in membrane remodelling during phagocytosis are under investigation. Treatment of macrophages with PI3K inhibitors such as wortmannin and LY 294002 results in the failure of pseudopods to extend around particles.

Degranulation and secretion

Degranulation and secretion are processes whereby the contents of phagocytic storage granules are released into the phagocytic vacuoles (degranulation) or into the extracellular space (secretion). Degranulation and secretion can be triggered by invading microorganisms, immune complexes, cytokines, chemotactic factors, and adhesion to tissue surfaces and activation of ICAMs. The processes of degranulation and secretion begin with the onset of phagocytosis. A number of morphological changes occur within the granules and they translocate and fuse their membranes with those of the phagocytic vacuoles formed by the invagination of the plasma membrane.

Cytoskeletal proteins are essential for this process, facilitating granule transfer to plasma membrane or phagolysosomes. The exact cause of membrane fusion is unknown but the process is likely to involve the activation of several phospholipases, leading to altered lipid composition of granule–phagosome or granule–plasma membrane contact points. Actin polymers act like a barrier between plasma membrane and granules, and in order for membrane fusion to occur the granules have to negotiate the physical barrier of such cytoskeletal elements in the cell periphery. Furthermore, the repulsive negative charge on the surface of both membranes, related to the negatively charged phospholipids phosphatidylserine and phosphatidylethanolamine, is a further barrier that needs to be overcome. A number of soluble molecules capable of provoking the release of granule content into the extracellular space have been described. These include many chemotactic factors such as C5a, FMLP, platelet-activating factor (PAF) and LTB $_4$, as well as phorbol myristate acetate and several non-chemotactic interleukins, cytokines and growth factors such as TNF- α , IL-1, IL-4, IL-6 and GM-CSF. Importantly, phagocytes are capable of

rapidly replenishing cellular stores of proteins and forming new granules, thus allowing repeated degranulation and secretion.

Regulation of granule release is mediated by a number of factors such as calcium, guanine nucleotides and G-proteins, which regulate changes in the cytoskeleton, resulting in actin polymerization and clearing of the cytoskeleton along the plasma membrane fusion site. These proteins include members of the annexin family, the calcium-binding protein calmodulin, PKC and phospholipases.

Phagocytic killing: the respiratory burst

Activation of phagocytes is associated with a rapid and dramatic increase in oxygen consumption described as the respiratory burst. This process is non-mitochondrial and is mediated by the activation of a latent enzyme system referred to as NADPH oxidase, which transfers a single electron to molecular oxygen (O $_2$) to form the superoxide anion (O $_2^-$). The superoxide anion then dismutates to hydrogen peroxide (H $_2$ O $_2$), a process occurring either spontaneously or through the catalytic function of superoxide dismutase. H $_2$ O $_2$ then reacts with superoxide anion, forming the highly reactive hydroxyl radical (OH \cdot), which is highly microbicidal. This and other reactive oxidative products not only contribute to microbial killing but also activate metalloproteinases such as elastase and collagenase, leading to the surrounding tissue injury that often accompanies phagocyte activation.

The NADPH oxidase is a multicomponent enzyme, with several subunits located in various regions of the quiescent phagocytes (Figure 17.1). These subunits, called phox (phagocyte oxidase) proteins, are identified by their molecular weight (e.g. p40 phox). In the quiescent neutrophil, p47 phox protein resides in the cytosol, along with p67 phox complexed with p40 phox. Activation of NADPH oxidase results from PKC-mediated phosphorylation of p47 phox and the subsequent binding of the p47 phox phosphoprotein and the p67 phox–p40 phox complex to the membrane flavocytochrome b_{558} located primarily in the specific granules, gelatinase granules and secretory vesicles of neutrophils. The cytochrome b_{558} is the terminal component of the superoxide-generating system allowing the efficient transfer of electrons from the cytoplasmic NADPH to the surface of phagolysosome or the extracellular surface, where oxygen is reduced to the superoxide anion. Other GTP-binding proteins such as Rap1A and Rac2 associate with the above molecules and regulate phagocyte activation and oxidase activity through their preferred substrate GTP (Figure 17.1).

Phagocytic killing: nitric oxide

Generation of reactive nitrogen intermediates through nitric oxide synthase (NOS) is another mechanism for phagocytic

Figure 17.1 Components of the NADPH oxidase system. The components include a 47-kDa cytosolic protein (p47), a 67-kDa cytosolic protein (p67), a 40-kDa cytosolic protein (p40), cytosolic G-proteins (Rac and Rap1), and a membrane-bound cytochrome (b_{558}). The cytochrome consists of haem-containing p22-phox and gp91-phox. The gp91 subunit is an FAD-dependent flavoprotein shuttling electrons to molecular oxygen,

forming O_2^- . The p47 component can be phosphorylated to various extents. In activated cells, the p40, p47 and p67 proteins translocate to the membrane to form an activation complex with cytochrome b_{558} . Similarly, the Rac and Rap1 proteins also translocate. The activated oxidase passes electrons from NADPH via FAD to oxygen, thereby generating superoxide.

killing of microbes. Nitric oxide (NO) is the highly reactive free radical product of the oxidation of L-arginine in phagocytes during inflammation. Three distinct isoforms of NOS have been described in blood cells. Two are found in endothelial and neuronal cells and the third, inducible NOS, is induced by cytokines, such as IFN- γ , in a number of cell types. Cofactors required for the activity of NOS include flavine adenine dinucleotide (FAD), flavine mononucleotide (FMN), NADPH and tetrahydrobiopterin. The calcium-binding protein calmodulin is tightly bound to the macrophage NOS. The activity of NOS is also regulated by kinases and phosphatases and its production is influenced by other cytokines such as IL-4, IL-10, IL-8 and transforming growth factor (TGF)- β .

NO has an important role in the antimicrobial activity of both neutrophils and mononuclear phagocytes. In contrast to NADPH oxidase, which is active at the plasma and phagolysosome membrane, NOS is located in the cytoplasm and mediates defence against facultative intracellular pathogens, as well as other prokaryotic and eukaryotic pathogens. Its inhibitory effects are due to nitrosylation of proteins and interaction with transition metals at the active sites of enzymes. Furthermore, NO scavenges superoxide to form peroxynitrite ($OONO^-$), which can disrupt protein phosphorylation.

Phagocytic killing: antimicrobial proteins

Phagocytic cells such as neutrophils can kill microorganisms using proteins present in various granules. The importance of such non-oxidative killing is evident in chronic granulomatous disease neutrophils that are still capable of killing many potent microorganisms. Furthermore, this process is important for defence against organisms such as *Escherichia coli* and *Salmonella typhimurium*, which do not produce their own source of oxidants and are killed under anaerobic conditions. The contents of each phagocytic cell type are specific. Neutrophil antimicrobial proteins include defensins, serpocidins (including cathepsin G and azurocidin) and bacterial permeability-increasing protein (BPI). The antimicrobial proteins within neutrophils are summarized in Table 17.3.

These microbicidal proteins exert their killing effect through enzymatic means such as proteolysis or by non-catalytic mechanisms, and their combinations potentiate bactericidal activity. Cathepsin G is a serine protease that exerts its bactericidal action by binding to penicillin-binding proteins of bacteria and interfering with the synthesis of peptidoglycans. Azurocidin is another serine protease effective against a number of bacteria and fungi. Defensins constitute as much as 50% of neutrophil

Table 17.3 Neutrophil microbicidal proteins.

<i>Protein</i>	<i>Characteristics</i>	<i>Target organisms</i>	<i>Effects on target</i>
<i>Non-enzymatic proteins</i>			
BPI	Highly cationic, neutralizes LPS, most potent cidal protein, not released from granule	Gram-negative bacteria	Binds lipid A region of LPS, increases bacterial membrane permeability, activates bacterial degradative enzymes
Defensins	Comprise 30–50% of azurophil granule protein	Gram-positive > Gram-negative bacteria, fungi, viruses, mammalian cells	Increases membrane permeability
Lactoferrin	Cationic, stimulates hydroxyl radical formation	Gram-positive and Gram-negative bacteria, fungi	Oxidative damage
<i>Catalytic proteins and analogues</i>			
Proteinase 3	Serine proteinase	<i>Escherichia coli</i> , <i>Streptococcus faecalis</i> , <i>Candida albicans</i>	Growth inhibition
Cathepsin G	Serine proteinase	Gram-positive and Gram-negative bacteria, fungi	Inhibition of peptidoglycan synthesis
Azurocidin	Serine proteinase	Gram-negative bacteria	Non-catalytic mechanisms

Elastase	No direct cidal activity		Co-active with lysozyme, potentiation of MPO–halide–H ₂ O ₂ system

BPI, bacterial permeability-inducing factor; LPS, lipopolysaccharide; MPO, myeloperoxidase.

granule protein content and exert their cidal activity by inserting into hydrophobic channels, forming voltage-dependent ion channels in the lipid bilayer. BPI kills Gram-negative bacteria by binding to their LPS capsule and altering their bacterial membrane permeability to extracellular solutes. A mutant strain of *S. typhimurium* that is resistant to BPI has also been found to be resistant to neutrophil bactericidal activity under strict anaerobic conditions, demonstrating the importance of BPI in non-oxidative killing by neutrophils. Other neutrophil granule proteins include lactoferrin, which kills some Gram-negative bacteria by generating free radicals from iron bound to it, and lysozyme, which is involved in the digestion of killed bacteria in phagolysosomes of neutrophils. These antimicrobial proteins can also enhance the effects of other cidal mechanisms such as complement lysis and oxidative killing. Combinations of these proteins can also enhance their killing action, as seen with the combination of neutrophil lysozyme and elastase against Gram-negative bacteria. Some of the microbicidal proteins of the phagocytes have other effects at lower concentrations, such as stimulation of mast cell degranulation, release of proinflammatory molecules and monocytic chemotaxis, as well as regulation of phagocytosis and granulopoiesis.

Production, structure and dysfunction of phagocytes

White blood cells are produced from pluripotent haemopoietic stem cells located within the bone marrow. Development of white blood cells along different lineages is governed by external stimuli including cytokines, matrix proteins and other cellular products within the marrow environment. The combination of specific cytokines and growth factors influence the maturation of white blood cell progeny along specific lineages. Although there is significant overlap between these growth factors, certain cytokines have been found to be associated with specific maturation pathways. Some of these cytokines are now manufactured commercially and are in clinical use to influence the speed of recovery of white blood cells following administration of chemotherapy.

Neutrophils (Figure 17.2a)

Development and function

Neutrophils are the predominant white blood cells involved in phagocytic killing of bacteria and certain fungi. They are also

Figure 17.2 Morphology of phagocyte cell types: (a) neutrophil; (b) eosinophil; (c) basophil; (d) monocyte; (e) macrophage.

Figure 17.3 Stages of neutrophil maturation, showing a myeloblast, a promyelocyte, several myelocytes and metamyelocytes, a band cell and a segmented neutrophil.

referred to as polymorphonuclear or segmented leucocytes, owing to their characteristic lobulated nucleus (their nucleus is segmented into two to five lobes, connected by thin chromatin strands). They are at the end stage of maturation (Figures 17.3 and 17.4) and generally uniform in size (13µm in diameter), with pink cytoplasm and fine azurophilic granules. The production of neutrophils involves the action of a variety of growth factors, including G-CSF, GM-CSF, IL-3 and macrophage

colony-stimulating factor. In addition to G-CSF-induced neutrophil production, G-CSF has also been implicated in leucocyte trafficking into tissues involved with active inflammation, such as inflamed joints in a collagen-induced arthritis murine model. Other factors such as IL-11, stem cell factor (SCF) and FLT-3 ligand enhance clonal neutrophil expansion *in vitro*. GM-CSF induces neutrophil, eosinophil and macrophage colony expansion *in vitro*, but there is no evidence that it induces neutrophil differentiation in the absence of G-CSF.

Granulopoiesis is the process of terminal differentiation from a pluripotent haemopoietic stem cell via a multipotent common myeloid progenitor and bipotent granulocyte–macrophage progenitor stage to a committed mature neutrophil. Granulocyte differentiation depends on the coordinated expression of certain transcription factors, including Pu.1, CCAAT enhancer-binding protein (*C/EBPα*), *C/EBPε* and GFI1. Microarray technologies utilized for the analysis of human bone marrow populations highly enriched for promyelocytes, myelocytes, metamyelocytes and neutrophils have been successful in defining the transcriptional programme of terminal granulocytic differentiation. Chemokine and cytokine receptors and ligand pairs are upregulated in the transition from myelocyte to neutrophil and involve the constitutive activation of NF-κB.

Neutrophils contain four types of granules that can be identified by marker enzymes or proteins (Table 17.4). The lysozyme-like azurophilic granules, otherwise known as primary granules, are present in promyelocytes and all further stages of neutrophil

Figure 17.4 Neutrophil lifespan and stages of maturation. Of every 100 nucleated cells in the bone marrow, 2% are myeloblasts, 5% promyelocytes, 12% myelocytes, 22% metamyelocytes and bands, and 20% mature neutrophils (i.e. about 60% developing neutrophils). The times indicated for the various compartments were obtained by isotopic labelling techniques. The ordinate shows the flux, and the abscissa the time, in each compartment. The stepwise increase in cell

differentiation and contain microbicidal proteins and acid hydrolases (e.g. myeloperoxidase, defensins, lysozyme) involved in oxidative and non-oxidative killing of bacteria and fungi. These granules release their contents exclusively into phagocytic granules, with little discharge outside the cell except for release from disintegrating neutrophils. Specific or secondary granules are smaller than azurophil granules and contain other distinct hydrolases, as well as chemotactic, opsonic and adhesion protein receptors. They release their contents into both phagocytic vesicles and the extracellular medium. Haptoglobin has been identified in specific granules of mature neutrophils and has been shown to be synthesized during the myelocyte–metamyelocyte stage of granulocytic differentiation. The release of haptoglobin from specific granules after neutrophil activation in sites of inflammation would act to reduce local tissue injury and bacterial growth. Other granules, collectively known as tertiary granules, include secretory vesicles, which contain alkaline phosphatase, and gelatinase granules rich in gelatinase. Degranulation of neutrophils begins with the onset of phagocytosis and involves their translocation and fusion with phagocytic vacuoles created by invagination of the plasma membrane.

numbers through the dividing compartments represents serial divisions. Note that no mitoses occur after the myelocyte stage. (From Bainton DF (1992) *Developmental Biology of Neutrophils and Eosinophils*. In: *Inflammation: Basic Principles and Clinical Correlates*, 2nd edn (JI Gallin, IM Goldstein, R Snyderman), pp. 303–324. Raven Press, New York, and Cronkite EP, Vincent PC (1969) *Granulocytopenia*. *Ser Haematology* 4: 3–43, with permission).

Degranulation may also occur by reverse endocytosis as a result of the action of complement, aggregated immunoglobulin or certain cytokines. Although the release of granule contents is important for phagocytosis and bacterial killing, extracellular release can also lead to tissue injury and inflammation.

Neutrophil clearance of infectious organisms is critical to the immune response and neutrophil function is impaired in the septic state. Peroxisome proliferator-activated receptor (PPAR)- γ , a ligand-activated nuclear transcription factor, has been shown to be constitutively expressed on isolated human neutrophils and upregulated in the presence of inflammatory cytokines. Inhibition of PPAR- γ activation has been shown to restore *in vitro* neutrophil chemotaxis.

Neutrophils exist in one of three states: quiescent, activated or primed. They circulate in the blood in the quiescent state and react weakly to stimuli, thus limiting potential damage to vascular walls. Priming of neutrophils is a process that does not immediately stimulate an effector response but allows an exaggerated response upon later stimulation. Therefore, this is a mechanism whereby phagocytes are selectively activated on recruitment to sites of infection and inflammation. Three main

Table 17.4 Neutrophil granules and their contents.

<i>Granule</i>	<i>Azurophilic (primary)</i>	<i>Specific (secondary)</i>	<i>Gelatinase (tertiary)</i>	<i>Secretory vesicles</i>

types of agonists are responsible for priming neutrophils, including chemotactic inflammatory mediators, serum immunoglobulin and complement opsonins, and inflammatory cytokines and growth factors. On neutrophil activation, a significant increase in oxygen consumption, termed respiratory burst, occurs that leads to the production of reactive oxygen species responsible for microbial killing.

Neutrophils are the most numerous leucocytes, comprising 65% of circulating phagocytes, with a normal range in the peripheral blood of $1.5\text{--}7.7 \times 10^9/\text{L}$. The term 'granulocyte' is often used synonymously with neutrophil despite the fact that neutrophils, eosinophils and basophils can all be classified as granulocytes. Neutrophils are made in the bone marrow at a rate of 10^{12} per day, and once released into the circulation have a half-life of 6–8 hours. The largest proportion of neutrophils

are present within the marrow (reserve pool), with circulating and tissue pools comprising smaller fractions (Figure 17.4). The circulating pool itself consists of a marginated pool of cells that are loosely adherent to the vascular endothelium and a freely circulating pool with the compartments in a constant state of dynamic equilibrium. Several factors including corticosteroids, exercise and infection can lead to an increase in the free circulating pool. Corticosteroids promote the release of neutrophils from the reserve pool into the circulation and prevent migration from the blood into the tissue pool. On the other hand, endotoxin and some complement components (C5a) result in increased margination and reduction in the circulatory pool (Figure 17.4). The variations in neutrophil morphology are shown in Figure 17.5. These include (i) Barr body, a drumstick appendage to the neutrophils in females; (ii) Pelger–Huët

anomaly, with bilobed nuclei; (iii) Alder–Reilly anomaly; (iv) May–Hegglin anomaly; (v) toxic granulation; (vi) hypersegmented neutrophils; and (vii) Chédiak–Higashi syndrome.

The May–Hegglin anomaly is a rare autosomal dominant condition characterized by thrombocytopenia and giant platelet forms. This disorder is due to a gene encoding a non-muscle myosin heavy chain II (*MYH9*) and results in neutrophils containing basophilic inclusions resembling Döhle bodies. Treatment is usually not needed except in severe cases when platelet transfusions are necessary due to severe thrombocytopenia.

Neutrophils undergo apoptosis within 24 hours of leaving the bone marrow through either intrinsic or extrinsic mechanisms. G-CSF plays an integral role in both the recruitment of neutrophils from the bone marrow and the inhibition of mature neutrophil apoptosis. Calpains are calcium-dependent cysteine proteases that activate pro-apoptotic factors such as Bax, and inhibit anti-apoptotic factors such as X-linked inhibitor of apoptosis (XIAP). G-CSF slows the influx of extracellular calcium and thus downregulates calpain activity, resulting in inhibition of caspase-3, the executioner of apoptosis. Neutrophil apoptosis is characterized by pyknocytosis and the loss of expression of L-selectin and CD16, and the increased expression of CD11b/CD18. Loss of functions including attachment, phagocytosis, degranulation and respiratory burst activity leave the apoptotic neutrophil without purpose and marked for clearance after an inflammatory response has been mounted. Certain drugs, cytokines and mediators of inflammation can delay/inhibit apoptosis in neutrophils, including glucocorticoids, G-CSF, GM-CSF, IL-3, IL-6, IL-15, endotoxin, TNF- α and IFN- γ .

Disorders of neutrophil function and number

Neutrophilia

Leucocytosis, or increased white blood cell count, may be due to either a primary (congenital or acquired) marrow disorder or secondary to a disease process, toxin or drug (Table 17.5). Neutrophil counts are high in neonates and decrease to normal adult levels with ageing. Secondary leucocytosis not associated with leukaemia but with a very high white cell count ($> 50 \times 10^9/L$) is often referred to as a 'leukaemoid reaction' and can be associated with the presence of Döhle bodies and toxic granulation within the cytoplasm (Figure 17.5), as well as with a 'left shift' (with the presence in blood of myelocytes, metamyelocytes and band forms) and an elevated leucocyte alkaline phosphatase score (compared with a low score in chronic myeloid leukaemia). In contrast with acute leukaemia, there is orderly maturation and proliferation of all normal myeloid elements in the bone marrow. Leukaemoid reactions have been described in patients with osteomyelitis, empyema, septicaemia, tuberculosis, Hodgkin disease, juvenile rheumatoid arthritis and dermatitis herpetiformis.

Asplenia and hyposplenism
<i>Neoplastic</i>
Chronic myeloid leukaemia
Other myeloproliferative disorders (myelofibrosis, polycythaemia vera, essential thrombocythaemia)

Leucocyte adhesion deficiency (LAD) is a congenital disorder that presents with persistent leucocytosis, delayed separation of the umbilical cord, recurrent infections, impaired wound healing and defects of neutrophil activation. The condition is caused by defects in adhesion of neutrophils to blood vessel walls. As a result, phagocytes do not migrate from the bloodstream to sites of infection. Two types of LAD have been described. In LAD type I, mutations of the gene encoding the β -subunit of the β_2 integrins (CD11b and CD18) have been detected. The molecular basis for the rare LAD type II is defective glycosylation of ligands on leucocytes recognized by the selectin family of adhesion molecules. The clinical features in the two types are similar, and because of the defect in neutrophil migration, abscesses and other sites of infection are devoid of pus despite the striking neutrophilia. Treatment involves the use of prophylactic antibiotics and aggressive therapy of periodontal disease. Stem cell transplantation can be considered in patients with severe disease. The LAD-I variant syndrome is a condition characterized by non-pus-forming bacterial and fungal infections, poor wound healing, mucosal bleeding and the potential for life-threatening intracranial bleeds that are seen early in life, with bone marrow transplantation as the only curative modality.

Hereditary neutrophilia has been described in a single family of four, with leucocyte counts chronically in the range $20\text{--}70 \times 10^9/L$ as well as splenomegaly, widened diploë of the skull and a high leucocyte alkaline phosphatase but without serious medical problems. Neutrophil function and adhesion to vessel

walls in these patients are normal and the condition appears to have an autosomal dominant inheritance.

Chronic idiopathic neutrophilia is an association of a chronically elevated neutrophil count (in the range $11\text{--}40 \times 10^9/\text{L}$) in healthy individuals without any associated clinical problems. In one series, several individuals were followed for up to 20 years without developing any disease.

Leukaemoid reactions have been described with congenital disorders such as amegakaryocytic thrombocytopenia, tetralogy of Fallot, dextrocardia with absent radii and in patients with Down syndrome. The neutrophilia in Down syndrome is transient but may be exaggerated in response to stress. The transient myeloproliferative disorder, or 'transient leukaemia', can be seen in up to 10% of children born with Down syndrome and is characterized by clonal proliferation of myeloid blasts that is asymptomatic and self-limiting in most cases. High white cell count, the presence of ascites, preterm delivery, bleeding diathesis and failure of spontaneous remission were all found to be positively correlated with the occurrence of early death in multivariable analysis. Approximately 20% of neonates with Down syndrome will develop an aggressive form of acute myeloid leukaemia (mostly FAB M7-like) requiring intensive chemotherapy. A syndrome of growth retardation, hepatosplenomegaly and leucocytosis has been described as a familial myeloproliferative disease, with some affected individuals dying in early life and others remaining stable or even improving with time. These patients had low leucocyte alkaline phosphatase scores and no detectable cytogenetic abnormalities. Others have reported families with several generations of affected individuals with a variety of myeloproliferative disorders but without cytogenetic abnormalities.

Familial cold urticaria and leucocytosis is a syndrome of fever, urticaria, rash and muscle and skin tenderness on exposure to cold that appears to be dominantly inherited. The onset of the disease is in infancy, with urticaria, rash and leucocytosis generally occurring several hours after cold exposure. The skin rash is histologically characterized by intense infiltration by neutrophils.

Non-malignant causes of neutrophilia include acute infections, with elevated counts in most bacterial infections. In response to overwhelming infection, marrow depletion of leucocytes can occur, resulting in neutropenia rather than neutrophilia. Neutrophilia in response to chronic inflammatory processes is usually more modest in degree and can be accompanied by monocytosis. Modest elevations of neutrophil counts are commonly seen in various forms of 'stress' such as exercise, adrenaline injection, myocardial infarction, in the postoperative period, in post-ictal states and with emotional distress. This is probably due to the migration of neutrophils from the marginated pool to the circulatory pool. Mild neutrophilia has also been reported with unipolar depression. A number of drugs and drug reactions are commonly associated with increased neutrophil counts. Steroids stimulate the release of neutrophils

from the bone marrow and diminish their egress from the circulation resulting in chronic neutrophilia. This can be distinguished from neutrophilia due to infection by the distinct lack of band forms in the former. The β -agonists produce an acute neutrophilia by releasing neutrophils from the marginated pool. Other drugs known to produce neutrophil leucocytosis include lithium, which increases the production of CSF and potentiates its effects on myeloid colony formation, and tetracycline, which has been associated with counts as high as $80 \times 10^9/\text{L}$. Growth factors such as G-CSF, GM-CSF and Neulasta (a pegylated form of G-CSF that has a prolonged half-life in circulation) are commercially available and are used commonly to reduce the duration of neutropenia associated with chemotherapy and to mobilize stem cells for transplantation. Their use in healthy individuals for the latter purpose is associated with significant neutrophilia and a left shift.

Neutropenia

Neutropenia can be due to impaired production by the bone marrow, shift from the circulating pool to marginated pool, increased peripheral destruction, or a combination of these (Table 17.6). It has been defined as an absolute neutrophil count (ANC) of more than two standard deviations below a normal mean value. There is variation of neutrophil counts among different ethnic groups, with black people generally having slightly lower counts (lower limit of normal $1.2 \times 10^9/\text{L}$) compared with white people (lower limit of normal $1.5 \times 10^9/\text{L}$). The lower count in black populations has been attributed to a relative decrease in the size of the marrow storage pool. In patients whose neutropenia is related to decreased production, the propensity to develop infections is directly related to the degree and duration of neutropenia.

On the other hand, in patients whose neutropenia is due to peripheral destruction or margination of neutrophils, there is no direct correlation between the degree of neutropenia and the propensity for infections. Neutropenia due to marrow failure states or associated with chemotherapy can predispose patients to severe life-threatening infections, although this is more likely in patients with neutrophil counts below $0.5 \times 10^9/\text{L}$. Common organisms encountered in this setting are *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *E. coli* and *Klebsiella* species. On the other hand, patients with some congenital or immune forms of neutropenia can tolerate low counts for prolonged periods without any apparent increase in the incidence of infections. Moderate asymptomatic neutropenia associated with specific ethnic groups such as African-Americans and Yemenite Jews is associated with a dominant inheritance pattern and requires no specific intervention.

Several well-defined inherited syndromes associated with neutropenia have been described and are worth mentioning. *Severe congenital neutropenia* (SCN) is a multigene heterogeneous group of disorders characterized by severe neutropenia at birth (ANC $< 0.5 \times 10^9/\text{L}$) and maturation arrest at the

developmental stage of the promyelocyte/myelocyte. Kostmann syndrome is an autosomal recessive form involving mutations of the *HAX1* gene encoding a mitochondrial-associated protein with structural similarity to other anti-apoptotic BCL-2 family members. Autosomal dominant and sporadic cases are more closely linked to gene mutations of *ELA2*, which codes for neutrophil elastase 2. It is still unclear as to the exact pathogenetic mechanism by which the *ELA2* mutation leads to neutrophil apoptosis but may involve structural rather than functional properties of the mutated protein. Less common mutations in genes encoding p14, G6PC3, GFI1, CSF3R, TAZ and WASP have all been documented in SCN. SCN is usually diagnosed in infancy in the setting of recurrent severe infections. Monocytosis,

eosinophilia and hypergammaglobulinaemia are often present. Myelopoiesis is blocked and the increased number of promyelocytes found in the bone marrow are characterized by atypical nuclei and cytoplasmic vacuolization. SCN associated with *HAX1* and *ELA2* has an increased risk of leukaemic transformation that is not observed in cases of SCN linked to the other gene mutations. Importantly, the risk of developing infection is independent of the underlying genetic defect and can be correlated to the ANC nadir. First-line treatment of infections in such patients is antibiotics with G-CSF. G-CSF is the cornerstone of therapy in reducing the infectious risk. Stem cell transplantation offers the potential of cure for those who do not respond to antibiotics and G-CSF. Transformation to myelodysplastic syndrome (MDS)/acute myeloid leukaemia (AML) in SCN is also independent of genetic defect and is approximately 21% at 10 years. The Severe Chronic Neutropenia International Registry has identified a group of patients with SCN who were less responsive to G-CSF in achieving and maintaining an adequate ANC; these patients have a cumulative incidence of developing MDS/AML or dying of sepsis at 10 years of 40% and 14%, respectively. These patients should be considered for haemopoietic stem cell transplantation earlier in life. The acquisition of *CSF3R* point mutations has also been shown to increase the risk of transformation to MDS/AML irrespective of the underlying genetic defect, and detection of monosomy 7 in the bone marrow of MDS/AML-associated SCN may indicate the occult presence of a G-CSF-sensitive leukaemic clone.

Cyclic neutropenia is a rare autosomal dominant disorder with variable expression that is characterized by repetitive episodes of fever, pharyngitis, stomatitis and other bacterial infections attributable to recurrent severe neutropenia occurring every 15–35 days. The nadir neutrophil count, usually between zero and $200 \times 10^9/L$, lasts 3–7 days and is frequently associated with monocytosis. Cycling of red cell and platelet production is also observed in some cases. The bone marrow is characterized by transient arrest at the promyelocyte stage before each cycle. Both childhood and adult onset have been reported. Recent studies have shown that autosomal dominant and sporadic cases of this disease are due to a mutation in *ELA2*, the gene for neutrophil elastase (a chymotryptic serine protease of neutrophil and monocyte granules), located on chromosome 19p13.3. This enzyme is synthesized in neutrophil precursors early in the process of primary granule formation. The present hypothesis suggests that the mutant neutrophil elastase functions aberrantly within the cells to accelerate apoptosis of the precursors, resulting in oscillatory production. The cyclic nature of this disorder provides evidence of a regulatory mechanism gone awry, likely due to a defective feedback circuit in which neutrophils inhibit cell proliferation thereby regulating progenitor cell proliferation. Recently, the process has been shown to involve interactions between PFAAP5, a protein mediating transcriptional repressor GFI1, and neutrophil elastase. This disorder is effectively treated with G-CSF, and no

transformation to AML or MDS has been observed in these patients, with or without G-CSF therapy.

Schwachman–Diamond–Oski syndrome is an autosomal recessive disorder characterized by exocrine pancreas insufficiency, metaphyseal dysostosis and bone marrow dysfunction (see Chapter 12). Recurrent severe bacterial infections and susceptibility to leukaemia are the major causes of morbidity and mortality, although many affected individuals have relatively few problems with infections. Neutrophil count is commonly less than $500 \times 10^9/L$ and many patients are also anaemic and thrombocytopenic. Bone marrow is usually hypoplastic and a number of neutrophil functional disorders such as chemotactic defects may be present. A variety of physical anomalies including short stature, strabismus, syndactyly, cleft palate and microcephaly may exist. The propensity to develop leukaemia and aplastic anaemia suggests that a stem cell defect may be present. Treatment involves the use of G-CSF in patients with recurrent infections, and the use of pancreatic enzyme supplements for the gastrointestinal insufficiency and steatorrhoea. Some anaemic patients respond to steroids.

Reticular dysgenesis is associated with neutropenia, lymphoid hypoplasia, and thymic hypoplasia with normal erythropoiesis and megakaryopoiesis. Patients have a hypoplastic marrow and low levels of IgM and IgG and die from overwhelming infections usually in early infancy. Dyskeratosis congenita is a rare disease characterized by abnormal skin pigmentation, nail dystrophy and mucosal leucoplakia. More than 80% of the affected individuals develop bone marrow failure, which is the major cause of death. The disorder is caused by defective telomere maintenance in stem cells. The major X-linked form of the disease is due to mutations in the *DKC1* gene located at Xq28 and coding for dyskerin, a nucleolar protein (see Chapter 12). Dyskerin is part of small nucleolar ribonucleoprotein particles involved in processing ribosomal RNA. It is also found in the telomerase complex, pointing to a possible link between these two processes. An autosomal dominant form is due to mutations in the RNA component of telomerase. Patients with this form of the disease are more severely affected in the later generations carrying the mutations, possibly due to the inheritance of shortened telomeres, and may be considered to have aplastic anaemia.

Neutropenia has been seen with immunological abnormalities such as hyper-IgM syndrome and X-linked agammaglobulinaemia. Hyper-IgM syndrome is an X-linked disorder characterized by lymphoid hyperplasia, low concentrations of IgG and IgA but high concentration of IgM, and severe neutropenia. A genetic defect in the T-cell CD40 ligand has been implicated as the cause of the disease. CD40 ligand is a 39-kDa protein expressed on the surface of activated CD4⁺ T cells that delivers contact-dependent signals to CD40-expressing cells: B cells, monocytes, dendritic cells, epithelial cells, endothelial cells and fibroblasts. The loss of interaction between CD40 and its ligand results in impairment of T-cell function, of B-cell dif-

ferentiation and of monocyte function. Patients commonly die of overwhelming infections by the age of 5 years unless treated with intravenous immunoglobulin and long-term G-CSF.

Chronic benign neutropenia, *chronic idiopathic neutropenia* and *autoimmune neutropenia* are very similar in laboratory findings and differ only with regard to age of onset and association with other immune disorders. Chronic benign neutropenia commonly presents in older children or young adults. Patients are usually asymptomatic and have neutrophil counts in the range $0.2\text{--}0.5 \times 10^9/L$. Bone marrow examination is commonly normocellular or occasionally moderately hypocellular. They usually have a peripheral monocytosis and often a benign course, although occasional cases progressing to acute leukaemia have been reported. Anti-neutrophil antibodies, detected in some patients, are not commonly present but antibodies to the progenitor cells or other precursors may be the inciting factor in these patients. As these patients generally have a benign course, treatment to increase neutrophil counts should be reserved for those who have recurrent infections. Corticosteroids, splenectomy, cytotoxic agents and G-CSF have all been used successfully in this setting. Chronic benign neutropenia of infancy and childhood is probably a related disease, with the majority of patients presenting during the first year of life. There is no familial predisposition and anti-neutrophil antibodies are commonly detected. Furthermore, the neutropenia responds to immunosuppressive therapy, suggesting an immune mechanism. There is a compensatory increase in neutrophil precursors in the marrow. Some patients have a measurable defect of neutrophil mobility, otherwise described as 'lazy leucocyte syndrome'.

Infants of hypertensive mothers also commonly have moderate to severe neutropenia lasting for several days. This is probably related to bone marrow suppression. Moderate to severe neutropenia can also occur in newborn infants as a result of the transfer of maternal IgG anti-neutrophil antibodies in a manner similar to rhesus haemolytic disease of the newborn. This isoimmune neutropenia develops antenatally and is due to maternal production of antibodies against antigens on fetal neutrophils.

Pure white cell aplasia is a rare condition associated with recurrent pyogenic infections and with thymoma in 70% of the affected patients. There is almost complete absence of myeloid precursors without any abnormality of erythroid or megakaryocytic precursors in the marrow. In the majority of patients, the marrow inhibitory activity is in the IgG and IgM fractions of serum but, in some, the inhibition is due to the lymphocytes. The immunoglobulin is directed against progenitor cells or myeloid precursors. The disorder has been associated with therapy with ibuprofen, certain natural remedies and chlorpropamide. If associated with thymoma, surgical removal of the thymus gland can partially correct the neutropenia. Other treatment options include corticosteroids, ciclosporin, cyclophosphamide and intravenous immunoglobulin.

Humoral and cellular immune responses are responsible for the development of neutropenia in a number of settings. Autoimmune neutropenia due to circulating antibody can occur as an isolated condition or in association with other autoimmune disorders such as autoimmune thrombocytopenic purpura and autoimmune haemolytic anaemia. The antibodies may be directed at the mature neutrophils or morphologically identifiable myeloid precursors.

Inhibition of granulopoiesis by suppressor or cytotoxic T lymphocytes can occur in patients with collagen vascular disorders as well as in patients with T- γ lymphocytosis. Patients with T- γ lymphocytosis commonly present with recurrent infections at a median age of 55 years. There is clonal proliferation of either CD3⁺/CD56⁺ T cells or CD3⁺/CD56⁺ natural killer (NK) cells. NK cells do not express CD5 and T-cell receptor (TCR) proteins, and their TCR locus is not rearranged, whereas CD3⁺ large granular lymphocytes have rearranged TCR genes and are thought to represent *in vivo* activated cytotoxic T cells. The characteristic findings include peripheral blood lymphocytosis with most lymphocytes being large granular lymphocytes. Patients may also have lymphadenopathy and hepatosplenomegaly; the bone marrow is commonly normocellular with increased lymphocytes and arrested myelopoiesis at the myelocyte stage. The CD3⁺ subset of the disease most commonly has an indolent course, although most patients need treatment for recurrent episodes of life-threatening infections. G-CSF therapy is used in managing acute infections and methotrexate, prednisolone, cyclophosphamide or ciclosporin can be effective in improving neutrophil counts for sustained periods. In contrast, the CD3⁺/CD56⁺ NK-cell disorders are clinically aggressive, occurring in younger patients and presenting with fever, massive hepatosplenomegaly, jaundice and marrow infiltration with the abnormal clone. They typically have a rapidly progressive course unresponsive to combination chemotherapy.

Neutropenia is also associated with collagen vascular diseases such as systemic lupus erythematosus (SLE) and with rheumatoid arthritis. IgG or IgM antibodies may be directed against mature neutrophils or their precursors. Recent advances have allowed better understanding regarding the mechanism of neutropenia and improved options for treatment. Target antigens for anti-neutrophil antibodies have been identified for both Felty syndrome and SLE. In Felty syndrome, severe neutropenia is associated with rheumatoid arthritis, splenomegaly and leg ulcers. Therapy for neutropenia with methotrexate and ciclosporin has been attempted with variable success. The efficacy of both GM-CSF and G-CSF in reversing neutropenia and decreasing the risk of infections in Felty syndrome and SLE has been well documented. Of concern, however, have been flares of symptoms or development of leucocytoclastic vasculitis in some patients following the use of these cytokines. Recent results suggest that G-CSF should be administered at the lowest dose effective at elevating the neutrophil count above $1.0 \times 10^9/L$.

Neutrophil counts between 0.1 and $0.45 \times 10^9/L$ are seen in WHIM syndrome, a rare disorder characterized by warts, hypogammaglobulinaemia, infections and myelokathexis. The bone marrow is usually hypercellular with normal-appearing early myeloid forms and abnormal metamyelocytes, bands and mature neutrophils with diploid and tetraploid nuclei. Autosomal dominant inheritance of a CXC-chemokine receptor (CXCR)4 mutation is associated with WHIM syndrome and leads to impaired receptor downregulation. Leucocyte CXCR4 engagement by stem cell-derived factor (SDF)-1 as presented by bone marrow stromal cells is an important signal promoting the retention of leucocytes within the bone marrow microenvironment niche. The overexpression of CXCR4 by leucocytes in WHIM leads to impaired egress of mature neutrophils from the bone marrow and resultant neutropenia. Decreased expression of BCL-X in myeloid precursors is also a feature of WHIM and is associated with an increased rate of apoptosis. G-CSF can be used to improve the neutropenia in WHIM syndrome.

Drug-induced neutropenia is probably the commonest cause of isolated neutropenia. A thorough evaluation of the medication history of a patient with neutropenia is important for excluding drugs as the inciting factor. Usually the mechanisms involve suppression of bone marrow activity or are immunological in nature. The neutropenia commonly develops 1–2 weeks after initiation of the drug and resolves soon after discontinuation of the offending agent. Agents most commonly associated with this side-effect include antibiotics (e.g. penicillins, cephalosporins, chloramphenicol), anticonvulsants (e.g. carbamazepine, phenytoin), anti-inflammatory agents (e.g. gold, phenylbutazone), antithyroid drugs (e.g. carbimazole, methylthiouracil), hypoglycaemic agents (e.g. chlorpropamide), diuretics (e.g. hydrochlorothiazide, bumetanide) and phenothiazine. The use of cytotoxic agents in cancer therapy is frequently associated with the development of neutropenia.

Neutropenia can also be a factor in aplastic anaemia. Other miscellaneous causes of neutropenia include the following.

- Viral infections: HIV, varicella, measles, rubella, infectious mononucleosis, influenza, hepatitis A and B, parvovirus and cytomegalovirus.
- Overwhelming bacterial infections (by exhausting the neutrophil reserve pool).
- Metabolic diseases: orotic aciduria, methylmalonic aciduria, glycogen storage disease type Ib.
- Nutritional deficiencies: vitamin B₁₂, folate (which causes hypersegmented nuclei; see Figure 17.5f) or copper.
- Hypersplenism.

Disorders of neutrophil function

A number of congenital and acquired conditions with abnormal neutrophil morphology (see Figure 17.2a) and/or function have been recognized (Table 17.7). Some of these are associated with abnormal neutrophil numbers and have been discussed earlier.

Table 17.7 Disorders of neutrophil morphology and/or function.

<i>Functional defect</i>	<i>Congenital</i>	<i>Acquired</i>
Minimal	Hereditary neutrophil hypersegmentation (AD) Pelger–Huët anomaly (AD) Alder–Reilly anomaly (AR) May–Hegglin anomaly (AD) Myeloperoxidase deficiency (AR)	Megaloblastic hypersegmentation Mucopolysaccharidoses
Adherence/migration	Leucocyte adhesion deficiency (AR) Neutrophil-specific granule deficiency (AR) Schwachman syndrome (?AR) Hyper-IgE syndrome Job syndrome (AR) Familial Mediterranean fever (AR)	Renal failure Diabetes Neonates Malnutrition Leukaemia
Phagocytic killing	Chronic granulomatous disease Papillon–Lefevre syndrome (AR)	Malnutrition Vitamin E deficiency Severe iron deficiency Neonates Diabetes Viral infections Sickle cell disease

AD, autosomal dominant; AR, autosomal recessive.

Chédiak–Higashi syndrome

Chédiak–Higashi syndrome is a rare autosomal recessive disorder characterized by oculocutaneous albinism, recurrent and severe bacterial infections, giant blue-grey granules in the cytoplasm of white blood cells (see Figure 17.5g), a mild bleeding diathesis, progressive peripheral neuropathy and cranial nerve abnormalities. Morbidity results from patients succumbing to frequent bacterial infections or to an ‘accelerated phase’, a progressive lymphoproliferative syndrome. Patients eventually succumb to a profound pancytopenia. Neutrophils contain a highly heterogeneous population of giant granules probably derived from coalescence of azurophil and secondary granules. The giant granules are seen more commonly in the bone marrow than peripheral blood, as many of the abnormal myeloid precursors are destroyed before release, leading to moderate neutropenia.

Chédiak–Higashi syndrome neutrophils also have a deficiency of antimicrobial proteins as well as disordered degranulation and chemotaxis. Dysfunction of other elements of the immune system, such as cytotoxic T lymphocytes and NK cells, contribute to the propensity for infection and the development of the accelerated phase of the disease. Mutations in the lysosomal trafficking regulator gene, *LYST*, located on chromosome 1q42.1–q42.2, have been implicated as the cause of this disease. At present, treatment for the disorder is allogeneic stem cell transplantation, which alleviates the immune problems and the accelerated phase but does not inhibit the development of neu-

rological disorders that frequently become increasingly worse with age.

Chronic granulomatous disease

Chronic granulomatous disease (CGD) is an inherited disease characterized by severe and recurrent purulent bacterial and fungal infections, including pneumonia, lymphadenitis, hepatic abscesses and osteomyelitis. The majority of patients present in the first year of life with infections with catalase-positive organisms. Phagocytic cells of CGD patients have a defect in the phagosomal and plasma membrane-associated NADPH oxidase, resulting in impaired superoxide formation necessary for efficient bacterial and fungal killing. In addition, a failure to switch off the inflammatory response leads to the formation of granulomas, the distinctive hallmark of the disorder. All the subtypes of X-linked CGD are caused by mutations in the gene for the gp91-phox subunit of cytochrome *b* (*CYBB*) located at Xp21.1. There is significant heterogeneity in the mutations in the gene, with most being family specific. This accounts for the clinical heterogeneity seen in X-linked CGD. Other mutations in recessively inherited forms of the disease have also been described.

The incidence of CGD is 1 in 200 000 to 1 in 250 000 live births and the diagnosis is suggested by failure of neutrophils to reduce nitroblue tetrazolium (NBT slide test). The diagnosis can be further established by directly measuring respiratory burst activity as oxygen consumption, oxygen production or

H₂O₂ production. Severe deficiency of glucose-6-phosphate dehydrogenase (G6PD) in neutrophils, as seen in a rare X-linked disorder, can result in a greatly attenuated respiratory burst and a condition resembling CGD. Therapy involves prevention and early treatment of infections, aggressive parenteral antibiotic therapy for established infections, and use of prophylactic trimethoprim–sulfamethoxazole. In a prospective multicentre trial of CGD patients, recombinant human IFN- γ has been shown to augment host defence and reduce the incidence of life-threatening infections via unknown mechanisms other than reversing the respiratory burst defect; its efficacy in reducing serious bacterial and fungal infections has been confirmed in a prospective multicentre study in CGD. Haemopoietic stem cell transplantation, if performed at the first signs of a severe course of the disease, is a valid therapeutic option for children with CGD. Newer approaches using reduced conditioning stem cell transplantation are still being investigated; more recently, Phase I clinical trials with retrovirally transduced autologous peripheral blood CD34⁺ stem cells may make gene therapy for CGD a possibility in the future.

Myeloperoxidase deficiency

Myeloperoxidase (MPO) deficiency is the most common inherited disorder of phagocytes and is inherited in an autosomal recessive manner. The gene encoding MPO is located at 17q21.3–q23 near the breakpoint of the translocation in acute promyelocytic leukaemia. Despite the key role of MPO in the microbicidal function of neutrophils, persons with MPO deficiency lack any clinical symptoms and therapy is not required, except for a higher incidence of fungal infections when aggressive antifungal therapy is indicated.

Neutrophil specific granule deficiency

Specific granule deficiency is a rare congenital disorder characterized by recurrent bacterial and fungal infections of skin and lungs. The inheritance is autosomal recessive and although the precise molecular defect has not been elucidated, recent data implicate functional loss of the myeloid transcription factor CCAAT/enhancer-binding protein, C/EBP ϵ , as important in the development of specific granule deficiency. The neutrophils of these patients display atypical bilobed nuclei, lack expression of at least one primary and all secondary and tertiary granule proteins, and possess defects in chemotaxis, disaggregation, receptor upregulation and bactericidal activity. Similar neutrophil granule deficiencies have been described in some patients with leukaemia.

Papillon–Lefevre syndrome

This is a rare autosomal recessive disorder characterized by palmoplantar keratoderma and early-onset periodontitis. Pyogenic liver abscesses are an increasingly common complication. Consanguinity is common and the disease is commonly manifested in the first 6 months of life, with early progressive

loss of both primary and secondary dentition. A phagocytic defect in microbicidal activity and degradation of ingested material is thought to be present. This is attributed to loss-of-function mutations of the *CTSC* gene located on chromosome 11q14.2, which encodes the protease cathepsin C.

Eosinophils (Figure 17.2b)

Development and function

Eosinophils, which account for 5–10% of leucocytes ($0.2 \times 10^9/L$), are similar to neutrophils morphologically except for the presence of a bilobed nucleus and numerous bright-orange cytoplasmic granules. There are three distinct granule populations: the round, uniformly electron-dense primary granules present mainly in the eosinophilic promyelocyte/myelocyte stages; secondary or specific granules; and the less well characterized small granules (Table 17.8).

Primary granules contain eosinophil peroxidase and Charcot–Leyden crystal protein. The eosinophil peroxidase is distinct from neutrophil MPO and can mediate damage to microorganisms and tissues and bronchoconstriction in asthma. Charcot–Leyden crystal protein is found in tissues and fluids in association with eosinophil inflammatory reactions and may have a role in respiratory disease.

The large specific granules contain the eosinophil's cytotoxic and proinflammatory proteins and account for more than 95% of granules in the mature eosinophils, conferring the characteristic appearance of the cell. Eosinophil granules contain a number of enzymes similar to those found in the lysosomes of the neutrophil, but lack lysozyme. Different cationic polypeptides are the major constituents of eosinophil granules and include major basic protein (MBP), eosinophil cationic proteins (ECP) and eosinophil-derived neurotoxin (EDN). MBP is toxic to cells, including parasites and mammalian epithelial cells, and evokes release of mediators from basophils and mast cells. Eosinophils have a significant cytotoxic and proinflammatory function and play an important part in the pathogenesis of a number of allergic, parasitic and malignant disease processes.

Eosinophils are derived from bone marrow stem cell-derived myeloid progenitors in response to a number of T cell-derived cytokines and growth factors including IL-3, GM-CSF and IL-5. Mast cells, macrophages, NK cells, endothelial cells and stromal cells also produce these cytokines. IL-5 is the most lineage-specific factor and plays an important role in regulation of terminal differentiation and post-mitotic activation of eosinophils. Therefore, IL-5 is a late-acting cytokine that is both necessary and sufficient for eosinophil development *in vivo*, a finding that has been confirmed by IL-5 transgenic and IL-5 knockout mice.

In normal individuals, eosinophils exist transiently in the circulation and localize specifically to certain tissues and organs

Table 17.8 Contents of eosinophil granules.

<i>Granule</i>	<i>Protein content</i>	<i>Comment</i>
Primary granule (Charcot–Leyden granule)	Charcot–Leyden crystal (CLC) protein	Weak lysophospholipase, carbohydrate-crystal protein-containing binding properties
Specific granule (secondary granule)	Eosinophil peroxidase	Toxic to parasites
	Major basic protein (MBP)	Ribonuclease, bactericidal, toxic to parasites
	Eosinophil cationic protein (ECP)	Ribonuclease, toxic to parasites
	Eosinophil-derived neurotoxin (EDN)	Antibacterial
	Eosinophil peroxidase (EPO)	
	Lysophospholipase	
	Acid phosphatase	
	Arylsulphatase B	
	Phospholipase A ₂ (secretory)	Antibacterial

CD63	Tetraspanin	
Proteoglycan		
α ₁ -Antitrypsin		
Small-type granule	Arylsulphatase B	Lysosomal hydrolase
Secretory vesicle	Cytochrome <i>b</i> ₅₅₈	NADPH oxidase component
	CR3	β ₂ integrin

BPI, bactericidal permeability-increasing protein; FAD, flavin adenine dinucleotide; LPS, lipopolysaccharide; NAMLAA, *N*-acetylmuramyl-L-alanine amidase.

exposed to the external environment. Eosinophils are recruited in response to early- and late-phase components of immediate hypersensitivity reactions as well as other immunologically mediated reactions. Their activation and recruitment involves the interaction of several adhesion pathways and chemotactic agents including the complement fragment C5a, PAF, IL-3, IL-5, GM-CSF, IL-2, RANTES, eotaxins and the CD8⁺ T cell-derived lymphocyte chemoattractant factor (LCF).

The specificity and intensity of the microbicidal function of eosinophils differ from those of other leucocytes; their bactericidal activity is less efficient than that of neutrophils, but not because of any deficiency of specific enzymes. In fact, eosinophil peroxidase is more bactericidal than MPO. However, the major protective role of eosinophils in host defence is the destruction of metazoan parasites. Eosinophils readily degranulate in response to stimulation by antigens, cytokines and complexed or secretory IgA, IgE and IgG. Proteins released from eosinophils result in histamine release from basophils and mast cells, and amplify the inflammatory response. These proteins are also powerful toxins towards host cells, leading to tissue injury. A further role of eosinophils is tissue repair and remodelling through regulation of the deposition of extracellular matrix proteins.

Disorders of eosinophils

Eosinophilia

Eosinophilia is considered as an absolute eosinophil count of $0.5 \times 10^9/L$ or more. Blood and tissue eosinophilia can be seen in a number of parasitic, neoplastic, collagen vascular and allergic diseases (Table 17.9). Because of the varied causes of eosinophilia, diagnostic evaluation should include complete physical examination and history, routine chemistries, serum IgE, vitamin B₁₂ levels, HIV serology, stool ova and parasites, electrocardiogram, echocardiogram, pulmonary function tests, chest and abdominal computed tomography, and bone marrow biopsy and aspirate.

In these disorders, a variety of abnormal stimuli lead to the increased production and tissue localization of eosinophils. When no underlying cause can be identified, the hypereosinophilic syndrome (HES) may be present. Several reactive pulmonary and cutaneous eosinophilic syndromes (e.g. Churg–Strauss syndrome, Loeffler syndrome and eosinophilic lymphofolliculosis or Kimura disease) as well as an eosinophilia–myalgia syndrome have also been described. Eosinophilia–myalgia syndrome is related to metabolites and contaminants in preparation of the drug *L*-tryptophan and presents with peripheral

blood eosinophilia, fatigue and severe myalgia. It responds slowly to cessation of L-tryptophan therapy in a number of the patients.

HES is characterized by sustained eosinophilia of 30–70% of total leucocyte count ($> 1.5 \times 10^9/L$) for longer than 6 months, absence of other underlying causes of eosinophilia and evidence of organ dysfunction due to eosinophilic tissue infiltration. Presenting features include anorexia, weight loss, fever, sweating, thromboembolic episodes, heart failure, splenomegaly, and skin and central nervous system (CNS) disease. Peripheral blood eosinophils have a variety of cellular abnormalities, and bone marrow eosinophils are increased (30–60%) but myeloblasts are usually not. It has been difficult to assess the clonality of HES. Cases that are clonally derived, as demonstrated by clonal karyotypic abnormalities and the performance of restriction polymorphism analysis in females, are now reclassified by WHO (2008) as chronic eosinophilic leukaemia.

This clinically variable disorder has various subtypes, including the myeloproliferative variant (10–50%) (these are now classified as chronic eosinophilic leukaemia; see also Chapters 27 and 36), lymphoproliferative variant (5–50%), familial form, episodic form and benign form. Patients with the myeloproliferative variant of HES are typified by male predominance, end-organ damage, elevated serum tryptase, splenomegaly, anaemia, thrombocytopenia and bone marrow myeloproliferation with reticulin fibrosis. This variant was historically recognized as unresponsive to steroid therapy, with a mortality greater than 50%, most commonly due to cardiac dysfunction from endomyocardial fibrosis. The myeloproliferative variant is usually caused by an interstitial deletion on chromosome 4q12, resulting in a *FIP1L1–PDGFRA* fusion gene. The protein product of this fusion gene is a tyrosine kinase with enhanced activity and particular sensitivity to low-dose imatinib therapy, leading to durable complete haematological and cytogenetic remission. Even rarer cases with often different haematological features are due to rearrangement of *PDGFRB* or *FGFR1* (see Chapter 36). In a prospective multicentre study of primary HES, all 27 patients with the *FIP1L1–PDGFRA* fusion gene achieved complete haematological and molecular remission at doses of imatinib between 100 and 400 mg daily. This response was durable with a median follow-up of 25 months, and re-emergence of the fusion gene was detectable by reverse transcriptase polymerase chain reaction in only three patients who stopped imatinib for several months. In HES patients negative for the *FIP1L1–PDGFRA* fusion gene, 14% achieved a complete haematological remission with imatinib therapy that was short-lived.

The lymphoproliferative variant of HES is a distinct clinical syndrome characterized by hypereosinophilia occurring in response to IL-5 stimulation by a clonal $CD3^+CD4^+CD8^-$ activated T-cell population. Patients with this variant are more likely to have skin, gastrointestinal and pulmonary involvement and less likely to have endomyocardial fibrosis and myelofibrosis. Unique to this group of patients is the increased incidence

of progression to lymphoma. The other variants of HES are rare and include a form with cyclic episodes of eosinophilia and angio-oedema (also referred to as Gleich syndrome) and a rare familial form with predominant autosomal dominant transmission and gene involvement at 5q31–33.

The goal of treatment in HES is to limit organ damage by controlling the eosinophil count and, except for treatment of *FIP1L1–PDGFRA* associated HES with tyrosine kinase inhibitors, steroids remain first-line therapy. In patients who are refractory or intolerant to the side-effects of steroids, cytotoxic agents such as hydroxycarbamide (hydroxyurea), vincristine and cytarabine have been used, as well as immunomodulatory therapy with interferon alfa, ciclosporin and intravenous immunoglobulins.

Basophils and mast cells (Figure 17.2c)

Development and function

The functions of basophils and mast cells are similar but not identical. They express the receptor that binds with high affinity the Fc portion of IgE antibody (FcεIR) on their surface and they have large metachromatic (purple-black) granules rich in histamine, serotonin and leukotrienes. Basophils have a bilobed nucleus, in contrast to mast cells, which have a unilobed nucleus. More recent studies have demonstrated that despite their significant similarities, basophils and mast cells are terminally differentiated progeny of distinct bone marrow progenitors. Basophils develop from haemopoietic stem cells and mature in the bone marrow and circulate in the blood, whereas mast cells mature in the tissues. They both play significant roles in the development of a number of allergic and inflammatory disorders as well as host defence mechanisms against parasites.

Mechanisms mediating the maturation of basophils and mast cells differ. Mast cells are derived from CD34⁺, c-Kit-positive progenitors and leave the marrow before their terminal maturation and home to vascularized peripheral tissues where they mature. A complex array of cytokines, elaborated by T cells, macrophages and stromal cells, regulates the production of basophils and mast cells. The major growth and differentiation factor for basophils is IL-3, whereas the growth and development of mast cells requires the presence of SCF.

Basophils are the least abundant leucocytes, accounting for less than 0.5% of bone marrow and peripheral blood leucocytes. Basophils arise from a common basophil–eosinophil progenitor cell, mature in the marrow over a period of 2–7 days and after release in the circulation last for up to 2 weeks. They are the key mediators of immediate hypersensitivity reactions such as asthma, urticaria and anaphylaxis. In addition, they have been implicated in the delayed cutaneous hypersensitivity reaction. Basophils are stimulated by a number of mediators, such as IgE, IL-3, C5a, GM-CSF, insect venoms and morphine, to release the contents of their granules such as histamine. Synergistic

induction of both proinflammatory and immunoregulatory cytokines by IL-33-expressing resident tissue cells, IL-3-expressing mast cells, Th2 lymphocytes, and IgE receptor activation by allergen exposure may provide the mechanism by which basophils are activated without the required involvement of the adaptive immune system.

The interaction between IgE and basophil/mast cell FcεIR and antigen bridging results in basophil degranulation and initiation of their effects of granule contents. The granules of basophils and mast cells contain sulphated glycosaminoglycans responsible for their intense staining, as well as histamine, LTD₄, PAF, eosinophil chemotactic factor and kallikrein responsible for type I immediate hypersensitivity reactions and chronic inflammation (Table 17.10). Histamine is derived from histidine by decarboxylation and is stored as a complex with heparin or chondroitin sulphate proteoglycans. The primary protease of mast cells, tryptase, is mainly released during the early phase of allergic response and is a marker of mast cell activation in chronic inflammatory diseases. Other neutral proteases such as carboxypeptidase B, chymase and sulphatases are also released and degrade extracellular matrix proteins. Basophil and mast cell activation also leads to the elaboration of cytokines such as GM-CSF, TNF-α, IFN-γ, IL-3, IL-4 and IL-5, which serve to amplify the inflammatory response; TNF-α and GM-CSF recruit and prime neutrophils, IL-5 activates eosinophils and IL-4 enhances cell adhesion molecule expression on endothelial cells, recruits eosinophils into tissues and induces helper T cells to mediate IgE production by B cells.

Disorders of basophils and mast cells

High basophil numbers are commonly seen in patients with myeloproliferative disorders, in particular chronic myeloid leukaemia (CML). Basophil number can be strikingly elevated in patients with CML, accounting for over 20% of circulating leucocytes in the more advanced stages of the disease. They are a part of the neoplastic clone expressing the Philadelphia chromosome or the *BCR–ABL* fusion gene. In other myeloproliferative disorders such as primary myelofibrosis and polycythaemia vera, elevation of basophil numbers is usually more modest. Cases of AML with high levels of immature basophils have also been reported. Rarely, basophils may constitute over 80% of circulating leucocytes, a condition sometimes referred to as basophilic leukaemia. These patients may exhibit clinical features related to the release of histamine and other basophil granular contents, and their treatment can be difficult owing to the possibility of massive release of these mediators secondary to cellular lysis. Other causes of basophilia include ulcerative colitis, myxoedema, recovery from acute illness and drug allergies, although these conditions are usually associated only with modest elevations of circulatory basophils.

As discussed earlier, SCF or c-Kit ligand is an important factor in mast cell development. Therefore, it is plausible that conditions leading to its excessive production and mutation of

Table 17.10 Basophil and mast cell granules, and their contents.

Component	Function	Main physiological role	Other properties	Cell specificity
<i>Protein</i>				
Histamine	Binds to H ₁ , H ₂ , H ₃ receptors	Hypersensitivity reactions and inflammation		Basophils, mast cells
<i>Proteoglycan</i>

Charcot–Leyden crystal protein	Lysophospholipase	Phospholipid metabolism	Neutralizes pulmonary surfactant	Basophil
Major basic protein Sulphatase Exoglycosidase		Disrupts membranes		Basophil

c-kit, leading to its constitutive activation, can cause mastocytosis. An increased number of tissue mast cells can be seen in a number of disorders, including atopy, parasitic diseases, Hodgkin disease and other lymphoproliferative disorders, some neoplasms and rheumatoid arthritis. The zebrafish has also been validated as an efficient *in vivo* system for studying mast cell development and has led to the identification of key transcription factors necessary for development and may serve as a potential model of human mast cell diseases.

Several conditions, ranging from isolated cutaneous mastocytomas to mast cell leukaemia, are associated with mast cell proliferation. Solitary mastocytomas generally regress spontaneously. The more common cutaneous mastocytosis or urti-

caria pigmentosa typically presents with multiple, small, round, reddish-brown maculopapular lesions that, when subjected to minimal trauma, lead to intense pruritus. In some patients, this disease progresses to the systemic variety, with involvement of bone marrow, spleen, liver and the gastrointestinal tract. Systemic mastocytosis can also occur without prior or concurrent cutaneous disease, and in association with haematological disorders, including leukaemias and lymphomas. Organ dysfunction may be secondary to the release of biochemical mediators by mast cells, such as peptic ulcer disease secondary to histamine release. Mast cell leukaemia, a rare condition, presents with circulating mast cells of abnormal morphology (accounting for up to 95% of circulating nucleated cells), peptic ulcer

disease, constitutional symptoms, anaemia and hepatosplenomegaly. It should be distinguished from AML, which can develop in association with systemic mastocytosis.

Management of patients within all categories of mastocytosis includes careful counselling of patients and care providers, avoidance of factors triggering acute mediator release, treatment of acute and chronic mast cell mediator release, an attempt to treat organ infiltration by mast cells, and treatment of any associated haematological disorder. The agents and modalities commonly used in treating patients with mastocytosis include antihistamines, histamine H₂-receptor blockers, adrenaline, steroids, cromolyn sodium, proton pump inhibitors, psoralen with ultraviolet light (PUVA), chemotherapy, radiation, interferon alfa, ciclosporin, 2-chlorodeoxyadenosine and splenectomy. With increased availability of small-molecular-weight inhibitors of intracellular signalling pathways, targeting of the constitutively active mutated *c-kit* has attracted more attention. Two classes of constitutive activating *c-kit* mutations have been reported. The more frequent occurs in the catalytic pocket coding region, with substitutions at codon 816, and the other in the intracellular juxtamembrane coding region. Therefore, kinase inhibitors that block mutated *c-kit* activity might be used as therapeutic agents in systemic mastocytosis. Imatinib mesylate inhibits both wild-type and juxtamembrane mutant c-Kit kinase activity, but has no effect on the activity of the D816V mutant, commonly seen in patients with mastocytosis. Therefore, imatinib mesylate does not appear to be an effective therapy for this disease. However, activity of imatinib has been reported in a subset of mastocytosis patients with associated eosinophilia who express the *FIP1L1-PDGFR*A fusion gene.

Monocytes and macrophages (Figure 17.2d,e)

The mononuclear phagocyte system has been defined as a family of cells comprising bone marrow progenitors, blood monocytes and tissue macrophages. Monocytes develop from a pluripotent haemopoietic stem cell in the bone marrow termed CFU-GEMM (colony-forming unit – granulocyte, erythrocyte, monocyte, megakaryocyte) and the more committed CFU-GM. This progenitor cell can commit to both the neutrophil and monocytic pathways. Cytokines and growth factors, such as monocyte colony-stimulating factor, GM-CSF and IL-3, allow commitment along monocytic pathways. Monocyte colony-stimulating factor, also known as colony-stimulating factor (CSF)-1, is the most important factor in the development of monocytes and macrophages, and is necessary but not sufficient for their activation. Macrophage colony-stimulating factor is the primary macrophage growth factor detected in peripheral blood and has been shown in mouse models to be essential for macrophage differentiation, unlike GM-CSF. Macrophages stimulated by macrophage colony-stimulating factor can also clear apoptotic cells by macropinocytosis in the same fashion as dendritic cells.

Following their release into the circulation, monocytes rapidly partition between the marginating and circulating pools. The circulating monocytes have a highly convoluted surface and a lobulated nucleus. They can be further characterized by non-specific esterase and contain a single type of nucleus with staining characteristics of lysosomes. After migration into tissues, they become larger and acquire the characteristics of tissue macrophages. Monocytes contain lysosomal hydrolases and the intracellular enzymes elastase and cathepsin. After transformation into tissue macrophages they produce predominantly metalloproteases and metalloprotease inhibitors, lose expression of hydrolases, and express macrophage-specific genes and products such as inducible NOS and IFN- γ . Tissue macrophages are long-lived and self-sustaining cells.

Kupffer cells, phagocytic cells residing within the lumen of hepatic sinusoids, represent up to 90% of fixed tissue macrophages and are the first phagocytes to encounter bacteria originating from the colon. Recent advances in the understanding of Kupffer cells suggest that two subsets exist: a sessile radioresistant hepatic-derived population that does not participate in inflammatory reactions and a radiosensitive population that is replaced by bone marrow-derived precursor cells and is recruited to sites of inflammation by CD8⁺ T cells. These two subsets can be distinguished by flow cytometry and immunohistochemical techniques. Phagocytosis by Kupffer cells may not be the principal mechanism of organism removal from the bloodstream but likely involves a complex interaction with neutrophils recruited to the liver within 2 hours of infection. Kupffer cells are also implicated in the removal of neutrophils after the clearance of an organism, downmodulating the inflammatory response and abrogating the tissue destruction sometimes seen in overwhelming sepsis.

Macrophage activation is the acquisition of competence to perform specific and complex functions as a result of exposure to a constellation of cytokines and other factors in their environment, rather than achievement of a universal activated state. Physiological factors from the host such as cytokines and growth factors as well as environmental factors from microorganisms constitute this constellation and their combined effect is synergistic. Macrophage activating factor, identified as IFN- γ , as well as IL-2, IL-4, macrophage colony-stimulating factor and GM-CSF are either directly or indirectly, through IFN- γ , responsible for macrophage activation. They stimulate monocyte/macrophage proliferation, increase adhesion receptor expression and stimulate the production of proteolytic agents responsible for pathogen clearance. The hypothalamic–pituitary–adrenal axis and autonomic nervous system communicate with the inflammatory system via catecholamine-induced activation of macrophage NF- κ B and subsequent release of macrophage-derived proinflammatory cytokines.

Although production of IFN- γ by Th1 cells results in a cytocidal macrophage state, IL-4 and IL-13 produced by the Th2 population of T lymphocytes stimulate the antigen-presenting

cell state. These cytokines then enhance macrophage stimulation of T cells by inducing class II MHC antigen and costimulatory molecule expression. Activated macrophages, in turn, produce cytokines that stimulate both types of helper T cells.

Several cytokines, including IL-4, IL-10, IL-13 and TGF- β , can inhibit different aspects of macrophage function. Furthermore, prostaglandin (PG) E_2 , elaborated by macrophages, as well as corticosteroids can suppress various actions of macrophages. These provide a feedback mechanism for control of the immune response.

Recently, a subset of activated macrophages has been shown to express a folate receptor that can bind and internalize folate-linked drugs and dyes, which opens the possibility for folate-linked radioimaging techniques of joints as well as selective drug delivery to sites of active inflammation.

Disorders of monocyte/macrophages

Monocytosis and monocytopenia

Chronic inflammatory conditions, both infectious and immune in nature, are associated with monocytosis (Table 17.11). These include tuberculosis, bacterial endocarditis, syphilis, collagen vascular disease, sarcoidosis and ulcerative colitis. Monocytosis is also commonly seen in a number of haematological malignancies such as AML, Hodgkin disease, non-Hodgkin lymphomas and histiocytosis. Decreased number of circulating monocytes has been reported with endotoxaemia, corticosteroid administration and hairy cell leukaemia.

Histiocytic disorders

As described above, bone marrow monocytes enter the circulation and transform into tissue-specific macrophages under the influence of the local environment, thus becoming cells of the mononuclear phagocytic system. Dendritic cells also have their origin in the bone marrow and share common progenitors with macrophages. Progenitors of dendritic cells are released from the bone marrow and enter tissues in which they differentiate into functional antigen-presenting dendritic cells. The ordinary tissue macrophages have IgG Fc receptors, whereas the tissue-based dendritic cells comprising the dendritic cell system lack phagocytic capacity or Fc receptors and are predominantly antigen-presenting cells. The dendritic Langerhans cells are found in virtually all tissues except the brain and are the major immunological cellular components of the skin and mucosa. Their racquet-shaped ultrastructural inclusions (Birbeck bodies) distinguish them from other tissue cells. They interact with and process antigen, then migrate to lymphoid organs where, through interaction with T cells, they generate cellular and humoral immune responses. This ability of dendritic cells to interact with T cells and other inflammatory cells contributes to the often varied clinical manifestations of the histiocytic disorders.

Miscellaneous

Cyclic neutropenia
Chronic idiopathic neutropenia
Kostmann syndrome
Post splenectomy

The histiocytic disorders comprise various haematological disorders, with cells of the mononuclear phagocytic system or the dendritic cell system involved in their pathogenesis. In general, diseases associated with proliferation of histiocytes can be grouped into two different categories: inflammatory disorders and neoplastic (clonal) disorders (Table 17.12). In the more recent classifications by the World Health Organization Committee on Histiocytic/Reticulum Cell Proliferations, other disorders in which histiocytes are implicated, such as storage diseases (Gaucher and Niemann–Pick), have been excluded. Abnormal immune responses mediated by cytokines has been proposed to be the inciting factor for the two more common disorders: Langerhans cell histiocytosis and haemophagocytic lymphohistiocytosis. However, it is unclear whether the histiocytes themselves or other immune cells are the defective cell population.

Langerhans cell histiocytosis

Histiocytic sarcoma (malignant histiocytosis): localized or disseminated

Siwe disease and Hand–Schüller–Christian disease) have the characteristics of epidermal Langerhans cells. These disorders, now collectively referred to as Langerhans cell histiocytosis (LCH), have variable clinical features depending on the organs infiltrated by the responsible Langerhans and accompanying cells. The true prevalence of these disorders is seven cases per million. The majority of cases occur in children under 15 years of age, but they can occur at any age.

The aetiology of these disorders is far from clear, but a number of clues from their biology and epidemiology are emerging. Associations with malignancies and an inherited predisposition based on studies in identical twins have been suggested. No seasonal variations or geographic or racial clustering has been reported, disputing the possibility of an infectious aetiology. Flow cytometric and chromosomal analysis of cells from LCH infiltrates as well as methods to assess clonality based on restriction fragment length polymorphisms have suggested the possibility of a clonal nature, although no consistent chromosomal alterations have been reported so far.

It is now clear that LCH is characterized by clonal proliferation of CD1a-positive cells. The Langerhans cells from the

lesions of patients demonstrate several phenotypic changes that distinguish them from their normal counterparts. Differences in staining by the lectin peanut agglutinin, expression of placental alkaline phosphatase, expression of the IFN- γ receptor, and expression of costimulatory receptors such as CD86 and CD80 allow one to distinguish between LCH lesional cells and their normal counterparts. There is extensive expression of GM-CSF, IL-1, IL-3, IL-4, IL-8, TNF and leukemia inhibitory factor (LIF) in the lesions of LCH, suggestive of activation of T lymphocytes as well as recruitment of macrophages, eosinophils and granulocytes. The accumulation of IL-1 and PGE₂ may explain the association of these lesions with bone loss. Such increases in immunostimulatory and tissue-damaging cytokines occur at local sites, usually without high systemic levels.

The diagnosis of LCH is based on a biopsy of the involved organs, with the key diagnostic feature being the presence of pathological Langerhans cells, which can be identified by demonstration of either CD1a surface antigen or the presence of Birbeck granules on electron microscopy. Mitoses are usually not present and when found have no prognostic significance. Early lesions are generally cellular and locally destructive, with abundance of essentially normal Langerhans cells. As the lesions mature, there are fewer Langerhans cells with occasional necrosis.

The lesions of LCH occur in skin, bone, lymph nodes, liver, spleen, bone marrow, lungs, the CNS and the gastrointestinal tract. Clinical features are varied and depend on the organs involved. It may involve single organs or involve multiple systems, and assessment of organ function is important as it can have prognostic significance. Initial investigations should include a full blood count, assessment of renal and hepatic function, a skeletal survey and a technetium bone scan; these latter studies are complementary, with the latter being more sensitive for early lesions. Other investigations include chest radiography and possibly magnetic resonance imaging (MRI) of the brain to rule out CNS involvement. Additional testing for diabetes insipidus and other organ involvement should be carried out as indicated.

Langerhans cells play an integral role in antigen recognition and presentation in immune responses throughout many tissues. Pulmonary Langerhans cell histiocytosis (PLCH) is a non-neoplastic collection of reactive Langerhans cells that causes interstitial lung disease in adult smokers. PLCH is uncommon and comprises 5% of all interstitial lung disease, predominantly afflicting middle-aged men and women smokers. PLCH typically presents with dyspnoea, non-productive cough and constitutional symptoms and radiographic features of reticulonodular changes with cyst formation. Diagnosis is made with open lung biopsy and, depending on the stage of the lesion, histopathology can range from an abundance of Langerhans cells, lymphocytes, eosinophils, plasma cells in a background of mild to dense fibrosis. Langerhans cells in PLCH are phenotypi-

cally similar to lymphostimulatory dendritic cells within the lymphoid organs and can be identified by positive immunostaining for CD1a, langerin, E-cadherin and S-100, as well as the presence of Birbeck granules. The treatment of PLCH is smoking cessation and although no randomized studies exist, reports can be found in the literature supporting the use of corticosteroids and chemotherapy for progressive disease. Prognosis is variable and cases of spontaneous regression even without intervention have been documented.

Solitary or multifocal eosinophilic granuloma occurs mainly in older children and young adults and accounts for the majority of cases of LCH. Hand–Schüller–Christian disease occurs in younger children (2–5 years) and often presents with exophthalmos due to a tumour mass in the orbital cavity. Letterer–Siwe disease is the rarest and often most severe form of LCH, typically presenting with a scaly, seborrhoeic, eczematoid and, occasionally, purpuric or ulcerative rash in infants younger than 2 years. Bone involvement in LCH can lead to a tender swelling (as a result of infiltration of adjacent tissues) and inability to bear weight. Radiographically, lesions appear as ‘punched-out’ holes sometimes with sclerotic edges. Other clinical manifestations include rashes, which may be maculopapular, nodular or vesicular; ear discharge; lymphadenopathy; diabetes insipidus, due to involvement of the hypothalamus and the pituitary; respiratory symptoms, with radiographic changes such as micronodular infiltrates due to lung involvement; hepatomegaly with laboratory evidence of liver dysfunction; splenomegaly; CNS disease, with ataxia, dysarthria and cranial nerve palsies; and, rarely, gut involvement with diarrhoea, malabsorption and protein-losing enteropathy.

The prognosis of patients with LCH depends on age of onset, number of involved organs and degree of dysfunction. In general, infants with multiorgan disease have the worst prognosis. There is also growing realization that multiple recurrences of the disease can occur indefinitely, and those patients with multisystem involvement can have long-term sequelae of their disease and/or its treatment. These include neurocognitive and psychosocial problems, neurological complications with a neurodegenerative pattern of CNS involvement, orthopaedic problems, hearing loss, and hypothalamic–pituitary axis deficiencies leading to stunted growth and other endocrine problems.

Spontaneous resolution in a significant proportion of patients with LCH can occur and patients with limited disease usually do not require systemic therapy. In contrast, patients with multifocal disease generally benefit from systemic therapy. Treatment options have included low-dose radiation for symptomatic single lesions, local injection of steroids, topical steroids, PUVA, non-steroidal anti-inflammatory drugs, high-dose systemic steroids, and systemic combination chemotherapy regimens with agents such as prednisolone, vinblastine, vincristine, etoposide and 6-mercaptopurine. Other treatments that have been tested in patients with disease progression while on

therapy include ciclosporin, antithymocyte globulin, 2-chlorodeoxyadenosine, thalidomide, TNF inhibitors, anti-CD1a antibodies and haemopoietic stem cell transplantation.

Haemophagocytic lymphohistiocytosis

These disorders include genetic (familial and immunodeficiency-related syndromes) and acquired forms. Familial forms affecting neonates and infants occur in 1 in 50 000 live births. Males and females are equally affected and over two-thirds of cases occur in siblings. The familial form is an autosomal recessive disease without a well-defined genetic defect. Recently, several defects in genes with important immune functions have been reported in patients with familial haemophagocytic lymphohistiocytosis (HLH) and include mutations in the genes for perforin (*PRF1*), Munc13-4 (*UNC13D*) and syntaxin 11 (*STX11*). The acquired form is associated with Chédiak–Higashi syndrome, Griscelli syndrome and X-linked lymphoproliferative syndrome.

It is hypothesized that the disease is caused by impaired lymphocyte-mediated cytotoxicity and defective triggering of apoptosis. Perforin, normally secreted by cytotoxic T cells and NK cells, can form cell death-inducing pores through which toxic granzymes may enter the target cell and trigger apoptosis. Mutations of the perforin gene have been reported in several patients with familial HLH and result in defective lymphocyte cytotoxic activity. The manifestations of the disease are thought to be mediated by hypersecretion of proinflammatory cytokines such as IFN- γ , TNF- α , IL-6, IL-10 and macrophage colony-stimulating factor (M-CSF). Such excess of proinflammatory cytokines results in tissue infiltration by lymphocytes and macrophages, leading to haemophagocytosis and the characteristic laboratory abnormalities including cytopenias, coagulopathies and hypertriglyceridaemia.

Both familial and acquired forms of HLH are commonly precipitated by viral (particularly Epstein–Barr virus and other herpesviruses), bacterial, fungal and protozoan infections, occurring frequently in an immunocompromised host. Other factors that have been associated with acquired HLH include malignancies (particularly lymphoproliferative disorders), drugs (such as phenytoin) and rarely with inborn errors of metabolism (lysine protein intolerance and multiple sulphatase deficiency). It is important to distinguish patients with the secondary form of the disease from individuals with familial HLH and a precipitant viral infection.

Symptoms of HLH commonly include high fever, anorexia, malaise, irritability and vomiting. Hepatosplenomegaly, lymphadenopathy and neurological signs such as cranial nerve palsies and seizures are also common. Laboratory features include pancytopenia, hypertriglyceridaemia, hypofibrinogenaemia, cerebrospinal fluid pleocytosis, coagulopathy, transaminitis and hyperbilirubinaemia. The marrow is often hyperplastic with increased numbers of haemophagocytic histiocytes. Histopathological features of the lymph nodes or other

Table 17.13 Diagnostic criteria for haemophagocytic lymphohistiocytosis.

<i>Familial disease/known genetic defect</i>
<i>Clinical and laboratory criteria (5/8 criteria)</i>
Fever
Splenomegaly
Cytopenia in two or more cell lines
Haemoglobin < 9 g/dL (below 4 weeks < 12 g/dL)
Platelets < 100 × 10 ⁹ /L
Neutrophils < 1 × 10 ⁹ /L
Hypertriglyceridaemia and/or hypofibrinogenaemia
Fasting triglycerides ≥ 3 mmol/L
Fibrinogen < 1.5 g/L
Ferritin ≥ 500 µg/L
sCD 25 ≥ 2400 U/mL
Decreased or absent NK cell activity
Haemophagocytosis in bone marrow, CSF or lymph nodes

Supportive evidence includes cerebral symptoms with moderate pleocytosis and/or elevated protein, elevated transaminases and bilirubin, lactate dehydrogenase > 1000 U/L. sCD 25, soluble interleukin-2 receptor.

involved tissue are often diagnostic, showing infiltration by lymphocytes and histiocytes and characteristic prominent erythrophagocytosis and haemophagocytosis, features required for diagnosis. During the acute phase of the illness, the plasma concentrations of inflammatory cytokines and the α -chain of the soluble IL-2 receptor as well as impaired NK cell activity are abnormal. Revised criteria from the Histiocyte Society for the diagnosis of HLH are shown in Table 17.13.

Treatment of familial HLH has included the use of corticosteroids (dexamethasone is preferred over prednisolone due to its ability to cross the blood–brain barrier), immunoglobulin infusions, ciclosporin and etoposide. Although early responses are observed, disease recurrence within months is common. Adequate control of CNS disease is important and intrathecal therapy using methotrexate with or without corticosteroids is merited in patients with recurrent CNS disease. Patients are at risk of developing opportunistic infections due to their underlying immune dysfunction and the effects of therapy. If a treatable infectious agent is identified, appropriate antimicrobial therapy should always be employed, regardless of whether the patient has genetic or acquired HLH. Haemopoietic stem cell transplantation from a matched sibling or unrelated donor remains the definitive treatment modality in patients with genetic forms of HLH.

Sinus histiocytosis with massive lymphadenopathy or Rosai–Dorfman syndrome is characterized as a benign, frequently chronic, painless lymphadenopathy involving the cervical nodes

and less commonly other nodal areas and has no known aetiology. Other features may include fever, weight loss and extranodal disease in skin, soft tissues, orbits, upper respiratory mucosa, bone and other organs. Although the disease commonly occurs in the first two decades of life, all ages can be affected. Diagnostic evaluation of involved lymph nodes reveals infiltration by histiocytes and multinucleated giant cells associated with erythrophagocytosis. The proliferating histiocytes are morphologically distinguished from the Langerhans cells of LCH by the absence of Birbeck granules on electron microscopy as well as their surface phenotype. Nodal disease is often self-limited and regresses without intervention. However, bulky extranodal disease can cause symptoms and even organ impairment. Therapy depends on the extent of involvement and ranges from observation to surgical debulking and/or radiation. Chemotherapy plays no role in treatment.

Erdheim–Chester disease is a rare non-Langerhans cell histiocytosis that occurs in adults and may be of clonal origin. Bony pain with symmetric osteosclerosis of the metaphyses and diaphyses of long bones is characteristic of the disease. Extraosseous lesions can be found in approximately 50% of cases and can involve lung, heart, skin, kidney, CNS, muscle, breast and sinonasal mucosa. Because of the very rare nature of this disease, only anecdotal reports of treatment with steroids, interferon, chemotherapy, radiation and stem cell transplantation with variable rates of success are found in the literature. Prognosis is dependent on the extent of extraosseous disease and many patients die within a few years due to progressive pulmonary and retroperitoneal involvement.

Although monocytic leukaemias are included in the classification of histiocytic disorders, their discussion is beyond the scope of this chapter and are dealt with elsewhere.

Selected bibliography, 342**Lysosomes**

Lysosomes are membrane-bound intracellular organelles that represent the major degradative compartment of mammalian cells. They are morphologically heterogeneous and are distinguished from other organelles by the presence of a range of catalytic enzymes and lysosome-associated membrane proteins (LAMPs). More than 50 lysosomal hydrolases, active at acidic pH, catalyse the degradation of macromolecules (lipids, proteins, nucleic acids, glycosaminoglycans and oligosaccharides). These include breakdown products of blood cell membranes, gangliosides from neurones, and glycosaminoglycans derived from connective tissue and extracellular matrix. Substantial flows of substrate of intracellular origin are also generated as a product of intermediary metabolism and turnover of macromolecules. Substrate is delivered to the lysosome by the processes of endocytosis, pinocytosis, phagocytosis or autophagocytosis, or is imported from the cytoplasm using a system of biological chaperones.

The lysosomal membrane and its LAMPs protect cytoplasmic components from the acid hydrolases. LAMPs are transmembrane proteins with highly glycosylated intralysosomal domains, among the most densely *N*-glycosylated proteins so far reported. The lysosomal membrane is also involved in fusion with other organelles, in maintenance of an acidic intralysosomal pH and in the efflux of amino acids and monosaccharides and oligosaccharides produced by the lysosomal hydrolases.

Soluble lysosomal enzymes are synthesized on the rough endoplasmic reticulum and acquire *N*-linked oligosaccharide side-chains in the Golgi apparatus. Here, asparagine-linked

high-mannose residues are phosphorylated at position 6. This modification is specific for lysosomal enzymes and is essential for the routing of the enzymes to the lysosomal compartment via mannose 6-phosphate receptors (Figure 18.1). The small proportion of newly synthesized enzyme that does not bind to the intracellular receptor is secreted into the interstitial fluid, where it may bind mannose 6-phosphate receptor located on the plasma membrane. This enzyme is then recovered by receptor-mediated endocytosis and transported to the lysosome. Trafficking signals for lysosomal membrane glycoproteins probably reside in the cytosolic tails of the proteins and differ from those of lysosomal enzymes. This knowledge of the sorting mechanism for lysosomal enzymes has allowed the development of enzyme replacement therapy of lysosomal storage disorders.

Pathophysiology of lysosomal storage disorders

In most lysosomal storage disorders, an inherited deficiency of a specific lysosomal enzyme results in the accumulation of undegraded substrates within the lysosome. In others, accumulation of storage product results from deficiency or malfunction of activator proteins or transport proteins. Individual mutations of the relevant genes give rise to variable levels of residual enzyme activity. The resulting diseases are grouped according to the major stored substance, for example the mucopolysaccharidoses, sphingolipidoses and glycoproteinoses. Storage product within the lysosomes causes disruption of cellular organization and disturbance of normal membrane functions including signal transduction and ion transport. Different lysosomal storage diseases have the characteristic organ distribution patterns of the stored metabolites. For example, in mucopolysaccharidosis (MPS) type III (Sanfilippo disease)

Figure 18.1 Routes of lysosomal enzyme cycling. Extracellular enzyme binds to the plasma membrane via mannose 6-phosphate receptors and is internalized by a clathrin-coated vesicle into an early endosome. As the early endosome acidifies to become a late endosome, the enzyme dissociates from the mannose 6-phosphate receptor, which recycles to the plasma membrane. The late endosome fuses with a primary lysosome derived from the Golgi apparatus to form a secondary lysosome, which may remain in the cell as a residual body or fuse with the plasma membrane in the process of exocytosis of digested products.

there is accumulation of heparan sulphate, an essential component of the neuronal membrane. This results in mental retardation. In contrast, in MPS type IV (Morquio disease) accumulation of keratan sulphate results in severe skeletal deformities. However, even within a discrete storage disorder there are often wide-ranging clinical manifestations and considerable interindividual heterogeneity. Furthermore, genotype–phenotype relationships are generally unclear and even siblings with the same mutation can have widely disparate clinical manifestations.

Although knowledge of the genetics and biochemistry of the disorders has recently improved, little is known of the pathological processes that actually result in end-organ damage. These processes do not simply relate to the burden of storage product but extend to involve a complex host reaction to abnormal cells. This may result in cytokine secretion, cellular proliferation, disturbed calcium homeostasis, exaggerated inflammation and perturbed control of apoptosis. In Gaucher disease, where storage cells are macrophages that play an essential role in host physiology and pathogenesis of inflammatory and immunological responses, a wide variety of enzymes, cytokines and coagulation factors are perturbed (Table 18.1). Interleukin (IL)-1, IL-6, IL-10 and tumour necrosis factor (TNF) have been implicated in the pathogenesis of Gaucher disease. Elevated serum levels of IL-6, which is produced by macrophages, endothelial cells, fibroblasts and T cells, have been found to correlate with an index of severity in patients with Gaucher disease, and may be instrumental in the pathogenesis of B-cell dysregulation and bone disease. IL-10, which in general inhibits the synthesis of other inflammatory cytokines,

is also elevated and may represent an abnormal state of immune activation.

Prevalence

Recent studies suggest that the true prevalence of lysosomal storage disorders may be higher than previously thought. This is because patients with minimal symptoms, such as homozygotes for the Gaucher N370S mutation, may not come to medical attention and also because of misdiagnosis of multisystem disorders such as Fabry disease. Studies in Europe, the USA and Australia suggest that although the diseases are individually rare, their combined overall birth prevalence is 1 in 5000–8000. In a study performed in the Netherlands, lipidoses were the most frequent as a group followed by mucopolysaccharidoses. Mucopolipidoses and oligosaccharidoses were very rare. Metachromatic leucodystrophy, Krabbe disease and Gaucher disease were the most frequent individual disorders (Table 18.2). Attenuated forms of some lysosomal storage disorders (e.g. Fabry disease) may be much commoner and may underlie diverse late clinical manifestations in adults, including stroke, renal failure and left ventricular hypertrophy (see below).

Diagnosis

In the absence of an informative family history, diagnosis of lysosomal storage disorders requires a high degree of clinical

suspicion. Storage product may be identified within biopsy specimens, plasma or urine. These may have been requested incidentally, for example the finding of Gaucher disease in the bone marrow biopsy of a thrombocytopenic patient or Fabry disease in a renal biopsy, or may be a specific directed examination such as a skin biopsy in a patient with the characteristic rash of Fabry disease. Levels of lysosomal enzymes may be measured in plasma or leucocytes using commercially available synthetic or naturally occurring labelled substrates. Once a can-

didate enzyme is identified, analysis of the corresponding gene may identify a specific mutation and facilitate rapid screening of other family members. As effective treatment becomes available for a larger number of disorders, it is increasingly important that patients should be diagnosed as early as possible as presymptomatic individuals may be candidates for early intervention.

Therapy

Effective treatment of lysosomal storage disorders self-evidently involves reduction of the stored compound and prevention of its reaccumulation. This has been achieved by elevation of enzyme activity by stem cell transplantation, infusion of the missing enzyme (enzyme replacement therapy or ERT) or stabilization of protein folding variants by pharmacological chaperones. Conversely, reduction of the substrate can also be achieved by limiting its synthesis through inhibition of anabolic enzymes, so-called substrate reduction therapy (SRT).

Many patients with Gaucher disease, metachromatic leucodystrophy, Krabbe disease and MPS type I have undergone stem cell transplantation. Donation of stem cells has largely been from HLA-identical siblings but as the highest level of enzyme activity will be supplied by donor cells from non-carriers, cord blood from unrelated donors has recently been used with good results.

ERT is now available or under investigation for several lysosomal storage disorders (Table 18.2). A range of production platforms has been developed recently. Recombinant human enzyme can be produced in Chinese hamster ovary cells or plant (e.g. carrot) cells. Gene activation technologies have been applied to cultured human fibroblasts. The resulting translated proteins are chemically modified, purified and prepared for infusion. The effectiveness of ERT depends on the accessibility of the site of the pathology to exogenous enzyme and the ability of affected cells to internalize the enzyme. ERT is effective in reducing the non-neuronopathic manifestations of a number of disorders, including Gaucher disease type I, Fabry disease, Pompe disease and MPS types I, II, III and VI. However, infused enzymes do not cross the blood–brain barrier and ERT does not prevent the onset and progression of neurological symptoms. Intrathecal administration is under investigation but is likely to be of limited success. Furthermore, ERT for systemic therapy has to be given by intravenous infusion. Antibodies readily develop to infused enzyme and this certainly attenuates effectiveness in some diseases (e.g. Pompe disease) but data are lacking in other conditions (e.g. Gaucher disease, Fabry disease).

Recently, other treatment strategies have been developed. One approach, SRT, is to decrease the rate of synthesis of the stored component so that it is approximately equal to the rate of degradation. Analogues of small molecules are used to inhibit the activity of synthetic enzymes. Thus, glucose and ceramide

analogues can be used separately to reduce the activity of the enzyme glucosylceramide synthetase. This approach is only feasible in individuals with later-onset forms of the diseases who harbour mutations associated with detectable levels of residual enzyme activity. The small molecules used in SRT can be given orally, are easily absorbed and have a wide tissue distribution. Furthermore, SRT may have therapeutic utility in crossing the blood–brain barrier.

Some mutations lead to reduced levels of residual enzyme activity by causing misfolding of peptide chains or abnormal intracellular transport. The oral administration of small molecules (pharmacological chaperones) that can rescue misfolded or unstable enzymes is currently under active investigation for several lysosomal storage disorders. Such chaperones are designed to bind specifically to mutant peptides, aid their passage through the endoplasmic reticulum, rescue them from proteosomal degradation and guide them to the lysosome. They would dissociate from the enzyme within the acidic lysosomal environment. Combinations of ERT and chaperone therapy are also being evaluated in clinical trials.

Agents that bind to ribosomes (e.g. derivatives of gentamicin) and which modify the processing of RNA transcripts to allow ‘read-through’ of premature stop codon mutations are another class of mutation-specific therapy currently being evaluated in lysosomal storage disorders. Finally, gene therapy is under investigation in animal models of lysosomal storage disorders and has been reported as an adjunct to ERT in Gaucher disease.

Prognosis

The clinical course of infants diagnosed with a lysosomal storage disorder usually follows a predictable path of loss of learned skills and neurological deterioration until death results from infection and progressive organ damage. When onset is later, in adolescents and adults, the clinical course is more varied and the prognosis depends on the major organ systems affected. However, patient heterogeneity is such that it is not possible to predict which patients are most likely to experience significant morbidity or early mortality.

Clinical manifestations

The key clinical features of the major lysosomal storage disorders are presented in Table 18.3. In view of recent advances in therapy, Gaucher disease, Fabry disease and Pompe disease are presented in greater detail below.

Gaucher disease

Gaucher disease is due to deficiency of the enzyme β -glucocerebrosidase, a lysosomal enzyme that hydrolyses glucosylceramide to glucose and ceramide (Figure 18.2). It is an

autosomal recessive condition arising as a result of mutation within the *GBA* gene. Affected individuals have a mutant enzyme with reduced activity, resulting in accumulation of the substrate (glucosylceramide) in lysosomes of reticuloendothelial cells. It is one of the commonest lysosomal storage disorders, with an estimated incidence of 1 in 60 000 to 1 in 80 000 individuals.

Clinical features

Clinical manifestations are due to cellular and tissue damage consequent upon accumulation of sphingolipid-laden macrophages in reticuloendothelial organs. Three main clinical phenotypes are observed (Table 18.4), determined in large part by the residual activity of the mutant enzyme. All three types are progressive disorders. Residual enzyme activity in type II is so low that abnormal cells accumulate in the central nervous system (CNS). This is the acute neuronopathic form of the disease, which presents with neurological complications in early infancy and usually leads to death before the age of 2 years. Type III disease is the subacute neuronopathic form that leads to a slowly progressive neurodegenerative disorder. Type I is the commonest form of Gaucher disease and typically does not cause neurological disease. It is particularly common among subjects of Ashkenazi Jewish origin; within this community, as many as 1 in 15–20 subjects are carriers, and approximately 1 in 800–1000 subjects are homozygous. Type I Gaucher disease is a heterogeneous disorder that may present in childhood or in late adult life (> 60 years old). It is likely that many undiagnosed subjects are asymptomatic. Symptomatic individuals have hepatosplenomegaly, skeletal disease and bone marrow infiltration, leading to pancytopenia. Rarer manifestations of type I Gaucher disease include pulmonary disease, skin involvement and peripheral neuropathy. Patients with type I Gaucher disease have an increased incidence of malignancy generally and an increased incidence of haematological malignancies, especially B-lymphocyte disorders (myeloma, monoclonal gammopathy of undetermined significance) and myelodysplasia. There is an increased incidence of Parkinson disease among affected individuals and carriers.

Laboratory features

Affected individuals have mutations within the *GBA* gene; more than 300 different mutations have been described. The commonest mutation causing type I disease is a single base-pair substitution in codon 370 (N370S), which accounts for approximately 70% of mutant alleles in affected Ashkenazi Jewish subjects. A base-pair substitution in codon 444 (L444P) is the commonest mutation underlying neuronopathic Gaucher disease. Diagnosis is confirmed by enzymatic assay of β -glucocerebrosidase activity in leucocytes, fibroblasts and urine. However, enzymatic assay does not always identify heterozygote subjects and measured enzyme activity correlates poorly with clinical severity.

Table 18.3 Lysosomal storage disorders: clinical features.

<i>Category</i>	<i>Disease</i>	<i>Clinical features</i>
Mucopolysaccharidoses	MPS I	Hurler disease: developmental delay, ENT infections, coarse facial features, macrocephaly, thick skin, corneal clouding, hepatosplenomegaly, bony deformity including large skull, pelvic dysplasia, deformed vertebrae and shortened tubular bones (dysostosis multiplex) Scheie disease: mild skeletal abnormalities, stiff joints, corneal opacities, carpal tunnel syndrome, cardiac valvular abnormalities and respiratory infections
	MPS II	Like MPS I but without corneal clouding
	MPS III	Loss of acquired skills, aggression, hyperactivity, coarse hair, hirsutism, seizures, may become tetrapastic
	MPS IV	Disproportionate dwarfism, joint contractures, kyphoscoliosis, corneal clouding
	MPS VI	Like Hurler disease but without neurological involvement
	MPS VII	Skeletal disease, hepatosplenomegaly, lethal hydrops, normal
	Mucopolipidoses	ML I
ML II		Like Hurler disease, mild corneal clouding and hepatosplenomegaly, prominent gum hypertrophy, severe dysostosis multiplex
MLIII		Progressive arthropathy, bone lesions, low intelligence, cardiac valvular lesions, corneal clouding
ML IV		Like ML I
Sphingolipidoses	GM1 gangliosidosis	Infantile: coarse features, seizures, progression to decerebrate rigidity and spastic quadriplegia by 2 years Juvenile: psychomotor and neurological degeneration over 2–10 years Adult: progressive cerebellar impairment, spasticity and intellectual impairment
	GM2 gangliosidosis	Tay–Sachs disease: motor weakness, psychomotor retardation, blindness, lapsing into vegetative state with decerebrate rigidity Sandhoff disease: like rapidly evolving Tay–Sachs disease
	Globoid cell leucodystrophy	Developmental delay and progressive neurological degeneration aged 3–9 months
	Metachromatic leucodystrophy	Flaccid paresis, lack of coordination and hyporeflexia, psychomotor retrogression, juvenile and adult forms have later onset, intellectual deterioration
	Fabry disease	Left ventricular hypertrophy, renal impairment, angiokeratoma and acroparaesthesia
	Gaucher disease	Type 1: hepatosplenomegaly, skeletal disease and pancytopenia Type 2: death from neurological complications by 2 years Type 3: slowly progressive neurodegenerative disorder
	Farber disease	Hoarse cry, painful arthropathy, pulmonary infiltration, cherry-red spot, mental handicap, thickened heart valves
	Niemann–Pick disease	A: Hepatosplenomegaly, lymphadenopathy, neurological regression, epileptic seizures, macular cherry-red spot B: Hepatosplenomegaly and pulmonary infiltration C: Psychomotor delay and regression
Oligosaccharidoses	α -Mannosidosis	Mild skeletal deformity, coarse facial features and moderate to marked mental retardation
	β -Mannosidosis	Hearing loss and swallowing difficulties
	Fucosidosis	Neurological degeneration, neurological impairment, seizures, angiokeratoma and mild skeletal dysplasia
	Aspartylglucosaminuria	Progressive psychomotor retardation, coarse facial features and mild skeletal dysplasia
	Schindler disease	Progressive psychomotor retardation, blindness and seizures
Glycogen	Pompe disease	Cardiomegaly, hepatosplenomegaly, muscular weakness and macroglossia

Table 18.3 *Continued*

Category	Disease	Clinical features
Lipid	Wolman disease	Failure to thrive, malabsorption, adrenal gland enlargement and calcification, fatal by 1 year
	Cholesterol ester storage disease	Hypercholesterolaemia and premature atherosclerosis
Monosaccharide amino acids and monomers	ISSD	Visceral involvement, skeletal dysplasia, psychomotor retardation and early death
	Salla disease	Mental retardation, ataxia and near-normal lifespan
	Cystinosis	Polyuria, thirst, failure to thrive, renal tubular acidosis, rickets, photophobia and hypothyroidism
	Cobalamin F disease	Stomatitis, glossitis, convulsions and developmental delay
Peptides	Danon disease	Cardiomyopathy, myopathy, variable mental retardation
	Pycnodysostosis	Short stature, osteosclerosis, short fingers, open fontanelle, hypodontia
Ceroid lipofuscinosis	CLN	Mental impairment, seizures, loss of vision and motor skills
Multiple enzyme deficiencies	Multiple sulphatase deficiency	Resembles a combination of metachromatic leucodystrophy and Hurler disease
	Galactosialidosis	Hypotonia, coarse features with facial oedema, retinal cherry-red spot

Table 18.4 Clinical manifestations of Gaucher disease.

Manifestation	Type I	Type II	Type III
Onset	1 year	< 1 year	2–20 years
Hepatosplenomegaly	++	+/-	+
Bone disease	++	-	+/-
Cardiac valve disease	-	-	+
CNS disease	-	+++	+/-
Oculomotor apraxia	-	+	+/-
Corneal opacities	-	+/-	+/-
Age at death	60–90 years	< 5 years	< 30 years

Splenic enlargement and marrow infiltration frequently lead to anaemia, thrombocytopenia and leucopenia.

Changes in serum immunoglobulins are frequent. Polyclonal hypergammaglobulinaemia is found in more than one-third of patients, and monoclonal gammopathy of undetermined significance is seen in up to 20%. Liver function tests are often abnormal, reflecting infiltration of the liver by Gaucher cells leading to necrosis, fibrosis and, occasionally, even frank cirrhosis. There is an increased incidence of gallstones. The serum cholesterol level is typically lowered. Gaucher disease is associated with a bleeding diathesis, attributable to abnormal platelet function and thrombocytopenia. Factor XI deficiency is commonly observed and is largely due to co-inheritance of other genetic abnormalities that are also common among Ashkenazi Jews.

The abnormal lipid-laden macrophages are readily detected on tissue biopsy (e.g. bone marrow aspirate; Figure 18.3), although biopsy is no longer considered necessary to make the diagnosis. The serum levels of ferritin, angiotensin-converting enzyme (ACE) and acid phosphatase are typically elevated. The enzyme chitotriosidase is derived from macrophages and is typically grossly elevated in untreated Gaucher disease, and declines progressively with treatment. Levels may be as high as 30 000 U/L (normal range < 150 U/L); values below 1000 U/L generally indicate stable disease and with prolonged (> 7 years) ERT, values may even come down into the normal range (Figure 18.4). However, up to 6% of the population are deficient in this enzyme because of a 24-bp duplication in the chitotriosidase gene. These individuals cannot be monitored by measurement of plasma chitotriosidase activity. A new surrogate marker, pulmonary activation-regulated cytokine (PARC, CCL18), is also elevated in plasma of patients with Gaucher disease and is useful for monitoring those patients with chitotriosidase deficiency. PARC is a member of the CC chemokine family and its over-expression may be relevant to some of the pathophysiological features of Gaucher disease such as abnormalities in neutrophil chemotaxis.

Treatment

All patients with Gaucher disease should be evaluated by experienced physicians. Gaucher disease is the first lysosomal storage disorder to be treated by ERT, and a number of different ERT preparations are now available for the treatment of type I Gaucher disease. Indications for ERT include significant pancytopenia (e.g. Hb < 10 g/dL, platelets < 100 × 10⁹/L), skeletal

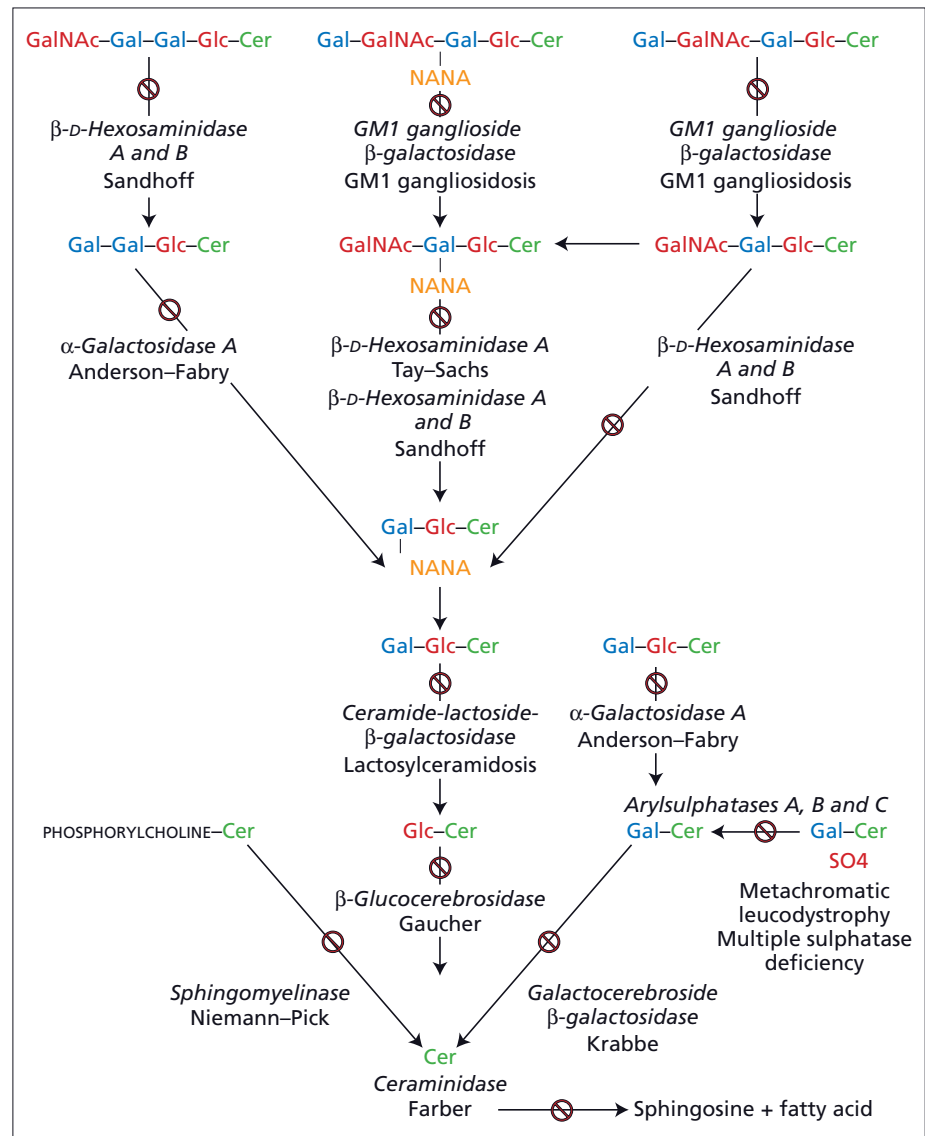

Figure 18.2 Biochemistry of lysosomal storage disorders.

disease and significant hepatosplenomegaly. High-dose ERT (> 100 U/kg every 2 weeks) has been evaluated in type II Gaucher disease but recombinant enzyme does not cross the blood-brain barrier and although hepatosplenomegaly improves, ERT has no discernible impact on CNS disease.

However, ERT has recently (2003) been licensed for patients with type III Gaucher disease, who typically have milder CNS abnormalities (e.g. ophthalmoplegia) in association with advanced systemic changes. SRT has been evaluated in combination with ERT in type III Gaucher disease but again no significant benefits on CNS manifestations have hitherto been demonstrated. ERT is administered by intravenous infusion (typically in the patient's home) every 1–2 weeks. The dose of therapy is titrated against the severity of clinical and laboratory changes. Type I patients with extensive bony disease and

hepatosplenomegaly require in excess of 30 U/kg every 2 weeks (> 60 U/kg for type III), and these high doses should be continued for 2–3 years or more. Patients are monitored regularly with blood tests (the chitotriosidase assay is particularly helpful) and an annual skeletal magnetic resonance scan. Some patients with advanced type I and III disease may benefit from more frequent infusions (e.g. weekly) for the first year or more. The dose of ERT is gradually lowered as the disease burden declines. Patients with less advanced disease may require lower doses, and some patients may only require monthly infusions. ERT is well tolerated and has been available for over 10 years. A small proportion of patients (< 10%) develop antibodies, but these are not usually neutralizing and do not affect treatment efficacy. Infusion reactions are rare and easily managed.

Figure 18.3 Gaucher cells in the bone marrow.

An oral form of therapy (miglustat, Zavesca) has recently been developed and is licensed for mild to moderate type I disease. It is a form of SRT (see above). It is a small molecule that reduces the amount of substrate (glucosylceramide) being produced within lysosomes, such that patients with reduced residual enzyme activity will benefit. It is being evaluated at present in other lysosomal storage disorders (e.g. Niemann–Pick type C) as its administration leads to reduction of a range of substrates in addition to glucosylceramide.

Supportive therapy is frequently required. The skeletal disease in Gaucher disease (Figure 18.5) is painful and patients may require analgesia. Prior to the use of ERT, patients frequently developed acute ‘bone crisis’ – episodic severe pain, typically in the limbs and often precipitated by dehydration. Bisphosphonate therapy is under evaluation for its potential to reduce pain and rate of progression of skeletal disease. Blood component therapy may be required for pancytopenic patients.

Figure 18.4 Clinical course in Gaucher disease treated with enzyme replacement therapy.

Figure 18.5 MRI scan showing skeletal changes in Gaucher disease.

Splenectomy should be avoided if possible as splenectomized subjects are more likely to develop tissue infiltration in other organs (e.g. liver, lungs, skeleton). Allogeneic stem cell transplantation is curative and has a definite role in carefully selected children with neuronopathic Gaucher disease.

Fabry disease

Fabry disease (or Anderson–Fabry disease) is an X-linked lysosomal storage disorder due to mutation within the gene for α -galactosidase A (*GLA*) (see Figure 18.2). The resulting inability to catabolize glycosphingolipids leads to progressive accumulation of the substrate globotriaosylceramide in a range of tissues. In contrast to Gaucher disease, the lipid accumulation in Fabry disease affects a range of cells (e.g. endothelial cells, epithelial cells, myocytes) within a broad range of tissues and organs, particularly the kidneys (leading to renal failure), heart (causing ventricular hypertrophy and conduction disturbances) and vasculature of the CNS. It is one of the commonest lysosomal storage disorders, with an incidence of approximately 1 in 100 000. It is pan-ethnic. Milder variants of Fabry disease may be much commoner and may present as left ventricular hypertrophy, stroke/transient ischaemic attack and renal failure. Although it is X-linked, Fabry disease typically causes manifestations in females, though these occur later and are usually less severe than in males.

Diagnosis

Diagnosis is by assay of α -galactosidase A activity in leucocytes and detection of molecular abnormalities within the *GLA* gene. More than 200 different mutations have been described, and most lead to complete loss of enzyme activity. Tissue diagnosis is by renal, skin or cardiac biopsy.

Clinical features

Clinical features are legion. Although females are heterozygous, they are usually symptomatic and may be as severely affected as males. A skin rash (angiokeratoma) and pain in limbs (acroparaesthesia) are early symptoms (under 10 years old). In late childhood, reduced sweating, abdominal symptoms and lymphoedema are characteristic. Renal failure, cardiac failure, stroke, epilepsy and CNS/sensory organ involvement are later features. Life expectancy is 40–50 years for men and 50–65 years for most women.

Treatment

ERT for Fabry disease has been available since 2001. Two formulations are available: a recombinant galactosidase that is translated in Chinese hamster ovary cells and mannose-terminated (agalsidase beta, Genzyme Corporation, MA, USA); and an enzyme of identical amino acid sequence that is translated in a human fibroblast cell line wherein post-translational modification is performed within the human cell itself (Shire, MA,

USA). The infused enzyme in Fabry disease must be taken up by lysosomes within cells in diverse organs and tissues, so targeting is of crucial importance. Beneficial clinical effects of ERT have been observed in renal and cardiac function, pain, hearing loss and gastrointestinal symptoms.

Pompe disease

Pompe disease (glycogen storage disease type II) is caused by deficiency of acid α -glucosidase. It is characterized clinically by an early infantile subtype associated with cardiomyopathy, hypotonia and reduced survival, and a later-onset form with features consistent with a limb girdle muscle disease phenotype and survival into adulthood. On blood film examination lymphocytes show glycogen vacuolation, which is positive on PAS staining. The prevalence of Pompe disease has been estimated to be 1 in 146 000, although it is higher in certain populations such as African-Americans (1 in 40 000) and Chinese (1 in 50 000). In untreated patients with the late-onset form of Pompe disease, muscle strength and pulmonary function deteriorate over time.

Alglucosidase alfa (Myozyme) is a recombinant formulation of human acid α -glucosidase generated from the transduction of Chinese hamster ovary cells. In infantile-onset patients, enzyme therapy has been shown to significantly extend overall and ventilator-free survival compared with data on historical controls. Trials involving the Chinese hamster ovary-derived enzyme in late-onset patients are in progress.

Niemann–Pick disease

Niemann–Pick disease is divided into subtypes A and B resulting from sphingomyelinase deficiency and subtype C resulting from defects in cellular cholesterol trafficking. Patients with type A exhibit neurodegenerative disease resulting in death in infancy, those with type B have lung but not neurological involvement, and those with type C show slowly progressive neurological disturbance. Hepatosplenomegaly may be found in all three types. Over 100 sphingomyelinase mutations causing Niemann–Pick disease type A or B have been described and DNA-based carrier screening has been implemented in the Ashkenazi Jewish community. Murine knockout mouse models have also been constructed and used to investigate disease pathogenesis and treatment. Based on these studies in the mouse model, a clinical trial of ERT has been initiated in adult patients with non-neurological sphingomyelinase-deficient Niemann–Pick disease. The use of inhibitors of glycolipid synthesis including miglustat appears promising in the therapy of Niemann–Pick disease type C. A recent 24-month randomized trial of miglustat in 29 patients with Niemann–Pick disease type C has recently been published and demonstrated improvement in, or stability of, several clinical markers including swallowing capacity and hearing acuity.

Introduction

The immune system has evolved to provide protection against infection and is believed to play an important role in the control of malignant disease. The immune response is often considered to comprise two functional components, known as the *innate* and *adaptive* arms of the immune response, but in reality these have a broad overlap. The innate immune system is responsible for the initial response to infection and inflammation and is mediated by cells such as macrophages, neutrophils and dendritic cells as well as lymphoid subsets such as natural killer (NK) cells, $\gamma\delta$ T cells and B1 B cells. The adaptive or specific immune system is mediated by antigen-specific lymphocytes that are selected and expanded following recognition of antigen on antigen-presenting cells.

The anatomy of the immune system

The cells of the immune system are of haemopoietic origin and derive ultimately from the haemopoietic stem cell in the bone

marrow. The myeloid and lymphoid lineages diverge during differentiation, with separation of a common myeloid progenitor and a common lymphoid progenitor. There are three broad classes of lymphocyte – B cells, T cells and NK cells – and these have different developmental pathways.

T cells are generated in the thymus following the migration of prothymocytes from bone marrow to thymus followed by selection of thymocyte precursors. Over 95% of thymocytes die in the thymus, but the minority population emerges from the thymus as single-positive CD4⁺ or CD8⁺ T cells and enters the lymphoid system as naive precursors that can survive for many years. The antigen receptor on T cells, the T-cell receptor (TCR), exists only as a cell-surface molecule and is not secreted. T cells have extremely diverse functions including (i) providing signals that help induce T cells and B cells to proliferate and differentiate, (ii) specifically deleting virally infected cells or foreign cells, (iii) activating macrophages to enhance cellular cytotoxicity, and (iv) regulation of established immune responses.

Most *B cells* are generated from within the bone marrow, the 'B' in their name referring to an obscure avian structure called the bursa of Fabricius in which the B cells of birds develop. Naive mature B cells enter the lymphoid circulation but, if triggered by antigen in the periphery, a proportion of cells will return to the bone marrow as long-lived plasma cells that secrete immunoglobulin. B lymphocytes are the precursors of

antibody-producing cells. Each B cell produces and expresses on its surface immunoglobulin with a distinct specificity for antigen. The specificity of the immunoglobulin is determined by the way the immunoglobulin variable-region genes are rearranged during B lymphopoiesis. B cells that bind antigen through their surface immunoglobulin have to obtain accessory signals if they are to proliferate and differentiate into antibody-secreting cells. These can be provided by helper T cells, which recognize antigen that has been taken up and presented by the B cell.

NK cells similarly appear to develop from within the environment of the bone marrow. They are able to kill cells that fail to express major histocompatibility complex (MHC) class I molecules on their surface or that express molecules associated with cellular stress.

The bone marrow and thymus are therefore the sites of lymphocyte development and are known as the *primary lymphoid organs*. However, immune responses are initiated when lymphocytes encounter antigen and this occurs primarily in *secondary lymphoid tissues* such as lymph nodes and the spleen.

Lymphocytes circulate around the body tissues via the blood and lymphatic vasculature. Lymphatic vessels drain extravascular spaces and lymph nodes are collections of lymphoid tissue in lymphatic vessels, which are organized to optimize encounters between lymphocytes and antigen. Afferent lymph drains into the lymph nodes, bringing circulating lymphocytes and populations of antigen-loaded dendritic cells from regional tissue. Efferent lymph returns lymphocytes to the bloodstream, where naive cells continue this circulatory pattern in a continuing quest for antigenic encounter. Antigen-experienced lymphocytes migrate to a variety of tissues in order to mediate their effector functions. The pattern of homing is largely determined by the chemokine receptor profile on the lymphocyte (see below).

Nature of the antigen-specific receptors on T and B cells

Antigen recognition by lymphocytes

Each B or T lymphocyte expresses approximately 20 000–100 000 antigen-specific receptors on their surface and all the receptors on a single T cell or B cell are identical. However, although the antigen receptors on a single cell are identical, they are different from the receptors on other B or T lymphocytes. During lymphoid development, a repertoire of billions of B and T cells is generated and all have slightly different antigen receptors on their surface. At the initiation of an immune response, only a few of these cells are able to recognize the antigen and these are then expanded during their differentiation into effector cells. This is the basis of the *clonal selection* theory of immunology. The mechanisms that generate this great diversity of antigen

Figure 19.1 The structure of the antigen-specific receptor of B cells (BCR). Antibody (immunoglobulin) molecules on the surface of B cells provide their antigen-specific receptors. The green structures are the heavy (H) chains and the orange the light (L) chains. The antigen-combining (variable) regions are shown as open circles; the locations of the antigen-combining sites are indicated by arrows. The binding of antigen by B cells through their surface immunoglobulin can lead to antigen being internalized and can result, indirectly, in proliferation by the B cell and its differentiation to become an antibody-secreting cell or a memory cell. Signals delivered to the B cell when the surface immunoglobulin binds antigen are delivered through the α and β CD79 transmembrane signalling molecules and other surface immunoglobulin-associated molecules, including the complex of CD21 and CD19 with TAPA. CD21 binds the complement component C3d, which is derived from C3, and attaches to bacterial and other cell membranes; when CD21 and the surface immunoglobulin are cross-linked, the stimulus for B-cell activation is considerably more than that delivered through surface immunoglobulin alone. All B-cell surface immunoglobulin, such as plasma IgG and IgA, has two heavy and two light chains per molecule; IgA secreted from the body is a dimer and most IgM found in body fluids a pentamer of this basic four-chain structure.

receptors on lymphocytes are described in the next section. Figure 19.1 shows the structure of surface immunoglobulin on B cells.

T cells recognize peptides presented in association with MHC molecules. In humans, the MHC molecules are also known as human leucocyte antigens (HLAs) and there are two classes of MHC molecule. MHC class I molecules (Figure 19.2) are expressed by all nucleated cells except germ cells. They are not expressed by erythrocytes but are found on the surface of erythroblasts. The peptides recognized by T cells in association with class I MHC molecules are, in most circumstances, derived from proteins produced from within the cell. This places MHC class I molecules in an excellent position to present peptides

Figure 19.2 T cells recognize peptides held in MHC molecules. A class I MHC molecule is depicted on the left and a class II MHC molecule on the right. Some of the protein produced within each cell is broken down to peptides, which are presented on the cell surface in the peptide-binding groove of MHC molecules, usually class I (Figure 19.3). Extracellular molecules are taken up by antigen-presenting cells, broken down within the cell and presented on the cell surface in the peptide-binding groove of MHC molecules, usually class II (Figure 19.3). There are three isotypes of class II molecules, known as DP, DQ and DR, and three main class I isotypes, A, B and C. All of these are encoded within the MHC gene complex at 6p21.3. The genes encoding the peptide-binding grooves of each of these isotypes show extraordinary variability within the human population, so-called 'allelic polymorphism' (see Figure 19.5). The range of peptides that can be held by different MHC molecules varies. Consequently, this polymorphism is reflected in differences between individuals in the ability to recognize specific peptides. Any one T-cell receptor (TCR) will only recognize a particular peptide within a particular groove structure. β_2 -Microglobulin is a non-polymorphic immunoglobulin-like domain that is non-covalently associated with HLA class I MHC molecules; it stabilizes peptide binding and is essential for the expression of class I on the cell surface.

derived from viral proteins following intracellular viral infection (Figure 19.3). It is now clear that antigen-presenting cells are also able to take up proteins from outside the cell and process them such that peptides gain access to the MHC class I presentation. This process is called *cross-presentation* and may be particularly important in generating CD8⁺ T-cell responses to tumour-associated proteins.

MHC class I antigen presentation starts with the intracellular breakdown of proteins by a multimolecular proteolytic complex known as a *proteasome*. These peptides are actively transported by TAP (transporter associated with antigen processing) proteins into the endoplasmic reticulum, where empty MHC class

I molecules are being assembled. The nascent MHC molecules are able to 'fold' around the peptides, which make non-covalent interactions with the peptide-binding groove at the top of the molecule. This complex is then stabilized by the association of β_2 -microglobulin before being transported to the cell surface. In this way, the cells are continuously advertising the peptide composition of the proteins that they are producing.

The selection of T cells during their development in the thymus involves the processes of negative selection and positive selection. T cells that have high affinity for self peptides held in the groove of a self MHC molecule are deleted by apoptosis in a process known as negative selection. T cells with lower affinity for self peptide-MHC complexes are positively selected and survive to become peripheral T cells. T cells that recognize peptide presented by MHC class I molecules express a molecule, CD8, that binds to the $\alpha 3$ domain of the MHC class I molecule (Figure 19.2). When any cell in the body presents immunogenic peptides, these may be recognized by a cytotoxic CD8 T lymphocyte that can then kill the target cell. This is most likely to occur as the result of virus infection when virus-encoded proteins are produced; it may also occur following the acquisition of a genetic mutation within a cell.

The other class of MHC molecule, MHC class II (Figure 19.2), is less widely expressed. The only cells that constitutively express large amounts of this class of MHC molecule are specialized antigen-presenting cells collectively known as dendritic cells, B lymphocytes and thymic epithelial cells. Dendritic cells are derived from haemopoietic stem cells and codevelop with monocytes; they can be derived from blood mononuclear preparations by culture with granulocyte/macrophage colony-stimulating factor (GM-CSF) and interleukin (IL)-4. They migrate to many tissues, particularly epithelia, where they remain until activated by local tissue injury. On activation, they take up fluid and particles from their surrounding environment (Figure 19.3). The pinocytotic activity in these cells can be induced by IL-1 and tumour necrosis factor (TNF) released at sites of injury. The pinocytotic vesicles fuse with an antigen-presenting endosomal compartment; proteolytic enzymes within this compartment are activated and proteins are broken down to peptides by the action of lysosomal enzymes. Class II molecules with peptide-binding grooves sealed by invariant chain (CD74) are inserted into the endosome wall. The invariant chain is digested and this allows peptides within the compartment to associate with MHC class II molecules. The MHC class II-peptide complex is then taken to the cell surface.

The scrutiny of antigen-presenting cells by T cells starts when dendritic cells have moved from peripheral tissues to the T cell-rich areas of adjacent secondary lymphoid organs. In this site they are known as interdigitating dendritic cells (IDCs), which express increased amounts of MHC class II and constitutively express other molecules associated with T-cell activation such as CD40, CD80 (B7.1) and CD86 (B7.2). In the T zones of secondary lymphoid organs, CD4⁺, and to a lesser extent CD8⁺,

Figure 19.3 Antigen processing and presentation in association with MHC molecules. *Left:* Antigen presentation of proteins produced within cells is mainly the property of class I MHC molecules. A proportion of proteins (black ribbons) produced within a cell on ribosomes (yellow) are broken down to peptides (black fragments) within a cytoplasmic molecular complex known as a proteasome. The resulting peptides are actively transported by TAP proteins (blue) through the wall of specialized endoplasmic reticulum (ER) that has MHC class I molecules in its wall. The peptides and β_2 -microglobulin associate with class I molecules and are then expressed on the cell surface (detailed in Figure 19.2). *Right:* Antigen presentation in association with class II MHC molecules involves pinocytosis of

antigen (black ribbon) and fusion with an antigen-processing endosome, which has class II MHC molecules (magenta and blue) inserted in its wall. The antigen-presenting grooves of the class II MHC molecules are kept empty by the association with invariant chain (CD74). Fusion of the pinosome with the endosome heralds the activation of proteolytic enzymes; the invariant chain and the ingested proteins are broken down to peptides. The resulting peptides (black fragments) are assembled into the antigen-presenting groove of class II MHC molecules that are held in the endosomal wall. The HLA class II molecules with bound peptides are then carried to the cell surface (detailed in Figure 19.2).

recirculating T cells are constantly migrating to the surface of IDCs, which they appear to scrutinize for the presence of an MHC-peptide complex to which they can bind with their TCR. In this way, the T cells continually screen for the presence of peptides derived from both extracellular and intracellular antigens (see section Immune responses).

The TCR (Figure 19.4) has certain similarities to immunoglobulin in that it is composed of two non-identical polypeptide chains that have constant and variable regions. In addition, as described in the next section, the genes that encode for TCR and immunoglobulin are remarkably similar. The TCR has only one antigen-binding site per molecule, as opposed to the two antigen-binding sites of immunoglobulin. There are two types of TCR, the most common being a heterodimer comprising an α -chain and a β -chain. The minority population of $\gamma\delta$ TCRs is less well characterized, but they appear to recognize antigen in a different way from $\alpha\beta$ TCR. A number of different molecules are associated with the two TCR polypeptide chains in order to

generate the TCR complex. This transmembrane signalling complex of molecules is collectively known as CD3 (detailed in Figure 19.4) and is linked to second messenger signalling molecules, whose expression varies between different T-cell subsets and at different stages of T-cell differentiation. CD4 or CD8 molecules are closely associated with the CD3 complex and determine the class of MHC molecule to which the TCR can bind.

Polymorphism of MHC molecules

There is extensive polymorphism of MHC class I and class II molecules (Figure 19.5). These were first recognized as targets for allograft rejection and the allelic forms of the MHC molecules differ in the fine structure of their MHC-binding grooves. This is reflected in differences in the range of peptides that different MHC alleles can present to T cells. Crossover during meiosis is relatively rare; consequently the alleles on each chro-

mosome 6 are usually inherited en bloc and are named the MHC haplotype of that chromosome. It follows that approximately one in four siblings share the same MHC haplotype on both chromosomes. For the purposes of stem cell transplantation, the patient and donor must usually be fully matched for HLA alleles and thus only 25% of siblings are appropriate for donation.

Figure 19.4 The $\alpha\beta$ T-cell receptor (TCR) complex. The $\alpha\beta$ TCR is composed of two polypeptide chains, each with a variable (open ovoid) and constant (closed ovoid) domain. Peptide plus MHC is recognized by the combined variable regions. The TCR is surrounded by the CD3 complex of transmembrane signalling molecules. This is composed of four types of polypeptide chain, γ , δ , ϵ and ζ , that are present as three pairs: ϵ with δ , ϵ with γ and a pair of ζ -chains or ζ plus η (a splice variant of ζ with a longer intracellular tail). Most monoclonal antibodies against CD3 are directed against antigenic determinants on CD3 ϵ . Most peripheral T cells express CD4 or CD8 with their TCR. In the thymus, the TCR is first expressed on thymocytes that express both CD4 and CD8, allowing the possibility for selection on the basis of either class II or class I-recognizing properties (see section on T-cell development).

Certain MHC alleles are associated with relative protection against specific infections. Conversely, some alleles, or combinations of alleles, are associated with a greater chance of developing autoimmunity. Many diseases, including diabetes mellitus, Graves disease and ankylosing spondylitis, are distinctly more common in individuals with a particular MHC allele or MHC haplotype. It seems logical that in evolution most alleles have been retained because they have certain advantages without too many disadvantages. The advantages of an allele might relate to a particular infection that is prevalent in one part of the world but almost unknown in another; for example, the HLA-B53 allele has a high prevalence in West Africa and is associated with relative protection from a potentially lethal form of malaria.

Generation of antigen-specific receptors on T and B lymphocytes

There are six pairs of genes that encode antigen-specific receptors: three for immunoglobulin (κ and λ light chains, and heavy chains) and three for TCRs (β , γ and a combined α and δ locus; see Table 19.1). These genes show marked similarities, indicating that the gene complexes evolved from a common precursor gene. The genetic organization of the variable-region genes and the way in which they are rearranged can generate a huge diversity of antigen recognition structures for subsequent display on the surface of mature B and T lymphocytes. For T cells, this is the only way in which diversity of V region structure is achieved. In B cells, there is an additional mechanism that increases the variable-region gene repertoire. This is called *somatic hypermutation*, which is activated during B-cell maturation in germinal centres and which introduces mutations into the rearranged immunoglobulin variable-region genes.

Both the immunoglobulin and TCR variable-region genes have to undergo a process of *gene rearrangement* from their germline configuration before they can encode an antigen recognition structure. As an example, the immunoglobulin heavy chain gene is located at 14q32.3 and the germline organization of the part of the gene that encodes for the variable region of IgH is shown at the top of Figure 19.6. The variable-region component of the immunoglobulin heavy chain gene is divided into three types of *gene segment*: V segments, D segments and J

Figure 19.5 MHC polymorphism. This is a simplified diagram of the main genes that encode MHC class I and MHC class II molecules and their exceptional polymorphism.

Table 19.1 The variable region genes of human T-cell and B-cell antigen receptors.

Gene complex	Chromosomal location	Gene segments	
		Type	Approximate number
Immunoglobulin heavy chain	14q32.3	V _H	51
		D _H	~27
		J _H	6
		C _H	10
Immunoglobulin κ light chain	2p12	V _κ	40
		J _κ	5
		C _κ	1
		V _λ	~29
Immunoglobulin λ light chain	22q11	J _λ	4

		V _α	~70
		J _α	61
TCR α-chain	14q11.2 (contains TCR δ locus)	C _α	1
		V _δ	~4
		D _δ	3
		J _δ	3
TCR δ-chain	14q11.2 (between Vα and Jα of TCR α)	C _δ	1
		V _β	52
		D _β	2
		J _β	13
TCR β-chain	7q32.5	C _β	2
		V _γ	12
		J _γ	5
		C _γ	2
TCR γ-chain	7p15		

C, constant regions; D, diversity segments; J, joining segments; V, variable segments.

Where the number of functional gene segments is uncertain, this is denoted by '~'. There are many non-functional gene segments (pseudogenes); these are disregarded in this table. Because TCR α and δ genes are encoded in the same gene complex on chromosome 14, successful rearrangement of the TCR α genes inevitably results in looping out of the δ genes so that α and δ genes cannot be coexpressed.

segments. A large number of individual V gene segments are encoded within the genome. The V gene segments are longer than J or D segments and encode much of the framework of the variable-region domain, together with the first and second hypervariable regions (known as the complementarity-determining regions, CDR1 and CDR2). The CDR1 and CDR2 regions encode two of the three parts of the variable region that determine the antigenic specificity of the heavy-chain V region.

There are fewer D and J gene segments. The third hypervariable region (CDR3) is encoded at the site of joining of one of the functional D segments with any one of the functional J segments and includes the downstream end of one of the V segments. Heavy-chain rearrangement involves two looping-out manoeuvres (Figure 19.6). In the first of these, one of the J segments becomes spliced to one of the D segments and the intervening sequences are deleted. Next, one of the two rearranged

D–J pairs becomes linked to one of the V segments and again the intervening sequences are deleted. The association of segments appears to occur at random and the theoretical number of different variable region genes that might be generated in this way is the product of the number of functional V, D and J segments, i.e. about 8262. In practice, D to J and V to D–J joining is not exact and additional random nucleotides may be added at the point where the gene segments join. This results in very much greater diversity, which is seen only in CDR3 and which includes both the D to J and V to D–J junctions.

The diversity of CDR1 and CDR2 is therefore much less than that of CDR3. Junctional diversity in CDR3 is sufficiently great to allow the conclusion that B cells with the same CDR3 sequence are almost certainly derived from the same clone and this fact is used widely to identify the origin and relationship of malignant B cells.

Figure 19.6 Immunoglobulin heavy-chain variable-region genes and their rearrangement. The germline structure of the variable-region gene complex is shown in the top line. The genes are present in this form in haemopoietic stem cells. The approximate number (n) of V_H , D_H and J_H segments are given in Table 19.1. The constant-region genes are downstream of the V-region genes. The first of these, μ , encodes the IgM heavy chain constant-region domain. This is followed in sequence by δ , $\gamma 3$, $\gamma 1$, a non-functional pseudo- ϵ gene, $\alpha 1$, $\gamma 2$, $\gamma 4$, ϵ and $\alpha 2$. The boxes represent exons and lines introns. During rearrangement, first one of the J segments becomes aligned with one of the D segments and the intervening sequences are deleted; DJ rearrangement is always attempted on both chromosomes 14. The aligned DJ pair on one chromosome 14 then becomes linked to one of the V segments on that chromosome, and again

intervening sequences are deleted. If this V to DJ rearrangement is able to encode a variable region, then there is no V to DJ rearrangement on the other chromosome; if it has been unsuccessful (e.g. the rearrangement is out of frame) the cell goes on to attempt to rearrange a V segment to the DJ on the other chromosome. The D to J and V to DJ alignment is made possible by the presence of recombinase signalling sequences that flank (i) the upstream end of each J segment and the downstream end of each D segment and (ii) the upstream end of each D segment and the downstream end of each V segment. Additional diversity at the junctions between the rearranged V, D and J segments results in part from imprecise splicing and partially through the insertion of additional non-encoded (N) basepairs at the D to J and V to DJ junctions through the action of terminal deoxynucleotidyltransferase.

B lymphopoiesis

B-cell production starts in the fetal liver at the end of the first trimester of pregnancy and normally ceases at this site later in pregnancy. Subsequently, B cells are also produced in the bone marrow and production in this tissue continues throughout life such that approximately 2% of adult marrow mononuclear cells are B-cell progenitors.

The events that occur as cells differentiate towards B cells are summarized in Figure 19.7. The associated phenotypic changes are set out in Table 19.2. The earliest signs associated with differentiation of haemopoietic cells towards the B lineage are the expression of CD19, CD24 and MHC class II molecules on the cell surface and CD22 inside the cell. These changes are followed by the expression of molecules such as the recombinase-activating genes *RAG1* and *RAG2*, which are involved in immunoglobulin gene rearrangement.

Almost always, heavy-chain gene rearrangement precedes light-chain gene arrangement. The first rearrangements to occur are in the joining of one of the J segments to one D segment, with the looping out of the intervening sequences (see previous section for details). The rearrangement or attempted rearrangement of D to J is completed on both chromosomes 14 before an attempt is made to rearrange the D–J to a V segment on one of the chromosomes. If this is successful, the rearranged V–D–J sequence will be transcribed together with the genes encoding the μ constant region. After translation of this transcript, the cell has cytoplasmic μ heavy chain and is known as a *pre-B cell*. During all the preceding stages of B lymphopoiesis, cells showing differentiation towards B cells are known as *pro-B cells*.

When intact μ heavy chain is expressed, an essential further step has to take place if the B cell is to proceed to light-chain rearrangement. The μ chain is expressed on the cell surface at low level with a 'surrogate' light chain that is composed of two

Figure 19.7 Outline of the main stages of B lymphopoiesis. The central process in B-cell formation is the rearrangement of immunoglobulin variable-region genes. For rearrangement of V-region genes to occur in either T or B cells, the recombinase-activating genes *RAG1* and *RAG2* have to be expressed. Absence of these genes totally blocks further differentiation towards B or

T cells. After a successful heavy-chain VDJ has been made, a B cell must express the heavy chain with the surrogate light chain composed of V_{preB} and $\lambda 5$ if further differentiation is to occur. Cells that fail to make either a productive heavy- or light-chain rearrangement destroy themselves by apoptosis.

Table 19.2 Phenotypic changes during B-cell lymphopoiesis.

	Surface CD34	Cytoplasmic CD22 with surface CD19 and CD24	Nuclear TdT	Surface CD10	Surface CD20	Cytoplasmic μ	Surface IgM
Pro-B cell	+	+	+	-	-	-	-
Early pre-B cell	+	+	+	+	-	-	-
Late pre-B cell	-	+	-	+	+	+	-
Virgin B cell	-	+	-	-	+	+	+

TdT, terminal deoxynucleotidyltransferase.

peptides, V_{preB} and $\lambda 5$. If this surface expression does occur, the pre-B cell receives a signal for further differentiation to proceed, exits cell cycle and starts light-chain gene rearrangement. On the other hand, if the first attempt to rearrange V to D–J is not successful and no $\mu V_{preB}\text{--}\lambda 5$ complex is expressed at the surface, an attempt is made to rearrange a V segment to D–J on the other chromosome 14. If this also fails and the cell is still unable to express $\mu V_{preB}\text{--}\lambda 5$ at its surface, it will die by apoptosis. When the second heavy-chain rearrangement is successful, the cell proceeds, as above, towards light-chain gene rearrangement. The first expression of IgM on a B-cell surface marks the transition from pre-B cell to a newly produced virgin B cell.

Extensive analysis of variable-region genes in pre-B cells of mice has failed to identify cells with two functional VDJ rearrangements. One functional VDJ rearrangement can only be

seen with a non-functional VDJ rearrangement or a D–J rearrangement. This *allelic exclusion* of antigen receptor genes means that only one functional antigen-binding protein is expressed on the surface of the cell.

The enzyme terminal deoxynucleotidyltransferase (TdT) is expressed during variable-region gene rearrangement and introduces non-encoded (N) sequences at the junctions of V to D–J and D to J. The enzyme is expressed both in pro-B cells in the marrow and in cortical thymocytes during TCR gene rearrangement. The expression of TdT is much greater in the bone marrow than in the fetal liver and, as a result, junctional diversity is less marked in the first B cells that are produced. These are mainly B1 cells, which are described later. The enzyme TdT is not expressed in late pre-B cells at the time of light-chain gene rearrangement and N sequences are not a feature of light chain

V–J junctions. Normally, B cells will express only light chains encoded by one of their four light-chain gene complexes, i.e. they express either a κ -chain or a λ -chain. The ratio of κ -expressing B cells to λ -expressing B cells is closely regulated and in humans is close to 60:40. Major deviation from this ratio has been observed only in B-cell neoplasia, when there is massive expansion of a neoplastic clone of B cells. Disturbance of the κ/λ B-cell ratio to more than 10:1 or less than 0.1:1 can therefore be taken as a reliable indicator of the presence of a neoplastic clone.

Intact heavy chains can be exported to the surface of a B cell only if they are complexed with light chain or surrogate light chain. This does not apply to free light chains, which are able to pass out of B cells and plasma cells. Physiological light chain production is always greater than that required to complex all the available heavy chain, and measurement of serum free light chain is now a useful tool in the management of paraproteinemia. The heavy chains that are secreted in heavy chain disease are able to leave the cell only because they are truncated heavy chains.

T-cell production and selection in the thymus

Although the earliest progenitors of T cells are produced in the bone marrow, the development and selection of most mature immunologically competent T cells occurs in the thymus. The thymus is an encapsulated gland that is organized into lobules by capsular septa. Within each lobule, there is a complex meshwork of epithelial and other cells that are responsible for regulating the development of prothymocytes into mature T cells. The subcapsular region of the thymus is divided into the more peripheral cortex and the deeper medulla.

CD8 and CD4 thymocytes are selected on the basis of their potential to recognize peptides held in association with either MHC class I or MHC class II molecules respectively. Immature $\alpha\beta$ TCR thymocytes are subject to two selection processes: *positive selection*, which allows cells that have the potential to recognize foreign peptide in association with self MHC to mature into functional T cells, and *negative selection*, which removes T cells that recognize self peptides in association with a self MHC molecule. During the development from prothymocytes to mature lymphocytes, T cells pass from the outer cortex, through the inner cortex and on through the medulla before emerging as immunocompetent T cells in the peripheral circulation. T cells whose TCR molecules fail to engage with MHC–peptide complexes within the thymus die by neglect, whereas those whose TCR can interact with these complexes are subject to positive and negative selection (see below). It has been estimated that 95% of all thymocytes die within the thymus either as a result of failure to rearrange their TCR genes in an express-

ible form or as a consequence of elimination during the T-cell selection process.

Thymic epithelial cells in the cortex are critical in the positive selection of thymocytes that have moderate affinity for MHC–peptide complexes. The boundary of the cortex and medulla is populated by macrophages (often called sentinel macrophages) that phagocytose cells undergoing apoptosis. The medulla contains bone marrow-derived dendritic cells that express MHC class I and II antigens. It is here that the process of negative selection is mediated, in which T cells with high affinity for self MHC–peptide complexes are deleted. Structures known as Hassall corpuscles, which are whorled aggregates of epithelial cells, can also be seen in the medulla though their function is uncertain.

TCR gene rearrangements and phenotypic changes

Bone marrow-derived T-cell progenitors (prothymocytes) seed the subcapsular region of the thymic lobule (Figure 19.8). At this stage of ontogeny the cells have not started to rearrange their TCR genes, do not express the mature T-cell markers CD3, CD4 or CD8, and may not be irreversibly committed to the T-cell lineage. They may be identified by expression of CD7 and CD34. Interaction with the thymic stroma is accompanied by proliferation and expression of CD2, soon followed by cytoplasmic expression of CD3 genes. By this stage, the cell is committed to the T-cell lineage and TCR gene rearrangement is underway.

The configuration of the TCR and its genes is discussed in the section on antigen-specific receptors on T and B cells and is summarized in Figure 19.4 and Table 19.1. During early fetal development, the first cells to leave the thymus as mature T cells have successfully rearranged their γ and δ genes and express the $\gamma\delta$ form of the TCR. Many $\gamma\delta$ T cells do not express CD8 or CD4, suggesting they may not be interacting with antigen in association with MHC class I or class II molecules. During later stages of human fetal development and throughout the rest of life, 85–98% of T cells that leave the thymus have undergone successful α and β gene rearrangement and express the $\alpha\beta$ TCR.

Rearrangement of the gene encoding the TCR β -chain occurs first with D to J rearrangements followed by V to D–J rearrangements. Successful rearrangement leads to low-level expression of the β -chain at the cell surface in a complex with CD3 and a surrogate α -chain analogous to V_{preB} – $\lambda 5$ in B-cell development. It is at this stage that the cell starts to express low levels of both CD4 and CD8; further β -chain gene rearrangement is halted and α -chain gene rearrangement starts (Figure 19.8). TCR α -chain gene rearrangement may involve sequential rearrangements of V–J pairs, which enables the cell to express different TCR α -chains until a successful TCR $\alpha\beta$ heterodimer is generated.

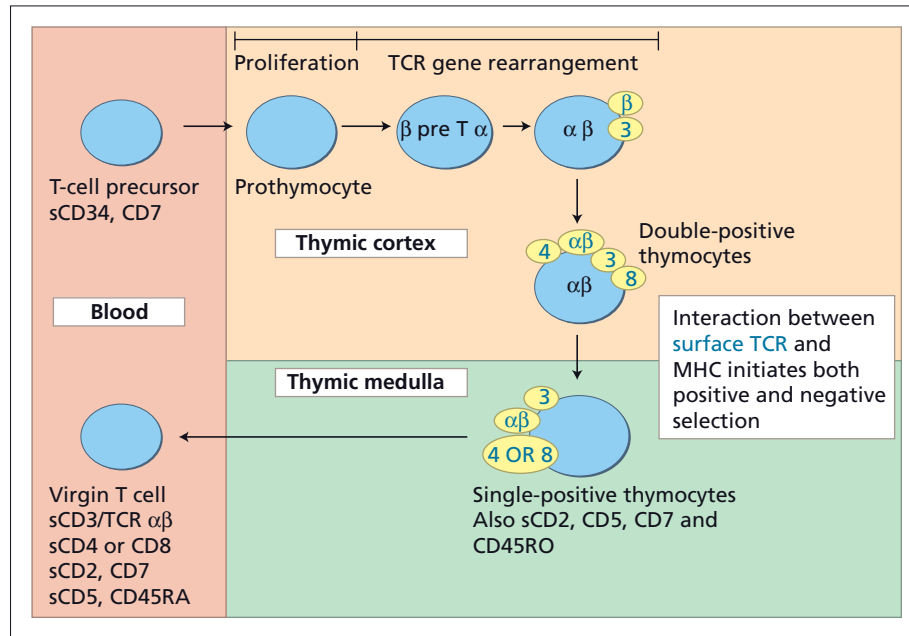

Figure 19.8 T-cell maturation in the thymus. Molecules within cells (red) or on a cell’s surface (blue) are depicted without the prefix CD. T-cell progenitors enter the thymus from the marrow or other primary lymphoid site to become a prothymocyte. At this stage their T-cell receptor (TCR) genes are in germline configuration. The proliferative potential and lack of commitment of prothymocytes is reflected in the ability of a single prothymocyte to populate an entire thymic lobe and generate a full T-cell repertoire. Prothymocytes proliferate in the outer cortex. Towards the end of the proliferative phase, TCR rearrangement starts: first, β -chain genes are rearranged, then these are expressed with a surrogate α -chain (pre-T α -); after this, α -chain genes rearrange. As with B cells, these

rearrangements require *RAG1* and *RAG2* genes to be expressed, and junctional diversity is increased by the addition of N sequences using terminal deoxynucleotidyltransferase. Selection occurs at the double-positive stage when the full TCR complex is expressed with CD3 and both CD4 and CD8. These cells are selected on their ability to recognize self peptide presented by a self MHC molecule at low avidity. Those cells recognizing peptide with class I go on to become single-positive CD8 expressors; those recognizing peptide with class II continue to express CD4 without CD8. Cells recognizing self peptide at high avidity and cells failing to recognize a self MHC molecule are deleted.

The B-cell repertoire

B cells constitute around 10–20% of the peripheral lymphoid pool and two broad lineages have been recognized, *B1 cells* and *conventional (or B2) cells*. B1 cells are the predominant B-cell subtype in fetal life and during the first year after birth, and are capable of antigen-independent self-renewal in the periphery. The antigen-binding specificity of the antibodies produced by these cells tends to have broad reactivity including autoreactivity. The function of B1 cells and the background IgM antibody they produce is still far from clear. It has been suggested that they may play a regulatory role in selection of the B-cell repertoire and they are highly conserved during evolution. B1 B cells often express CD5 and share many features in common with the malignant cells of B-cell chronic lymphocytic leukaemia.

The majority of B cells are conventional (B2) B cells and are produced in the marrow after the first year of life. Three stages of conventional B-cell differentiation can be identified: newly produced virgin B cells, recirculating B cells and marginal zone B cells (Table 19.3). Most recirculating B cells are virgin cells, whereas the B cells of the marginal zones do not recirculate and are a mixture of virgin and memory cells.

Naive B cells are small non-dividing virgin B lymphocytes that classically are positive for surface IgM and IgD. They are in a constant state of migration between the follicles of secondary lymphoid organs. On their way to the follicles, they migrate through the T cell-rich zones that contain antigen-presenting cells and have an average lifespan of 4 weeks or more.

Marginal zone cells, like recirculating B cells, respond to T cell-dependent antigens and to bacterial cell wall lipopolysaccharides (thymus-independent type 1, or TI-1, antigens).

Table 19.3 Differences between the three main types of human B cell found in adults.

	<i>Marrow IgM⁺, IgD⁻</i>	<i>Recirculating</i>	<i>Marginal zone</i>
Diameter		~ 8 μm	~ 10 μm
Chromatin	Condensed	Condensed	Open
Cytoplasm volume/basophilia	Scanty/little	Scanty/little	Moderate/moderate
Proliferating	No	No	No
Lifespan	About 3 days	4 weeks or more	3 weeks or more
Antigen-independent movement	Migrate from marrow to secondary lymphoid tissue	Migrate between the secondary lymphoid tissues	Remain in the marginal zones
Surface immunoglobulin	IgM	IgM and IgD	IgM or IgG or IgA
Memory or virgin	All virgin	Almost all virgin	Variable mixture of virgin and memory
Immunoglobulin V-region mutations	None	Not present	Present in memory cells
<i>Molecules expressed on the cell surface</i>			
CD19, CD20, CD37, CD40 and class II MHC	Positive	Positive	Positive
CD21, CD39	Negative	Positive	Positive
CD5	Negative	Some positive	Negative
CD23	Negative	Positive	Negative
CD25	Negative	Negative	Positive
CD38	Negative	Negative	Negative
<i>Capacity to respond to different classes of antigen</i>			
Bacterial cell wall lipopolysaccharide	+	+	+
Bacterial capsular polysaccharide	-	-	+
Protein-based antigens	+	+	+

IgM⁺, IgD⁻ cells of the marrow are representative of newly produced virgin B cells.

Unlike recirculating B cells, they will also respond to bacterial capsular polysaccharides. Capsular polysaccharides are thymus-independent type 2 (TI-2) antigens. These antigens do not evoke antibody responses until several months after birth, and levels of antibody produced in response to these antigens do not reach adult levels until 5 years of age.

The T-cell repertoire

The majority (around 95%) of peripheral T cells express αβ TCR. When these αβ T cells leave the thymus, most express either CD4 or CD8 on their surface and are restricted to the recognition of peptides in the context of MHC class II or class I molecules respectively. A minority of T cells express a γδ TCR and exhibit antigenic specificity for non-peptide molecules.

CD4⁺ and CD8⁺ T cells and their functions

CD4⁺ T cells can have one or more of a variety of functions. Their major role is in the provision of signals that induce proliferation or differentiation of T or B cells, generally known as *T-cell help*. They can also activate macrophages and may mediate HLA class II-restricted cytotoxic activity. Increasing attention is being given to their regulatory role in T-cell immune responses and this is mediated through a FoxP3-positive subset.

CD8⁺ T cells have a predominant role in the recognition of virally infected cells and recognize antigen in association with HLA class I. Antigen recognition is followed by lysis of the target cell or secretion of cytokines or interferon (IFN)-γ. There are two main killing mechanisms which both induce apoptosis in the target cell. Firstly, enzymes known as *granzymes* and pore-forming molecules termed *perforins* are transferred from the T cell to the target cell. Granzymes and perforins are present in

granules that stain crimson and are easily seen against the featureless pale cytoplasm of cytotoxic T cells and NK cells in Jenner–Giemsa preparations. These features have given rise to the term ‘large granular lymphocyte’. The second cytotoxic mechanism involves the expression of the Fas ligand (FasL) by the effector cell. The resulting engagement of Fas on the target cell induces the target to undergo apoptosis. Fas is a member of the TNF receptor family and FasL is an analogue of TNF- α and TNF- β .

Once the peripheral T-cell pool is established, it can maintain itself without further input from the thymus. Even neonatal thymectomy in humans during cardiac surgery does not cause clinically noticeable immunodeficiency. This indicates that T-cell clones can be very long-lived and this certainly applies to CD45RA^{high} virgin T cells. Unlike the peripheral pool of recirculating B cells, which cannot replenish itself when depleted, small numbers of transferred recirculating T cells will proliferate to fill a depleted peripheral T-cell pool in a process known as *homeostatic proliferation*. Some experiments suggest that memory T-cell clones persist only if there is periodic restimulation by antigen, but other experiments indicate that in some instances this is not required.

Natural killer cells

NK cells are cytotoxic lymphocytes that lack expression of a TCR and have a range of functional activities in the immune system. They express a range of inhibitory and activating receptors and it is the balance of signals received through these molecules that determines whether the target cell will be recognized. Inhibitory signals include (i) killer inhibitory receptors (KIRs) that bind to HLA-C or HLA-B alleles on the surface of the target cell and (ii) CD94–NKG2 heterodimers that bind to HLA-E. Activating receptors include (i) activating forms of KIR molecules, whose ligands are uncertain at present; (ii) NKG2D, which binds to proteins such as MICA and ULBP expressed on cells under physiological stress; and (iii) the immunoglobulin receptor (FcR) CD16.

HLA class I expression is often downregulated on the surface of cells following viral infection and is also a common feature of malignant cells. This provides some protection from recognition by CD8⁺ T cells but renders the cell susceptible to lysis by NK cells (Figure 19.9). Thus, CD8⁺ T cells and NK cells can be viewed as having complementary recognition systems based on the level of HLA class I on the target cell. The ability of NK cells to recognize ligands such as MIC-A, which are expressed on the surface of damaged or stressed cells, demonstrates that NK cells may also have the ability to target cells at the site of inflammation, irrespective of HLA class I expression level.

The lytic mechanisms of NK cells seem to be the same as those used by cytotoxic T cells. NK cells proliferate in the presence of IL-2 and their activity can be augmented by exposure

Figure 19.9 Mechanism by which NK cells kill target cells that fail to express HLA class I. NK cells express two classes of receptors which either activate (b) or inhibit (a) NK cell killing. Activating receptors can bind to a range of ligands on the target cell whose expression is often constitutive. In contrast, the major forms of inhibitory receptor bind to HLA class I molecules. If HLA class I expression is downregulated on the target cell, no inhibitory signal is delivered to the NK cells and the target cell is killed.

to IFN- γ . They characteristically express a range of receptors such as CD56 (NCAM) and CD57 but these are also expressed on a subset of T cells.

Natural killer T cells

Natural killer T (NKT) cells represent a small (< 1%) population of peripheral blood T cells and appear to be positioned somewhere between conventional T cells and NK cells in that they express a TCR but also a range of receptors typically associ-

ated with NK cells. Moreover, the TCR is invariant, with the same V β 11V α 24 heterodimer being expressed on all cells. NKT cells recognize lipid antigens presented on the surface of CD1d molecules, CD1d being a protein with homology to MHC class I. It appears that NKT cells are activated very early in an immune response, although their functional significance is uncertain.

The immune response

In this section we consider how an immune response is developed within the secondary lymphoid tissue. The general structure of a lymph node is shown in Figure 19.10 to provide an anatomical context for immune physiology.

Lymph nodes have an afferent lymphatic supply that is fed by lymph draining the extravascular tissue spaces and this provides the main source of antigen for the node. Dendritic cells activated by local disturbance take up and process antigen, and then pass through afferent lymph into lymph nodes (Figure 19.11). The afferent lymph passes into the subcapsular sinus, which forms a lake of lymph that covers the cortical surface of the node. From the subcapsular sinus, lymph passes through intranodal lymph sinuses that surround and separate the cone-like segments that make up the solid tissue of the node. The intranodal lymphatics, as they pass the follicles and T zone, are difficult to see as they are crossed by fibrous cords. Attached to these and the walls of the tissue cones are macrophages and other poorly defined cells. Increased numbers of these cells in the intranodal lymph sinuses and similar cells in the subcapsular sinus are described by histopathologists as *sinus histiocytosis*. The intranodal lymph sinuses passing the medullary cords

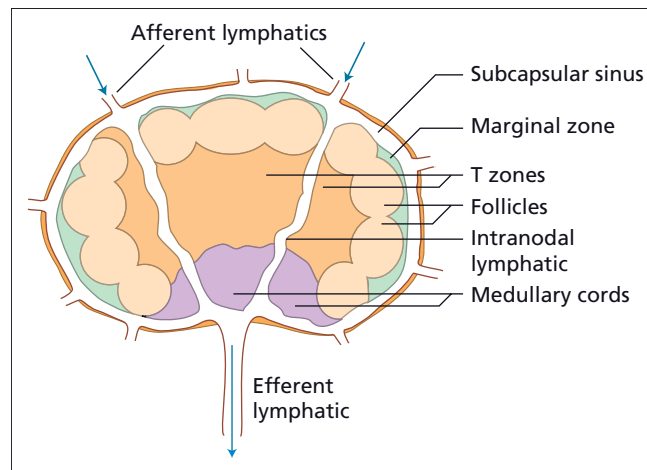

Figure 19.10 The main compartments of a lymph node. Note that the size of the marginal zone is variable; although it is often obvious in mesenteric lymph nodes, it may not be obvious in small nodes such as the popliteal nodes, particularly if these have not been sites of recent immune responses.

contain fewer fixed cells and are easier to identify. In the medulla, the intranodal lymph sinuses feed into the efferent lymphatic vessel that returns the lymph to the venous blood supply; in the case of the gut and lower half of the body, via the thoracic duct to the left subclavian vein.

The solid tissue of the node is composed of variable numbers of roughly cone-like segments (Figure 19.10). The base of each cone abuts onto the subcapsular lymph sinus in the cortex of the node and the apex is in the medulla. These cones fit together, but are separated by the intranodal lymphatic sinuses, to form the roughly kidney-shaped structure of lymph nodes. The cones have three main zones: the follicles in the cortex, the T zones and the medullary cords. The medullary cords form a convoluted apex to the cone. The contents and functions of each of these zones are described in detail in subsequent sections. The blood supply to the node enters and leaves the node through the medulla, and the specialized small blood vessels termed *high endothelial venules* through which recirculating B and T cells and newly produced virgin B cells enter the node are located in the T zones. Virgin B and T cells, and some memory cells, enter the T zone by passing across the high endothelial venules. Here they encounter IDCs (Figure 19.11), which present peptides on MHC molecules and initiate immune responses. The series of stages leading to T cell-dependent B-cell activation in the T zones is shown in Figure 19.11. If a T cell is able to recognize a peptide–MHC complex, it is activated through TCR signalling. Costimulation is provided by interaction between molecules such as CD80 and CD86 expressed on IDCs and CD28, which is constitutively expressed by T cells. The effect of this interaction is to bring about changes in the T cell that are collectively called *T-cell priming* (Figure 19.12).

Cytokines are produced by the T cell following this interaction and the nature of the cytokines produced in different situations is considered later. Short-term proliferation of the T and B cells is also induced, and most B cells migrate to local sites of antibody production. In the spleen this is the red pulp, and in lymph nodes the medullary cords. The lifespan of most of these plasma cells is 3 days. The extent of immunoglobulin class switching will depend on the conditions of dendritic cell activation and T-cell priming. In primary antibody responses, the plasma cells generated by B-cell activation in T zones do not have somatic mutations in their immunoglobulin V-region genes. On the other hand, in secondary responses, marginal-zone memory B cells that have somatic mutations in their V-region genes can be induced to migrate to T zones on contact with antigen and give rise to short-lived plasma cells.

The other pathway of migration of T and B cells activated in T zones is to the follicles. Both antigen-specific B blasts and T blasts migrate to the follicles at an early stage in T-zone responses and give rise to *germinal centres*. Germinal centres are present in the first 3 weeks following an immune response and build around B blasts that migrate to follicles and undergo massive clonal expansion such that the spaces in the follicular dendritic

Figure 19.11 T-cell priming and T-cell-dependent B-cell activation in a lymph node. Local disturbance induces dendritic cells in the tissues to take up material from their surroundings. Ingested proteins are processed to peptides inside the cell (see Figure 19.3). Dendritic cells that have taken up antigen migrate through afferent lymphatics to draining lymph nodes or through the blood to the spleen. By the time they reach a T zone, they have differentiated into interdigitating cells (IDCs), which are specialized at presenting antigenic peptides, held in MHC molecules, to recirculating T cells. Virgin T cells migrating through the T zones move over the surface of the interdigitating cells and are activated if they meet antigen they recognize. As the result of this priming process, they move to the outer T zone and become targets for B cells that have taken up and processed

antigen. The primed as opposed to virgin T cells are able to deliver costimulatory signals via CD40 and B7.1 and B7.2 to B cells that specifically engage their TCR. B cells activated in this way migrate to extrafollicular foci of B-cell proliferation – the medullary cords in lymph nodes – where they generate short-lived plasma cells. Other B cells migrate to follicles where they may form germinal centres. T cells, after a brief period of proliferation in the T zone, either leave the node as effector cells/recirculating memory T cells or migrate to follicles, where they proliferate further and participate in the selection of B cells that have mutated the immunoglobulin variable-region genes in germinal centres (see Figure 19.14). The consequences of this cognate T cell–B cell interaction are described in more detail in the text.

cell (FDC) network become filled with blasts. At this stage, changes occur whereby the classical germinal centre structures of dark and light zones develop. The dark zone is formed by the blasts moving to the edge of the FDC network next to the T

zone. These blasts, now termed *centroblasts*, activate the somatic hypermutation mechanism that acts on their rearranged immunoglobulin V-region genes. Centroblasts continually give rise to *centrocytes*, non-dividing cells that migrate into the FDC

Figure 19.12 Surface molecules involved in T-dependent B-cell activation in T zones. B cells take up antigen that they bind specifically through their surface immunoglobulin. This is internalized, broken down to peptides and the peptides are presented on the B-cell surface, held in the peptide-binding grooves of MHC class II molecules (see Figure 19.3). Cross-linking of surface immunoglobulin by antigen induces the endocytosis of the antigen–antibody complex and signals upregulation of CD40 expression and *de novo* B7.1 and B7.2 expression. If this B cell interacts with a primed T cell that recognizes the peptide complex with class II MHC molecules, there will be costimulation through the molecule CD28, which is constitutively expressed by CD4 T cells, and this can result in further signalling through costimulatory molecules that are transiently expressed on the T-cell surface; CD40 ligand exemplifies these transiently expressed signalling molecules. These interactions can lead to B- and T-cell proliferation and differentiation and may also induce cytokine secretion by the cells. Cytokine receptor expression by the B cell and the T cell is initiated or upregulated. The arrows indicate that TCR engagement induces CD40 ligand expression and that engagement of these molecules by their counterstructures on the B cell delivers further signals to the T cell. CD40 ligation induces immunoglobulin class switching in the B cell and migration as indicated in Figure 19.11.

Figure 19.13 Selection of cells that have undergone immunoglobulin V-region gene hypermutation in germinal centres. The hypermutation mechanism is active in centroblasts, which are the rapidly dividing cells of the dark zone that give rise to centrocytes. Centrocytes die by apoptosis unless they (i) pick up and process antigen held on follicular dendritic cells (FDCs) and (ii) find a T cell in the germinal centre that recognizes the peptides from this antigen presented on centrocytes in association with self class II. The T cell-dependent selection mechanism makes it unlikely that centrocytes with mutated immunoglobulin V-region genes that encode self-reactive antibody will be selected. Most B cells that are selected leave the germinal centre to (i) migrate to distant sites of antibody production, the gut or bone marrow, where they differentiate to become plasma cells and (ii) differentiate into memory B cells. Some selected cells remain within the germinal centre and return to the dark zone as centroblasts.

network that forms the light zone of the germinal centre. Centrocytes either leave the light zone within 12 hours or die *in situ*. They can leave the light zone only if they receive antigen-specific selection signals (Figure 19.13).

Centrocytes pick up antigen from FDCs in order to process peptides for T-cell recognition. This requirement for the B cells to receive T-cell help in the germinal centre protects against potential autoimmune responses as those B cells that have developed reactivity against autoantigens are unlikely to receive selection signals from germinal centre T cells. Centrocytes that survive selection within germinal centres leave the light zone as

either plasmablasts or memory B cells. The plasmablasts migrate to bone marrow or the lamina propria of the gut and differentiate into plasma cells.

Immunoglobulin class switching

Most plasma cells and memory B cells undergo *switch recombination* in which rearranged V-region genes become linked to heavy chain constant region genes downstream from IgD. This process is similar to immunoglobulin variable gene rearrangement, with the DNA forming loops between complementary switch region genes that lie upstream of each set of heavy chain gene exons. The order of the heavy chain constant-region genes that encode the different heavy chain isotypes is located downstream from the variable-region genes: μ , δ , $\gamma 3$, $\gamma 1$, a non-functional pseudo- ϵ gene, $\alpha 1$, $\gamma 2$, $\gamma 4$, ϵ and $\alpha 2$. Thus, switching to $\gamma 2$ involves looping out μ , δ , $\gamma 3$, $\gamma 1$, pseudo- ϵ and $\alpha 1$. Switch recombination within B cells is driven by cytokines produced following recognition by antigen-specific T cells, and variation in the distribution of immunoglobulin isotypes underlies disorders such as allergy in which there is excess IgE production.

Differentiation of primed T cells into effector cells

Following recognition of antigen, most CD8⁺ T cells differentiate into cytotoxic effector cells. Differentiation of primed CD4⁺ cells is directed into one of four major pathways (Figure 19.14) and it appears that factors such as the nature of the antigen, associated inflammatory stimuli and the affinity of T-cell engagement can influence the subtype of CD4 T cell that is produced. CD4⁺ T cells stimulated in the presence of IL-12, which is produced by macrophages, and dendritic cells are more likely to differentiate into Th1 cells. IFN- γ secreted by NK cells or Th1 cells themselves has a similar effect, which is partly attributable to inhibition of differentiation towards Th2 cells. In contrast, IL-4 produced by either NKT cells or Th2 cells promotes production of Th2 cells and inhibits Th1 cell formation.

Th1 cells produce cytokines that are associated with macrophage activation, granuloma formation and delayed hypersensitivity. These cytokines are principally IL-2, IFN- γ and TNF- β . Macrophages work in concert with Th1 cells to provide a major mechanism by which mycobacteria and other pathogens are destroyed. Inflammatory CD4⁺ T cells enhance this activity through the action of cytokines following recognition of peptides presented by MHC class II molecules on macrophages. Some Th1 cells have cytolytic potential and can kill infected macrophages through granzyme/perforin or Fas ligand.

Th2 cells produce cytokines associated with antibody production, particularly IL-4, IL-10 and, in some instances, IL-6,

Figure 19.14 Maturation pathways of CD4⁺ T helper cells. CD4⁺ T cells that have been activated by antigen acquire the capacity to produce cytokines. The cytokines that they produce depends on the environment in which they are activated. Two major subsets of effector Th cell are recognized, Th1 and Th2 cells. The cytokines produced by Th1 cells tend to promote further Th1 cell formation and inhibit Th2 cell formation, and IL-4 produced by Th2 cells promotes further differentiation towards Th2 cells. Th1-promoting cytokines are also produced by activated macrophages, dendritic cells and NK cells, whereas mast cells produce IL-4. Th17 cells are an additional effector subset that is induced through the activity of IL-23 and produce large amounts of IL-17 and IL-22. T regulatory cells can be induced through the activity of transforming growth factor (TGF)- β and play an important role in the control of autoimmune responses. IDC, interdigitating dendritic cell.

although the last of these is mainly produced by macrophages and osteoclasts.

Th17 cells produce large amounts of the cytokine IL-17 and are associated with inflammatory disorders. They may play an important role in the control of fungal disease and could represent an important target for future immunotherapeutic interventions.

The balance between Th1 and Th2 cells can be an important determinant of immunopathology. Tuberculoid leprosy exemplifies apparent dominance of a Th1 response, while atopic disease seems to reflect an imbalance towards Th2. Nevertheless, manipulation of these cytokine networks provides a potential means of modifying established immune responses to avoid the complications associated with overactivity of either Th1 or Th2 cells.

Regulatory CD4⁺ T cells

Immunological tolerance is mediated by a number of mechanisms, including deletion of self-reactive B and T cells in the bone marrow and thymus respectively. In addition, it is now clear that a specialized population of T lymphocytes can actively suppress immune responses. These cells have been termed regulatory T (Treg) cells and their dominant phenotype is that of expression of the transcription factor FoxP3 in association with CD4. In addition, these cells usually express high levels of CD25, the IL-2 receptor α -chain, as well as low levels of CD127, a component of the IL-7 receptor. Treg cells are involved in maintenance of peripheral T-cell tolerance to self antigens and protection against autoimmunity. They constitute approximately 1–5% of peripheral blood CD4 lymphocytes and may be derived either from a discrete thymic lineage (natural Treg cells) or following the differentiation of CD4⁺CD25⁻ T cells in the presence of cytokines such as transforming growth factor (TGF)- β (induced Treg cells). The role of Treg cells in a range of human diseases is being explored at present and typically they are deficient, in either number or function, in autoimmune disorders while relative overactivity may be apparent in malignant disease. Immunotherapeutic strategies that involve cellular therapy with Treg cells, or which utilize reagents such as anti-CTLA-4 antibody to suppress their function, are now in clinical trial.

Cytokines and their classification

Cytokines are soluble proteins produced by leucocytes and other cells that influence the behaviour of cells that carry cytokine receptors. Many are secreted, but others, such as TNF- α , are cell membrane proteins that are active when bound to the cell that produced them but which also have activity as a soluble protein. The potency of cytokines *in vivo* has been exemplified clearly by the dramatic effects of recombinant granulocyte colony-stimulating factor (G-CSF) in inducing accelerated recovery of neutrophil counts after the administration of myelotoxic therapy and the effect of interferon alfa in the management of haematological malignancies. It seems likely that many cytokines act only at very short range and some appear to be more potent as membrane-bound forms than as released proteins. The families of cytokines are summarized in Table 19.4 and a fuller description of the known cytokines that act on cells of the immune system is given in Table 19.5.

Chemokines and their classification

Chemokines are a class of cytokines with chemoattractant properties and are all related in sequence. There are two groups, the CC chemokines, which have two adjacent cysteine residues in

Table 19.4 The cytokine and cytokine receptor families.

Cytokine family	Members of family	Type of receptor
β -Trefoil	IL-1 α , IL-1 β	Immunoglobulin family
Haematopoietins	IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-13, IL-15, GM-CSF	Class I cytokine receptor
	IL-10, interferons	Class II cytokine receptor
Tumour necrosis factor	TNF- α , TNF- β	Nerve growth factor receptor family
Cysteine knot	NGF	Nerve growth factor receptor family
	TGF- β	Serine threonine kinase
Chemokines	IL-8, MIP-1 α , MIP-1 β , I-309, MCP-1, MCP-2, MCP-3, γ IP-10	Rhodopsin family

their sequence, and the CXC chemokines, in which these two cysteine residues are separated by another amino acid. Chemokine receptors are integral membrane proteins linked to G-proteins and have seven membrane-spanning domains. They are classified according to the type of chemokine that they bind, i.e. CCR1–9 and CXCR1–5. Cells that express chemokine receptors are attracted towards an increasing concentration of chemokine molecules, and these interactions are critical to many functions of the innate and adaptive immune response (Table 19.6). Some chemokines are expressed in a constitutive fashion, whereas others are released in response to inflammation.

Interpretation of blood lymphocyte counts

Blood provides the most accessible view of the lymphoid system but it must be remembered that peripheral blood contains only around 2% of total body lymphocytes. The cells present in the blood are in transit and many are recirculating T and B lymphocytes that will pass rapidly into secondary lymphoid organs in less than 30 min.

The numbers of different lymphocyte subsets normally found in the blood in different age groups is given in Table 19.7. These numbers are derived from studies in which whole blood was labelled by fluorescent dye/monoclonal antibody conjugates, followed by red cell lysis and flow cytometry. When this method is used to measure the proportion of lymphocytes that belong to different subsets, much of the interlaboratory variation that

Table 19.5 The main cytokines that have been described as having activity on cells of the immune system.

<i>Cytokine</i>	<i>Molecular family (molecular mass)</i>	<i>Cytokine produced by</i>	<i>Family and size of receptors</i>	<i>Receptors expressed by</i>	<i>Immunological actions</i>
IL-1 α	β -Trefoil (17.5 kDa)	Macrophage, epithelia	Immunoglobulin superfamily: type I (CD121a, 80 kDa), type I (CD121b, 60–68 kDa)	Very broad, including T, B and NK cells	Activates T, macrophage, is pyrogenic
IL-1 β	β -Trefoil (17.3 kDa)	Macrophage, epithelia	As IL-1 α	As IL-1 α	Activates T, macrophage, is pyrogenic
IL-2 (TCGF)	Haematopoietin (15–20 kDa)	Th0 and Th1	CKR class I: α (CD25, 55 kDa) + β (CD122, 70–75 kDa) + γ_c (64 kDa)	Activated T, some B, NK, macrophage	Induces T growth and differentiation; also induces growth and differentiation of some B
IL-3 (multi-CSF)	Haematopoietin (14–30 kDa)	T, thymic epithelium	CKR class I: α (CD123, 70 kDa) + β_c (KH97, 120 kDa)	Haemopoietic, B, macrophage	Apart from effect on haemopoiesis, induces growth and differentiation of some B
IL-4	Haematopoietin (15–19 kDa)	Th2, mast, marrow stroma	CKR class I: α (CD124, 140 kDa) + γ_c	Activated B and some T, others	B growth, switch to IgG4 and IgE
IL-5	Haematopoietin (45 kDa)	T, mast, eosinophil	CKR class I: α (CD125, 60 kDa) + β_c	Eosinophil and basophil	Eosinophil growth and differentiation; growth and differentiation of mouse but not human B
IL-6	Haematopoietin (26 kDa)	T, macrophage, some B, osteoclast, others	CKR class I: CD126 (gp80) + CD130 (gp130)	Activated B, plasma, T, macrophage, others	Inflammatory, cytokine induces acute-phase reaction, plasmacytoma growth factor, influences T and B activity
IL-7	Haematopoietin (20–25 kDa)	Bone marrow and thymic stroma	CKR class I: CD127 (68 kDa) + γ_c	T and B progenitors, mature T	Pre-B and thymocyte growth, some action on mature T

IL-8	Chemokine (7 kDa)	Lymphocyte, macrophage, granulocyte, endothelia, others	Rhodopsin family: CDw128 (40 kDa)	Neutrophil, basophil, some lymphocyte	Chemoattractant neutrophil and basophil, inflammatory and angiogenic
IL-9	Haematopoietin (35 kDa)	Th2	CKR class I: IL-9R (64 kDa), may associate with γ_c	Th, macrophage	Growth T, erythroblast, mast and megakaryoblastic leukaemia lines
IL-10	Haematopoietin (35–40 kDa)	Th0, Th2, m ϕ	CKR class II (90–110 kDa)	B, T	Suppresses macrophage activation by Th1 and NK, with TGF- β induces B switch to IgA
IL-11	Haematopoietin? (23 kDa)	Fibroblasts	Unassigned: IL-11R (151 kDa)	Plasmacytoma, haemopoietic	Plasmacytoma, megakaryocyte and macrophage precursor growth factor
IL-12	Unassigned (35 + 40 kDa)	B, macrophage	CKR class I? IL-12R(180 kDa)	T, NK	Differentiation Th0 to Th1, promotes NK cytotoxic activity, induces IFN- γ secretion
IL-13	Haematopoietin (132 kDa)	T	CKR class I (IL-13R may share components with IL-4R)	?	Growth and differentiation of B; like IL-4, suppresses production of IL-1 β , IL-6, TNF- α by activated macrophage
IL-14	Unassigned (60 kDa)	T, some B	Unassigned: IL-14R	B	B growth factor, inhibits immunoglobulin synthesis
IL-15	Probably haematopoietin (14 kDa)	Epithelial, macrophage	CKR class I: includes IL-2R β and γ_c but not CD25	?	Actions like IL-2
GM-CSF	Haematopoietin (22 kDa)	T cells, macrophage	CKR class I: α (CDw116) + β_c	GM series, Langerhans, others	GM precursor growth and differentiation, some plasmablasts

Table 19.5 Continued

<i>Cytokine</i>	<i>Molecular family (molecular mass)</i>	<i>Cytokine produced by</i>	<i>Family and size of receptors</i>	<i>Receptors expressed by</i>	<i>Immunological actions</i>
IFN- γ	Haematopoietin (40–70 kDa)	T, NK	CKR class II: CDw119	Leucocyte, others	Macrophage and NK activation, expression MHC class I raised
IFN- α	Haematopoietin, many isoforms (16–21 kDa)	Leucocytes	CKR class II: complex includes CD118	Most cells	Growth, differentiation of some B, expression MHC class I raised
NGF	Cysteine knot (26 kDa)	Nervous system, prostate	NGFR (70–75 kDa)	Neurones, B, macrophage	Apart from role in nervous system, growth and differentiation B
TNF- α	TNF family (52 kDa)	Activated m ϕ , NK, T, B, fibroblast	NGF family: type I CD120a (gp55); type II CD120b (gp75)	Type I most cells, not resting T or red, type II haemopoietic	Induces apoptosis of some transformed cells synergizing with IFN- γ , inflammation, lymphocyte growth synergy with IL-6
TNF- β (lymphotoxin)	TNF family (soluble, 25 kDa)	Activated T and B	NGF family: as TNF- α Rs		Induces apoptosis of some cells, inflammation, fibroblast growth factor
TGF- β	Cysteine knot (25 kDa \times 2), there are three isoforms	Platelet, T, macrophage, others	Serine/threonine kinase: type I and II high affinity and type III low affinity (53, 65 and 250–350 kDa) act in concert	Most	Inhibits cell growth, involved in wound repair and bone remodelling

This list is not comprehensive and some of the information about the function of these molecules is based on studies *in vitro* that will not necessarily be found to be relevant to activity *in vivo*.

β_c and γ_c , common receptors shared by more than one of the class I cytokine receptor family; CKR, cytokine receptor family; CSF, colony-stimulating factor; 'growth', used to mean proliferation of cells; GM, granulocyte macrophage, IFN, interferon; IL, interleukin; NGF, nerve growth factor; R, receptor; TCGF, thymus cell growth factor; TGF, transforming growth factor; Th, helper T cell; TNF, tumour necrosis factor.

The word 'cell' has been omitted, e.g. T for T cell.

is observed in calculating absolute numbers of subsets can be attributed to the method of measuring the total white cell count and the percentage of lymphocytes. A wide range of results is to be expected between different individuals. The most consistent variation is seen in childhood, but from adolescence onwards age-related changes are small and there is also little difference in relation to ethnicity or gender.

Alteration of the lymphocyte count can result from an absolute change in the number of cells or alteration in the distribution of lymphocytes within tissues. Redistribution of lymphocytes accounts for much of the variation in lymphocyte subset numbers found in serial measurements within a healthy individual. Some of these changes in lymphocyte number follow a diurnal pattern, with peak levels at night and nadir in the

morning; accordingly, time of sampling should be taken into account.

Increased number of effector cells in the blood usually reflects an active immune response. Analysis of the phenotype of these effector cells provides some information on the type of immune response, especially in differentiating between cytotoxic and inflammatory CD4⁺ T cells. Particularly in viral infections, this response may be of sufficient magnitude to cause a lymphocytosis. Some non-malignant causes of lymphocytosis are given in Table 19.8.

Redistribution of lymphocytes is probably the cause of the lymphocytosis seen in *Bordetella pertussis* infection. Although lymphocytosis is uncommon in bacterial infections, in children over the age of 6 months the second and third weeks of infection

Table 19.7 Normal ranges for lymphocyte subsets in the blood.*

Percentile	0–2		2–3		4–8		1–2 years		2–5 years		5–12 years		Adults	
	months		months		months

There is considerable variation in the normal ranges reported from different studies and this table is only intended to be illustrative.

*All values (except CD4/CD8 ratio) are $\times 10^9/L$.

Table 19.8 Non-malignant causes of lymphocytosis.

Viral infections

Infectious lymphocytosis, infectious mononucleosis, cytomegalovirus infection; occasionally rubella, hepatitis, adenoviruses, varicella, HIV, human herpesvirus 6, mumps, chickenpox, dengue

Bacterial infections

Pertussis; occasionally healing tuberculosis, brucellosis, secondary and congenital syphilis, cat scratch fever, typhoid fever, diphtheria

Protozoal infections

Toxoplasmosis; occasionally malaria

Other conditions

Serum sickness, allergic drug reactions, splenectomy, dermatitis herpetiformis, metastatic melanoma, hyperthyroidism, congenital adrenal hyperplasia

with pertussis are usually associated with a lymphocytosis in excess of $10 \times 10^9/L$ (in some cases $> 50 \times 10^9/L$). The lymphocytosis consists of small lymphocytes and is believed to be caused by a protein toxin from *B. pertussis* that prevents migration of lymphocytes across endothelium into tissue.

Acute infectious lymphocytosis is a benign disease, usually of children. In most cases there are no symptoms, but in some there is fever and in a small proportion gastrointestinal symp-

toms. Increase in the size of secondary lymphoid organs, anaemia and thrombocytopenia are rare. There is an increased number of small lymphocytes, persisting for 3–7 weeks, with an average peak level of $30\text{--}40 \times 10^9/L$. This is usually associated with an eosinophilia (average $2 \times 10^9/L$), but the aetiology of the condition is unknown.

Lymphopenia some lymphopenias predominantly reflect redistribution rather than a depletion of total body lymphocyte numbers. A dramatic short-term lymphopenia is induced by corticosteroids. This causes the retention of lymphocytes in secondary lymphoid organs but these are released again after about 2 days and the blood lymphocyte count returns to near-normal levels. Endogenous secretion of corticosteroids during acute illnesses may be partly responsible for the lymphopenias often seen in conditions such as heart failure or pneumonia. In many other conditions, lymphopenia reflects an increased rate of death of lymphocytes and/or a reduction in their rate of formation. Some of the causes of secondary lymphopenia are listed in Table 19.9. A normal absolute lymphocyte count can belie an underlying deficit of one or more lymphocyte subsets. This is often seen in HIV infection, when a severe deficit of CD4⁺ T cells may be disguised by expansion of CD8⁺ T cells.

Infectious mononucleosis

Infectious mononucleosis (IM) is caused by Epstein–Barr virus (EBV), which infects B lymphocytes. EBV enters B cells via CD21, a surface receptor for the C3d component of comple-

Table 19.9 Causes of secondary lymphopenia.*Infections*

Influenza; occasionally other viral infections, Colorado tick fever, miliary tuberculosis, pneumonia, septicaemia, malaria, HIV

Loss of lymphocytes

Intestinal lymphangiectasia, Whipple disease, severe right-sided heart failure, rarely inflammatory bowel disease, lymphatic fistula

Therapeutic procedures

Radiotherapy, anti-lymphocyte globulin, corticosteroids, cytotoxic drugs, purine analogues

Neoplastic conditions

Metastatic carcinoma, advanced Hodgkin disease

Nutritional/metabolic

B₁₂ or folate deficiency, zinc deficiency, uraemia

Other conditions

Systemic lupus erythematosus and other collagen vascular diseases, myasthenia gravis, aplastic anaemia, graft-versus-host disease, pancreatic necrosis, sarcoidosis, idiopathic

ment. After the acute infection has been resolved, lifelong sub-clinical infection is maintained, with a low frequency of infected B cells and detectable virus in the saliva – a main vehicle for contagion.

EBV infection of children usually results in immunity without development of the typical clinical manifestations of IM. This immunity can be detected serologically and is associated with lifelong protection. Usually only after the age of 10 years is infection by EBV associated with the clinical manifestations of IM. In developing countries, the rate of seroconversion before the age of 10 years can be so high that clinically evident IM is rare. IM has its highest prevalence in young adults and a study of medical students showed that the syndrome was seen in 25% of individuals who underwent seroconversion. It is uncommon after the age of 30 years and rare after the age of 40 years. The determinants of clinical symptoms are unknown but may relate to host immunogenotype, viral load or viral polymorphisms.

Clinical features

The symptoms of IM usually develop abruptly, with fatigue, malaise and fever after an incubation period of up to 7 weeks. These symptoms last for about 3 weeks. Sore throat occurs in over 80% of cases and is usually accompanied by anorexia and nausea. The sore throat develops in the first week and subsides in the second week, rarely generating severe symptoms or massive tonsillar/pharyngeal oedema. Sharply defined red spots at the junction of the soft and hard palates are of diagnostic

value. Positive throat swabs for β -haemolytic streptococci are frequently found. Bilateral non-inflammatory cervical lymphadenopathy is almost invariable, and inguinal and axillary lymphadenopathy is usual. The spleen is palpable in more than half of cases, although only occasionally does it extend to the iliac crest. These secondary lymphoid organs increase in size in the first week and subside slowly after the second week. Slight hepatomegaly and jaundice occurs in about 10% of cases. Fever is present in most cases but of no characteristic type and may be transient. A few patients develop a fine macular rash, but rashes are more usually found as temporary reactions to penicillin and especially ampicillin.

Blood picture

In most patients, IM is associated with a leucocytosis; this peaks in the second and third weeks and usually persists for 1–2 months (the first week is occasionally associated with a leucopenia). In two-thirds of patients, the leucocytosis ranges from 10 to 20 $\times 10^9/L$ but in some cases may substantially exceed these levels. The leucocytosis is attributable to an absolute increase in numbers of both normal small lymphocytes and of activated T cells (atypical lymphocytes). Most of the activated cells are CD8⁺ T cells but they also include CD4⁺ T cells and CD3⁻ NK cells. Most of these activated lymphocytes are cytotoxic for virus-infected cells and target viral peptides presented on MHC class I molecules. Although infection of B cells by EBV stimulates their proliferation, this appears to be controlled by the T-cell response such that the proportion of blood mononuclear cells that is EBV infected rarely exceeds 0.1%.

A peripheral neutrophilia may be seen early in the disease, but a neutropenia is equally common and eosinophilia is not unusual. Thrombocytopenia may occur and is occasionally severe. Anaemia is rare and then usually associated with anti-i antibodies. EBV infection may trigger a haemophagocytic syndrome in rare cases.

Serological changes

Three categories of antibody are produced as a result of EBV infection: virus specific, heterophile and autoimmune. The first virus-specific antibodies to appear are directed against the EBV capsid antigen (VCA). IgM anti-VCA antibodies probably develop during the incubation period and peak in the second week of the illness followed by a rapid decline. IgG anti-VCA antibodies peak in the second to third weeks and persist for life. Most patients also have a transient response to EBV early antigen (EA), which peaks in weeks 2–3. Antibodies to EBV nuclear antigen (EBNA) do not develop until some weeks into the illness but are present lifelong in all patients by 6 months. Serological diagnosis of acute IM is most accurately made by the presence of IgM anti-VCA and anti-EA antibodies and the absence of anti-EBNA antibodies.

Paul and Bunnell demonstrated that patients with IM have serum agglutinins directed against sheep erythrocytes (heterophile antibodies) and that a serum titre in excess of 1:112 is highly suggestive of IM. Similar agglutinins are found in low titre in healthy individuals (directed against Forssman antigen) and in some leukaemias and lymphomas as well as serum sickness. However, in these conditions the heterophile antibody can be absorbed onto guinea pig red cells. Formalin-treated horse erythrocytes appear to be agglutinated exclusively by heterophile antibodies of IM, and this forms the basis of the *Monospot test*. Heterophile antibodies provide the routine serological test for IM but are commonly negative, particularly in children and in patients over the age of 25 years. EBV-specific serodiagnostic tests should be applied in cases with strong clinical suspicion but negative heterophile antibodies. Total serum immunoglobulin levels increase around 4 weeks following onset of symptoms, and raised levels may persist for many months. The greatest proportional increase is in IgM, but IgG may also be raised. The specificity of most of these immunoglobulins is unknown but a variety of autoantibodies may be found, including cold-reactive anti-i antibodies, Donath–Landsteiner cold haemolysins and, occasionally, antibodies against smooth muscle, thyroid, stomach, rheumatoid factors and antinuclear antibodies.

Differential diagnosis and treatment

The diagnosis and course of IM are usually uncomplicated. Signs of significant respiratory, cardiovascular, intestinal, urinary or joint disease make consideration of other diseases mandatory; some of these other diseases are listed in Table 19.8. Perhaps the commonest problem is when the patient is heterophile antibody negative. In this situation, other viral infections, particularly cytomegalovirus (CMV), should be considered, with assay for CMV-specific IgM. Primary EBV infection is rare in older patients and there may not be conspicuous lymphadenopathy. Occasionally, the blood picture may raise the suspicion of a leukaemia, in which case immunophenotyping of the blood mononuclear cells may be appropriate. Persistent lymphadenopathy beyond a few weeks suggests the need for diagnostic biopsy, particularly if heterophile antibodies are negative, but the possibility of a false-positive Monospot test should also be considered. Virus-specific serology may be helpful in both these situations.

There is no specific therapy for IM. In patients with severe fever or lymphadenopathy, corticosteroids produce prompt lysis of fever and reduction of lymph node hyperplasia. Steroids may be indicated in management of associated haemolytic anaemia, thrombocytopenia, progressive neurological complications and incipient airway obstruction. Patients should be advised of the small risk of splenic rupture from minor abdominal trauma and contact sports should be avoided for several months.

X-linked lymphoproliferative syndrome (Duncan syndrome) is a rare inherited X-linked condition in which there is specific immunodeficiency against EBV. These individuals may die as a result of primary infection or the subsequent development of an EBV-driven B-cell lymphoma. Patients receiving immunosuppressive therapy for allografts and who are carriers of EBV can develop proliferations of B lymphocytes that carry the EBV genome. These cases of *post-transplant lymphoproliferative disease* are heterogeneous, and B-cell proliferations vary from a polyclonal diffuse B-cell hyperplasia to monoclonal B-cell lymphomas. There is evidence for a causal role of EBV in the development of Burkitt lymphoma, in association with both HIV infection and in the form endemic in African children. In less than 20% of sporadic cases of Burkitt lymphoma, EBV-associated DNA can be demonstrated in the lymphoma cells.

Secondary associations of infectious mononucleosis

In the 1950s it was reported that there was an increased incidence of Hodgkin lymphoma in individuals with a history of IM. Although the epidemiological challenges of confirming this association are profound, several very large studies have revealed

Figure 19.15 Relative risk of Epstein–Barr virus (EBV)-positive and EBV-negative Hodgkin lymphoma after infectious mononucleosis. Solid lines represent the relative risks of EBV-positive (blue) and EBV-negative (red) Hodgkin lymphoma, given that EBV status was determined in an unbiased way and that the missing data on viral status in 11 tumours were uninformative with respect to their true EBV status. Short dashed lines represent the relative risks of EBV-positive and EBV-negative Hodgkin lymphoma given that all tumours whose EBV status was unknown were EBV-positive. Long dashed lines represent the relative risks given that all tumours whose EBV status was unknown were EBV-negative. The analyses were restricted to the period 2 years or more after infectious mononucleosis. (From Hjalgrim *et al.* 2003 with permission.)

a definite association. Hjalgrim and colleagues studied 38 555 people with a confirmed diagnosis of IM and identified 29 cases of Hodgkin lymphoma, of which 16 had evidence of EBV. The study revealed a 4.1-fold increased risk of EBV-associated Hodgkin lymphoma in patients with a history of IM, with a median incubation time of just over 4 years to development of lymphoma (Figure 19.15).

IM is also associated with an increased risk of multiple sclerosis later in life. Thacker and colleagues have estimated this relative risk at 2.3 and this is likely to reflect the growing appreciation that EBV infection is associated with the pathogenesis of multiple sclerosis, although the mechanisms involved are unclear.

It is not yet clear whether individuals who suffer from IM carry a genetic predisposition to a variety of immunopathological disorders or if these secondary events are a direct consequence of the IM syndrome. However, these observations do offer important clues as to the pathogenesis of these important disorders.

The spleen has several important and diverse roles in homeostasis. Its normal functions are affected in a number of primary blood diseases as well as in other clinical disorders when its dysfunction can give rise to haematological abnormalities. These haematological effects are usually a minor phenomenon but in some cases may come to dominate the clinical presentation.

Evolution of the spleen

The spleen evolved around 500 million years ago with the appearance of the adaptive immune system between the origin of vertebrates and the development of the jawed vertebrates. It has undergone more functional and structural diversification than the thymus and this may reflect its varied physiological roles. The spleen shares a capsule of fibromuscular tissue in all animals and this extends inwards as a reticular network. The red pulp is present in all species but there have been marked changes in the anatomy of the white pulp and this is likely to reflect increasing sophistication of cellular immunity.

The spleen is derived from a condensation of mesenchymal cells that arise in the mesentery close to the pancreatic rudiment. The mesenchymal cells differentiate into reticulum cells, pluripotent stem cells and colony-forming units. Together with the liver, the spleen has a transient role in haemopoiesis from the third month, continuing until birth. From about 20 weeks the bone marrow becomes a site of haemopoiesis and this

increases rapidly during the last trimester of pregnancy, whereas haemopoietic activity in the spleen disappears (Figure 20.1). There is no evidence for a specific inhibitor of haemopoiesis and the spleen remains a potential site for blood production in the adult, particularly for the maintenance of erythropoiesis. This occurs during pathological states and the development of such extramedullary haemopoiesis after birth is described below.

Structure and function

The major functions of the spleen are (i) filtration and 'quality control' of red cells within the circulation; (ii) capture and destruction of blood-borne pathogens; and (iii) generation of adaptive immune responses. In order to achieve these aims the spleen has evolved a unique anatomical structure that is based on the filtering of blood through two main systems. These constitute a white pulp, which is concerned mainly with immunological function, and a red pulp, which regulates the selection of red cells for re-entry into the circulation. A major feature is the presence of both 'open' and 'closed' circulatory systems and these are described in detail in the subsequent sections.

The spleen lies in the left hypochondrium with its long axis beneath the proximal half of the tenth rib. Its convex surface rests under the diaphragm whereas the visceral surface is in contact with the stomach and left kidney, with the tail of the pancreas reaching the hilum at the medial side. The normal spleen weighs about 150–250 g but there is considerable variation between normal individuals and at various ages in the same individual. At puberty it weighs about 200–300 g but after the age of 65 years this decreases to 100–150 g or less. In the adult

Figure 20.1 Site of erythropoietic tissue in fetus and throughout life.

its length is 8–13 cm, width 4.5–7.0 cm, surface area 45–80 cm² and volume less than 275 cm³. Interestingly, up to 10% of people have accessory spleens, normally as a single piece of tissue that can be found in a variety of sites either locally or more distantly in the abdomen. A spleen greater than 14 cm long is usually palpable (see later). It enlarges in a wide range of diseases and has been measured at up to a massive 2 kg or more in some blood disorders.

The spleen has a complicated structure and several different functions. Essentially, it is enclosed by a connective tissue framework that extends inwards to form a fibrous network. Blood enters at the pelvis and the majority of vessels open into these open networks (the *red pulp*) before re-entering the closed venous system. There is no afferent lymphatic to the spleen and the efferent lymphatic system leaves along the route of the splenic vein. The spleen contains a large amount of lymphatic tissue that is mostly concentrated in concentric rings around the arterioles (*white pulp*). Between the red pulp and white pulp is an *intermediate marginal zone*, which lies at the periphery of the white pulp, blending into the red pulp.

Splenic blood flow and the red pulp

The circulation within the spleen is illustrated in Figure 20.2. Blood is brought to the spleen via the splenic artery, which branches into the trabecular arteries and then arborizes in a pattern that lacks interarterial connections and thus effectively generates end arteries. The central arteries acquire a coaxial sheath of lymphocytes containing lymphoid follicles and this together constitutes the white pulp (see below). These central arteries then split into many arterioles and capillaries, some of which terminate in the white pulp while others go on to enter the red pulp.

In the red pulp there are two major forms of blood circulation: a *closed system*, typical of the rest of the vascular system, in which arteries and veins communicate through endothelial-

lined vessels; and an *open circulation*, in which arterioles terminate in free endings on *splenic cords* (also known as the cords of Billroth) and from which cells must subsequently cross an endothelial layer to re-enter the circulation. The cords consist of a fibroblast-like reticular meshwork containing numerous macrophages and erythrocytes and they are critical to the filtration function of the spleen. Red cells in the cords need to gain entry to a venous sinus if they are to be allowed to re-enter the systemic circulation. The sinuses, 20–40 mm in diameter, are lined by endothelial and adventitial cells with a basement membrane and possess narrow interendothelial spaces in the sinus wall through which flexible red cells may pass. Red cells with inflexible membranes, mostly elderly, are not able to pass through these gaps and are ingested by macrophages in the cords. The great majority of blood flows in this unique open system and only a minority of arteries enter the sinuses and connect directly via the collecting vein to the trabecular vein in a typical vascular closed system.

There is thus both a rapid and a slow transit component in the splenic circulation. The rapid transit is of the order of 1–2 min, whereas the open circulation has a circulation time of 30–60 min or even longer. In normal subjects, the blood flows through the spleen as rapidly as through other organs, at a rate of about 5% of blood volume per minute, so that each day the blood has repeated passages through the spleen. During the flow, by a process called *plasma skimming*, the plasma and the leucocytes pass preferentially to the white pulp, while the red cells remain in the axial stream of the central artery. The passage of cells into the sinuses is controlled by their ability to squeeze through the interendothelial spaces, assisted by contraction of the reticular cells.

Blood pooling

The normal red cell content of the spleen is 30–70 mL, which represents less than 5% of the total red cell mass. When the

Figure 20.2 The vascular and lymphatic organization of the spleen. (a) Schematic representation of blood flow in the spleen. Blood enters through the splenic artery and then breaks up into splenic arterioles. The white pulp is an aggregation of lymphoid tissue around these vessels. The arterioles then open into splenic cords lined with macrophages. Blood must then re-enter the circulation by passing into a venous sinus. (b) Cross-section of white pulp at section A–B in (a). The central arteriole is surrounded a periarteriolar lymphoid sheath of T lymphocytes and occasional follicles that are rich in B cells. The marginal zone is divided into an inner and outer zone around which there is a large perfollicular zone. (c) Schematic representation of the organization of the red pulp. Blood cells are released by a splenic arteriole into a reticulum-lined splenic cord. Red cells that have flexible membranes are able to gain entry into the venous sinus by passing through gaps in the endothelial lining. Cells that are unable to achieve this are ‘filtered’ from the blood through ingestion by macrophages. (Adapted from Mebius & Kraal 2005 with permission.)

splénomegaly due to cellular infiltration, the pool is less prominent. Conversely, in the congestive splénomegaly of portal hypertension, spleen size with an increased red cell pool is a dominant feature.

The normal spleen contains a reservoir of granulocytes that is in dynamic equilibrium with the circulating granulocytes. It represents 30–50% of the total marginating pool, with a mean transit time through the spleen of about 10 min. Splenic sequestration of granulocytes is thought to be responsible for the neutropenia that often occurs in patients with splénomegaly. Platelets have also been shown to have a significant reservoir in the spleen and are rapidly interchangeable with the circulation. In normal subjects 20–40% of the total platelet mass is pooled in the spleen and the platelets spend up to one-third of their lifespan there. The pool increases when the spleen is enlarged. This pooling and temporary sequestration must be distinguished from the destruction of platelets in the spleen that occurs in many cases of thrombocytopenia.

There is no evidence that the normal spleen is involved in the regulation of plasma volume but splénomegaly is frequently associated with an increased plasma volume that may lead to a dilutional pseudo-anaemia. The mechanism of this effect is uncertain but may include expansion to fill the additional intravascular space, activation of neurohumoral regulation, or protein alterations resulting in a change in colloid cellular osmotic pressure. The clinical importance is that in splénomegaly the blood count may give an exaggerated impression of anaemia and measurement of red cell and plasma volumes can be valuable.

spleen is enlarged, expansion of the vascular bed occurs. This results in a considerable pool with a high haematocrit and only a slow exchange of red cells with the general circulation. In states of massive hypersplenism, such as myelofibrosis, as much as 40% of the red cell mass may be pooled in the spleen. This pooling will functionally exclude a relatively large volume of red cells from the main arteriovenous circulation, and thus be an important cause of anaemia. In such cases, it should be noted that the red cell mass, as measured by a radionuclide labelling technique, may give a misleadingly normal result, whereas the peripheral blood packed cell volume will give a more reliable measurement of the effectively circulating red cell mass. In

Role of the spleen in ensuring quality control of red cells

The spleen is the body's largest filter of blood and a major function of the spleen is the quality control of red cells. Red cells are normally flexible, whereas cells with abnormal membranes, or those with inclusions that render them relatively inflexible, remain in the cords where they either become conditioned for later transit or are destroyed. *Sequestration* is a reversible process whereby cells are temporarily trapped by adhesion to the reticular meshwork of the cords on their passage through the spleen. Phagocytosis is the irreversible uptake by macrophages of particulate matter, non-viable cells and viable cells that have been damaged by prolonged sequestration or by antibody coating.

In the presence of metabolically active macrophages, the densely packed red cells are deprived of oxygen and glucose. This stress increases membrane rigidity and reduces the natural deformability of the biconcave cell. This effect is particularly marked if there is an underlying abnormality of the red cell metabolic system, if cells are coated with antibody or if they are fragmented or misshapen in other ways. In these situations they remain trapped in the cord space and undergo phagocytosis. Siderotic granules, Howell–Jolly (DNA) bodies, nuclear remnants and Heinz bodies are removed by culling or pitting during temporary sequestration. After removal of the inclusions the red cells return to the circulation. Reticulocytes may be retained in the splenic cords for a considerable proportion of the 2–3 days of their maturation period and during this time they lose their intracellular inclusions, alter the lipid composition of their surface and become smaller in size. It is not clear whether the spleen has any special role in the removal of normal aged red cells and it seems more likely that such cells are removed by the general reticuloendothelial system, which includes both the spleen and the bone marrow.

Immunological function

The spleen is the largest single accumulation of lymphoid tissue in the body and is estimated to contain 25% of the T-lymphocyte pool and 10–15% of the B-lymphocyte pool. T cells, mainly of the CD4⁺ subtype, are found predominantly in the periarteriolar lymphatic sheath, whereas B cells are located in the follicles and marginal zones of the white pulp. There is also an abundance of macrophages and dendritic cells and the architecture is maintained through a complex anatomical organization that includes a tubular conduit system that transports a range of chemokines and other molecules. The spleen has a unique role in acting as an immunological filter for the bloodstream. Lymphocytes and dendritic cells enter the splenic tissue by initial entry into the marginal zone, and from there can pass into the periarteriolar lymphatic sheath by crossing a lining of sinus cells. There is a constant flow of both T and B cells through

the spleen, with T cells typically staying in the spleen for a few hours whereas B cells stay in the follicle and marginal zone for prolonged periods. At present it is not certain how lymphocytes exit the white pulp.

One interesting feature of the immunological function of the spleen is that it is able to act as an important site for both innate and adaptive immune responses. The marginal zone acts as the site for both of these processes, whereas the white pulp is restricted to adaptive immunity. Blood is filtered directly into the marginal zone and here the predominant cell populations are macrophages and marginal-zone B cells. The macrophages express a range of pattern-recognition receptors that recognize bacterial molecules such as lipopolysaccharide, as well as proteins such as SIGNR1 and MARCO that bind directly to both bacteria and viruses. These cells thus act as an important filter for the clearance of blood-borne pathogens. The marginal-zone B cells are a unique B-cell subset that bridges the innate and adaptive immune responses. They are able to recognize bacterial pathogens without the help of T cells and this T-independent antibody response consists largely of low-affinity IgM and can play an important role in limiting bacterial replication. In addition, these B cells can act as antigen-presenting cells and are able to migrate to the periarteriolar lymphatic sheath where they present antigen to T cells and facilitate the production of high-affinity IgG antibody. B-cell maturation and clonal expansion occurs in the follicles and plasmablasts, and plasma cells subsequently migrate to the red pulp where they are retained through their expression of CXCR4, which binds to CXCL12 in red pulp tissue.

The T-cell-independent antibody response produces a spectrum of low-affinity IgM antibody clones that provide a first line of immune defence against bacterial sepsis, especially from *Streptococcus pneumoniae*, *Haemophilus influenzae* type b and *Neisseria meningitidis*. The spleen also appears to act as a defence against viral infections and intraerythrocyte parasitic infections such as *Plasmodium* and *Babesia*. The singular role of the spleen in this regard is shown in the immunization of splenectomized individuals with T-independent antigens and in this case antibody titres are typically only 10% of those seen in control subjects.

Given these unique features it is perhaps no surprise that splenectomy is associated with a degree of relative immunosuppression. This deficiency is not profound but there is a small but definite increase in susceptibility to infection with encapsulated bacterial species.

Extramedullary haemopoiesis

As indicated above, the spleen is an important site of haemopoiesis *in utero* and retains the ability to reactivate this process after birth. This can occur as a compensatory erythroblastic hyperplasia in severe anaemia, such as chronic haemolysis, megaloblastic anaemia and thalassaemia major, or as a more

generalized haemopoiesis often seen in myelofibrosis or other malignant disorders in the bone marrow. The mechanisms involved in this extramedullary haemopoiesis are poorly understood. It is not clear if pluripotent stem cells are present in the spleen or migrate from the bone marrow. It is even conceivable that changes in the stroma or primary haemopoietic cells that arise due to the underlying pathological process are involved in favouring initiation of the haemopoietic process.

Splenomegaly and hypersplenism

Spleen size

An enlarged spleen is a frequent and important clinical sign. It is thus essential to have a reliable picture of the presence and extent of splenomegaly. In the adult, an enlarged spleen is usually palpable when its length exceeds 14 cm. However, the measurement of spleen size by means of a physical examination of the abdomen is unreliable, as minor enlargement is often undetected by palpation and even a grossly enlarged spleen may be missed in an obese person. Conversely, a lax phrenic–colic ligament or loss of tone of the abdominal wall may give rise to a ‘wandering spleen’ which will be palpable, as will one that is pushed downwards by a flattened diaphragm in obstructive airways disease.

Reliable information is obtained by radiology through ultrasonic imaging, magnetic resonance imaging (MRI) and computed tomography (CT), all of which give an accurate representation of the anatomy of the spleen and its position in relation to adjacent organs (Figure 20.3). PET-CT may be used to detect tumours, e.g. lymphoma in the spleen (Figure 20.3c). Another method of scanning the spleen is by means of a scintillation camera following radiolabelling of red cells with ^{51}Cr , ^{111}In or $^{99\text{m}}\text{Tc}$ (Figure 20.4). Although laborious, it does provide information on the functional size of the spleen, and functional asplenia or atrophy is well demonstrated by this procedure. It is also useful in identifying abnormally positioned and accessory splenic tissue. It is, however, not widely available.

Pathological basis of splenomegaly

Most of the clinical interest in splenomegaly is related to the secondary effects or the underlying aetiology. However, the pathological basis of enlargement can be of value to the histopathologist and may prove valuable in making a diagnosis:

- 1 reactive increase of white pulp in inflammation and infection;
- 2 congestive expansion of the red pulp compartment;
- 3 increased blood pool;

- 4 increased macrophage function;
- 5 proliferative cellular infiltration;
- 6 extramedullary haemopoiesis;
- 7 storage disease;
- 8 cysts;
- 9 solid tumours.

As examples, the characteristic feature of autoimmune red cell haemolysis is intrasinusoidal red cell phagocytosis, whereas hereditary spherocytosis demonstrates red cell sequestration.

Causes of splenomegaly

Splenomegaly is a frequent and important clinical sign. The diseases in which it occurs are listed in Table 20.1. The relative incidence of each cause of splenomegaly is subject to geographical variation. In Western countries, leukaemia and lymphomas, myeloproliferative disorders, haemolytic anaemias, glandular fever and portal hypertension account for most cases. In tropical countries, however, the incidence of these haematological causes of splenomegaly is overtaken by the preponderance of splenic enlargement caused by the parasitic tropical infections: malaria, leishmaniasis and schistosomiasis.

Specific causes of splenomegaly

Malaria

Malaria demonstrates how several pathogenetic mechanisms may be involved in splenomegaly. There are reactive lymphoid changes and the red pulp sinuses dilate with expanded phagocytic activity. The tropical splenomegaly syndrome, associated with recurrent malaria, is particularly common in New Guinea and Central Africa.

Haemoglobin disorders

Splenomegaly is associated with HbC disease in West Africa, with HbE disease in the Far East and with thalassaemia syndromes, which have a wide distribution throughout the tropics. HbSS sickle cell disease is usually associated with splenic atrophy, but the spleen usually remains enlarged in adults with HbS/C and HbS/ β -thalassaemia syndromes.

Malignant haematological disorders

In primary proliferative polycythaemia, the increase in spleen size is mainly due to vascularity, with expansion of the red pulp and an increased red cell pool. In myelofibrosis, the red cell pool is remarkably increased and the spleen size is further augmented by myeloid metaplasia and expansion of the reticular elements. In contrast, in chronic myeloid leukaemia and lymphoproliferative disorders the increase in size is attributed mainly to cellular infiltration, while vascularity and red cell pooling have only a minor influence.

tomography (CT) scan. (iii) CT scan: the spleen is enlarged and shows multiple low density areas. A diagnosis of diffuse large cell B lymphoma was made histologically after splenectomy. (d) Ultrasound scan of enlarged spleen. (Figures (c, i) and (c, ii) courtesy of Dr T. Ogunremi).

(d)

Figure 20.3 Continued

Primary splenic tumours

Primary splenic tumours are rare. Metastatic carcinoma, such as from the breast or lung, is also a rare event.

Portal hypertension

This may be both a cause and a consequence of splenomegaly. In a spleen that is massively enlarged from any cause, the huge increase in blood flow can lead to an increased portal pressure that leads to back-pressure on the spleen and a spiral of compression leading to widening and fibrosis of the red pulp cords. On the other hand, portal vein obstruction due to liver disease can also enlarge and damage the spleen.

Hypersplenism

Hypersplenism is a clinical syndrome and does not imply a specific causal mechanism. It has the following characteristic features:

- 1 enlargement of the spleen;
- 2 reduction in one or more of the cell lines in the peripheral blood;
- 3 normal or hyperplastic cellularity of the bone marrow;
- 4 premature release of cells into peripheral blood, resulting in reticulocytosis and/or large immature platelets;
- 5 increased splenic red cell pool, decreased red cell survival and increased splenic pooling of platelets with shortening of their lifespan.

It is not possible to determine all these criteria in each case and the diagnosis of hypersplenism is ultimately confirmed by the response to splenectomy. Most of the diseases listed in Table 20.1 can give rise to secondary hypersplenism. In these conditions, the haematological features of hypersplenism may be obscured or dominated by the primary disease, especially if it

Table 20.1 Causes of splenomegaly.

Haematological

- Acute leukaemia
- Chronic myeloid leukaemia*
- Chronic lymphocytic leukaemia
- Malignant lymphomas (some cases present as 'non-tropical primary splenomegaly')*
- Chronic (primary) myelofibrosis*
- Polycythaemia vera
- Essential thrombocythaemia (some cases)
- Hairy cell leukaemia*
- Gaucher disease*, Niemann–Pick disease, Langerhans cell histiocytosis X*
- Primary splenic hyperplasia
- 'Non-tropical splenomegaly'
- Splenic anaemia/neutropenia
- Thalassaemia
- Sickle-cell disease, HbSC disease and other haemoglobinopathies
- Haemolytic anaemias
- Acute anaemia (rare)
- Megaloblastic anaemia (rare)

Systemic

- Acute infections: septicaemia, typhoid, infectious mononucleosis, cytomegalovirus
- Subacute and chronic infections: tuberculosis, syphilis, brucellosis, subacute bacterial endocarditis, AIDS
- Tropical parasitic infections (tropical splenomegaly*): malaria*, leishmaniasis*, schistosomiasis*, trypanosomiasis
- Collagen diseases: systemic lupus erythematosus, rheumatoid arthritis (Felty)
- Sarcoidosis
- Amyloidosis
- Cysts
- Haemangiomas
- Carcinoma (rare)
- Congestive splenomegaly
 - Portal hypertension
 - Cirrhosis
 - Splenic/portal/hepatic vein obstruction
 - Congestive cardiac failure

*Common causes of splenomegaly.

involves the marrow. Hypersplenism also occurs rarely as a primary event, due to an unknown pathogenetic stimulus, and is sometimes termed *primary splenic hyperplasia*.

Splenectomy

Surgical excision of the spleen has been a standard treatment for the diagnosis and management of a number of disorders

associated with an enlarged or hyperactive spleen and also when an otherwise normal spleen mediates the clinical problems associated with an extrasplenic defect such as hereditary spherocytosis or autoimmune acquired haemolytic anaemia. Splenic rupture may also occur from trauma, glandular fever or, rarely, use of colony-stimulating factors such as G-CSF. Splenectomy may also be valuable in making the diagnosis of organomegaly and can bring about significant disease control in some malignant conditions, such as splenic marginal zone lymphoma, where the bulk of the tumour population is located in the spleen. Finally, the spleen is often removed incidentally as part of another surgical procedure. At a surgical level, laparoscopic splenectomy has become the treatment of choice in the absence of portal hypertension or significant medical comorbidity.

Concern about the risks of sepsis after splenectomy in both children and adults has led to a search for alternative procedures for controlling hypersplenism while preserving some degree of splenic function. These include (i) partial arterial embolization; (ii) partial surgical amputation in selected patients in whom some splenic function may be preserved; (iii) localized irradiation; and (iv) immunosuppressive and cytotoxic drugs.

The role of splenectomy in individual diseases is discussed in the relevant chapters but when splenectomy is contemplated for any reason, the preoperative evaluation of the patient requires close cooperation between the surgeon and the haematologist. Vaccinations should be performed and it is valuable to check liver function, obtain appropriate imaging and potentially evaluate the hepatic and portal blood flow by Doppler ultrasound examination.

Complications of splenectomy

Immediate postoperative complications

These are dominated by bleeding, particularly when there is thrombocytopenia and subphrenic abscess. Haemorrhage usually comes from the peritoneal and diaphragmatic surfaces rather than from identifiable blood vessels. Frequently, no specific bleeding source is found at reoperation. The incidence of subphrenic abscess is variable, and appears more likely to occur when adjacent organs are injured either by trauma or during surgery. Infection is also liable to occur following embolization.

Delayed complications

These include overwhelming post-splenectomy infection and a tendency to develop thrombocytosis with a risk of thromboembolic incidents.

Thrombocytosis

In the immediate postoperative period in uncomplicated splenectomy patients, the platelet count rises steeply to a

maximum of usually $600\text{--}1000 \times 10^9/\text{L}$, with a peak at 7–12 days. In a number of patients, the thrombocytosis persists indefinitely after splenectomy. This usually appears to be a consequence of continuing anaemia with a hyperplastic marrow; an inverse relationship exists between the severity of the anaemia and the height of the platelet count. Although a reactive thrombocytosis is not usually associated with thromboembolic problems, the high platelet count may have contributed to the serious and sometimes fatal episodes of pulmonary embolism that have occurred following splenectomy. Mesenteric infarction secondary to portal vein occlusion is more common in patients with myeloproliferative disorders who undergo splenectomy. Postoperative prophylaxis with heparin is usually needed. It is advisable to give antiplatelet therapy (e.g. aspirin 75 mg daily) as long as thrombocytosis is present.

Overwhelming postoperative infection

This may occur in adults as well as in children but it is in children, especially in the first few years of life, that splenectomy is more frequently associated with overwhelming bacterial infections. *Streptococcus pneumoniae* is the most common cause of infection but while *H. influenzae* type B, *N. meningitidis*, *E. coli* and *Pseudomonas* are much less common, they are also associated with serious infection. Death is usually due to septicaemia or meningitis and typically occurs within 5 days of the onset of infection. The vulnerability of young children and their dependence on the spleen to deal with blood-borne infection can be explained by the general immaturity of their lymphoreticular systems. In the absence of the spleen, the defective reticuloendothelial clearance of an encapsulated rapidly growing organism such as pneumococcus may lead to a dangerous bloodstream concentration in too short a time for immunological defence to be mounted. Splenectomy should therefore be postponed until after the age of 5 wherever possible.

When splenectomy is being planned, the patient should be immunized against pneumococcal pneumonia, *H. influenzae* type B (HIB) and meningococcal infection. However, while pneumococcal vaccine contains antigens to a number of strains of *Streptococcus pneumoniae*, it does not give complete protection because some strains are not covered and antibody response to the different antigens is variable. To obtain the maximum immune response, patients should, if possible, be immunized 2–3 months before splenectomy, and a booster dose should be given 5 years later. Most children will have received HIB vaccine but this should be checked; booster doses are not necessary for those who received the full course of three injections. Meningococcal vaccines are effective against types A and C but not against type B, the most prevalent in the West. The patient should also receive meningococcal C conjugate vaccine at a 6-month interval as this gives a higher and more lasting immunization against type C organism. Influenza vaccine is also recommended for asplenic or hyposplenic patients.

Figure 20.4 Demonstration of residual splenunculus by a scan of heat-damaged isotope-labelled red cells: (a) anterior view; (b) posterior view. Uptake is predominantly in the liver.

Postoperatively, lifelong prophylactic antibiotics should be advocated in all cases but if this is not possible, antibiotics should be administered at least for the first 2 years after splenectomy for all children up to 16 and when there is underlying impaired immune function. Oral penicillin 250 mg b.d. is usually recommended and patients who are allergic to penicillin should be offered erythromycin 250 mg b.d. When away from home, patients not allergic to penicillin should take a supply of amoxicillin to be used immediately if infective symptoms (pyrexia, malaise, shivering) develop; penicillin-sensitive patients should increase their dose of erythromycin or change to a broader-spectrum preparation. In all such cases, the patient should seek immediate medical help. When travelling to tropical areas, asplenic patients should be advised of the increased risk of severe *Plasmodium* infection and must adhere scrupulously to antimalarial prophylaxis. *Neisseria meningitidis* and *H. influenzae* type B vaccines are also recommended for those travelling abroad. Education of patients or parents is perhaps the most important aspect of management to ensure that they are alert to the possibility of infection and know how to react appropriately. A card indicating that a splenectomy has been carried out should be carried.

Recurrence of symptoms

Accessory splenic tissue may be overlooked at operation; after splenectomy, it may enlarge and cause a recurrence of the symptoms for which the original operation was carried out. The haematological features of hyposplenism (see below) such as Howell–Jolly bodies and increased pitting may be absent; CT or

radionuclide scanning (Figure 20.4) will demonstrate the presence of a ‘splenunculus’ and identify its location for subsequent surgical removal should this be required.

Hyposplenism

Hyposplenism (excluding that induced by medical or surgical intervention) occurs in a wide range of conditions. In some disorders such as sickle cell disease, gluten-induced enteropathy (coeliac syndrome) and dermatitis herpetiformis, hyposplenism occurs frequently; it is seen less frequently in Crohn’s disease, ulcerative colitis and essential thrombocythaemia, and it occurs only occasionally in the other conditions listed in Table 20.2. Congenital absence of the spleen is rare and may be associated with organ transposition and with severe malformations of the heart and lungs.

After the age of 65–70 years there is evidence of a decrease in splenic function. In old age, there is a rapid decrease in the weight of the spleen, together with increasing atherosclerotic vascular obstruction and fibrosis.

Patients with functional hyposplenism have impaired immunity to blood-borne bacterial and protozoal infections, and persistent thrombocytosis. Management is similar to that required after splenectomy. It includes prophylactic antibiotics and vaccines (see above) and advice to the patient to seek medical attention immediately in the event of illness or fever. Antiplatelet therapy is advisable when the platelet count is high.

Haematological effects of splenectomy or splenic atrophy

Characteristic blood changes occur following splenectomy. Similar changes are seen with atrophy of the spleen to less than 20% of normal size and when there is functional asplenia, with or without reduction in the size of the organ.

Red cell changes

The changes in red cell morphology include the presence of Howell–Jolly bodies, siderotic granules and target cells. In a proportion of subjects, irregularly contracted or crenated acan-

Figure 20.5 Blood film showing features of hyposplenism: Howell–Jolly bodies, target cells and contracted cells.

thocytic forms are also a feature (Figure 20.5). There is usually an increase in the number of reticulocytes in the circulation and occasionally isolated erythroblasts are seen. However, there is no alteration in red cell survival.

Because the number of cells with siderotic granules that enter the circulation is related to the sideroblastic percentage in the bone marrow, the siderocyte count in the peripheral blood is increased in haemolytic anaemias, thalassaemia and sideroblastic anaemia. The number of Howell–Jolly bodies is also variable and is most marked in conditions characterized by dyserythropoiesis. Other red cell inclusions may be prominent in the hyposplenic state: Heinz bodies are found following oxidative injury by drugs and in patients who have glucose-6-phosphate dehydrogenase deficiency or an unstable haemoglobin; precipitated β -chains are found in α -thalassaemia; and crystalline deposits of haemoglobin C in HbC disease.

Leucocyte changes

After splenectomy, there is a rise in the total leucocyte count. A neutrophil leucocytosis in the immediate postoperative period is later replaced by a significant and permanent increase in both lymphocytes and monocytes. Usually the total white cell count stabilizes at between 10 and $15 \times 10^9/L$ but occasionally it may rise to twice this level. Minor increases in blood eosinophils and basophils have been noted after splenectomy but this is not a regular feature.

In response to infection, splenectomized subjects produce a much greater leucocytosis than persons with intact spleens. Often there is a marked left shift in the differential leucocyte count, with myelocytes and occasionally more primitive cells.

Platelet changes

As indicated above, the thrombocytosis after splenectomy is usually transitory and falls to normal or near-normal values over the following 1–2 months. However, even if the platelet

count has returned to normal values, occasional large and bizarre platelets can be seen in the blood films of many splenectomized subjects. Their presence suggests that these particular platelets are normally removed by the spleen.

Immunological effects

The spleen plays an important role in immunoglobulin synthesis; a fall in the IgM fraction of the serum immunoglobulins is commonly found after splenectomy. IgG levels do not change while IgA and IgE increase. The removal of an organ with a unique ability to recognize and phagocytose circulating particulate antigens would be expected to have serious consequences. Despite this, splenectomy in adults without complicating disease is not usually associated with a substantially increased incidence of infection. It must be assumed therefore that an increase in activity of other lymphoreticular organs compensates for any defects in the immunological defence mechanisms that result from this operation.

Introduction

Cancer is proving to be more complex and molecularly diverse than we ever imagined, yet the present era is one of optimism that its conquest may be approaching. This apparent oxymoron has come about as a result of dramatic advances in our understanding of carcinogenesis, many derived from research into the pathogenesis of haematological malignancies.

The standard model of leukaemogenesis posits the stepwise acquisition of genetic mutations in a susceptible cell and its progeny, leading to the development of an autonomous clone that expands enough to cause a clinical syndrome. The phenotype of the resulting malignancy is dependent on the nature of the specific mutations and the ontogeny of the host cells. The crux of this model remains largely unchallenged, although the discovery of identical mutations in phenotypically diverse malignancies and the flexibility of the leukaemic stem cell compartment have added new layers of complexity.

This chapter describes the basic concepts of leukaemogenesis and then discusses the types of oncogenic mutations encountered in leukaemia and lymphoma before reviewing selected groups of mutant genes and pathways.

Basic concepts in leukaemogenesis

Genes and environment

Most haematological malignancies are sporadic and not attributable to identifiable genetic or environmental risk factors. Nevertheless, the risk of developing these neoplasms is higher in individuals with certain uncommon inherited syndromes, in those exposed to specific environmental agents and in people with acquired preleukaemic disorders (Table 21.1).

Genetic predisposition to cancer operates through inherited genetic variants that are either oncogenic themselves or which accelerate the rate of acquisition of somatic oncogenic mutations. Although uncommon among haematological malignancies, familial cases can offer important insights into the pathogenesis of these neoplasms. Familial acute myeloid leukaemia (AML), albeit very rare, is one of the better understood forms of familial haematological malignancies. In particular, mutations in the haemopoietic transcription factor genes *RUNX1* and *CEBPA* have been identified in rare families with incompletely penetrant autosomal dominant AML syndromes. *RUNX1* mutations are associated with familial platelet syndrome with predisposition to AML, and *CEBPA* mutations with isolated AML. Somatic mutations in *RUNX1* and *CEBPA* are well known to occur in sporadic AML, but their occurrence in familial cases offers strong additional evidence of their leukaemogenic pedigree and argues that although not sufficient to cause AML, they have a primary role in its pathogenesis. Recent dramatic advances in sequencing and genomic technologies are

likely to identify the molecular lesions behind many other forms of familial haematological neoplasms and this is in turn likely to inform our understanding of the sporadic forms of these diseases.

Clonality

Studies of haematological malignancies have been instrumental in establishing the clonal nature of cancer. Three main lines of evidence serve to establish the fact that haematological malignancies are clonally derived from a single ancestral cell.

First, in nearly all lymphoproliferative disorders the malignant cells carry a unique rearrangement in their immunoglobulin or T-cell receptor (TCR) genes. In contrast, proliferating normal lymphocytes show polyclonal and therefore diverse pat-

terns of antigen receptor rearrangements, each with a different antigenic specificity. This offers strong evidence for a clonal origin of lymphoid malignancies and suggests that clonal expansion occurs after antigen receptor rearrangement has been completed.

Second, acquired cytogenetic abnormalities that arise during the development of a malignancy are usually found in all cells of the clone. These microscopically visible clonal markers do not only offer further support to the concept of clonality but in most cases also harbour causative mutations. This is exemplified by the original paradigm, the Philadelphia (Ph) chromosome.

Third, studies of X-chromosome inactivation patterns (XCIPs) in female patients offer a distinct type of evidence in support of clonality. X-inactivation is the physiological process of random inactivation of either the maternal or the paternal X chromosome in all cells of the early female embryo. Once this pattern is set in a cell, it remains fixed in all its subsequent progeny. As a result, normal adult female tissues are mosaics composed, in approximately equal numbers, of cells with one or other X chromosome inactivated. In contrast, neoplastic cells, being derived from a single cell, all have the same X chromosome inactivated and therefore exhibit clonal XCIP, a feature that can be determined by standard molecular tests. One caveat in interpreting apparently clonal XCIPs is that they can sometimes be due to a phenomenon known as skewing. Acquired skewing is thought to arise with advancing age in some normal females as a result of a proliferative difference between cells with one X chromosome inactivated over those with the other (Figure 21.1). This phenomenon can limit the utility of XCIPs as a clonality marker in clinical diagnosis.

Establishing that cancers are clones derived from a single cell sets the framework for understanding carcinogenesis. The next question that needs to be addressed is how a single cell is able to overcome physiological checks to produce a progeny of trillions of cells and what factors dictate the nature of that progeny and by extension its clinical phenotype.

Clonal evolution

Carcinogenesis starts with the acquisition of an advantageous mutation in a single cell through which the cell enters a pre-malignant phase. Somatic mutations happen at a set frequency in adult cells and although most of them have no biological effects, some do. It is axiomatic that these mutations lead the host cell down the path of carcinogenesis, but it is also firmly established that entering this process does not inevitably lead to cancer.

The process that follows the acquisition of the first precancerous mutation has often been thought to represent a cellular equivalent of Darwinian evolution and recent scientific advances offer support to this dictum. Current evidence suggests that the founding cell establishes a small clonal progeny that remains fairly stable in size until one of its cells acquires an additional

Figure 21.1 X-inactivation and clonality. Both the paternal (Xp or P) and maternal (Xm or M) X chromosomes are active in cells of the early female embryo. However, during the early blastocyst phase, each cell inactivates one or other X chromosome at random. As a result approximately half the cells will have an active Xp (light blue) and half an active Xm (pink). Normally this is followed by symmetrical cell divisions such that this polyclonal population of cells is maintained during life. In some females, one of the two populations of cells slowly outgrows the other as a result of genetic differences between their active X chromosome leading to a skewed population. Alternatively, a single cell (dark blue) acquires an advantageous or cancerous mutation and produces a monoclonal population of cells that outgrows both types of normal cells.

advantageous mutation and establishes a new subclone that expands more aggressively than the original. This *clonal evolution* continues with further subclones emerging harbouring mutations that accelerate their growth, often at the expense of their ability to function normally (Figure 21.2). Eventually, a ‘visible’ clone emerges whose clinical manifestations are determined by its cellular phenotype, in turn dictated by the nature of the host cell, the type of somatic mutations, or both.

Recent scientific developments, particularly those pertaining to the systematic study of cancer genomes, are revealing that different types of cancer harbour mutations in characteristic combinations of cellular pathways. Mutations in genes within each of these pathways are thought to represent the steps taken during clonal evolution. However, two important aspects of the process remain incompletely understood: first, which cell types within a tissue are susceptible to malignant transformation and, second, whether the mutations are acquired in a specific order or not.

Leukaemia stem cells

Several lines of experimental data suggest that a variable proportion of cells in a given cancer are more primitive compared with the bulk of tumour cells and demonstrate stem cell properties, i.e. self-renewal and differentiation, as well as tumour-initiating properties.

Myeloid malignancies

The similarities between normal and cancer stem cells led scientists to propose that normal stem cells are the cellular targets of cancerous mutations. In this context, oncogenic mutations exploit the self-renewal properties of a normal stem cell to turn it into a cancer-initiating cell. Studies of myeloid malignancies were the first to give credence to this theory beginning with the demonstration that the *BCR-ABL1* fusion gene could be detected in cells of several different lineages, suggesting that the transformed cell had stem cell properties. Subsequently, studies

Figure 21.2 Clonal evolution in cancer. The process starts with the acquisition of an advantageous somatic mutation in a single cell (*). Subsequently, the progeny of this cell acquire additional mutations in a stepwise manner that increase their survival advantage leading to enlarging clone sizes until an overtly malignant clone emerges. It is worth noting that the majority of somatic mutations do not give cells any survival advantage and only those that do so are depicted here.

of AML went on to show that blast cells with an immunophenotype similar to that of haemopoietic stem cells (HSCs) could act as leukaemia stem cells (LSCs), while slightly more mature cells could not.

However, the theory that HSCs are the unique hosts of leukaemogenic mutations has recently been challenged with the demonstration that some mutations have the ability to transform maturing haemopoietic progenitors into LSCs (Figure 21.3). It is also worth noting that the ability to impart 'stemness' is not unique to such oncogenes or to haemopoietic cells. In fact the most striking example of dedifferentiation is the recent demonstration that, after the transient ectopic expression of as few as three key normal genes, mature skin fibroblasts can be transformed into induced pluripotent stem cells capable of differentiation to all normal lineages.

Lymphoid malignancies

Unlike many other cancers, mature lymphoid malignancies do not appear to result from transformation of normal stem cells. In contrast, it appears that these malignancies routinely arise in maturing lymphoid cells and that oncogenic mutations such as chromosomal translocations are often attributable to errors made during antigen receptor rearrangement. During normal B-cell development, the immunoglobulin heavy chain (*IGH*) locus undergoes sequential V(D)J recombination, somatic hypermutation and class switching. Therefore, in B-cell malignancies, the timing of an associated translocation can be inferred

Figure 21.3 Leukaemia stem cells and oncogenes. Oncogenes such as the *BCR-ABL* fusion gene are able to transform normal haemopoietic stem cells (HSC) to leukaemia stem cells (LSC). Strikingly, some other fusion oncogenes, such as the acute

leukaemia oncogenes *MOZ-TIF2* and fusions involving the *MLL* gene, are not only able to transform HSCs to LSCs, but are also able to transform committed progenitors to LSCs.

from analysis of the immunoglobulin locus adjacent to the breakpoint.

The cell of origin for mantle cell lymphomas and follicular lymphomas may well be a pre-germinal or germinal centre B cell undergoing immunoglobulin gene rearrangement. The breakpoints of the t(11;14) and t(14;18) translocations tend to occur between the D and J segments of the *IGH* locus, suggesting that they arise from mistakes in DJ recombination. In Burkitt lymphoma, the *c-MYC* gene is frequently juxtaposed with a fully V(D)J rearranged and hypermutated *IGH* variable region in the t(8;14) translocation. Breakpoints are found clustered in the VJ sequences that are particular targets for somatic hypermutation, suggesting that the double-stranded DNA breaks that occur during hypermutation may cause the translocations. Class switch recombination appears to be responsible for many of the translocations that occur in multiple myeloma, because the breakpoints are found in immunoglobulin heavy-chain switch regions (Figure 21.4).

These observations provide evidence that the translocations associated with different B-cell malignancies occur at distinct times within B-cell ontogeny. However, two caveats should be emphasized. First, *IGH* translocations may not represent initiating events. It remains formally possible that an unknown earlier lesion precedes the translocation and occurs in a more primitive cell. Second, transformed cells undergo partial differentiation even after acquiring an *IGH* translocation. For example, follicular lymphoma cells have both the histological appearances and gene expression signatures of germinal centre cells. For this continued differentiation to occur, the pre-germinal centre cell with the t(14;18) translocation must have been able to participate in an antigen-driven germinal centre response. Consistent with this idea, there is evidence that somatic hypermutation can occur within the tumour clone.

Finally, despite their likely origin in maturing cells, at least some of these lymphoid malignancies also appear to harbour cancer stem cell compartments. This has been very clearly dem-

onstrated for multiple myeloma but may also be true of other lymphoid disorders.

The existence of leukaemic stem cells has significant implications for the treatment of malignant haematological disorders. A curative strategy must eliminate all malignant cells with the ability to self-renew and hence the capacity to re-establish the malignancy. Moreover, like their normal counterparts, a fraction of leukaemic stem cells reside within the G₀/G₁ phase of the cell cycle so that many conventional cell treatments are not able to eliminate them.

Phenotype–genotype correlations

A conspicuous feature of haematological malignancies is the close relationship between certain cytogenetic or molecular abnormalities and unique morphological and clinical features. For example, the cells of Burkitt lymphoma are characterized by a very distinctive morphological appearance and are almost universally associated with translocations involving the *MYC* gene. Similarly, acute myelomonocytic leukaemia with abnormal eosinophil precursors (AML M4Eo) is strongly associated with the inv(16) abnormality and acute promyelocytic leukaemia (APL) with the *PML–RARA* fusion gene. Furthermore, many myeloproliferative disorders are specifically connected to particular tyrosine kinase mutations, as is the case for systemic mastocytosis and KIT Asp816Val (*KIT* D816V), eosinophilic leukaemia and *FIP1L1–PDGFRA*, and others (discussed later in this chapter).

There are two potential mechanisms for such associations: first, that the nature of the mutation may determine the phenotype of the resultant leukaemia/lymphoma or, second, that a specific chromosome rearrangement may only provide a selective advantage for progenitor cells committed to a particular lineage. In fact it appears that the former model is operative in many myeloid disorders where targeting of the same or similar stem/progenitor cell leads to different disorders depend-

Figure 21.4 The cellular origin of B-cell malignancies. Normal B-cell maturation involves rearrangement and class switching of the immunoglobulin genes. Mistakes occurring during these

DNA recombination events can result in chromosomal translocations. Analysis of sequences adjacent to the translocation breakpoints identifies the cell of origin of the translocation.

ing on the nature of the mutation. It is interesting to note, for example, that in systemic mastocytosis the KIT Asp816Val can be detected in cells other than mast cells (e.g. neutrophils), yet it is mast cells that are dramatically increased in number and that generate the clinical features. In contrast, several translocations involving the *IGH* or TCR loci are restricted to lymphoid tumours because sequences adjacent to the oncogenes mimic sequences involved in *IGH* rearrangement and are thus subjected to erroneous DNA recombination events. The translocations may therefore only occur in cells at particular stages of lymphoid differentiation. Another fact relevant to the ontogeny of lymphoid tumours is that lymphoid cells uniquely harbour very potent regulatory elements driving the expression of immunoglobulin loci, which can be recruited by oncogenes as a result of chromosomal rearrangements. This limits the type of oncogenes that can exploit this mechanism to those genes that can transform cells by overexpression, rather than those that need to be activated by other types of mutation such as point mutation or formation of a fusion gene (see later).

Types of somatic mutations

Cancer is a product of somatic mutations, which can be large-scale (e.g. chromosomal translocations, inversions and numerical aberrations) or small-scale (e.g. point mutations, microdeletions and epigenetic changes).

Chromosomal translocations

Chromosomal translocations are probably the most extensively studied genetic abnormalities in haematological malignancies. Balanced translocations involve a reciprocal exchange of genetic material between two chromosomes and may result in aberrant function of genes adjacent to the breakpoint. Two common mechanisms have been described (Figure 21.5).

First, a fusion gene may be generated encoding a fusion protein with oncogenic properties. This mechanism is seen in many of the translocations associated with myeloid malignancies and some associated with acute lymphoblastic leukaemia (ALL). Fusion genes can also result from interstitial deletions (such as deletion of chromosome 4 giving rise to the *FIP1L1-PDGFR*A fusion gene in chronic eosinophilic leukaemia) or intrachromosomal inversions (such as inversion 16 in AML M4Eo). Fusion proteins contain a combination of functional modules donated by the two partner proteins. As a consequence, the fusion protein is endowed with novel functions. For example, in fusion proteins that involve a tyrosine kinase, the partner protein contributes a homotypic interaction domain that leads to spontaneous dimerization or oligomerization of

Figure 21.5 Common mechanisms of gene activation by chromosomal translocations: (i) formation of a chimeric gene by fusion of the two genes spanning the chromosomal breakpoints; and (ii) overexpression of an intact gene through the action of a potent enhancer translocated upstream.

the fusion protein, thus resulting in constitutive activation of the kinase moiety (discussed later in this chapter).

The second category of translocations results in a structurally intact gene being placed next to regulatory elements from a gene on the partner chromosome. This scenario is frequently observed in lymphoid malignancies in which a malfunction in the normal process of antigen receptor rearrangement results in translocations involving immunoglobulin or TCR loci. For example, in some B-cell tumours, genes such as *MYC* and *BCL2* are aberrantly expressed in B-cell precursors because they have been placed under the control of the strong enhancers of one of the immunoglobulin loci. Similarly, in some cases of T-cell ALL (T-ALL), the *SCL* (*TAL1*) and *HOX11* (*TLX1*) genes are ectopically expressed in T-cell precursors as a result of translocating next to enhancers from the TCR loci. Transcriptional dysregulation can also occur as a consequence of deletions, such as chromosome 1 deletions resulting in dysregulation of the *SCL* gene in T-ALL.

Balanced translocations give rise to two abnormal derivative chromosomes, one of which usually harbours the main pathogenic event, although the other may also have a role. For example, in chronic myeloid leukaemia (CML) associated with t(9;22), it is clear that the Ph (derivative 22) chromosome carries the *BCR-ABL1* fusion gene, which is central to the development of this leukaemia. However, in a subset of patients, the

derivative 9 chromosome also carries a deletion adjacent to the translocation breakpoints. These deletions arise at the time of the Ph translocation and are associated with a poor prognosis, perhaps reflecting the loss of one or more tumour-suppressor genes.

Similarly, in APL, t(15;17) results in the production of a *PML-RARA* fusion transcript from the derivative 15 chromosome and considerable evidence supports a pivotal role for this transcript in leukaemogenesis. However, in 70–80% of patients, the derivative 17 chromosome also expresses a *RARA-PML* transcript, which encodes a fusion protein with p53-binding domains that influences the development of leukaemia in a mouse model.

What causes translocations to occur in the first instance? In the case of lymphoid tumours, genomic rearrangements and (hyper)mutation are features of normal lymphocyte development. Normal rearrangements of the immunoglobulin and TCR genes require a series of double-strand DNA breaks, with loss of intervening sequences and religation. Oncogenic translocations are likely to represent rare mistakes that arise during this process and there may be several reasons why certain genes are preferentially involved in these translocations. First, motifs similar to those recognized by the immunoglobulin or TCR recombinase have been found adjacent to the *BCL2* and *SCL* genes, which are involved respectively in the t(14;18) translocation of follicular lymphoma and the t(1;14) translocation associated with T-ALL. Second, it is probable that there are only a limited number of genes that, when dysregulated, can transform lymphoid progenitors. Third, physical proximity may play a role, as genes such as *MYC*, *BCL1* and immunoglobulin loci, which are recurrently involved in B-lymphoid translocations, are preferentially positioned in close physical proximity relative to each other in normal B-cell interphase nuclei.

For most myeloid malignancies, the mechanism of translocation is poorly understood. However, double-strand breaks in genomic DNA are thought to be essential and although these can occur spontaneously, their frequency is increased by exposure to ionizing radiation and other DNA-damaging agents known to increase the risk of leukaemia. Normal repair mechanisms, such as homologous recombination or non-homologous end joining, are then recruited to join the broken ends of DNA. However, these mechanisms are not infallible, and it is conceivable that they could misrepair two simultaneous breaks on different chromosomes to generate a translocation. Germline mutations in DNA repair genes (such as Bloom syndrome, Fanconi anaemia and ataxia telangiectasia genes) increase the frequency of chromosome rearrangements as well as the incidence of many cancers, including haemopoietic ones. It may also be relevant that Alu repeat sequences appear to cluster at or near translocation breakpoints in CML and other malignancies, as it has been suggested that the Alu core sequence acts as a binding site for proteins mediating homologous recombination and DNA repair.

Consensus sites for topoisomerase II binding may play a role in some translocations, particularly those involving the *MLL* locus. Topoisomerase inhibitors, such as etoposide and anthracyclines, are well-recognized causes of therapy-related leukaemia, often associated with translocations involving the *MLL* gene on chromosome 11q23. Topoisomerase II creates double-strand breaks during execution of its function of relaxing overwound DNA, and it appears that topoisomerase II inhibitors may stabilize complexes that are formed between the enzyme and free DNA ends, thus increasing the likelihood that those ends might participate in a translocation. It remains controversial whether naturally occurring topoisomerase II inhibitors have any role in infant or childhood leukaemia.

Large deletions and aneuploidy

Chromosome deletions and disorders of chromosome number (aneuploidy) are frequently seen in haematological malignancies. It is thought that quantitative chromosomal changes of this sort contribute to tumorigenesis by altering the expression levels of key oncogenes or tumour-suppressor genes. However, it is likely that in many cases such chromosomal changes may not be directly pathogenic in themselves, but simply a consequence of genomic instability.

Hyperdiploidy is the most frequent cytogenetic abnormality in childhood ALL and can involve any chromosome; thus it may not have a specific pathogenetic function in this disease. Trisomy 8 is the most common numerical abnormality of clonal myeloid disorders and can be seen in AML, myelodysplasia and myeloproliferative disorders. It has been shown that trisomy 8 is associated with increased expression of chromosome 8 genes, but it is not known which, if any, of these genes may have a pathogenetic role.

Cytogenetically visible chromosomal deletions are large and frequently involve several megabases encompassing numerous genes. Identifying the relevant molecular consequences of a deletion is therefore difficult. Classic studies of retinoblastoma demonstrated that deletions act to remove the second copy of the tumour-suppressor gene *RBI*, the other allele of which was inactivated by mutation. This *two-hit model* operates for different tumour-suppressor genes in several solid tumours and may also apply to a subgroup of mantle cell lymphoma, in which 11q deletions remove one copy of the *ATM* gene in up to 50% of cases. The remaining *ATM* allele carries inactivating mutations in virtually all such cases, revealing the key role of inactivating both copies of the gene in this disease.

However, the two-hit model does not apply to many of the deletions associated with haematological malignancies. An alternative model was recently shown to operate in the myelodysplastic 5q- syndrome, where previous studies had failed to identify biallelic inactivation of any of the 40 or so genes within the common deleted region (CDR, the minimal region that is deleted in all cases). Recent advances show that loss of just one

copy of the CDR gene *RPS14* may be responsible for many of the features of his disease, while other features may be secondary to the loss of two non-coding microRNAs also within the CDR. The finding that loss of one copy of a gene can be sufficient to affect cellular behaviour is termed *haploinsufficiency*. Additionally, this example suggests that it may be necessary for a deletion to remove more than one critical target gene in order to exert its full tumorigenic effect. Indeed, different combinations of critical genes may be removed by overlapping deletions of varying sizes that affect a similar genomic region.

Submicroscopic mutations

Much of our initial understanding of the molecular pathogenesis of haematological malignancies came from studies of cytogenetically visible chromosomal abnormalities. However, it has since become clear that submicroscopic mutations also play a similarly critical role in many malignancies. Small-scale mutations such as small deletions can disrupt two or more genes; however, most mutations in this group affect single genes by disrupting their coding sequence, which in turn enhances, attenuates or entirely alters the function of the coded protein. Many of these mutations have been described, but it is widely agreed that many examples are yet to be identified.

Activating mutations commonly involve oncogenes encoding tyrosine kinases and members of the RAS pathway and are usually missense mutations or tandem duplications. For example, around 90% of cases of systemic mastocytosis, particularly those with bone marrow involvement, have an activating point mutation in the *KIT* (*c-KIT*) gene, most frequently Asp816Val. This mutation replaces aspartate with the hydrophobic residue valine in the activation loop of the kinase domain of KIT, leading to activation of its kinase activity. *FLT3*, which encodes another receptor tyrosine kinase, is activated by internal tandem duplications, which are seen in 20% of cases of AML. Although the length of DNA duplicated varies, it is always transcribed in-frame and leads to constitutive activation of the kinase, conferring a growth advantage to the cells and translating into a poor prognosis for the patient. In a further 7% of AMLs, constitutive activation of *FLT3* occurs through a single amino acid substitution of Asp835 for a hydrophobic residue, analogous to the *KIT* mutations in systemic mastocytosis.

Activating mutations in genes of the RAS family, comprising the highly homologous proto-oncogenes *HRAS*, *KRAS* and *NRAS*, are among the commonest somatic aberrations in human cancers of all cell types. Up to 20% of all cancers, including haemopoietic malignancies, have mutations in a RAS family member, most commonly *KRAS* or *NRAS*. The RAS family members are critical components of multiple signal transduction networks, especially those that transmit extracellular growth signals to the nucleus. Oncogenic mutations, such as Gly12Val, render the GTPase domain of RAS insensitive to inactivation signals and thus the protein is stuck in a perma-

nent 'on' state and generates a constitutive growth signal. Several related genes such as *BRAF*, as well as genes belonging to related signalling pathways such as *NF1*, are also targets of carcinogenic mutations. As a result the pathway is being targeted by rationally designed drugs, albeit with limited success so far.

Inactivating point mutations are less commonly seen than is the case for solid tumours. Nevertheless, important cell cycle regulators such as the p53 and retinoblastoma genes are not infrequently inactivated by mutation in lymphomas. However, these are thought to be secondary events, occurring during clinical progression and their presence usually correlates with poor prognosis, transformation to higher-grade disease and/or drug resistance. While such tumour-suppressor genes generally require biallelic inactivation to promote tumorigenesis, heterozygous inactivating point mutations of the *CEBPA* gene encoding the transcription factor C/EBP α are found in 20% of cases of M2 AML. Within the haemopoietic system, this gene is expressed exclusively in, and is critical to, the differentiation of myelomonocytic cells. The mutation leads to truncation of the normal protein, but allows the translation of a smaller protein initiated downstream of the mutation. The smaller protein then acts in a *dominant-negative* manner to block the function of the wild-type protein translated from the intact allele, leading to a differentiation block in myelomonocytic cells. Hence, although heterozygous, mutations of this sort can be functionally equivalent to homozygous loss-of-function mutations.

Finally, some mutations appear to alter the function of their target gene/protein in a way which cannot be described as activating or inactivating. Perhaps the best examples of this are mutations in the gene for nucleophosmin (*NPM1*), which are usually in the form of a 4-nucleotide duplication/insertion within its last exon. This leads to a frameshift in the mRNA code and the creation of a novel 13-amino-acid sequence at the C-terminal of the protein. This novel sequence behaves as a nuclear export signal and transforms nucleophosmin from a mainly nucleolar protein to a principally cytoplasmic protein. It is not clear how this leads to leukaemogenesis, but it may be partly due to novel actions of the displaced protein within the cytoplasm or codisplacement of other proteins bound to nucleophosmin out of the nucleus.

Epigenetic effects

In a normal cell, epigenetic mechanisms control several important functions including gene transcription, DNA replication, imprinting and X-inactivation. Somatically acquired epigenetic changes affecting these processes can, without altering nucleotide sequence, alter gene expression and thus have a role in tumorigenesis just as genetic mutations can.

Methylation of DNA sequences within regions involved in the regulation of gene expression is generally associated with transcriptional silencing of the associated genes. Disordered

patterns of DNA methylation have been found in a wide variety of haematological malignancies. For example, there is global genomic hypomethylation in chronic lymphocytic leukaemia (CLL) lymphocytes and AML blasts compared with normal haemopoietic cells. In addition, certain candidate genes implicated in neoplasia can be either hypermethylated or hypomethylated compared with their status in normal cells. DNA hypomethylation has been identified at a number of loci implicated in haematological malignancies, including *BCL2* in CLL, *LTA* (the gene encoding tumour necrosis factor β) in CML and AML, and others. Given that hypomethylation generally promotes transcriptional activity, it can cause overexpression of these oncogenes, as has been shown for *BCL2*. Conversely, DNA hypermethylation of several tumour-suppressor genes, such as *p16INK4A* (also called *CDKN2A*), E-cadherin (*CDH1*) and *HIC1*, has been described in CLL and AML, as has hypermethylation of *SOCS1*, an inhibitor of cytokine signalling in many malignancies including AML, CML, myelodysplastic syndrome, lymphoma and myeloma.

It is therefore clear that, as in other cancers, epigenetic modifications are widespread in haematological malignancies. However, most are unlikely to represent initiating lesions and probably reflect downstream consequences of genetic changes. Nonetheless, they still represent pertinent targets for therapeutic intervention, as reflected in the effectiveness of the DNA methyltransferase inhibitor 5-azacytidine and its analogue decitabine in myelodysplastic syndromes.

Molecular basis of malignant transformation

This section illustrates the mechanisms by which acquired genetic changes may result in malignancy. Four specific examples have been chosen to illustrate how distinct cellular processes may be corrupted: tyrosine kinase signalling (the myeloproliferative disorders); intracellular signal transduction (juvenile myelomonocytic leukaemia); regulation of gene transcription (AML); cell cycle control and apoptosis (mantle cell and follicular lymphomas).

Tyrosine kinases and myeloproliferative disorders

Tyrosine kinases are critical for the response of haemopoietic progenitor cells to external growth stimuli. The binding of a ligand to the extracellular surface of a receptor tyrosine kinase (RTK) promotes receptor dimerization, which in turn stimulates autophosphorylation of specific tyrosine residues within the intracellular aspect of the protein. The dimerization and the associated increase in kinase activity result in recruitment of effector molecules and activation of downstream signalling

pathways. Many cytoplasmic tyrosine kinases are also thought to be activated by phosphorylation and dimerization.

Individual myeloproliferative disorders are specifically associated with activation of different tyrosine kinases (Figure 21.6). In some of these diseases, activation of the tyrosine kinase stems from formation of a fusion protein, which undergoes spontaneous dimerization (Figure 21.7a). However, kinase activity can also be increased by more subtle mutations (e.g. *JAK2* Val617Phe in polycythaemia vera and *KIT* Asp816Val in systemic mastocytosis). As a consequence of these changes, the corresponding signalling pathway is activated and this provides the transformed cell with a proliferative or survival advantage.

In CML, the *BCR* gene becomes fused in-frame with the *ABL1* tyrosine kinase gene as a consequence of the Ph translocation (Figure 21.7b). This usually results in the formation of a fusion protein of 210kDa (hence p210^{BCR-ABL}). The fusion protein affects multiple different cellular processes, including intracellular signalling, apoptosis, transcriptional regulation and cellular adhesion. Transgenic mouse models have demonstrated that *BCR-ABL* is capable of inducing dramatic expansion of myeloid precursors *in vivo* and can produce a phenotype that resembles the human form of the disease.

Several critical domains in the fusion protein have been mapped, and have provided important insights into its biological activity (Figure 21.7b). The coiled-coil domain of the BCR protein provides a dimerization motif, which promotes spontaneous BCR-ABL1 dimerization leading to constitutive ABL kinase activity. Other domains implicated in oncogenicity are the SH2 domain and the C-terminal actin-binding domain, both in the ABL1 portion; these domains appear to be important for interaction with regulatory molecules and subcellular localization of the fusion protein. Numerous downstream pathways are activated by the BCR-ABL1 protein, including the RAS, phosphatidylinositol 3-kinase, STAT and MAP kinase signalling cascades. The breadth of the pathways perturbed explains the protean effects of the fusion protein. For example, activation of the RAS pathway is thought to contribute to the increased cell division and proliferation seen in CML cells; altered interaction with the actin cytoskeleton and adhesion complexes may underlie the diminished adhesion to inhibitory bone marrow stromal cells; and STAT5-dependent upregulation of BCL-XL is implicated in the reduced apoptosis of CML progenitors.

As shown in Figure 21.7b, two other versions of the BCR-ABL1 protein exist in which the breakpoint occurs in different introns of the *BCR* gene than that usually seen in CML. The smaller protein, p190^{BCR-ABL}, is found in Ph-positive ALL and has a higher level of constitutive tyrosine kinase activity than the p210^{BCR-ABL} protein. This is thought to contribute to the more aggressive behaviour of the ALL. A p230^{BCR-ABL} isoform is also found rarely in patients with CML. In some cases, it is associated with a morphological picture resembling chronic neutrophilic leukaemia and possibly a lower rate of blast trans-

Figure 21.6 Tyrosine kinase mutations in the myeloproliferative disorders. Each disease is associated with a specific activating mutation in a tyrosine kinase gene and this leads to preferential expansion of specific haemopoietic cell progeny. CEL, chronic

eosinophilic leukaemia; CML, chronic myeloid leukaemia; CMML, chronic myelomonocytic leukaemia; ET, essential thrombocythaemia HSC, haemopoietic stem cell; PV, polycythaemia vera; SM, systemic mastocytosis.

formation. These variants illustrate how small structural differences in a fusion protein can cause significant differences in disease phenotype.

A group of related tyrosine kinase fusion genes (*PDGFRA*, *PDGFRB* and *FGFR1*) are associated with eosinophilic myeloproliferative disorders. A striking feature of these syndromes is the large number of fusion partners for these kinases, with eight partners currently known for *FGFR1*, six for *PDGFRA* and 17 for *PDGFRB*. As with *BCR* in *BCR-ABL*, most of these partners harbour dimerization domains that facilitate constitutive activation of the tyrosine kinase. However, reflecting their molecular heterogeneity, these disorders exhibit significant clinical diversity. For example, cases associated with the *FIP1L1-PDGFR α* fusion exhibit marked eosinophilia, while those associated with *ETV6-PDGFRB* often show dysplastic features and a lesser degree of eosinophilia. Additionally, cases involving *FGFR1*, collectively known as the 8p11 myelo-

proliferative syndrome, are usually associated with a coexisting non-Hodgkin lymphoma. Notably, cases associated with rearrangements of the *PDGFR* genes respond well to imatinib, while those associated with *FGFR1* fusions do not.

RAS family signalling and juvenile myelomonocytic leukaemia

Juvenile myelomonocytic leukaemia (JMML) is a rare disorder of childhood characterized by a marked expansion of both myeloid and monocytic lineages, with varying degrees of dysplasia and exquisite sensitivity to granulocyte/macrophage colony-stimulating factor (GM-CSF) in colony assays. These features reflect the fact that components of the GM-CSF receptor signalling pathway are frequently mutated in JMML (Figure 21.8).

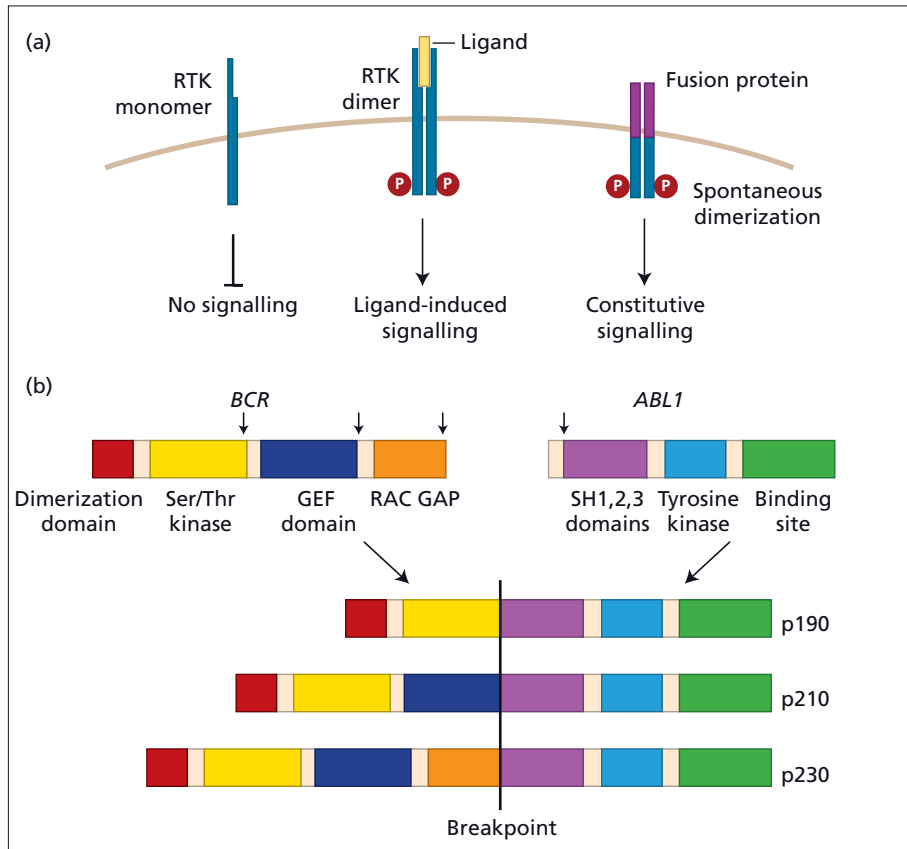

Figure 21.7 Fusion tyrosine kinases. (a) In normal cells, receptor tyrosine kinases (RTK) exist as inactive monomers which, upon ligand binding, become activated by dimerization and autophosphorylation. In contrast fusion tyrosine kinases dimerize spontaneously and are constitutively active. (b) Different forms of *BCR-ABL1* fusion genes containing varying lengths of *BCR* as a result of different breakpoints (arrowheads). These are associated with different molecular effects (see text).

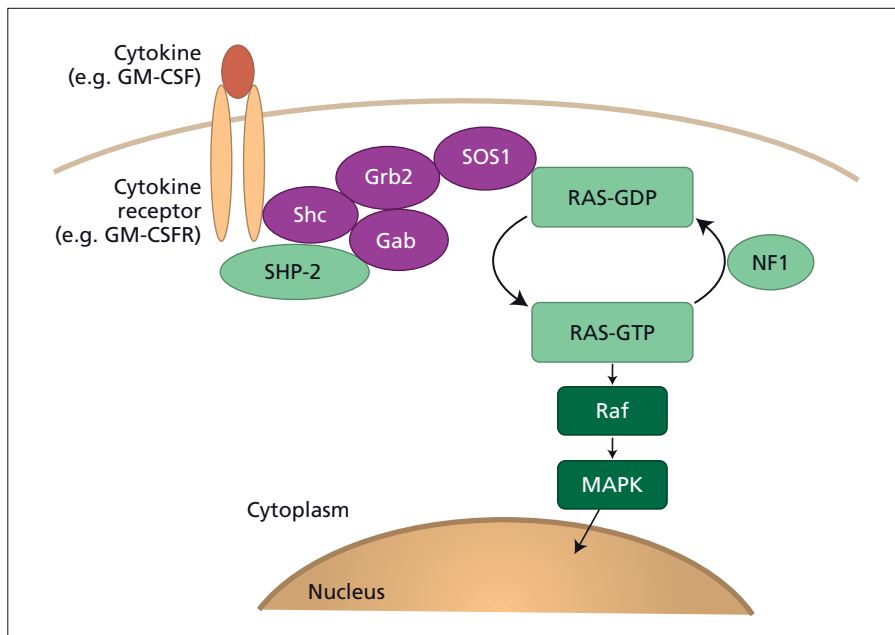

Figure 21.8 The RAS pathway and juvenile myelomonocytic leukaemia (JMML). The Ras pathway mediates many of the downstream effects of cytokine receptor activation. In most cases of JMML, the pathway is activated by mutations in one of three genes depicted in black text: *PTPN11*, the gene coding for the protein SHP-2 (35% of cases), *RAS* (25% of cases) or *NF1* (15% of cases). As a result JMML cells are extremely sensitive to GM-CSF.

Mutations in the *NRAS* or *KRAS* genes are seen in many haematological malignancies, including AML, myelodysplastic syndrome and chronic myelomonocytic leukaemia, especially in subtypes with a monocytic component. Analyses of samples from patients with JMML show point mutations in *NRAS* and *KRAS* in approximately 25% of cases. The point mutations cause single amino acid substitutions, which result in constitutively active forms of the protein and thus mimic markedly amplified signalling from the GM-CSF receptor.

The neurofibromin (*NF1*) gene is also a target for mutations in JMML, but in this case the result is loss of NF1 activity. The incidence of JMML is increased in neurofibromatosis type 1, an autosomal dominant disorder caused by inactivating mutations in the *NF1* gene. This gene encodes a protein that directly interacts with, and inhibits the activity of, RAS proteins. Patients who have both neurofibromatosis type 1 and JMML have a high frequency (60%) of inactivating mutations of the second *NF1* allele in the leukaemic cells. Furthermore, inactivating *NF1* mutations are found in 15% of sporadic cases of JMML without the clinical syndrome of neurofibromatosis. It appears therefore that *NF1* acts as a tumour-suppressor gene, and that inactivation of both alleles allows unchecked signalling through the RAS pathway.

A similar story holds true for *PTPN11*, the gene that encodes the tyrosine phosphatase SHP2. Germline mutations of this gene can cause a developmental disorder, Noonan syndrome, which is associated with an increased incidence of JMML. Up to 35% of non-syndromic patients with JMML have somatic mutations of *PTPN11* in the leukaemic cells. The mutations all cause amino acid substitutions clustering in the N-terminal SH2 domain of the protein, which are thought to result in enhanced phosphatase activity and activation of the downstream RAS pathway that give the host cells a growth advantage over their normal counterparts.

Thus, within the GM-CSF receptor signalling pathway, activation of an activating component (such as RAS) has the same pathological consequences as inactivation of an inhibitory component (*NF1*). Moreover, the mutations in *RAS*, *NF1* and *PTPN11* are mutually exclusive. In other words, individual patients carry mutations in only one of these genes, suggesting that mutation of just one component is sufficient to activate the signalling pathway and that additional mutations in the pathway offer no further advantage. This phenomenon, of mutations in the same pathway being mutually exclusive in any one tumour, is increasingly recognized for various different pathways in other haematological and solid tumours.

The core-binding factor complex and acute myeloid leukaemia

Genes encoding transcription factors are common targets for rearrangements or mutations in acute leukaemia. Many of these

genes have been found to play important roles in regulating the behaviour of normal haemopoietic stem or progenitor cells, implying that perturbation of normal transcription programmes can be leukaemogenic. Individual transcription factors usually function as part of a multiprotein complex and it has become clear that different components of a given complex may be involved in distinct forms of acute leukaemia.

These principles are exemplified by the core-binding factor (CBF) complex, comprising RUNX1 (also known as AML1 or CBF α) and CBF β . The normal CBF dimer recognizes and binds specific DNA sequences through the RUNX1 subunit and regulates the expression of many genes important for the differentiation of haemopoietic cells, such as interleukin (IL)-3, GM-CSF and the enhancer for immunoglobulin heavy chain (Figure 21.9a). Adjacent binding sequences in the DNA are important for other transcription factors, and it seems that the CBF dimer acts as a transcriptional organizer by recruiting other transcription factors into a large multimeric complex that regulates expression of target genes. Mice lacking RUNX1 have a complete failure of blood formation, confirming its critical importance for normal haemopoiesis.

The genes for the two CBF subunits represent the most commonly involved genes in acute leukaemia translocations, with t(12;21) (*ETV6-RUNX1*) found in 25% of childhood ALL, t(8;21) (*RUNX1-ETO*) in 15% of AML, and inv(16) (*MYH11-CBFB*) in 10% of AML. It appears that the leukaemogenic effects of these fusion genes are mediated in large part through dominant-negative inhibition of CBF function. For example, *in vitro* experiments confirm that binding of wild-type *RUNX1* to gene enhancers is inhibited in the presence of *RUNX1-ETO*. Moreover, mice carrying the *RUNX1-ETO* fusion gene and a wild-type *RUNX1* allele have exactly the same embryonic lethal phenotype as mice completely lacking *RUNX1*.

The mechanisms by which the fusion genes exert their dominant inhibitory effects are beginning to be understood. The fusion partners of the *CBF* genes appear to recruit nuclear corepressor complexes, leading to transcriptional inhibition of target genes. In fact, in the case of the *RUNX1-ETO* fusion, the *ETO* moiety recruits a complex comprising three proteins, NcoR, SIN3 and a histone deacetylase, resulting in histone deacetylation, a change in chromatin structure and target gene repression (Figure 21.9b). Similarly, the CBF β -MYH11 fusion protein of inv(16) forms a complex with the normal RUNX1 subunit through the CBF β moiety, and recruits several transcriptional repressors via the MYH11 component (Figure 21.9c). The end result is similar for both fusion genes, namely transcriptional silencing of genes required for normal differentiation and a consequent maturation arrest.

However, in keeping with the multistep theory of tumorigenesis discussed above, rearrangement of an individual transcription factor gene is not sufficient to give rise to acute leukaemia. Instead, there is mounting evidence for a model in which development of AML requires both a block of differentiation, fre-

Figure 21.9 Core-binding factor gene fusions, transcriptional repression and acute leukaemia. (a) The normal CBF dimer (composed of RUNX1 and CBFβ) binds specific DNA sequences through the RUNX1 subunit and recruits transcriptional activators (TA) that upregulate the expression of many genes important for haemopoietic cell differentiation. (b) In leukaemic cells carrying the *RUNX1-ETO* fusion gene, the ETO moiety

recruits a corepressor complex comprising NcoR, SIN3 and a histone deacetylase (HDAC). This leads to histone deacetylation and inhibition of the expression of haemopoietic differentiation genes. (c) Similarly, the CBFβ–MYH11 fusion binds to normal RUNX1 through its CBFβ moiety and recruits different transcriptional repressors (TR) via MYH11 with analogous effects.

quently provided by subversion of a transcription factor gene (type II mutation), and a proliferative signal, frequently provided by an altered tyrosine kinase (type I mutation). For example, the *FLT3* gene, coding for a receptor tyrosine kinase, is activated in 25% of AML and has been shown to cooperate with *PML-RARA* in a mouse model of APL. In fact most cases of AML harbour both a type I and a type II mutation, and there are several well-characterized examples of both mutation types (Figure 21.10).

Cell cycle control, apoptosis and lymphoma

There is an intimate relationship between the cell cycle and apoptosis. Each phase of the cell cycle is tightly controlled by specific molecular checkpoints, which monitor for DNA damage and mitotic spindle formation before permitting cell cycle pro-

Figure 21.10 Cooperating mutations in acute myeloid leukaemia (AML). The majority of cases of AML harbour at least two types of mutations, a type I mutation which increases proliferation and a type II mutation that blocks haemopoietic differentiation. Some of the most common mutations in each group are listed.

gression. If a checkpoint recognizes damage to the DNA or the mitotic apparatus, this triggers programmed cell death (apoptosis). The enzymes involved in cell cycle control and apoptosis are among the commonest targets of mutation in all cancers, including haematological ones.

Figure 21.11 summarizes some of the main components controlling cell cycle progression and apoptosis, many of which are known to be corrupted in different types of lymphoma. The characteristic chromosomal abnormality associated with mantle cell lymphoma is the t(11;14) translocation, leading to juxtaposition of the cyclin D1 gene (also known as *BCL1*) to an *IGHJ* segment. Cyclin D1 functions in G₁ phase, binding and activating two kinases, CDK4 and CDK6. The cyclin–CDK complex then phosphorylates and inactivates the retinoblastoma (Rb) protein, which is then unable to repress transcription of genes (e.g. E2F) important for the transition to S-phase. Experimental evidence confirms that forced overexpression of cyclin D1 similar to that seen in mantle cell lymphoma leads to a shortened G₁ phase, although overexpression in itself is not sufficient to induce lymphoma in transgenic mice.

Cooperating mutations and epigenetic changes have been found in other genes in the cyclin D1–CDK4–Rb pathway in patients with mantle cell lymphoma. In one study, deletions of

p16INK4A (*CDKN2A*), which codes for an inhibitor of the cyclin D1–CDK4 complex, were seen in 40% of mantle cell lymphomas, and deletions of Rb were present in a further 40% of cases. These additional mutations in genes of the cyclin D1 pathway correlated with markers of active cell proliferation and more aggressive clinical behaviour. Furthermore, epigenetic modifications have been found, such as hypermethylation of *p16INK4A*, which may also reflect gene inactivation. This pattern of several coexisting and synergistic mutations in the same pathway contrasts with the situation in JMML, in which mutations in different components of the RAS–MAP kinase pathway tend to be mutually exclusive. A possible explanation for this discrepancy is that several genes need to be disrupted to overcome the multiple cell cycle checkpoints.

Up to half of all mantle cell lymphomas also exhibit deletions of 11q and the deleted region includes the locus of the *ATM* gene. The *ATM* gene is essential for checkpoint controls at the G₂–M transition in particular, and is activated by double-strand breaks in DNA (Figure 21.11). The remaining *ATM* allele in patients with 11q deletions is almost invariably affected by inactivating mutations, associated with aberrant splicing, truncation or abnormal structure of the protein. Similarly, in the absence of 11q deletions, biallelic point mutations in *ATM* have

Figure 21.11 Apoptosis and cell cycle control in lymphomagenesis. Proliferative signals activate cyclin D1 (cD1 or BCL1), which complexes with and activates the kinases CDK4 and CDK6. The complex then phosphorylates (P) the retinoblastoma protein (pRb), which is then unable to repress cell cycle progression proteins such as E2F. The proteins p16 and p15 antagonize this process by inhibiting CDK4 and CDK6. Another important cell cycle checkpoint involves activation of

ATM signalling secondary to DNA damage. This activates p53, which in turn inhibits cell cycle progression and promotes apoptosis. BCL2 can inhibit the actions of p53 and other apoptotic signals. These genes are frequently mutated in different types of lymphoma (see text). Genes that promote growth are depicted in green and those that inhibit growth or promote apoptosis in red.

been found in mantle cell lymphoma, and patients with a germline mutation in the *ATM* gene (heterozygote carriers for ataxia telangiectasia) have a marked increase in incidence of lymphoma. Taken together, these observations support the hypothesis that *ATM* functions as a tumour-suppressor gene in mantle cell lymphoma.

Follicular lymphoma is characterized by overexpression of the anti-apoptotic protein *BCL2* (Figure 21.11), as a result of translocation t(14;18) in which the *BCL2* gene is placed under control of an *IGH* enhancer. Increased levels of *BCL2* protein protect the lymphoma cells from a range of apoptotic signals, suggesting a model whereby cells do not have a proliferative advantage as such but accumulate through lack of cell death. *BCL2* overexpression also reduces the ability of chemotherapeutic agents to induce apoptosis, and this may explain why it is difficult to cure patients with follicular lymphoma. Transgenic mice in which *BCL2* is placed under the control of an *IGH* enhancer show an accumulation of mature B cells, a propensity to autoimmune diseases and follicular hyperplasia. Malignant lymphomas only develop in these mice after a long latency, and tend to be associated with disruption of other key genes, such as the proto-oncogene *MYC*.

Follicular lymphoma may transform into an aggressive, chemotherapy-resistant, diffuse large B-cell lymphoma. Numerous second hits have been associated with this transformation, and these mutations preferentially involve cell cycle regulators such as those involved in mantle cell and other lymphomas. In particular, deletions involving *p16INK4a* (also called *CDKN2A*) and *p15INK4b* (*CDKN2B*) are found in 70% and mutations in *TP53* (coding for the transcription factor p53) in up to 30% of transformed follicular lymphomas. Presumably these additional mutations confer a proliferation advantage on the cells, resulting in the more aggressive growth.

Summary

Our understanding of the molecular foundations of haematological malignancies has advanced spectacularly in the last two decades. Having established many fundamental principles underpinning leukaemogenesis, we are systematically exposing the key molecular events involved in the process and identifying targets for therapeutic intervention. This progress is steadily transforming the practice of clinical haematology at all levels from diagnosis to treatment and most importantly it is benefiting patients. The introduction of the first molecularly targeted treatments in the form of imatinib for CML and all-*trans* retinoic acid for APL is being followed by the development of an increasing number of therapeutic agents against different dis-

eases and molecular targets. Over the next few years we can expect to witness a revolution in the practice of malignant haematology and hope to harvest the benefits of decades of progress in leukaemia research.

Introduction

The diagnosis of a haematological neoplasm usually starts from a clinical suspicion, although for chronic leukaemias the diagnosis is sometimes an incidental one. A blood count and blood film is an essential first step whenever leukaemia, lymphoma or other haematological neoplasm is suspected. The next step in the diagnostic process depends on the clinical features and the specific condition that is suspected. In this chapter we discuss the laboratory techniques that are available and how they are integrated into an efficient diagnostic pathway (Figure 22.1). It is of crucial importance that all laboratory investigations are done with an awareness of the medical history and physical findings. It is also essential that a conclusion as to diagnosis is based on integrating the results of all laboratory investigations and imaging in the context of the clinical features. Achieving this can be a challenge if investigations are done in different laboratories on different sites. One possible solution, if all procedures are not performed in a single laboratory, is that a haematologist/haematopathologist should take the lead in making a final diagnosis when the diagnosis depends primarily on the blood and bone marrow and that a haematopathologist/histopathologist should take the lead when the diagnosis depends primarily on a biopsy of another tissue. Three important factors contribute to accurate diagnosis:

- 1 the provision of very detailed clinical information to laboratories;
 - 2 the correct sample, e.g. blood or bone marrow aspirate specimen (anticoagulated with EDTA or heparin), blood and bone marrow films, trephine or fine-needle biopsy specimen, should all be sent to the laboratory in the shortest possible time;
 - 3 the integration of information technology across different sites dealing with diagnostic samples from a single patient.
- Consideration should also be given to the need for centralized diagnosis by a panel of experts when experience has shown that misdiagnosis is common, as for example in lymphoma. It is also necessary to ensure that a diagnosis is achieved in a timely manner, particularly when treatment may be urgent, as in acute leukaemias and aggressive lymphomas.

Blood count and blood film

The most important information that must be extracted from the blood count is the white cell count, the haemoglobin concentration and the platelet count. The red cell indices should also be noted since macrocytosis and, less often, microcytosis can occur in haematological neoplasms. The automated instrument will generally provide a differential count and 'flags' indicating the likely presence of blast cells, abnormal lymphocytes or granulocyte precursors. An abnormal total or differential count should always be verified on a blood film and a blood film should also be examined when there are relevant 'flags'. Even if the blood count is normal, a blood film should be examined for the presence of abnormal cells in any patient with

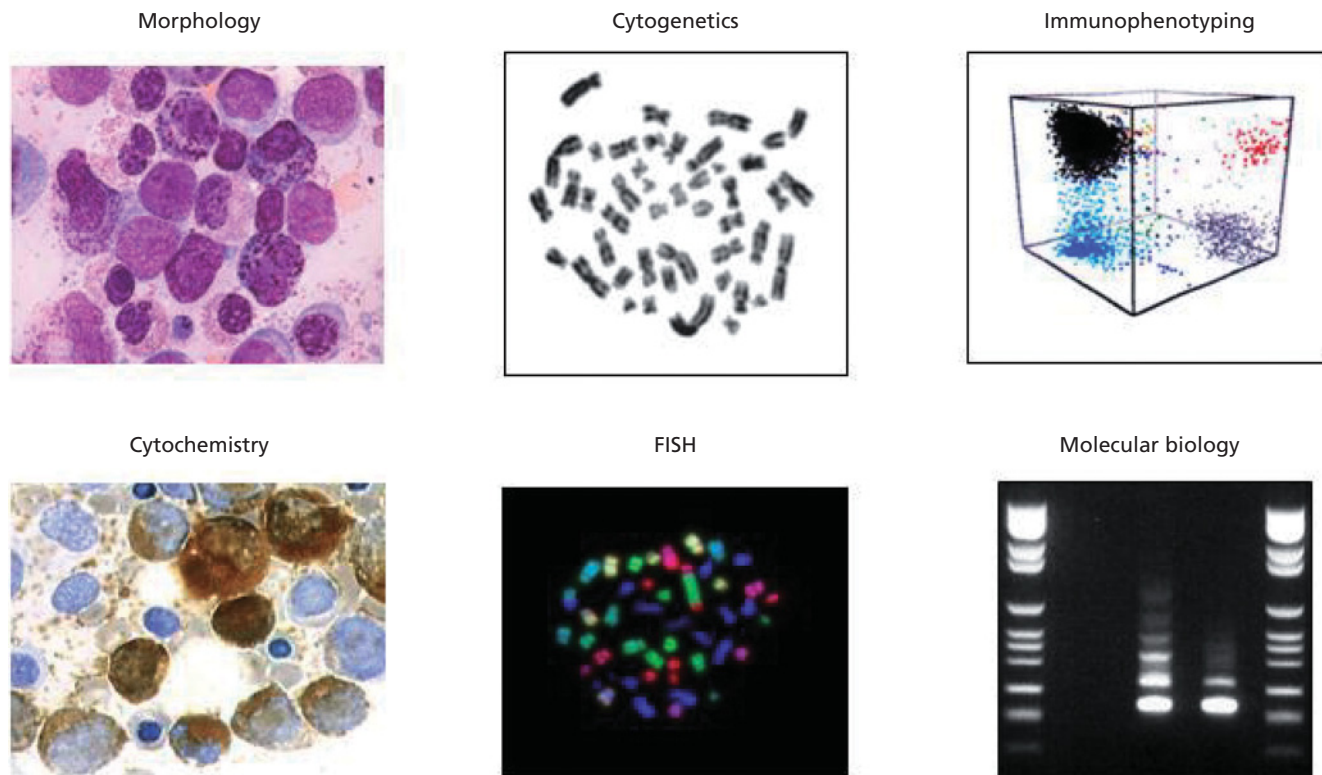

Figure 22.1 The principal methods employed in hematological diagnosis.

lymphadenopathy, splenomegaly, skin infiltration or any other reason to suspect a haematological neoplasm.

The blood film has two major roles. In some circumstances it provides strong evidence of a specific diagnosis that can be confirmed on further testing. In others it suggests a differential diagnosis and indicates the appropriate direction of further tests. A blood film also has the advantage that a rapid provisional diagnosis can be made, something that is important when treatment is urgent. For example, when there are circulating neoplastic cells, a rapid provisional diagnosis of Burkitt lymphoma (Figure 22.2) and acute hypergranular promyelocytic leukaemia (Figure 22.3) can be made from the blood film. Acute microgranular/hypogranular promyelocytic leukaemia (Figure 22.4) should also be suspected from the blood film. Even very infrequent neoplastic cells can suggest the correct diagnosis, for example in hairy cell leukaemia. Other diagnoses that may be strongly suggested by the blood film include most subtypes of acute myeloid leukaemia (AML), chronic lymphocytic leukaemia (CLL) (Figure 22.5), chronic myelogenous leukaemia (CML) (Figure 22.6), follicular lymphoma, splenic marginal zone lymphoma (when the cytological features of splenic lymphoma with villous lymphocytes are present), large granular lymphocyte leukaemia and plasma cell leukaemia.

Sometimes the blood film suggests only a differential diagnosis. Although the cytological features of the previously used FAB

(French–American–British) L1 category of acute lymphoblastic leukaemia (ALL) (Figure 22.7) are very likely to indicate that the diagnosis is ALL, this is not so of FAB L2 type (Figure 22.8), which can be cytologically very similar to AML of FAB M0 or

M1 types (Figures 22.9 and 22.10). Similarly, acute monoblastic leukaemia (Figure 22.11) can be cytologically indistinguishable from large-cell lymphoma or even plasma cell leukaemia.

In suspected myeloid malignancy the blood film is important for the detection of myelodysplastic features, particularly hypogranular and pseudo-Pelger–Huët neutrophils (Figure 22.12). Sometimes the blood film shows only non-specific but nevertheless useful features, for example eosinophilia, rouleaux formation, red cell agglutinates or cryoglobulin deposition.

Whatever the findings on the blood count and film, confirmatory tests are needed. The nature of these will vary according to circumstances but several useful algorithms are guided by information that can be gained from the peripheral blood.

Figure 22.5 Chronic lymphocytic leukaemia showing mature small lymphocytes and a smear cell. Peripheral blood film, MGG.

Bone marrow aspirate

A bone marrow aspirate is indicated in virtually all patients with suspected ALL, AML (Figure 22.13), CML, myelodysplastic syndrome (MDS) (Figure 22.14) or multiple myeloma (Figure 22.15). However, a bone marrow aspirate is not necessary for the diagnosis of CLL. The diagnosis of promyelocytic leukaemia may be more readily made on an aspirate than on the peripheral blood since, particularly in the hypergranular form, there may be few leukaemic cells in the blood and in the microgranular/

Figure 22.7 Acute lymphoblastic leukaemia FAB L1 subtype showing blast cells that vary in size but which otherwise have fairly uniform cellular characteristics; the nucleocytoplasmic ratio is high and there are small inconspicuous nucleoli. Bone marrow film, MGG.

hypogranular form there may be more hypergranular cells in the bone marrow, thus facilitating the diagnosis. The characteristic cytological features of AML with *inv(16)* or *t(16;16)* are apparent in the bone marrow (Figures 22.16 and 22.17) but not usually in the peripheral blood. In the acute leukaemias and in CML and other myeloproliferative neoplasms, a bone marrow aspirate provides material for cytogenetic analysis as well as for morphological assessment (Figure 22.18). Successful cytogenetic investigations from peripheral blood are only worth considering if immature leukaemic cells are present or, particularly when investigating suspected myeloproliferative neoplasms, if

Figure 22.8 Acute lymphoblastic leukaemia FAB L2 subtype showing medium-sized and large pleomorphic blast cells with one or two prominent nucleoli; there are no characteristics that identify the lineage. Bone marrow film, MGG.

Figure 22.9 Acute myeloid leukaemia FAB M0 subtype showing large blast cells with large prominent nucleoli; there are no cytological features that identify the lineage and Sudan black B and myeloperoxidase cytochemical stains were negative. On immunophenotyping, all B and T lineage markers were negative but there was expression of CD13 and CD33. Without immunophenotyping such a case could not be distinguished from acute lymphoblastic leukaemia L2 subtype. Bone marrow film, MGG.

the white cell count is at least $10 \times 10^9/L$, as mature cells will not enter metaphase.

Bone marrow aspiration may also be indicated in patients with unexplained cytopenia or a leucoerythroblastic blood film. An aspirate can be useful in lymphoma diagnosis, particularly if accompanied by a trephine biopsy, and can provide suitable material for immunophenotyping and for fluorescence *in situ* hybridization (FISH).

Figure 22.10 Acute myeloid leukaemia FAB M1 subtype showing small to medium-sized blast cells with a high nucleocytoplasmic ratio; one contains an Auer rod. Sudan black B and myeloperoxidase were positive. In the absence of Auer rods and granules, M1 acute myeloid leukaemia may be indistinguishable from acute lymphoblastic leukaemia without the aid of cytochemistry. Peripheral blood film, MGG.

Figure 22.12 A pseudo-Pelger–Huët anomaly in a neutrophil of a patient with myelodysplastic syndrome. Peripheral blood film, MGG.

Figure 22.11 Acute monoblastic leukaemia FAB M5a subtype associated with $t(9;11)(p22;q23)$ showing large cells with plentiful cytoplasm; one cell shows nuclear lobulation (defining it as a promonocyte in the WHO classification). In the WHO classification this type of acute myeloid leukaemia is a specific entity within the group ‘AML with recurrent genetic abnormalities’. Bone marrow film, MGG.

Bone marrow trephine biopsy

A bone marrow trephine biopsy is indicated whenever there is a ‘dry tap’ or the aspirate obtained is aparticle or dilute. A core biopsy is often necessary in hairy cell leukaemia, acute panmyelosis with myelofibrosis, acute megakaryoblastic leukaemia (Figure 22.19) and in patients being investigated for pan-

Figure 22.13 Acute myeloid leukaemia showing leukaemic blast cells, several with Auer rods. Bone marrow film, MGG.

cytopenia or a leucoerythroblastic blood film. If the bone marrow is being examined for suspected non-Hodgkin lymphoma (NHL), a trephine biopsy is always indicated since an aspirate may be normal cytologically and immunophenotypically despite there being focal infiltration readily detectable on a core biopsy. Hodgkin lymphoma is very rarely detected in an aspirate whereas a trephine biopsy specimen may provide the primary diagnostic material, particularly in patients with HIV infection who often present with widespread disease. A trephine biopsy should be part of the initial investigation of suspected multiple myeloma; sometimes this confirms the diagnosis when the aspirate findings are equivocal and, even when this is not so, it is useful to have a baseline biopsy to compare with

Figure 22.14 Composite image of myelodysplastic syndrome showing the hypolobulated megakaryocytes characteristic of the 5q- syndrome; myelodysplastic syndrome with isolated del(5q) is a specific category in the WHO classification. Bone marrow film, MGG.

Figure 22.15 Multiple myeloma (plasma cell myeloma) showing virtual effacement of the marrow by myeloma cells. Bone marrow film, MGG.

Figure 22.16 Acute myeloid leukaemia (AML) associated with inv(16)(p13.1;q22) showing myelomonocytic leukaemia with an abnormal eosinophil precursor that has pro-eosinophilic (purple-staining) granules. This subtype of AML is often referred to, using an adaptation of FAB terminology, as M4Eo. In the WHO classification this subtype of AML, together with similar cases with t(16;16), constitutes a specific entity within the category 'AML with recurrent genetic abnormalities'. Bone marrow film, MGG.

Figure 22.17 Acute myeloid leukaemia (AML) associated with t(16;16)(p13.1;q22) showing blast cells and an abnormal eosinophil precursor with pro-eosinophilic granules. In the WHO classification this subtype of AML, together with similar cases with inv(16), constitutes a specific entity within the category 'AML with recurrent genetic abnormalities'. Bone marrow film, MGG.

Figure 22.18 Polycythaemia vera with a *JAK2* V617F mutation showing panmyelosis; the large hyperlobulated megakaryocyte (top right) shows emperipolesis. Bone marrow film, MGG.

post-treatment investigations. A trephine biopsy is not generally necessary in CML or CLL whereas it is diagnostically important in suspected essential thrombocythaemia and polycythaemia vera and is essential in primary myelofibrosis and systemic mastocytosis.

There are other indications for trephine biopsy that are more controversial. This procedure may be necessary in ALL or AML

Figure 22.20 Acute myeloid leukaemia (AML) FAB M1 subtype showing Auer rods. This patient had the translocation $t(8;21)(q22;q22)$, identifying a specific entity within the WHO category 'AML with recurrent genetic abnormalities'. Peripheral blood film, myeloperoxidase reaction.

if no aspirate or a poor aspirate is obtained. However, if there are numerous circulating neoplastic cells and if a cellular aspirate is obtained, it does not yield any important extra information. In suspected MDS useful extra information that may contribute to the diagnosis is more likely since marrow architecture is often abnormal and immature ($CD34^+$) cells may be detected only on histology or immunohistochemistry.

Cytochemistry

With advances in immunophenotyping and other techniques the role of cytochemistry in haematological diagnosis has declined considerably. A limited role remains. In acute leukaemia, cytochemistry is indicated if there is limited access to immunophenotyping or if delay in obtaining results is expected. For example, FAB M1 AML (and the 2008 WHO category of AML without maturation) can be distinguished from ALL by means of a Sudan black B or myeloperoxidase stain (Figure 22.20) and acute monoblastic/monocytic leukaemia can be distinguished from large-cell lymphoma by means of a non-specific esterase stain (Figure 22.21). Careful attention to cytological detail usually permits the distinction between FAB M3 variant and M5b AML but if there is any doubt the former diagnosis is supported by strong reactions for Sudan black B, myeloperoxidase and chloroacetate esterase and the latter by a positive non-specific esterase reaction. Rarely, a specific diagnosis of a subtype of AML is aided by demonstration of blast cells of basophil lineage showing metachromatic staining with a toluidine blue stain (Figure 22.22). Perls stain for iron remains a very important cytochemical stain in suspected MDS (Figure 22.23).

Figure 22.21 Acute monoblastic leukaemia FAB M5a subtype showing strong reaction for non-specific esterase, which confirms the monocytic differentiation. Cytospin preparation, α -naphthyl-acetate esterase.

Periodic acid–Schiff and acid phosphatase reactions can help in the diagnosis of ALL (Figures 22.24 and 22.25) but reactions are not specific and we do not recommend their continued use in a routine diagnostic setting if there is any possibility of carrying out immunophenotyping. A neutrophil alkaline phosphatase score is likewise redundant in the diagnosis of CML, which now depends on cytogenetic and molecular genetic analysis. A tartrate-resistant acid phosphatase reaction can confirm a diagnosis of hairy cell leukaemia but is no longer necessary as long as the immunophenotyping laboratory has an appropriate range of antibodies for this purpose or if immunohistochemistry can be performed in the case of a ‘dry tap’.

Histology

Microscopic examination of sections of tissues other than bone marrow remains an essential technique for the diagnosis of many lymphomas. It may also be necessary for the diagnosis of myeloid sarcoma. Immunohistochemistry (see below) is an essential part of histological assessment for haematological neoplasms.

Flow cytometric immunophenotyping

Immunophenotyping can be based on flow cytometry, immunohistochemistry (on tissue sections) or immunocytochemistry (on cytospin preparations or films). The first two of these techniques are of major importance in haematological diagnosis. Flow cytometry is now carried out using multichannel instruments that permit the simultaneous assessment of forward light scatter (indicative of cell size), sideways light scatter (indicative

(a)

(b)

Figure 22.22 Acute myeloid leukaemia (AML) associated with $t(6;9)(p23;q34)$: (a) MGG-stained bone marrow film shows blast cells and two degranulated basophil precursors; (b) toluidine blue-stained bone marrow film demonstrates metachromatic granules and confirms basophilic differentiation. In the 2008 WHO classification, this subtype of AML constitutes a specific entity within the category ‘AML with recurrent genetic abnormalities’.

of granularity and cell complexity) and the expression of up to 10 surface membrane antigens, all simultaneously in one vial (Figure 22.26). With the addition of techniques to ‘permeabilize’ the cells, cytoplasmic and nuclear antigens can also be studied. When there are numerous circulating neoplastic cells, immunophenotyping is conveniently done on a peripheral blood sample. Otherwise it can be done on a bone marrow aspirate or on a cell suspension from any infiltrated tissue. The main indications for immunophenotyping are as follows.

- 1 Confirmation of a diagnosis of ALL and its subclassification and identification of an aberrant immunophenotype (leukaemia-associated immunophenotype) that can be used to monitor minimal residual disease (MRD).

Figure 22.23 Ring sideroblasts and Pappenheimer bodies in erythrocytes in myelodysplastic syndrome. Bone marrow aspirate, Perls stain.

Figure 22.24 Acute lymphoblastic leukaemia showing block positivity to periodic acid–Schiff (PAS) stain. Cytospin preparation of cerebrospinal fluid, PAS stain.

2 Confirmation of a diagnosis of FAB M0 and M7 AML (WHO 2008 classification: AML with minimal differentiation and acute megakaryoblastic leukaemia) and, if not already confirmed by cytochemistry, confirmation of a diagnosis of FAB M5a AML (acute monoblastic leukaemia); support for a diagnosis of acute promyelocytic leukaemia (either hypergranular or hypogranular) by demonstration of lack of expression of CD34 and especially HLA-DR and by non-specific background autofluorescence observed in the isotype controls; identification of leukaemia-associated immunophenotype that can be used to monitor MRD.

3 Identification of mixed-lineage acute leukaemia.

4 Demonstration of light chain restriction, providing presumptive evidence of monoclonality, in B-lineage disorders.

Figure 22.25 T-lineage acute lymphoblastic leukaemia showing focal (Golgi zone) positivity to acid phosphatase in lymphoblasts. Cytospin preparation, acid phosphatase reaction.

5 Confirmation of a diagnosis of CLL, assessment of prognosis by quantification of CD38 and ZAP70 expression (both prognostically adverse) and monitoring of MRD.

6 Confirmation of a diagnosis of NHL rather than CLL, and support for specific diagnoses such as follicular lymphoma (CD10 often positive) or mantle cell lymphoma (CD5 and nuclear cyclin D1 positive) (see also Chapter 33).

7 Confirmation of a diagnosis of hairy cell leukaemia by demonstration of expression of all or most of CD11c, CD25, CD103 and CD123 (see also Chapter 29).

8 Confirmation of a diagnosis of multiple myeloma or monoclonal gammopathy of undetermined significance (MGUS) by demonstration that plasma cells (identified by expression of CD138 and strong CD38) have light chain-restricted cytoplasmic immunoglobulin and often aberrant expression of CD56 together with failure to express CD19 and CD45 (see also Chapter 31).

9 Support for monoclonality of a T-lymphocyte population by demonstration of a uniform aberrant immunophenotype and restricted expression of CD158 (KIR) epitopes and support for specific diagnoses such as T-prolymphocytic leukaemia (CD7 often positive), adult T-cell leukaemia lymphoma (CD25 positive), large granular lymphocyte leukaemia (usually CD8⁺CD4⁻), and hepatosplenic T-cell lymphoma, which is usually T-cell receptor (TCR)- $\gamma\delta$ positive and TCR- $\alpha\beta$ negative.

10 Confirmation of a diagnosis of blastic plasmacytoid dendritic cell neoplasm by demonstration of expression of CD4, CD56, CD123 and possibly CD7 in the absence of expression of other lineage-specific markers.

11 Demonstration of an antigen that is a potential target of monoclonal antibody therapy, such as CD20, CD33 or CD52.

12 Diagnosis of paroxysmal nocturnal haemoglobinuria by demonstrating that a subpopulation of neutrophils, monocytes

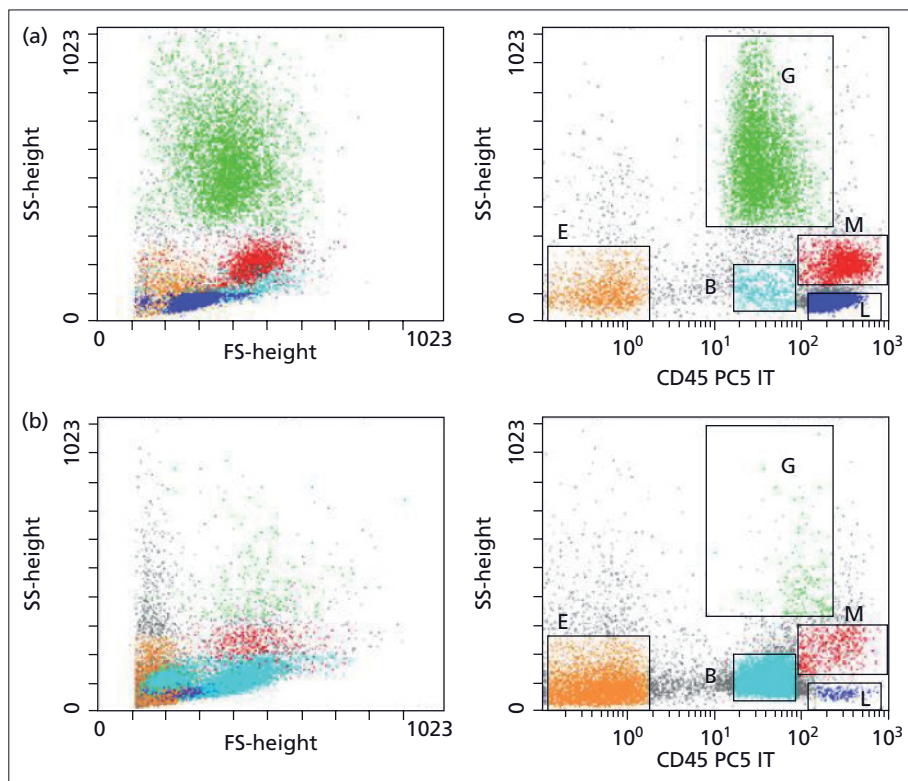

Figure 22.26 Flow cytometry immunophenotyping showing improvement of separation of populations by CD45 and sideways light scatter (SSC) gating. Forward light scatter (FSC) is also shown. (a) Normal bone marrow (left, SSC–FSC plot; right, SSC–CD45 plot); (b) acute myeloid leukaemia bone marrow (left, SSC–FSC plot; right, SSC–CD45 plot). G, granulocytes; M, monocytes; L, lymphocytes; E, erythrocytes; B, blasts. SSC–CD45 gating permits isolation of bone marrow blasts from all other populations, which is not possible by SSC–FSC gating.

or erythrocytes fails to express antigens, such as CD55 and CD59, that are bound to glycosylphosphatidylinositol.

13 Detection and quantification of fetomaternal haemorrhage.

14 Quantification of lymphocyte subpopulations.

15 Support for a diagnosis of MDS based on quantification of blasts and detection of aberrant antigen expression.

16 Assessment of infiltration of body fluids (cerebrospinal fluid, pleural effusion) by leukaemia and/or lymphoma.

Immunohistochemistry

Immunohistochemistry for haematological diagnosis is carried out on tissue sections, particularly from lymph nodes or trephine biopsy specimens. It is an essential part of the diagnostic procedure in haematological neoplasms, particularly lymphoma but also myeloid neoplasms. Examples that illustrate its value in lymphoma diagnosis include the following.

1 Confirmation of follicular lymphoma by demonstration that cells forming neoplastic follicles express CD10 and BCL2 (whereas follicles of reactive follicular hyperplasia are BCL2 negative).

2 Confirmation of mantle cell lymphoma by demonstration of CD5-positive B cells with nuclear expression of cyclin D1.

3 Confirmation of a diagnosis of classical Hodgkin lymphoma (CD15 usually positive, CD30 positive) and its distinction from

nodular lymphocyte-predominant Hodgkin lymphoma (CD15 and CD30 negative and more likely to express B cell-associated antigens such as CD20 and CD79a).

4 Confirmation of Burkitt lymphoma by demonstration of BCL2-negative BCL6-positive B cells with a very high proliferative fraction (approaching 100%) shown using Ki-67 or an equivalent monoclonal antibody.

5 Division of diffuse large B-cell lymphoma (DLBCL) into prognostic groups (see below).

6 Confirmation of hairy cell leukaemia by showing that B cells express CD25, CD72 (DBA44) and annexin A1.

7 Confirmation of clonality in suspected MGUS or multiple myeloma by demonstration of light chain restriction of cytoplasmic immunoglobulin.

8 Confirmation of infiltration in a trephine biopsy specimen in non-Hodgkin and Hodgkin lymphoma (particularly important in patients in whom no neoplastic cells are detected in the bone marrow aspirate and for detection of subtle interstitial or intravascular infiltration in NHL).

DLBCL has been demonstrated by microarray analysis (see below) to be divisible into three major groups with different patterns of gene expression: (i) germinal centre cell; (ii) activated B-cell-like; and (iii) other or indeterminate (see also Chapter 33). Lymphomas showing the gene expression pattern of germinal centre B cells were found to have a better prognosis than activated B-cell-like DLBCL. It is now possible to assign DLBCL to these two major groups on the basis on immunohis-

tochemistry. The germinal centre group express CD10 or, if they do not, they express BCL6 in the absence of MUM1 expression. DLBCL of the activated B-cell-like group are either negative for both CD10 and BCL6 or are CD10 negative but express both BCL6 and MUM1. The prognostic significance is seen clearly in patients treated with CHOP (cyclophosphamide, doxorubicin, vincristine and prednisolone) but may no longer reach statistical significance in those treated with R-CHOP (CHOP plus rituximab). In R-CHOP-treated patients, prognostic significance is shown by the demonstration of BCL2 expression, the best prognosis being in those with a germinal centre phenotype but without BCL2 expression, whose survival curves separate from the other three groups. However, it must be noted that scoring of these immunohistochemical markers is inconsistent between laboratories unless many technical factors are standardized; use of the assignment to germinal centre or non-germinal centre phenotypes to aid treatment decisions would be premature.

In ALL, it is usually possible to perform immunophenotyping on either peripheral blood or a bone marrow aspirate; immunohistochemistry is therefore usually redundant. In AML, immunohistochemistry should be viewed as supplementary to flow cytometric immunophenotyping. It is often unnecessary. However, in the absence of peripheral blood blast cells and if a bone marrow aspirate cannot be obtained, it becomes essential for diagnosis. It can thus be important for the diagnosis of acute megakaryoblastic leukaemias, acute pancytopenia with myelofibrosis and some cases of acute erythroleukaemia, when bone marrow fibrosis may prevent an adequate aspirate being obtained. It is needed for the diagnosis of myeloid sarcoma and blastic plasmacytoid dendritic cell neoplasm (which shows expression of CD4, CD56 and CD123). Immunohistochemistry can be a useful way to demonstrate the presence of an *NPM1* mutation in AML, cytoplasmic rather than nuclear expression being a surrogate marker for these mutations.

Immunohistochemistry for mast cell tryptase is important in confirming a diagnosis of systemic mastocytosis. Aberrant expression of CD2 and CD25 by the mast cells is also useful (although this pattern of reactivity is not specific for systemic mastocytosis). Immunohistochemistry is much less often needed in other myeloproliferative neoplasms.

Cytogenetic analysis

Cytogenetic analysis refers to study of chromosomes by recognition of their morphology and their characteristic banding pattern, demonstrated by staining with a Giemsa stain (for viewing by light microscopy) (Figure 22.27) or a quinacrine stain (for viewing as fluorescent bands under UV illumination). Chromosomes or specific genes of interest in either interphase or metaphase can also be studied by FISH analysis; this technique is both a cytogenetic and molecular genetic technique since the morphology of the chromosomes can be recognized to some extent, at least in metaphase cells, but the probes used are dependent on hybridization to specific DNA sequences. Cytogenetic, FISH and molecular techniques are complementary and which of these is most useful in an individual patient depends on the suspected diagnosis and the aberrations likely to be present. Classical cytogenetic analysis (chromosome banding analysis) requires cells in metaphase so that for conditions with a low mitotic rate, such as CLL and low-grade NHL, FISH or molecular analysis may be preferred. However, with the newer techniques it is possible to achieve metaphases in more than 90% of cases of CLL. Cytogenetic analysis can (i) provide evidence of clonality and thus confirm that a condition is neoplastic when other evidence is absent or equivocal (e.g. in chronic eosinophilic leukaemia, myeloproliferative neoplasms or NK cell leukaemia/lymphoma); (ii) confirm a specific diagnosis (e.g. CML, AML with recurrent translocations or Burkitt lymphoma); and (iii) give prognostic information (e.g. in CLL,

Figure 22.27 A karyogram of Giemsa-stained chromosomes showing $t(9;22)(q34;q11.2)$. The derivative chromosome 22 is the Philadelphia chromosome.

AML, ALL, MDS and multiple myeloma) or indicate that a neoplasm is therapy-induced (t-AML and t-MDS).

It is particularly important that cytogenetic or molecular genetic analysis is performed whenever there is a specific treatment available for patients with a particular genetic abnormality. This includes the following.

- 1 Conditions sensitive to tyrosine kinase inhibitors (with either *BCR-ABL1* or rearrangement of *PDGFRA* or *PDGFRB*).
- 2 Acute promyelocytic leukaemia with *PML-RARA* (sensitive to all-*trans* retinoic acid and As_2O_3).
- 3 MDS with 5q- (sensitive to lenalidomide).
- 4 MDS with monosomy 7 (sensitive to azacytidine).
- 5 Burkitt lymphoma with juxtaposition of *MYC* to the immunoglobulin heavy chain, κ or λ locus (responsive to intensive chemotherapy incorporating certain specific agents plus monoclonal antibody treatment).

Table 22.1 The 2008 WHO classification of acute myeloid leukaemia (AML), with categories where genetic analysis is, or may be, essential for categorization shown in blue.

Therapy-related myeloid neoplasms

De novo myeloid neoplasms

AML with recurrent genetic abnormalities*

- AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*
- AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
- AML with t(15;17)(q22;q12); *PML-RARA*

AML with myelodysplasia-related changes†

AML not otherwise categorized

Myeloid sarcoma

Myeloid proliferation related to Down syndrome‡

- Transient abnormal myelopoiesis
- Myeloid leukaemia associated with Down syndrome

Blastic plasmacytoid dendritic cell neoplasm

*Either cytogenetic or molecular genetic analysis essential for classification.

†Meeting cytogenetic criteria for myelodysplastic syndrome (MDS)-associated cytogenetic abnormalities permits assignment of a case to this category (assignment can also be on the basis of multilineage dysplasia or a previous diagnosis of MDS).

‡Cytogenetic analysis may be necessary to confirm the diagnosis of Down syndrome, particularly in mosaic Down syndrome; an acquired *GATA1* mutation is also present.

Cytogenetic analysis can be considered appropriate whenever it contributes to diagnosis, indicates the prognosis or guides the selection of treatment. It can therefore be considered indicated in the following.

- 1 All cases of AML: essential for application of the WHO classification, indicates prognosis and is thus relevant to treatment choice (Table 22.1).
- 2 All cases of ALL: essential for application of the WHO classification, indicates prognosis and is thus relevant to treatment choice; necessary for detection of *BCR-ABL1*-positive cases, although for this purpose FISH and molecular analyses are alternatives (Table 22.2).
- 3 All cases of mixed-phenotype acute leukaemia: essential for detecting *BCR-ABL1*-positive cases.
- 4 All cases of suspected CML: essential to confirm *BCR-ABL1*, although FISH or molecular analyses are alternatives.
- 5 All cases of suspected MDS: necessary for application of the WHO classification including identification of the 5q- syndrome (Figure 22.28) and essential for application of the International Prognostic Scoring System (IPSS) and WHO classification-based Prognostic Scoring System (WPSS).
- 6 All cases of suspected chronic eosinophilic leukaemia: necessary for detection of translocations that lead to *PDGFRB* rearrangement (imatinib sensitive) and *FGFR1* rearrangement.
- 7 All cases of suspected NK leukaemia/lymphoma: can demonstrate clonality and thus confirm the diagnosis.

If resources permit, cytogenetic analysis can also be useful in other myeloproliferative and myelodysplastic/myeloproliferative neoplasms. Cytogenetic analysis can be used for the confir-

Table 22.2 The WHO classification of acute lymphoblastic leukaemia, with categories where genetic analysis is essential for categorization shown in blue (see also Chapter 25).

B lymphoblastic leukaemia/lymphoma

B lymphoblastic leukaemia/lymphoma, not otherwise specified

B lymphoblastic leukaemia/lymphoma with recurrent genetic abnormalities

- With t(9;22)(q34;q11.2) and *BCR-ABL1*
- With t(4;11)(q21;q23) and *MLL-MLL2* or other 11q23 and *MLL* rearrangement
- With t(12;21)(p13;q22) and *ETV6-RUNX1**
- With hyperdiploidy (>50 chromosomes)
- With hypodiploidy (<46 chromosomes)
- With t(5;14)(q31;q32) and *IL3-IGH*
- With t(1;19)(q23;p13.3) and *TCF3-PBX1*

T lymphoblastic leukaemia/lymphoma

*Molecular genetic analysis is needed since the translocation is cryptic.

Figure 22.28 An explanatory diagram (top), karyogram of Giemsa-stained chromosomes showing $\text{del}(5)(\text{q}13\text{q}31)$ (bottom left), and FISH showing retention of signal for 5p15 and loss of signal for 5q31 (bottom right) in a patient with 5q- syndrome.

mation of a diagnosis of Burkitt lymphoma, follicular lymphoma or mantle cell lymphoma but FISH may be preferred. Use of the two techniques may give complementary information. Prognostically relevant information is also obtained in multiple myeloma. However, this is best done with preliminary magnetic activation cell sorting using CD138-positive antibodies, as plasma cells may be low and FISH performed on direct bone marrow films may result in insufficient cells for analysis and give misleading results.

Fluorescence *in situ* hybridization

FISH uses labelled oligonucleotide probes that bind to specific DNA sequences. These may be locus-specific probes (including those detecting oncogenes and tumour-suppressor genes), centromeric probes, telomeric probes and whole chromosome paints. Centromeric probes can be used for the detection of monosomies and trisomies. Otherwise, locus-specific probes are those most widely used. By labelling two probes with different fluorochromes it is possible to study two genes that are involved in a specific translocation or other rearrangement. If the probes span the breakpoint, both will be disrupted by the translocation and signals will be adjacent or optically fused on the derivative chromosomes, a double-colour double-fusion technique. Often one probe gives a green signal and the other a red signal so that the fusion signal is yellow. Alternatively, two probes that span the 5' locus and 3' locus and overlap can be used in a double-colour break-apart technique; this can be

useful when a single gene, such as *MLL*, is involved in rearrangements with a large number of other genes. FISH is applicable to both metaphase cells and interphase cells (Figure 22.29).

FISH is particularly useful in the following circumstances.

- 1 Screening for *BCR-ABL1* fusion (peripheral blood cells are suitable whereas cytogenetic analysis is better done on bone marrow) (Figure 22.30).
- 2 Confirming a specific lymphoma diagnosis by demonstration of *BCL2-IGH* in follicular lymphoma, *CCND1-IGHG1* in mantle cell lymphoma or *MYC-IGHG1* in Burkitt lymphoma (Table 22.3).
- 3 Detection of translocations or inversions or aneuploidy that was not detected on metaphase cytogenetic analyses because the leukaemic cells did not enter mitosis or the metaphases were of too poor quality, e.g. detection of $\text{t}(8;21)(\text{q}22;\text{q}22)$, $\text{t}(15;17)(\text{q}22;\text{q}12)$, $\text{inv}(16)(\text{p}13.1\text{q}22)$ or *MLL* rearrangement in AML (Figure 22.31) or detection of high hyperdiploidy in ALL (by using centromeric probes for the chromosomes that are most often triplicated).
- 4 Screening for a cryptic *FIP1L1-PDGFR* fusion (by detection of loss of *CHIC2*) in chronic eosinophilic leukaemia.
- 5 Producing prognostically relevant information in CLL by investigation for trisomy 12, $\text{del}(6)(\text{q}21)$, $\text{del}(11)(\text{q}22-23)$, $\text{del}(13)(\text{q}14.3)$ (Figure 22.32) and $\text{del}(17)(\text{p}13)$.

Spectral karyotyping, also known as 24-colour FISH, is a modification of FISH that permits visualization of each pair of chromosomes in a unique colour. It can be used as a supplement to metaphase cytogenetics to clarify the nature of complex rearrangements (Figure 22.33). Inversions are not detected.

Figure 22.29 Locus-specific probes for *BCR* (green) and *ABL1* (red) applied to an interphase cell and to a metaphase of a patient with chronic myelogenous leukaemia after hybridization with probes for *ABL1* (red) and *BCR* (green) showing *BCR-ABL1* colocalization signals (yellow) on the Philadelphia chromosome and *ABL1-BCR* colocalization signals on derivative chromosome 9.

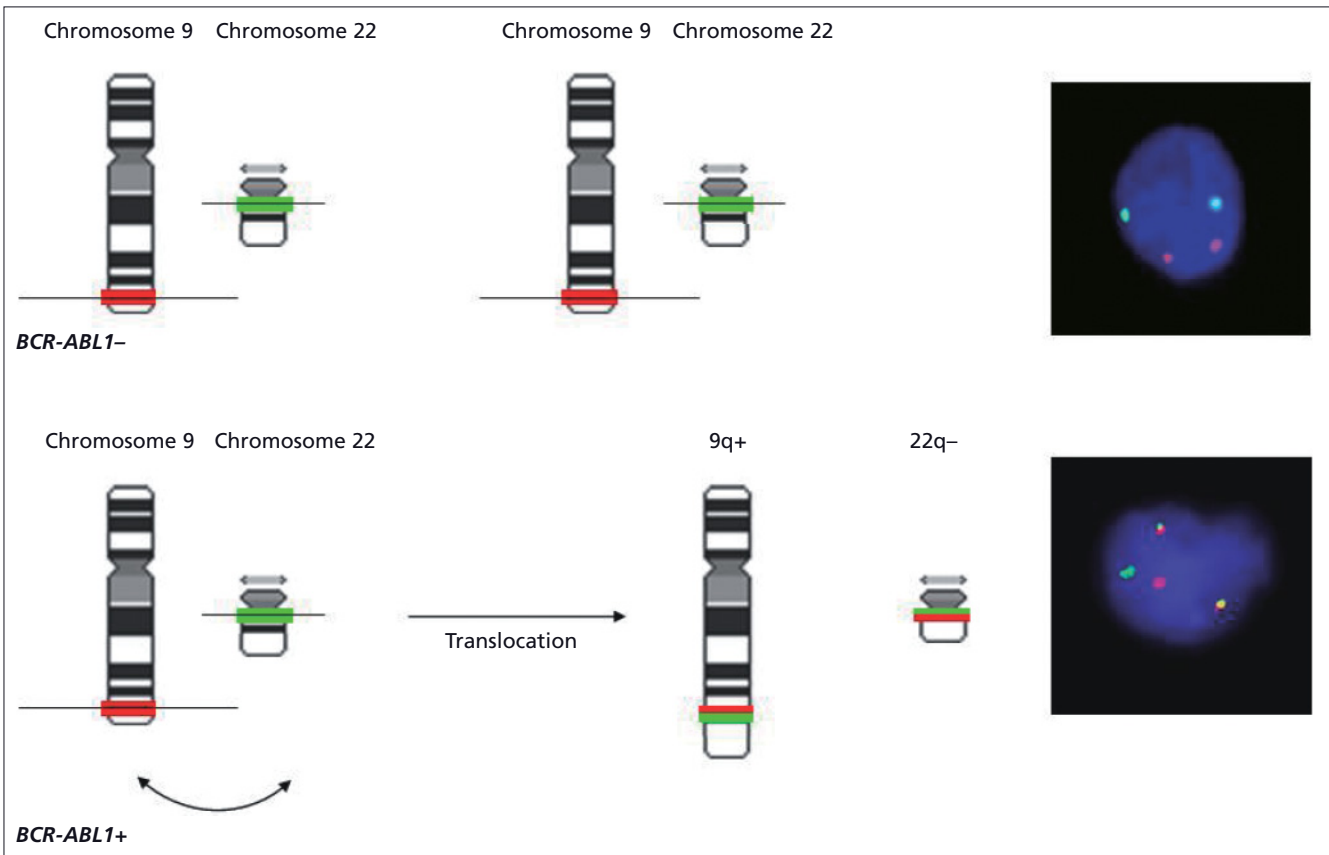

Figure 22.30 Diagram showing the principle of fluorescence *in situ* hybridization for detection of *BCR-ABL1*. Locus-specific probes for *BCR* (green) and *ABL1* (red) have been applied to interphase cells. The normal cell (top) shows two red signals and

two green signals, whereas the cell with *BCR-ABL1* shows two normal signals and two fusion signals (*BCR-ABL1* and *ABL1-BCR*).

Table 22.3 Cytogenetic/molecular genetic abnormalities that are incorporated into the 2008 WHO classification of neoplasms of mature T and B cells.

<i>Genetic abnormality</i>	<i>Gene dysregulated</i>	<i>Diagnosis*</i>
t(14;18)(q32;q21) or t(2;18)(p12;q21) or t(18;22)(q21;q11.2)	<i>BCL2</i>	Follicular lymphoma
t(11;14)(q13;q32) or, rarely, t(11;22)(q13;q11)	<i>CCND1</i>	Mantle cell lymphoma
t(8;14)(q24;q32) or t(2;8)(p12;q24) or t(8;22)(q24;q11.2)	<i>MYC</i>	Burkitt lymphoma
inv(14)(q11q32) or t(14;14)(q11;q32) or, less often, t(X;14)(q28;q11)	<i>TCL1</i>	T-prolymphocytic leukaemia
t(2;5)(p23;q35) or one of at least five variant translocations with a 2p23 breakpoint	<i>NPM1-ALK</i> fusion or other fusion gene incorporating part of <i>ALK</i>	Anaplastic large-cell lymphoma, ALK positive

*The genetic abnormality confirms the diagnosis only in an appropriate cytological/histological and immunophenotypic setting.

Figure 22.33 Metaphase of a patient with acute myeloid leukaemia and a complex aberrant karyotype after 24-colour fluorescence *in situ* hybridization.

Molecular genetic analysis

Molecular genetic analysis includes Southern blotting (now little used in routine diagnosis), the polymerase chain reaction (PCR) to study genomic DNA (Figures 22.34 and 22.35), and reverse transcriptase polymerase chain reaction (RT-PCR) to study RNA after its reverse transcription. A PCR reaction can also be made quantitative, as in real-time quantitative PCR, an important technique for monitoring MRD (Figure 22.36). PCR and RT-PCR can be alternatives to metaphase cytogenetic anal-

ysis in several subgroups of leukaemia and lymphoma. However, unlike metaphase cytogenetic analysis but similar to FISH, this is a targeted investigation so that only the abnormality that is specifically sought will be detected. Thus, in some diseases additional diagnostic or prognostic information will be found only by using metaphase cytogenetics. On the other hand, PCR has the advantage that only a small amount of DNA is needed and there is no need for dividing cells. Molecular analysis permits the detection of prognostically and therapeutically relevant cryptic rearrangements, such as the *ETV6-RUNX1* rearrange-

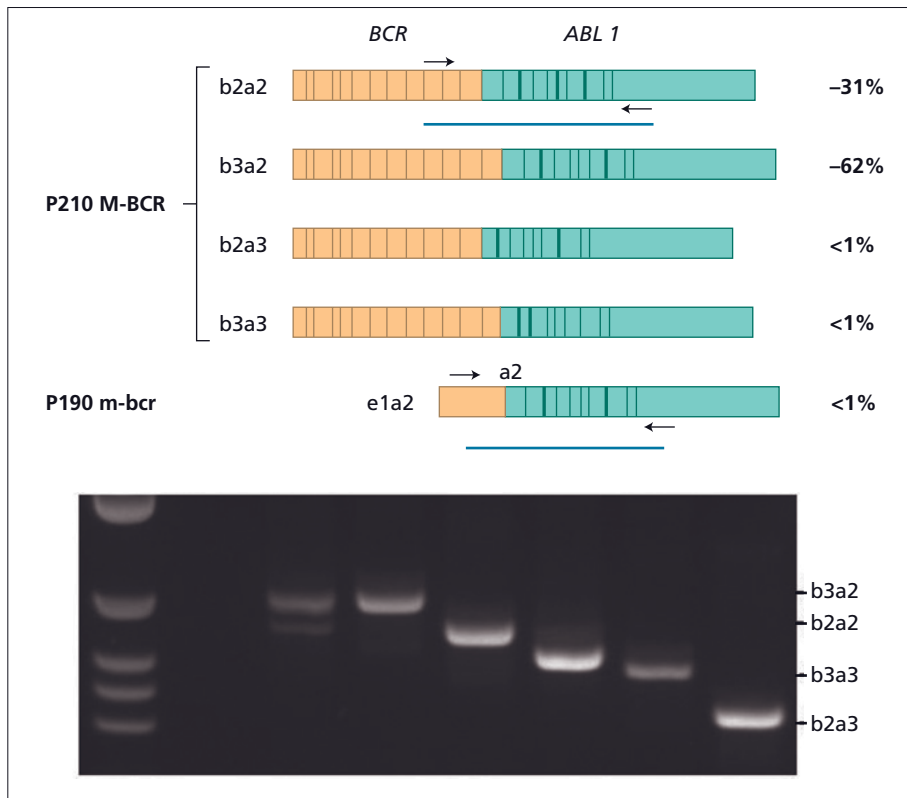

Figure 22.34 An explanatory diagram and a PCR gel showing the various *BCR-ABL1* transcripts that can be identified by PCR.

Figure 22.35 *BCR-ABL1* multiplex PCR containing different oligonucleotide ('oligo') combinations. -C, negative control sample containing water instead of a nucleic acid template; +C, positive controls for p210 and p190 fusion types. P, patient samples: P1 and P4 are positive for b3a2 fusion types, P3 and P7

are positive for b2a2 fusion types, P2, P5, P6, P8 and P9 are *BCR-ABL1* negative patient samples. MW, molecular weight standard; BCR, amplification of the non-rearranged *BCR* gene as internal quality control reaction.

Figure 22.36 Real-time quantitative PCR. Fluorescence is plotted against PCR cycle number. (a) A 10-fold limited dilution series of a *BCR-ABL1*-containing plasmid showing high sensitivity of the PCR. It also serves as a calibration curve for subsequent *BCR-ABL1* calculations. (b) Run with chronic myeloid leukaemia follow-up samples: the large arrow shows a sample with high *BCR-ABL1* load, the small arrow low *BCR-ABL1* load.

ment associated with a cryptic $t(12;21)(p13;q22)$ in ALL. Genomic PCR can be applied to stored samples.

The roles of genomic PCR and RT-PCR include the following.

1 Detection of rearrangement of immunoglobulin heavy and light chain loci and TCR loci, providing evidence of a clonal disorder if a monoclonal rather than an oligoclonal or polyclonal pattern is detected.

2 Detection of leukaemia-related and lymphoma-related chromosomal rearrangements by demonstration of gene juxtaposition or fusion in order to confirm a diagnosis, for example detection of *CCND1-IGHG1* indicative of $t(11;14)(q13;q32)$ to confirm suspected mantle cell lymphoma or detection of *BCL2-IGH* indicative of $t(14;18)(q32;q21)$ to confirm suspected follicular lymphoma. Note that neither of these rearrangements is absolutely specific for the disease in question since *CCND1-IGHG1* also occurs in multiple myeloma and *BCL2-IGH* also occurs in DLBCL, but in the context of appropriate cytology or histology they do permit confirmation of a diagnosis.

3 Detection of gene mutations relevant to diagnosis, for example *KIT* D816V in systemic mastocytosis or either *JAK2* V617F or *JAK2* exon 12 mutation in polycythaemia vera (*JAK2* V617F also occurs in many patients with essential thrombo-

cythaemia or primary myelofibrosis but its detection in a patient with a high haemoglobin concentration confirms the diagnosis of polycythaemia vera and since it is present in the great majority of patients with this diagnosis, measurement of the total red cell mass and plasma volume is generally rendered unnecessary).

4 Prognostic stratification, for example in ALL detection of *ETV6-RUNX1* associated with cryptic $t(12;21)(p13;q22)$ (good prognosis), *TCF3-PBX1* associated with $t(1;19)(q23;p13.3)$ (good prognosis), *MLL-MLL2* associated with $t(4;11)(q21;q23)$ (poor prognosis) and *BCR-ABL1* associated with $t(9;22)(q34;q11.2)$ (poor prognosis); multiplex PCR, combining a number of primer pairs in a single reaction, is useful for screening simultaneously for more than one rearrangement.

5 Prognostic stratification in AML with normal karyotype, for example *FLT3* internal tandem duplication (ITD) (poor prognosis), *MLL* partial tandem duplication (PTD) (poor prognosis), *NPM1* mutation (good prognosis if not associated with *FLT3* ITD), *CEBPA* mutation (good prognosis if not associated with *FLT3* ITD).

6 Prognostic stratification in CLL: somatic hypermutation, defined as *IGHV* showing less than 98% homology with germline, is found in 50–60% of all cases and correlates with a better

prognosis than is found in patients with unmutated *IGHV* genes.

7 MRD detection using *RUNX1–RUNX1T1*, *CBFB–MYH11*, *PML–RARA*, *MLL* rearrangement, *MLL* PTD, *FLT3* ITD, *NPM1* mutation or *CEBPA* mutation.

Whole-genome scanning

There are a number of molecular techniques available for whole-genome scanning. Thus far, these have mainly been used to address research topics, but it is likely that they will soon find a place in routine diagnostic work. These techniques include comparative genomic hybridization (CGH), in which labelled test DNA is hybridized to normal metaphase preparations, and microarray analysis, in which there is hybridization of the labelled test DNA of interest to probes positioned in high density on a microarray surface. Microarray analysis includes CGH arrays and, more frequently used, genome-wide single-nucleotide polymorphism (SNP) arrays. CGH is labour-intensive, less sensitive for the detection of small regions harbouring copy number alterations and likely to remain a research technique. Microarray analysis has a greater potential for diagnostic application since it has a much higher resolution for the detection of genomic aberrations, requires a low amount of starting material and has the potential to be developed as a fully automated molecular laboratory assay.

In CGH assays, test and reference DNAs are labelled with different fluorochromes before being hybridized to microarrays of either oligonucleotides or bacterial artificial chromosome (BAC) probes. CGH microarray analysis is used for the detection of under-representation or over-representation of specific genomic regions in the test DNA. Deletions and amplifications can thus be detected, for example deletion of 13q14 and 11q22 in CLL or intrachromosomal amplification of 21q in ALL.

In SNP array analysis, genomic DNA of a sample of interest is digested by restriction enzymes, amplified, labelled and hybridized to oligonucleotide probes. Probes are either bound to microbeads or are synthesized *in situ* in high density on a microarray surface (Figure 22.37). SNP analysis can be applied to genotyping and is able to distinguish heterozygosity from homozygosity. It can thus be used to detect both loss of heterozygosity and alterations of copy numbers of a genomic region, i.e. gains and losses (Figure 22.38). Acquired somatic uniparental disomy can be detected by comparison of tumour DNA with constitutional DNA. Sensitivity for the detection of a clonal population is similar to that of metaphase cytogenetics. With SNP array technology it is possible to identify uniparental disomy for chromosomal regions that include mutated genes such as *JAK2*, *CEBPA*, *FLT3* and *RUNX1*.

Microarray analysis of gene expression

Microarray analysis was initially applied to the study of cellular gene expression by hybridization of test and control RNA speci-

Figure 22.37 High-density single-nucleotide polymorphism (SNP) microarray scan showing the surface of a high-density SNP microarray (Affymetrix SNP 6.0). This chip was designed as hybrid genotyping array to simultaneously measure 906 600 SNPs and copy number alterations at approximately 1.8 million genomic locations.

mens, processed and labelled with different fluorochromes, to single-stranded DNA. The DNA probes were either complementary (c)DNA or synthetic oligonucleotides, arrayed in multiple rows of dots on a microarray surface with each dot interrogating a fragment of a single gene. High-density gene expression profiling (GEP) is a well-established molecular method and has been demonstrated to yield information of both diagnostic and prognostic value.

Primary mediastinal B-cell lymphoma can be distinguished from both DLBCL and Hodgkin lymphoma by its molecular signature. Burkitt lymphoma has a distinctive pattern of gene expression, which can help in making a distinction with DLBCL with *MYC* overexpression. Similarly, small lymphocytic lymphoma, marginal zone B-cell lymphoma and mantle cell lymphoma can be characterized by their differential gene expression signatures.

Prognostic information is provided in DLBCL. Microarray studies have shown that this diagnostic category encompasses at least two molecularly distinct diseases, differing in differentiation stage (i.e. cell of origin), oncogenic mechanisms and clinical outcome. Microarray analysis can also divide mantle cell lymphoma into groups with very different prognosis.

From a diagnostic perspective, GEP has been demonstrated to offer a robust technology platform. For multiple categories of acute leukaemias, for example based on immunophenotype (B-cell and T-cell lineages), chromosomal aberrations (translocations and inversions) or molecular mutations (*NPM1*, *CEBPA*), characteristic gene expression signatures have been identified (Figure 22.39). Moreover, international multicentre studies have demonstrated high intra- and inter-laboratory pre-

Figure 22.38 Molecular karyotype based on high-density SNP microarray analysis. Alterations are given by arrows indicating either gains or losses of chromosomal material. The karyotype using conventional chromosome banding techniques is given for comparison.

Figure 22.39 Principal components analysis of various subtypes of acute leukaemia. Patient samples are plotted in a three-dimensional space using the three components capturing most of the variance in the microarray dataset. Each patient sample is represented by a single colour-coded sphere. Adult acute myeloid leukaemia samples from the entities $t(8;21)(q22;q22)$, $t(15;17)(q22;q12)$, $inv(16)(p13.1q22)$ and $t(11q23)/MLL$ can clearly be distinguished based on the differential expression of signature genes.

cision in the performance of gene expression analyses, underlining that array-based GEP is a promising molecular assay that could be applied in the diagnosis of haematological malignancies.

Laboratory techniques and the WHO classification of tumours of haemopoietic and lymphoid tissues

The 2008 WHO classification is based on the integration of clinical and pathological features. Among the pathological features, morphology (cytology and histology) is fundamental but there is an increasing use of immunophenotyping for classification of lymphoid, mixed lineage and some myeloid neoplasms and of cytogenetic and molecular genetic information for classification of both lymphoid and myeloid neoplasms. Tables 22.1 and 22.2 illustrate how cytogenetic and molecular genetic information is integrated into the classifications of AML and B-lineage ALL respectively. Two categories of acute leukaemia of ambiguous lineage are also defined by the presence, in addition to the required immunophenotypic characteristics, of $t(9;22)(q34;q11.2)/BCR-ABL1$ and $11q23/MLL$ rearrangement respectively. The 2008 WHO classification has also introduced a new genetically defined categorization for lymphoid and myeloid neoplasms associated with rearrangement of *PDGFRA*, *PDGFRB* or *FGFR1*; these categories encompass cases of *BCR-ABL1*-negative chronic myeloid leukaemia (often with eosino-

nophilic differentiation), AML, ALL and lymphoid or myeloid transformation of a myeloproliferative neoplasm.

Otherwise, among the myeloproliferative neoplasms, only the demonstration of t(9;22)(q34;q11.2)/*BCR-ABL1* to confirm or exclude a diagnosis of CML is essential for classification. However, the demonstration of the *JAK2* V617F mutation or a somatic *MPL* mutation is important for making a diagnosis of a myeloproliferative neoplasm rather than a secondary or familial disorder. A *JAK2* exon 12 mutation similarly confirms that polycythaemia is polycythaemia vera rather than a familial or secondary condition.

Cytogenetic and molecular genetic abnormalities are critical in the diagnosis of certain neoplasms of mature lymphocytes (Table 22.3). However, for the majority of cases of CLL and NHL, such analysis is not needed for diagnosis and classification, although it may provide information of prognostic value.

Conclusions

Modern diagnosis, classification and monitoring of haematological neoplasms require integration of multiple diagnostic tools in a systematic manner in order to provide all the information necessary for optimal management of the patient. In addition, application of new diagnostic tools is constantly increasing our understanding of these disorders. New research tools not only give new information but are often rapidly integrated into diagnostic practice. Classifications of lymphoid and myeloid neoplasms increasingly incorporate, and depend on, immunophenotypic and genetic analysis.

Selected bibliography, 432**Epidemiology of disease**

Acute myeloid leukaemia (AML) has an incidence of 2–3 per 100 000 per annum in children, rising to 15 per 100 000 in older adults. It can occur at all ages but has its peak incidence in the seventh decade (Figure 23.1). The incidence does not appear to be increasing beyond that expected in an ageing population, which in itself will considerably increase the burden of the disease to healthcare systems in future years. The fact that most cases occur in older patients has important implications for treatment strategies, in that biological variation associated with chemoresistance and comorbidity, which limits treatment options, increases with age.

Pathophysiology

The more carefully AML is studied, the clearer it becomes that there is considerable heterogeneity between cases with respect to morphology, immunological phenotype, associated cytogenetic and molecular abnormalities and, more recently, patterns of gene expression. This is reflected in the substantially different responses to treatment. Some entities are becoming so distinct that they are regarded as different diseases with specific approaches to treatment.

AML is a malignant clonal disorder of immature cells in the haemopoietic hierarchical system. Leukaemic transformation is assumed to occur in many cases at, or near, the level of the haemopoietic stem cell before it has embarked on any lineage commitment. Some cases may originate at a slightly later stage in cells that are committed to lineage differentiation. These cells

have abnormal function characterized by failure to progress through the expected differentiation programme and/or to die by the process of apoptosis. Associated with this may be retention of the stem cell characteristic of self-renewal. This leads to the accumulation of a clone of cells, which dominates bone marrow activity and leads to marrow failure. The potential for arrest of haemopoiesis at different time points partially explains why there can be such variation in the leukaemic or 'blast' population characterizing the individual case. Adenopathy or organomegaly can occur but are not usual features. Extramedullary disease can occur, including cerebrospinal infiltration, but this is not usual, unlike in lymphoblastic leukaemias. Similarly, most patients present with low peripheral blood counts. While in the majority of cases no direct cause is found, there is an association with irradiation, smoking, some rare congenital abnormalities, chemical exposure and obesity. Perhaps the most frequently identified cause is progression from other myeloproliferative disorders, e.g. myelodysplasia, or as a consequence of prior chemotherapy for another malignancy.

Non-random chromosome abnormalities are found in the majority of cases. These may be structural (gain or loss of material) or reciprocal balanced translocations. The significance of these changes is developing at a steady pace and is discussed below as far as the clinical implications are concerned.

Several molecular changes have also been discovered, either by association with the known cytogenetic abnormalities or somewhat by chance (Table 23.1). There is a variable level of proof at this stage as to whether the recognized molecular abnormalities are sufficient in themselves to cause leukaemia. The most common molecular mutation associated with AML has been found in the FLT receptor.

FMS-like tyrosine (FLT)-3 is a member of the platelet-derived growth factor receptor (PDGFR) subfamily of receptor kinases and is most similar to FMS, KIT and the PDGF receptors. The receptor is expressed in haemopoietic cells restricted to the

Figure 23.1 Age distribution of AML in the population of Wales: a population study.

CD34-positive fraction and a CD34-negative subfraction of dendritic cell precursors. It is also expressed on neural tissues. Normal FLT-3 receptor is expressed on AML blasts in most cases and can be overexpressed or asynchronously expressed in that it can be expressed not strictly in association with CD34 expression. Most mutations are present in the juxtamembrane domain of the receptor and comprise internal tandem duplications (ITDs) of variable size that are always in-frame and therefore expressed. Such mutations are found in approximately 25% of younger AML cases. Additional point mutations have been found on the activation loop of the interrupted kinase domain, usually at aspartate 835. The consequence of these mutations are activation of the receptor by phosphorylation, which promotes proliferation and resistance to apoptosis. Not only is the mutation the commonest mutation in AML but a large clinical experience confirms that it is strongly predictive of relapse, although it has no implications for the achievement of remission. Mutations are associated with high white cell counts and blast percentage at diagnosis. They are not uniformly distributed across the FAB or cytogenetic subgroups, being rare in FAB M0, M6 and M7 and most common in M3. The incidence is highest in patients with $t(15;17)$, trisomy 8 and normal karyotype and uncommon in other favourable groups and in virtually all poor-risk cytogenetic groups.

There is an increasing belief that most tumours are a result of multiple 'hits' or molecular changes and that a single change may be insufficient to cause the full leukaemic phenotype. In AML, the phenotype is a consequence of both a proliferative lesion and a failure of differentiation, and it seems probable that molecular abnormalities which affect both functions are required. This understanding is now leading to the testing of therapeutic agents which inhibit the molecular consequences of these abnormalities.

Disease classification

The disease is confirmed by an excess of primitive 'blast' cells in the bone marrow, originally in the FAB classification required to be at least 30%. The French–American–British (FAB) morphological classification has been useful in developing a common vocabulary, but has little predictive value with the widespread use of genetic markers. Quality cytochemistry can provide valuable additional diagnostic information. Further precision can be added by immunophenotyping. Although widely used, in many cases where high-quality morphology and cytochemistry is available it is not strictly required to confirm the diagnosis as AML. A revised classification devised under the auspices of the World Health Organization (WHO) recognizes accumulating knowledge of the cytogenetic and molecular characteristics. As discussed later, the leukaemic blasts may demonstrate an 'aberrant' immunophenotype, which together with molecular characterization of cloned breakpoints or mutations has potential use in monitoring response to treatment.

Cytogenetics

The recognition of non-random chromosome abnormalities associated with the various types of AML has had a major impact on understanding of the disease, opening the way for the molecular genetic defects to be unravelled and aiding in the appropriate choice of treatment. A typical range of the more common abnormalities is shown in Figure 23.2. Some of the consequential molecular changes have been carefully investigated and, in the case of some of the reciprocal translocations,

the molecular breakpoints have been cloned. Some of these are illustrated in Table 23.1.

The morphological, cytogenetic, immunological and molecular abnormalities are frequently associated as illustrated in Table 23.2 and Figure 23.3. This, together with clinical response data, has led to a recognition that a predominantly morphological classification is no longer adequate to define some subsets which are better recognized as distinct clinically relevant entities based on cytogenetics and molecular characteristics. The previous WHO classification introduced a lower marrow blast threshold of 20% to define the disease, but this is relatively arbitrary and many patients enter treatment with 10% marrow blasts, i.e. high-risk myelodysplastic syndrome.

Treatment

Aspirations for treatment

Given the age distribution of patients who will present with the disease, it must first be decided what the goals of treatment are in an individual patient. In young people, there is little doubt that there is the prospect of significant benefit to be gained from an intensive approach. With increasing age, which is often associated with comorbidity and less responsive disease, the balance of benefit changes to a more palliative approach. Much of what is known about the prospects of successful treatment is derived

Figure 23.3 Cytogenetics and molecular characteristics of AML. (After Grimwade & Hills 2009 with permission.)

Figure 23.4 Survival of AML in relation to patient age. Data from a Welsh population database.

from large clinical trials. In young patients, these results are usually representative of what can be expected for any age-matched patients. However, only a selected minority of older patients (>60 years) will enter trials, so trial-derived information may be less transferable to the whole population in this age group. A substantial majority of older patients are not considered fit for the usual intensive approach and the priority for such patients is palliative care, optimization of quality of life and minimal hospitalization. Examination of survival in population studies illustrates the dominant effect of age (Figure 23.4); indeed, a substantial proportion of patients over the age of 60 years do not receive more than a palliative treatment approach.

Treatment strategy

The initial clinical priority is to apply chemotherapy to improve marrow function by inducing complete remission (CR). Conceptually, this means an approximate 2-log reduction in tumour burden. This becomes compatible with a bone marrow that appears normal morphologically and is functionally able to produce normal numbers of circulating cells. The traditional consensus definition of CR is based on these premises: less than 5% blast cells in a cellular marrow durable for at least 28 days with a peripheral neutrophil count of $1.5 \times 10^9/L$ and platelet count above $100 \times 10^9/L$, and absence of extramedullary disease. In some cases, these criteria may be met but the

morphology is dysplastic. It is not clear whether this is associated with a greater risk of relapse. Similarly, some patients meet the marrow criteria but do not achieve full peripheral count regeneration, now called CRi, i.e. either the neutrophil or platelet count has failed to reach the level required for the definition of CR. This subgroup tends to have a poorer overall survival. In some circumstances, these features may represent a pre-existing dysplastic state; in others it may represent the effects of over-treatment of that particular individual. In the former case, this may have adverse connotations while in the latter it represents optimum treatment. As more sophisticated molecular techniques have become available, it is clear that it is still possible to detect residual disease when all morphological and functional criteria are met. Techniques such as real-time quantitative polymerase chain reaction (RQ-PCR) are capable of detection at a level of 1 in 10^4 or 1 in 10^5 residual cells, but such markers are available for only a minority of cases in which the molecular lesion has been characterized. When it is possible (i.e. in an individual who is heterogeneous for an X-linked marker) to use molecular markers of clonality, it has been noted that in some cases marrow remissions are clonal when they would be expected to represent both alleles of the clonal marker. Sometimes the molecular signature is that of the same clone as the leukaemic cells, suggesting that what the remission represents is a precursor or differentiated state of the

malignant clone. It has also been noted that clonal remissions may be derived from the uninvolved allele. As discussed below, there is now intense interest in using validated molecular markers and leukaemia-associated immunophenotypes to predict imminent relapse before this becomes apparent clinically.

Clinical experience has demonstrated that further intensive post-remission treatment is required to 'consolidate' CR. This is delivered at the same intensity as induction in order to achieve further cytoreduction. Under these circumstances, it is possible to achieve disease levels that are beyond the level of molecular detection. It is not clear how many intensive consolidation courses are required, but two or three are generally used in younger patients, and stem cell transplantation may be included. Where intensive induction and consolidation can be given, for example in younger patients, maintenance chemotherapy is not required. A pictorial description of treatment is shown in Figure 23.5.

Treatment details

Induction of remission

The backbone of treatment for 30 years has been the combination of daunorubicin and cytarabine. Usually daunorubicin is given for 3 days in a dose of 45–50 mg/m². Cytarabine is given

Figure 23.5 Diagnostic presentation of treatment strategy.

Table 23.3 Relationship between complete remission rate and patient age. Patients were all given intensive chemotherapy.

Age (years)	<35	35–55	55–60	61–65	66–70	71–75	75+
Complete remission (%)	88	82	77	62	63	48	59

Source: data derived from the UK Medical Research Council AML Trial database.

for 7–10 days as a continuous infusion or by bolus doses of 100–200 mg/m² daily. Many clinical trials have been conducted that have tested variations of this standard of care. Alternatives to daunorubicin (doxorubicin, mitoxantrone, idarubicin, aclaurubicin) or different doses have not yet been shown to be superior overall, although recent studies that have explored higher anthracycline doses may improve the remission rate in older patients. Idarubicin may achieve a better quality of remission, as reflected in a reduced relapse risk in younger patients, but it is more myelosuppressive and limits the intensity of consolidation treatment. In general, on a dose-equivalent basis, daunorubicin remains the anthracycline of choice. Higher doses of cytarabine (3 g/m²) in induction have been tested in recent years, with mixed results and no convincing evidence of overall benefit. Intermediate doses (400 mg/m² daily vs. 200 mg/m² daily) have been tested in younger patients without demonstrating a difference.

Comparison of induction treatment is not simply measured by the rate of remission. By achieving a greater degree of cytoreduction, without necessarily getting more patients into CR, one treatment may be superior because it results in less subsequent relapses. The beneficial effect of the addition of a third drug to the induction combination has some evidence to support it. This will usually be etoposide or thioguanine. A large comparative study did not show any difference between these two drugs when used as the third drug in combination with daunorubicin and cytarabine. The majority of patients who are going to enter remission will do so after one course of treatment. If an incomplete response is obtained, then a second course of the same combination is indicated. A further group will enter remission but these patients have thus shown themselves to have less sensitive disease, and this is reflected in a modestly increased risk of relapse later. If patients fail to achieve a substantial reduction in marrow blasts in the first course or fail to enter CR with a second course, they should be considered refractory to the drugs used up to that point and transferred to an alternative treatment schedule where they can still have a prospect of achieving CR, even though they tend to have a higher risk of rapid relapse.

Results of induction treatment

With this approach to treatment, 50–85% of patients will achieve remission. Of those who do, about 70% will require one course. A number of factors influence the prospects of achieving remission. Age is a dominant and independent risk factor and

a continuous variable; 80% of patients under 60 years will achieve CR, but this prospect diminishes with age (Table 23.3). Clinical performance score at diagnosis is also highly predictive. In younger patients, fewer tend to present with poorer performance scores so this prognostic factor does not move the overall remission rate to any great extent. A larger proportion of older patients will have a poorer risk score and therefore the score has more predictive impact. The distribution of cytogenetic subtypes is related to age, with more-responsive subtypes frequently seen in younger patients and less-responsive subtypes aggregating in older patients. Tumour burden at diagnosis, as represented by white blood count, serum albumin or lactate dehydrogenase levels, will adversely impact on response to induction treatment. It is now possible to measure a number of proteins involved in drug efflux in leukaemic blasts. These 'resistance' proteins, for example P-glycoprotein (see below), tend to be more frequent in older patients and to correlate with a lower remission rate. If patients have had an antecedent haematological disorder, e.g. myelodysplasia, the remission rate will be about 20% lower than in age-matched groups. About 10–25% of older patients embarking on intensive induction chemotherapy will die during the aplastic phase from non-leukaemic causes, which is essentially a failure of supportive care. Induction deaths tend to be associated with the adverse features already mentioned.

Supportive care

It is unusual for induction chemotherapy not to clear most of the leukaemic blasts, however, this is at a cost of 3–4 weeks of severe pancytopenia. Supporting patients through the period of marrow suppression is crucial to treatment outcome; indeed many hold the view that the main reason that treatment has improved is due to improvements in supportive care. It is therefore important that patients are treated in an environment where all necessary supportive facilities are available. Several components of supportive care have to be in place during this period. Careful monitoring of biochemical parameters of renal and hepatic function and coagulation is required. Central venous access is now considered essential, together with high-quality and readily available blood product support.

A priority is the prevention and management of infection. Most patients will receive prophylactic oral antibiotics and antifungals to minimize the risk of infection during the neutropenic period, although routine use of the latter can still be debated. Since hospital-acquired infections are becoming an increasing

problem, it can be safer for the patient to be at home provided that close monitoring can be undertaken in the day hospital and that rapid readmission to specialist care is available.

Despite prophylactic measures, most patients will become febrile during neutropenia. This must be considered an indication of a serious, and potentially fatal, infection. The common pathogens are staphylococcal, caused by the use of central catheters, and, increasingly, fungal infections (*Candida* and *Aspergillus*), which are related to the duration of severe neutropenia that results from the more intensive chemotherapy now used. Particular patterns of infection will be determined within individual institutions and will dictate the specific approach to empirical antimicrobial intervention. Fungal infections are a particular problem, not only related to more intensive treatment but also because of the continuous construction that is such a feature of hospital environments. Guidance on intervention should not only be based on evidence from the literature but should also incorporate local microbiological issues (exemplified in Figure 23.6). Nursing expertise is an essential component. It seems probable that improvements in remission rates

in recent years can largely be attributed to better supportive care and nursing skills, which have enabled more intensive treatment to be given safely.

Recombinant growth factors such as granulocyte colony-stimulating factor (G-CSF) or granulocyte/macrophage colony-stimulating factor (GM-CSF) have potential use in two respects. First, if they could curtail the duration of neutropenia, there would be less risk of death during the aplastic phase following induction chemotherapy; this may increase the rate of remission. Second, as many leukaemia cells exhibit receptors for these growth factors, it may be possible to pretreat the patient with growth factor to bring the leukaemic cells into cycle and thereby make them more susceptible to chemotherapy. Extensive studies using G-CSF or GM-CSF to curtail neutropenia have been carried out and some general conclusions can be made. The duration of neutropenia can be reduced by a few days, but it is less easy to demonstrate a reduction in episodes of febrile neutropenia. There is generally no improvement in remission rate. Growth factor use has not increased leukaemic growth or involved relapse.

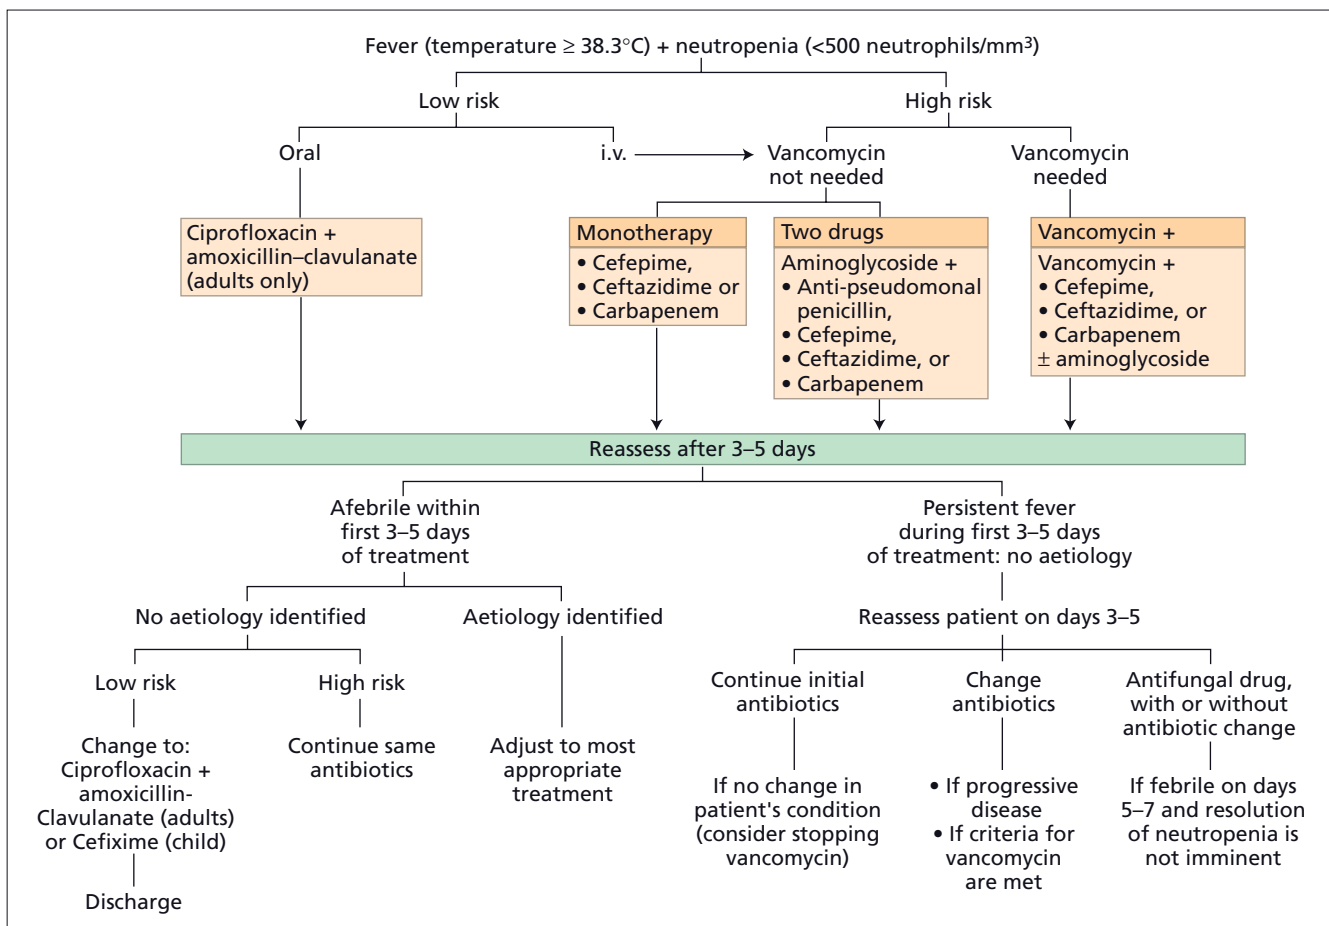

Figure 23.6 Management of febrile neutropenia. (Adapted from Hughes *et al.* 2002 with permission.)

It is primarily a health economics decision that determines whether growth factors are incorporated into routine practice or not. Their use may enable patients to leave hospital earlier. If the local policy is to hospitalize patients during neutropenia, this may save resources. Fewer studies have been carried out to see whether growth factor 'priming' of the leukaemic population would be advantageous. These have generally been unsuccessful but a recent positive study may rekindle interest in this approach, particularly because newer mobilizing agents such as CXCR4 antagonists may soon become available.

Consolidation treatment

Having achieved remission, the priority is to prevent relapse. Optimization of induction treatment is still required as it will influence the quality of remission and thereby the subsequent rate of relapse. Preliminary data suggest that the risk of relapse can be reduced by the addition of the immunoconjugate gemtuzumab ozogamicin (Mylotarg) to induction treatment but it does not change remission rate. Three options are available for younger patients once remission has been achieved: further chemotherapy at induction level of intensity, chemotherapy with autologous stem cell transplantation, or allogeneic stem cell transplantation with or without prior chemotherapy. Chemotherapy will usually involve a further two or three chemotherapy courses. At this point in the treatment, there is a theoretical logic in using different drugs to minimize the

risk of selecting chemoresistant leukaemic clones. Combinations, using cytarabine at increased dosage, amsacrine, etoposide and alternative anthracyclines, are often used (Figure 23.7). Few studies have made direct comparisons between specific combinations, but rather try to work out how many consolidation courses are needed. Two or three courses that are intensive enough to induce 3–4 weeks of neutropenia appears to be achievable but is reaching the limit of tolerability and compliance. High-dose cytarabine (3 g/m² on alternative days over 5 days) has been shown to be superior to lower doses (400 mg/m² or 100 mg/m²), but only in patients with more sensitive disease. Trials have also shown that intermediate cytarabine doses may be just as effective with less toxicity. It has been suggested that high-dose cytarabine is more effective in the most responsive subtypes of disease (i.e. those with lower-risk disease) based on cytogenetic prognostic markers. Overall, 50–55% of younger patients who enter remission will relapse, usually within the first 2 years. In older patients, the risk is much higher (80%).

Allogeneic stem cell transplantation

There is little doubt that the most effective way to prevent leukaemic relapse in younger patients is allogeneic transplantation from an HLA-compatible sibling donor. Most of the extensive data available are derived from patients in whom the graft was of bone marrow. In these circumstances, the relapse risk will be

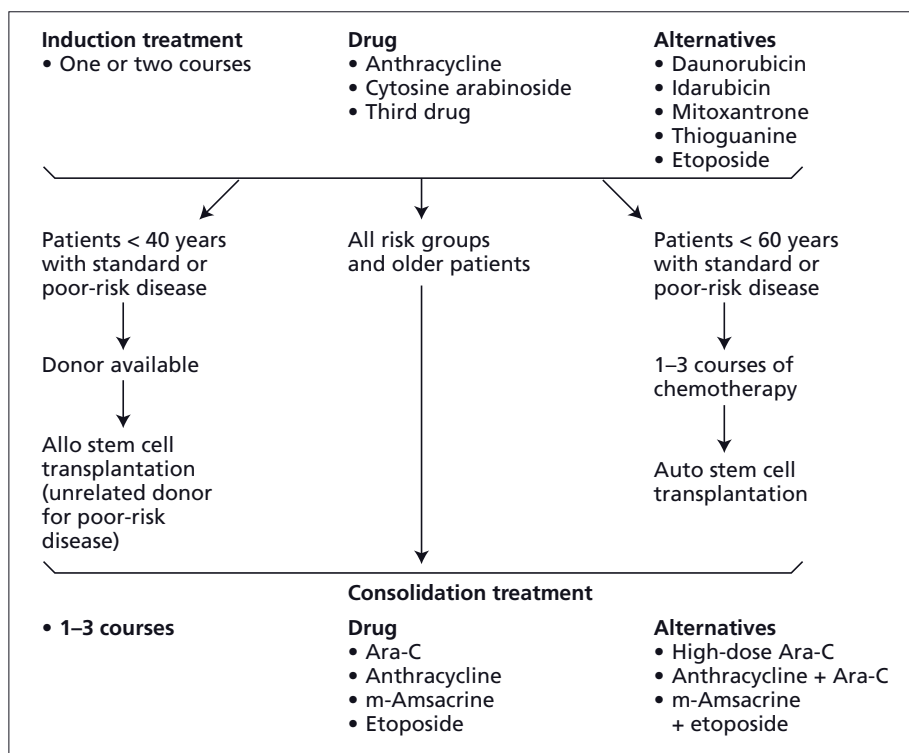

Figure 23.7 Treatment options in AML.

reduced from 45% to about 20%. As there are non-leukaemic causes of death, the overall expectation of cure for recipients of allogeneic bone marrow transplantation is around 60% from the time of transplantation. Some of these survivors will have morbidities that survivors of chemotherapy will avoid, and this needs to be taken into account when advising patients. As the risk of transplant complications, graft-versus-host disease (GVHD) and infections, in particular, increases with age, this approach is normally limited to patients under 45 years, although the precise age cut-off remains controversial and will be a matter of the relative risk of the transplant and of disease recurrence.

Some transplant-related factors may predict for a more favourable outcome, such as a male donor, a cytomegalovirus (CMV)-negative donor when the host is CMV negative and a higher cell count in the graft, and so influence the decision to undergo the treatment, but these seem to be less powerful than disease characteristics in predicting outcome. The extent to which the high-dose preparative regimen necessary to ensure engraftment or the immunological reactivity of the donor marrow via donor T cells eliminates residual leukaemia has been debated extensively. It is assumed that at least some (and probably a major) contribution comes from the immunological graft-versus-leukaemia (GVL) effect. Experience with donors who are mismatched at more than one HLA locus has not been encouraging, but using fully matched unrelated donors has become more reliable, particularly with the development of molecular methods of tissue typing. In expert hands, in carefully selected young patients, this approach may be equivalent to having a sibling donor.

Once remission has been achieved, there is probably no definite requirement to administer more than one course of consolidation chemotherapy before the allograft; however, because of the time required to identify a donor and make the necessary arrangements for the transplant more than one course is usually necessary. It appears that variations in transplantation protocols do not have a major effect on overall survival, for example choice of myeloablative schedule, GVHD prophylaxis or whether bone marrow or peripheral blood is the source of stem cells. However, it may be that the level of immunosuppression with ciclosporin can be manipulated to influence the risk of relapse.

Because the applicability of transplantation is limited, by treatment-related complications, to younger patients, and yet has a very powerful antileukaemic effect, there is recent interest as to whether non-ablative allogeneic transplantation will have a role in older patients. This approach does not require the traditional intensive treatment to ablate the host marrow but provides enough immunosuppression to enable the donor stem cells to engraft. Over a period of weeks, the host haemopoiesis becomes donor, i.e. changes from host to mixed to donor chimerism. It is now clear that that full chimeric engraftment in older patients can be achieved with treatment modalities that

are not ablative to the bone marrow. The hope is that this provides sufficient GVL effect. In AML, in a conventional allogeneic transplant, it is not clear how important the GVL effect is, so it remains to be seen whether non-ablative transplantation has a role in consolidation of AML in older patients. However, the preliminary results have shown that this is a viable approach and that over the 2–4 year term the outcomes are encouraging. The reason why use of this procedure in first remission is still debated is that the risk of relapse is highly variable, and because the encouraging results are distorted by the fact that patients who actually receive the transplant have been selected by surviving in remission until the transplant is performed. The assessment of disease-free survival as the measure of comparison ignores the prospect of rescuing patients who relapse by deploying the transplant in second remission.

Autologous stem cell transplantation

Harvesting of stem cells from the bone marrow or peripheral blood during remission and using them after a period of cryopreservation for haematological rescue after myeloablative chemoradiotherapy has been widely used for younger patients who lack donors. This approach has also been shown to be a more effective way of preserving remission compared with chemotherapy. The treatment-related mortality is lower (5–10%) than with allogeneic transplantation, but it lacks a GVL mechanism so the relapse risk is higher (around 35–40%). This results in an overall survival of 50–55% of those who receive this approach. Because the complications are not particularly age related, patients up to their mid-fifties can safely undergo this procedure, but the results of autologous transplantation in older patients (>60 years) is not encouraging.

Patients who receive the autograft early in remission (e.g. within 3 months) do less well than those treated at 3–6 months because of a higher relapse rate. This may reflect patient selection, but it has also been interpreted to mean that, for an autograft to be successful, consolidation chemotherapy beforehand has an important role in cyto-reduction of leukaemia cells before the marrow is harvested, so-called *in vivo* purging of disease. Initially there was concern that returning stem cells to patients would be illogical unless efforts were made to eliminate contaminating leukaemia cells first, so-called *ex vivo* purging. Various chemical, cellular and immunologically based techniques were used without clear evidence of benefit. Most clinical experience was gained using ‘unpurged’ bone marrow supporting myeloablative chemoradiotherapy, which usually comprised cyclophosphamide with total body irradiation or busulfan with cyclophosphamide.

One of the problems with the use of autologous bone marrow has been delayed peripheral blood count recovery, particularly of platelets. This seems to be a feature of AML and is less obvious in other disease indications. Current practice uses peripheral blood or combines peripheral blood and marrow stem cells to ameliorate this problem. This has

improved haemopoietic recovery but may be associated with an increased risk of relapse, thus giving no overall survival advantage.

Comparison of consolidation options

For patients under 55 or 60 years, all three treatment options are available, so the dilemma is which treatment approach to take. About 45% of patients entering remission will survive with chemotherapy alone. Of those who receive an allogeneic or autologous stem cell transplant, 55–60% and 50%, respectively, will survive. Patients who receive a transplant are not equivalent to patients receiving chemotherapy alone. They have survived long enough to receive the transplant, whereas those who could not have the transplant may not have done so because they relapsed. Some studies demonstrate that 40% of patients with a donor do not receive an allograft.

Another less frequently considered option is to delay the transplant until there is disease recurrence. Primary treatment of relapse with transplantation is associated with a high rate of failure, so it is necessary to establish a second remission first. However, it is possible to salvage overall about 15% of patients who relapse from chemotherapy. Based on risk factors, it is possible to define those patients who, if they relapse, are likely to enter second remission. In this subgroup the transplant can therefore be delayed because, if first-line treatment does fail, a second CR can be reliably obtained and a transplant delivered. If there is a low chance of second remission, there is a stronger case for transplantation as part of first-line treatment.

Several prospective randomized trials have compared chemotherapy with autologous transplantation and allotransplantation with chemotherapy. In the latter case, these comparisons are not truly randomized but rather compare patients found to have donors, and assumed to be intended to receive an allograft, with those for whom no donor is found. This 'donor versus no-donor' comparison is a substitute for randomization. Although the conclusions are not universal, and despite the superior ability of allograft to reduce the risk of relapse and in some studies to improve the disease-free survival, there have been no differences in survival between these approaches. When those with donors are then compared overall there is only a modest but statistically significant survival benefit in favour of allotransplantation; this may, however, be less clinically significant. When the cytogenetic risk of relapse is taken into account (discussed below), it would appear that transplantation is not required for good-risk patients, and in the absence of an emerging improvement for poor-risk patients, allogeneic transplantation including from unrelated donors is the chosen approach. There is a prospect that chemotherapy may continue to improve so the question of whether allotransplantation will continue to be the best option for standard-risk patients remains a matter of considerable debate, particularly with the emergence of several new prognostic markers. The evidence continues to evolve and the challenge is to apply it to individual patients in

daily clinical practice. Part of the problem is that there is a lack of allograft data in the setting of powerful prognostic information.

Factors influencing the risk of relapse

As treatment of disease in younger patients has improved, so the heterogeneity of disease has also become apparent with respect to differences in relapse risk. On multivariate analysis a number of factors have emerged that can predict the risk of relapse irrespective of treatment schedules used, including stem cell transplantation.

Cytogenetics

Patients with t(8;21) and inv(16) have a high remission rate, a lower risk of relapse and a higher rate of second remission, and have a 5-year survival of 65–75%. These patients tend to have lower expression of the 'resistance proteins' and a low frequency of *FLT3* mutations (described below). Acute promyelocytic leukaemia (APL) is now regarded as a separate entity that is uniquely responsive to retinoic acid. In most cases, the disease is characterized by t(15;17), which predicts sensitivity for a differentiation and apoptotic response to retinoic acid. These abnormalities are frequently associated with additional abnormalities such as -X or Y or 9q- in the case of t(8;21), and trisomy 8 in the case of t(15;17). These additional changes do not adversely affect the favourable prognosis. Similarly, the *FLT3* mutation is expressed in about 35% of APL cases but does not affect prognosis in this group of patients. Together, these good-risk patients comprise about 25% of patients under 60 years (Figure 23.2), with a tendency to accumulate in the younger age groups. When good-risk patients occur in the older group, they continue to represent a more favourable group, with a survival of 35% compared with an overall survival of 15–20% in that age group in those treated with intensive chemotherapy.

About 15% of younger patients have cytogenetic abnormalities that are associated with a lower remission rate and a relapse risk on conventional chemotherapy of 85%. These can be identified as -5, del(5q), -7, abnormal 3q, t(9;22), and complex (more than three unrelated changes). Such patients need to be identified early because, even if a remission is achieved, it will be short-lived. Currently, transplantation represents the only viable treatment, but even that is associated with a high relapse risk. There is little evidence that the outlook for this high-risk group has improved over the last 20 years.

Patients who do not fall into the categories described are regarded as standard risk. They have a 5-year survival of 40–45% (Figure 23.8). The impact of this risk stratification is apparent irrespective of chemotherapy used or whether patients receive an allograft or autograft. There are some minor discrepancies between published series, for example trisomy 8 and 11q23 are regarded as poor risk in some series. In larger series, it emerges that patients with 11q23 and a t(10;11) rearrange-

Figure 23.8 The impact of cytogenetic risk groups on treatment outcome. (a) The survival of patients aged under 60 years with good-risk abnormalities – t(8;21), inv (16), t(15;17) – with or without other abnormalities. Poor risk is associated with changes involving chromosome 5 or 7, del 3q or complex abnormalities (more than three abnormalities). The standard-risk group comprises patients who do not have the abnormalities included in the good- or poor-risk categories. (b) The outcome for patients over 60 years old with these abnormalities who were treated with intensive chemotherapy. The relative proportion of the abnormalities in each age group is shown in Figure 23.2.

ment are poor risk (17% survival), whereas other series show in excess of 50% survival in younger patients. As larger databases are accumulated it will be possible to allocate less-frequent abnormalities to risk groups.

In older patients, the overall survival of chemotherapy is around 15–20% at 5 years; it is therefore less easy to delineate cytogenetic risk subgroups. Adverse groups are more frequent, and favourable subgroups are less common. This partly accounts for the poorer prognosis of AML in older patients. It is still possible to derive a hierarchical risk stratification in the older patients based on similar criteria already described for younger patients. Some extremely poor subgroups can be identified (Figure 23.8b).

Age

Increasing age, from children to the elderly who are given intensive chemotherapy, is associated not only with a poorer chance of achieving remission but also with an increasing risk of

Table 23.4 Relationship between blast status and cytogenetic group after course 1.

Cytogenetic group	CR (%)	PR (%)	RD (%)
Favourable	77	68	76
Standard	49	41	16
Poor	26	24	4

CR, complete remission; PR, partial remission; RD, resistant disease.

relapse, even allowing for obvious differences in comorbidities and distribution of cytogenetic risk groups. Leukaemias in the elderly more frequently express the drug transport proteins associated with chemoresistance (discussed below).

Response to induction chemotherapy

Patients who enter remission with the first course will have a lower relapse risk than those who require a further course. This has been recognized in various ways. For example, the presence of residual blasts in the bone marrow on day 14 can be used as a reason to give additional treatment. The blast percentage in the bone marrow assessed on recovery from the first treatment course has been shown to be highly predictive, i.e. patients who have more than 20% blasts, even though remission is subsequently achieved, will have a high relapse risk. Both cytogenetics and age are related to this response. When the morphological appearances are related to cytogenetic risk group, it is clear that, for good-risk patients, failure to clear the marrow with the first course is not an adverse feature, whereas in poor-risk patients even those who clear blasts in the first course will have a poor prognosis. In standard cytogenetic risk patients, it is those who fail to clear the marrow that have an adverse risk. From such data, a risk definition incorporating cytogenetics and marrow response can be obtained and this identifies those in the standard cytogenetic risk group who fail to clear the marrow and are thus poor-risk (Table 23.4). This can be further related to age, which suggests that the impact of older age is clearest in the standard-risk patients who clear marrow blasts.

FLT3 mutations

Not only has this mutation emerged as the most frequent in AML but several large series conclude that it is also a major prognostic factor, not for the achievement of remission but particularly for predicting relapse. It provides additional refinement to cytogenetic predictive groups (Figure 23.9). The question of whether *FLT3* status should be used to direct patients' treatment remains unclear, with studies supporting both sides of the argument. As discussed below, *FLT3* mutation is of interest as a potential therapeutic target. Mutations of the activation loop, which occur in 7–10% of patients, have not been shown to be adverse in all studies and may even be favourable, which

might be explained by the different methods of detection used. *FLT3* mutation status is complicated by the requirement for rigorous definition of meaningful mutation and a knowledge of the mutant to wild-type ratio, where a high ratio has a more negative impact.

Other molecular abnormalities

The discovery that the nucleophosmin 1 (*NPM1*) gene was mutated in around 50% of cases, usually in those with a normal karyotype, stimulated considerable effort to further subdivide the prognostic groups using molecular information. Overall,

the presence of an *NPM1* mutation confers a favourable outcome. However, it frequently coexists with a *FLT3* mutation, where it modulates the negative effects of *FLT3*. In a large UK study on patients in MRC trials, the prognostic implications of the four possible combined genotypes is clear (Figure 23.10). While it is tempting to suggest that the poor outcome for patients with a *FLT3*-positive *NPM1*-negative genotype could be improved by transplantation, so far there are insufficient data to confirm that this is the case.

About 10% of cases, usually those with a normal karyotype, have a mutation of the CCAAT/enhancer-binding protein α (*CEBPA*) gene. This can occur as a single mutation in about half of cases, which does not influence prognosis, or as two mutations, which confer a favourable prognosis equivalent to patients with favourable cytogenetics. Mutations of *c-KIT* have been reported in 20–30% of patients within the core binding factor (CBF) subset of favourable cases, where it identifies a subset who have a higher risk of relapse.

Mutations of the Wilms tumour (*WT1*) gene have recently been identified, and it is generally agreed that they predict for an increased risk of treatment failure. The use of gene overexpression is a little more problematic because of the need to standardize methodology, but proteins in this category include *EVI1* and *BAALC*, which have been reported to predict poorer survival if overexpressed.

The addition of the molecular subdivision to the prognostic assessment adds considerable complexity for prospective validation and for assessing whether any specific treatment is beneficial, or indeed whether the molecular characteristics add prognostic information to that which is already available, or simply identifies the same patient groups.

Figure 23.9 The impact of the presence of *FLT3* mutation on relapse risk in each of the risk groups shown in Figure 23.8a. The presence of a mutation in good-risk patients is predominantly in the t(15;17) group but does not significantly change the relapse risk in good-risk patients.

Figure 23.10 The impact of *FLT3/NPM1* genotypes on survival. (After Gale *et al.* 2008 with permission.)

Performance score

In older patients, standard assessments of performance vary considerably. These scores are highly predictive for induction treatment success, and will also inevitably relate to which patients are considered candidates for an intensive approach to treatment.

White cell count

High tumour load is an adverse feature for both induction and relapse risk. The threshold for risk is not definitive. A white cell count of $50 \times 10^9/L$ is often quoted. In subgroups, a prognostic influence is apparent at much lower counts, for example in APL a white cell count at diagnosis of greater than $10 \times 10^9/L$ is usually agreed as predictive of a higher relapse risk. The impact of a high white cell count is less than that of cytogenetics but may have isolated value when cytogenetics is not available.

Resistance proteins

One of the important biological differences between disease in older patients and that in younger ones is the increased frequency in older patients of the expression of proteins involved in drug transport. These are associated with chemoresistance to some of the drugs used in AML, such as anthracyclines and etoposide. Expression also tends to be associated with a stem cell phenotype and adverse cytogenetics. The most widely studied is P-glycoprotein (P-gp), an energy-dependent transporter protein product of the *MDR1* gene on chromosome 7 and which belongs to the ATP-binding cassette (ABC) transporter family. AML in older patients frequently overexpresses this protein, which has been shown to be predictive for inferior rates of remission and remission duration. The expression levels reported may vary in different series because of differences between measurement techniques. Quantitative flow cytometry has brought a degree of consistency to measurement, but a functional assessment (of dye efflux) and blockade with a P-gp inhibitor is also recommended. *In vitro* preclinical studies have demonstrated that agents such as ciclosporin or its analogue PSC-833 can block P-gp function; however, only one trial to date has so far shown that using such agents has clinical benefit. This may be because P-gp is not the only mechanism of chemoresistance.

Multidrug resistance protein 1 is another member of the ABC transporter family and the gene (*MRP1*) is located on chromosome 16. Lung resistance protein (LRP) is a subunit of the major vault protein, which has been identified in some anthracycline-resistant cell lines and appears to be involved in drug transport. LRP expression has been reported in 30–50% of AML cases in different series, but the majority of studies have been unable to show a correlation with response. Above-normal MRP expression can be found in 50% of patients with untreated AML, but there is no consensus about its impact on survival.

Detection of minimal residual disease

Modern treatments of AML ever more frequently apply the concepts of risk-adapted intensification. An additional, equally crucial, objective is to deliver effective therapies that avoid under- or over-treatment; achieving this has prompted precise measurements of persisting disease, or minimal residual disease (MRD), beyond the threshold of light microscopy. Recently, a significant correlation has been shown between MRD quantified by RQ-PCR or multiparametric flow cytometry and outcome. Therefore, the assumption behind the assessment of MRD is that it will add greater definition to risk prediction by the prognostic factors already recognized. In particular, four major areas of application to the post-remission decision-making process have been identified and are being evaluated: (i) assessment of the quality of response to improve risk stratification and enhance post-consolidation choice (e.g. transplant vs. no transplant); (ii) post-treatment serial monitoring to anticipate overt relapse and plan pre-emptive therapy; (iii) post-stem cell transplantation monitoring to assess the risk of relapse and decide the use of donor lymphocyte infusions; and (iv) identification of markers to pinpoint in the context of targeted-therapy approaches.

Because of the relative insensitivity of techniques such as cytogenetics and fluorescence *in situ* hybridization, molecular and flow cytometry approaches have become the most popular laboratory tests for detecting residual disease. Nucleic acid-based approaches involving RT-PCR have been used particularly in APL. The cloning of a number of breakpoints (Table 23.1) provides the opportunity to utilize a PCR-based approach. Most experience has been gained in APL cases using the PML-RAR α hybrid protein as the target, with assays with a sensitivity of 1 in 10^4 . A number of conclusions have emerged that currently influence clinical practice. If RQ-PCR remains positive after consolidation chemotherapy, the risk of relapse is high (>70%). However, most of the relapses that subsequently occur are in patients who were found to be negative after consolidation. The majority of patients are molecularly negative at this time, but 20% will nevertheless relapse.

A strategy of regular monitoring of bone marrow (e.g. 3-monthly) is capable of detecting the reappearance of molecular positivity about 3–6 months before haematological relapse. No randomized studies have compared the strategy of retreatment at the time of molecular relapse with intervention at the time of haematological relapse. As the risk of haematological relapse in a patient who was RQ-PCR negative but who then becomes positive is very high, early intervention in this disease seems justified.

Anecdotal evidence suggests that intervention at molecular relapse has a better outcome than intervention at haematological relapse. Less information is available about monitoring of the *AML-ETO* or *CBFB-MYH11* fusion genes associated with t(8;21) and inv(16). Longitudinal studies using the *AML-ETO*

fusion have demonstrated that patients in long-term remission may have molecularly detectable 'disease'. This has been attributed to the presence of transcript in other lineages (e.g. monocytes). It seems probable that molecular data will have to be accumulated for each transcript before firm clinical decisions can be based on this information. The transcripts most amenable to monitoring occur in 20–25% of cases which have favourable-risk cytogenetics with fewer relapses, so large prospective trials will be required to accumulate enough patients and enough events to clarify the situation. More sensitivity may be added to this approach using RQ-PCR.

Although several other molecular targets are available, they individually represent small numbers of patients. It may be possible to use a more ubiquitously available molecular target. The *WT1* gene is overexpressed in the majority of AML cases compared with normal haemopoiesis and has been reported to have potential for molecular monitoring in the majority of cases. Mutations of the *RAS* or *FLT3* genes are not likely to be useful in this context because some cases that have the mutation at diagnosis lose it at relapse and vice versa. Conversely, *NPM1* mutations have promise as a stable MRD target. Initial attempts at MRD monitoring have suggested that the *NPM1* mutant allele level reveals residual disease and predicts relapse.

Quantification of MRD by flow cytometry requires the identification at diagnosis of leukaemia-associated aberrant immunophenotypes. These are absent or very infrequent in normal bone marrow but, using a large panel of monoclonal antibodies, can be described in up to 85% of AML cases at diagnosis. These leukaemia-associated immunophenotypes include overexpression of an antigen, coexpression of antigens normally associated with different stages of maturation but which does not occur in novel haemopoiesis, the absence of myeloid antigen expression or the expression of non-myeloid antigens.

The need to test as comprehensive a panel of monoclonal antibodies as possible makes immunological MRD monitoring a quite expensive technology. However, the major impulse for using it derives from its applicability to the vast majority of AML cases, with a sensitivity of 1 in 10^4 or 1 in 10^5 . Although this sensitivity is at least 1-log below that of molecular techniques, improvements are expected using six to eight colour technology. Since most published data have been based in single laboratories, additional concerns pertain to lack of common standard operating procedures in order to generate comparable results. From a clinical point of view, several published studies have demonstrated that the immunophenotypic detection of MRD, at post induction or post consolidation, is independently associated with the risk of relapse. There is also evidence that in MRD-positive patients, the use of allogeneic stem cell transplantation confers a superior outcome whereas autologous stem cell transplantation does not alter the unfavourable course dictated by MRD positivity.

The contribution of molecular biology and flow cytometry to the delivery of MRD-directed therapy in AML may be relevant. In fact, given the broad applicability of flow cytometry and the ever rising number of molecular targets identified, one can expect that virtually every patient with AML will be suitable for MRD monitoring and then for individualized management of disease. There is also demand for establishing whether determination of MRD can enhance current risk-stratification strategies based on pretreatment parameters. All these issues can be addressed in the context of large prospective and cooperative studies including parallel determination of MRD by RQ-PCR and flow cytometry.

Impact of prognostic factors on treatment choice

It is becoming routine to take into account the risk of relapse, as defined by some of the factors described, in order to target treatment. The most obvious example is the growing acceptance that transplantation is not required for patients with good-risk disease. Poor-risk patients must be identified promptly and offered either transplantation or some experimental approach since currently available chemotherapy is inadequate. Further data regarding whether transplantation (sibling or unrelated) significantly benefits high-risk patients are needed. Similar information is also required about the significance of *FLT3* status and associated genotypes with respect to the impact of transplantation. Children respond very well to intensive chemotherapy, with the majority enjoying prolonged remissions. Only the small number of children with high-risk features require first-line transplantation.

In older patients (>60 years), either patients or doctors make a judgement at diagnosis as to whether intensive chemotherapy will be beneficial. Prognostic factors such as cytogenetics and performance score can inform this choice. Very poor-risk cytogenetics (e.g. complex changes) carries such a low prospect of success that the question arises as to whether such patients should receive intensive treatment even if considered sufficiently fit.

Acute promyelocytic leukaemia

APL is a special case in which the presence of t(15;17) predicts sensitivity to treatment with all-*trans* retinoic acid (ATRA). It has been recognized for more than 20 years that this leukaemia subtype is sensitive to anthracyclines. Recent experience has clearly demonstrated that the combination of ATRA and chemotherapy has made a dramatic improvement, with survival now expected to exceed 80%. Even better prospects are becoming apparent when the combination of an anthracycline (idarubicin) and ATRA form the backbone of treatment. Simple maintenance with courses of ATRA and orally available agents such as methotrexate and 6-mercaptopurine has been shown in some studies to provide additional benefit. Since the molecular consequences of t(15;17) are known, evaluation of the role of

molecular monitoring is most developed in APL and provides a model for disease monitoring in AML.

Treatment in the older patient

Improvement in survival in older patients over the last 20 years has been much more elusive. With better supportive care, intensive chemotherapy can expect to achieve remission in 50–60% of cases. However, 80% of cases will relapse by 2 years. This result has been achieved with various combinations of induction and consolidation schedules and is not improved by maintenance to any great extent. There will be a greater interest in maintenance in future studies. Because the outcome is poor, two issues arise. Are there prognostic factors that confirm which patients will benefit from an intensive treatment approach? The data are less convincing than in younger patients, but younger age (60–70 years), higher performance score and favourable cytogenetic risk group can identify a minority of patients with a better than average outcome. However, several patients have adverse factors: older age, poorer performance score, complex cytogenetics or a chemoresistant phenotype. These patients will have a worse prognosis, which raises the issue of whether they should receive palliative care from the start. One modestly sized study compared a palliative treatment approach with conventional chemotherapy and demonstrated that the use of intensive chemotherapy, because it achieved remission, was more beneficial in older patients; however, no study has yet been large enough to ask that question within the risk groups.

One strategy for improvement is to target the function of P-gp. Only one of several studies using ciclosporin or its analogue has managed to improve survival in relapsed disease, but other studies combining it with first-line treatment have been unsuccessful. This may be because P-gp is not the only resistance mechanism present in leukaemic cells, and once a cell has become resistant by one mechanism there are already other resistance routes.

Management of relapse

The majority of patients will relapse. If this happens after stem cell transplantation, the benefit of further therapy is questionable. However, this is dependent on when the relapse occurs. Within 1 year, further treatment is unlikely to have sustained benefit and retransplantation is usually associated with a very high complication rate. If the relapse occurs later, further chemotherapy with retransplantation may save a few patients. The development of donor lymphocyte infusions has been a very effective approach for the treatment of post-allograft relapse in chronic myeloid leukaemia, but has a low rate of success in AML.

For patients who relapse after chemotherapy, three factors dictate the clinical outcome: duration of first remission, age and cytogenetic risk group. Patients with good-risk disease have a high (75–80%) rate of second remission. Patients who are young with a long CR1 will have a reasonable survival, whereas

Table 23.5 Outcome of relapse in patients over 60 years receiving reinduction treatment (*N* = 1529).

5	CR1 (months)		
	<6	6–12	>12
<i>Remission rate</i>			
15–59 years (%)	15	33	56
60–69 years (%)	11	29	67
>70 years (%)	13	26	53
<i>Survival from relapse at 2 years</i>			
<35 years (%)	10	16	41
35–60 years (%)	7	14	27
60+ years (%)	4	8	16

older patients with a short CR1 will do poorly (Table 23.5). Since the second remission rate in good-risk disease defined by cytogenetics is relatively good, transplantation is usually delayed until second remission. There is no clear 'best choice' chemotherapy for other risk groups, so this is often the setting for experimental therapy development.

APL is again a special case. Patients can respond again to retinoic acid and chemotherapy, but recently arsenic trioxide and the CD33-directed immunoconjugate gemtuzumab ozogamicin have been found to be effective. Remission rates above 80% have been reported; interestingly, following consolidation therapy, a similar proportion can be returned to RQ-PCR negativity. This permits the opportunity for autologous transplantation, the successful outcome of which depends on the autograft and, preferably, the patient being molecularly negative. For patients who remain molecularly positive after reinduction, allogeneic transplantation is indicated.

For non-APL patients, whatever treatment is used to re-establish remission, it is unlikely to be durable without a transplant. Although prospective studies are rare, transplant registry data suggest that about 30% of patients can be salvaged with a transplant with little overall difference whether the source of stem cell is allogeneic or autologous.

Future developments

Classification

The classification of this disease will no doubt continue the trend of taking into account molecular, genetic and clinical features as well as morphology. The technology could eventually allow subgroups to be identified on the basis of a gene expression signature, as shown in Figure 23.11. High-density microarray gene chips can already distinguish major cytogenetic and FAB groups and the presence of an *FLT3* mutation,

Figure 23.11 A gene cluster of AML samples. A gene list was identified from the 22 283-gene probe set on the Affymetrix U133A gene chip, which was capable of predicting cytogenetic risk group. This list was used to cluster the samples into similar groups and cluster genes showing similar expression profiles (within the cluster, red indicates high expression whereas green is

low or absent expression). One group for each of the good- and poor-risk groups was obtained, but several clusters of standard-risk patients were identified, which may correlate with the diverse nature of this subgroup. Blue, good-risk patients; pink, standard-risk patients; yellow, poor-risk patients. Note that the right-hand cluster contains patients with good, standard and poor risk.

and using this information up to 16 subtypes have been proposed. This technology offers no advantage over currently available methods but is at the developmental stage. It will throw light on associated molecular abnormalities that may eventually become targets for drug design and which may be capable of predicting disease or toxicity response. The bioinformatics challenges are considerable given the enormous amount of information that these methods produce.

Therapeutics

There is general acceptance that little further progress will be made by simply shuffling currently available drugs with respect to either scheduling or dosage. There may still need to be refinements with respect to toxicity. There is much interest in targeting treatment, either by matching the treatment approach to the patient based on prognostic factors or by immunologically directing treatment to leukaemic cells and thereby enhancing the selectivity of treatment. Gemtuzumab ozogamicin is an immunotoxin that is being extensively explored in this respect. This is an immunoconjugate combining an IgG4 anti-CD33 humanized monoclonal antibody with the highly potent anti-tumour antibiotic calicheamicin. The key to its utility is that

when the antibody combines with CD33 antigen, the complex is rapidly internalized to the cell, where the chemical linker between drug and antibody is lysed. A crucial property is that the linker is lysed only intracellularly and not in the circulation. Although expressed in 90% of cases of AML, CD33 is not leukaemia specific. There is expression on haemopoietic precursors but not on stem cells or, as far as is known, other tissues. The conjugate is clearly active. As a single agent, it can achieve CR in relapse or as first-line treatment in older patients. Pancytopenia is not avoided and transient hepatotoxicity will be seen in some patients. It does not result in the alopecia or mucositis usually associated with chemotherapy. Its use in AML is under investigation in a number of areas, for example in induction in older patients before chemotherapy; for induction in patients unfit for chemotherapy; as maintenance of remission; as first-line and relapse treatment in APL; as part of transplant conditioning; and in simultaneous combination with conventional chemotherapy. All these approaches are still experimental.

Allogeneic transplantation has proved over the years to be a highly effective immunological approach. However, as previously pointed out, the overall survival advantage is not always clear. Part of the reason is that because it is only safely applicable

to younger patients, it is competing with the group of patients with the most favourable responses to chemotherapy. Non-intensive transplants have demonstrated that it is feasible to achieve full chimeric status, i.e. 100% donor cells in the bone marrow, without using intensive chemoradiotherapy. This can be done safely in older patients, but there remain concerns about the balance between avoiding relapse on the one hand and GVHD on the other. This could represent a consolidation option for older patients for whom conventional chemotherapy is less successful and where there is an antileukaemic effect of standard allograft. The approach presumes that there will be a significant GVL effect operating in AML. There are only preliminary data on this approach in AML, which is still experimental; assessment in a prospective clinical trial is required.

Many small molecules, particularly tyrosine kinase inhibitors, are becoming available for cancer treatment. So far none has matched the impact of Glivec in chronic myeloid leukaemia. The recognition of the *FLT3* mutation as a common mutation in AML has led to the discovery of several powerful, but not specific, inhibitors of the receptor tyrosine kinase FLT-3, which autophosphorylates the receptor and downstream molecules. Preclinical models provide considerable encouragement for efficacy. Initial clinical studies show a response in about 50% of patients with relapsed disease, with only occasional CRs; the duration of any responses tended to be short. Because of lack of specificity, it is likely that these agents will need to be used in combination with each other, or with chemotherapy. Inhibitors of RAS pathway molecules have also undergone preliminary assessments. Some responses have been seen, but it is also clear that the agents tested are not specific.

Newer more conventional agents (e.g. clofarabine, clorzazine, tipifarnib and demethylation agents) hold promise from unrandomized trials. Since many new treatments will be available, novel approaches to clinical trial design will need to develop to make more rapid progress. Much greater international collaboration is needed to provide sufficient numbers of the patient subgroups or different statistical methods will be required.

Diagnosis

The classification of blast cell phenotype in adult acute lymphoblastic leukaemia (ALL) requires morphological and cytochemical evaluation, immunophenotyping, cytogenetic and molecular genetic analysis. Morphology remains the method by which acute leukaemia is initially detected and, together with cytochemical reactions, is the major aid in distinguishing between ALL and acute myeloid leukaemia (AML). For more precise subclassification of ALL into B or T lineages, immunological techniques must be used to detect lineage-specific antigens as well as surface or intracytoplasmic molecules (see also Chapter 22). Cytogenetic analysis is generally part of the diagnostic evaluation of ALL because it may have prognostic value, but molecular genetic techniques for identification of particular subsets of ALL (e.g. *BCR-ABL*-positive ALL) are even more important. Molecular markers and cell surface markers are presently used to evaluate therapeutic efficacy in individual patients by detecting minimal residual disease (MRD).

Morphology

Leukaemic blast cells were formerly divided into L1 to L3 according to the French–American–British (FAB) classification. The subtype L3, observed in approximately 5% of adult ALL patients, was the only one with clinical relevance because it is indicative of mature B-cell ALL, which is subject to different treatment. The diagnosis should be confirmed by surface marker analysis.

According to the new World Health Organization (WHO) classification, ALL is summarized together with lymphoblastic lymphoma under the heading of precursor lymphoid neoplasms, with the major subgroups comprising B lymphoblastic leukaemia/lymphoma not otherwise specified, B lymphoblastic leukaemia/lymphoma with recurrent genetic abnormalities, and T lymphoblastic leukaemia/lymphoma. Mature B-ALL is not mentioned as a separate entity and is included as Burkitt lymphoma under the heading of mature B-cell neoplasms. The WHO classification for ALL is based on cytogenetic aberrations, which may be of limited relevance for clinical management and risk stratification.

Cell surface marker analysis

Acute lymphoblastic leukaemia is divided into subtypes by immunological criteria based on the presence of specific

Table 24.1 Immunological classification, corresponding cytogenetic and molecular aberrations and frequencies in adult ALL.

	Adults (%) [*]	Surface marker	Cytogenetics [†]	Molecular genetics [†]
<i>B-lineage</i>				
		HLA-DR ⁺ , TdT ⁺ , CD19 ⁺ and/or CD79a ⁺ and/or CD22 ⁺		
Pro B-ALL	11	No further differentiation markers	t(4;11)	<i>ALL1(MLL)-AF4</i>
Common-ALL	50	CD10 ⁺	t(9;22)	<i>BCR-ABL</i>
Pre B-ALL	12	CD10 ^{+/-} , cyIgM ⁺	t(9;22), t(1;19)	<i>BCR-ABL, E2A-PBX1</i>
B-ALL	5	CD10 ^{+/-} , sIgM ⁺	t(8;14)	<i>MYC-IGH</i>
<i>T-lineage</i>				
		TdT ⁺ , cyCD3 ⁺ or sCD3 ⁺		
Early T-ALL	6	cyCD3 ⁺ , CD7 ⁺ , CD5 ^{+/-} , CD2 ^{+/-}	t(11;14)	<i>LMO1-TCRα/δ</i>
Cortical T-ALL (Thy ALL)	10	cyCD3 ⁺ , CD7 ⁺ , CD1a ⁺ , sCD3 ^{+/-}	t(10;14)	<i>HOX11-TCRα/δ</i>
Mature T-ALL	6	sCD3 ⁺ , CD1a ⁻		

^{*}Frequencies according to central immunophenotyping of the GMALL Study Group; personal communication of Professor E. Thiel and Dr S. Schwartz, Free University of Berlin, Germany.

cyIgM, cytoplasmic IgM; sIgM, surface IgM; cyCD3, cytoplasmic CD3; sCD3, surface CD3; TdT, terminal deoxynucleotidyltransferase.

receptors or antigens on the cell surface of leukaemic blast cells. Within B- or T-lineage ALL, the subtypes are defined according to their stage of differentiation. For more details on the immunological classification of ALL, see Chapter 22. The frequency and definition of subtypes in adult ALL is given in Table 24.1. The European Group for the Immunological Characterization of Acute Leukaemia (EGIL) has proposed a unified classification for ALL immunophenotypes.

B-lineage ALL

Pro-B ALL, also termed *pre-pre-B ALL* or early pre-B, is CD10 negative and lacks specific B- or T-cell differentiation markers but expresses human leucocyte antigen (HLA)-DR, terminal deoxynucleotidyltransferase (TdT) and CD19, and has rearranged immunoglobulin genes. It occurs in approximately 9–11% of adult ALL.

Common ALL (c-ALL) is the major immunological subtype in adult ALL. It constitutes more than 50% of cases of adult ALL. c-ALL is characterized by the presence of CD10. Blast cells do not express markers that characterize relatively mature B cells such as cytoplasmic or surface membrane immunoglobulins. The blast cells are positive for CD19 and TdT.

Pre-B ALL is characterized by the expression of cytoplasmic immunoglobulin, which is absent in c-ALL, but is identical to c-ALL with respect to the expression of all other cell markers.

Mature B-cell ALL is found in approximately 5% of adult ALL patients. The blast cells express surface antigens of mature B cells, including surface membrane immunoglobulin. CD10 may be present, as well as, occasionally, cytoplasmic immunoglobulin.

T-lineage ALL

Approximately 22% of adult ALL cases have blast cells with a T-cell phenotype. All cases express the T-cell antigen gp40 (CD7) and they may, according to their degree of T-cell differentiation, express other T-cell antigens, for example the E rosette receptor (CD2) or the cortical thymocyte antigen T6 (CD1) (Table 24.1). A minority of T-cell ALL blast cells expresses CD10 together with T-cell antigens. In most cases of T-cell ALL, one or more of the T-cell receptor (TCR) genes are rearranged. These properties make it possible to classify T-cell ALL according to their stage of differentiation.

Early T-precursor ALL accounts for 6% of adult ALL. It shows characteristic T-cell markers (cyCD3 and CD7) but no further differentiation markers.

Thymic (cortical) T-ALL is the most frequent subtype of T-ALL (10%). It is characterized particularly by the expression of CD1a. Surface CD3 may be present. Since this subtype is associated with a better prognosis, its identification is of particular importance.

Mature T-ALL has a frequency of 6%. The blast cells do not express CD1a but they are positive for surface CD3.

Cytogenetic and molecular genetic analysis

Cytogenetic abnormalities are independent prognostic variables for predicting the outcome of adult ALL. In several multicentre studies, clonal chromosomal aberrations could be detected in approximately 62–85% of adult ALL patients.

The Philadelphia (Ph) chromosome, t(9;22)(q34;q11), results from a translocation involving the breakpoint cluster region of

the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9 (see also Chapters 22 and 27). Polymerase chain reaction (PCR) analyses has revealed that *BCR-ABL*-positive ALL occurs in 20–30% of adults compared with 3% of children. One-third of adult ALL patients with a Ph chromosome show *M-BCR* rearrangements (resulting in a 210-kDa protein), similar to patients with chronic myeloid leukaemia (CML), whereas two-thirds have *m-BCR* rearrangements (resulting in a 190-kDa protein). It is noteworthy that the molecular aberration *BCR-ABL* is more frequently detected than the corresponding chromosome abnormality t(9;22) because of occasional difficulties in obtaining adequate material for cytogenetic analysis (see also Chapter 22). The most frequent form of 11q23 abnormality in ALL is t(4;11)(q21;q23). The translocation is frequently detected in infant leukaemia and in patients with the pro-B ALL subtype (CD10 negative). The overall incidence in adults is approximately 5%. Typical molecular aberrations in ALL with associated cytogenetic translocations and immunological subtypes are summarized in Table 24.1.

The role of cytogenetic analysis in adult ALL has to be re-evaluated critically. The most frequent cytogenetic aberrations and those with the largest prognostic impact can also be detected by the corresponding molecular genetic abnormalities, as mentioned above. These techniques are more reliable and have a greater sensitivity, for example a detection level of more than 10^{-6} for *BCR-ABL*. They are therefore more useful for initial detection of the aberrations and for follow-up analysis of MRD (see below). In addition, the observed incidence of the majority of cytogenetic aberrations is very low and therefore correlation to clinical outcome, and especially therapeutic consequences, are limited. Nevertheless, cytogenetic analysis is still recommended as a routine diagnostic method in ALL.

Minimal residual disease

The detection of blast cells by cytological analysis of bone marrow smears has a sensitivity of 1–5%. More sensitive methods of blast cell detection are available for the identification of MRD. Sensitivity reaches 10^{-4} or more, corresponding to 0.01% blast cells (one leukaemia cell within 10 000 normal cells). MRD evaluation allows quantitative follow-up of individual response after achievement of complete remission detected by bone marrow cytology.

Quantitative PCR can be directed to fusion genes associated with ALL-type translocations such as *BCR-ABL*. These markers are available in 30–40% of adult ALL patients. The detection of individual clonal rearrangements of immunoglobulin (*IGH*, *IGK*) and TCR- β , TCR- δ and TCR- γ genes is more broadly applicable. For this method a high level of standardization regarding methodology and interpretation of results has been achieved (see also Chapter 22). The individual marker can only be detected in blast cells and therefore diagnostic material

is required. With multiparameter flow cytometry, individual leukaemia-specific phenotypes, i.e. characteristic constellations of surface antigens, can be detected with high specificity and sensitivity. MRD detection with any method should be restricted to experienced laboratories that participate in quality control rounds taking place on an international level in Europe.

Clinical features

Most adult ALL patients initially present with clinical symptoms resulting from bone marrow failure. Physical findings such as pallor, tachycardia, weakness and fatigue are due to anaemia; petechiae or other haemorrhagic manifestations are attributable to thrombocytopenia; infectious complications are due to neutropenia. Clinical signs of leukaemia related directly to infiltration of typical organs with leukaemic blasts, such as lymphadenopathy, splenomegaly and hepatomegaly, are present in most patients but are infrequently the reason for which the patient first seeks medical advice.

Symptoms and clinical manifestations of adult ALL patients, aged 15–65 years, entering two consecutive German multicentre trials are given in Table 24.2 according to their classification into the different immunological subtypes. One-third had infection or fever at presentation, and one-third presented with haemorrhagic episodes. Approximately half of the patients presented at diagnosis with lymphadenopathy, splenomegaly and hepatomegaly, and hilar lymph node enlargement or a thymic mass (detected on chest radiography or computed tomography) in approximately 14% of patients. Most patients (85%) with mediastinal masses had T-cell ALL. Massive thymic enlargement can cause dyspnoea, especially when associated with pleural effusions. Although 7% of ALL patients at presentation had central nervous system (CNS) involvement (as demonstrated by leukaemic blast cells in the cerebrospinal fluid), only 4% of these initially had CNS symptoms such as headache, vomiting, lethargy, nuchal rigidity and cranial or peripheral nerve dysfunction.

Virtually any organ can be infiltrated by ALL blast cells, and approximately one-tenth of the patients had such organ involvement but with wide variation between subtypes (Table 24.2). Most often a pleural effusion was observed, and this occurred almost exclusively in those patients with mediastinal enlargement and T-cell ALL. Some of these patients also had a pericardial effusion. Bone or joint pain was rarely observed compared with childhood ALL; bone lesions could be found in only 1% of cases. Initial involvement of the testis was very rare (<1%). Leukaemic infiltration of retina, skin, tonsils, lung or kidney was observed only occasionally, particularly in mature B-cell ALL and to a lesser extent in T-cell ALL, all of them associated with a poorer outcome.

Laboratory evaluation

The peripheral blood cell counts at diagnosis of the same cohort of patients are given in Table 24.3, which again shows differences between the subtypes of adult ALL. Overall, the leucocyte count was elevated in 59% of the cohort, 14% had normal counts and 27% had leucopenia. In 92% of the patients, leukaemic blast cells were seen in the blood film. Thus, ‘aleukaemic’ leukaemias account for only a small proportion of cases of adult ALL. With automated blood counting, the diagnosis may be missed in patients with normal or decreased white blood cell (WBC) counts and with low or zero blast cells in peripheral blood. Regardless, microscopic examination of blood films in people suspected of having acute leukaemia is an absolute requirement. A blood count above $100 \times 10^9/L$ was observed in 16% of the patients, and occasionally WBC counts above $500 \times 10^9/L$ occurred. In general, a high WBC count is found more frequently in patients with T-cell ALL compared with those with B-lineage ALL (Table 24.3).

Neutrophils below $0.5 \times 10^9/L$ were seen overall in 23% of the patients. Severe neutropenia at diagnosis is observed more often in B-precursor ALL (28%). Thrombocytopenia below $25 \times 10^9/L$ occurred in one-third of adult ALL patients, corresponding roughly with the symptoms of infection and bleeding present at diagnosis. Anaemia at diagnosis is observed in most adult ALL patients, but only in a small proportion is it severe, with haemoglobin under 8 g/dL (Table 24.3).

Bone marrow aspiration or biopsy is mandatory for diagnosis. In less than 15% of patients, the bone marrow cannot be

aspirated and a biopsy must be performed. Dry taps are due to densely packed blast cells, fibrosis or inadequate technique; the first two resolve after therapy. Most patients have more than 50%, or even more than 90%, of blast cells in the bone marrow. In under 3% of cases, the blast cells constitute less than 50% of the nucleated marrow cells.

A lumbar puncture should be done to determine whether the CNS is involved. If there is a risk of bleeding as a result of a very

low platelet count, or of blast cell contamination due to a very high leukaemic blast content in the peripheral blood, lumbar puncture should be postponed. When the leucocyte count in the spinal fluid is low or the morphological detection of blasts is inconclusive, demonstration of an immunologically defined blast cell population can confirm a diagnosis of CNS involvement.

The most frequent metabolic abnormality is an increased serum uric acid level in approximately half of the patients; hypercalcaemia is rare. Serum lactate dehydrogenase (LDH) is often elevated as a result of cell destruction in patients with a large tumour mass. In a small proportion of patients, the initial fibrinogen level was less than 1 g/L. Disseminated intravascular coagulation in ALL was rarely observed at diagnosis.

Differential diagnosis

Difficulty is rarely experienced in establishing the diagnosis of ALL. The differentiation from lymphocytosis, lymphadenopathy and hepatosplenomegaly in viral infections and other acute or chronic leukaemias can usually be done by lymphocyte surface markers.

Aleukaemic pancytopenic ALL without blast cells in peripheral blood (<10%) has to be distinguished from aplastic anaemia, which may also be a preleukaemic syndrome. In contrast to ALL, in aplastic anaemia the bone marrow is hypocellular. In rare cases with low bone marrow infiltration, an arbitrary distinction between ALL and lymphoblastic non-Hodgkin lymphoma is usually chosen according to the degree of infiltration (above or below 25%).

Mixed or hybrid leukaemias are those in which blast cells express lymphoid as well as myeloid antigens; they may also be described as biphenotypic or bilineage leukaemias. Biphenotypic leukaemias are defined as those in which markers of lymphoid and myeloid lineages are coexpressed on the same leukaemic cells. EGIL has suggested a scoring system that is helpful for definition of biphenotypic leukaemia depending on the type and degree of expression of lymphoid and myeloid markers. Bilineage leukaemias are those with two populations of blast cells that have either lymphoid or myeloid antigens and which might be allocated to an ALL or AML treatment strategy. After the start of therapy with either regimen, one population may disappear whereas the other is maintained and may require a shift of therapy.

Occasionally, difficulties can occur in distinguishing Ph/*BCR-ABL*-positive ALL from primary lymphoid blast crisis of CML. Sometimes the final diagnosis can be done only after treatment initiation. In ALL patients achieving complete clinical remission (CR), the peripheral blood count shows normal values, whereas in CML it may revert to a chronic phase picture showing leftshift.

Initial evaluation and supportive therapy

Speed in clinical evaluation and diagnosis is important in order to initiate supportive measures and to decide on appropriate therapy. In only a few cases is the leukaemic process so advanced that immediate treatment is necessary (e.g. in patients with symptoms due to a large mediastinal mass and pleural effusion, a very high WBC count or a rapidly progressing B-cell ALL).

A few general measures should be initiated at once. Sufficient fluid intake to guarantee urine output of 100 mL/hour throughout induction therapy should be maintained to reduce the danger of uric acid formation. Patients should also receive allopurinol to reduce the risk of the latter and avoid the danger of urate nephropathy. Allopurinol blocks the enzyme xanthine oxidase, which mediates the generation of uric acid from xanthine as a product of purine catabolism. Allopurinol should be given at a dose of 300 mg/day, which may be increased to 600 mg/day if high leucocyte counts or organomegaly persist. The dose of allopurinol has to be reduced when 6-mercaptopurine is given because it potentiates the action of this drug. Rasburicase is a new recombinant urate oxidase enzyme that catalyses the oxidation of uric acid to allantoin. Rasburicase can reduce high uric acid faster and more safely than allopurinol, thereby preventing tumour lysis syndrome in almost all cases. It might therefore be an alternative in patients with high risk of tumour lysis syndrome.

Parenteral fluid administration may be required when the patient's oral intake is inadequate because of nausea or difficulty in swallowing. Placement of an implantable port system is advantageous when anticipating a long period of induction therapy (see also Chapter 26).

Blood substitution (see also Chapter 26)

In general, platelet transfusions should be given in response to bleeding episodes and to prevent bleeding according to standard recommendations. HLA-matched platelets are given to patients who become refractory to random donor platelets. Red cell transfusions have a lower priority than platelet substitution. They should be given according to haemoglobin values but depending on age, comorbidity (e.g. cardiac) and clinical symptoms.

Infection management

Infection management is of increasing importance in adult ALL. Infections are the major cause of early death (2–20% depending on age), with equal contributions of fungal and bacterial pathogens. Antifungal prophylaxis during vincristine therapy in induction is a problem since azoles may enhance neurotoxic effects. There are also no standards for antibacterial prophylaxis. Moreover, the parallel application of chemother-

apy, antifungals and antibiotics may enhance the risk of toxicities (e.g. liver toxicity, nephrotoxicity) and thereby contribute to treatment delays. The optimization of supportive care is a major goal in treatment of adult ALL since early complications not only lead to early death but also to treatment delays and thereby compromise outcome.

Long-term neutropenia is the most important risk factor, but CD4 lymphopenia, antibody deficiency and multiple immunosuppression in allogeneic stem cell transplantation also lead to severe and lethal infections. Whereas formerly Gram-negative microorganisms were the leading cause of febrile neutropenia, in the last decade Gram-positive bacterial infections, mostly caused by staphylococci, have increased and are frequently correlated with indwelling central venous access. However, invasive fungal infections are the most dangerous development, with increasing frequency particularly of mould infections.

The successful management of febrile neutropenia is based on hygienic procedures including body hygiene, germ-reduced food, reverse isolation or high-efficiency particulate air filtration, antibiotic prophylaxis, sufficient diagnostics, and consequent empirical antimicrobial therapy. Prophylaxis and treatment of bacterial, viral and fungal infections should be performed according to published standards as well as institutional guidelines.

Haemopoietic growth factors

The use of haemopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) is a valuable component of supportive therapy during the treatment of ALL. There is no indication that these CSFs stimulate leukaemic cell growth in a clinically significant manner. Most clinical trials have demonstrated that the prophylactic administration of G-CSF significantly accelerates neutrophil recovery, and several prospective randomized studies have also shown that this is associated with a substantially reduced incidence and duration of febrile neutropenia and of severe infections and reduced induction mortality.

The scheduling of G-CSF is of great importance. When G-CSF is first given at the end of a 4-week induction chemotherapy regimen, potential benefits are limited. Therefore, it is noteworthy that G-CSF may even be given in parallel with chemotherapy without aggravating the myelotoxicity of these specific regimens and that this scheduling is an important determinant of clinical efficacy. On the other hand, after short consolidation cycles, G-CSF is probably more effective if given after the cycle.

Closer adherence to the dose and schedule of chemotherapeutic regimens should be theoretically possible with the use of G-CSF. A benefit in terms of long-term outcome due to increased dose intensity achieved by using G-CSF has not yet been demonstrated in any trial.

Chemotherapy

Chemotherapy of ALL is usually divided into several phases, beginning with remission induction. The objective of induction chemotherapy is to achieve CR, i.e. eradication of leukaemia as determined by morphological criteria and, more recently, also by molecular markers. Post-remission therapy usually consists of intensification or consolidation cycles and maintenance treatment. Most often, specific prophylactic CNS treatment is added.

Remission induction therapy

Correct diagnosis and management of the initial complications are the prerequisites for successful induction therapy. A cautious cell reduction phase is often recommended for patients with a large leukaemic cell burden or a high leucocyte count. Patients with extreme leucocytosis ($>100 \times 10^9/L$) have been treated initially with leucapheresis, but these patients can generally be managed with steroids alone or in combination with vincristine or cyclophosphamide. For mature B-cell ALL, initial treatment with cyclophosphamide and prednisone for 1 week usually results in safe reduction of large tumour masses, in most cases without tumour lysis syndrome.

Standard induction therapy for ALL includes prednisone, vincristine, anthracyclines (mostly daunorubicin) and also L-asparaginase. Further drugs, such as cyclophosphamide, cytarabine (either conventional or high dose), mercaptopurine and others, are added in many protocols, sometimes termed 'early intensification'.

Prednisone and prednisolone have been most frequently administered, although dexamethasone shows higher antileukaemic activity *in vitro* and better penetration of the cerebrospinal fluid. However, extensive use of dexamethasone may be associated with an increased risk of septicaemias and fungal infections, which may be circumvented if treatment time and dose is reduced.

Anthracycline dose intensity and schedule may play an important role in induction therapy of adult ALL. In the past daunorubicin was mostly administered as a weekly schedule, but recently many trials include dose intensification with doses of 30–60 mg/m² on a 2–3 day schedule. Intensive anthracycline therapy may be associated with a higher induction mortality. Therefore, intensive supportive care and probably the use of growth factors is recommended with these protocols.

Asparaginase does not affect CR rate but improves leukaemia-free survival (LFS). If not used during induction therapy, it is often included as part of consolidation treatment. Three different asparaginase preparations with significantly different half-lives are available: native *E. coli* asparaginase (1.2 days), *Erwinia* asparaginase (0.65 days) and asparaginase bound to polyethylene glycol (pegaspargase, 5.7 days). Availability may vary between different countries. In order to reach equal effi-

cacy, the application schedule has to be adapted and is generally daily for *Erwinia* asparaginase, every second day for *E. coli* asparaginase and every 1–2 weeks for pegaspargase. Pegaspargase has the advantage of less frequent administration and even more activity distribution.

The role of cyclophosphamide, generally administered at the beginning of induction therapy, has been evaluated in several studies. A randomized study by the Italian GIMEMA group comparing a three-drug induction with or without cyclophosphamide did not show a difference in terms of CR rate (81% vs. 82%). However, in several non-randomized trials, high CR rates (85–91%) were achieved with regimens including cyclophosphamide pretreatment, particularly in adult T-ALL.

High-dose chemotherapy with cytarabine or methotrexate has no role during induction with the exception of a few trials.

Failure of induction therapy

With current regimens the remission rate in ALL is 85–90% (Table 24.4) with low failure rates and a variable early mortality up to 11%, increasing with age from less than 3% in adolescents to 20% in patients over 60 years of age. The main cause of death in approximately two-thirds of the patients is infection, in part fungal infection. Besides mortality, morbidity (e.g. due to

extended cytopenias, subsequent infections such as fungal pneumonias) also has to be considered, which may compromise further treatment and dose intensity. The remaining non-responders may achieve a partial remission or may be refractory to standard treatment. These patients have an extremely poor prognosis. They are therefore candidates for experimental treatment approaches or consideration for stem cell transplantation (SCT), even if not in CR but in good partial remission.

Consolidation therapy

Consolidation therapy refers to high-dose chemotherapy, to the use of multiple new agents or to readministration of the induction regimen. These measures are aimed at eliminating residual leukaemia after induction chemotherapy and thereby preventing relapse as well as emergence of drug-resistant cells.

Intensive consolidation is standard in the treatment of ALL, although consolidation cycles in large studies are very variable and it is impossible to evaluate their individual efficacy. In general it seems that intensive application of high-dose methotrexate is beneficial. However, in adults dosages are probably limited at 1.5–2 g/m² if given as a 24-hour infusion. Otherwise toxicities, particularly mucositis, may lead to subsequent treat-

*Abstract.

[†]Survival of patients in CR.

PO, prospective stem cell transplantation (SCT) in all patients with donor (type a); Ph+, SCT in Ph-positive ALL (type b); PR, SCT according to prospective risk model (type c); HR, prospective SCT in a study for high-risk patients only; NR, not reported.

ment delays and decreased compliance. From paediatric ALL trials there is increasing evidence that intensified application of asparaginase leads to improved overall results. In adult ALL this approach appears to be useful particularly in consolidation, where less toxicity can be expected compared with induction. Several studies have also demonstrated that a modified induction (reinduction) improves outcome. The role of high-dose anthracyclines, podophyllotoxins and high-dose cytarabine in consolidation remains open. Overall, in adult ALL stricter adherence to protocols with fewer delays, dose reductions and omission of drugs due to toxicities would be an important contribution to therapeutic progress.

Maintenance therapy

Maintenance even after intensive induction and consolidation is still standard for ALL patients since all attempts to omit it led to inferior long-term outcome. Therefore some groups even prolong maintenance therapy beyond 2 years of total treatment duration. Methotrexate preferably given intravenously and mercaptopurine given orally are the backbone of maintenance. The role of intensification cycles during maintenance remains to be determined. The aim is to eliminate MRD. The optimal form and duration of maintenance therapy remains open but can hopefully be better defined by tailoring according to MRD, to ALL subtype (e.g. none for mature B-ALL) and including new therapeutic options (e.g. a tyrosine kinase inhibitor for *BCR-ABL*-positive ALL).

Prophylaxis of CNS leukaemia

CNS leukaemia occurs in 6% (range 1–10%) of patients with adult ALL at diagnosis, with a higher incidence in T-cell ALL (8%) and mature B-cell ALL (13%). Treatment and prophylaxis of CNS leukaemia may consist of intrathecal methotrexate alone or in combination with cytarabine or prednisone, systemic treatment with high-dose cytarabine or high-dose methotrexate and/or cranial irradiation.

Adult ALL patients who did not receive specific prophylactic CNS treatment in earlier trials have a CNS relapse rate of 30% (range 29–32%). With intrathecal chemotherapy alone, the rate of isolated and combined CNS relapses could be reduced to 13% (range 8–19%). In many adult ALL trials, additional prophylactic CNS irradiation (24 Gy) has been included. Long-term toxicities are apparently less severe than in paediatric patients. This combined approach further reduced the CNS relapse rate to 9% (range 3–19%). There is some evidence that early irradiation after remission induction is superior to delayed irradiation during consolidation treatment.

In many recent trials, combined treatment approaches have shown high efficacy. For high-dose chemotherapy with intrathecal therapy, the rate of CNS relapses was 7% (range 2–16%); with additional CNS irradiation, the relapse rate was 6% (range

1–13%). Several more recent trials have omitted prophylactic CNS irradiation or restricted irradiation to patients with high-risk features.

Because the risk for CNS relapse is associated with other prognostic factors, such as T-cell ALL, B-cell ALL, extreme leucocytosis, high leukaemia cell proliferation rate, high serum LDH level and extramedullary organ involvement, a risk-adapted CNS prophylaxis has been suggested. However, this approach, in contrast to childhood ALL, is not widely used in adults.

Therapy for relapsed and resistant leukaemia

Patients who fail to achieve CR or those who relapse subsequently have been treated with a variety of protocols. The use of regimens including vincristine, anthracyclines and steroids, similar to standard induction treatment, led to CR rates of approximately 60% in earlier studies but these patients generally had no intensive first-line treatment.

High-dose cytarabine has been extensively studied in relapsed adult ALL. From several small pilot studies comprising less than 100 patients, the weighted mean CR rate was 37%. Higher CR rates (50–60%) were achieved with combination regimens that included high-dose cytarabine and mitoxantrone, amsacrine or vincristine plus steroids. Because high-dose cytarabine is increasingly administered during front-line treatment, its efficacy during relapse treatment may be impaired. Therefore, new combinations with idarubicin (CR rate 46–64%) or fludarabine (CR rate 67–83%) or other agents have been evaluated. Nelarabine is a promising new drug for treatment of relapsed T-ALL.

The most significant predictive factor for treatment response in relapsed patients is the duration of first remission. Patients with longer previous remission (>18 months) have a higher CR rate and longer remission duration than those with a short previous remission (<18 months). Therefore in patients with early relapse and also in patients with molecular non-response (MRD persistence), high chemotherapy resistance has to be expected and experimental treatments should be considered for remission induction if available.

For all chemotherapy regimens, the duration of second remission is usually short (<6 months), and the long-term survival rate with chemotherapy alone is less than 5%. Thus, the only cure for adult patients with relapsed or resistant ALL is SCT, and the major aim of relapse treatment is the induction of a second remission with sufficient duration to prepare for SCT.

Stem cell transplantation

Stem cell transplantation from peripheral blood, and to a lesser extent from bone marrow, is an important post-remission strat-

egy for eradication of residual disease in adult ALL. Despite a great number of trials, the indications for SCT in first CR, scheduling and procedures are still not defined satisfactorily. The potential advantages of SCT (short treatment duration, favourable outcome in some trials) must be balanced against the disadvantages (mortality of 20–30%, morbidity, late complications, reduced quality of life) and assessed in relation to the improving outcome of conventional and targeted chemotherapy regimens.

Allogeneic SCT from sibling donors

The outcome of allogeneic SCT from sibling donors for ALL depends on age and remission status of the patient. The best results have been obtained with patients transplanted during first remission, among whom the probability of survival is approximately 50% (Table 24.5). Relapse rate (RR) and transplant-related mortality (TRM) both range between 25 and 30%. Although TRM is strongly correlated with age, the upper age limit for sibling donor SCT has increased continuously up to 50–55 years. After sibling donor SCT in second remission the LFS rate is 34%, and in advanced ALL (refractory or in relapse) it results in an 18% long-term survival rate (Table 24.5).

There is evidence that a graft-versus-leukaemia (GVL) effect is also present in ALL, as indicated by several observations, such as lower RR in patients with acute and/or chronic graft-versus-host disease, lower RR after matched unrelated donor SCT, and induction of remission by withdrawal of prophylaxis against graft-versus-host disease or donor lymphocyte infusions in single patients with relapsed ALL.

Matched unrelated donor SCT

The role of matched unrelated donor SCT has become more important since only one-third of patients have a sibling donor.

The survival in first CR is around 42–45%, with lower RR and higher TRM compared with sibling donor SCT. The results are similar in large prospective trials, with higher RR for sibling donor SCT and higher TRM for matched unrelated donor SCT. The ECOG/MRC study reported an overall survival (OS) of 55% for sibling donor SCT and 46% for matched unrelated donor SCT (restricted to Ph/BCR-ABL-positive ALL); in the German Multicenter Study Group for Adult ALL (GMALL) study 06/99, OS was 53% for sibling donor SCT and 44% for matched unrelated donor SCT. TRM reaches 25–35% in matched unrelated donor SCT, particularly in patients older than 35–40 years. Nevertheless, improved results of matched unrelated donor SCT can be expected in the future due to better supportive care, donor selection and extension of indications beyond very high-risk patients.

Cord blood or haploidentical SCT in adult ALL is still experimental and an option only for rare cases; it has been explored by a few very experienced SCT centres.

Autologous SCT

According to published studies, OS after autologous SCT in first CR is 42%. This type of SCT is associated with a higher RR (>50%) because of the risk of reinfusing residual leukaemic cells and even more so because of the lack of a GVL effect. Several randomized studies have shown a similar or poorer outcome for autologous SCT compared with chemotherapy.

The intensity of pretreatment has an important impact on outcome in autologous SCT, since it leads to reduction of tumour load. Thus autologous SCT may be an option in MRD-negative high-risk patients without a donor. Maintenance therapy after autologous SCT, for example with mercaptopurine and methotrexate, or imatinib in Ph-positive ALL (particularly in MRD-positive patients), is also a useful approach.

Table 24.5 Recent results of stem cell transplantation in adult ALL.

Stem cell transplant	Disease stage	N	LFS/OS* (%)	Relapse incidence* (%)	TRM* (%)
Allogeneic	CR1	1100	50 (21–71)	24 (10–50)	27 (12–42)

LFS, leukaemia-free survival; OS, overall survival; TRM, transplant-related mortality.

Non-myeloablative SCT

Non-myeloablative SCT or reduced-intensity conditioning regimens are new approaches that deserve evaluation in ALL and which may lead to an extension of indications for allogeneic SCT (see Chapter 38). In contrast to conventional SCT, which mainly relies on cell kill by high-dose chemotherapy and total body irradiation, non-myeloablative SCT relies on the GVL effect. Immunosuppression, for example with purine analogues, other cytostatic drugs and/or low-dose total body irradiation, is followed by the infusion of donor stem cells from a sibling or a matched unrelated donor with adapted immunosuppression to establish host tolerance.

First results indicate that in first CR stable remissions can be achieved in some patients. Literature results show an LFS rate of 23% for patients in all stages, with TRM of 42% and RR of 47%. According to an analysis by the European Group for Blood and Marrow Transplantation, the LFS in 91 adult ALL patients with a median age of 40 years was 18%, with TRM of 24% and RR of 58%. LFS in both studies was considerably higher if non-myeloablative SCT was conducted in first remission.

Indications for SCT in adult ALL

An evidence-based review has underlined the finding that SCT offers an advantage compared with chemotherapy in high-risk patients and in second remission. Other aspects of the review are summarized in Table 24.6. According to a meta-analysis of seven studies, OS for SCT was superior to chemotherapy with

Table 24.6 Evidence-based recommendations for stem cell transplantation (SCT) in adult ALL.

<i>Decision</i>	<i>Recommendation</i>
CR1: allogeneic SCT vs. chemotherapy	Comparable results SCT probably superior in high risk No SCT in standard risk
CR2: allogeneic SCT vs. chemotherapy	SCT superior
Autologous SCT vs. chemotherapy	Comparable results
Sibling donor vs. matched unrelated donor	Comparable results
Conditioning regimen	Data insufficient Advantage for TBI-based regimens
Allogeneic vs. autologous SCT	Advantage for allogeneic SCT

TBI, total body irradiation.

a particular advantage in high-risk patients. Thus the role of allogeneic SCT in standard-risk ALL remains unclear.

The indications for SCT in first remission are not uniformly defined. The major question is whether all patients with a sibling donor should be transferred to SCT or only those with specific risk factors. Currently, in the majority of trials, at least in Europe, SCT indications are based on the presence of adverse prognostic factors including MRD. Allogeneic sibling and matched unrelated donor SCT are considered in a similar way. The status of MRD is of increasing importance in the indications for SCT.

There is general agreement that all patients in second or later remission are candidates for SCT. Depending on donor availability and general condition, experimental procedures such as non-myeloablative SCT, cord blood SCT and haploidentical SCT may be considered.

Outcome of ALL subtypes and prognostic factors

The outcome of adult ALL varies strongly according to age and prognostic factors. Appreciation of the impact of such risk factors (Table 24.7) can result in the generation of risk-adapted treatment protocols for adult ALL.

Age

Age is the most important prognostic factor for ALL. There is a continuous decrease in outcome with increasing age from childhood to elderly patients. It is difficult to define an age limit where a change in prognosis occurs, but in almost all studies the LFS rate is inferior in patients older than 50–60 years. This age limit seems to be practical because patients below this age are candidates for intensified treatment approaches such as SCT, whereas for the older age group new strategies need to be explored, carefully weighing the gain in survival against quality of life. There is increasing evidence that with age-adapted moderate-dose chemotherapy, at least in some of the older patients, long-term remission can be achieved. Patients over 50–55 years of age with high-risk features who have achieved a CR and are in good clinical condition are potential candidates for autologous SCT or non-myeloablative SCT.

Adolescent patients (15–20 years) with ALL are treated either according to protocols for paediatric ALL or in adult ALL trials. Generally, more dose-intensive chemotherapy is applicable in young adults and may contribute to better results.

White blood cell count

An elevated WBC count at diagnosis (above $30\text{--}50 \times 10^9/\text{L}$) has been confirmed in various trials as a poor prognostic feature. The biological reason for the highly resistant behaviour of

Table 24.7 Adverse prognostic factors for adult ALL.

Factor	All subtypes	B-precursor	T-ALL
<i>At diagnosis</i>			
High WBC count		>30 (range 20–50) × 10 ⁹ /L*	>100 × 10 ⁹ /L [‡]

*Established prognostic factors.

[†]Prognostic factors used by several groups.

[‡]Rarely used prognostic factor.

B-precursor ALL with high WBC count is unclear. Probably in the future additional molecular markers will help to clarify the underlying mechanisms. Because of the high relapse rate, evaluation of MRD and use of experimental drugs and SCT modalities seem particularly important.

Immunophenotype and cytogenetics

The immunophenotype is an important independent prognostic variable in ALL. In ongoing trials, it is used to adjust treatment regimens accordingly, for example separate regimens for mature B-cell ALL. A further example for clinical application is the identification of patients for antibody therapy, for example anti-CD20 (rituximab) in CD20-positive B-lineage ALL.

T-lineage ALL

The outcome of T-lineage ALL is generally considered superior compared with B-lineage ALL. It comprises the subtypes early T-ALL, thymic (cortical) T-ALL and mature T-ALL, with LFS rates of 25%, 63% and 28%, respectively. Subtype was the most relevant prognostic factor for T-ALL in GMALL studies, with poorer outcome for early and mature T-ALL, whereas high WBC count (>100 × 10⁹/L) had no prognostic impact.

The biological relevance of immunophenotype is underlined by the fact that overexpression of *HOX11*, *HOX11L2*, *SIL-TAL1* and *CALM-AF10* is associated with subtypes (i.e. maturation states) of thymocytes. A number of other potential poor-prognosis molecular markers have been reported for T-ALL. The variety of new prognostic markers does not allow integration into current risk models but may serve to identify pathogenetic mechanisms and therapeutic targets. With current

treatment regimens, CR rates of more than 90% and an LFS rate of 40–60% can be achieved in T-ALL.

B-precursor ALL

Pro-B ALL and/or t(4;11)-positive ALL is considered high risk in nearly all trials. It appears to be particularly susceptible to high-dose cytarabine-based regimens and SCT as reported from the GMALL studies. Common ALL/pre-B ALL has a large proportion of Ph-positive ALL. Based on prognostic factors (WBC count and time to achievement of CR) it can be subdivided into standard- and high-risk groups, with significantly different OS rates of 50–60% and 30–40%, respectively. The difference in OS between paediatric and adult ALL is mainly due the poorer outcome of B-precursor ALL.

Ph-positive ALL

The translocation t(9;22) and the respective fusion gene *BCR-ABL* until recently marked the most unfavourable subgroup of adult ALL. Ph/*BCR-ABL*-positive ALL occurs almost exclusively in conjunction with B-precursor ALL (c-ALL, pre-B ALL). The incidence increases with age. In Ph-positive leukaemia, the *BCR-ABL* fusion gene is causally involved in leukaemogenesis and is considered to be essential for leukaemic transformation. Using an inhibitor of the ABL tyrosine kinase (imatinib, Gleevec), cellular proliferation of *BCR-ABL*-positive CML and ALL cells can be prevented selectively (see Chapter 27).

A combination of imatinib with chemotherapy leads to remission rates of 90% and molecular remission even in 50% of patients. In addition, the OS rate is improved to 55–65% compared with 15% in historic trials and the proportion of

patients transferred to SCT is increased. Compared with chemotherapy (all combination regimens), no increased toxicity has been described. Furthermore, there have been no reports of unfavourable influence on subsequent SCT, which is still considered the best curative option in Ph-positive ALL.

Results after SCT may be improved by the use of imatinib. A GMALL study showed that the majority of patients with persistent MRD after SCT who achieve molecular remission with imatinib have long-term survival. Thus post-transplant imatinib, either up-front or after detection of MRD, can reduce the relapse rate. In patients undergoing chemotherapy and SCT, it remains open whether and when treatment with imatinib can be stopped.

Older patients with Ph-positive ALL do not have the option of SCT and because of the extremely unfavourable results with chemotherapy, imatinib was evaluated as single-drug treatment for induction. A randomized trial compared imatinib monotherapy with dose-reduced chemotherapy for remission induction. After induction, all patients received imatinib in combination with consolidation chemotherapy. The remission rate for monotherapy was 93% compared with 54% for chemotherapy. OS was improved compared with a historic cohort but in both arms the relapse rate was high and no difference in terms of survival was detected. Therefore optimal remission induction and consolidation for elderly Ph-positive ALL remains to be defined.

Close monitoring of MRD allows the early detection of molecular resistance or molecular relapse. Thereby relapse treatment may be introduced earlier, before detection of cytological relapse. One reason for relapse is probably the development of resistance caused by kinase domain mutations. Therefore, before relapse treatment is started, bone marrow analysis for resistance-inducing mutations should be performed. The efficacy of imatinib treatment, and also of second-generation tyrosine kinase inhibitors such as dasatinib or nilotinib, may be impaired by these mutations. The aim of relapse treatment is achievement of second CR and SCT. For salvage therapy, second-generation inhibitors with or without additional chemotherapy may be considered. Dasatinib and nilotinib have increased efficacy compared with imatinib and are active in the majority of mutations, except the T315I mutation. The remission rates achieved with these drugs in patients failing to respond to imatinib are approximately 30%. They are currently being evaluated in relapse treatment, but trials for *de novo* Ph-positive ALL are starting.

Mature B-ALL

Mature B-ALL is grouped with Burkitt lymphoma according to the WHO classification and is treated according to a specific concept. Treatment is based on childhood B-cell ALL studies that significantly improved outcome. The drugs responsible for the improvement were high doses of fractionated cyclophosphamide, ifosfamide, high-dose methotrexate ($0.5\text{--}8\text{ g/m}^2$) and

high-dose cytarabine in conjunction with the conventional drugs for remission induction in ALL, given in short cycles at frequent intervals over a period of 6 months.

The application of these childhood B-cell ALL protocols in original or modified form also brought a substantial improvement for adult patients with B-cell ALL. CR rate was increased to approximately 75% (range 62–83%) and LFS rate to 55% (range 20–71%). More than 80% of the cases of mature B-ALL or Burkitt lymphoma express CD20 on their surface. Further significant improvement in survival rates to 80–90% was achieved by the use of rituximab in combination with chemotherapy.

B-cell ALL has a higher incidence of CNS involvement at diagnosis, and of CNS relapse. Therefore, effective measures against CNS disease, such as high-dose methotrexate and high-dose cytarabine, as well as intrathecal therapy, are important components of treatment regimens. On the other hand, maintenance treatment has been omitted. Because relapses occur almost exclusively within the first year in childhood as well as adult B-cell ALL, patients thereafter can be considered cured.

Response to treatment and minimal residual disease

Beside age, the most relevant prognostic factor in ALL is still the achievement of CR. Further prognostic factors related to treatment response are delayed time to CR or response to prednisone therapy. A more accurate approach for assessing individual response is MRD evaluation since this is an independent prognostic factor that reflects primary drug resistance and unknown host factors. There are two major aims of longitudinal MRD evaluation in adult ALL.

1 Identification of high-risk patients as candidates for SCT or experimental therapy. After the start of consolidation, high MRD ($>10^{-4}$) at any time is associated with a high relapse risk of 66–88%. In the GMALL studies, patients with high MRD ($>10^{-4}$) after induction and first consolidation are identified as high risk and are candidates for SCT in CR1. Persistent MRD thereby becomes an important new indication for SCT in CR1. However, outcome after SCT is also influenced by MRD status and patients with high MRD before SCT or persisting MRD after SCT have a poorer outcome. However, the optimal treatment of persistent MRD remains to be defined.

2 Identification of low-risk patients in whom treatment reduction may be justified. This is an aim that is more difficult to reach. An early and rapid decrease of MRD during induction is associated with a relapse risk of only 8%. However, this is observed in only 10% of patients. Overall, it is difficult to identify adult low-risk patients in whom reduction of therapy would be justified.

Furthermore, MRD evaluation offers a new refined definition of response to treatment, namely molecular CR (defined as MRD level $< 10^{-4}$) and molecular relapse (defined as reappear-

ance of MRD $> 10^{-4}$). Molecular CR is the aim of induction therapy. During treatment and follow-up molecular relapse is highly predictive of cytological relapse. Molecular bone marrow relapse is also often present in patients with apparently isolated extramedullary relapse. In clinical trials molecular relapse should be treated similarly to cytological relapse.

New integrated risk classification

Prognostic factors are the basis for risk-adapted treatment regimens, with treatment intensity and combination defined according to risk of relapse. The main purpose is to identify patients with a high risk of relapse in order to treat them with the most intensive available therapy, i.e. SCT. However, this is not applicable for all factors. Thus higher age is associated with poorer prognosis but is not an indication for SCT because older patients also have a worse prognosis after transplantation. For other subgroups with originally poor prognosis, improvement was achieved by subgroup-specific treatment, such as for mature B-ALL or Ph-positive ALL. Finally, MRD evaluation allows the assessment of individual response and relapse risk. The majority of adult ALL study groups in Europe use MRD for risk stratification (www.leukaemia-net.org) and most of them combine MRD-based and conventional risk factors. In the past decade a large number of molecular factors with potential correlation to prognosis have been reported. Each new candidate prognostic factor should be evaluated prospectively within specific treatment protocols. Currently agreed poor-prognosis features are summarized in Table 24.7.

Overall outcome of adult ALL

In more than 7000 patients treated in prospective clinical trials the CR rate was 84% (range 74–93%), with 7% (range 1–11%) early death. The OS was 35% (range 27–54%). One major question in the treatment of adult ALL is the role of SCT in post-remission therapy. Notably, no difference is evident in studies focused on SCT ($N = 2696$), with a weighted mean of 84% for CR and 35% for OS, and in studies using risk-adapted approaches ($N = 2443$), with mean CR rates of 83% and OS of 36%. For specific subgroups there is a wide range, from 30–40% for high-risk ALL to 50–60% for standard-risk ALL and 80–90% for mature B-ALL. Outcome is strongly correlated with age.

New treatment approaches for adult ALL

Risk and subtype-adjusted treatment strategies have led to considerable improvement in outcome in mature B-ALL, T-ALL and Ph-positive ALL but less so in adult B-precursor ALL. The poorer outcome of B-precursor ALL is also the major factor contributing to the poorer overall outcome in adults compared

with paediatric patients. The most promising new treatment options are based on targeted and subtype-specific approaches with preferably alternative mechanisms of action in order to avoid chemotherapy-induced toxicity.

Antibody therapy

ALL blast cells express a variety of specific antigens, such as CD20, CD19, CD22, CD33 and CD52, which may serve as targets for treatment with monoclonal antibodies. Monoclonal antibody therapy is an attractive approach since it is targeted, subtype specific and, compared with chemotherapy, has different mechanisms of action and side-effects. Their use may be most promising in relation to MRD status and in combination with chemotherapy. The anti-CD20 antibody has been successfully integrated in the therapy of mature B-ALL. It is now also being explored in several studies for CD20-positive B-precursor ALL. Studies with anti-CD52 are ongoing, either in relapse or according to MRD. Single cases showing efficacy of anti-CD33 or anti-CD22 have been reported. Another new promising approach is the use of bispecific T-cell engager antibodies targeted to CD19.

Successful chemotherapy approaches from paediatric protocols

Most of the adult ALL trials are originally based on paediatric protocols. In contrast to adult study groups, which to some extent are focused on high-dose therapies as used in AML and extensive use of SCT, in paediatric trials the major focus has been placed on optimization of intensive chemotherapy regimens. This is one important aim of several planned trials for adult ALL, aiming at intensification of vincristine, steroids, asparaginase, reinduction cycles and maintenance as in paediatric trials. Intensive chemotherapy should be complemented by targeted and individualized treatment elements. Furthermore, better adherence to protocols and encouragement of patients to improve their compliance (e.g. psychosocial counselling, documentation of compliance) are warranted in adult ALL.

Stem cell transplantation

SCT offers an advantage in adult high-risk patients and has contributed to improved outcome. However, procedures need to be optimized, including age limits for dose-reduced conditioning. In younger patients the rate of SCT may be reduced as soon as adaptation of paediatric treatment elements improves survival with chemotherapy only.

Risk-adapted treatment

Optimization of management needs to consider additional factors, such as the availability of a stem cell donor, patient-

related factors, disease markers, treatment response and availability of targeted drugs. Prognostic factors and patient characteristics therefore no longer only serve for identification of candidates for SCT in first CR but to define individualized, flexible and patient-specific treatment approaches.

New drugs

Finally, a number of new drugs are under evaluation for treatment of ALL, including antibodies, purine analogues and related drugs such as nelarabine, clofarabine, kinase inhibitors and liposomal preparations of vincristine and cytarabine for intrathecal use. After proof of efficacy these drugs can be integrated in risk- and subgroup-adjusted treatment regimens.

Clinical trials

A standard treatment for adult ALL has so far not been defined. Therefore as many patients as possible should be treated within clinical trials in order to contribute to further treatment optimization. New end points for clinical trials are needed, such as molecular CR, molecular relapse, evaluation of SCT and quality of life. Despite these short-term end points, improvement in OS of the total patient population including all risk groups is the final proof for all new risk-adapted treatment approaches.

Introduction

Leukaemia is the most common childhood cancer and acute lymphoblastic leukaemia (ALL) is the most common subtype, accounting for 75–80% of all cases. Childhood ALL comprises different biological subtypes defined by cell morphology, immunophenotype, gene expression features and genetic abnormalities, some of which are associated with disease aggressiveness and treatment response.

Progress in the treatment of childhood ALL over the last four decades has been steady, with cure rates (i.e. no evidence of disease for 10 years or more) now surpassing 80%. This advance can be attributed to three main factors: recognition of reliable prognostic factors leading to increasingly refined risk-directed therapies, development of clinical trials designed to gain substantial increments in knowledge, and improvements in supportive care. In this chapter, we review the current status of the biological studies and treatment of childhood ALL and discuss future directions for research and treatment.

Epidemiology

The median age at diagnosis for ALL is 13 years and approximately 60% of cases are diagnosed under the age of 20. ALL is the most common malignancy diagnosed in patients younger than 15 years, accounting for 23% of all cancers and 76% of all leukaemias in this age group. In general, the incidence is higher in boys than in girls (four times for T-cell ALL), except that girls have a slightly higher (1.5 times) incidence of leukaemia in the first year of life. The reported incidence of ALL is higher in northern and western Europe, North America and Oceania, and lower in Asia, South America and Africa. In industrialized countries, the incidence is higher among children of European descent than among those of African descent. For example, the annual rate (per million population) of childhood ALL from birth to 19 years of age is 29.7 in the UK and 11.0 in India; in the USA, it is 32.9 for white people and 14.8 for African-Americans.

In developed countries, the incidence of ALL is highest between ages 2 and 5 years. This age peak is accounted largely by ALL with hyperdiploidy (>50 chromosomes) or *ETV6-RUNX1* (also known as *TEL-AML1*) gene fusion. The incidence of childhood ALL is higher among white people than among those of African descent, especially among children 2–5 years

of age. T-cell ALL and pre-B leukaemia with *t(1;19)/TCF3-PBX1* (also known as *E2A-PBX1*) fusion are more prevalent among African-American children, who are less likely to have hyperdiploid ALL with more than 50 chromosomes.

Only a small proportion (<5%) of patients with childhood ALL have underlying hereditary genetic abnormalities. Children with Down syndrome have a 10- to 30-fold increased risk of developing ALL. Mutations in the *JAK2* gene, generally found in higher-risk ALL, are frequent in ALL cells of Down syndrome children. Other genetic disorders associated with an increased incidence of ALL include ataxia telangiectasia and Bloom syndrome. The association between leukaemia and congenital immunodeficiencies such as X-linked agammaglobulinaemia and common variable immunodeficiency is not well supported.

Fraternal twins and siblings of affected children are at a twofold to fourfold greater risk of leukaemia during the first decade of life than are unrelated children. In the case of identical twins, when leukaemia occurs in one twin, there is a 20% probability that it will also occur in the other twin, owing to ALL transfer *in utero* via the shared placental circulation. When leukaemia is diagnosed before 1 year of age it almost invariably develops in the other twin, generally within a few months. In identical twins with *t(4;11)/MLL-AF4*, the concordance rate is nearly 100%, with a short latency period (weeks to a few months). In contrast, the concordance rate in twins with the *ETV6-RUNX1* fusion or T-cell phenotype is lower and the postnatal latency period longer, in keeping with the requirement for additional genetic events for leukaemic transformation in these subtypes of ALL. Hyperdiploid ALL also appears to arise before birth but requires postnatal events for full malignant transformation. In contrast, *t(1;19)/TCF3-PBX1* ALL appears to have a postnatal origin in most cases.

Aetiology

Ionizing radiation and chemical mutagens have been implicated in the induction of leukaemia but clear aetiological factors for ALL cannot be identified in nearly all cases. *In utero* exposure to diagnostic X-rays is associated with a slightly increased risk of ALL, proportional to the number of exposures. The association between leukaemia and maternal exposure to potential mutagens, neonatal administration of vitamin K, parental use of medications and drugs, proximity to electromagnetic fields, and exposure to other potential mutagens has been studied but no definitive conclusions reached. A case-control study identified a significantly increased risk of leukaemia among the offspring of men employed in occupations with increased exposure to electromagnetic fields or radiation, a finding that warrants further studies. Industrialization, higher socioeconomic status and social isolation appear to be associated with an increased risk of childhood B-lineage ALL, and occasional clustering of

childhood ALL appears to be associated with rural-urban population mixing. Greaves has postulated that absence or diminution of infections early in life might predispose the immune system to aberrant responses to subsequent exposures which in turn might precipitate ALL development from a preleukaemic clone through proliferative or apoptotic stress.

A case-control study found that *in utero* exposure to DNA-damaging drugs, herbal medicines or pesticides was significantly associated with infant leukaemia with *MLL* rearrangements. Deficiency of the detoxifying enzymes glutathione S-transferase (GST)-M1 and GST-T1 is associated with infant leukaemia without *MLL* rearrangement, and with ALL in black children, and polymorphisms of NADPH:quinone oxidoreductase have been associated with the development of ALL. Cytochrome P450 CYP1A1*2A and NQO1*2 variant genotypes have also been linked to an increased risk of childhood ALL, and a report has indicated an association between a polymorphism on intron 4 of the gene for aldo-keto reductase 1C3 (*AKR1C3*) and the development of leukaemia. There are also data suggesting that variable expression levels of cell-cycle inhibitor genes *CDKN2A*, *CDKN2B* and *CDKN1B* due to regulatory polymorphisms could contribute to leukaemogenesis. These studies implicate host pharmacogenetics in the development of ALL, a notion that warrants further study.

It has been reported that children diagnosed with ALL had significantly more clinically diagnosed infectious episodes in infancy than did controls; the average number of episodes was 3.6 (95% confidence interval 3.3, 3.9) versus 3.1 (2.9, 3.2). This difference was most apparent in the neonatal period, suggesting that a dysregulated immune response to infection in the first few months of life might promote transition to overt ALL.

Pathogenesis

Genetic changes are central to the development of leukaemia. The dysregulation of genes encoding transcription factors and the resulting subversion of transcriptional pathways that regulate haemopoietic cell homeostasis provides a mechanistic explanation for leukaemogenesis. Haemopoiesis can also be altered by the dysregulated activity of tyrosine kinases, as in the case of the *BCR-ABL1* fusion gene. Alternatively, activating mutations in tyrosine kinase receptors for growth factors may confer a growth advantage to leukaemic cells. This mechanism is exemplified by mutations of *FLT3*, which encodes a receptor tyrosine kinase expressed by immature haemopoietic cells that acts synergistically with other growth factors to stimulate proliferation of haemopoietic progenitor cells. These mutations typically involve small tandem duplications of amino acids that result in constitutive tyrosine kinase activity. Activating mutations of *NOTCH1*, a gene encoding a transmembrane receptor that regulates normal T-cell development, are frequently detected in T-cell ALL. Activating mutations of *NOTCH1*

produce constitutive NOTCH1 signalling, which is sufficient to induce T-cell ALL in experimental models, and appears to be an early event in leukaemogenesis. A multicomponent membrane-associated enzyme, γ -secretase, is required for NOTCH1 signalling through mutant NOTCH receptors in T-cell ALL, a finding that provided a rationale for the clinical testing of γ -secretase inhibitors in T-cell ALL. An initial trial with such an agent was disappointing and revealed intolerable gastrointestinal toxicity; more recent data from a murine model suggest that the combination of γ -secretase inhibitors with high-dose glucocorticoids may enhance antileukaemic activity while diminishing toxicity.

A recent large-scale study of DNA single-nucleotide polymorphism (SNP) analysis examined 242 cases of paediatric B-cell precursor ALL and identified lesions in genes encoding key regulators of B-cell differentiation in 40% of the cases. Most prominent were deletions and cryptic translocations involving the *PAX5* gene, which was altered in almost one-third of cases and which would be predicted to block normal B-progenitor cell differentiation prior to immunoglobulin heavy-chain gene rearrangement. Other mutated genes were found in concert with several of the more common translocation-induced chimeric oncogenes, such as *TCF3-PBX1* and *ETV6-RUNX1*, including the essential B-cell developmental genes *TCF3*, *EBF*, *LEF1*, *IKZF1* (Ikaros) and *IKZF3* (Aiolos). A subsequent study showed deletion of *IKZF1* in 83.7% of *BCR-ABL1*-positive ALL; the deletion was also found in chronic myelogenous leukaemia (CML) in blast crisis but not in chronic phase. The *IKZF1* deletions resulted in haploinsufficiency, expression of a dominant-negative Ikaros isoform, or the complete loss of Ikaros expression. Together, these findings suggest that genetic lesions resulting in the loss of Ikaros function are an important event in the development of *BCR-ABL1*-positive ALL.

Clinical and laboratory features

Table 25.1 summarizes clinical and laboratory features of children with newly diagnosed ALL. On physical examination, children with ALL frequently present with pallor, petechiae and ecchymoses, and occasionally mucosal bleeding. Because of anaemia, they may have fatigue and lethargy, dyspnoea, angina and dizziness. Neutropenia may lead to severe infection. Bone pain and arthralgia caused by leukaemic infiltration and, less frequently, haemorrhage or infection can be especially severe in young children. Fever can be caused by infection or by pyrogenic cytokines such as interleukin (IL)-1, IL-6 and tumour necrosis factor released from the leukaemic cells. Liver, spleen, thymus, lymph nodes and central nervous system (CNS) are common sites of extramedullary involvement. An anterior mediastinal mass is typical of T-cell ALL. Painless enlargement of the scrotum can be a sign of testicular leukaemia or hydrocele resulting from lymphatic obstruction. Very rarely, ALL is

Table 25.1 Presenting clinical and laboratory features of children with newly diagnosed ALL.

Feature	Percentage of white children (SJCRH)	Percentage of total (BFM)
Age (years)		
≤1	2.7	2.7
2–9	71.6	79.6
≥10	25.7	17.7
Male	56.0	57.9
Liver edge below costal margin >4 cm	31.6	30.9
Spleen edge below costal margin >4 cm	30.4	27.0
Mediastinal mass	10.4	8.1
Central nervous system leukaemia (CNS3)*	2.7	2.5
Leucocyte count ($\times 10^9/L$)		
<10	46.2	45.9
10–50	29.3	31.8
≥50	24.5	22.3
Haemoglobin <8 g/dL	51.8	53.7
Immunophenotype		
Early pre-B	53.7	69.3
Pre-B	28.9	17.0

*CNS3 status denotes the presence of leukaemic cells in a cerebrospinal fluid that contains ≥ 5 leucocytes/ μL .

BFM, Berlin–Frankfurt–Münster 90 (1990–95, not including B-ALL) (Schrappe et al. 2000); SJCRH, St Jude Children's Research Hospital (1979–2002).

detected during routine examination in the absence of signs or symptoms.

Blood examination typically reveals anaemia, neutropenia and thrombocytopenia, due to bone marrow replacement and suppression of normal haemopoiesis by leukaemic cells. Haemoglobin is commonly below 8 g/dL. Profound neutropenia ($<0.5 \times 10^9/L$) occurs in 40% of patients, rendering them at high risk of infection. Initial leucocyte counts may range from 0.1 to $1500 \times 10^9/L$ (median $12 \times 10^9/L$); they are greater than $10 \times 10^9/L$ in slightly over half of patients and greater than $100 \times 10^9/L$ in 10–15% of patients. Most patients have circulat-

ing leukaemic blast cells but in cases with low initial counts ($<2 \times 10^9/L$) lymphoblasts are often absent in blood smears. Hypereosinophilia, generally reactive, may be present at diagnosis. Coagulopathy, usually mild, may occur in T-cell ALL and is only rarely associated with severe haemorrhage. A large leukaemic cell burden is commonly accompanied by elevated serum lactate dehydrogenase activity and elevated uric acid and phosphorus concentration. An enlarged kidney can be detected in 30–50% of patients but has no prognostic or therapeutic implications. Liver dysfunction due to leukaemic infiltration occurs in 10–20% of patients, is usually mild and has no important clinical or prognostic consequences. Abnormalities of the bone, such as metaphyseal banding, periosteal reactions, osteolysis, osteosclerosis or osteopenia, can be revealed by radiography in half of the patients. As these changes do not affect treatment and outcome, routine diagnostic imaging studies (except for chest radiography to rule out mediastinal mass) is not necessary.

Leukaemic blast cells are identified morphologically at diagnosis in the cerebrospinal fluid (CSF) of approximately one-third of children with ALL, most of whom have no neurological symptoms. Although CNS leukaemia is defined by the presence of at least five leucocytes per microlitre of CSF and the detection of leukaemic blast cells, or by the presence of cranial nerve palsy, the presence of any leukaemic cells in CSF (even from iatrogenic introduction due to a traumatic lumbar puncture) predicts an increased risk of ALL relapse.

Differential diagnosis

The acute onset of petechiae, ecchymoses and bleeding may suggest idiopathic thrombocytopenic purpura (often associated with a recent viral infection, large platelets in blood smears and no evidence of anaemia). Like ALL, aplastic anaemia may also present with pancytopenia and complications associated with bone marrow failure but hepatosplenomegaly and lymphadenopathy are rare, and the skeletal changes associated with ALL are absent.

Infectious mononucleosis and other viral infections can be confused with ALL. Detection of atypical lymphocytes or elevated viral titres aid in the diagnosis. Patients with pertussis or parapertussis may have marked lymphocytosis, but the affected cells are mature lymphocytes rather than lymphoblasts. Bone pain, arthralgia and occasionally arthritis may mimic juvenile rheumatoid arthritis, rheumatic fever, other collagen diseases or osteomyelitis.

Childhood ALL should also be distinguished from paediatric small round cell tumours that involve the bone marrow, including neuroblastoma, rhabdomyosarcoma and retinoblastoma. Generally, in such cases, a primary lesion can be found by routine diagnostic studies, and disseminated tumour cells often form clumps.

Morphology and cytochemistry

Morphological analysis of leukaemic cells distinguishes three subtypes of ALL (L1, L2 and L3) as classified by the French–American–British (FAB) schema. This classification cannot accurately distinguish between ALL and non-lymphoid acute leukaemia, and has no prognostic or therapeutic relevance with contemporary therapy. Cytochemical stains such as periodic acid–Schiff reacts positively with cells in over 70% of ALL cases, while myeloperoxidase, Sudan black and non-specific esterases, including α -naphthyl butyrate and α -naphthyl acetate esterase, are typically negative. Nevertheless, classification of acute leukaemias is currently based on immunophenotypic and genetic analyses.

Immunophenotypic classification

Early pre-B ALL

Leukaemic blast cells of early pre-B ALL resemble normal marrow B-cell precursors. The leukaemic cells always express CD19 and almost all cases have cytoplasmic CD22 and CD79 α ; surface CD22 expression is also evident in most cases. CD10 and terminal deoxynucleotidyltransferase (TdT) are expressed in 90% of cases, and CD34 in more than 75% of cases. The CD20 antigen is present on a minor proportion of blast cells in half of cases but its intensity might increase during treatment. Early pre-B ALL cells lack expression of surface and cytoplasmic immunoglobulins.

ALL with rearrangement of the *MLL* gene typically has an early pre-B ALL phenotype with distinctive features such as expression of CD15, CD65 and chondroitin protoglycan sulphate, and absence of CD10. Hyperdiploidy (chromosome number >50) is typically associated with weak or undetectable CD45 expression.

Pre-B ALL

The pre-B immunophenotype is defined by the accumulation of cytoplasmic immunoglobulin μ heavy chains with no detectable surface immunoglobulins and is found in approximately 20–25% of cases. Leukaemic cells that express both cytoplasmic and surface immunoglobulin μ heavy chains without κ or λ light chains, a rare finding, have been designated transitional pre-B ALL. Pre-B ALL expresses CD19, CD22 and CD79 α and, usually, CD10 and TdT but only two-thirds express CD34. In many cases of pre-B ALL, surface CD20 is absent or is weakly expressed. ZAP-70 expression is more prevalent in cases with a pre-B phenotype. Between 20 and 25% of pre-B ALL cases have either t(1;19)(q23;p13) or der(19)t(1;19)(q23;p13).

B-cell ALL

In 2–4% of childhood ALL cases, cells express surface immunoglobulin μ heavy chains plus either κ or λ light chains. Commonly, cells have L3 morphology according to the FAB classification and express CD19, CD22, CD20 and frequently CD10; CD34 is negative. The less common subtype of B-cell ALL is characterized by blast cells with L1 or L2 morphology, and expression of TdT and/or CD34.

T-lineage ALL

T-lineage ALL cells express CD7 and CD3, the latter most commonly only in the cytoplasm. Other markers commonly expressed include CD2, CD5 and TdT; CD1a, surface CD3, CD4 and CD8 are detected in fewer than 45% of cases. HLA-DR expression is uncommon, and 40–45% of cases are positive for CD10 and/or CD21. CD79 α is also weakly expressed in approximately one-third of cases.

T-lineage ALL has been divided into three stages of immunophenotypic differentiation: early (CD7⁺, cCD3⁺, surface CD3⁻, CD4⁻ and CD8⁻), mid or common (cCD3⁺, surface CD3⁻, CD4⁺, CD8⁺ and CD1a⁺) and late (surface CD3⁺, CD1a⁻ and either CD4⁺ or CD8⁺). However, many cases have immunophenotypic patterns that do not fit these thymic maturation stages. T-cell receptor (TCR) proteins are heterogeneously expressed in T-lineage ALL. In approximately two-thirds of cases, membrane CD3 and TCR proteins are absent. In half of these cases, however, TCR proteins (TCR- β , TCR- α , or both) are present in the cell cytoplasm. Most cases with membrane CD3 and TCR chains express the $\alpha\beta$ form of the TCR, whereas a minority express TCR $\gamma\delta$ proteins.

Several studies have yielded conflicting conclusions about the prognostic significance of the expression of surface CD3 and the absence of CD2, CD5 or CD10. We recently identified a subtype of T-ALL, named early thymic precursor (ETP) ALL, which exhibits the gene expression profile of normal ETP cells, a population of recent immigrants from the bone marrow to the thymus that retains multilineage differentiation potential. These leukaemias are positive for CD7 and CD3, lack CD1a and CD8 expression, have weak or absent CD5 expression and express at least one stem cell or myeloid-associated antigen (e.g. CD34, CD117, CD13, CD33, CD11b). These cases are characterized by a dismal response to therapy and a high rate of relapse.

Cytogenetic and molecular classification

Hyperdiploid and hypodiploid ALL

In approximately half of ALL cases, leukaemic cells are hyperdiploid. Hyperdiploid cases with a chromosome number of

51–65 represent a distinct biological subset of B-lineage ALL with an excellent prognosis. Leukaemic lymphoblasts with this karyotype have a marked propensity to undergo apoptosis, and accumulate greater quantities of methotrexate and its active polyglutamate metabolites. These features help to explain the relatively low leukaemic burden at presentation and the favourable prognosis of this ALL subtype. Among chromosomes that are over-represented, only the trisomies of chromosome 4, 10 and 17 were associated with a favourable prognosis in some studies.

In contrast to the overall favourable prognosis of cases with 51–65 chromosomes, ALL cases with near-triploidy (69–81 chromosomes) have a response to therapy similar to that of non-hyperdiploid ALL; cases with near-tetraploidy (82–94 chromosomes) have a high frequency of T-cell immunophenotype. Hypodiploidy (<45 chromosomes) occurs in less than 2% of ALL cases and is associated with a poor outcome.

ALL with *TEL-AML1 (ETV6-RUNX1)* rearrangements

The t(12;21)(p12;q22) translocation brings together the 5' portion of the *TEL (ETV6)* gene and the nearly complete *AML1 (RUNX1)* gene. This translocation can usually be detected only by fluorescence *in situ* hybridization (FISH) or reverse-transcriptase polymerase chain reaction (RT-PCR). The non-translocated *ETV6* allele is frequently deleted. This gene fusion is found in approximately 20% of ALL cases. In some series, the *TEL-AML1* abnormality was not significantly associated with outcome, but in most studies it defined a subgroup with excellent prognosis. ALL cells bearing this abnormality reportedly have increased *in vitro* sensitivity to L-asparaginase, as well as to doxorubicin, etoposide, amsacrine and dexamethasone. Similar to T-cell ALL, blast cells with *ETV6-RUNX1* accumulate significantly lower levels of methotrexate polyglutamates than do those with other genetic abnormalities, suggesting that patients with this leukaemia subtype might benefit from an increased dose of methotrexate.

The *ETV6* gene belongs to the Ets family of transcription factors. It is widely expressed and appears to have an essential role in haemopoiesis. *RUNX1* encodes a transcription factor that binds DNA as a heterodimer with core-binding factor (CBF)- β and is essential for the development of definitive haemopoiesis. Transduction of murine bone marrow cells with *ETV6-RUNX1* is associated with a higher frequency of leukaemia resembling ALL. It was recently shown that the ETV6-RUNX1 protein binds to Smad3, a transforming growth factor (TGF)- β signalling target, and alters its capacity to activate target promoters, resulting in reduced sensitivity to TGF- β -mediated inhibition of proliferation. Expression of ETV6-RUNX1 in human cord blood progenitor cells led to the expansion of a candidate preleukaemic population that had a growth advantage in the presence of TGF- β .

ALL with *E2A–PBX1* (*TCF3–PBX1*) rearrangements

Approximately 20–25% of pre-B ALL cases have the t(1;19)(q23;p13) translocation abnormality that juxtaposes the *E2A* (*TCF3*) gene on chromosome 19 and the *PBX1* gene on chromosome 1. The resulting *E2A–PBX1* fusion protein contains the transcriptional activation domains of *E2A* linked to the DNA-binding domain of *PBX1* and the encoded protein inappropriately activates the transcription of genes normally regulated by *PBX1*. Expression of *E2A–PBX1* in mice leads to the development of lymphomas and myeloid leukaemias. Another *E2A* fusion gene is created by t(17;19)(q22;p13), in which *E2A* is fused to the gene that encodes the transcription factor hepatic leukaemia factor (*HLF*). Patients with ALL and this gene fusion frequently present with hypercalcaemia and coagulopathy, and have poor prognosis.

The t(1;19) abnormality was associated with an unfavourable outcome in earlier trials. With contemporary treatment protocols, however, patients with this leukaemia subtype have excellent response to initial therapy, and a favourable overall outcome although they still have increased risk of leukaemia relapse in the CNS.

ALL with *MLL* gene rearrangements

Structural alterations involving band 11q23 of chromosome 11 are the most frequent cytogenetic abnormality in infant ALL. In most cases, the target is the *MLL* gene (for mixed-lineage leukaemia; also known as *HRX*, *ALL-1* and *TRX1*). The most common 11q23 abnormality in ALL is t(4;11)(q21;q23), which produces a chimeric protein that contains the N-terminal portion of *MLL* linked to the C-terminal portion of *AFF1*, but *MLL* has been reported to be linked to more than 50 other genes. The *MLL* gene encodes a DNA-binding protein that regulates the expression of many genes including multiple *HOX* genes. *MLL* is crucial for embryonic development and haemopoiesis, and *MLL* fusion proteins can transform haemopoietic cells into leukaemia-initiating cells.

Treatment outcome of ALL with an *MLL* gene rearrangement differs by age group, with infants having the worst outcome. Infant ALL with the *MLL–AFF1* gene fusion also has a high prevalence of immature, non-productive and/or oligoclonal antigen-receptor gene rearrangements. Several genes normally expressed in non-lymphoid haemopoietic lineages are overexpressed in *MLL*-rearranged ALL, including *FLT3*, *LMO2*, and *HOX* genes such as *HOXA9*, *HOXA5*, *HOXA4* and *HOXC6*.

ALL with *BCR–ABL1* rearrangements

The t(9;22)(q34;q11) translocation encodes a chimeric gene consisting of the 5' portion of *BCR* fused to the 3' portion of *ABL1*, whereby N-terminal sequences of *ABL1* are replaced by

BCR sequences. In ALL, breaks tend to occur in the minor breakpoint cluster regions, forming a 190-kDa *BCR–ABL*. This alteration results in a constitutively active ABL tyrosine kinase that induces aberrant signalling and activates multiple cellular pathways. Expression of the *BCR–ABL1* chimeric protein results in malignant transformation of haemopoietic cells and causes leukaemia in murine experimental systems. In mice, aggressiveness of *BCR–ABL1* leukaemias is enhanced if the activity of the Arf tumour suppressor is compromised. Genome-wide analysis of *BCR–ABL1* ALL samples revealed deletions of *IKZF1* in 84% of cases whereas deletions were not found in chronic-phase CML samples. Moreover, deletion of *IKZF1* appeared to be a lesion acquired at the time of transformation from CML to lymphoid blast crisis.

BCR–ABL1 ALL has poor prognosis with standard chemotherapy. The development of the tyrosine kinase inhibitor imatinib mesylate has provided a way to disable the molecular mechanisms that drive leukaemic cell growth, and patients with *BCR–ABL1* ALL show dramatic responses. In a recent report, combination chemotherapy together with imatinib yielded an excellent 3-year event-free survival (EFS) exceeding 80% in childhood cases. The development of resistance due to the outgrowth of clones with mutations in the *BCR–ABL1* kinase domain led to the development of newer and more potent inhibitors, such as nilotinib and dasatinib.

Genetic abnormalities in T-cell ALL

Genes that are dysregulated in T-cell ALL include *SCL* (*TAL-1*), *LMO1* (*TTG-1*), *LMO2* (*TTG-2*) and *HOX11*. In a small fraction of cases, *SCL* (a gene involved in early haemopoiesis located on chromosome 1) is inserted into the TCR- δ locus on chromosome 14. Much more frequent (approximately 25% of cases) is the internal deletion in the 5' untranslated region of *SCL*, which juxtaposes a locus called *SIL* with the *SCL* coding region, resulting in the expression of a fused *SIL–SCL* transcript that encodes a normal *SCL* protein. *LMO1* is inserted into the TCR- α/δ locus in t(11;14)(p15;q11), while *LMO2* is inserted into this locus in t(11;14)(p13;q11). Activation of *LMO2* by retroviral insertion in its proximity has been implicated in the development of T-cell leukaemia in patients with X-linked severe combined immunodeficiency treated with gene therapy. An additional alteration found in T-cell ALL is the deletion from chromosome 9p21 of the *CDKN2A* (*INK4A*) and *CDKN2B* (*INK4B*) genes, which encode p16INK4a and p15INK4b, inhibitors of the Cdk4 cyclin D-dependent kinase. This locus, which is deleted in more than 50% of T-lineage cases, also encodes another important regulator of cell cycle and apoptosis, p19ARF.

Levels of *HOX11*, *TAL1* and *LYL1* mRNA expression have been used to recognize distinct subtypes of T-ALL. Overexpression of *LMO1* or *LMO2* was observed in most samples also overexpressing *TAL1*, and high levels of *LMO2*, but not *LMO1*, were found in cases with high *LYL1* expression.

Table 25.2 Biological features of leukaemic lymphoblasts in T-ALL and prognosis.

Parameter	Prognostic impact	Reference
↑ <i>TAL1</i> , <i>LYL1</i> or <i>HOX11L2</i>	Unfavourable	Ferrando <i>et al.</i> (2000)
↑ <i>HOX11L2</i>	None	Cavé <i>et al.</i> (2004)
↑ <i>HOX11L2</i>	Unfavourable	Ballerini <i>et al.</i> (2008)
↑ <i>HOX11L2</i>	Unfavourable	van Grotel <i>et al.</i> (2008)
<i>NOTCH1</i> mutations	None	van Grotel <i>et al.</i> (2008); Larson Gedman <i>et al.</i> (2009)
<i>NOTCH1</i> mutations	Favourable	Breit <i>et al.</i> (2006); Park <i>et al.</i> (2009)
ETP signature	Very unfavourable	Coustan-Smith <i>et al.</i> (2009)

High expression of *HOX11L2*, a transcriptional regulator closely related to *HOX11*, is frequent and has been associated with poor outcome in some studies (Table 25.2). Activating mutations of *NOTCH1* are frequently found in T-ALL and have been implicated in its pathogenesis. Although there has been some discussion on their prognostic significance, most studies showed either a favourable or no prognostic impact (Table 25.2). Among cases of T-ALL, those bearing the gene expression profile of ETP have a dismal outcome.

Novel subtypes of ALL identified by genome-wide gene expression studies

In early studies using microarray methods for measuring gene expression, profiles that distinguished B-lineage ALL from T-lineage ALL were identified. Moreover, among cases of B-lineage ALL, those with hyperdiploidy (>50 chromosomes), *BCR-ABL1*, *TCF3-PBX1*, *ETV6-RUNX1* or *MLL* gene rearrangement could be clearly distinguished. Subsequent studies have confirmed that gene expression profiling can recognize known subtypes of ALL with accuracy, a capability that may improve risk classification in ALL. To this end, a subset of ALL, identified by hierarchical cluster analysis of gene expression data, comprised many cases that clustered with *BCR-ABL1*-positive cases and had unfavourable outcome. The majority of cases with *BCR-ABL1*-like disease also had deletions in genes involved in B-cell development such as *PAX5* and *IKZF1* (Figure 25.1). Another study showed that *IKZF1* deletions and mutations were associated with a *BCR-ABL1*-like gene expression profile and strongly predicted poor response to chemotherapy and relapse. Finally, it was recently shown that the *P2RY8-CRLF2* fusion (resulting from a recurring interstitial deletion of

Figure 25.1 Prevalence of genetic abnormalities in newly diagnosed childhood B-lineage ALL. The prevalence of established abnormalities (discovered by conventional karyotyping and fluorescence *in situ* hybridization) and novel abnormalities (discovered by genome-wide analysis with SNP arrays) is shown. Deletions and mutations of *PAX5* and *IKZF1* may occur in cases with established genetic abnormalities. Hyperdiploidy, >50 chromosomes; hypodiploidy, <45 chromosomes.

the pseudoautosomal region 1 of chromosomes X and Y) is present in 53% of ALL occurring in patients with Down syndrome.

Prognostic factors

Presenting features

Presenting clinico-biological features are commonly used to define subtypes of ALL with different risk or relapse. Presenting age and leucocyte count have prognostic strength in B-lineage but not T-lineage ALL. However, as many as 20% of patients with B-lineage ALL who are considered at lower risk of relapse by these criteria (e.g. age 1–9 years with leucocyte count <50 × 10⁹/L) may relapse. Moreover, cases with a very high risk of relapse cannot be reliably distinguished by these criteria. For unclear reasons, boys have worse outcome than girls in many treatment protocols. In some studies, patients of African-American and Hispanic origin had a significantly worse outcome but this was not the case in our single-institution protocols, a finding that might be attributed to equal access to effective contemporary treatment to all patients.

As discussed earlier, primary genetic abnormalities of leukaemic cells are excellent predictors of outcome but correlations are not perfect. For example, as many as 15% of children with

favourable genetic features (*ETV6–RUNX1* fusion and hyperdiploidy >50 chromosomes) will eventually relapse, while approximately one-third of those with unfavourable genetic abnormalities (*BCR–ABL1* or *MLL–AF4*) can be cured with chemotherapy alone. It was shown that among patients with *BCR–ABL1*-positive ALL, age over 10 years or a high leucocyte count was associated with a poor outcome; in those with *MLL–AF4*-positive ALL, infant age group (<12 months) conferred a particularly poor outcome. Patients with ETP ALL have a dismal outcome with contemporary therapy irrespective of other presenting features.

Minimal residual disease

A slow reduction of the leukaemic cell burden by remission induction therapy is associated with a poor treatment outcome. Response to therapy, as assessed by morphological examination of bone marrow and peripheral blood smears, has limited sensitivity and accuracy. The advent of methods for detecting minimal residual disease (MRD), which are at least 100 times more sensitive than conventional morphological techniques, has introduced a profoundly new way to monitor response to treatment. The most reliable methods for measuring MRD include flow cytometric profiling of aberrant immunophenotypes, PCR amplification of fusion transcripts and chromosomal breakpoints, and PCR amplification of antigen-receptor genes.

The prognostic importance of MRD in childhood ALL has been unequivocally established by the results of numerous correlative studies. In our studies, patients who had MRD of 0.01% or more in bone marrow during or at the end of remission induction therapy had a significantly higher risk of relapse, while those with MRD of 1% or more at the end of remission induction therapy and those with MRD of 0.1% or more during continuation therapy had an extremely high relapse hazard. In contrast, patients with undetectable MRD on day 19 had a particularly favourable outcome. Investigators of the International Berlin–Frankfurt–Münster (I-BFM) Study Group found that the combined information about MRD on days 33 and 78 could identify three groups of patients with a significantly different outcome: 10-year EFS was 93% for patients who were MRD negative at both time points, 16% for patients with MRD of 0.1% or more at both time points, and 74% for the remaining patients. Investigators of the Dana–Farber Cancer Institute ALL Consortium reported a 5-year risk of relapse of 5% for patients with no detectable (<0.01%) MRD at end of remission induction and 44% for those with detectable MRD. An MRD cut-off level of 0.1% was the best predictor of 5-year relapse hazard in this series: 72% for patients with higher levels of MRD and 12% for those with lower levels. Investigators of the Children’s Oncology Group reported that the presence of MRD (0.01% or higher) at the end of remission induction (day

29) was the strongest prognostic indicator, superior to other commonly used prognostic parameters in childhood ALL, and predicted both early and late relapses. Examples of risk classification schema that combine presenting features and MRD assessments are shown in Table 25.3. The prognostic value of MRD in childhood ALL also extends to specific subsets of patients with presenting features traditionally used for risk assignment, and to infants.

Pharmacogenetic variables

Mutations and polymorphisms of genes encoding several drug-metabolizing enzymes have been associated with response to therapy. The best-established association regards the thiopurine S-methyltransferase gene, which encodes the enzyme that catalyses the inactivation of mercaptopurine. Approximately 1 in 300 patients have an inherited homozygous deficiency of thiopurine S-methyltransferase and are therefore extremely sensitive to mercaptopurine. Patients who are heterozygous for this mutation (approximately 10%) have intermediate levels of enzyme activity. Both homozygous and heterozygous deficiencies are associated with a better EFS, likely due to higher dose intensity of mercaptopurine, but they also carry the increased risk of acute toxicities and a higher rate of irradiation-induced brain tumours and therapy-related acute myeloid leukaemia. Hence, mercaptopurine dosages must be carefully adjusted in these patients, an approach that abrogated the clinical impact of these mutations.

The null genotype for the glutathione S-transferase genes *GSTM1* or *GSTT1* and for *GSTP1* V105/V105 is also associated with increased treatment-related toxicity and a lower risk of relapse, perhaps because of reduced detoxification of cytotoxic chemotherapy. In one study, 16 polymorphisms in genes involved in drug metabolism, including *GSTM1* and *TYMS* (thymidylate synthetase), were associated with treatment outcome, while polymorphisms in genes involved in folate metabolism, including those for methylenetetrahydrofolate reductase (*MTHFR*) and methionine synthase reductase (*MTRR*), affected methotrexate sensitivity *in vitro*. A study comparing the polymorphisms of 16 genes with functions related to treatment response to MRD levels on day 8 in blood and on day 28 in bone marrow found that the G allele of a common polymorphism in the gene for the chemokine receptor 5 (*CCR5*) was associated with better MRD clearance than the A allele; the molecular mechanisms underlying this association are unclear. Another study identified 102 SNPs associated with MRD, including 21 in genes associated with antileukaemic drug disposition and five in the *IL15* gene. The mechanisms linking alterations in IL-15 and poor response to chemotherapy are also unclear but recall findings that IL-15 overexpression is associated with increased CNS involvement at diagnosis and CNS relapse in childhood ALL. Significantly higher concentrations

Table 25.3 Current risk classifications of childhood ALL.

Risk group	Features
<i>St Jude Children's Research Hospital</i>	
Low	B-cell precursor immunophenotype and age 1–9 years with leucocyte count $<50 \times 10^9/L$, DNA index ≥ 1.16 and <1.60 , or <i>ETV6–RUNX</i> ; without CNS (CNS1)* or testicular leukaemia, or t(1;19), t(4;11), t(9;22), <i>MLL</i> rearrangement or hypodiploidy <44 chromosomes; MRD $<1\%$ at day 15 or remission induction and $<0.01\%$ at the end of 6-week remission induction
Standard	T-cell phenotype (except ETP ALL) and B-cell precursor cases not classified as low or high risk
High	ETP ALL phenotype, induction failure, or MRD $\geq 1\%$ at the end of 6-week remission induction
<i>Children's Oncology Group (B-lineage cases)</i>	
Standard risk – low	1–9 years with leucocyte count $<50 \times 10^9/L$, trisomy 4, 10 or 17 or <i>ETV6–RUNX1</i> , no CNS leukaemia (CNS1), or <i>BCR–ABL1</i> or <i>MLL</i> rearrangement or hypodiploidy; rapid early response (day 15), MRD $<0.1\%$ on day 29
Standard risk – average	1–9 years with leucocyte count $<50 \times 10^9/L$, CNS1 or 2, no <i>BCR–ABL1</i> or <i>MLL</i> rearrangement or hypodiploidy, rapid early response, MRD $<0.1\%$ on day 29
Standard risk – high	1–9 years with leucocyte count $<50 \times 10^9/L$; no <i>BCR–ABL1</i> or hypodiploidy; slow early response or MRD $\geq 0.1\%$ on day 29 or <i>MLL</i> rearrangement and rapid early response
High	≥ 10 years or leucocyte count $\geq 50 \times 10^9/L$ or 1–9 years with leucocyte count $<50 \times 10^9/L$ with testicular leukaemia; no <i>BCR–ABL1</i> or hypodiploidy
Very high risk	t(9;22)/ <i>BCR–ABL1</i> or hypodiploidy or <i>MLL</i> rearrangement with slow early response or induction failure or MRD $\geq 1\%$
<i>Berlin–Frankfurt–Münster Consortium</i>	
Standard	Prednisone good response; no t(9;22)/ <i>BCR–ABL1</i> or t(4;11)/ <i>MLL–AF4</i> ; MRD negative on days 33 and 78
Medium	Prednisone good response; morphological remission on day 33; no t(9;22)/ <i>BCR–ABL1</i> or t(4;11)/ <i>MLL–AFF1</i> ; do not fulfill other standard- or high-risk criteria
High	Prednisone poor response; M2 or M3 marrow on day 33; presence of t(9;22)/ <i>BCR–ABL1</i> or t(4;11)/ <i>MLL–AFF1</i> ; MRD $\geq 0.1\%$ on day 78

*CNS1, absence of leukaemic blasts in cytocentrifuge preparations of cerebrospinal fluid; CNS2, presence of blasts but leucocytes $<5/\mu L$; CNS3, presence of leukaemic cells in a cerebrospinal fluid that contains ≥ 5 leucocytes/ μL .

of methylmercaptapurine nucleotides were found in patients with a non-functional allele of the gene for inosine triphosphate pyrophosphatase, which were associated with a higher probability of severe febrile neutropenia.

Treatment

Overview

The more successful contemporary clinical trials for children with newly diagnosed ALL have resulted in 5-year EFS rates ranging from 75 to 87% (Table 25.4). The general treatment approach relies on three main phases: remission induction, intensification (consolidation) therapy, and continuation treatment. In patients with mature B-cell ALL, regimens of intensive chemotherapy are typically shorter and based primarily on cyclophosphamide, methotrexate and cytarabine, resulting in cure rates of 74–87%. All patients require treatment for sub-

clinical leukaemia of the CNS, which should be initiated early in the form of intrathecal therapy.

Remission induction

Rates of complete remission (i.e. absence of leukaemic cells detectable morphologically and restoration of normal haemopoiesis) currently range from 96 to 99%. Remission induction regimens typically include a glucocorticoid (prednisone, prednisolone or dexamethasone), vincristine and asparaginase, with or without one or more additional drugs (e.g. an anthracycline, cyclophosphamide). Intensification of induction therapy may achieve a more effective clearance of leukaemic cells but it might not be necessary for patients lacking unfavourable prognostic features and having a good early response, particularly if they receive post-induction intensification therapy. Intensified induction therapy may increase early morbidity and mortality.

Because of its reported longer half-life and increased penetration into CSF, dexamethasone may be more effective than prednisone or prednisolone. Its use yielded an improved outcome in some trials but resulted in excessive life-threatening infections and septic deaths in another study. A small randomized study showed that an increased dose of prednisone produced results comparable to those achieved with dexamethasone in the context of other intensive treatment, suggesting dose rather than type of glucocorticoid influences treatment outcome.

Most remission induction regimens include asparaginase. However, clinical trials limiting that use of asparaginase to the post-induction period yielded low morbidity (especially in terms of thrombotic complications) and excellent overall outcome. The currently available asparaginase for newly diagnosed patients is derived from *Escherichia coli* and there is a polyethylene glycol-bound form of the *E. coli* product (pegaspargase); asparaginase derived from *Erwinia chrysanthemi* is typically used in patients who have hypersensitivity reactions to *E. coli* product. Each type has a different half-life, pharmacokinetics and immunogenicity. In terms of antileukaemic activity, the key issue is the amount of asparagine depletion achieved. Because of lower immunogenicity and less frequent administration, pegaspargase has become the first-line treatment in the USA and is also increasingly used in other childhood ALL trials worldwide. Patients with allergic reactions to either *E. coli* preparation should be treated with *Erwinia* asparaginase.

Intensification (consolidation)

Patients who achieve remission typically receive intensification (also called consolidation) therapy. This consists of the same drug schema used in the remission induction regimen or of a combination of drugs not previously used. Patients with different subtypes of leukaemia may respond particularly well to

certain intensification regimens. For example, patients with *ETV6–RUNX1* had an especially good outcome in clinical trials featuring intensive post-remission treatment with glucocorticoids, vincristine and asparaginase, while a very high dose of methotrexate (5 g/m²) improved treatment outcome of patients with T-cell ALL. Other regimens have not proven to be advantageous, such as high-dose intravenous mercaptopurine and high-dose cytarabine.

Delayed intensification (or reinduction), first introduced by investigators of the I-BFM Study Group, is a widely used approach consisting of a repetition of the first remission induction therapy 3 months after the end of remission induction. Investigators at the Children’s Cancer Group and of the Associazione Italiana Ematologia ed Oncologia Pediatrica (AIEOP) group reported that double delayed intensification improved patient outcome in patients with intermediate risk. Extended and stronger intensification therapy also significantly benefited patients with high-risk ALL and slow response to initial induction therapy. While reinduction or delayed intensification therapy is probably beneficial to all patients, double or prolonged intensification appears to be beneficial primarily to those with features predicting a higher risk of relapse.

Continuation therapy

With the exception of patients with B-cell (surface immunoglobulin positive) ALL, all children with ALL require prolonged continuation treatment, which typically lasts for 2–2.5 years. Attempts to shorten its duration have led to inferior outcomes, although it should be noted that up to two-thirds of patients could be cured with only 12 months of treatment in one trial. Continuous uninterrupted therapy appears to be more effective than high-dose pulse therapy with prolonged rest periods to recover from myelosuppression.

The classical components of continuation therapy are methotrexate and mercaptopurine, administered weekly and daily, respectively. Low systemic exposure to methotrexate and low dose intensity of mercaptopurine have been associated with an inferior outcome. Conversely, administration of doses gauged to produce the lowest tolerable neutrophil counts reportedly improved outcomes. However, following such an approach too strictly may be counterproductive, resulting in dose interruption and reduction of the overall dose intensity. Parenteral administration of methotrexate circumvents problems of decreased bioavailability and poor compliance associated with oral administration, especially in adolescents. In contrast, mercaptopurine is most effective when it is given orally daily; weekly intravenous administration at a higher dose was shown to be ineffective. In some studies, thioguanine appeared to have a superior antileukaemic effect than mercaptopurine but its use at a daily dose above 40 mg/m² was associated with a higher rate of toxicities, such as profound thrombocytopenia and hepatic veno-occlusive disease. Intensive treatment with mercaptopurine and methotrexate maintenance therapy has been related to the occurrence of second malignancies, especially in patients with thiopurine methyltransferase deficiency.

Studies have shown that adding intermittent pulses of vincristine and a glucocorticoid (prednisone or dexamethasone) to the methotrexate/mercaptopurine combination is beneficial. Whether this pulse therapy is necessary in contemporary regimens featuring early intensification of therapy remains to be determined.

Prevention and therapy of CNS leukaemia
