The infiltration of the leptomeninges by leukaemic cells poses a challenge because the blood–brain barrier provides a pharmacological sanctuary for leukaemic cells and protects them from systemic therapy. Hence, cranial irradiation (12–24 Gy) and methotrexate administered intrathecally after induction of complete remission as a prophylactic measure to prevent CNS leukaemia has become a key feature of childhood ALL treatment since the 1970s. Cranial irradiation can cause serious side-effects and a reduction of the radiation dose to a less harmful 12 Gy appeared to provide adequate protection against CNS relapse. Complete omission of cranial irradiation as tested in early clinical trials also resulted in an acceptable rate of CNS relapse but produced low overall survival rates. A recent study at St Jude Children's Research Hospital tested the feasibility of total omission of prophylactic cranial irradiation. The 5-year survival rate for the 498 patients enrolled was 93.5% and the cumulative risk of an isolated CNS relapse rate was only 2.7%, demonstrating that cranial irradiation can be avoided in the context of effective risk-adapted intrathecal and systemic chemotherapy. Intensive systemic and intrathecal treatment, without cranial irradiation, appears to provide adequate CNS prophylaxis

even in infants who have CNS leukaemia at diagnosis. Therefore, most investigators now treat infants (a group of patients particularly vulnerable to CNS irradiation toxicities) without cranial irradiation. Importantly, patients with an isolated CNS relapse have a very high retrieval rate if they did not receive cranial irradiation as CNS prophylaxis.

Systemic treatment including high-dose methotrexate, intensive asparaginase, and dexamethasone as well as optimal intrathecal therapy are essential to control CNS leukaemia. Triple intrathecal therapy with methotrexate, cytarabine and hydrocortisone is more effective than intrathecal methotrexate alone in preventing CNS relapse. Intrathecal therapy should be intensified in patients with detectable ALL blasts in the CSF (even because of traumatic lumbar puncture) as this finding carries an increased risk of CNS relapse and inferior overall outcome.

Allogeneic haemopoietic stem cell transplantation

Patients with the *BCR–ABL1* gene fusion, ETP ALL, poor early response or early haematological relapse are the more frequent candidates for transplantation. Nevertheless, the indications for transplantation should be continuously reviewed as treatment improves and new agents become available. For example, the use of imatinib and other tyrosine kinase inhibitors has dramatically improved early treatment response in patients with *BCR–ABL1*-positive ALL, questioning whether transplantation in first remission should be recommended in these cases. Transplantation has not been shown to improve outcome of other subtypes of very high risk leukaemia, including infant cases and those with *MLL* rearrangement.

Levels of MRD prior to transplant predict the risk of relapse after transplant. In patients receiving T-cell-depleted grafts, high levels of MRD PCR positivity (0.1–1%) before transplant were consistently associated with relapse after transplant, and patients with lower levels of MRD had a 2-year EFS of 35–50% compared with 70% for MRD-negative patients.

Treatment sequelae

Improvements in supportive care have reduced the early death rate to less than 2%. Remission induction therapy including prednisone, vincristine and asparaginase causes hyperglycaemia in 10–20% of patients, particularly adolescents and patients with obesity, a family history of diabetes mellitus or Down syndrome. The same induction regimen can also lead to a hypercoagulable state in 3–5% of patients, promoting cerebral and/or peripheral vein thromboses. The intensified use of methotrexate and glucocorticoids has been associated with an increased frequency of neurotoxicity and osteonecrosis. High cumulative doses of anthracyclines can produce severe cardio-

myopathy, especially in young children. Cranial irradiation may cause second neoplasms within the irradiated field, as well as neuropsychological deficits and endocrine abnormalities, leading to obesity, short stature, precocious puberty and osteoporosis.

Relapse

Leukaemia relapse may occur during or after treatment, usually within 2 years after cessation of therapy but occasionally later (relapses occurring as late as 10 years after diagnosis have been reported). The bone marrow remains the most common site of relapse, while the frequency of relapse in extramedullary sites, such as the CNS and testes, has steadily decreased. Even when extramedullary relapse appears to be an isolated event, it is often associated with submicroscopic residual disease in the bone marrow.

There have been reports of leukaemias morphologically and immunophenotypically characterized as ALL that relapse as acute myeloid leukaemia while retaining the karyotypic and molecular features of the original clone. More insights on the genetic evolution of ALL at relapse were revealed by a recent study where genome-wide DNA copy number analyses were performed on matched diagnosis and relapse samples from 61 children with ALL, indicating that most relapse samples lacked some of the genetic abnormalities present at diagnosis. Backtracking studies revealed that cells corresponding to the relapse clone were often present as minor subpopulations at diagnosis.

Bone marrow relapse, with or without extramedullary involvement, is associated with a poor outcome. Paradoxically, patients with isolated bone marrow relapse generally do worse than those with combined bone marrow and extramedullary relapse. In children with relapsed ALL, adverse risk factors include short initial remission, T-cell immunophenotype, *BCR-ABL1* ALL, presence of circulating blast cells or a high leucocyte count at relapse. The presence of MRD at the end of second remission induction is a strong adverse prognostic indicator. Chemotherapy may be sufficient to induce prolonged second remissions in patients without high-risk features but allogeneic haemopoietic stem cell transplantation is a reasonable treatment option for the remaining patients, particularly those who experience haematological relapse during therapy or shortly thereafter, those with T-cell ALL, and those with persistent MRD. The Acute Lymphoblastic Leukaemia Relapse Berlin–Frankfurt–Münster Study Group recently reported the results of a prospective trial including 91 children with relapsed ALL receiving stem cell transplantation. The probability of EFS after transplantation was significantly associated with MRD burden before transplantation, and MRD was the only independent predictive parameter.

Concluding remarks

The current cure rates for children with ALL demonstrate the remarkable progress that has been made in treating this disease through improvements in risk classification, chemotherapy, transplantation and supportive care. Classification of ALL into prognostically meaningful subtypes defined by clinical presenting features and genetic abnormalities of the leukaemic cells is well established. The uncovering of new genetic lesions in leukaemic lymphoblasts using novel screening techniques and the definition of their prognostic significance should further improve risk classification. Genome-wide expression profiling studies may also facilitate the discovery of molecules that critically influence drug resistance. This is shown by studies that established the association of gene expression in leukaemic lymphoblasts with response to treatment *in vitro*.

The development of robust MRD assays and the understanding of the clinical significance of MRD have opened a new approach to monitoring the response to treatment and have introduced a new concept of 'remission'. MRD assays have been incorporated into many major treatment protocols and are now an integral part of the modern management of childhood ALL. Simplification of MRD methods should widen the application of this powerful prognostic parameter, and extend its potential benefits to most patients, including those living in areas with limited resources. Further progress in optimizing intensity of treatment for each patient is coming from a better understanding of the relation between pharmacogenomic features and responses to chemotherapy, which should lead to significant refinements of treatment schedules and dosages.

Despite these remarkable improvements, standard chemotherapy still produces low cure rates for patients with some subtypes of ALL, such as infants with *MLL* rearrangement and those with ETP ALL; for these patients, substantial improvements can only come from the development of new treatment modalities. Imatinib mesylate and other ABL kinase inhibitors are the paradigm of molecular therapy of leukaemia. Other novel agents include inhibitors of FLT3, farnesyltransferase, proteasome, DNA methylation and histone deacetylase. Moreover, there are new formulations of existing agents that may improve efficacy and decrease toxicity. To this end, nucleoside analogues of more recent generation, such as gemcitabine, clofarabine and nelarabine, have shown promise. The application of gene expression-based drug screening might facilitate the identification of new effective compounds, while the detailed understanding of the cooperating genetic abnormalities associated with ALL could identify new targets.

Immunotherapeutic options are progressively emerging. Rituximab (anti-CD20), gemtuzumab ozogamicin (anti-CD33), alemtuzumab (anti-CD52) and epratuzumab (anti-CD22) have already been incorporated into some clinical trials;

recombinant immunotoxins and bispecific antibody derivatives have also been developed and are being tested. In the context of haemopoietic stem cell transplantation, donors can be selected so that their natural killer (NK) cells can exert maximum cytotoxicity against the leukaemic cells of the host, and infusions of haploidentical NK cells are being evaluated. Chimeric receptors, composed of single-chain variable domain of murine antibodies and human signalling molecules, can redirect the specificity of autologous or allogeneic immune cells against ALL cells and may therefore enhance the effectiveness of T and NK cell infusions.

For many decades, oncologists have been familiar with the concept that pharmacological sanctuaries (e.g. the CNS) contribute to protect leukaemic cells from chemotherapy. More recent evidence indicates that the bone marrow microenvironment can also antagonize the effects of chemotherapy. For instance, we found that bone marrow mesenchymal cells protect ALL cells from asparaginase cytotoxicity by forming an asparagine-rich microenvironment, suggesting a scenario whereby ALL cells that reside in mesenchymal cell niches become relatively resistant to chemotherapy. Because agents that interfere with the interaction between ALL and mesenchymal cells are available for clinical use, it should be possible to design protocols that attempt to improve chemotherapy effectiveness by mobilizing ALL cells.

Introduction

The outlook for patients with acute and chronic leukaemias has improved considerably in the past 40 years, mainly because of more effective therapy. Better understanding and management of the complications have also improved survival and quality of life. These complications vary with the pace of the disease (acute or chronic), with specific subtypes of myeloid and lymphoid leukaemias, and with the intensity and duration of therapy.

The effectiveness of support depends on the coordinated work of specialist doctors, nurses, therapists and pharmacists and laboratories, working in facilities dedicated to the care of these patients. In the intensive care of patients with acute leukaemia, it is especially important that there should be clear rules about when and why nurses should ask medical staff to review their observations and equally clear rules about the doctors' responses. Timely and accurate communication between professional groups is essential, and all should be working to agreed written standards. Management of all the complications requires careful and regular recording of basic observations by nurses,

most of whom should be registered and experienced in leukaemia care. This team needs a high skill mix and an overall nurse-patient ratio above 1 to allow internal shift rotation that provides a continuous level of expertise. Whatever the type of leukaemia, patients should be treated according to protocols as part of well-designed controlled clinical trials.

The management of each group of complications is described both in general and with reference to specific types of leukaemia and forms of therapy. Complications requiring supportive care can be classified as follows.

1 Psychological: due to loss of performance and self-determination and protracted treatment-related complications, such as the need for isolation as protection against infection.

2 Reproductive: due to the need to prevent pregnancy in female patients during intensive cytotoxic exposure and to preserve fertility in patients of childbearing age.

3 Anaemia: due to failure of red cell production, bleeding or haemolysis.

4 Bleeding: due to thrombocytopenia and lack of clotting factors, through either failure of production or excessive consumption (disseminated intravascular coagulation).

5 Infections: due to failure of production of adequate numbers of functionally normal neutrophils, and monocytes/macrophages, immune dysregulation and failure of the innate immune response, including the gut mucosal barrier.

6 Metabolic: due to disturbances in fluid and electrolyte and acid–base balance, related to the disease or the treatment or both.

7 Nutritional: when oral intake fails and loss of lean body mass is significant.

8 Nausea and vomiting: due to chemotherapy and other drugs.

9 Pain: due to involvement of specific anatomical sites in the disease or as a result of specific therapies.

10 Palliative supportive care: necessary when cytotoxic therapy fails to induce or maintain lasting complete remission; this does not exclude further cytotoxic therapy as part of other efforts to control distressing symptoms.

Psychological support

Regardless of the subtype of disease and form of therapy, this support starts with an explanation of the diagnosis and treatment by a senior haematologist accompanied by a specialist nurse, both of whom should be active and experienced in this type of care and communication. It is essential to gain the trust of patients and their immediate families or partners from the outset so that they can understand and accept the need for the proposed intensity and duration of treatment and the risks of complications. As well as needing support for their distress on learning the diagnosis, most will also ask for detailed information including prognosis. Any relevant clinical trial can be described, and informed consent can be obtained for enrolment and randomization between different treatment options. A relationship of mutual and complete openness should be established as soon as possible, and questions and discussion encouraged.

Most patients may appear to be psychologically able to deal with these illnesses and all their complications. However, many patients find that loss of control of their normal daily activity is difficult to manage, particularly prolonged stays in hospital, including periods in protective isolation. Nearly all will suffer some loss of self-assurance and self-esteem, particularly if they fall ill at the peak of their responsibilities and abilities in their domestic and working lives. Fear of failure of therapy may be lessened if remission is achieved, but patients' anticipation of the complications of subsequent cycles of therapy may add to their psychological problems.

Having little control over this cumulative experience, patients can develop significant neurotic or psychotic pathology, sometimes well after therapy is finished and as they attempt to resume a normal life. The clinical team must be alert to the development of any signs that such problems are impending and deal with them before patients suffer significant and lasting harm. In dealing with these problems, it is difficult for professional carers to maintain a balanced approach that suits each patient. It is as easy to be too intrusive with those patients who can cope without help as it is to fail to detect psychopathology

in those who cannot. This area of supportive care underlines the need for integrated teamwork.

Regardless of age and subtype, patients with acute leukaemias present with a short history, are often seriously unwell due to acute marrow failure and require immediate admission to a haematology unit for intensive therapy. Their psychological complications are often more intensely expressed and require equally intensive support because their loss of function is so acute and severe. This type of supportive care should be an integral part of any therapy, whether it is given with the intention to achieve complete remission in younger patients or as palliation in the elderly and frail.

Reproductive issues

Before any chemotherapy is given to adolescents and young men, they should be counselled about the possibility of loss of fertility and offered the opportunity to store sperm. If therapy cannot be delayed, sperm should be collected as soon as possible to minimize the risk of damage to sperm already formed and stored and because of the potential infertility induced by any cytotoxic therapy, particularly intensive chemotherapy. Patients who opt to store sperm need expert counselling in all the associated ethical issues before collection, particularly their wish to destroy or preserve the collection should the patient die. They and their partners may wish to conserve the sperm for future fertilization after the patient's death. Loss of fertility due to chemotherapy is much less likely in women, who should avoid falling pregnant while receiving such therapy because of likely damage to the embryo and fetus. Preservation *in vitro* of unfertilized ova is not yet possible and not undertaken routinely.

Impaired sexual function can be a problem in both sexes following intensive chemotherapy. Patients and their partners are often reluctant to discuss these problems with their specialist carers and are more likely to discuss them with nursing colleagues. Expert counselling or psychological care can be effective in restoring potency.

Anaemia and thrombocytopenia

In all types of leukaemias, and with all types of treatment, there is a risk of marrow failure leading to anaemia and thrombocytopenia. The pace at which they develop and their severity vary with the type of leukaemia and therapy, and many of the complications are seen whatever the intensity of therapy. As these causes and effects are most marked in the acute leukaemias, the support needed in that context is described in greater detail. By the time most patients present, their ability to produce red cells and platelets will be severely impaired and they will need regular and frequent transfusions of both. Administration of a wide

Table 26.1 Ten rules for transfusion and coagulation failure in acute leukaemia.

<i>Rule</i>	<i>Reason</i>	<i>Exceptions</i>
1 In younger patients use CMV-negative blood until CMV status known	High transplant-related CMV death risk	No transplant planned
2 Transfuse if Hb <8 g/dL	Symptom control	Cardiac failure
3 Delay if white count >100 × 10 ⁹ /L	Hyperviscosity risks bleeds and clots	None
4 Give platelets priority	Red cells dilute low count	Big bleeds; give both
5 Big volumes need diuretics	Circulatory overload	None but plan K ⁺ and Na ⁺ infusions too
6 Keep platelets >10 × 10 ⁹ /L	Prevent bleeding	>20 × 10 ⁹ /L during sepsis
7 Use ABO-identical platelets	Maximize effect	No clinical harm if only non-identical available
8 HLA-restricted platelets if refractory to donations	Loss of effect	May resolve allowing use of non-restricted donations
9 Use pethidine for allergic/febrile reactions	Avoid undetected cumulative steroid immunosuppression	None
10 Use only ABO-compatible plasma-derived products to correct clotting times	Avoid ABO haemolytic reactions	None; therapy determined by specific bleeding problems

range of intravenous therapies, including blood products, may be necessary simultaneously. Long-lasting, tunneled, multilumen, central venous catheters (CVCs) facilitate rapid intravenous access for such multiple therapies, and also reduce the risk of blood-borne infection by reducing the need for multiple and repeated peripheral venous access. Sterile handling of these lines is therefore essential at all times. It is not necessary to transfuse either whole or fresh blood but there are some simple basic rules that should be followed regarding red cell and platelet transfusion (Table 26.1).

Cytomegalovirus-negative blood products

As transfusion of both red cells and platelets may be required at the outset, it is important to establish immediately whether elective allogeneic stem cell transplantation (SCT) is likely as part of the care plan. If it is, those patients should always be transfused with blood products that are less likely to increase the risk of cytomegalovirus (CMV) transfusion, using leucodepleted or filtered donor blood or blood only from known CMV-negative donors until the patient's own CMV status is known. This applies to all patients under the age of 55 years who have potential sibling donors. CMV infection is a major cause of morbidity and mortality in allogeneic SCT and prevention is more effective than treatment.

Acute anaemia

Onset of anaemia is often rapid in patients with acute leukaemia so they are unable to compensate haemodynamically as in anaemia of slower onset. Because of their acutely reduced red

cell mass and hence oxygen-carrying capacity, they are likely to be symptomatic and should be transfused as soon as they have been assessed clinically and the result of their blood count is known. This rule may need to be modified in the presence of symptomatic or treated cardiac disease (see section Planning large-volume transfusions). With chemotherapy, red cell production remains suppressed and the patient remains dependent on repeated transfusions.

Conventional teaching is to try to maintain the haemoglobin level above 10 g/dL. This has been challenged recently and it is possible to lower the threshold of haemoglobin at which red cell transfusion is indicated. There is evidence that patients in other critically ill categories will tolerate much lower levels (as low as 6 g/dL) and that transfusing at higher levels may be harmful. In practice, many leukaemia and transplant units already withhold red cell transfusion until the haemoglobin drops to 8 g/dL depending on other factors such as the degree of compromise of cardiorespiratory function.

Excessive red cell transfusion may lead to alloimmunization, with red cell blood group and white cell HLA antigens potentially creating difficulties for future transfusion and SCT. In the transplant patient (autologous and allogeneic), there is also the risk of iron overload, but this appears unlikely to be a problem with conventional chemotherapy.

Hyperviscosity of high white cell counts

Patients who present with acute leukaemias with very high white blood cell (WBC) counts, particularly over 100 × 10⁹/L, should be given blood only if it is not possible to wait for reduction of the WBC count by either leucapheresis or

chemotherapy. These patients are already at risk of thrombotic and haemorrhagic events due to hyperviscosity, and transfusion will increase that risk, even if it is slow. It is probably safe to allow such patients to start their chemotherapy with a haemoglobin level as low as 8 g/dL. Patients with high WBC counts in chronic myeloid leukaemia (CML) may develop hyperviscosity problems, but these are rare in chronic lymphocytic leukaemia (CLL).

Planning large-volume transfusions

When planning a large red cell transfusion, it is essential to estimate in advance the total intravenous fluid load these patients will receive over any following 24-hour period. Most patients with acute leukaemia are elderly and will already have some degree of cardiovascular pathology. Some chemotherapy, such as the anthracyclines commonly used in remission induction of acute myeloblastic leukaemia (AML) and acute lymphoblastic leukaemia (ALL), are also unpredictably cardiotoxic below a total cumulative dose in individual patients. If a large intravenous fluid load is unavoidable and intravascular overload is likely, elective diuretic therapy should be prescribed, usually with small doses (20 mg) of intravenous furosemide (frusemide) at planned intervals throughout a prolonged infusion. The use of diuretics in this way may lead to electrolyte depletion, which requires correction (see section Metabolic support). Careful observation of basic vital signs, more simply daily weights, will indicate whether there is an excessive intravascular fluid load contributing to compromised cardiac and respiratory function.

Platelets take priority

When these patients require both red cell and platelet transfusions, platelets should always be given first. Platelet production is compromised to such a degree that a large red cell transfusion will dilute the platelet count to a potentially dangerous lower level. Platelets for transfusion are provided in single packs known as an adult therapeutic dose, which contains approximately 10^{11} platelets. These are obtained either by apheresis from a single donor or by pooling platelets harvested from the buffy coats of packs of blood from six donors.

Platelets can be given so quickly through a CVC that even with sudden and heavy bleeding it is seldom necessary to give red cells first, and red cells and platelets can be given simultaneously.

Minimum platelet level

There is good evidence to suggest that the previous threshold for the transfusion of platelets ($20 \times 10^9/L$) was overcautious and a threshold of $10 \times 10^9/L$ is equally unlikely to lead to significant bleeding. Platelet transfusions may also alloimmunize against red cell and HLA antigens.

In general, platelets are not given until the count falls below the lower limit, but there are exceptions to this rule. It is important to remember that a count just over this lower threshold is often obtained early in the morning and that the count may drop below it within the following 24 hours before a further count is undertaken. Thus the rate of fall in previous counts should prove a useful guide as to when platelet concentrate should be infused. Platelet function and survival may both be compromised in the presence of sepsis and some systemic antibiotics (particularly penicillins in high dose), so the higher threshold of $20 \times 10^9/L$ should be used in patients with these risk factors. Whenever possible, platelet infusions should not be given temporally close to infusions of amphotericin (see section Infections) because of the evidence that this drug will interfere with platelet function and thus reduce the effectiveness of the donation. This may not be the case with liposomal amphotericin given in conventional doses.

It has been suggested that patients who are stable and not infected may tolerate platelet counts as low as $5 \times 10^9/L$, provided the count is unlikely to fall further. This policy requires considerable faith in the accuracy and reproducibility of the laboratory technology for counting platelets.

'Compatible' platelets

Whenever possible, platelet concentrate of a red cell ABO group identical to that of the patient should be transfused. If non-identical platelets are used, there may be loss of platelet function and an inferior increment in the recipient's count. Whether this technical benefit is ever clinically significant has never been proven conclusively, but it seems reasonable to give patients the theoretical best possible donation if they need platelets at all, especially if one applies the policy of only transfusing at the lower count of $10 \times 10^9/L$.

Platelet 'increments'

Regular platelet counts are needed to plan platelet transfusions and will also reveal failure to obtain a satisfactory increment in the patient's platelet count following transfusion of an adult therapeutic dose. Such patients are described as 'refractory' to platelet transfusion because of the development of alloantibodies to the HLA antigens borne by platelets, and may manifest bleeding or bruising even before a failure of increment is detected. This refractory state should be confirmed with two platelet counts, one before transfusion and one taken 30 min after transfusion. On confirmation of this problem, the patient's HLA type should be determined immediately if this has not already been performed for the purposes of subsequent transplantation. The National Blood Service will then supply HLA-restricted, if not HLA-identical, platelet donations until such time as a trial of HLA-unrestricted donations can be safely given again. Platelet refractoriness need not be permanent but can recur and is not necessarily heralded by a febrile reaction to transfusion.

Febrile reactions

During the course of treatment, patients will experience many episodes of fever for which there will be many potential explanations. Febrile reactions to blood and blood products are usually easy to identify as they occur during or immediately after the transfusion and should not be confused with the fever of infection (see section Infections). If the reaction occurs during transfusion, transfusion should first be slowed, but if this does not reduce the severity of symptoms and signs then transfusion should be stopped. If this fails to abort the first febrile reaction, only then should a single intravenous injection of an antihistamine, such as chlorpheniramine 25 mg, be given. If that is insufficient, many haematologists will give intravenous hydrocortisone 100 mg, and some will give both hydrocortisone and chlorpheniramine simultaneously.

The frequency and severity of these reactions may lead to the prescription of these two drugs either 'as required' or as prophylaxis for these reactions, which leads in turn to their uncontrolled use by inexperienced junior doctors and nurses. The total cumulative dose of immunosuppressive steroids may go unseen, and the use of hydrocortisone in the management of these febrile reactions should be discouraged. Whether these reactions are due to blood products or drugs such as amphotericin, the most effective treatment or prophylaxis is intravenous pethidine 12.5 mg. This drug is not immunosuppressive and this dose is neither sedating nor, on repetition, addictive, but it should not be used in fever that is probably due to infection.

Specific bleeding problems

In addition to the risk of bleeding because of low platelets, there are further specific coagulation problems that require early detection and planned management. Patients should be monitored for evidence of failure of coagulation, even when they are receiving regular platelet infusions. Clinical observation should include regular fundoscopy for retinal bleeding and testing for haematuria. During remission induction and consolidation therapy for acute leukaemia, platelet transfusion is unavoidable. Fresh-frozen plasma and cryoprecipitate are needed infrequently and should only be used for specific indications and in the absence of virally inactivated products. When correcting coagulation deficiency with plasma-derived products, red cell ABO group-compatible donations should be used to avoid ABO haemolytic reactions. The use of any blood products should follow best practice guidelines provided at present.

Asparaginase in the remission induction phase of the treatment of ALL can inhibit synthesis of coagulation factors, particularly fibrinogen, which should be replaced using fresh-frozen plasma or cryoprecipitate. Very rarely, asparaginase may cause superior sagittal vein thrombosis without warning, but espe-

cially in children with unsuspected genetic thrombophilia, for example factor V Leiden.

The hypergranular variant of acute promyelocytic leukaemia (M3) carries a very high risk of bleeding because of disseminated intravascular coagulation (DIC) or fibrinolysis. This can be present at diagnosis or is precipitated by chemotherapy, in either case because of the systemic prothrombotic action of the cytoplasmic granules released by the malignant blasts. The treatment, as in all cases of DIC, is to deal with the primary cause, in this case to lower the blast count as soon after diagnosis as possible. It may be accompanied by microangiopathic haemolytic anaemia. All-*trans* retinoic acid is now a standard part of initial chemotherapy for these patients, as it induces maturation of granulocytes, reducing release of the prothrombotic contents of their granules and lowering the risk of DIC.

Many older adult patients are now anticoagulated with warfarin, aspirin and clopidogrel, or a combination of these, to lessen their risk of acute myocardial infarction or stroke. The physician who initiated this therapy should be identified, if possible, to discuss the risks of stopping these immediately after diagnosis and throughout the treatment of the leukaemia. All antiplatelet therapy should be stopped because protracted and severe thrombocytopenia will recur during the course of therapy. The long action of aspirin and clopidogrel make rapid reversal of their antiplatelet effect impossible if the platelet count drops suddenly. Low-molecular-weight heparin should replace warfarin in those patients who have a high risk of arterial or venous thrombosis, and should be stopped once the platelet count falls below $50 \times 10^9/L$. Long-term anticoagulation should not be restarted until all chemotherapy is finished and the patient is in a stable remission with a platelet count above $100 \times 10^9/L$.

In patients with chronic and relapsed or refractory leukaemia, there may be chronic mucosal blood loss due to persistent and severe thrombocytopenia, which may be refractory to donor platelet transfusions. Oral tranexamic acid can reduce such blood loss and hormonal suppression can prevent endometrial bleeding. Persistent marrow failure without overt blood loss may require repeat red cell transfusions in patients with chronic leukaemias, particularly CLL. These should be given to relieve symptoms and not according to any set level of haemoglobin. Red cell alloantibodies and iron overload complicate repeated transfusion. Patients with CLL can develop autoimmune haemolysis and thrombocytopenia. The management of these complications is described in Chapter 29.

In all SCT patients, all blood products must be irradiated before transfusion to avoid the risk of graft-versus-host disease (GVHD) mounted by donor lymphocytes against the immunocompromised host. Irradiated blood products are also required in patients having chemotherapy with the aim of early SCT and in those treated with a purine analogue (e.g. fludarabine) to prevent GVHD. The risk of transfusion-related GVHD is much

lower in autografts than in allografts. Any transfusion given to those patients whose peripheral blood stem cells (PBSCs) are to be collected within the subsequent 2–3 weeks must also be irradiated, as transfused donor lymphocytes in the PBSC collection may remain alloreactive until after the autograft and lead to clinically significant GVHD.

Growth factor support for anaemia

The most comprehensive reviews of the evidence for the use of granulocyte colony-stimulating factor (G-CSF) and erythropoietin in cancer care are available from the US National Comprehensive Cancer Network (www.nccn.com). The recommendations for the use of erythropoietin are summarized below but these guidelines should be read in full to assess their applicability to the care of individual patients with haematological tumours.

Although it is difficult to define a level of anaemia at which intervention is needed, NCCN emphasizes the need to assess all causes of anaemia (haemoglobin <11.0 g/dL) in cancer patients (tumour-related, chemotherapy-related and all other causes) before correction with either red cell transfusion or erythropoietins. A recent meta-analysis has shown increased mortality associated with the use of erythropoietins in solid tumours and they are not recommended from 6 weeks onwards following the end of cancer treatment. In patients with previous venous thromboembolic episodes, they are also associated with an increased risk of further venous and arterial events, particularly in the presence of ongoing concomitant thrombogenic risk factors, because of either an increased haematocrit (to $42 \pm 3\%$) or as potentially thrombogenic in their own right. In all cases the relative risks and benefits of erythropoietins versus red cell transfusion should be discussed with the patient. Despite the recent Cochrane meta-analysis, there is some uncertainty about the efficacy of erythropoietins in improving quality of life. During initiation and subsequently, the blood pressure should be carefully monitored because of the risk of hypertension associated with erythropoietins.

In solid tumours, NCCN has a level 1 recommendation for the use of erythropoietins in symptomatic patients with chemotherapy-induced anaemias (haemoglobin <10.0 g/dL); however, if the haemoglobin is between 10.0 and 11.0 g/dL, the recommendation to use erythropoietins drops to a level 2b, and in both cases only if there is likely benefit to cancer treatment goals or relief of symptoms. In asymptomatic patients with a haemoglobin of less than 10.0 g/dL, a clear recommendation is not possible and the risks and benefits of both erythropoietins and red cell transfusion should be discussed with the patient. In patients with cancer-related anaemia outside the treatment period, erythropoietins are not recommended. In the treatment of myelodysplastic syndrome (MDS), erythropoietin is recommended by NCCN where intrinsic erythropoietin levels are below 500 mU/mL with or without synergistic G-CSF.

Erythropoietins are not recommended in the treatment of acute leukaemias.

NICE guidance issued in May 2008 is unhelpfully much more prescriptive, recommending the use of erythropoietins only in women with a haemoglobin of 8.0 g/dL or less treated for ovarian carcinoma with platinum-based therapies or those with very severe anaemia who cannot be transfused.

Infections

Some infections occur with all types of leukaemia and therapy, whereas others show more specific associations. As a general rule, the greater the duration and severity of immunosuppression, the greater the risk of life-threatening infection with a bigger range of organisms. During chemotherapy, patients with acute leukaemia have a high risk of life-threatening infections because of neutropenia due to the disease and the chemotherapy, combined with damage to the mucosal barrier and impairment of the innate immune system induced by chemotherapy. The risk is greatest with the profound and protracted immunosuppression required in allogeneic SCT from an unrelated donor.

Infectious agents can be viewed either as professional pathogens (group A streptococci, *Salmonella typhi*) or opportunistic pathogens as depicted in Table 26.2. This limited range of bacteria accounts for most of the opportunistic infections identified during the course of neutropenia, despite the fact that the

Table 26.2 Origins of common potential bacterial pathogens.

	Endogenous	Exogenous
Gram-negative bacilli	<i>Escherichia coli</i> <i>Klebsiella pneumoniae</i>	<i>Pseudomonas aeruginosa</i> <i>Enterobacter cloacae</i>
Gram-positive bacilli	<i>Corynebacterium</i> spp. <i>Clostridium</i> spp., e.g. <i>C. septicum</i>	<i>Bacillus</i> spp.
Gram-positive cocci	<i>Staphylococcus aureus</i> Coagulase-negative staphylococci, e.g. <i>Staphylococcus epidermidis</i> Viridans streptococci, e.g. <i>Streptococcus mitis</i> <i>Enterococcus faecalis</i> <i>Stomatococcus mucilaginosus</i>	<i>Enterococcus faecium</i>

body is colonized with so many more. Strictly anaerobic bacteria are rarely the cause of systemic infection, although they outnumber other bacteria by several billion. Fungal infections tend to occur later during therapy than bacterial infections. The body's surfaces, particularly the oral cavity and gut, are inhabited by billions of bacteria comprising many hundreds of genera, and the environment contains hundreds more bacteria and fungi. Most remain harmless and are never shown to be causes of fever during profound immunosuppression, despite the patient's close encounter with them.

All protocols for prophylaxis, investigation and treatment of infection should be agreed by haematologists and microbiologists and contain all the elements of an integrated plan to reduce morbidity and mortality arising from infection. All protocols should be complemented with regular discussion of individual patients' investigations and results, and by audits of responses to results and of effectiveness of the protocols.

Fever as evidence of infection during chemotherapy and SCT

Most patients with acute leukaemia will be repeatedly neutropenic for prolonged periods and therefore are at risk of becoming febrile at some point. A minority of these episodes will be accompanied by symptoms and signs of localizing infection, such as dysuria and urinary frequency or inflammation around the CVC exit site or tunnel. Because of the perceived need to treat presumed bacteraemia promptly in most cases, the fever will be, at least initially, of unknown origin. This empirical approach has proven of immense value in reducing mortality attributed to Gram-negative bacillary infection but may have some unfavourable consequences including undue reliance on drugs at the expense of microbiological diagnosis, more adverse

drug reactions, emergent bacterial resistance and increased costs. There are indeed many other causes of fever in these patients, including blood products, drugs (chemotherapy and antibiotics), tumour lysis syndrome, DIC and, in SCT, total body irradiation and GVHD. It is sometimes possible to identify one or more of these as the cause(s) of fever and thus avoid unnecessary antibiotic therapy. It has also become clear that fever may arise from the tissue damage associated with mucosal barrier injury induced by certain chemotherapeutic agents, including melphalan, cyclophosphamide, anthracyclines and cytarabine. The initial phase of mucosal barrier injury is characterized by an inflammatory response. Infection cannot be easily and reliably ruled out so fever should always be assumed to herald infection unless there is clear evidence to the contrary.

Infections can go unnoticed because the inflammatory response is muted and pus cannot be formed because of neutropenia. Foci of infections can also be easily overlooked unless physical examination is frequent and thorough. Infections may start as fever with or without bacteraemia, followed by clinical evidence of localized infection, and constant vigilance is needed to detect the sequential development of systemic infection (Figure 26.1). Despite the meagre signs and symptoms of infection in an immunocompromised patient, it is still essential to conduct a careful physical examination, paying particular attention to the oropharynx, including the dentition, the lungs, the skin, nails and exit sites of venous access devices, and the perianal region. Rectal examination is inadvisable in the severely neutropenic and thrombocytopenic patient because of the risk of bacteraemia. The most common sites of infection when present are the oral cavity, the lung and the skin, with its underlying soft tissues. Clinically detectable sources of infections occur in up to one in five cases and tend to be those in the skin

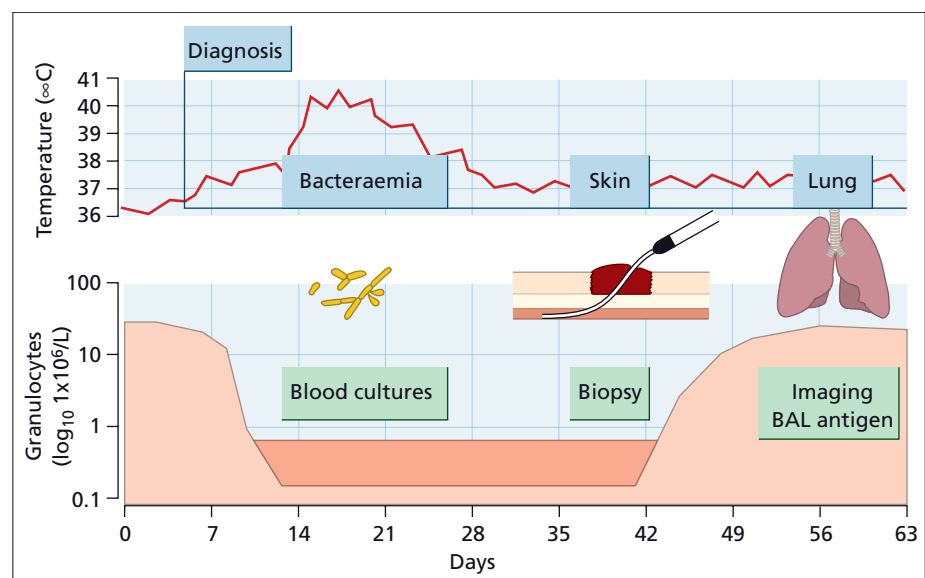

Figure 26.1 Common infections during neutropenia.

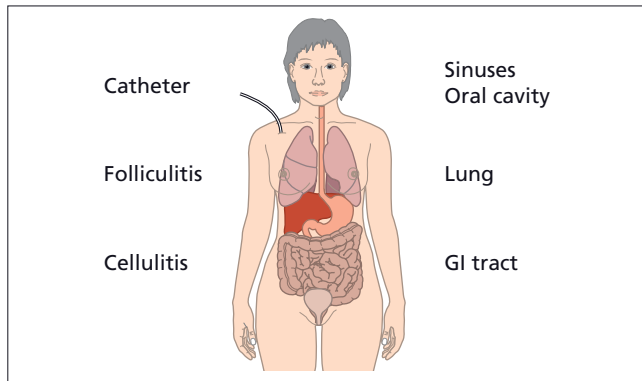

Figure 26.2 Sources of infection.

and its structures or in the mucosal barrier, including the respiratory tract (Figure 26.2). Microbiological proof of infection is found in only 20–30% of cases of neutropenic fever and a further 10–20% of cases can be defined as clinical infections.

All units treating these patients must have a clear written protocol that balances the risks and benefits of exact diagnosis against empirical therapy by making good use of all available evidence at the onset of fever. This protocol must include a description of the specimens to be obtained by the microbiology laboratory. Many diagnostic opportunities are missed if the laboratory is not clear about what is to be done with samples from these patients, and how results should be interpreted and reported. Obtaining specimens from some infectious foci may be difficult if this requires aspiration or biopsy during severe thrombocytopenia. Even when a specimen is obtained from a normally sterile site, the yield of pathogens is usually low, interpretation is difficult and the results may not influence management. Failure to identify a focus of infection and to obtain appropriate samples may leave the fever unexplained. In most cases, microbiological diagnosis depends on identification of pathogens in blood cultures.

Laboratory investigation of neutropenic fever of unknown origin

Blood cultures

The utility of blood cultures depends on adherence to a few simple rules (Table 26.3). The specificity of blood cultures is increased if samples are taken from at least two separate sites, preferably including all lumina of a CVC. Ideally blood should be drawn from a peripheral vein and from the CVC to confirm the significance of growing skin commensals such as the Gram-positive coagulase-negative staphylococci. Other isolates including Gram-negative bacilli and viridans streptococci seldom if ever colonize the lumen of a CVC because they normally originate from the oral cavity and gut in the setting of

Figure 26.3 Mucosal barrier injury (MBI: the role of mucositis), the systemic inflammatory response and bacteraemia.

Table 26.3 Blood cultures.

When	At onset of fever
How	A sample of 20 mL blood from a peripheral vein and, when present, samples of 20 mL from each lumen of an indwelling vascular catheter
Method	Each sample divided between an aerobic and an anaerobic bottle
Time to positivity	Most organisms are detected within 24 hours and 50% within 12 hours
Time to identify	24–48 hours, i.e. within the empirical phase
Utility	Identifies cause of fever in 20–30% of cases

mucosal barrier injury, better known by mucositis, its clinical counterpart (Figure 26.3). The fever associated with mucositis may originate from the mucosal damage induced by chemotherapy, and the loss of mucosal integrity that results may permit bacterial translocation leading to systemic infection. Even coagulase-negative staphylococcal bacteraemia may originate in some cases from the gastrointestinal tract or thromboses and may not represent catheter colonization.

The total amount of blood sampled at any one time constitutes a single blood culture. In adults, sensitivity and specificity

are increased if at least 20 mL, and preferably 30 mL, of blood taken from each sampling site at each time is divided between an aerobic and an anaerobic bottle to detect the majority of common pathogens.

Oral/rectal swabs

Viridans streptococci of the *mitis* group (*Streptococcus mitis* and *Streptococcus oralis*) are universal residents of the oral cavity and, with the exception of bacterial endocarditis, are seldom associated with infectious diseases. However, in the last two decades, these bacteria have been causing bacteraemia regularly in patients with severe oral mucositis. Similarly, *Clostridium* spp., for example *C. septicum*, are also normal commensal bacteria of the large bowel but can cause bacteraemia in patients suffering from a particularly severe form of gut mucositis, namely neutropenic enterocolitis (typhlitis). Given their presence in most individuals as part of the normal flora, it is pointless to obtain specimens from the oral cavity or rectum to detect these bacteria.

Specimens for pulmonary infection

Investigating pulmonary infection has become more demanding and involves obtaining blood samples as well as specimens from the respiratory tract. Bronchoalveolar lavage (BAL) specimens are advised for patients with pulmonary infiltrates and can yield the pathogen in 30–50% of cases. There are no standards for handling such specimens in the laboratory or in the diagnostic tests themselves. The residue of BAL samples after centrifugation is examined for *Pneumocystis jirovecii* (formerly *carinii*), the acid-fast bacilli and *Nocardia* spp., common bacteria, and moulds (*Aspergillus* spp.) and is subjected to culture for fungi and bacteria, including *Legionella* spp. and *Mycobacterium* spp. BAL should also be examined for the presence of *Aspergillus* galactomannan antigen, which is found frequently in cases of invasive pulmonary aspergillosis, and microbial DNA may be detected by polymerase chain reaction (PCR) techniques.

Standards for virological investigations vary, but the influenza and parainfluenza viruses, adenovirus, respiratory syncytial virus and CMV may also be detected. When superficial pulmonary lesions are present, specimens might be obtained by percutaneous or open lung biopsy, provided that the benefit outweighs the risk, diagnosis is uncertain and treatment is clearly not working. Although neutropenic patients do not produce sputum, they frequently expectorate mucous secretions, which should be sent for microscopy and culture. Recovery of moulds including *Aspergillus* on two or more consecutive occasions increases the likelihood of their being involved in invasive fungal diseases (IFDs) in the presence of pulmonary infiltrates on computed tomography (CT) consistent with invasive aspergillosis. The common practice of microbiology laboratories in discarding expectorated secretions without pus cells should not apply to these patients.

Skin lesions

Identifying the cause of a skin or soft-tissue infection is difficult because culturing superficial swabs of lesions rarely discriminates between pathogens and commensal flora. Culture and histological examination of skin punch-biopsy specimens is very helpful in diagnosing disseminated infections due to *Candida* spp., *Trichosporon* spp. and *Fusarium* spp. To achieve this it is important to ensure that the specimen is actually sent to histopathology and microbiology and not assume that it will be. In contrast, aspiration of skin lesions is seldom successful as pus is usually absent.

Gut investigations

In oesophagitis, endoscopy occasionally distinguishes infection due to herpes simplex from that due to *Candida* spp. but clinical suspicion of infective oesophagitis rarely leads to endoscopy because appearances are usually non-specific and the procedure is hazardous. Persistent diarrhoea or abdominal pain requires a cytotoxicity assay on a stool sample for *Clostridium difficile* toxin, and patients with right lower quadrant pain suggestive of typhlitis should have blood cultures taken to exclude the presence of *C. septicum* or *C. tertium*, as recovery of these bacteria usually indicates neutropenic enterocolitis. Although infections due to *Candida* spp., the Gram-negative bacilli, *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Clostridium* spp. and enterococci, including vancomycin-resistant enterococci (VRE), usually originate from the large bowel, there is no value in culturing faeces as, not surprisingly, there are many more patients colonized than infected.

Urinary tract

Urine should be obtained as cleanly as possible for standard culture when there are signs or symptoms of a urinary tract infection but not otherwise. Urine from SCT recipients with haemorrhagic cystitis should be tested for adenovirus and BK virus.

Non-cultural techniques

The role of non-cultural methods for diagnosis is small but expanding. *Legionella* antigen detection in urine is specific but detects only *L. pneumophila* type 1. Detection of CMV DNA by quantitative PCR may replace detection of the pp65 antigen in peripheral blood neutrophils among SCT recipients, and there is increasing expertise in using PCR to detect fungal DNA in blood and urine, but these remain investigational as there is no standard at present. Kits for the detection of *Aspergillus* antigen in serum, plasma and other sterile body fluids using an enzyme-linked immunosorbent assay (ELISA) are commercially available and can be used to screen patients at risk of aspergillosis. The specificity is generally high but the sensitivity has varied considerably, depending on the nature of the specimen (blood, bronchial material, cerebrospinal fluid), the threshold employed

(0.5–1.5), the characteristics of the population (age, underlying disease), the frequency of sampling (once or twice weekly or less) and the prevalence of the disease in the population under study. The manufacturer now recommends a cut-off of 0.5, which increases sensitivity at the expense of specificity. The sampling frequency of two to three times weekly appears optimal to screen for galactomannan, and detection of the substance in BAL fluid is considered sufficient to upgrade a case of possible invasive pulmonary aspergillosis to the level of probable IFD. There is also a test for detecting the fungal cell wall component β -D-glucan, which shows promise as it detects *Candida* and *Aspergillus* as well as other less frequently encountered moulds including *Fusarium*. However, experience is limited and the optimal positioning of this test for screening and confirming a diagnosis remains to be established. While the detection of the *Aspergillus* antigen and of β -D-glucan is considered equivalent to recovery by culture as mycological evidence, the detection of DNA by PCR is not until, and unless, a standard is established and the test is formally validated.

Surveillance cultures

There is no point in undertaking surveillance cultures unless the results are used to guide therapeutic or prophylactic choice. Obtaining nasal swabs to detect *Staphylococcus aureus* is useful as there is a strong association between carriage and subsequent bacteraemia. Once identified, a carrier can be treated with mupirocin. Carriers of methicillin-resistant *Staphylococcus aureus* (MRSA) should be managed according to local practice but should normally remain isolated from other patients until shown to be free of the bacterium. Surveillance cultures of faeces are used if there is a risk of emergent ciprofloxacin-resistant *E. coli* or *P. aeruginosa* when the drug is being used for prophylaxis. Testing faeces for carriage of these bacteria is a prudent form of surveillance to permit early detection of rising resistance before there is a corresponding rise in the infections caused by resistant bacteria. Detection of *Candida* carriage can be used to start prophylaxis; conversely, failure to detect the yeast or opportunistic Gram-negative bacilli in oral samples or faeces indicates that infection is highly unlikely as the negative predictive value of these cultures exceeds 95%.

Proven systemic infection during neutropenia

Surveys show that the rate of proven bacteraemia during periods of neutropenia has remained between 20 and 25% over many years. In adults, the range of bacteria identified has also altered very little, although the ratio of Gram-positive to Gram-negative organisms has varied. In the 1970s, there were two to three times as many Gram-negative as Gram-positive infections, in the late 1980s and early 1990s this ratio was reversed and now the risks of Gram-negative and Gram-positive infection are approximately equal. It is not entirely clear why this has happened, and individual units can have a pattern of causative

organisms that is unique and unlike that found elsewhere. Therefore, it is important for each unit to monitor local rates of isolation of bacterial and other pathogens and their patterns of antibiotic susceptibility in liaison with the microbiologists, who should be active members of the multidisciplinary team.

There have been changes in practice that have been widely applied and are blamed for the changing Gram-negative and Gram-positive rates. For example, in the management of adult acute leukaemia there has been a trend towards more intensity of therapy, with an increasing risk of gut mucositis. In the presence of this complication, blocking gastric acid production increases the risk of viridans streptococcal bacteraemia. The widespread use of indwelling CVCs provides another portal of entry for Gram-positive staphylococci, and to a lesser extent *Candida parapsilosis*, as the microorganisms often colonize the surfaces of the skin in that area. The cause of greatest concern has been the indiscriminate use of oral quinolone antibacterials (ofloxacin, ciprofloxacin, levofloxacin) as prophylaxis against Gram-negative bacteraemia, which has not reliably reduced the overall risk but simply shifted the common causes of bacteraemia towards the Gram-positive organisms. Such prophylaxis is justifiable in allogeneic SCT recipients prepared by myeloablative therapy and in those receiving intensive chemotherapy to induce remission of AML and MDS, but is seldom appropriate in lower-risk patients who are receiving chemotherapy.

Recent studies suggest that the risk of Gram-negative bacteraemia has not diminished in many single centres and is on the increase in some that have never used quinolones as prophylaxis, in those which have recently discontinued this use and even in those in which this use continues (Figure 26.4). The risk of proven bacteraemia fluctuates but may be as high as one in three of febrile episodes, mainly due to a significant doubling of the risk of Gram-negative infections.

It is difficult to reconcile these data with a unifying explanation. However, it does seem clear that despite a relatively high risk of bacteraemia, there is insufficient evidence to support continuous prophylaxis against bacterial infections with broad-spectrum antibiotics during conventional chemotherapy. It is also doubtful that this will substantially reduce the risk of such infections and may actually compromise the efficacy of these antibiotics when they are needed.

In bacteraemia associated with onset of fever, the most commonly identified Gram-negative bacilli are *E. coli*, *P. aeruginosa*, *Klebsiella* and *Enterobacter* spp. and the Gram-positive cocci *Staphylococcus epidermidis*, the viridans streptococci belonging to the *mitis* group *S. mitis* and *S. oralis* and *Staph. aureus* (increasingly the methicillin-resistant strains, i.e. MRSA). Bacteraemia due to other species such as *Enterococcus faecalis* and *Clostridium* spp. tends to occur only after 7–10 days' therapy with broad-spectrum antibiotics, in association with gut mucositis, including neutropenic enterocolitis (typhlitis).

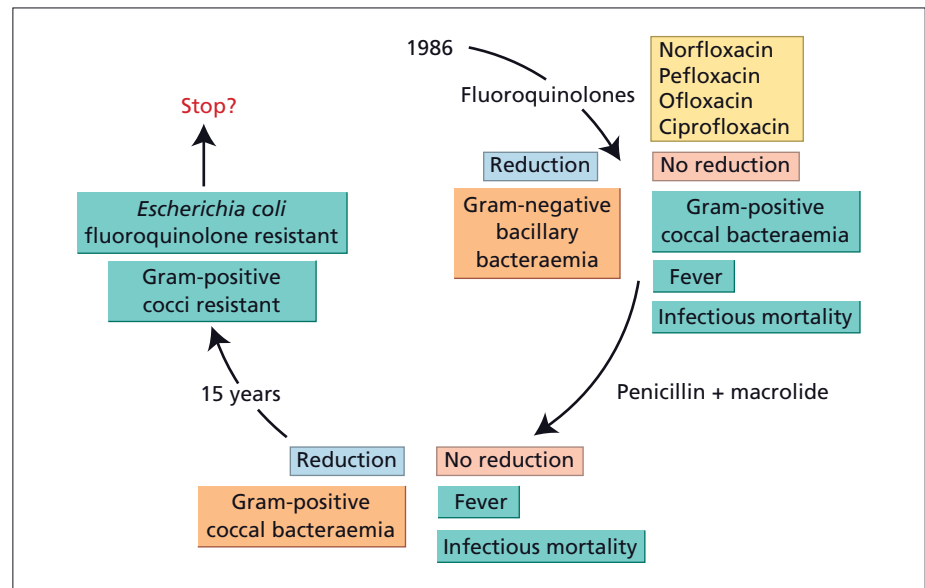

Figure 26.4 The life cycle of fluoroquinolone prophylaxis.

The reported incidence of proven IFD is 5–15% among allogeneic SCT patients, and the risk rises in severe chronic GVHD requiring prolonged immunosuppression with steroids. The majority of these infections are now due to *Aspergillus* spp. and about one in three are seen more than 100 days after engraftment. The mortality rate of IFD remains high in these patients. The rate of IFD during conventional chemotherapy is equally high among those given remission induction chemotherapy for AML and MDS but is less clear among other patients groups. IFD appears to be a significant risk for patients treated for a long time with corticosteroids and also when T-cell suppression is induced by potent purine analogues such as fludarabine and high-dose cytarabine. Patients receiving allogeneic SCT after non-myeloablative therapy may be at greater risk but the data are sparse. The risk is low in the predictably brief duration of neutropenia with autologous SCT.

In allogeneic SCT, the rate of CMV seropositivity and clinical CMV infection vary according to the pretransplant status of the donor and recipient. The post-transplant CMV-associated fatality rate is around 40%. Other herpesviruses may also reactivate including Epstein–Barr virus (EBV), which is associated with lymphoproliferative disorders, and HHV-6 which is associated with fever.

Prophylaxis of infections

Given that some infections occur frequently and arise from body sites harbouring an abundant normal commensal flora, it is not surprising that antimicrobial prophylaxis is advocated and adopted by many centres treating patients with acute leukaemia. Essentially, when adopted, prophylaxis is started just before chemotherapy is begun with the aim of suppressing or

eradicating potentially opportunistic pathogens ahead of the anticipated neutropenia (Figure 26.5).

The early cocktails of non-absorbable antibiotics, such as framycetin, colistin and nystatin (FRACON) or gentamicin, vancomycin and nystatin (GVN), were superseded by cotrimoxazole and colistin and later by the fluoroquinolones norfloxacin, pefloxacin, ofloxacin, ciprofloxacin and levofloxacin. The need for antibacterial prophylaxis is still in doubt. As described above, antibacterial prophylaxis had no impact on the overall incidence of fever or mortality over many years, and almost all patients given such prophylaxis will also be given further broad-spectrum antibiotics for unexplained fever. Some institutes are now faced with patients harbouring fluoroquinolone-resistant *E. coli*, causing them to abandon prophylaxis altogether. Recent meta-analysis confirms a reduction in bacteraemia due to Gram-negative bacilli and even an impact on mortality. However, this should be seen in the context of prevalence, risk and the numbers needed to treat. Patients most likely to benefit are those likely to experience at least 10 days of neutropenia induced by chemotherapy that also causes marked damage to the mucosa of the alimentary tract. These are still patients treated for AML-MDS with intensive chemotherapy and those receiving myeloablative therapy for SCT.

The risk of IFD varies with the intensity of therapy and its complications and is greatest in SCT patients with protracted GVHD. Non-absorbable polyenes, such as amphotericin and nystatin, do not provide systemic protection. Fluconazole reduces the risk of *C. albicans* significantly in SCT, but not in conventional chemotherapy; it is not effective in suppressing certain yeasts, including *C. krusei* and *C. glabrata*, and of course there is no activity against moulds (e.g. *Aspergillus* spp.). In contrast, itraconazole, voriconazole and posaconazole are active

Figure 26.5 Antibiotic choices for prophylaxis during neutropenia.

against a wide range of yeasts and moulds. With the availability of interchangeable oral solution and intravenous formulations, itraconazole is more effective than fluconazole in preventing a range of infections due to *Candida* spp. and *Aspergillus* in SCT and conventional chemotherapy, provided that sufficient drug is given to achieve protective systemic levels. The newer triazole posaconazole has been shown to be effective as prophylaxis for patients given chemotherapy for AML and MDS and for those suffering GVHD. Liposomal amphotericin has been shown to reduce the incidence of IFD when given as an aerosol. There are no data on voriconazole as prophylaxis. This patchy picture has led to considerable confusion that various guidelines have struggled to clarify. Once again the difficulty lies in transplanting trial results to one's own practice. One rule of thumb is to estimate the numbers needed to treat in order to achieve the reported reduction. So, for instance, if the prevalence of invasive aspergillosis in a given centre is around 5%, to reduce this by half would require 20 patients to be treated to prevent a case of invasive aspergillosis. Also, it is proper for any centre with long experience of an effective strategy to critically examine whether the incidence of IFD can be further reduced cost-effectively by adopting prophylaxis with posaconazole or aerosolized liposomal amphotericin. Every centre should have a fairly accurate estimate of the incidence of IFD before making informed decisions about when and what prophylaxis to use.

There is no evidence to support antiviral prophylaxis during neutropenia that is induced by conventional chemotherapy, except in patients with CLL and a strong past history of herpes infection if they are given fludarabine. In allogeneic SCT, all patients are given aciclovir or its equi valent as prophylaxis to reduce their risk of infection with herpes viruses, There is no specific prophylaxis for CMV infection, which carries a high fatality rate. Post-SCT CMV is best prevented by transplanta-

tion from a negative donor to a negative recipient, with exclusive use of leucodepleted blood products. Prophylaxis against EBV infection is also lacking.

Empirical therapy of fever of unknown origin

In the 1960s, the combined mortality rate from Gram-negative and Gram-positive bacteraemia during neutropenia induced by therapy for acute leukaemia was estimated at 90%. The introduction of the prompt empirical use of broad-spectrum antibiotics at the onset of fever was a major advance in supportive care. This routine practice (usually with a β -lactam and an aminoglycoside or else a β -lactam alone; Figure 26.6) has resulted in a mortality rate due to proven bacterial infections of 7% overall, 10% for Gram-negative organisms and 6% for Gram-positive organisms, at 30 days from onset of fever.

Each unit should establish and audit the application of rules for using these antibiotics in the treatment of fever. Other causes of fever have been described above and the likelihood of them explaining a new episode of fever should be carefully considered before antibiotics are given. There should be a working definition of when fever is likely to be due to bacteraemia or other systemic infection to justify systemic antibiotic therapy, including the degree of neutropenia, the day of onset in relation to chemotherapy, whether the temperature has suddenly become elevated, and height and duration of fever. A review of the literature shows wide variation in such definitions as they are applied to clinical trials. For patients receiving conventional chemotherapy for acute leukaemia, one practical suggestion is that once the neutrophil count drops below $0.5 \times 10^9/L$ and the temperature reaches $38^\circ C$ twice in 1 hour despite the use of paracetamol, empirical antibiotic therapy should be given. Alternatively, a single temperature exceeding $38^\circ C$ is also

Figure 26.6 Initial empirical antibiotic options during neutropenia.

taken to indicate fever. Clearly, if the patient is in shock or shows early signs of haemodynamic and respiratory instability, a single temperature reading of 38°C is sufficient. The peripheral temperature may be normal or the patient may even be hypothermic on development of shock due to sepsis. Blood cultures should always be taken from both a CVC and a peripheral vein, and always before antibiotics are started. With the increasing use of multilumen CVCs, blood should be taken from more than one lumen, which increases the sample size and also allows identification of possible colonization.

Despite the dramatic reduction in mortality associated with the use of broad-spectrum antibiotics, they have their limitations: they exhibit relatively poor activity against staphylococci (including MRSA) and some streptococci, may provide inadequate coverage when the rate of Gram-negative bacteraemia is increasing, and β -lactams must be given in several daily infusions occupying considerable CVC access time. Infections due to extended-spectrum β -lactamase-producing Gram-negative bacilli should prompt reappraisal of the regimens used for empirical therapy. Similarly, with VRE being associated with increased use of third-generation cephalosporins (e.g. ceftazidime), this class of antibiotics may not be appropriate for empirical therapy in centres facing infections due to these enterococci. The toxicity of the aminoglycosides requires proper monitoring of levels and adjustment of dose or timing of administration.

Meta-analysis of randomized controlled trials confirms that the rate of response of unexplained fever is around 50%, whether an aminoglycoside is used in addition to a β -lactam or not, suggesting that monotherapy using ceftazidime, cefepime, piperacillin–tazobactam, imipenem or meropenem is adequate. There is also no need to add vancomycin or teicoplanin to the initial empirical regimen as there is no measurable benefit in

outcome nor in reducing the rate of defervescence, subsequent infections, use of additional antimicrobial agents or mortality.

Subsequent antimicrobial therapy

When fever persists and no microbiologically or clinically defined infection has been identified, there may be no need to switch to an alternative regimen provided the patient's condition is stable. When a CVC is in place the assumption is often made that CVC-related staphylococcal infection may explain persistent fever, prompting the addition of vancomycin or teicoplanin empirically. However, randomized placebo-controlled trials have shown that there is no impact on response rates or mortality. This practice also encourages the emergence of VRE, so such 'second-line' antibacterial empirical therapy is only justifiable when there is clinical evidence of infection around the exit site or along the track of the CVC or evidence of an infected thrombus related to the location of the catheter in the vein.

Subsequently, antibiotic therapy may be modified, depending on whether a microbiologically defined infection or a clinically defined infection has been identified or the development of a new infection is defined clinically or microbiologically. The empirical regimen should be continued and complemented with other drugs such as a glycopeptide (e.g. vancomycin) or an antifungal agent. There are individual infections that may be proven microbiologically (e.g. *Candida* in blood cultures) or which may be suggested clinically or radiologically (e.g. invasive pulmonary aspergillosis or *Pneumocystis jirovecii* pneumonitis), and these justify switching to alternative therapies or complementing the existing regimen. A readiness to perform early CT of the chest may shorten the time to starting systemic antifungal therapy when invasive pulmonary aspergillosis is suspected. Plain chest radiography is notoriously unreliable and should

not be used to confirm or exclude this diagnosis. The use of galactomannan detection in plasma or serum should also be incorporated into the algorithm of management. The relatively high sensitivity that results from the lower threshold of 0.5 means that a positive result can be taken to support antifungal therapy, especially when a CT scan shows lesions consistent with the diagnosis.

Each unit should devise a protocol in which the criteria for adding subsequent therapy are clearly defined, based on clinical and microbiological findings (Table 26.4), either given on the basis of the organism causing a microbiologically defined infection (Figure 26.7) or on the basis of the site involved in a clinically defined infection (Figure 26.8). There is little evidence to

Table 26.4 Rules for additional therapy.

support precise times when additional or substitute antibiotics should be introduced and the automatic rotation or modification of antibiotics should be discouraged. The superiority of any one therapeutic agent over any other active against proven *Aspergillus* spp. IFD or probable or possible IFD is based on relative toxicity. In presumed or proven *Pneumocystis* pneumonitis, the drug of choice is high-dose co-trimoxazole, with steroids to reduce the risk of post-infective fibrosis.

Allogeneic stem cell transplantation patients

The febrile SCT recipient represents a special case of neutropenic fever because of the increased risk of opportunistic infection with viruses, particularly those of the herpes group, herpes simplex and CMV and, increasingly, EBV. The procedures involved in SCT are broadly similar across units and can be divided into myeloablative conditioning therapy or reduced-intensity conditioning. The infective risks and related prophylaxis are also very similar, for example valaciclovir or aciclovir for herpesviruses and a fluoroquinolone to suppress infections due to Gram-negative bacilli.

An alternative approach is to only use these agents prophylactically when the patient is known to be a carrier of the particular organism. SCT recipients predictably develop fever shortly after the time of transplant, typically within a week, and it is essential not to treat the immediate fever of total body irradiation with broad-spectrum antibiotics. There is disagreement about whether broad-spectrum therapy should be started at a predetermined time after transplant on the assumption that fever is imminent, or empirically at the onset of fever. Whichever approach is followed, the pattern of infection during the neutropenia of SCT is fairly predictable, justifying screening for CMV using a pp65 antigen ELISA or PCR, and *Aspergillus* infection using a galactomannan ELISA or PCR, although the latter still lacks standardization. Treatment may be pre-emptive if infection due to either CMV or *Aspergillus* spp. is detected.

In contrast with other neutropenic patients, the risk of infection to SCT recipients extends long after the neutropenia has resolved, particularly with chronic and severe GVHD treated with corticosteroids. These are now the major risk factors for IFD due to *Aspergillus fumigatus*, with perhaps as many as two-thirds of cases occurring after 100 days, with a high case fatality rate, justifying prolonged prophylaxis. Bacteraemia due to certain Gram-negative bacilli, including *P. aeruginosa*, also occurs at this late stage. In addition, the hypogammaglobulinaemia of SCT persists for months or years after transplant, with an increased risk of infection by the encapsulated bacteria *S. pneumoniae* and *Haemophilus influenzae*. During the post-transplant period, prolonged prophylaxis against these bacteria may be justified as diagnosis and appropriate treatment may come too late, but there is limited evidence that prophylaxis is cost-effective. Immunization with a polyvalent pneumococcal

vaccine is also recommended. These patients also need to be seen regularly and frequently, and have to be clear about when to report to the transplant or follow-up unit if they are unwell.

Stopping antibiotics after an episode of fever when neutropenic

Antibacterial therapy can be stopped if there is no evidence of a microbiologically or clinically defined infection provided that fever has resolved and the temperature has been normal for at least 5 days. However, antibiotics should be given for at least 10 days after the onset of bacteraemia. Infections (bacterial or yeast) related to colonization or infection of a CVC or the adjacent tunnel may require removal of the device to reduce the risk of recurrence. Bacteraemia that persists after catheter removal may indicate an infected thrombus which, if confirmed by ultrasound, should be treated with vancomycin and thrombolytic agents for at least a week until blood cultures become sterile. It is less clear when systemic antifungal therapy can be safely stopped for invasive aspergillosis, as radiological changes may persist well after eradication of the causative organism. Typically therapy is given for 4–6 weeks.

Infections specific to childhood and adult ALL

The significant additional risk in these patients is *Pneumocystis jirovecii* pneumonitis, which may be lessened by co-trimoxazole 960 mg b.d. orally twice weekly or 480 mg orally every day. The infection has a characteristically rapid onset and presentation with marked hypoxia, relatively few abnormal physical signs apart from increased respiratory effort and extensive pulmonary shadowing on chest radiography. Confirmation of the diagnosis is difficult as there are no reliable objective tests.

Growth factors and granulocyte infusions

The most comprehensive reviews of the evidence for the use of G-CSF in cancer care are available from the NCCN. The recommendations for the use of growth factors are summarized below but these guidelines should be read in full to assess their applicability to the care of individual patients.

Guidelines from the American Society for Clinical Oncology (ASCO) and European Organization for Research and Treatment of Cancer (EORTC) classify patients according to the rates of febrile neutropenia or, more correctly, fever and neutropenia. If the rate of febrile neutropenia is greater than 20% (previously described as >40%) for any chemotherapy regimen, intermediate risk at 10–20% and low risk at less than 10%, NCCN classify therapy as ‘with curative intent’ or as ‘adjuvant therapy’ for the highest level of risk, as ‘with the intention to prolong survival’ for the next level, and as ‘with the

intention of symptom control' only for the lowest risk level. In solid tumours they make a level 1 recommendation for the prophylactic use of G-CSF in chemotherapy aimed at cure or prolongation of survival for the end points of risk of febrile neutropenia, hospitalization, use of intravenous antibiotics and the support of intended dose intensity. Some factors that lead to high risk have been identified in a validated study, such as the use of more than two myelosuppressive agents, certain types of drugs (e.g. anthracyclines), more than 85% of planned dose intensity, certain cancer types and no G-CSF use. The guideline recommends evaluation of the patient after each cycle of therapy. If there has been no episode of febrile neutropenia, then G-CSF may not be needed subsequently. If febrile neutropenia has occurred without G-CSF support, it should be considered for subsequent cycles. If febrile neutropenia occurs despite G-CSF support, then dose intensity should be reduced.

Use of G-CSF should be considered on an individual patient basis for intermediate-risk regimens (10–20%); for low-risk regimens (<10%) it is declared unnecessary unless treatment is with curative intent and there is significant risk of serious medical consequences of febrile neutropenia for other reasons. Use of G-CSF in therapy aimed at symptom control depends on the intensity of the therapy so that the combination of a patient at high risk plus a regimen of high intensity may sometimes justify G-CSF support. Alternative less myelosuppressive or dose-reduced therapy, if of comparable benefit, may be preferable.

The British Committee for Standards in Haematology (www.bcshguidelines.com) issued guidelines in 2003 for the use of G-CSF in acute leukaemia, with a level 1a recommendation for its use following intensive consolidation (post-remission) chemotherapy for AML, following intensive chemotherapy for ALL and following intensive chemotherapy for MDS and a level 1b recommendation for its use in accelerating neutrophil recovery after autologous or allogeneic SCT. G-CSF is used routinely to mobilize stem cells for harvesting from peripheral blood. G-CSF may also exert a synergistic effect with erythropoietin in the treatment of anaemia in MDS.

Recombinant human G-CSF may reduce the severity and duration of neutropenia after chemotherapy or SCT, but only if the patient has sufficient stem cells to be stimulated. The response will not be immediate and it remains unclear, despite all the evidence referred to above, that this reduces the risk of serious systemic infection, the mortality rate from these infections or the mortality rate overall. Infusion of high-dose granulocyte collections from donors stimulated by G-CSF may be indicated if infection is resistant to antimicrobials and delayed neutrophil recovery is expected. However, there is little evidence to support their use, and they should be avoided in patients with pre-existing HLA alloimmunization or in those requiring mechanical ventilation.

Infection risks in chronic leukaemias

In the CLLs there is a wide range of suppression of both humoral and cell-mediated immunity and consequently a wide spectrum of potential infecting organisms, from the relatively low-risk superficial herpetic infections to potentially fatal bacterial pneumonia. These risks increase with progression of disease and intensity of therapy. The use of the more potent purine analogues, fludarabine and cladribine, intensify these risks not only by inducing short-term neutropenia but also by profound suppression of T-cell function. Atypical infections such as *Pneumocystis jirovecii* pneumonitis, *Listeria* and fungal infections have been reported, and prophylactic co-trimoxazole is indicated during and for 6 months after these drugs are given in order to allow sufficient recovery of T-cell function. In CLL patients treated with the anti-CD52 antibody alemtuzumab (Campath), there is a high risk of reactivation of CMV infection. In hairy cell leukaemia, there is often combined neutropenia and monocytopenia with a major bacterial infection at presentation. These patients require the same prophylaxis as other CLLs if treated with purine analogues.

The infection risks of CML are similar to those of the acute leukaemias, although less severe in chronic stable phase. Since the introduction of imatinib, which induces rapid, smooth and lasting control of the disease, the risk of infection has been greatly reduced.

Metabolic complications

Fluid balance

Fluid intake and output must be monitored carefully in patients treated intensively. Accurate observation and recording of these data is the task of specialist nurses, and medical staff must review these regularly. Maintenance of fluid balance is a continuous problem in these patients, particularly the elderly, who have an increased risk of renal and congestive heart failure. The delivery of chemotherapy, blood and blood products, antibiotics and parenteral feeding needs large volumes that may exceed physiological requirements without oral intake. Fluid overload happens relatively quickly if monitoring is overlooked and it should be anticipated and avoided (see sections Anaemia and thrombocytopenia, Planning large-volume transfusions).

Vomiting, diarrhoea, sweating and insensible respiratory loss may singly, or in combination, lead steadily, sometimes rapidly, to dehydration. The vasodilatation and hypotension of sepsis will exacerbate hypovolaemia, which should be anticipated. Replacement of volume is achieved with normal saline solution alternating with 5% dextrose solution. Acute onset of these complications can require rapid infusion of colloid (polysaccharide solutions such as gelofusin) for expansion of intravas-

cular volume, particularly when a shift of body fluid from the intravascular space into tissues is suspected as can occur in septic shock. However, polysaccharide solutions are metabolized quickly and solutions of albumin are preferable when loss of plasma osmotic pressure is due to chronic hypoalbuminaemia. Fresh-frozen plasma should not be used for this indication. Prolonged hypovolaemia will result in acute renal tubular necrosis (ATN) and therefore an early decision is needed about the likely cause of oliguria, in case this is due to a 'renal' rather than the 'prerenal' hypovolaemic cause of acute renal failure (ARF). Supporting a balanced throughput of fluid volume is complicated by a number of electrolyte and metabolic problems.

Hyperuricaemia and tumour lysis syndrome

The rapid rate of cell proliferation and death in acute leukaemia increases the catabolism of nucleic acids, which terminates with the excess production of uric acid. Therefore, patients may present with biochemical hyperuricaemia or its clinical consequences or develop these once treatment starts. The most extreme form of this is tumour lysis syndrome (TLS), in which severe hyperuricaemia, hyperphosphataemia, hyperkalaemia and hypocalcaemia are associated with supersaturation of the urine with uric acid, which is then deposited in crystals in the renal tubules and distal collecting system. These biochemical abnormalities result in a major increase in the morbidity and mortality of patients, including ARF, which requires haemodialysis.

TLS is a frequent complication of advanced-stage Burkitt lymphoma and B-cell ALL in childhood and of any adult leukaemia with a very high presenting blast count; despite attempts to manage the metabolic problems, as many as 25% of such children develop ARF on starting chemotherapy. The precise incidence of clinical and subclinical TLS is not known. Subclinical TLS could cause unrecognized morbidity and adversely affect the efficacy and safety of other therapies, some of which are also nephrotoxic.

Standard management for hyperuricaemia is allopurinol (300 mg daily orally), hydration and attempted urinary alkalinization. Hydration is technically easy with CVCs, but the complexities of maintaining fluid balance and avoiding overload are described above. Urinary alkalinization is achievable but complicates the management of fluid and electrolyte balance and, in practice, it is difficult to maintain the urinary pH above 8. Allopurinol blocks the formation of uric acid by inhibition of xanthine oxidase, increasing plasma and urinary concentrations of hypoxanthine and xanthine. Xanthine is less soluble than uric acid in urine and occasional cases of nephropathy are described as a consequence of this therapy. Patients have a backlog of excess uric acid that they must excrete, particularly those with a high tumour burden, and allopurinol has no effect

on that. Hypersensitivity to allopurinol is well recognized, especially in the elderly, and causes distressing allergic dermatitis that may exfoliate. Interaction with other medications (warfarin, thiazide diuretics, antibiotics such as ampicillin and amoxicillin, and chemotherapy such as mercaptopurine and azathioprine) is well described. Many patients have difficulty taking the drug orally; this may not be widely recognized and the alternative intravenous formulation is not sufficiently prescribed. Allopurinol reduces or normalizes the serum uric acid level in the great majority of adult and paediatric patients. The recombinant enzyme rasburicase produces a fall in uric acid concentrations within 1 hour and is a safe and effective alternative for those patients who require rapid control of hyperuricaemia or who cannot tolerate allopurinol. At present, recommended dosage schedules may be excessive and the drug is expensive, but rasburicase also avoids the need for hyperhydration and urinary alkalinization.

Abnormalities of renal function and electrolyte balance

The hyperphosphataemia, hyperkalaemia and hypocalcaemia associated with TLS are described above, but other electrolyte problems occur more commonly. Hypokalaemia and hyponatraemia are the most frequent, and require regular intravenous supplements. Prolonged and copious diarrhoea will also result in hypokalaemia. Both hypokalaemia and hyponatraemia are also intrinsic to the acute leukaemias because of the high plasma levels of lysozyme (particularly in the monocytic FAB subtypes M4 and M5), which interferes with proximal tubular function. Intravenous amphotericin also induces renal tubular wasting of potassium and magnesium. This can be at least partially blocked by the diuretic amiloride (20 mg daily orally) but intravenous supplements of potassium, and less often of magnesium, are usually also required in patients receiving intravenous conventional amphotericin. Oral replacement of these electrolytes is ineffective. Liposomal amphotericin is less likely to create these electrolyte problems.

It is common practice to estimate urea and electrolyte levels daily during the aplastic phase of intensive chemotherapy, and magnesium levels should be estimated twice weekly. Otherwise, hypomagnesaemia may not be appreciated as the cause of confusion, neuropathy assumed to be due to hypocalcaemia and unexplained arrhythmia. Aminoglycosides and vancomycin are also toxic to renal tubules and can exacerbate these problems. Ciclosporin therapy in SCT is also nephrotoxic. Regular and frequent monitoring of the levels of all these drugs will reduce the risk of renal damage.

The same problems with electrolyte balance may occur in the ATN that results from hypotension due to sepsis, major blood loss and pulmonary capillary leak syndrome in acute respiratory distress syndrome. ATN is accompanied by failure of glomeru-

lar filtration, with oliguria or anuria, and a rise in the levels of serum creatinine and urea. In these patients, if the primary insult is treated successfully, then ATN resolves with a compensatory diuretic phase and full recovery of renal function. It is important to keep pace with the diuresis with adequate fluid replacement.

Amphotericin is also toxic to glomeruli and it should be discontinued or switched to the liposomal form once the creatinine has exceeded twice the level on starting the drug, assuming that was a normal value. The renal toxicity of amphotericin is almost always reversible and should not exclude its use if there is no pre-existing renal pathology or toxicity related to another drug. Before liposomal preparations were available, intravenous sodium loading was recommended to lessen the renal and electrolyte problems of amphotericin. This is seldom used now although it has never been compared prospectively against liposomal amphotericin.

Liver function abnormalities

In patients presenting with acute leukaemia, raised levels of lactate dehydrogenase are common because this is derived from bone marrow as well as liver. Some will also have non-specific elevation of alkaline phosphatase and transaminase levels. About half will develop abnormally high levels of one or all of these measures of liver function owing to the direct hepatocellular toxicity of chemotherapy, with increased levels of serum bilirubin sufficient to cause clinical jaundice. It is seldom necessary to modify doses of remission induction drugs because of these abnormalities but recently there has been some concern about the hepatotoxicity of the antimetabolite purine analogue thioguanine, which is no longer available. Cytarabine, another purine analogue, also induces cholestasis and this hepatotoxicity may have been underestimated in the past.

Hyperbilirubinaemia with clinical jaundice is a frequent and sometimes overlooked complication of red cell transfusion that does not of itself indicate liver disease but is more obvious if liver function is impaired for any other reason. The hepatotoxicity of most chemotherapy is transient and resolves spontaneously with regeneration of normal marrow and induction of remission. It is usually asymptomatic and seldom progresses to severe liver failure, ascites, cirrhosis or portal hypertension except in specific cases described below. However, even minor impairment of liver function will affect other drugs that are dependent on liver metabolism to a degree that may require modification of doses.

Severe and fatal liver damage may occur with veno-occlusive disease in allogeneic SCT, described in detail in Chapter 38. This is thought to be a complication of preparatory or conditioning therapies prior to infusion of stem cells. A similar syndrome is seen with the new drug Mylotarg, which is now part of remission induction in the latest MRC AML 15 trial in adults.

Mylotarg, now commonly used in trials of therapy for acute myeloblastic leukaemia, consists of the cytotoxic antibiotic ozogamicin linked to the anti-CD33 monoclonal antibody gemtuzumab and is activated by hydrolysis once it is internalized following attachment of the antibody to leukaemic myeloblasts. This compound has dose-limiting hepatotoxicity. As with the simultaneous use of nephrotoxic drugs, careful monitoring of all potentially hepatotoxic drugs or any drugs that are metabolized by the liver will be necessary if they are used simultaneously. These drugs include the triazole antifungal group (fluconazole, itraconazole, voriconazole, posaconazole and ravuconazole), all of which impair liver function to variable degrees.

Chronic liver damage, including cirrhosis and the greatly increased risk of hepatocellular carcinoma, is now a well-recognized late effect of blood transfusion owing to infection with hepatitis C virus. Attempts to eradicate or reduce the viral load of these patients, using ribavarin and interferon, have met with limited success. As UK blood donors are routinely screened for this virus, the problem should become less prevalent in the future among multiply transfused patients.

The iron overload of multiple transfusion during therapy for acute leukaemias appears to cause clinical liver problems only in transplanted patients and can be reduced subsequently by venesection with or without iron chelation. In patients who are transfusion dependent due to marrow failure associated with chronic leukaemias, myelodysplasia or failure of therapy for any form of leukaemia, the inconvenience and side-effects of iron chelation usually outweigh any potential benefit, especially when life expectancy is short.

Nutritional support

During intensive therapy, anorexia persists, even if nausea and vomiting and the pain of mucositis can be controlled. Loss of total body mass is inevitable, the extent of which depends on the duration of anorexia and the impact of additional catabolic insults such as severe infection. All dietary supplementation should be managed by dietitians and pharmacists in order to calculate accurately the contents of the supplements, on the basis of regular blood results. Oral supplementation may be sufficient to maintain an adequate caloric intake in less severe cases. For patients with a predictable or actual 10% or greater reduction in pretreatment weight, total nutrition is indicated. This is likely in the majority of patients receiving myelo-ablative allogeneic SCT. This can be given through a nasojejunal fine silastic tube, provided that this is inserted before the onset of mucositis, otherwise nutritional support must be given by indwelling intravenous catheter. As soon as patients recover the will to eat, all such dietary supplements can be cautiously withdrawn.

Nausea and vomiting

There is a high risk of severe and acute emesis with intensive chemotherapy. Every effort should be made to prevent this distressing complication and to avoid the development of anticipatory emesis should prophylaxis be ineffective. If control fails early, then the chances of later successful control are reduced. It must be remembered that emesis may be due to other drugs (e.g. analgesics and antimicrobials), to acute infection and to other complications of leukaemia and its treatment such as meningeal relapse, intestinal obstruction (e.g. secondary to hypokalaemia and gut or retroperitoneal bleeding) or intracranial bleeding.

There are three major groups of antiemetic drugs: the serotonin antagonists (e.g. ondansetron, granisetron), the steroids (mainly dexamethasone) and a wide range of drugs that are sedative as well as antiemetic (e.g. metoclopramide, domperidone, haloperidol, lorazepam, cannabinoids and phenothiazines). Of these three classes, the serotonin antagonists will control emesis induced by intensive chemotherapy completely in about two-thirds of patients. Additional dexamethasone may benefit a further 10–20% of patients. All the sedating antiemetic agents are of second choice in intensive therapy. Their dosage, route of administration and scheduling should be strictly controlled and they should not be given on an uncontrolled or as-required basis. Cumulative oversedation is a major risk in these patients, particularly if they need simultaneous opiates for mucositis and antihistamines for allergic reactions to blood and drugs and develop hypoxia of infection or heart failure. Many of these drugs can also cause distressing dyskinesias.

For nausea due to less intensive oral therapy of CLL, oral busulphan or hydroxyurea for CML metoclopramide may suffice and many patients do not need any antiemetic drug. There is a very low risk of nausea with imatinib.

Pain

Bone pain is an uncommon presenting feature of acute leukaemia, is due to an expanded marrow cavity packed with blasts and can occur or recur on relapse. Such pain is relieved by remission induction but may need temporary control with opiates. G-CSF and granulocyte/macrophage colony-stimulating factor (GM-CSF) can cause the same problem by expansion of normal marrow cells due to excessive stimulation.

Avascular necrosis of bone is seen in less than 5% of patients with ALL and lymphomas, particularly in association with high-dose steroids and cyclophosphamide. It usually affects younger patients, involves the ends of long bones and can cause permanent bone death requiring subsequent joint replacement. The diagnosis is elusive and requires magnetic resonance imaging. The pain is often severe enough to need relief with opiates.

High-dose cytarabine can cause a painful vasculitis severe enough to lead to necrosis of soft tissue and skin. The neuropathy of the vinca alkaloids (usually vincristine but occasionally vinblastine) may present as limb pain or as painful constipation. The serotonin antagonists may cause headache in susceptible individuals and headache may also be due to intracranial bleeding or infection. Any bleed in any confined compartment will be painful, for example chest wall pain following haemorrhagic insertion of a CVC.

In SCT, the use of total body irradiation and high-dose chemotherapy make gut mucositis inevitable. The extent, duration and severity vary but most patients will need some level of opiate relief. In most patients, this starts in the second week after therapy and resolves spontaneously without lasting sequelae from the third to fourth week onwards. As with all causes of pain, this requires whatever level of controlled drug analgesia is necessary to make the symptoms bearable without inducing brain or respiratory failure. Continuous intravenous infusion of an opiate is often required in severe mucositis and additional continuous antiemetic may be needed in the same infusion. Palifermin (recombinant human keratinocyte growth factor) has been shown to reduce oral mucositis after intensive chemotherapy. All units should have a written protocol for pain control similar to that used by the local palliative care team.

Palliation

The above account of supportive care of the patient with leukaemia describes a holistic approach. It is common for patients who have experienced this to wish to remain with the same haematology team for their terminal care when there is no further prospect of control of their underlying disease. There should be choices at this stage, which include the transfer of the patient to the palliative care team and joint management by them with haematology in whichever unit the patient and family feel most suits the patient's needs. These choices should include dying at home, an option that requires some help from the acute care unit to mobilize the resources available in some communities to support this option. Most of the issues which arise in this palliative phase of care are described above. There can be much more flexibility in the frequency and choice of blood support, in pain control and in the use of antibiotics. Wherever palliative care is given, the patient and family should not feel abandoned by the team who supported them during previous periods of treatment.

Introduction

The term 'myeloproliferative neoplasm' has recently been introduced by the panel of experts convened by the World Health Organization (WHO) to classify tumours of the haemopoietic and lymphoid systems and chronic myeloid leukaemia (CML) is the most common subtype (Table 27.1). This chapter covers CML, chronic neutrophilic leukaemia, chronic eosinophilic leukaemia and some other variants, but the other myeloproliferative neoplasms are described elsewhere in this book.

Chronic myeloid leukaemia (also known as chronic myelogenous leukaemia and chronic granulocytic leukaemia) is a clonal disease that results from an acquired genetic change in a pluripotential haemopoietic stem cell. This altered stem cell proliferates and generates a population of differentiated cells that gradually displaces normal haemopoiesis and leads to a greatly expanded total myeloid mass. One important landmark in the study of CML was the discovery of the Philadelphia (Ph) chromosome in 1960, the next was the characterization in 1973 of the t(9;22)(q34;q11) translocation, a third was the identification in the 1980s of the *BCR-ABL* (now renamed *BCR-ABL1*) chimeric gene and associated oncoprotein, and a fourth was the

demonstration that introducing the *BCR-ABL* gene into murine stem cells in experimental animals caused a disease that simulated human CML.

Until the 1980s, CML was generally assumed to be incurable and was treated palliatively, in the early days with radiotherapy and later with alkylating agents, notably busulfan. We now know that CML can be permanently eradicated in the majority of patients who survive haemopoietic stem cell transplantation (SCT), but the proportion of patients eligible for SCT is still relatively small. The introduction into clinical practice in 1998 of the original tyrosine kinase inhibitor (TKI) imatinib mesylate was an extremely important therapeutic advance, as with this agent most patients achieve a complete cytogenetic response and may expect substantial prolongation of survival compared with earlier methods of treatment. Current data suggest that the second-generation TKIs, dasatinib, nilotinib and bosutinib, may be more effective than imatinib.

Epidemiology, aetiology and natural history

The incidence of CML appears to be constant worldwide. It occurs in about 1.0–1.5 per 100 000 of the population per annum in all countries where statistics are adequate. CML is rare below the age of 20 years but occurs with increasing frequency with each decade of life. Currently, the median age of onset is 50–60 years. The incidence is slightly higher in males than in females.

The risk of developing CML is slightly but significantly increased by exposure to high doses of irradiation, as occurred in survivors of the atomic bombs exploded in Japan in 1945, and in patients irradiated for ankylosing spondylitis and malignant diseases but, in general, almost all cases must be regarded as sporadic without identifiable predisposing factors. In particular, there is no familial predisposition and no definite association with HLA genotypes. No contributory infectious agent has been incriminated.

Clinically, CML is classically a biphasic or triphasic disease that is usually diagnosed in the initial ‘chronic’, ‘indolent’ or ‘stable’ phase. Until 10 years ago the disease evolved spontaneously after some years into an advanced phase, which could often be subdivided into an earlier accelerated phase and a later acute or blastic phase. This pattern has altered fundamentally since the introduction of TKIs and today the majority of patients may never progress beyond the chronic phase. There has been much debate about the duration of the leukaemia before the diagnosis is established, a question that is essentially unanswerable. If it is assumed that the disease starts with a transforming event in a single stem cell, it could be 5–10 years before the disease becomes clinically manifest. This estimate depends on the assumption that the leucocyte doubling time before diagnosis is not fundamentally different from the doubling time after diagnosis (which may not be the case), and on the observation that the latent interval between exposure to irradiation from atomic bombs and the earliest identifiable increased incidence of CML was about 7 years. One study concluded that a routine blood count might have identified CML on average 6 months before it was actually diagnosed in individual patients.

Patients are usually in the chronic phase when CML is diagnosed. This chronic phase used to last about 2–7 years and these figures may still be valid for the 20% of patients who fail treatment with TKIs; however, for most patients who respond well to TKIs, survival is likely to exceed 20 years and some could have a normal lifespan. In about 50% of the patients who fail TKI treatment the chronic phase transforms unpredictably and abruptly to a more aggressive phase that used to be referred

Table 27.2 Sokal index for predicting survival prognostic indices.

Good prognosis	<0.8
Moderate prognosis	0.8–1.2
Poor prognosis	>1.2

Mathematical expression

$$\text{Exp}[0.0116(\text{age} - 43.4)] + 0.0345(\text{spleen size} - 7.51) + 0.188[(\text{platelet count}/700)^2 - 0.563] + 0.0887(\text{percentage of blasts} - 2.10)$$

to as ‘blastic crisis’ and is now usually described as acute or blastic transformation, which may have myeloblastic or lymphoblastic features; in the other half of cases, the disease evolves somewhat more gradually through an intermediate phase described as the accelerated phase, which may last for months or years, before frank blastic transformation supervenes. Occasional patients have a disease that progresses gradually to a myelofibrotic or osteomyelosclerotic picture that is characterized by extensive marrow fibrosis and sometimes gross overgrowth of bony trabeculae; the clinical problems are then usually due to failure of haemopoiesis rather than to blast cell proliferation, but a predominantly blastic disease can still supervene. The duration of survival after onset of transformation is usually 3–9 months.

Classification

The majority of patients with CML have a relatively homogeneous disease characterized at diagnosis by splenomegaly, leucocytosis and the presence of the *BCR-ABL1* fusion gene in all leukaemic cells. The presence of this fusion gene is regarded today as the *sine qua non* for diagnosis of CML. A minority of patients have less typical disease that may be classified as atypical CML, chronic myelomonocytic leukaemia or chronic neutrophilic leukaemia (CNL). Children may have a disease referred to as juvenile chronic myelomonocytic leukaemia. In none of these variants (other than extremely rare variants of CNL) is there a *BCR-ABL1* fusion gene or a Ph chromosome.

Staging

Many attempts have been made to subclassify or ‘stage’ chronic-phase CML at diagnosis, in a manner that would permit some prediction of the duration of chronic phase in individual patients. The most commonly used classification, devised by Sokal and colleagues in 1984, is based on a formula that takes account of the patient’s age, blast cell percentage, spleen size and platelet count at diagnosis (Table 27.2) (<http://oncopda.com/sokal.htm>). A similar classification, which may or may not prove more useful than that of Sokal, was introduced by Hasford

Figure 27.1 Probability of survival and median survival values for a population of CML patients classified into three prognostic categories according to the Euro score devised by Hasford *et al.* (1998).

in 1998 and called the Hasford or Euro score (Figure 27.1); it makes use of eosinophil and basophil numbers in addition to the values included in the Sokal system.

In practice, patients who have a low leucocyte doubling time probably survive longer than those with more rapid doubling times. Moreover, the patient's response to initial treatment does give some information about duration of survival; for example, a complete cytogenetic response to interferon alfa or rapid reduction in *BCR-ABL1* transcript numbers in patients starting treatment with imatinib are both good prognostic factors. Conversely, other possible adverse prognostic factors, such as those that predict a poor response to TKI, may in the future be integrated into systems for staging patients with CML. However, it is likely that the results of gene expression profiling or characterization of genome-wide aberrations will eventually be the most informative approach for predicting overall duration of disease.

Cell biology

It is presumed that the leukaemic stem cell replicates and that its progeny give rise to increased numbers of myeloid progenitor cells and also of differentiated progeny. Thus, the normal marrow is gradually replaced by a leukaemic myeloid mass that expands to fill normal fat spaces and encroaches on areas of long bones that are normally devoid of haemopoiesis in the adult. The increased myelopoiesis involves primarily the granulocyte series, but megakaryocyte and platelet numbers are also usually increased. Obvious erythroid hyperplasia and polycythaemia occur only rarely.

In the absence of a convincing assay for human haemopoietic stem cells, a number of efforts have been made to quantify *in*

vitro its nearest counterpart, variously designated 'long-term culture-initiating cells', 'high-proliferative capacity progenitor cells' or 'blast colony-forming cells'. In general, the numbers of such cells seem to be moderately increased (threefold to tenfold) in CML marrow compared with normal marrow, but results are inconsistent. In contrast, the numbers of committed progenitors (i.e. CFU-GEMM, BFU-E and CFU-GM) are greatly increased compared with normal, and this increase is proportionately much larger in the blood than in the marrow of untreated CML patients. BFU-E and CFU-GM numbers in the blood are significantly correlated with the leucocyte count; their numbers are restored to normal or subnormal levels by appropriate treatment.

Theoretically, an apparently autonomous proliferation of myeloid progenitors could be due to increased responsiveness to one or more physiological stimulators of haemopoiesis or to loss of sensitivity to a normal inhibitor. As a consequence of this, many efforts have been directed to assessing the response of CML progenitors to haemopoietic growth factors, notably granulocyte colony-stimulating factor (G-CSF), granulocyte/macrophage colony-stimulating factor (GM-CSF), interleukin (IL)-3, stem cell factor and erythropoietin. There is some evidence that the autonomous proliferation could be due to an autocrine loop involving G-CSF and IL-3. It may also be due to increased production of elastase by the leukaemia cells that inhibits the response of normal but not leukaemia cells to G-CSF.

CML progenitors in *in vitro* culture systems adhere less well to preformed marrow stromal layers than their normal counterparts. This may be due to an abnormality of an integrin or absence of a glycosylphosphatidylinositol-anchored protein that has not yet been defined. Thus, it is possible that the excessive proliferation of CML progenitors is due partly to their

premature escape from physiological inhibitory influences in the stem cell niche.

Cytogenetics

The Philadelphia (originally designated Ph¹, now der22q- or Ph) chromosome (see Chapter 29) is an acquired cytogenetic abnormality that characterizes all leukaemic cells in CML. It is formed as a result of a reciprocal translocation of chromosomal material between the long arms of one chromosome 22 and one chromosome 9, an event referred to as t(9;22)(q34;q11) (Figure 27.2). The (9;22) translocation generates the *BCR-ABL1* fusion gene on the Ph chromosome (see below) and also a reciprocal fusion gene, designated *ABL1-BCR*, on the derivative 9q+ chromosome. Such translocations involving just two chromosomes are described as simple, whereas about 10% of patients have complex translocations involving chromosomes 9, 22 and one or sometimes two other chromosomes.

In CML patients, the Ph chromosome is present in all myeloid cell lineages, in some B cells and in a very small proportion of T cells. It is found in no other cells of the body. This distribution is not altered by traditional treatment with busulfan or hydroxycarbamide (hydroxyurea). Although valuable since the 1960s as a marker of the leukaemic cell, its true pathogenetic signifi-

cance remained uncertain until the identification of the *BCR-ABL1* chimeric gene on the Ph chromosome in the 1980s. About 15% of patients have small deletions of chromosomal material on der9q+, which usually include the reciprocal *ABL1-BCR* gene. Such deletions are thought to occur contemporaneously with the formation of the *BCR-ABL1* gene on the Ph chromosome and denoted a relatively poor overall prognosis in the era before imatinib; however, patients with 9q+ deletions respond as well to TKIs as those lacking such deletions. A small proportion of patients with clinically classical CML lack the Ph chromosome and have a normal karyotype; however, these do have a typical *BCR-ABL1* gene expressed as a p210 oncoprotein (see below) on a normal-appearing chromosome 22 (or very occasionally on a normal chromosome 9).

Some, but not all, patients acquire additional clonal cytogenetic abnormalities during the course of the chronic phase. There was suspicion that some such changes might be caused in part by administration of alkylating agents, but they can undoubtedly occur spontaneously. The observation of non-random changes, typically +8, +Ph, iso-17q or +19, sometimes means that such new clones will expand and that blastic transformation will manifest itself within weeks or months, but these new clones (other than iso-17q) can remain clinically unimportant for many years. In overt blastic transformation, 80% of patients have clonal cytogenetic changes in addition to the Ph translocation.

Figure 27.2 The t(9;22) translocation and its products: the *BCR-ABL1* oncogene on the Ph chromosome and the reciprocal *ABL1-BCR* gene on the derivative 9q+ chromosome. In classic CML, *BCR-ABL1* is transcribed into mRNA molecules with e13a2 or e14a2 junctions, which are then translated into the p210^{*BCR-ABL1*} oncoprotein. This oncoprotein is a hybrid containing functional domains from the N-terminal end of BCR (dimerization domain, DD), SRC-homology 2 (SH2)-binding

and the Rho GTP-GDP exchange factor (GEF) domains and the C-terminal end of ABL1. [Only SRC-homology regions 2, 3 and 1 (SH2, SH3 and SH1 respectively) and the DNA- and actin-binding domains are shown.] Tyrosine 177 (Y177) in the BCR portion of the fusion oncoprotein and tyrosine 412 (Y412) in the ABL1 portion are important for the docking of adapter proteins and for *BCR-ABL1* autophosphorylation respectively. P-S/T denotes phosphoserine and phosphothreonine.

Table 27.3 Definitions of cytogenetic and molecular responses.

Cytogenetic response		
Designation	Percentage of Ph-positive marrow metaphases	Molecular response (<i>BCR-ABL1</i> transcript numbers expressed on the international scale)
Complete	0	Baseline, 100%
Partial	1–35	Cytogenetic response, ~1%
Minor	36–65	Major molecular response, 0.1%
Minimal	66–95	Complete molecular response, ~0.001%
None	>95	

Note: The term ‘major cytogenetic response’ is used to refer to the sum of patients who achieve complete cytogenetic response and those who only achieve a partial cytogenetic response. The level of complete molecular response must depend on the sensitivity of the assay and the term ‘*BCR-ABL1* transcripts undetectable’ is formally more precise.

In the majority of patients at diagnosis all marrow metaphases show the Ph chromosome. In the past treatment with interferon alfa reduced the proportion of Ph-positive metaphases in a minority of patients. Since the introduction of TKIs, serial measurement of the percentage of Ph-positive marrow metaphases has become an important tool in assessing the level of response in individual patients (Table 27.3).

Molecular biology

It was shown in the early 1980s that the *ABL1* proto-oncogene, which encodes a non-receptor tyrosine kinase, was normally located on chromosome 9 but was translocated to chromosome 22 in CML patients. In 1984 the precise positions of the genomic breakpoint on chromosome 22 in different CML patients were found to be clustered in a relatively small 5.8-kb region to which the name ‘breakpoint cluster region’ (BCR) was given. Later, it became clear that this region formed the central part of a relatively large gene now known as the *BCR* gene, whose normal function is not well defined, and the breakpoint region was renamed ‘major breakpoint cluster region’ (M-BCR) (see Table 27.3). In contrast, the position of the genomic breakpoint in the *ABL* gene (now often referred to as the *ABL1* gene to distinguish it from the *ABL1*-related gene, *ARG* or *ABL2*) is very variable, but it always occurs upstream of the second (common) exon (a2). Thus, the Ph translocation results in juxtaposition of 5′ sequences from the *BCR* gene with 3′ *ABL1* sequences derived from chromosome 9 (Figure 27.3). It produces a chimeric gene,

designated *BCR-ABL*, or better *BCR-ABL1*, that is transcribed as an 8.5-kb mRNA and encodes a protein of 210 kDa. This p210^{*BCR-ABL1*} oncoprotein has far greater tyrosine kinase activity than the normal *ABL1* gene product.

In CML, there are two variants of the *BCR-ABL1* transcript, depending on whether the break in M-BCR occurs in the intron between exons e13 and e14, or in the intron between exons e14 and e15. A break in the former intron yields an e13a2 mRNA junction and a break in the latter intron yields an e14a2 junction. (It should be noted that exon e13 was previously termed exon b2 and exon e14 was previously b3; thus the two RNA junctions were known until recently as b2a2 and b3a2 respectively.) Most patients have transcripts with features of either e13a2 or e14a2, but occasional patients have both transcripts present in their leukaemia cells. The precise type of *BCR-ABL1* transcript has no prognostic significance for CML patients. Moreover, the reciprocal *ABL1-BCR* gene on der9q+ is expressed in about 70% of patients, but its expression or lack of expression does not have prognostic significance.

A minority of patients with Ph-positive acute lymphoblastic leukaemia (ALL), more often adults than children, also have *BCR-ABL1* fusion genes in their leukaemia cells (see Chapters 29 and 31). In about one-third of Ph-positive ALL patients, the molecular features of the *BCR-ABL1* gene are indistinguishable from those of CML; in the remaining two-thirds the genomic breakpoint occurs in the first intron of the *BCR* gene (a zone designated ‘minor breakpoint cluster region’ or m-BCR) and the *BCR-ABL1* gene results from fusion of the first exon (designated e1) of the *BCR* gene with the second exon (a2) of the *ABL1* gene. The mRNA is designated e1a2 and encodes a protein of 190 kDa (p190^{*BCR-ABL1*}). Very rare patients with CML have a p190 protein instead of the usual p210. Equally rare is the finding of a Ph chromosome in association with chronic neutrophilic leukaemia. Such patients may have an mRNA formed from an e19a2 fusion gene associated with a p230^{*BCR-ABL1*} oncoprotein.

The *BCR-ABL1* gene has been cloned and inserted into a retroviral vector that has been used to transfect murine haemopoietic stem cells; these transduced stem cells can generate a disease resembling human CML in mice. Thus, the *BCR-ABL1* gene is thought to play a pivotal role in the genesis of chronic-phase CML.

The mechanism by which the *BCR-ABL1* oncoprotein alters stem cell kinetics remains ill-defined. It undoubtedly aberrantly autophosphorylates and also phosphorylates a wide range of intracellular proteins that would not normally be phosphorylated, including Crkl, Mek 1/2, Rac and Jnk. It may act by activating the RAS or STAT signal transduction pathways. Alternatively, it may activate the phosphatidylinositol 3-kinase/AKT pathway involved in facilitating apoptosis (Figure 27.4). As an activated *ABL1* opposes cellular apoptosis, the *BCR-ABL1* gene might act by impeding programmed cell death in target stem cells.

Figure 27.3 The structure of the normal *BCR* and *ABL1* genes and the fusion transcripts found in CML and Ph-positive ALL. The *ABL1* gene contains two alternative 5' exons (named *lb* and *la*) followed by 10 'common' exons numbered *a2*–*a11* (orange boxes). Breakpoints in CML and Ph-positive ALL usually occur in the introns between exons *lb* and *la* or between exons *la* and *a2* (as shown by vertical arrows). The *BCR* gene comprises a total of 23 exons, 11 exons upstream of the M-BCR region, five exons in the M-BCR that were originally termed *b1*–*b5* and now renamed *e12*–*e16*, and seven exons downstream of M-BCR. For

convenience, only exons *e1*, *e12*–*e16* and *e23* are shown. Breakpoints in CML usually occur between exons *e13* (*b2*) and *e14* (*b3*) or between exons *e14* (*b3*) and *e15* (*b4*) of the M-BCR (as shown by two vertical arrows placed centrally). The majority of patients with Ph-positive ALL have breakpoints in the first intron of the gene, between *e1* and *e2* (not shown) (arrow at left). Three possible *BCR-ABL1* mRNA transcripts are shown below. The first two (*e13a2* and *e14a2* respectively) are characteristic of CML. The bottom mRNA (*e1a2*) is found in the majority of patients with Ph-positive ALL (see text).

The molecular basis of disease progression is still obscure, but it seems reasonable to infer that one or, more probably, a series of additional genetic events occurs in the Ph-positive clone. When the critical combination of additional events is achieved, clinically definable transformation ensues. At this stage, the leukaemia cells usually harbour one or other of the additional cytogenetic changes referred to above. About 20% of patients with CML in myeloid transformation have point mutations or deletions in the coding sequence of the *TP53* tumour-suppressor gene, a gene implicated in progression of a variety of solid tumours, notably colonic carcinoma. The retinoblastoma (*RB*) gene is deleted in rare cases of CML in megakaryoblastic transformation, and changes in the *LYN*, *EVII* and *MYC* genes are described. About half of the patients with lymphoid blast transformations have homozygous deletions in the *p16* (*CDKN2A*) gene, whose normal function is to inhibit cyclin-dependent kinase 4, and others have deletions of the *IKZF1* (Ikaros) gene. Molecular changes underlying the non-random cytogenetic changes described above have not been identified.

Clinical features

In the past, the majority of patients presented with symptoms, usually attributable to splenomegaly, haemorrhage or anaemia. In recent years, CML has been diagnosed in almost 50% of patients before the onset of symptoms as a result of routine blood tests performed as part of medical examinations in healthy persons, for pregnancy, before blood donation or in the course of investigation for unrelated disorders. When present, symptoms may include lethargy, loss of energy, shortness of breath on exertion or weight loss or haemorrhage from various sites. Increased sweating is characteristic. Spontaneous bruising or unexplained bleeding from gums, intestine or urinary tract are relatively common. Visual disturbances may occur. Fever and lymphadenopathy are rare in chronic phase. The patient may have severe pain or discomfort in the splenic area, often associated with splenic infarction, or may have noticed a lump or mass in the right upper abdomen. Visual disturbances may

Figure 27.4 Signal transduction pathways affected by BCR–ABL1. The cellular effects of BCR–ABL1 are exerted through interactions with various proteins that transduce the oncogenic signals responsible for the activation or repression of gene transcription, of mitochondrial processing of apoptotic responses, of cytoskeletal organization and of the degradation of inhibitory proteins. The key pathways implicated so far are those involving RAS, mitogen-activated protein kinases, signal transducers and activators of transcription (STAT), phosphatidylinositol 3-kinase (PI3-K) and MYC. Most of the interactions are mediated through tyrosine phosphorylation and require the binding of BCR–ABL1 to adapter proteins such as growth factor receptor-bound protein

2 (GRB-2), DOK, CRK, CRK-like protein (CRKL), SRC homology-containing protein (SHC) and casitas B-lineage lymphoma protein (CBL). As we start to dissect these various interactions, we can design drugs aimed at disrupting specific branches of these pathways in an attempt either to kill the CML cell or to cause its phenotype to revert to normal. It is obvious that the best target is BCR–ABL1 itself, as this is the only protein that is exclusive to the leukaemic clone. The second-best approach is to target key downstream effectors of BCR–ABL1; however, this approach might, in principle, adversely affect normal haemopoiesis as well. P, phosphate.

be due to retinal haemorrhages. Sudden hearing loss occurs very rarely. Patients may present with features of gout or priapism in males, both of which are also rare.

At diagnosis, 50–70% of patients have splenomegaly. The spleen varies from just palpable to being so large that it occupies all the left side of the abdomen and is palpable also in the right iliac fossa. The liver is frequently also enlarged but with a soft edge that is difficult to define. There may be no other abnormal findings. Ecchymoses of varying sizes and ages may be present and may form discoloured subcutaneous lumps. Some patients have asymptomatic retinal haemorrhages. Patients with very high leucocyte counts may have features of leucostasis, with retinal vein engorgement and respiratory insufficiency.

Patients presenting with more advanced disease nearly always have some of the features described above. In addition, they may have bone tenderness or signs of infection. In established blastic transformation, the spleen is frequently enlarged and may be painful. The liver may become very large. Patients may

develop fever, lymphadenopathy or very rarely lytic lesions of bone.

Laboratory haematology

Chronic phase

Patients with splenomegaly are usually anaemic, while the haemoglobin concentration may be normal in patients with 'early' disease. The leucocyte count at diagnosis is usually in the range $20\text{--}200 \times 10^9/\text{L}$, but the diagnosis of CML can be established by appropriate investigations in patients with persistent leucocytosis in the range $10\text{--}20 \times 10^9/\text{L}$; at the other extreme, occasional patients may present with leucocyte numbers in the range $200\text{--}800 \times 10^9/\text{L}$. The blood film shows a full spectrum of cells in the granulocyte series, ranging from blast forms to mature neu-

Figure 27.5 Peripheral blood appearances of a patient with CML at diagnosis. Note increased numbers of leucocytes including immature granulocytes and occasional blast cells.

trophils, with intermediate myelocytes and neutrophils predominating (Figure 27.5). The percentage of blast cells is loosely related to the absolute number of leucocytes, but a value higher than 12% suggests that the patient may already be in acceleration or transformation. The percentages of eosinophils and basophils are usually increased, and the absence of basophilia casts doubt on the diagnosis. Absolute numbers of lymphocytes and monocytes are slightly increased, but both are reduced as percentages in the differential count. Platelet numbers are usually increased in the range $300\text{--}600 \times 10^9/\text{L}$ but may be normal or even reduced. Occasional nucleated red cells are present in the circulation in some patients. The alkaline phosphatase content of the neutrophil cytoplasm is diminished or absent. *BCR-ABL1* transcripts can be demonstrated in the blood with ease, using real-time quantitative polymerase chain reaction (RQ-PCR). In a minority of patients, the leucocyte count, if left untreated, shows cyclical variation, but the overall trend is upwards.

Examination of the bone marrow by aspiration or trephine biopsy is not necessary to confirm the diagnosis of CML, but is usually carried out to assess the degree of marrow fibrosis, perform cytogenetic analysis on marrow cells and exclude incipient transformation. The marrow aspirate may show multiple small hypercellular fragments but is often so hypercellular that fragments cannot easily be discerned. When spread on a glass slide, the trails show a cellular composition resembling that of CML blood. Blast cells in chronic phase number 2–10%. Eosinophils and basophils are usually prominent; megakaryocytes are small, hypolobated and very numerous. Occasionally, Gaucher-like cells are present. The marrow biopsy shows complete loss of fat spaces with dense hypercellularity. The reticulin content may be normal or modestly increased.

Table 27.4 Criteria for distinguishing the chronic, accelerated and blastic phases of CML based on proposals published by WHO (2001).

Chronic phase

Ability to reduce spleen size and restore and maintain a 'normal' blood count with appropriate therapy

Accelerated phase (defined by one or more of the following features)

Blasts 10–19% of white blood cells in peripheral blood and/or of nucleated bone marrow cells

Peripheral blood basophils $\geq 20\%$

Persistent thrombocytopenia ($<100 \times 10^9/\text{L}$) unrelated to therapy, or persistent thrombocytosis ($>1000 \times 10^9/\text{L}$) unresponsive to therapy

Increasing spleen size and increasing white blood cell count unresponsive to therapy

Megakaryocyte proliferation in sheets or clusters in association with marked reticulin or collagen fibrosis

Blastic phase (defined by one or more of the following features)

Blasts $>20\%$ of peripheral blood leucocytes or of nucleated bone marrow cells

Extramedullary blast proliferation

Large foci or clusters of blasts in the bone marrow biopsy

Note: In this classification, unlike some other classifications, the acquisition of new cytogenetic abnormalities in addition to the Ph chromosome is not by itself a criterion for 'promoting' a chronic-phase patient to accelerated phase.

Advanced phases

The haematological picture in acceleration is very variable. It may differ little from chronic phase but blast cell numbers may be increased disproportionately (Table 27.4). There may be anaemia in the presence of a normal leucocyte count. Platelet numbers may be greatly increased ($>1000 \times 10^9/\text{L}$) or reduced ($<100 \times 10^9/\text{L}$) in a manner not accounted for by treatment. The marrow also shows a picture no longer consistent with chronic-phase disease, often with increased numbers of blast cells or promyelocytes and/or increased fibrosis.

Blastic transformation is defined by the presence of more than 20% blasts or blasts plus promyelocytes in the blood or marrow. Frequently, this criterion is irrelevant because blast cell numbers in both sites have risen abruptly to exceed 80%. Their morphology is very variable. About 70% of patients have blasts classifiable generally as myeloid, which resemble to a degree the cells that characterize acute myeloid leukaemia (AML) (see Chapter 29). Such cells may be predominantly myeloblastic, monoblastic, erythroblastic or megakaryoblastic, and blast cells of different myeloid lineages frequently coexist. These cells are best defined by their cytochemical and immunophenotypic

Figure 27.6 Peripheral blood appearances of a patient with CML in lymphoid blast cell transformation.

characteristics, although they do not usually fit neatly into the French–American–British (FAB) classification for AML. About 20% of patients have lymphoid blast cells; these may resemble the FAB L1 cells that typify childhood ALL or, more commonly, have L2 appearances (Figure 27.6). Immunophenotyping shows the typical membrane markers of a precursor B-cell ALL, namely CD10 (CALLA) and CD19 positivity, and further studies may show nuclear positivity for terminal deoxynucleotidyltransferase. Molecular studies show clonal rearrangement of immunoglobulin chains and occasionally of T-cell receptor genes. The remaining 10% of blast cell transformations have mixed myeloid and lymphoid characteristics.

The clinical features associated with advanced disease are quite variable. In some cases, the patient is initially completely asymptomatic and the diagnosis is based entirely on blood and marrow findings. In other cases, the patient may develop fevers, excessive sweating, anorexia and weight loss or bone pain. Rarely, there are localized lytic lesions of bone, which may be single or multiple. Occasionally, patients present with generalized lymphadenopathy; biopsy shows nodal infiltration with blast cells that may be myeloid or lymphoid. Localized skin infiltrates may be seen. Discrete masses of immature leukaemia cells may develop at almost any site; these are sometimes referred to as chloromas or granulocytic sarcomas. Patients with lymphoid blast cells in the blood and marrow may have involvement of the cerebrospinal fluid at the same time, or central nervous system (CNS) involvement may become symptomatic only at a later stage.

Biochemical changes

The biochemical changes seen in CML are non-specific. Patients diagnosed in chronic phase may have a slightly raised serum uric acid but the level is frequently normal. The serum alkaline phosphatase is usually normal or slightly raised. Lactate dehy-

drogenase is usually raised. Serum K^+ may be spuriously raised due to leakage of intracellular potassium from platelets or, less commonly, from leucocytes after the blood is drawn. In such cases, the K^+ level in freshly drawn citrated blood is usually normal, as is the electrocardiogram. The serum vitamin B_{12} and B_{12} -binding capacity are greatly increased due to raised levels of transcobalamin I.

In transformation, the serum uric acid may be raised, sometimes substantially, and tests of liver function are usually moderately abnormal. Hypercalcaemia is present occasionally and is usually due to bone destruction; very rarely, it may be attributable to a parathormone-like material ectopically produced by the blast cells.

Management of chronic myeloid leukaemia in chronic phase

The management of the newly diagnosed CML patient has changed very greatly in the last decade. In the 1970s, it was conventional for the physician to start treatment soon after diagnosis with busulfan and then to await further developments. The patient received little information about prognosis. Today, in most, but not all, countries, the patient is informed of the diagnosis and given as much information as possible about the disease and its prognosis. The various options for treatment are usually discussed at this stage, which for the younger patient include the possible need for allogeneic SCT at some stage in the disease. This means that the patient, all siblings and other family members should be HLA typed. The issue of gonadal function is important and men who have not completed their families should be offered semen cryopreservation before any treatment is started.

There is no urgency to start treatment immediately in asymptomatic patients with leucocyte counts below $100 \times 10^9/L$. This means that leucapheresis with cryopreservation of blood stem cells can be performed before anti-leukaemia treatment is instituted. Such stored cells may be used for autografting at a later date. However, drug treatment should ideally be started soon after the diagnosis is confirmed. The best single agent for patients in chronic phase who are not enrolled in a Phase III study is imatinib. Hydroxycarbamide is a reasonable alternative in the very short term if imatinib is not immediately available. Interferon alfa, until the advent of TKIs the treatment of choice, and busulfan should both be reserved for special indications.

Imatinib mesylate

Imatinib mesylate (Glivec or Gleevec; previously known as STI571), a 2-phenylaminopyrimidine compound, is an ABL1 tyrosine kinase inhibitor that entered clinical trials in 1998. It was thought originally to act by occupying the ATP-binding

pocket of the ABL1 kinase component of the BCR–ABL1 oncoprotein, thereby blocking the capacity of the enzyme to phosphorylate downstream effector molecules; it is now thought to act also by binding to an adjacent domain in a manner that holds the ABL1 component of the BCR–ABL1 oncoprotein molecule in an inactive or ‘closed’ conformation (Figure 27.7). The drug rapidly reverses the clinical and haematological abnormalities and induces major cytogenetic responses in over 80% of previously untreated chronic-phase patients. It is usually administered orally at a dose of 400 mg daily, although pilot studies suggest that initial treatment with 600 mg or even 800 mg daily gives more rapid responses.

Side-effects include nausea, headache, rashes, infraorbital oedema, bone pains and, sometimes, more generalized fluid retention. The rashes can from time to time be treated by temporarily interrupting imatinib and then reinstating it under short-term corticosteroid cover. Hepatotoxicity characterized by raised serum transaminases is occasionally seen and may necessitate stopping the drug. Some caution must also be exercised in the light of very rare reports of potentially fatal cerebral oedema. Patients with black skin may sustain areas of depigmentation. An interesting non-sinister effect, repigmentation of grey hair, has been reported in a small group of responders. The toxicity in general seems to be appreciably less than that associated with interferon alfa.

A significant minority of patients experience neutropenia and/or thrombocytopenia within the first few months of starting treatment with imatinib at standard dosage (400 mg daily).

In some cases, isolated neutropenia may be managed simply by adding G-CSF (300–480 µg subcutaneously on alternate days or less often) for a finite period, after which it may be possible to reduce or stop the drug. In other cases, G-CSF works less well and it may be necessary to reduce or stop imatinib. If thrombocytopenia develops, it may be necessary to reduce the dose, although some believe that the drug may expedite development of resistance at daily doses below 300 mg. Conversely, thrombocytosis sometimes persists in a patient whose leucocyte count is well controlled by imatinib; in such cases, the addition of hydroxycarbamide or anagrelide usually controls the platelet count.

The issue of how long to continue imatinib remains unresolved. For the patient who has achieved complete cytogenetic remission, stopping the drug usually leads to recurrence of Ph positivity and eventually leucocytosis in the majority of cases, although on occasion the cytogenetic remission continues without treatment for many months or even longer. A small proportion of the patients who achieved a complete molecular response that lasted more than 2 years have stopped taking imatinib without evidence of subsequent relapse, an interesting observation that raises the possibility that imatinib may have the capacity to eradicate CML in some cases. At present, the best advice for the responding patient is to continue the drug indefinitely.

A prospective randomized Phase III trial (the IRIS trial) designed to compare imatinib as a single agent with the combination of interferon alfa and cytarabine in previously

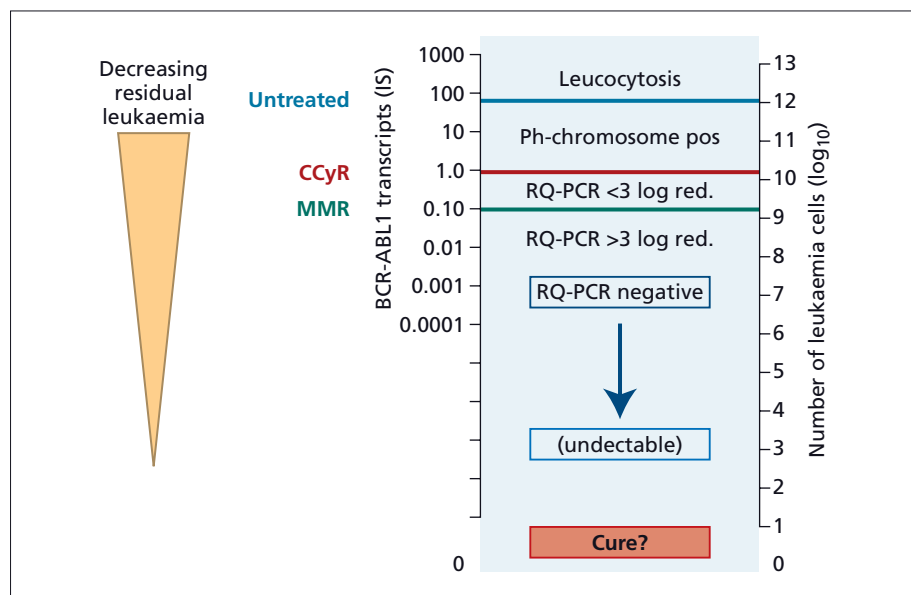

Figure 27.7 Schematic representation of the relationship between measurable parameters (blood leucocyte numbers, Ph-positive marrow metaphases and *BCR–ABL1* transcript numbers) and

presumed number of residual leukaemia cells in a patient responding to treatment with a tyrosine kinase inhibitor. CCyR, complete cytogenetic response; MMR, major molecular response.

untreated patients started in June 2000. Analysis after 6 years of follow-up showed that 74% of the patients treated with imatinib achieved complete cytogenetic remission compared with 14% of those in the control arm. The cumulative best complete cytogenetic response rate was 82%, and 63% of all patients randomized to receive imatinib were still on study and in complete cytogenetic remission. The event-free survival was 83% and overall survival 88%. A substantial proportion of the patients in complete cytogenetic remission also achieved a major molecular response (equivalent to a 3-log reduction in *BCR-ABL1* transcript numbers) and this proportion has continued to increase steadily with time on imatinib. A large proportion of the patients in the control arm discontinued interferon alfa and cytarabine for various reasons and thus a formal comparison of survival in the two arms could not be performed. However, comparison of survival of patients treated with imatinib with that of historical control patients treated predominantly with interferon-containing regimens showed highly significant superiority for those who received imatinib.

Predicting response to imatinib

Efforts are now being made to predict an individual patient's response to imatinib 400 mg daily but results are not yet totally reliable. This said, patients whose leukaemia cells tested *in vitro* have a low IC_{50} for imatinib seem to respond better than those with higher IC_{50} values. Patients with normal or high levels of the human organic cation transporter (hOCT)-1, which is responsible for cellular influx of imatinib, also seem to fare better than those with lower levels. Efforts have been made to predict response to imatinib on the basis of gene expression profiling but the results of the different studies are somewhat inconsistent and this method is not yet suitable for clinical application. It is interesting that the Sokal score based on a population of patients treated with busulfan more than 25 years ago still has predictive value for response to imatinib.

Monitoring responses to treatment

The quantity of leukaemic cells remaining in a patient's body while responding to treatment with TKIs can be monitored with considerable precision by use of three modalities in sequence, namely examination of the peripheral blood, bone marrow metaphase cytogenetics and the number of *BCR-ABL1* transcripts in the circulation. Thus for an individual patient the first target is normalization of the blood count, the second elimination of dividing cells in the bone marrow that show Ph-positive metaphases and finally elimination of *BCR-ABL1* transcripts in the blood or marrow. *BCR-ABL1* transcript numbers are usually measured by RQ-PCR and the results may be expressed either as a ratio of *BCR-ABL1* copy numbers to copy numbers of a control gene ($\times 100\%$ on a log scale) or as a \log_{10} reduction from standardized value of 0 for untreated patients. In practice the recommended way to express the results is to use a laboratory-specific conversion factor to convert the value obtained in

a given laboratory to a value on the International Scale where 100% is the value for a specific cohort of untreated patients studied in 2002. Patients who achieve a transcript number of 0.1% on the International Scale, equivalent to a 3-log reduction from the baseline for untreated patients, are said to have achieved a major molecular response, while those without detectable transcripts have achieved a complete molecular response (Figure 27.8). The use of fluorescence *in situ* hybridization to detect a *BCR-ABL1* gene in interphase cells is more sensitive than metaphase cytogenetics but much less sensitive than RQ-PCR.

Defining response and failure to respond to imatinib

In 2005 a group of haematologists convened under the aegis of the European LeukemiaNet produced a series of recommendations designed to help clinicians identify patients with newly diagnosed CML in chronic phase started on imatinib 400 mg daily and subsequently judged to have achieved only a suboptimal response or to have failed treatment. The implication was that patients who failed should have their treatment changed and those satisfying criteria for suboptimal response should be monitored closely with the expectation that they too might fail. These original recommendations were updated in 2009 (Table 27.5).

Figure 27.8 The presumed mechanism of action of imatinib. (a) The phosphorylation of a substrate is shown schematically. ATP occupies the pocket in the ABL1 component of the *BCR-ABL1* oncoprotein, whence it donates a phosphate (P) group to a tyrosine (Y) residue on an unspecified substrate. The substrate then detaches itself from the *BCR-ABL1* oncoprotein and makes functional contact with a further downstream effector molecule. (b) Imatinib occupies the ATP-binding site and thereby prevents phosphorylation of the substrate. This molecule in turn fails to make contact with the effector protein and the signal transduction pathway that would otherwise transmit the 'leukaemia signal' is interrupted.

Table 27.5 Evaluation of overall response to front-line imatinib in early chronic-phase CML.

	<i>Optimal response</i>	<i>Suboptimal response</i>	<i>Failure</i>	<i>Warnings</i>
3 months	CHR and at least minor cytogenetic response (Ph ⁺ ≤ 65%)	No cytogenetic response (Ph ⁺ > 95%)	Less than CHR	NA
6 months	At least partial cytogenetic response (Ph ⁺ < 35%)	Less than partial cytogenetic response (Ph ⁺ > 35%)	No cytogenetic response (Ph ⁺ > 95%)	NA
12 months	Complete cytogenetic response	Partial cytogenetic response (Ph ⁺ ≤ 35%)	Less than partial cytogenetic response (Ph ⁺ > 35%)	Less than major molecular response*
18 months	Major molecular response	Less than major molecular response	Less than complete cytogenetic response	NA
Any time	Stable or improving major molecular response	Loss of major molecular response Mutations [†]	Loss of CHR Loss of complete cytogenetic response Mutations [‡] Additional chromosome abnormalities in Ph-positive cells [§]	Any rise in transcripts level Other chromosome abnormalities in Ph-negative cells

*Major molecular response denotes *BCR-ABL1/ABL1* or other housekeeping genes ≤0.1% on the international scale.

[†]*BCR-ABL1* kinase domain mutations highly insensitive to imatinib (see Table 27.3).

[‡]*BCR-ABL1* kinase domain mutations still sensitive to imatinib (see Table 27.3).

[§]Additional chromosome abnormalities in Ph-positive cells are a warning factor at diagnosis, while their occurrence during treatment (clonal progression) is a marker of failure. Two consecutive cytogenetic tests are required, showing the same additional chromosome abnormalities in at least two Ph-positive cells.

CHR, complete haematological response; NA, not applicable.

Resistance to imatinib

Resistance to imatinib may be primary or secondary. A very small proportion of patients with newly diagnosed chronic-phase CML fail to achieve a haematological response and a small proportion never achieve a complete cytogenetic response. In these cases the resistance seems to be primary. A larger proportion of patients respond initially at the haematological or cytogenetic level and then lose their responses; such secondary resistance occurs most commonly in the first 2 years after starting treatment and appears to be increasingly rare in patients who have taken imatinib for more than 2 years. The cause of primary resistance is essentially unknown but is likely to reflect the underlying heterogeneity of CML at diagnosis. Similarly, the cause of secondary resistance is poorly defined. It has been associated with a variety of diverse mechanisms, including overexpression of the *BCR-ABL1* oncoprotein and overexpression of P-glycoprotein, which expedites efflux of the drug from individual cells, and the acquisition of point mutations in the *ABL1* kinase domain. Thus far, Ph-positive subclones with at least 50 different point mutations have been identified in leukaemia cells obtained from patients with variable degrees of resistance to imatinib, and some of these, but by no means all,

are clearly the cause of the resistance. Each mutation encodes a different amino acid substitution in the *ABL1* kinase component of the *BCR-ABL1* oncoprotein. Cells with one such substitution, the replacement of threonine by isoleucine at position 315 (referred to as the T315I mutation), seem to be especially resistant to the inhibitory action of imatinib and all other TKIs. Cells with other substitutions are relatively less resistant. It is probable that some of these subclones exist before the administration of imatinib but are allowed to expand when the unmutated oncoprotein molecule is inhibited by imatinib; in other cases the mutation may develop *de novo* after initiation of imatinib.

Second-generation tyrosine kinase inhibitors

The remarkable success of imatinib in chronic-phase CML led rapidly to development of other TKIs, notably dasatinib, nilotinib and bosutinib, all of which are clearly more potent than the original TKI. With each of these drugs the largest experience has been gained in treating patients who have failed imatinib, but all are now being tested as up-front treatment for newly diagnosed individuals with promising early results.

Dasatinib

Dasatinib (Sprycel) was first used to treat CML in 2003. Somewhat surprisingly it bears little chemical resemblance to imatinib but acts, like imatinib, by occupying the phosphate-binding pocket and blocking access for ATP. Unlike imatinib it is active with the kinase activation loop in both closed and open configurations. It differs also from imatinib in being active against a wide range of tyrosine kinases in addition to ABL1, of which the most notable are SRC and so-called SRC family kinases. It has therefore been termed a dual inhibitor, on the assumption that its value in CML could be based on its relatively wide spectrum of activity. The original dose was 70 mg twice daily but the recommended dose for patients is now 100 mg once daily. For patients who have failed imatinib, dasatinib induces complete cytogenetic responses in about 50% of patients and some of these responses seem very durable. It is definitely more myelosuppressive than imatinib and treatment must occasionally be interrupted or dosage reduced on account of neutropenia or thrombocytopenia. Other side-effects observed include nausea, gastrointestinal disturbances, rashes and pleural effusions, which may or may not be asymptomatic. The latter usually resolve on stopping the drug.

Nilotinib

Nilotinib (Tasigna) was developed by chemical modification of imatinib with the intention of increasing its activity. Nilotinib is about 30 times more active *in vitro* but the recommended oral dose, 400 mg twice daily, does not reflect the *in vitro* ratio. Like dasatinib, it induces complete cytogenetic responses in about 50% of patients who fail imatinib. It is usually well tolerated but side-effects have included headaches, nausea, gastrointestinal disturbances, pancreatitis, raised levels of bilirubin, and abnormal liver function tests. Prolongation of the QT interval has been observed in rare instances.

Bosutinib

The third second-generation TKI in clinical practice is bosutinib, which also targets a relatively wide spectrum of tyrosine kinases. It is also active in patients deemed to have failed imatinib and is being tested in a Phase III study of previously untreated chronic-phase patients. Its principal toxic effect is diarrhoea, which may be severe but usually responds to standard antidiarrhoeal agents.

Hydroxycarbamide

Hydroxycarbamide (also known as hydroxyurea) is a ribonucleotide reductase inhibitor that targets relatively mature myeloid progenitors in proliferative cycle. Its pharmacological action is rapid and readily reversible. Treatment for patients in chronic phase usually starts with 1.0–2.0 g daily by mouth and continued indefinitely. The leucocyte count starts to fall within days and the spleen reduces in size. It is usually possible to

reverse all features of CML within 4–8 weeks of starting treatment with hydroxycarbamide. The dosage can then be titrated against the leucocyte count, the usual maintenance dose being 1.0–1.5 g daily. In a patient whose leucocyte count is controlled, any reduction in the dose leads to a rapid increase in leucocyte numbers, a phenomenon that disturbs the patient but has no ominous significance. The drug has relatively few side-effects. At high dosage it may cause nausea, diarrhoea or other gastrointestinal disturbance. Some patients get ulcers of the buccal mucosa. Skin rashes are seen. Most patients develop megaloblastic changes in the marrow with macrocytosis in the blood. The drug remains useful today for rapid cytoreduction in the newly diagnosed patient and may also be useful in patients unable to tolerate imatinib, but it rarely causes any degree of reduction in Ph-positive cells in the bone marrow and must therefore be regarded as second- or third-line therapy.

Interferon alfa

Interferon alfa, like hydroxycarbamide, can no longer be regarded as first-line therapy for CML, but may still have a role in management of patients who have failed TKIs. It is a member of a large family of glycoproteins of biological origin with antiviral and antiproliferative properties. Studies in the early 1980s using material purified from human cell lines showed that it was active in reducing the leucocyte count and reversing all features of CML in 70–80% of CML patients. Of particular interest at the time was the observation that 5–15% of patients achieved major reduction in the percentage of Ph-positive marrow metaphases with restoration of Ph-negative (putatively normal) haemopoiesis. It raised the important question of whether these 'cytogenetic responders' would have their life prolonged by treatment with interferon alfa, and prospectively randomized controlled studies were initiated. Compared with hydroxycarbamide, interferon alfa offered a survival advantage that was maximal for those who achieved complete cytogenetic remissions. These observations meant that interferon alfa replaced hydroxycarbamide and busulfan in the 1980s as primary treatment for CML in chronic phase, and remained so until the introduction of imatinib.

Interferon alfa must be administered by subcutaneous injection at daily doses ranging from 3 to 5 million units/m². There is no good evidence that the higher doses are clinically superior. Toxicity is common in older patients, but is generally mild and reversible. Almost all patients experience fevers, shivers, muscle aches and general flu-like features on starting the drug; these last usually 2–3 weeks but may be alleviated by paracetamol. They recur when dosage is increased. A significant minority of patients cannot tolerate the drug on account of lethargy, malaise, anorexia, weight loss, depression and other affective disorders or alopecia. Autoimmune syndromes, such as thyrotoxicosis, may also occur. A long-acting form of interferon alfa, peginterferon alfa, has been introduced recently, but other than

ease of administration it seems to have little advantage over conventional formulations.

Busulfan

Busulfan (1,4-dimethanesulfonyloxybutane) is a polyfunctional alkylating agent that is now infrequently used (except as conditioning before transplant procedures). It targets a relatively primitive stem cell and the effects of administration are prolonged for some weeks after stopping the drug. It was the mainstay of treatment for CML in the period 1960–80. Treatment was conventionally started with 8 mg daily by mouth and the dosage was reduced as the leucocyte count began to fall. It was essential to reduce the dosage substantially or to stop the drug before the leucocyte count fell below $20 \times 10^9/L$ because profound and prolonged leucopenia might otherwise be produced.

Busulfan could be administered either in finite courses lasting up to 4 weeks or continuously at a maintenance dose between 0.5 and 2.0 mg daily. Occasional patients were hypersensitive to the effects of busulfan and developed severe, sometimes irreversible, pancytopenia with marrow hypoplasia on standard dosage. Overdosage could achieve the same effect in any patient. Gonadal failure (as mentioned above) invariably occurred within a few months of starting treatment and was almost always irreversible. Other toxic effects included cutaneous pigmentation, pulmonary fibrosis and a wasting syndrome resembling hypoadrenalism. These points notwithstanding, the drug may be useful in older patients whose compliance is uncertain as it can also be given orally in the clinic as a single dose of 50 or 100 mg, to be repeated as necessary after 4 weeks or longer.

Homoharringtonine

Another drug of interest for CML in chronic phase is homoharringtonine (omecetaxine), a semisynthetic plant alkaloid that enhances apoptosis of CML cells. It produces haematological responses in 60–70% of patients and major cytogenetic responses in 25% in small series of patients in chronic phase. The results appear to improve with the addition of interferon alfa. For the moment, it remains an investigational agent.

Allogeneic stem cell transplantation

Younger patients with suitable stem cell donors who fail treatment with TKIs may be offered the option of allogeneic SCT (see Chapter 24). Most specialist centres exclude from consideration patients who are over the age of 50 or 55 years. The major factors influencing survival are patient age, disease phase at time of SCT, disease duration, degree of histocompatibility between donor and recipient, and gender of donor. In general, patients are ‘conditioned’ for transplant with cyclophosphamide at high dosage followed by total body irradiation, or with the combination of busulfan and cyclophosphamide at high dosage. If all goes well, reasonable marrow function is achieved in 3–4 weeks after the infusion of donor haemopoietic stem cells and the patient leaves the hospital.

The possible major complications include graft-versus-host disease (GVHD), reactivation of infection with cytomegalovirus or other viruses, idiopathic pneumonitis and veno-occlusive disease of the liver. For patients with CML treated by SCT with marrow from HLA-identical siblings, the overall leukaemia-free survival at 5 years is now 60–80% (Figure 27.9). There is a roughly 20% chance of transplant-related mortality and a 15%

Figure 27.9 Probability of survival for patients with CML in chronic phase who received allogeneic stem cell transplants from an HLA-identical sibling or matched unrelated donor according to whether or not the transplant was performed within 1 year of diagnosis. (Data reproduced from the International Bone Marrow Transplant Registry, Milwaukee, Wisconsin, USA, with permission.)

chance of relapse. Patients surviving without haematological evidence of disease can be monitored by serial cytogenetic studies and by use of the much more sensitive RQ-PCR, which can detect very low numbers of *BCR-ABL1* transcripts in the blood or marrow. These studies suggest (but do not prove) that in the majority of long-term survivors the CML may truly have been eradicated.

The recognition that the graft-versus-leukaemia (GVL) effect plays a major role in eradicating CML after allografting led to the concept that the toxicity of the transplant procedure could be substantially reduced by decreasing the intensity of pretransplant conditioning. The strategy is thus to focus predominantly on the use of immunosuppressive rather than myeloablative agents in order to maximize the numbers of haemopoietic stem cells transfused and to exploit the GVL effect mediated by donor alloreactive immunocompetent cells to eliminate the leukaemia cells. Such procedures have been termed variously non-myeloablative SCT, reduced-intensity conditioning SCT or mini-SCT, and reflect advances in our understanding of how SCT actually works (see Chapter 24). It is still too early to say whether non-myeloablative SCT will prove superior to conventional transplantation in the longer term for the younger patient, but the technique could make SCT more widely available to higher risk and perhaps also to older patients.

The qualified success of conventional SCT using matched siblings led in the late 1980s to increasing use of matched unrelated donors for SCT for patients with CML. At present, serologically matched unrelated donors can be identified for about 50% of white patients and for lower percentages of patients of other ethnic origins. However, molecular methods for typing HLA class I and II have now largely superseded serological techniques, and complete matches for a given patient for five gene pairs (HLA-A, -B, -C, -DR and -DQ) are relatively rare. Thus, in the absence of a perfect match the clinician has to decide what degree of mismatch may be acceptable for a given transplant. In general, the results of transplants using such unrelated donors are less good at present than results using HLA-identical siblings, but some patients will probably prove to be cured.

About 10–30% of patients submitted to allogeneic SCT relapse within the first 3 years after transplant. The relapse is usually insidious and characterized first by rising levels of *BCR-ABL1* transcripts, then by increasing numbers of Ph-positive marrow metaphases and, finally (if untreated), by haematological features of chronic-phase disease. This provides some rationale for the recommendation that patients should be monitored after transplant by regular RQ-PCR and cytogenetic studies. Rare patients in cytogenetic remission relapse directly to advanced-phase disease without any identified intervening period of chronic-phase disease.

There are various options for the management of relapse to chronic-phase disease, including use of interferon alfa, hydroxycarbamide, imatinib, a second transplant using the same or

another donor, or lymphocyte transfusions from the original donor. Such donor lymphocyte infusion (DLI) has gained popularity in recent years, and is believed to reflect the capacity of lymphoid cells collected from the original transplant donor to mediate a GVL effect, even though they may have failed to eradicate the leukaemia at the time of the original transplant. In practice, mononuclear cells are collected from the transplant donor in one or two leucapheresis procedures and transfused to the patient (who receives no other conditioning and usually no prophylaxis for GVHD). Within 3–6 months the leukaemia is restored to complete cytogenetic remission in about 80% of CML patients treated in this way and these responders also achieve PCR negativity. Some responding patients sustain marrow aplasia, which can be reversed by transfusion of marrow cells from the donor. However, severe GVHD may occur and can, on rare occasions, prove lethal. However, the incidence and severity of GVHD can be greatly reduced by starting the lymphocyte transfusions at relatively low cell dose and repeating the transfusion with a higher cell dose at intervals of 4–12 weeks as required, a technique usually referred to as ‘escalating-dose’ DLI.

At present, opinions are evenly divided on the optimal management of the patient who relapses with increasing *BCR-ABL1* transcript numbers or increasing Ph positivity after allogeneic SCT. Some feel that escalating-dose DLI is the best approach, whereas others prefer to resume treatment with imatinib. It may be possible to resolve this issue with a suitably designed prospective study.

Treatment decisions for newly diagnosed patients in chronic phase

Whereas until recently there was still controversy about whether a newly diagnosed chronic-phase patient should be treated initially with a TKI or by allogeneic SCT if he or she had a suitable donor, there is now general agreement that such new patients should first receive treatment with a TKI. There are perhaps two exceptions to this general rule. First, some paediatricians feel that the results of allogeneic SCT in children are so comparatively good that it is reasonable to offer children with matched donors an allograft as initial treatment or after cytoreduction for a finite period with imatinib. Others feel that a child responding well to imatinib should be continued indefinitely on this agent. For treating children there seems at present no general consensus. Second, a case can be made for transplantation as initial therapy in patients for whom the cost of imatinib continued over many years would be totally prohibitive. For such patients a one-off procedure involving allografting might be a better option (Figure 27.10).

For an adult the question whether to start treatment with imatinib 400 mg daily or to embark on treatment with a second-generation TKI cannot currently be resolved. We have more than 10 years’ experience with imatinib and 65% of patients

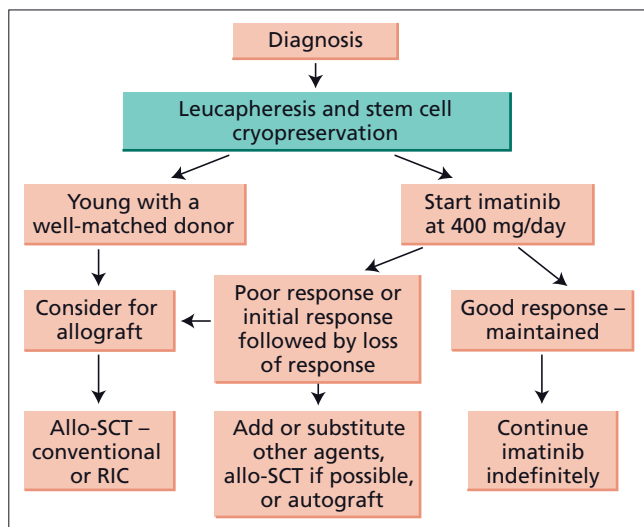

Figure 27.10 Algorithm showing a possible approach to the management of a patient with newly diagnosed CML in chronic phase. Children with HLA-identical siblings (or possibly well-matched unrelated donors) may be eligible for initial treatment by allografting. The great majority of newly diagnosed patients should be treated first with imatinib. Those who respond well and maintain their response should continue on the drug indefinitely. Patients who respond less well or who lose their response should be considered for other therapy including SCT. SCT, stem cell transplantation; RIC, reduced-intensity conditioning.

appear to be doing remarkably well. We have only very limited experience with use of the second-generation TKIs as initial therapy but preliminary results seem to be somewhat superior to those of imatinib. Would it be beneficial to start all new patients on a second-generation TKI? A number of Phase III studies are now in progress to address this question and the answer should become clear in the foreseeable future.

The decision-making process is especially complicated when CML is diagnosed in an asymptomatic patient presenting to an antenatal clinic. For a woman in the first trimester of pregnancy it is probably best to delay treatment, avoiding if possible all forms of chemotherapy, including imatinib. Leucapheresis and/or blood transfusion could be undertaken if essential. The same might apply to patients in the second trimester of pregnancy, but administration of interferon alfa is probably safe at this stage. It is clear that for the patient who conceives while taking imatinib, there is a low but finite risk that the fetus will sustain congenital abnormalities, such as hypospadias, defects in bone formation and exomphalos. The issue whether to recommend termination of pregnancy or to permit the pregnancy to continue will challenge the prospective mother and her medical adviser.

Experimental approaches

Immunotherapy

The demonstration of a powerful GVL effect in CML has renewed interest in the possibility that some form of immunotherapeutic manipulation could be effective in CML. Some evidence suggests that patients vaccinated with peptides corresponding to the junctional region of the BCR-ABL1 protein may generate immune responses that may be of clinical benefit. Other targets for vaccine therapy now under study include Wilms tumour (WT)1 protein, proteinase-3 (PR1) and PRAME, all of which are overexpressed in CML cells. Studies have been initiated in which two vaccines, WT1 and PR1, are combined.

Autografting in chronic phase

Because only a minority of patients are eligible for allogeneic SCT, much interest has focused on the possibility that life may be prolonged and some cures effected by autografting CML patients still in chronic phase. It is possible that the pool of leukaemic stem cells can be substantially reduced by an autograft procedure, and autografting may confer a short-term proliferative advantage on Ph-negative (presumably normal) stem cells. In practice, some patients have achieved temporary Ph-negative haemopoiesis after autografting. Preliminary studies have been reported in which patients have been autografted with Ph-negative stem cells collected from the peripheral blood in the recovery phase following high-dose combination chemotherapy; some such patients achieved durable Ph negativity.

Management of chronic myeloid leukaemia in advanced phase

Accelerated-phase disease

It is difficult to make general statements about the optimal management of patients in accelerated-phase disease as the criteria for this diagnosis are so very varied. Some patients can be managed merely with a minor alteration in their cytotoxic drug regimen. Those who have not been treated previously with imatinib may obtain benefit from the introduction of this agent. Other patients may benefit from splenectomy or regular red cell transfusion. Patients whose disease seems to be moving towards overt blastic transformation may benefit from appropriate cytotoxic drug combinations. Allogeneic SCT should certainly be considered for younger patients if suitable donors can be identified. Reduced-intensity conditioning allografts are probably not indicated, as the efficacy of the GVL effect in advanced-phase CML is not clearly established.

Blastic transformation

Patients in blastic transformation may be treated with combinations of cytotoxic drugs in the hope of prolonging life but cure can no longer be a realistic objective. Conversely, it is not unreasonable to use a relatively innocuous drug such as hydroxycarbamide at higher dosage to restrain blast cell numbers and maintain the patient at home for as long as possible. If the patient has a myeloid transformation, he or she can be treated with drugs that are appropriate to the induction of remission in AML, namely daunorubicin and cytarabine with or without other agents. Blast cell numbers will be reduced substantially in most cases but their numbers usually increase again within 3–6 weeks. Perhaps 20% of patients are restored to a situation resembling chronic-phase disease and this benefit may last for 3–6 months. A very small minority, probably less than 10%, may achieve substantial degrees of Ph-negative haemopoiesis. This is most likely in patients who entered blastic transformation very soon after diagnosis.

Patients in lymphoid transformation may be treated, with a little more optimism, with drugs applicable to the management of adult ALL (e.g. prednisolone, vincristine, daunorubicin and methotrexate with or without L-asparaginase). More than 50% of patients will be restored to 'second' chronic phase, at which point this status can be maintained with daily 6-mercaptopurine and weekly methotrexate. Because leukaemia involving the CNS is so relatively common in responding patients, those who achieve second chronic phase should have neuroprophylaxis with intrathecal methotrexate weekly for six consecutive weeks, but the administration of cranial irradiation is probably excessive. Some patients treated for lymphoid transformation of CML may sustain long periods of apparent 'remission'.

Imatinib may be remarkably effective in controlling the clinical and haematological features of CML in advanced phases in the very short term. In some patients in established myeloid blastic transformation, who received 600 mg daily, massive splenomegaly was entirely reversed and blast cells were eliminated from the blood and marrow, but such responses are almost always short-lived. Thus, imatinib should be incorporated into a programme of therapy that also involves use of conventional cytotoxic drugs and possibly also allogeneic SCT.

Allogeneic SCT using HLA-matched sibling donors can be performed in accelerated phase; the probability of leukaemia-free survival at 5 years is 30–50%. SCT performed in overt blastic transformation is nearly always unsuccessful. The mortality resulting from GVHD is extremely high and the probability of relapse in those who survive the transplant procedure is very considerable. The probability of survival at 5 years is consequently 0–10%. However, patients who can be restored to 'second' chronic phase by combination chemotherapy or by imatinib may have a relatively low risk of transplant-related

mortality and may therefore be considered for allogeneic SCT with a view to eliminating both chronic disease and residual blastic disease provided that a suitable donor can be identified.

Variants of chronic myeloid leukaemia (see also Chapter 28)

Ph-negative chronic myeloid leukaemia

About 6% of patients with haematologically acceptable CML lack the Ph chromosome (see above). About half of these patients have a *BCR-ABL1* gene that is molecularly identical to the *BCR-ABL1* gene of Ph-positive CML; this gene is usually on the morphologically normal chromosome 22q but may occasionally be found on chromosome 9q. Such patients have a clinical course similar to those with Ph-positive disease. Conversely, patients with no *BCR-ABL1* gene frequently have haematological features that are subtly different from Ph-positive disease. They may lack basophilia, lack blast and myelocyte peaks in the leucocyte differential, or show dysplastic features. They are more likely to have some degree of monocytosis. These patients respond poorly to imatinib, interferon alfa or hydroxycarbamide, and overall their survival is inferior to that of Ph-positive patients.

Chronic myelomonocytic leukaemia

This is a rare myeloproliferative condition affecting predominantly elderly men but found at all ages (see Chapter 28). The patient may present with features of anaemia or haemorrhage. The spleen is typically enlarged and thus the clinical picture superficially resembles CML. However, the blood and marrow are quite different. Marrow cells lack a Ph chromosome. Blood monocytosis is prominent and monocyte numbers may be as high as $50 \times 10^9/L$. Thrombocytopenia is common. Basophilia and eosinophilia are absent. Dysplastic changes are usually present in the granulocyte and erythroid series. Consequently, the disease is included in the FAB classification of the myelodysplastic syndromes (see Chapter 28).

Very rare patients have been described with a chronic myelomonocytic leukaemia-like blood picture associated with cytogenetic abnormalities in their leukaemia cells other than t(9;22). Most of these patients have either t(5;12) associated with fusion of the *ETV* and *PDGFRB* genes or t(8;13) associated with fusion of *ZNF198* and *FGFR1* genes, but in fact other fusion partners have also been reported (Table 27.6). *PDGFRB* and *FGFR1* both encode receptor tyrosine kinases and are presumably 'activated' by mechanisms analogous to those that activate the *ABL1* gene in *BCR-ABL1*-positive CML. The t(5;12) and t(8;13) leukaemias are both characterized by prominent eosinophilia but basophilia is usually absent. The t(5;12) leukaemias respond

<i>Cytogenetic abnormality</i>	<i>Fusion protein</i>	<i>Leukaemia</i>
t(9;22)(q34;q11)	BCR-ABL1	CML or acute lymphoblastic leukaemia

CML, chronic myeloid leukaemia; CMML, chronic myelomonocytic leukaemia.

extremely well to low doses of imatinib but the t(8;13) leukaemias do not.

Chronic neutrophilic leukaemia

This is an exceedingly rare disorder that is usually diagnosed incidentally. The patient has a raised blood neutrophil count, often with band forms but without more immature granulocytes, and without basophilia or eosinophilia. The marrow is hypercellular with neutrophil proliferation. The diagnosis is based largely on exclusion of other identifiable causes for the leucocytosis. Marrow cytogenetics are usually normal but clonal abnormality such as +8, +9, del(21q) may be present (see also Chapter 36). Very rare patients have a Ph chromosome and a *BCR-ABL1* fusion gene that codes for an oncoprotein larger than that usually seen in CML, namely 230 kDa (p230^{BCR-ABL1}). These cases have been called neutrophilic CML. Most patients have no symptoms referable to the neutrophilia and no physical signs, although some have minor degrees of splenomegaly. Treatment may not be required. Chronic neutrophilic leukaemia is discussed more fully in Chapter 36.

Chronic eosinophilic leukaemia

Most cases of raised eosinophil counts without identifiable primary cause have in the past been classified as examples of

hyper eosinophilic syndrome (see Chapter 17). However, it has been shown recently that some such patients respond well to treatment with imatinib, and some of these responding patients have evidence of a new fusion gene designated *FIP1L1-PDGFR1*, resulting from an interstitial deletion on chromosome 4 in their myeloid cells (see Table 27.6). In other cases in which no fusion gene has been identified, the number of immature cells in the blood and marrow is increased and the finding of a clonal cytogenetic abnormality in myeloid cells is strong evidence for a diagnosis of eosinophilic leukaemia or chronic eosinophilic leukaemia. It seems likely therefore that many, if not all, cases previously classified as hyper eosinophilic syndrome may turn out to be due to a fusion gene and thus be classified more correctly as examples of eosinophilic leukaemia. Occasional patients with eosinophilic leukaemia progress to blastic transformation in a manner similar to Ph-positive CML. Patients with the *FIP1L1-PDGFR1* fusion gene usually respond well to relatively low doses of imatinib (see Chapters 17 and 36).

Juvenile myelomonocytic leukaemia (see also Chapter 28)

Juvenile myelomonocytic leukaemia (Table 27.7) is a rare disease affecting children under the age of 12 years. It represents about 2% of all childhood leukaemias. It includes a heterogeneous spectrum of myelodysplastic/myeloproliferative diseases

Table 27.7 Diagnostic features of juvenile myelomonocytic leukaemia.

Peripheral blood monocytosis $>1 \times 10^9/L$
Blasts including promonocytes are $<20\%$ of the leucocytes in the blood and $<20\%$ of the nucleated cells in the marrow
No Ph translocation of <i>BCR-ABL1</i> fusion gene
<i>Plus two or more of the following</i>
Haemoglobin F level increased for patient's age
Immature granulocytes present in the blood
White blood cell count $>10^9/L$
Clonal chromosomal abnormality, e.g. monosomy 7
GM-CSF hypersensitivity of myeloid progenitors cultured <i>in vitro</i>

that may be difficult to classify. The cause is unknown but there seems to be a genetic predisposition. There is also an important association with neurofibromatosis type 1 with *NF1* mutations and Noonan syndrome characterized by *PTPN11* mutations. Patients usually have symptoms of anaemia with lymphadenopathy and hepatosplenomegaly. There is a variety of skin rashes. Leucocyte numbers are increased with variable numbers of blast cells in the peripheral blood. Such cells are hypersensitive to GM-CSF *in vitro*. The HbF level may be elevated. The marrow is hypercellular but usually lacks chromosomal abnormalities, although monosomy 7 may be present. The disease responds poorly to standard cytotoxic drugs but patients may benefit from allogeneic SCT. Relapse after SCT is relatively common but relapses may be treated successfully with DLI.

The myelodysplastic syndromes are a heterogeneous group of clonal stem cell disorders characterized by cytopenias due to impaired blood cell production, a hypercellular and dysplastic bone marrow, and an increased risk of leukaemic transformation. They each exhibit various morphological abnormalities of the blood and bone marrow that are indicative of defective haemopoiesis in one or more lineages. A majority of patients with a myelodysplastic syndrome (MDS) are over the age of 60 years, with the median onset occurring in the seventh decade of life. There is a variable clinical course reflecting the diverse pathobiology of the disease, with some patients having a more indolent progression and longer life expectancy while others present with aggressive disease that evolves rapidly into acute myeloid leukaemia (AML). Overall, approximately 40% of patients will transform to AML during the course of their disease. This broad heterogeneity of clinical course, which is reflected by the diversity of morphological features, provides the basis for the classification schemes and prognostic scoring

systems that guide patient management. Recent developments continue to broaden our understanding of the molecular pathogenesis of MDS and provide the rationale for exploring novel therapeutic strategies for patients with this disease.

History

The first description of MDS was in 1900 by Leube who used the term *leukanamie* to describe a patient with severe megaloblastic anaemia that progressed to acute leukaemia. In the 1930s, the term 'refractory anaemia' was coined to refer to a group of patients with a macrocytic anaemia that was unresponsive to iron or other dietary haematinics. While some of these anaemias were apparently attributable to coexisting chronic diseases, others arose *de novo* in otherwise healthy individuals. Bone marrow analysis often revealed a spectrum of abnormalities, notably aberrant maturation of marrow precursors, a variable increase in marrow blasts and, in some patients, the presence of ring sideroblasts. In the 1950s, it was appreciated that AML in the elderly was often preceded by a preleukaemic state characterized by peripheral blood cytopenias and increased numbers of blasts in the marrow. However, the term 'preleukaemia' fell away in the 1970s when it became apparent that many patients never developed leukaemia but died instead of

complications arising directly from the cytopenias. These included anaemia, infectious problems and bleeding complications. In the 1980s, the term 'myelodysplasia', or more properly *myelodysplastic syndromes* to reflect the heterogeneity of the disease, became more widely used. Indeed, it was the recognition that MDS is a heterogeneous entity of related disorders of haemopoiesis that provided the rational basis for devising diagnostic classification schemes that have evolved over the last three decades.

Incidence

According to European registry data, the overall annual incidence rate for MDS in adults is 3–4 per 100 000. However, this rate increases markedly with age, exceeding 30 per 100 000 for individuals over the age of 80 years. Over 60% of patients are over the age of 70 at diagnosis, with males more likely to be diagnosed with MDS than females by a ratio of 1.4:1. MDS in childhood is rare with an annual incidence of 2–3 per million, or less than 5% of paediatric haematological malignancies, tending to occur in children less than 5 years old.

Aetiology

The aetiology of primary MDS remains largely unknown. Various causes have been postulated including ionizing radiation, exposure to benzene, solvents and pesticides, and smoking, but case–control studies are inconsistent. There is some evidence to suggest that polymorphic variation in certain genes may increase susceptibility to MDS, particularly where the role of the encoded protein is to counter environmental insults to the cell. Examples include enzymes responsible for the metabolism of carcinogens, proteins involved with oxidative stress, and the proteins that function to repair damaged DNA.

In approximately 15% of patients, MDS occurs following prior exposure to cytotoxic chemotherapy and/or wide-field radiotherapy, when it is referred to as therapy-related MDS. These cases of MDS typically arise in patients who have received previous cancer treatment or prolonged immunosuppressive therapy. The most commonly implicated cytotoxic agents are the alkylating agents, such as cyclophosphamide, and the topoisomerase II inhibitors, such as etoposide, as well as ionizing radiation and antimetabolite drugs. The latency period between exposure to the mutagenic event and the onset of disease tends to be 5–6 years for the alkylating agents and for radiation but 2–3 years for the topoisomerase II inhibitors, but the range can vary from 1 to 10 years and beyond. The risk increases with age and with prolonged exposure to low-dose chemotherapy, such as prescribed for controlling vasculitic and other autoimmune disorders. The risk of developing therapy-related MDS following autologous transplantation for lymphoma varies widely

between series, with some reports as high as 12%. Most cases develop within 5 years of transplantation, with the major risk factors being the duration and amount of pretransplant chemotherapy and whether the patient received total body irradiation. By comparison with primary MDS, these cases of therapy-related MDS are associated with a higher incidence of trilineage dysplasia, genetic abnormalities, evolution to AML and poor response to treatment.

Classification

FAB classification

In 1982, the French–American–British (FAB) group proposed a morphological classification of MDS that divided the disease entity into five subgroups (Table 28.1). The FAB system was based on the percentage of blasts and ringed sideroblasts in the bone marrow and the presence or absence of a peripheral blood monocytosis. Refractory anaemia (RA) was defined as anaemia with a hypercellular marrow exhibiting dyserythropoiesis but minimal granulocytic or megakaryocytic abnormalities and a marrow blast count of less than 5%. If the proportion of ring sideroblasts exceeded 15% of erythroid cells, the patient was diagnosed as having refractory anaemia with ring sideroblasts (RARS). Patients with increased numbers of marrow blasts were diagnosed as having refractory anaemia with excess blasts (RAEB) if the blast percentage fell between 5 and 19% or refractory anaemia with excess blasts in transformation (RAEBt) if the blast percentage fell between 20 and 29%. A blast percentage

Table 28.1 The FAB classification of MDS.

<i>Subtype</i>	<i>Blood</i>	<i>Bone marrow</i>
Refractory anaemia (RA)	<1% blasts	Dysplasia <5% blasts
Refractory anaemia with ringed sideroblasts (RARS)	<1% blasts	As for RA and >15% ringed sideroblasts
Refractory anaemia with excess blasts (RAEB)	<5% blasts	Dysplasia 5–19% blasts
Refractory anaemia with excess blasts in transformation (RAEBt)	<5% blasts	Dysplasia 20–29% blasts or Auer rods
Chronic myelomonocytic leukaemia (CMML)	>1 × 10 ⁹ /L monocytes	Dysplasia <30% blasts

Table 28.2 The revised WHO classification of MDS.

<i>Subtype</i>	<i>Blood</i>	<i>Bone marrow</i>
Refractory cytopenias with unilineage dysplasia (RCUD) Refractory anaemia (RA) Refractory neutropenia (RN) Refractory thrombocytopenia (RT)	Unicytopenia or bicytopenia	Dysplasia in >10% of cells of one myeloid lineage only <5% blasts <15% ring sideroblasts
Refractory anaemia with ring sideroblasts (RARS)	Anaemia	Erythroid dysplasia only >15% ring sideroblasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenia(s)	Dysplasia in >10% of cells in two or more myeloid lineages <5% blasts <15% ring sideroblasts
Refractory cytopenia with multilineage dysplasia and ring sideroblasts (RCMD-RS)	Cytopenia(s)	Dysplasia in >10% of cells in two or more myeloid lineages <5% blasts >15% ring sideroblasts
Refractory anaemia with excess blasts-1 (RAEB-1)	Cytopenia(s) <5% blasts	Unilineage or multilineage dysplasia 5–9% blasts No Auer rods
Refractory anaemia with excess blasts-2 (RAEB-2)	Cytopenia(s) 5–19% blasts	Unilineage or multilineage dysplasia 10–19% blasts ± Auer rods
Myelodysplastic syndrome – unclassified (MDS-U)	Cytopenia(s) <1% blasts	Dysplasia in <10% of cells in one or more myeloid lineage Cytogenetic abnormality supportive of diagnosis <5% blasts
MDS associated with isolated del(5q)	Anaemia ± thrombocytosis <1% blasts	Prominent megakaryocytes with hypolobated nuclei Isolated del(5q) cytogenetic abnormality <5% blasts

greater than 30% was diagnostic of AML. Finally, chronic myelomonocytic leukaemia (CMML) encompassed all cases where the circulating monocyte count exceeded $1 \times 10^9/L$. However, this subgroup was particularly heterogeneous, comprising a spectrum of patients whose clinical course varied from more typical MDS to more proliferative states characterized by high monocyte counts and splenomegaly.

WHO classification

The World Health Organization (WHO) classification was first published in 2001 and more recently in a revised form in 2008 (Tables 28.2 and 28.3). It emerged through an international collaborative effort to improve the FAB classification by incorporating more recent clinical and genetic data. In particular, it recognized the fact that patients with RA but less than 5% marrow blasts had a poorer clinical prognosis if there was evidence of multilineage dysplasia as opposed to unilineage erythroid dysplasia. New diagnoses of refractory cytopenia with multilineage dysplasia (RCMD) and refractory cytopenia with

Table 28.3 Relative frequency of MDS subtypes.

<i>Subtype of MDS</i>	<i>Approximate percentage of MDS cases</i>	<i>Cytogenetic abnormalities</i>	<i>Median survival (months)</i>
RA	10	25	66
RARS	10	<10	72
RCMD	25	50	33
RCMD-RS	10	50	33
RAEB-1	25	30–40	18
RAEB-2	15	40–50	10
Isolated del(5q)	5	100	116

multilineage dysplasia and ring sideroblasts (RCMD-RS) were introduced for patients with bicytopenia or pancytopenia whose marrows exhibited dysplastic features affecting more than 10% of cells in two or more myeloid lineages. Those patients with pure erythroid dysplasia but otherwise lacking evidence of a

clonal karyotypic abnormality should be reassessed after 6 months to ensure persistence of these features before making a diagnosis of MDS.

A new subgroup recognized by the WHO classification was MDS with isolated deletion of the long arm of chromosome 5, so-called MDS with isolated del(5q). This was deemed to merit its own separate group based on the consistent clinical and morphological features associated with this cytogenetic abnormality (Figure 28.1). It occurs more usually in elderly women and is characterized by marked macrocytic anaemia and thrombocytosis that is commonly referred to as 5q- syndrome. The bone marrow is typically hypercellular with prominent megakaryocytes that are slightly decreased in size with conspicuously non-lobated or hypolobated nuclei. Erythroid activity is often reduced but dysplasia is generally minimal and myeloblasts comprise less than 5% of cells.

The RAEB entity was also refined to include two subgroups based on the precise percentage of blasts present. The term 'blast cell' here refers to myeloblasts, monoblasts, promonocytes and megakaryoblasts, but not erythroblasts. CD34-positive cells, defined immunophenotypically, are not considered to be synonymous with the blast cell. The two subgroups were denoted as RAEB-1 (blast count <5% in peripheral blood and 5–9% in marrow) and RAEB-2 (blast count 5–19% in peripheral blood and 10–19% in marrow), with the latter having a worse prognosis than the former. The morphological finding of Auer rods is also sufficient for making a diagnosis of RAEB-2. The FAB entity RAEBt, defined originally by a blast count in the marrow of over 20%, was abolished in favour of a diagnosis of AML with multilineage dysplasia that commonly yields

poor-risk cytogenetics and refractoriness to chemotherapy. In addition, patients with recurrent leukaemic chromosomal translocations typical of *de novo* AML, namely t(15;17), t(8;21), and inv(16) or t(16;16), are considered to have AML regardless of the percentage of blasts in the bone marrow.

In the revised version of the WHO classification, there has been some refinement of the system to include patients presenting with monocytopenia or bicytopenia and whose bone marrows exhibit dysplasia restricted to a single lineage. This category is denoted refractory cytopenia with unilineage dysplasia (RCUD), which includes RA, refractory neutropenia and refractory thrombocytopenia. There remains the entity of MDS unclassifiable (MDS-U) to denote patients with pancytopenia who fail to fit one of the other categories. Finally, childhood MDS has been incorporated as a separate entity to cover all forms of paediatric myelodysplasia, including a new subgroup of refractory cytopenia of childhood (RCC) to cover cases that fail to meet the criteria for the RAEB subgroups, specifically where there is evidence of dysplasia but fewer than 5% blasts in the marrow.

Finally, the WHO recognizes two additional histological subtypes of MDS, namely hypoplastic MDS and myelofibrotic MDS, each of which account for approximately 10% of cases. Hypoplastic MDS has no independent prognostic significance and may be difficult to distinguish from aplastic anaemia, although both may respond similarly to immunosuppression with antithymocyte globulin. Myelofibrotic MDS, which must be diagnosed from a trephine biopsy that often reveals an excess of blasts, generally follows an aggressive clinical course. Both hypoplastic and myelofibrotic MDS are histological

Figure 28.1 Diagnostic findings in 5q- syndrome demonstrating (a) chromosomal abnormality and (b) typical morphology. Note loss of material from long arm of chromosome 5 and

characteristic marrow features (arrows) including hypolobated megakaryocytes with occasional blasts.

entities based on trephine findings rather than diagnostic entities per se.

Pathogenesis

MDS is a complex disease and its pathogenesis is poorly understood. Many molecular abnormalities have been identified from genetic, cytogenetic and epigenetic analyses of the dysplastic cells and these are discussed in the following section. There are also important functional abnormalities relating to the haemopoietic stem cell, its microenvironmental niche, the propensity for apoptosis and the role of host immunity, all of which are undoubtedly relevant to the emergence and progression of the disease.

MDS: a stem cell disorder

In trying to understand the pathogenesis of MDS, most attention has focused on identifying defects in the haemopoietic stem/progenitor compartment. This largely reflects the fact that MDS is a clonal disorder which commonly affects all three myeloid lineages (i.e. megakaryocytic, erythroid and granulocytic/monocytic). Indeed, the presence of trilineage dysplasia and cytogenetic abnormalities provides irrefutable evidence for a multipotent stem/progenitor cell origin. However, whether this is a true haemopoietic stem cell or a myeloid progenitor cell, or indeed a lineage-committed cell in cases of unilineage dysplasia, is not entirely clear. Irrespective of the cell of origin, it is clear that these cells must be capable of sufficient self-renewal in order to perpetuate the disease. Studies using interphase fluorescence *in situ* hybridization (FISH) analysis have recently yielded some insights into the nature of the target cell in MDS and shown, perhaps unsurprisingly, that the situation is complicated and varies from one type of MDS to another. Thus, in 5q- syndrome, the cytogenetic abnormality can be found in both CD34⁺CD38⁻ myeloid progenitors and CD34⁺CD19⁺ pro-B cells, indicative of a true haemopoietic stem cell origin, while in patients with trisomy 8 the cytogenetic abnormality is often absent from the CD34⁺CD38⁻ fraction suggesting that there might be a different initiating event occurring within the haemopoietic stem cell. If so, then this would support the multistep theory of disease progression by which the dysplastic clone evolves over time through acquisition of additional mutational hits, allowing selection of more proliferative subclones.

If indeed the cell of origin in MDS is an aberrant stem or progenitor cell with the capacity for indefinitely perpetuating the dysplastic clone, then no less important is the bone marrow microenvironment in which the cells live. This is termed the stem cell niche, which comprises the stromal, endosteal and vascular environment responsible for maintaining the stem cell through intimate cell–cell contact. In many regards, the stem

cell niche is a restatement of the ‘seed and soil’ hypothesis proposed many years ago to explain how the cellular microenvironment plays a vital role in the pathogenesis of diseases such as MDS. Interfering with this niche by targeting the molecular interactions between the stem cell and its microenvironment represents a novel therapeutic strategy. Such targets include homing molecules such as CD44 or the ligand–receptor interactions between CXCR4 on stem cells and its chemokine ligand SDF-1 (CXCL12) and between Tie-2 on stem cells and angiopoietin-1 on osteoblasts. Murine models of MDS and xenograft transplantation may shed light on the role of the stem cell niche and how it might be disrupted.

Immunological abnormalities in MDS

Immunological abnormalities are commonly encountered in MDS, suggesting that they may play a role in the aetiology and pathogenesis of the disease. This is particularly apparent in cases of hypoplastic MDS that share a number of features in common with aplastic anaemia, notably clinical presentation with macrocytosis and varying levels of dyserythropoiesis. A hypocellular bone marrow is encountered in approximately 10% of cases of MDS and may indeed represent one end of the MDS spectrum that overlaps biologically with aplastic anaemia. Both disorders are characterized by a clonal expansion of T cells that are antigen driven, and there is also an association with HLA-DR15. While the full pathogenesis of hypoplastic MDS and aplastic anaemia remains unknown in detail, both these entities appear to be characterized by a pathological immune response triggered by abnormal haemopoietic stem cells that results in the autoimmune destruction of normal stem cells and/or their niche. In addition, acquired mutations in the *PIGA* gene characteristic of paroxysmal nocturnal haemoglobinuria (PNH) are also encountered, presumably through expansion of small clones in an otherwise hypoplastic marrow, suggesting that PNH similarly is part of this spectrum. Conversely, dysplastic clones carrying cytogenetic abnormalities can emerge in both aplastic anaemia and PNH after treatment and can evolve into frank MDS over time.

A role for the immune system in the pathogenesis of MDS is also borne out by the higher incidence of autoimmune disease in these patients. T-cell-mediated inhibition of haemopoiesis appears to be an important aspect of this mechanism, with oligoclonal CD8⁺ cytotoxic T cells being found in many patients. However, the antigens produced by the MDS cells that lead to these T-cell responses are largely unknown although, interestingly, WT1-specific CD8⁺ cells are often detectable in the peripheral blood of MDS patients with trisomy 8. Sometimes, the expanded T cells in MDS can themselves become neoplastic, resulting eventually in the diagnosis of T-cell large granular lymphocytic leukaemia that also falls into this overlap spectrum of bone marrow failure states. Recently, analysis of self-reactive T cells in MDS has focused on the regulatory T cells that play

a central role in maintaining immune tolerance. This has revealed a correlation between expanded numbers of CD4⁺CD25^{high}FoxP3⁺ regulatory T cells and more aggressive forms of MDS as defined by their blast cell percentage, possibly due to suppression of host antitumour mechanisms. However, the most persuasive evidence for immune dysregulation in MDS arguably comes from the recognition that some forms of the disease, notably hypocellular MDS, like aplastic anaemia can respond well to immunosuppressive therapy with antithymocyte globulin and/or ciclosporin resulting in durable haematological recovery and abrogation of T-cell clones.

Apoptosis in MDS

One of the defining, albeit paradoxical, features of MDS is the presence of cytopenias despite a typically hypercellular bone marrow. For those patients undergoing leukaemic transformation, the cytopenias arise due to maturation block of the malignant cells. However, in cases of MDS that lack an excess of blasts, the cytopenias are a reflection of the ineffective haemopoiesis that is a hallmark of the disease. The mechanism appears to be one of increased apoptosis of haemopoietic precursors in the marrow, as demonstrated using *in situ* end-labelling of fragmented DNA to reveal cells undergoing programmed cell death. Apoptosis is more prominent in early MDS, such as RA and RARS, than in advanced MDS with excess myeloblasts. Indeed, for the blasts to overcome this apoptotic tendency indicates that they have lost their G₂/M checkpoint control that appears to be a necessary requirement for progression to leukaemia. This progression is accompanied by a change in favour of pro-apoptotic proteins such as c-Myc in CD34-positive precursors at diagnosis to anti-apoptotic proteins such as Bcl-2 in leukaemic blasts at time of transformation. Moreover, patients with higher rates of apoptosis have a considerably better overall survival than patients with lower rates of apoptosis, likely reflecting the clonal evolution of the MDS towards AML. This finding is corroborated by flow cytometry analysis of MDS marrow samples to measure relative levels of apoptosis (by annexin V staining) versus proliferation (by Ki67) that demonstrates a shift from apoptosis to proliferation as the disease progresses. These findings underpin the theory that apoptosis plays a major role in the pathophysiology of MDS.

Apoptosis can be initiated by various cytokines, notably tumour necrosis factor (TNF)- α , Fas-ligand, and TNF-related apoptosis inducing ligand (TRAIL). Indeed, all these cytokines and related other ones are typically upregulated in the marrow in MDS, serving as negative regulators of haemopoiesis. Apoptosis can also be triggered by cytotoxic T cells and by signals from marrow stromal cells, probably via activation of similar pathways, and intrinsically following DNA damage and mitochondrial dysfunction that leads in turn to cytochrome *c* release and caspase activation. This balance of pro-apoptotic to anti-apoptotic signals swings in favour of the latter as the MDS

evolves towards AML, with upregulation of NF- κ B, altered expression of adapter molecules such as Flice inhibitory protein (FLIP), and enhanced activity of members of the BCL-2 and IAP (inhibitors of apoptosis protein) families. This is borne out by a murine model of MDS/AML in which BCL-2 is conditionally overexpressed alongside an activating *NRAS* mutant gene resulting in a disease entity reminiscent of MDS. In this model, using a stronger promoter to drive BCL-2 gene expression leads to more rapid AML progression, providing experimental insight into the process of leukaemogenesis.

Molecular basis of MDS

Despite the fact that the molecular basis of MDS is poorly understood, recent discoveries have provided important insights into the pathogenesis of the disease. MDS is a preleukaemic disorder characterized by impaired cellular differentiation that has the potential to transform to AML if this abnormality is coupled to enhanced survival and proliferation. Conversely, the myeloproliferative syndromes, including the myelodysplastic–myeloproliferative overlap, are characterized by enhanced survival and proliferation that has the potential to transform to AML if coupled to a block in differentiation. Thus, conceptually at least, both MDS and myeloproliferative disorders represent different routes to acquiring the multiple hits necessary for development of AML.

Cytogenetic abnormalities

Cytogenetic analysis of marrow samples plays an important role in the evaluation of MDS with regard to establishing clonality and determining prognosis. Clonal abnormalities are observed in approximately half of all primary MDS cases and in up to 90% of cases of secondary therapy-related MDS (Table 28.4). Defining such abnormalities and their clonal evolution over

Table 28.4 Cytogenetic abnormalities in MDS with approximate frequency.

Abnormality	Primary MDS (%)	Therapy-related MDS (%)
Complex karyotype	15–20	80–90
del(5q)/monosomy 5	15–20	30–40
del(7q)/monosomy 7	10–15	40–50
Trisomy 8	10–15	10–15
del(20q)	5–10	–
del(17p)	<5	–
del(13q)	<5	–
del(11q)	<5	–
del(12p)	<5	–

time has contributed to our broader understanding of the mechanistic basis of MDS and how it transforms into AML. However, apart from the 5q⁻ syndrome, cytogenetic abnormalities are not specific for particular clinico-morphological subtypes of MDS. Generally, the loss or gain of genetic material, through chromosomal deletions, unbalanced translocations and aneuploidy, is more characteristic of MDS than AML. Conversely, balanced translocations that are typical of *de novo* AML are rarely seen in MDS.

The common chromosomal abnormalities found in MDS include loss of Y, 5q⁻ or monosomy 5, 7q⁻ or monosomy 7, trisomy 8, 20q⁻, abnormalities of 11q23, and deletions of 17p, 12p, 13q and 11q among others. None of these is specific for MDS as they can also occur in AML and myeloproliferative states. Cytogenetic analysis is required for calculating a risk score according to established prognostic scoring systems, with normal, -Y, del(5q) and del(20q) recognized as good-risk karyotypes while chromosome 7 anomalies, complex (more than three abnormalities) and very complex (more than five abnormalities) are recognized as poor-risk karyotypes. For the three chromosomes (5, 7 and 20) that are commonly wholly or partially lost in MDS, it remains unknown whether the dysplastic phenotype arises due to a haploinsufficient dosage reduction of one or more genes or the complete functional loss of a key tumour-suppressor gene. Similarly, for trisomy 8, it is not clear if this simply causes a dosage increase of a number of normal genes or the gain of function of a mutant oncogene.

5q⁻ syndrome

The 5q⁻ syndrome was originally described in 1974 by Van den Berghe and was the first entity within the group of refractory cytopenias to be associated with a consistent chromosomal aberration, namely the interstitial deletion of 5q. The syndrome is associated with macrocytic anaemia, thrombocytosis, unilobular megakaryocytes and a low propensity to develop into AML. It is more common in females than males. However, not all patients with 5q abnormalities have this syndrome since del(5q), and indeed monosomy 5, are also found in more typical cases of MDS, frequently as part of a complex karyotype with other cytogenetic abnormalities.

The 5q⁻ syndrome, with del(5q) as the sole cytogenetic abnormality, has provided an opportunity to define precisely the molecular defect(s) underlying the pathogenesis of this disease. The search for a minimal common deleted region on the long arm of chromosome 5 has spanned three decades and relied on physical mapping methods. Using FISH analysis, this region has been narrowed down to a 1.5-Mb interval located on 5q32. The advent of high-resolution single-nucleotide polymorphism (SNP) arrays has provided greater refinement of the limits of this deleted region. The search for a tumour-suppressor gene located within this region has involved many different approaches over recent years and resulted in numer-

ous candidate genes. However, it was not known whether 5q⁻ syndrome required the loss of heterozygosity for a particular gene locus or could arise through haploinsufficiency alone of a particular gene.

The best candidate gene for 5q⁻ syndrome was recently identified by way of a functional screening study that used RNA interference (RNAi) to systematically 'knock down' expression of 40 genes in the 5q32 region in normal CD34-positive cells. These cells were cultured in conditions promoting either erythroid or megakaryocytic differentiation. Partial RNAi knock-down of the ribosomal protein S14 gene (*RPS14*) was found to cause a block in erythroid differentiation but preservation of megakaryocytic differentiation that recapitulates the phenotype of 5q⁻ syndrome. Moreover, *RPS14* was able to rescue the 5q⁻ phenotype by re-expression in CD34-positive cells from 5q⁻ syndrome patients. If this result is confirmed, then there would appear to be a remarkable similarity between 5q⁻ syndrome and the congenital bone marrow disorders of Diamond-Blackfan anaemia and Schwachman-Diamond syndrome that arise due to inherited abnormalities of related ribosomal protein genes, namely *RPS19* and *SBDS* respectively. However, while haploinsufficiency of *RPS14* may indeed explain the key clinical features of the 5q⁻ phenotype, this hypothesis fails to account for the growth advantage of the 5q⁻ clone and therefore may not represent the complete genetic pathogenesis of the disease. Nonetheless, with the discovery that the immunomodulatory drug lenalidomide is an effective treatment in 5q⁻ syndrome, studies are ongoing to see whether this drug works by correcting the ribosomal defect caused by deficiency of *RPS14*.

Chromosome 7 abnormalities

Monosomy 7 is the second most common chromosomal abnormality, occurring in up to 20% of MDS cases overall. It can present as a total or partial monosomy and may be an isolated abnormality or part of a complex karyotype. Clinically, monosomy 7 MDS is characterized by a lower median age of affected patients compared with deletions of 5q, severe refractory cytopenias, and tendency to life-threatening infections. Monosomy 7 confers a poor prognosis that ranges from 14 months as an isolated abnormality down to 7 months if the karyotype is complex and involves other abnormalities. At least two distinct regions of common deletions have been identified: the band 7q22 and the more telomeric regions of 7q31-32 and 7q36. This suggests the presence of more than one gene having tumour-suppressive functions located within these disparate regions of 7q. Whether the monosomy 7 MDS phenotype arises due to functional deletion through loss of heterozygosity of a particular gene locus or simply due to genetic haploinsufficiency is not known. There are a number of candidate genes within this region such as *MLL5*, a member of the Hox family, and genes involved with DNA repair. In addition, microRNAs involved in regulation of signalling pathways have been implicated as have associated mutations in *RAS* and *AML1* that commonly coexist

with monosomy 7. However, the precise mechanism relating monosomy 7 to MDS remains obscure.

Genetic abnormalities in MDS

Recurrent abnormalities in a large number of genes have been identified in MDS and continue to provide important insights into the disease. These include genes coding for cell surface molecules, signal transduction proteins, transcriptional factors, epigenetic modifiers, protein degradation pathways and many genes of unknown function (Table 28.5).

Mutations of the *AML1* gene (also known as *RUNX1*) have recently been recognized to occur in MDS, particularly where it is treatment-related or radiation-induced. In contrast with the mutations of *AML1* found in M0 AML that are often biallelic, those found in MDS are generally monoallelic and result in *AML1* haploinsufficiency rather than a dominant-negative protein. Moreover, while the mutations in AML tend to occur in the Runt domain and affect DNA binding, mutations in MDS occur more frequently in the C-terminus of the protein causing truncation and loss of its transactivating domain. Interestingly, individuals who inherit one abnormal copy of the *AML1* gene commonly exhibit congenital thrombocytopenia with a propensity to develop AML, suggesting the gene might be acting as a tumour suppressor in this setting.

The *AML1* gene is also involved in one of the few examples of a recurrent MDS-associated chromosomal lesion to be molecularly deciphered, namely the t(3;21) translocation found in some cases of MDS (and in blast crisis in chronic myeloid leukaemia). This translocation rearranges the *AML1* and *EVII* (also known as *MDS1*) genes, fusing the N-terminus of *AML1* with a small portion of *MDS1* and nearly all of *EVI-1* and resulting in a fusion protein that appears to deregulate normal haemopoiesis. *EVI-1* is a zinc finger protein that when overexpressed can block erythroid differentiation and promote transformation. Translocations that involve only chromosome 3, namely t(3;3) and inv(3), both cause overexpression of *EVII* and are associated with MDS and AML with abnormal megakaryocytes.

Table 28.5 Recurrent mutated genes in MDS according to their major function.

<i>Gene function</i>	<i>Abnormal gene</i>
Cell surface receptor	<i>KIT, FMS, PDGFRB, GCSFR, MPL, FLT3</i>
Signal transduction	<i>NRAS, JAK2</i>
Transcription factor	<i>AML1, GATA-1, PU.1, CEBPA, TP53</i>
Epigenetic factor	<i>MLL, ATRX</i>
Protein degradation	<i>CBL</i>
Unknown function	<i>TET2</i>

Another recurrent cytogenetic abnormality in MDS that is associated with characteristic morphological features is isolated del(20q), which typically involves erythroid and megakaryocytic lineages. Deletions of 20q generally carry a favourable prognosis although the implicated gene, which is likely to reside within the commonly deleted region 20q12, remains unknown.

Activating mutations of *RAS*, usually involving *NRAS*, are found in up to 20% of cases of MDS, especially CMML, and are often associated with *AML1* point mutations. Other genes occasionally found to harbour mutations in MDS include those encoding various cell-surface receptors with kinase activity such as *FMS* (now called *CSF1R*), *KIT*, *FLT3*, *PDGFRB* and *GCSFR*, and those encoding transcription factors such as *GATA1*, *PU.1* (*SPI1*), *CEBPA*, *MLL* and *TP53*. Mutations of the *ATRX* gene located on the X chromosome are associated with the rare phenomenon of acquired HbH disease, also termed acquired α thalassaemia in MDS, in which the dysplastic red cells are markedly microcytic and hypochromic with HbH inclusions.

Recently, the V617F mutation of the *JAK2* gene has been demonstrated in up to 50% of patients with the overlap condition of RARS with thrombocytosis (denoted RARS-T) that exists as a provisional new entity in the updated WHO classification. This mutation, which is more commonly associated with the myeloproliferative disorders, causes constitutive activation of the *JAK2* protein and downstream signalling. Similarly, mutations of the *MPL* gene, which are described in essential thrombocythaemia, have also been identified in patients with RARS-T.

A number of state-of-the-art techniques are increasingly being used to further refine our understanding of the molecular pathogenesis of MDS. These include gene expression profiling to identify expressed transcripts and comparative genomic hybridization (CGH) to identify small regions of DNA gain or loss. More recently, high-resolution SNP genotyping microarrays have been used to detect cytogenetically cryptic genomic aberrations (Figure 28.2). These SNP microarrays use chromosomal markers to identify regions of loss of heterozygosity, which occurs either through genetic deletion or functionally via copy-neutral uniparental disomy (UPD), leading to regions of hemizygosity or homozygosity respectively. One study of 119 low-risk MDS patients revealed that UPD occurs in 46% of cases, while deletions and amplifications occur in 10% and 8% of cases respectively. A number of state-of-the-art techniques are increasingly being used to further refine our understanding of the molecular pathogenesis of MDS. These include gene expression profiling using cDNA microarray analysis to identify expressed transcripts, and comparative genomic hybridization (CGH) to identify small regions of DNA gain or loss. More recently, high-resolution single-nucleotide polymorphism (SNP) genotyping microarrays have been used to detect cytogenetically cryptic genomic aberrations (Figure 2). These SNP microarrays use chromosomal markers to identify regions of

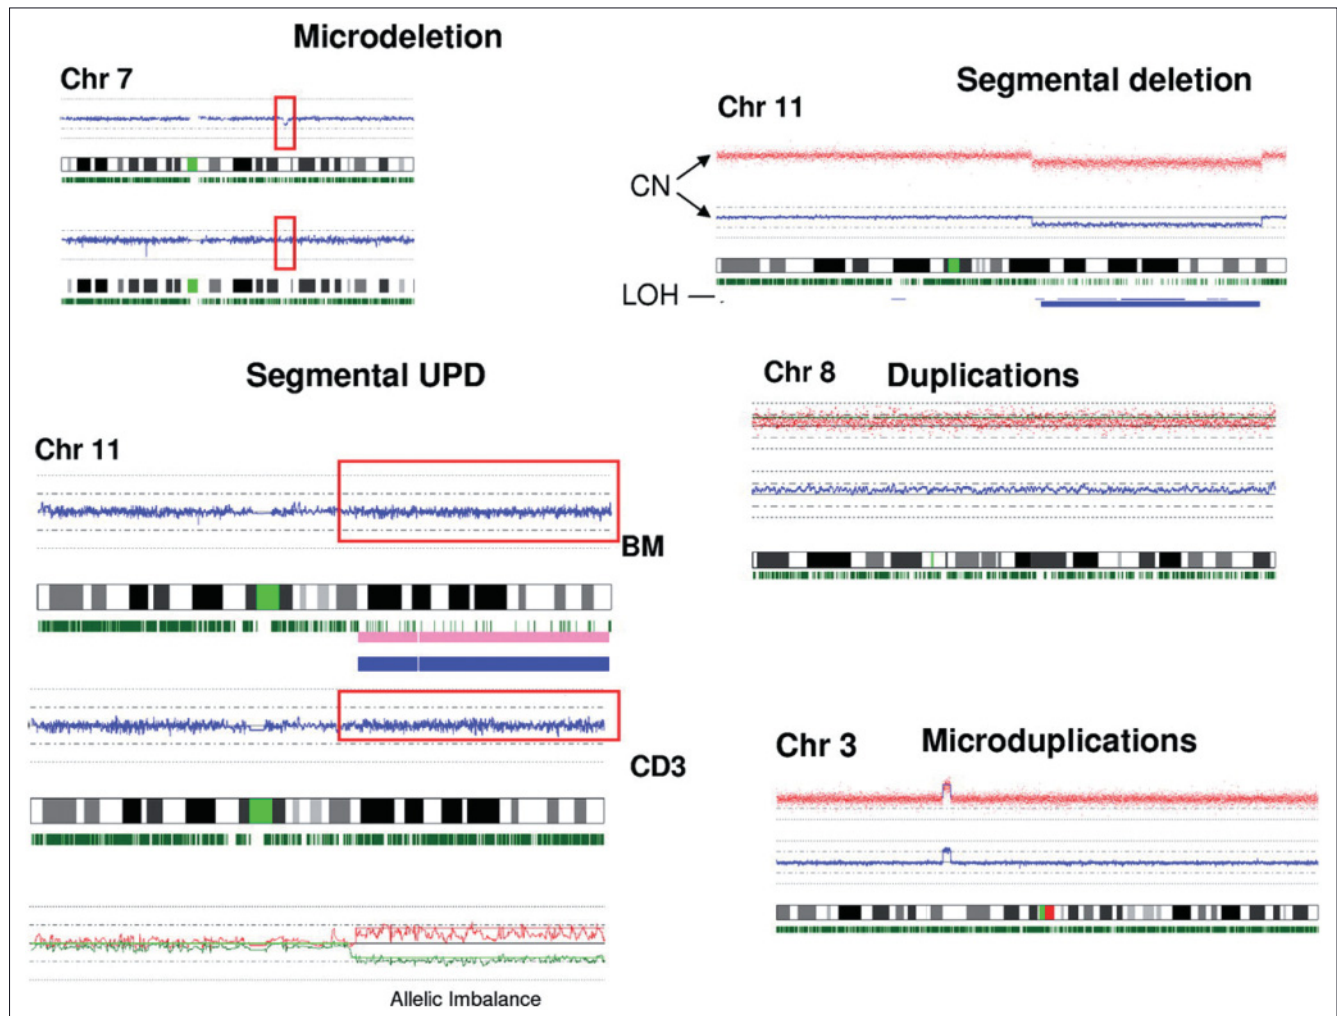

Figure 28.2 Representative examples of genomic mutations identified in MDS patients using single-nucleotide polymorphism analyses with high-density microarrays. BM denotes bone

marrow cells and CD3 denotes T lymphocytes. CN, copy number; LOH, loss of heterozygosity; UPD, uniparental disomy. (From Maciejewski & Mufti 2008 with permission.)

loss of heterozygosity, which occurs either through genetic deletion or functionally via copy-neutral uniparental disomy (UPD), leading to regions of hemizygosity or homozygosity, respectively. One study of 119 low-risk MDS patients revealed that UPD occurs in 46% of cases, whereas deletions and amplifications occur in 10% and 8% of cases, respectively. This approach has been used to identify a number of recurrent mutations involving various genes not previously implicated in the pathogenesis of MDS. Most notable amongst these is the *TET2* gene which is located within a region of UPD at chromosomal position 4q24 and is a candidate tumour suppressor gene mutated in 19% of patients with MDS. Importantly, *TET2* has also been shown to be defective in patients with other myeloid malignancies, including CMML (22%), secondary AML (24%) and myeloproliferative disorders (12%). *TET2* shares sequence homology with *TET1*, a fusion partner of the MLL oncogene in

AML that has recently been shown to catalyse the conversion of 5-methylcytosine to 5-hydroxymethylcytosine. However, unlike *TET1*, *TET2* lacks a DNA binding domain and its function remains largely unknown, although it is clearly implicated in the control of normal myelopoiesis. Of particular interest is the fact that the *TET2* mutation appears to be an early genetic lesion identifiable in haematopoietic stem cells that is generally acquired before other mutations, such as the *JAK2* V617F mutation, as evidenced by the fact that *TET2*+ve/*JAK2*+ve myeloproliferative states frequently transform into *TET2*+ve/*JAK2*-ve AML.

The *CBL* gene at chromosomal position 11q23.3 is another candidate tumour suppressor gene recently implicated in MDS. It was identified through demonstration of a recurrent UPD at 11q in 12 of 301 patients (4%) with various myeloid malignancies, including MDS/MPN, CMML and related disorders. Of

these, seven patients were found to carry mutations of the *c-CBL* gene, which functions as an E3 ubiquitin ligase involved with ubiquitination and degradation of active protein tyrosine kinases. Interestingly, mutations involving *CBL* appear to be particularly common in myeloproliferative states, showing features of transformation. Finally, one additional gene, the polycomb gene *ASXL1*, has also been shown to be mutated in 4 out of 35 patients with MDS (11%) and 17 out of 39 patients with CMML (43%) in one study and 2 out of 20 patients with RARS-T (10%) in another study. Although the specific function of *ASXL1* remains largely unknown, it appears to be a chromatin-binding protein important for regulating gene expression through epigenetic transcriptional control.

Epigenetic abnormalities

Epigenetics refers to various molecular modifications of chromatin that, without altering the DNA sequence, play a critical role in genomic regulation and control of gene expression. There are two important epigenetic modifications relevant to MDS, namely DNA methylation and histone modification. DNA methylation refers to the addition of a methyl group to cytosine, which can occur wherever this is followed by a guanine within a CpG dinucleotide pair. Such CpG pairs are under-represented in the human genome but cluster together within so-called CpG islands that tend to be located in the proximity of gene promoter regions. In normal cells, these CpG islands are typically unmethylated, allowing genes to be expressed. However, if a CpG island is methylated, then transcriptional activity at the promoter is impeded and the gene becomes silenced. Thus, aberrant promoter methylation leads to inactivation of the gene, thereby providing an alternative mechanism whereby tumour-suppressor genes can be functionally deleted. This is the paradigm that underpins the rationale for using hypomethylating agents as a novel therapeutic strategy in MDS.

The other major epigenetic control mechanism that works in conjunction with DNA methylation is histone modification. Histones form the chromatin scaffold and closely regulate whether the DNA exists locally in a repressed or permissive state. Biochemical alterations to the tails of the histone molecules influence the degree of compaction of the nucleosomes and hence the level of transcriptional activity of nearby genes. Unlike DNA methylation, which is largely irreversible, histone modifications are more dynamic, particularly acetylation/deacetylation of lysine residues of histones H3 and H4. Moreover, there is a close and cooperative interplay between these two epigenetic control mechanisms that together can render a gene permanently silenced. The significance of this is that combination epigenetic therapies that comprise a hypomethylating agent with a histone deacetylase inhibitor may be more effective than single agents in reawakening silenced tumour-suppressor genes.

Diagnosis

Clinical features

Approximately 20% of cases of MDS are detected incidentally in patients who have a routine blood count taken for unrelated reasons that reveals unexpected cytopenia or dysplasia. The majority of the remainder present with symptoms and signs of bone marrow failure, notably fatigue due to anaemia in up to 80% and infections or bleeding in up to 20%. Among the most common infections are bacterial pneumonias and skin abscesses, occurring particularly in patients with a neutrophil count of less than $1 \times 10^9/L$. Features of lymphadenopathy, splenomegaly and hepatomegaly are rarely found. There is a recognized association between MDS and several rare disorders that seem to have an immunological basis, including neutrophilic dermatosis (Sweet syndrome), pyoderma gangrenosum and cutaneous vasculitis.

Blood count

Anaemia is the predominant finding in most patients at presentation, occurring as pancytopenia in 30–50% or in combination with neutropenia or thrombocytopenia in 20–30%. Isolated neutropenia or thrombocytopenia is rarer, accounting for 5–10% of presentations. Occasionally, the blood count is normal and the diagnosis is suggested by abnormal parameters generated by automated cell counters that reflect aberrant morphology, such as the erythrocyte distribution width that can itself become a useful marker of MDS.

Peripheral blood morphology

Morphological abnormalities in the peripheral blood, while generally non-specific for MDS, can nonetheless be very helpful in arriving at a diagnosis. There is commonly marked anisocytosis/poikilocytosis and the red cells tend to be macrocytic and oval-shaped. In sideroblastic anaemia, the blood film is classically dimorphic, containing a minority population of hypochromic microcytic cells; Pappenheimer bodies, which can be confirmed with an iron stain, and basophilic stippling may also be seen. Microcytosis is present in the rare variant of acquired HbH disease. Some patients have occasional circulating erythroblasts in the peripheral blood that are often dysplastic or megaloblastic.

Neutropenia is common and neutrophils often exhibit reduced granulation and the acquired Pelger–Huët anomaly. Hypogranular neutrophils arise due to defective formation of secondary granules, with the agranular ones being highly specific for MDS. The pseudo-Pelger–Huët neutrophil is one that exhibits dense clumping of the chromatin and hypolobulation of the nucleus that is classically bilobed (resembling a pair of spectacles) or even non-lobed (resembling a dumb-bell). This

acquired abnormality, which resembles the inherited Pelger–Huët anomaly, is sufficiently characteristic of MDS to be almost pathognomonic.

Monocytosis is present, by definition, in CMML and monocytes can often be morphologically abnormal. While often reduced in MDS, basophils and eosinophils might also be raised in the proliferative overlap syndromes. Circulating blasts may be found in all categories of MDS but if present in significant numbers are more usually indicative of RAEB. Finally, the platelet count is often reduced and platelets may show dysplasia such as hypogranulated and giant forms.

Bone marrow morphology

The ability to diagnosis MDS according to the presence of dysplastic morphology is critically dependent on optimal staining of the marrow slides with a Romanowsky stain (Figure 28.3). Ideally, only a small volume of marrow should be aspirated to avoid excess dilution with peripheral blood. There is often considerable interobserver variation, particularly where the dyserythropoiesis or neutrophil hypogranularity is subtle, but better consistency among observers in identifying frankly abnormal cells such as ring sideroblasts, pseudo-Pelger–Huët cells, micromegakaryocytes and increased blasts.

The bone marrow is hypercellular in the majority of patients, due to erythroid and/or granulocytic hyperplasia, but can be normocellular or, in 10–20% of cases, hypocellular. Dysplastic features can be recognized in any number of lineages and a minimum of 500 cells should be scrutinized to gain an accurate and representative differential of cells present.

Erythropoiesis is usually normoblastic but may exhibit megakaryoblastic-like features. In patients with sideroblastic anaemia, the erythroblasts are often poorly haemoglobinized or show cytoplasmic vacuolation. The list of dysplastic features is considerable and may include binuclearity and multinuclearity, internuclear bridging, nuclear budding and fragmentation, increased pyknosis, and basophilic stippling. Cytochemical iron staining should be performed in all cases of suspected MDS in order to quantify iron stores and to detect and enumerate ring sideroblasts and pathological non-ring forms.

Granulopoiesis is usually hyperplastic. Dysplasia of the granulocytic series is often quite difficult to appreciate and includes defective granulation and nuclear lobulation. There may be prominent basophilic and eosinophilic differentiation and increased numbers of blasts may be present.

Megakaryopoiesis is commonly dysplastic, of which the most specific feature is the micromegakaryocyte. This is typically the size of a myeloblast with an ill-defined or blebbed periphery and a single monolobed nucleus. Other megakaryocytes may exhibit hypolobulation or contain multiple disparate nuclei due to aberrant maturation. In the acquired 5q– syndrome, there are often increased numbers of megakaryocytes that are variably sized and contain a large non-lobulated nucleus.

Bone marrow histology

Histological analysis of the bone marrow can yield diagnostic information not apparent by morphology, particularly regarding architectural disorder, and should be undertaken routinely whenever a biopsy is being taken in suspected cases of MDS. The majority of patients with MDS will have hypercellular marrows but a significant minority will have a hypocellular marrow. Cytological evidence of dysplasia can be found in all lineages but is most easily detected in the erythroid precursors. Abnormal clustering of megakaryocytes is often seen as are micromegakaryocytes that can be more easily detected by immunohistochemical staining. Reticulin can be modestly increased. Abnormal localization of immature precursors is a much-debated finding that refers to the clustering of promyelocytes and myelocytes in an intertrabecular position. Their presence tends to correlate with the blast percentage in MDS and as such they may signify propensity to leukaemic transformation, but this finding is inconsistent.

Other investigations

Immunophenotyping does not play a major role in the diagnosis of MDS and need not be routinely performed. However, various abnormalities are sometimes discernible, notably low side-scatter, reduced expression of normal myeloid markers, and aberrant patterns of expression of other markers. CD34 expression, and to a lesser degree CD117, often correlates with the blast percentage, while coexpression of CD7 is significant for conferring a worse prognosis.

There are a number of further laboratory tests that are commonly abnormal in MDS but which are rarely indicated for purposes of diagnosis. These include the following.

- Granulocyte function tests to demonstrate defective phagocytosis, cell killing and motility.
- Platelet function tests to demonstrate reduced aggregation and prolonged bleeding time.
- Haemoglobin electrophoresis, or HPLC, to detect HbH (raised in acquired HbH disease) and HbF (raised in juvenile myelomonocytic leukaemia).
- Ferrokinetics to assess erythropoiesis.
- Autoantibodies (found in up to 50% of CMML patients).
- Serum protein electrophoresis to assess immunoglobulins and detect paraprotein.
- Lymphocyte populations to detect altered numbers of T-cell subsets and natural killer cells.

Natural history and prognostic factors

Natural history

The natural history of MDS is highly variable due to the considerable biological heterogeneity of the disease. The median

survival of adult patients with primary MDS is approximately 20 months but this varies from only a few months for patients with high-risk disease up to nearly 12 years for patients with low-risk disease. At one end of the MDS spectrum are patients whose disease rapidly transforms into AML, while at the other end are patients with modest levels of anaemia not requiring transfusion support. Many factors influence the clinical course of the disease, including the subtype of MDS, the levels of dysplasia and blast percentage, and the number of cytopenias present. The biology of the disease, which dictates the rates of clonal expansion and leukaemic evolution, clearly involves genetic and epigenetic abnormalities, although these are difficult to identify in individual patients.

Cytogenetic analysis represents the most important investigation at diagnosis, both for understanding the biology of the disease and for making prognostic recommendations for the patient. Indeed it is possible to construct a prognostic scheme in MDS based solely on the cytogenetic abnormalities. This was recently carried out by the German–Austrian MDS Study Group using data generated from 1202 patients treated with supportive care only. Their analysis was based on a total of 24 different karyotypic abnormalities, ranked according to the median survival of patients with each abnormality, that were then grouped into four risk subgroups. The most common cytogenetic abnormality in each of the four karyotypic subgroups, along with their respective median survival, were as follows: 5q– in good-risk group (55 months); trisomy 8 in intermediate I risk group (29 months); chromosome 7 anomalies in intermediate II risk group (15 months); and complex (more than three anomalies) in poor-risk group (8 months). However, normal karyotype accounted for just over 50% of all the cases

studied and these fell collectively within the good-risk group. For these patients, alternative techniques will be required to further delineate the genetic abnormalities, for instance high-resolution SNP microarrays. One such study of low-risk MDS patients with normal karyotypes identified UPD in 46% of cases analysed compared with deletions in 10%, both of which result in cryptic loss of heterozygosity and potential predisposition to development of MDS. In the future new analytical tools, including matrix CGH, microarray gene expression analyses, proteomics and methylation profiling, will no doubt add further to our understanding of the pathogenesis of MDS, identification of therapeutic targets, and individualization of prognosis and therapy. Until such time, we are left with a long list of clinical and laboratory criteria by which to determine prognosis and optimal management for an individual diagnosed with MDS.

International Prognostic Scoring System

The International Prognostic Scoring System (IPSS) was published in 1997 by an International MDS Risk Analysis Workshop (Tables 28.6–28.8). It was based on the retrospective evaluation of a clinical, morphological and cytogenetic dataset obtained from 816 patients with MDS that was compiled from seven large risk-based studies. These patients were either untreated or had received only short courses of low-dose oral chemotherapy or haemopoietic growth factors. The study included those patients diagnosed with MDS according to the FAB criteria, except for those patients with proliferative CMML defined as having a white cell count greater than $12 \times 10^9/L$. A global analysis was performed and critical prognostic variables were evaluated to generate a consensus prognostic scheme, particularly using more refined bone marrow cytogenetic information. In addition to patient age, univariate analysis indicated that the major variables having an impact on disease outcome for evolu-

Table 28.6 International Prognostic Scoring System (IPSS).

Variable	Score value				
	0	0.5	1.0	1.5	2.0
Bone marrow blasts (%)	<5	5–10	–	11–20	21–30
Karyotype*	Good	Intermediate	Poor	–	–
Cytopenias†	0/1	2/3	–	–	–

*Karyotype status: good category includes normal, –Y, del(5q), del(20q); poor category includes complex (three or more) abnormalities, chromosome 7 anomalies; intermediate category includes other abnormalities.

†Cytopenias defined as haemoglobin <10 g/dL, neutrophils < $1.8 \times 10^9/L$ and platelets < $100 \times 10^9/L$.

Table 28.7 Prognostic outcomes of MDS patients according to IPSS risk score.

Outcome measure	IPSS risk category			
	Low	Intermediate-1	Intermediate-2	High
Combined score	0	0.5–1.0	1.5–2.0	2.5
Leukaemic death	19%	30%	33%	45%
Median time to AML (years)	9.4	3.3	1.1	0.2
Median survival (years)	5.7	3.5	1.2	0.4

The median survival for each of these groups is stratified according to age at diagnosis but broadly ranges from 4 to 12 years for low risk, 2 to 4 years for intermediate-1, 1 to 2 years for intermediate-2, and to <1 year for high risk across all age groups.

Table 28.8 Median survival of MDS patients according to IPSS risk score and age.

Risk group	IPSS score	Median survival (years)			
		<60 years old	>60 years old	<70 years old	>70 years old
Low	0	11.8	4.8	9	3.9
Intermediate-1	0.5–1.0	5.2	2.7	4.4	2.4
Intermediate-2	1.5–2.0	1.8	1.1	1.3	1.2
High	2.5	0.3	0.5	0.4	0.4

tion to AML were cytogenetic abnormalities, percentage of myeloblasts in the marrow, and number of cytopenias.

The IPSS generates an overall score using three criteria, namely blast percentage, number of cytopenias and karyotype risk. Based on this score, patients are allocated into one of four risk groups, namely low, intermediate-1, intermediate-2 or high. The median survival for each of these groups is stratified according to age at diagnosis, but broadly ranges from 5–7 years for low risk, 3–5 years for intermediate-1, 1–2 years for intermediate-2, to 4–8 months for high risk. The value of such a prognostic scoring system is clearly dependent on the type of treatment that a patient receives. The IPSS has been validated in patients undergoing allogeneic transplantation, but the outcome of patients receiving intensive chemotherapy is more dependent on cytogenetic data than the percentage of marrow blasts and the IPSS appears less helpful in this setting. More recently, an alternative prognostic scoring system based on the WHO classification scheme has been promoted to address some of the shortcomings of the IPSS.

WHO Classification-based Prognostic Scoring System

One of the major shortcomings of the IPSS is the fact that the system was designed to be used only at diagnosis and may not be suitable for serial assessment of patients whose disease can evolve over time. In addition, the IPSS pre-dated the revised classification of MDS according to WHO criteria and therefore

incorporated some entities, notably CMML, that are now categorized as myeloproliferative overlap disorders. Finally, the IPSS fails to reflect whether or not the patient is dependent on transfusional support, which along with cytogenetics is one of the main prognostic factors affecting survival. For these reasons, the WHO Classification-based Prognostic Scoring System (WPSS) was developed based on the retrospective analysis of 467 Italian patients and validated against 620 German patients (Tables 28.9 and 28.10). All patients had a diagnosis of MDS according to one of the WHO subgroups, but CMML and other overlap disorders were excluded. Analysis of the data showed that the most significant variables for the model were WHO subgroup, the cytogenetic abnormalities and the transfusional requirements of the patient (Figure 28.4). These were incorporated into a scoring system that allowed stratification into five distinct risk groups showing significantly different overall survival and probability of leukaemic progression (Figure 28.5). The median survival (in months) of these five groups was 136 (very low), 63 (low), 44 (intermediate), 19 (high) and 8 (very high). The likelihood of developing leukaemia ranged from a 10-year probability of 7% in the very low risk group to a 50% probability at 8 months in the very high risk group.

The major difference from the IPSS is that the WPSS provides prognostic information from initial evaluation through treatment to follow-up. Thus, the WPSS permits a dynamic estimation of survival and risk of AML transformation at multiple time points during the natural course of MDS and is therefore more versatile than the IPSS in clinical decision-making and

Table 28.9 WHO Classification-based Prognostic Scoring System (WPSS).

Variable	Score value			
	0	1	2	3
WHO category	RA, RARS, 5q-	RCMD, RCMD-RS	RAEB-1	RAEB-2
Karyotype*	Good	Intermediate	Poor	-
Transfusion requirement†	No	Regular	-	-

*Karyotype status: good category includes normal, -Y, del(5q), del(20q); poor category includes complex (three or more) abnormalities, chromosome 7 anomalies; intermediate category includes other abnormalities.

†Transfusion dependency defined as having at least one transfusion every 8 weeks over a period of 4 months.

Criteria	WPSS risk category				
	Very low	Low	Intermediate	High	Very high
Combined score	0	1	2	3-4	5-6
Median survival (months)	136	63	44	19	8

Table 28.10 Median survival of MDS patients according to WPSS risk score.

selection of appropriate treatment options. Notably, patients with normal blast counts and those with only erythroid dysplasia have a better prognosis according to the WPSS model but this requires validation. No doubt further revisions will emerge in the future that incorporate additional discriminatory risk factors.

Management and treatment

Traditionally, the management of patients with MDS has been largely unsatisfactory. However, the advent of newer treatment options coupled with better prognostication systems has resulted in some improvements for patients diagnosed with MDS today. Nonetheless, for many such patients who are commonly elderly and with other significant comorbidities, management often consists solely of supportive care, which remains the cornerstone of treatment in MDS. Indeed, for some patients who present with transforming disease or whose health is otherwise very poor, the only realistic option is the palliative relief of their symptoms. On the other hand, some patients may require observation only or may respond to growth factors, thus obviating the need for transfusion support. At the other end of the spectrum are younger fitter patients for whom more intensive treatment options might be considered, including high-dose cytotoxic therapy and stem cell transplantation (SCT). In addition, certain criteria in MDS are now becoming established that predict likelihood of clinical response to newer treatment options including immunosuppression, immunomodulatory drugs and hypomethylating agents.

Three important considerations should be borne in mind in arriving at an appropriate management plan for a patient with MDS: firstly, in asymptomatic patients, a period of observation can be extremely helpful in determining the rate of disease progression; secondly, it can be unwise to base the treatment plan on blood and marrow results during an acute infective episode since neutrophil and blast counts may be transiently increased; and thirdly, the patient's own wishes and expectations, as well as his or her health and social circumstances, should all be part of the overall consideration before arriving at a management plan. The British Committee for Standards in Haematology (BCSH) has produced some consensus guidelines based on an evidence-based review of the published literature to guide optimal treatment of patients with MDS. The management recommendations in this chapter are drawn partly from these guidelines but have also sought to include newer treatment options that have emerged since the guidelines were published.

Supportive care

Patients who exhibit symptoms or signs of clinical anaemia should receive red cell transfusions in order to improve quality

of life. However, the potential risks of blood transfusions should always be considered, notably iron overload in multitransfused patients. Therefore, transfusions should only be used to alleviate symptoms of anaemia and not simply to maintain the haemoglobin above an arbitrary level. Other factors that might accentuate anaemia, such as nutritional haematinic deficiencies, haemorrhage, haemolysis or infection, should be sought and treated as appropriate.

Bleeding is a common and potentially serious complication of MDS resulting from both thrombocytopenia and the effect of functionally defective platelets. Platelet transfusions are indicated in MDS patients in the treatment of acute bleeding episodes, or as prophylaxis prior to surgery or following chemotherapy. However, their long-term use, for instance in the prevention of recurrent epistaxis or oral bleeding in elderly patients with persistent thrombocytopenia, presents significant logistical (and financial) issues. Moreover, as for red cell transfusions, platelet transfusions are not without potential complications including allosensitization that can lead to future refractoriness. Antifibrinolytic agents such as tranexamic acid can be useful on occasion but are not routinely recommended.

Chelation therapy

The decision to implement iron chelation in a transfusion-dependent MDS patient is not straightforward. There is a paucity of published literature to suggest that this expensive and inconvenient treatment improves overall survival in MDS. Current BCSH recommendations state that iron chelation should be considered once a patient has received 5g iron (approximately 25 units of red cells) but only in younger patients for whom long-term transfusion therapy is likely, such as those with sideroblastic anaemia, or in those with good-prognosis disease without significant comorbidities. Desferrioxamine 20–40 mg/kg should be administered by subcutaneous infusion over 10–12 hours for 5–7 days per week with annual audiometry and ophthalmology review. The target ferritin concentration should be below 1000 µg/L and vitamin C 100–200 mg daily can be added after 1 month to enhance chelation. However, these recommendations are likely to be revised in view of the increasing use of the oral iron chelator, deferasirox, in younger transfusion-dependent MDS patients, especially those awaiting allogeneic transplantation for whom iron overload, reflected by a high ferritin level, can adversely influence the outcome of the procedure. Early experience with deferasirox shows that it is well tolerated and controls or reduces iron levels in chronically transfused MDS patients when used at a daily dose of 20–40 mg/kg.

Growth factors

The aim of using recombinant erythropoietin in the treatment of anaemia in MDS is to normalize the haemoglobin level and

achieve transfusion independence with enhanced quality of life. However, those patients who stand to benefit the most are also those least likely to respond. Predictors of response include low serum erythropoietin concentration of less than 200 mU/mL (usually raised in MDS) and low transfusion requirements (two or less units per month). In such patients, there is evidence that cytokines can act on haemopoietic progenitor cells to reduce apoptosis and improve erythropoiesis.

Several small studies have demonstrated that erythropoietin is more likely to improve the haemoglobin level in patients with RA or RAEB, while patients with RARS rarely respond unless granulocyte colony-stimulating factor (G-CSF) is also used. A trial of erythropoietin alone at a dose of 10 000 units daily for 6 weeks should be undertaken to determine response. For non-responders, consideration should be given to the addition of daily G-CSF, to doubling the dose of erythropoietin, or both for a further 6 weeks. The synergism achieved by adding G-CSF to erythropoietin can improve response rates in RARS from 8% up to 50%. The precise role of both these cytokines in low-risk MDS patients is currently being assessed in a multicentre randomized trial in the UK to study quality of life, effect on survival and disease progression, and pharmacoeconomics.

The administration of G-CSF to patients with MDS typically results in a dose-dependent improvement in neutrophil numbers and function and is usually reserved for patients with severe sepsis or recovering from intensive chemotherapy. There is insufficient evidence to support its prophylactic use for preventing neutropenic infection, although some patients whose quality of life is compromised by recurrent infective exacerbations may respond to such an approach.

Immunosuppression

The serendipitous discovery that immunosuppression can sometimes yield responses in bone marrow failure states such as aplastic anaemia came from early experience of treating such patients with bone marrow transplantation and observing that some non-engrafters developed autologous haemopoietic recovery. In the case of MDS, there is accumulating evidence to implicate dysfunction of the immune system in the pathogenesis of the disease. Both these reasons provide the rationale for immunosuppression in the treatment of MDS, using either rabbit antithymocyte globulin (ATG) or horse antilymphocyte globulin (ALG), which are both polyclonal immunoglobulin preparations. A number of studies have shown that these treatments can benefit 30–60% of patients with MDS regardless of cellularity. Most clinically meaningful responses are in the erythroid lineage but bilineage and trilineage responses are also seen.

A number of studies have attempted to define key criteria that predict likelihood of response to immunosuppression. One multicentre study that retrospectively analysed 96 patients with MDS treated with ATG demonstrated that low IPSS score and

marrow hypocellularity are both associated with better outcomes. Indeed, for young fit patients presenting with hypoplastic MDS, a trial of immunosuppression with ATG should be considered first-line treatment before proceeding to allogeneic transplantation. This conclusion is supported by another study of patients with MDS from the National Institutes of Health cohort, which has demonstrated for the first time that immunosuppressive therapy with ATG and ciclosporin can confer a survival advantage in younger patients with low IPSS scores. Two predictors of response in this study were HLA-DR15 positivity and trisomy 8, with 9 of 12 patients with this cytogenetic finding achieving transfusion independence. Other reports have even documented benefit in some patients to ciclosporin alone, or with corticosteroids, presumably through its immunosuppressive effect, although the benefits appear small and are rarely durable.

Intensive chemotherapy

Treatment of MDS patients with intensive chemotherapy regimens generally yields low remission rates and high relapse rates. AML induction regimens often result in protracted chemotherapy-related hypoplasia with remission rates that are considerably lower than for *de novo* AML. Indeed, marrow samples from patients with AML should be rigorously scrutinized for the presence of morphological dysplasia, which suggests antecedent MDS and predicts poor response to standard chemotherapy. The reasons for this are not clear but may be related to intrinsic drug resistance, lower mitotic rate or expanded pool of malignant stem cells.

Studies from the mid to late 1990s reported remission rates for high-risk MDS of 38–79% but these were generally short-lived, lasting 5–15 months. The karyotype appears to be the major determinant of response to intensive chemotherapy in MDS, with normal karyotype associated with high complete remission (CR) rate and longer remissions while complex karyotypes, particularly loss of chromosome 5 or 7, are associated with low CR rate and shorter remissions. Similarly, patients with therapy-related MDS have a particularly poor prognosis.

There is some evidence from *in vitro* studies that fludarabine is better than daunorubicin when combined with cytarabine. Daunorubicin is a substrate for the P-glycoprotein commonly overexpressed in transforming MDS, resulting in drug resistance. Conversely, fludarabine is an effective DNA terminator that can potentiate the effect of cytarabine by increasing its intracellular concentration. The addition of G-CSF to this regimen in order to sensitize the cells to these drugs has not been shown to confer any significant clinical benefit.

Consolidation of remission by way of autologous SCT is only applicable to a minority of patients due to the difficulty in harvesting CD34-positive progenitors from patients with MDS. Moreover, despite achieving stable engraftment after myeloab-

lative high-dose chemotherapy, the graft is likely to be contaminated with residual disease cells that inevitably compromise any clinical benefit. Data from the European Group for Blood and Marrow Transplantation (EBMT) on 114 patients who received autologous transplantation in first CR have shown a 2-year disease-free survival (DFS) rate of 34% and relapse rate of 64% that is significantly worse than a 2-year DFS rate of 51% for patients with *de novo* AML treated similarly.

Allogeneic stem cell transplantation

Allogeneic SCT represents the only modality of treatment in MDS that has the potential for long-term cure. Historically, busulfan and cyclophosphamide, with or without total body irradiation, were used at high dose to condition the patient by way of total myeloablation allowing disease-free allogeneic stem cells to reconstitute the bone marrow. Over time, it became apparent that the curative potential of the transplant procedure was attributable to not only the toxic conditioning regimen but also the graft-versus-disease effect that clearly suppressed, or even eradicated, residual dysplastic/leukaemic cells. Traditionally, standard allografting was reserved for younger patients with good performance status and high-risk disease whose prognosis was otherwise very poor. Data from both the EBMT and the International Bone Marrow Transplant Registry (IBMT) confirm that at least one-third of patients with MDS are cured by allogeneic SCT from HLA-identical sibling donors. The status of the underlying disease is a major contributing factor in determining DFS at 3 years after transplantation, which according to registry data prior to 1998 is 53–55% for RA/RARS and 28–36% for RAEB/RAEBt/AML. A number of other criteria are recognized as being poor prognostic factors for outcome following allogeneic SCT, including older age, poor-risk cytogenetics, high IPSS score, advanced disease, therapy-related MDS, prolonged disease duration, and marrow fibrosis. However, advances in transplantation and supportive care are leading to a revision of the eligibility criteria for selecting suitable patients with MDS. The major driver for change over the last decade has been to address the extremely high transplant-related mortality (TRM) rate of 37–54% associated with standard allografting and this has resulted in the increasing use of reduced-intensity conditioning (RIC) regimens for MDS patients of all ages.

The optimal timing of transplantation in MDS is influenced by three factors, namely disease state, cytogenetics and age. Patients should be transplanted in a state of remission, after two or three cycles of intensive chemotherapy, since progressive or relapsed disease at time of SCT has a major adverse influence on outcome. Similarly, patients should be transplanted prior to cytogenetic evolution as poor-risk karyotypes are associated with poorer outcomes. Finally, the considerable TRM that accompanies SCT means that survival for older patients is considerably worse than for younger patients. Indeed, much of the

advance in transplantation in MDS has been directed to addressing these issues.

There are three possible sources of stem cells in allogeneic transplantation: sibling donor, volunteer unrelated donor and umbilical cord blood. Approximately one-third of patients receive an HLA-identical sibling donor transplant and this is associated with slightly better survival compared with unrelated donor transplant, with lower rates of TRM and graft-versus-host disease (GVHD). Volunteer unrelated donor transplants do have the advantage of a lower relapse rate compared with sibling donor transplants, illustrating the enhanced graft-versus-leukaemia (GVL) effect that occurs with unrelated donors. As for umbilical cord transplants, these are generally reserved for patients without a suitable HLA-matched donor. They are associated with a lower rate of GVHD and greater tolerance of HLA mismatch but at the expense of possible engraftment failure. However, the use of tandem cord transplants has been found to improve engraftment rates, making this approach a feasible alternative to established SCT procedures.

The major development in allogeneic transplantation that is responsible for expanding the number of eligible patients is the use of RIC regimens. Indeed, the introduction of non-myeloablative RIC has altered the landscape of SCT in MDS and rendered much of the outcome data from the SCT registries largely of historic interest (Table 28.11). Compared with standard conditioning, RIC regimens are characterized by reduced myelosuppression aimed at decreasing toxicity and related mortality. In addition, the RIC regimen must incorporate sufficient immunosuppression to prevent graft rejection by the host. A multitude of RIC protocols have been developed but typically they involve some combination of fludarabine, melphalan or busulfan, and alemtuzumab (Campath-1H) or ATG, occasionally with low-dose total body irradiation also. Alemtuzumab is a humanized IgG1 monoclonal antibody directed against the CD52 antigen expressed on all lymphoid cells, dendritic cells and monocytes, while ATG is directed primarily at T cells. Both alemtuzumab and ATG cause immunosuppression of the host and, because of their long half-lives, also of the donor graft resulting in *in vivo* T-cell depletion. This has the advantage of significantly reducing the incidence of GVHD that remains the major cause of morbidity and mortality following standard conditioning transplants. However, the long-term GVL effect of the transplant is retained, thereby controlling any minimal residual disease but at the expense of increased incidence of life-threatening infections due to delayed immune reconstitution.

A recent single-centre follow-up of allogeneic RIC transplants in 159 patients with MDS/AML (21–72 years, median age 53) reported a TRM rate of 31% and 1-year DFS rates for sibling donor and volunteer unrelated donor transplants of 61% and 59%, respectively. These rates correlated strongly with IPSS risk category, with DFS at 1 year of 86% for intermediate-1 patients, 63% for intermediate-2 patients and 33% for high-risk patients.

Table 28.11 Comparative outcomes from standard myeloablative and reduced-intensity conditioning allogeneic stem cell transplantation in MDS patients from the European registry.

Criteria	Standard myeloablative conditioning (N = 621 patients)	Reduced-intensity conditioning (N = 215 patients)	P-value
Patients over 50 years (%)	28	73	<0.001
Acute GVHD (%)	58	43	<0.001
Chronic GVHD (%)	52	45	Not significant
NRM at 3 years (%)	32	22	0.04
Relapse at 3 years (%)	27	45	<0.01
PFS at 3 years (%)	41	33	Not significant
OS at 3 years (%)	45	41	Not significant

Note that the 3-year progression-free survival (PFS) and overall survival (OS) are comparable between the two groups despite significant age differences, but that the risk of graft-versus-host disease (GVHD) and non-relapse mortality (NRM) are higher for standard transplants while the relapse rate is higher for transplants with reduced-intensity conditioning.

Figure 28.6 Kaplan–Meier survival plot and data for 159 patients with advanced MDS/AML who received a reduced-intensity conditioned allogeneic transplant at King’s College Hospital, London. (Figure courtesy of Ziyi Lim.)

In addition, DFS rates correlated strongly with disease status at time of transplantation, with poorer outcomes in patients with relapsed/progressive disease or in partial remission. The survival curve shows evidence of plateau at around 3 years, with overall survival at this time of 46% and a relapse rate of 41%, with 14% of patients experiencing extensive chronic GVHD (Figure 28.6). A more intensive conditioning regimen comprising fludarabine, cytarabine and amsacrine (FLAMSA) combined with ATG, cyclophosphamide and 4-Gy total body irradiation has recently been pioneered by a German group in patients with refractory disease at time of transplantation, with impressive 2-year survival rates of 40%.

The GVL effect that is responsible for much of the therapeutic success associated with allogeneic transplantation can be

further harnessed by use of donor lymphocyte infusions in the post-transplant setting. Donor lymphocyte infusions have been used to reinduce remission in patients with clinically relapsed haematological malignancy and to pre-emptively treat patients with molecular/cytogenetic evidence of mixed chimerism or relapsed disease. Durable remissions have been documented in cases of relapsed MDS/AML after transplantation, although results following morphological relapse are often poor. Considerable uncertainty remains regarding the optimal timing and dose of donor lymphocyte infusions in order to maximize the GVL effect while minimizing the risk of precipitating severe GVHD.

Hypomethylating drugs

Promoter hypermethylation leading to epigenetic silencing of tumour-suppressor genes is believed to be a key contributor to the molecular pathophysiology of MDS. This occurs by aberrant cytosine methylation at CpG dinucleotides, leading to inactivation of genes that control cell growth, differentiation and apoptosis. Hypomethylating agents are incorporated into the DNA where they covalently bind to the methyltransferase molecule, thereby inhibiting its function and leading to loss of methylation as DNA is replicated during mitosis. Currently, there are two hypomethylating agents that are approved for use in the treatment of MDS, namely 5-azacytidine (azacitidine) and 5-aza-2'-deoxycytidine (decitabine). Both of these drugs are cytosine nucleoside analogues that were initially developed as cytarabine analogues but had limited activity and unacceptable toxicities when used at high dose. However, at lower doses, they promote myeloid differentiation *in vitro* through gene activation.

The first demonstration of clear therapeutic benefit of hypomethylating agents came from a pivotal Phase III trial of

azacitidine in patients with MDS conducted by the Cancer and Leukaemia Group B that has led to its approval by the US Food and Drug Administration (FDA). This study randomized patients to azacitidine 75 mg/m² administered subcutaneously daily for 7 days every 4 weeks or best supportive care with the option of crossover at 4 months. Responses were seen in all FAB subtypes, with 47% of patients achieving CR and 36% demonstrating haematological improvement. The median time to AML transformation or death was 21 months for patients receiving azacitidine compared with 12 months for those receiving best supportive care.

A more recent Phase III trial in MDS patients with intermediate-2 or high-risk disease, the AZA-001 study (Figure 28.7), compared azacitidine with conventional care regimens (best supportive care, low-dose cytarabine or intensive chemotherapy as deemed appropriate) and demonstrated that azacitidine confers a median survival benefit of over 9 months (24.5 vs. 15 months), with almost doubling of the survival at 2 years (51% vs. 26%). Moreover, the haematological improvements seen with azacitidine in this study were of longer duration than those of other care regimens, with higher rates of transfusion independence, fewer infections and overall delay in progression to AML. In addition, subgroup analysis demonstrated that azacitidine is associated with significant benefit in patients with adverse cytogenetics involving chromosome 7, with a 67% reduction in deaths and a survival advantage at 2 years of 33% compared with 8%. This latter finding has been confirmed by another study that found a significant survival advantage in high-risk patients, with median survival of 24.8 months for patients with monosomy 7 or 7q- and 17.3 months for patients with complex cytogenetics. For this challenging group of patients, azacitidine may serve to induce cytogenetic remissions while transplant-eligible patients await donor selection. Current studies are seeking to explore alternative treatment regimens and also to study the role of azacitidine as maintenance therapy to prolong remissions following intensive chemotherapy.

Decitabine has also received FDA approval for the treatment of patients with MDS based on a Phase III evaluation of the drug that demonstrated a 35% overall response rate compared with best supportive care and a significant prolongation of the time to AML or death in the high-risk/intermediate-2 group of patients. However, unlike the azacitidine trial, decitabine failed to produce a statistically significant survival advantage, possibly for dosage reasons, and therefore azacitidine should be considered the preferred therapeutic option. In lower-risk patients a shorter 5-day regimen may yield adequate haematological improvements with acceptable toxicity profile, while in higher-risk patients azacitidine offers an option for individuals who are not suitable for intensive therapy and allogeneic transplantation. Clinical trials are ongoing to study the benefit of other epigenetic modifiers, notably histone deacetylation inhibitors that might enhance the benefit produced by hypomethylation agents.

Lenalidomide

Lenalidomide belongs to a class of compounds termed 'immunomodulatory drugs' that have shown broad activity on the bone marrow microenvironment, including anti-angiogenic activity and cytokine suppression. It has a superior toxicity profile than its predecessor thalidomide, and appears to lack any significant teratogenicity. Moreover, it causes enhancement of erythropoietin receptor signalling, making it an attractive candidate for studying in transfusion-dependent MDS. Lenalidomide was first studied in an open-label single-centre trial in 43 patients with mostly lower-risk MDS; 63% of patients who were transfusion-dependent became independent of transfusion, with the most marked responses observed in those patients with del(5q) compared with normal karyotype or other cytogenetic abnormalities (83% vs. 57% vs. 12%, respectively). A complete cytogenetic response was observed in 10 patients, all but one of whom had del(5q) and this provided the basis for

Figure 28.7 Kaplan–Meier plot comparing overall survival for MDS patients randomized to either azacitidine treatment or conventional care regimens (CCR) in the Phase III AZA-001 study. Median survival favours azacitidine over CCR by 9.5 months (24.5 vs. 15 months) with doubling of 2-year survival (51% vs. 26%). (From Fenaux *et al.* 2009 with permission.)

a pivotal Phase II study in 148 transfusion-dependent patients who carried this abnormality. In this larger study, two-thirds of patients became transfusion-independent, with a median time of onset of 4.6 weeks and a median duration that had not been reached at 2 years of follow-up. Cytogenetic response was seen in 73% of patients, of whom 61% had a complete cytogenetic response and this strongly correlated with haematological improvement. No significant difference in response was observed between the two dosing regimens of 10 mg daily or 10 mg daily for 21 days of a 28-day cycle.

Although the precise mechanism of action of lenalidomide in MDS remains unknown, there are a number of hypotheses. The evidence clearly supports the view that the drug directly targets the dysplastic clone given the cytogenetic response and normalization of haemoglobin and platelet levels. One mechanism would be that lenalidomide corrects for the dosage haploinsufficiency caused by the 5q deletion, resulting in normalization of cell cycle arrest and apoptosis. However, lenalidomide is also known to have potent immunomodulatory and anti-angiogenic properties that may clearly be relevant to its therapeutic action. Indeed, clinical benefit from lenalidomide is not only restricted to del(5q) patients, as demonstrated by

another recent study of MDS patients lacking this abnormality that has shown a response rate of 43% with 26% achieving transfusion independence. Thus, lenalidomide represents a promising, albeit expensive, advance in the treatment of some forms of MDS.

Therapeutic strategy

Therapeutic goals

Arriving at the best management plan for an individual patient with MDS can be difficult (Figure 28.8). The initial decision to resolve is whether the goal of treatment should be to extend patient survival or to palliate symptoms with supportive care. This decision is helped by considering prognosis according to the IPSS/WPSS coupled to the patient's age and performance status, always ensuring that any plan is fully in accordance with the patient's own wishes. Treatment of MDS has historically been separated into low-intensity and high-intensity therapies, based on the risk of toxicities. Low-intensity therapies, which include immunosuppressive therapy, biological response modi-

Figure 28.8 Schematic diagram illustrating the treatment options available for patients with MDS.

fiers and cytokines, were reserved for lower-risk patients with the goal of improving cytopenias and quality of life without improving survival. Other low-intensity therapies such as low-dose chemotherapy and methyltransferase inhibitors aim to extend survival, whereas high-intensity therapies such as high-dose chemotherapy and allogeneic SCT aim to alter the course of the disease or even achieve cure.

Many patients with MDS receive supportive care alone, particularly lower-risk patients with chronic cytopenias or patients with higher-risk disease who are unable to tolerate high-intensity therapy. Such patients often become dependent on frequent red cell or platelet transfusions and experience repeated infective and haemorrhagic complications. Regardless of disease status, many patients experience significantly impaired quality of life simply as a consequence of the physical toll caused by frequent laboratory monitoring and transfusions, physician visits, and the fatigue that accompanies this. Thus, improvement in quality of life and alleviation of disease-related symptoms are the key goals of therapy.

Assessing response

In 2000, the International Working Group (IWG) of investigators proposed standardization of response criteria by which to assess the results of different therapies in MDS. These criteria have been widely accepted into clinical practice and were updated in 2006. The investigators grouped patients into IPSS risk categories and recommended that the major goal of therapy for patients with lower-risk disease (low-risk and intermediate-1 categories) is to achieve haematological improvement. For higher-risk patients (intermediate-2 and high-risk categories), the focus turns to altering the natural history of the disease and prolonging life. The IWG criteria define four specific aspects of responses based on treatment goals: haematological improvement, cytogenetic improvement, alteration of disease progression, and quality of life. Haematological improvement is scored for each lineage according to whether there is a major or minor response, while cytogenetic improvement is scored according to whether there is a partial or complete response. Alteration of the natural course of the disease is determined according to various measures of disease progression and survival.

IPSS low

The median survival for low-risk MDS is 4.8 years for those aged over 60 years to 11.8 years for those under 60 years. For this reason, intensive chemotherapy and SCT cannot be justified given their potential for morbidity and mortality. Individuals should be monitored for disease progression and supported as necessary. Where possible, a trial of erythropoietin with or without G-CSF should be undertaken in patients with symptomatic anaemia, while those with del(5q) should ideally receive lenalidomide.

IPSS intermediate-1

For older patients above the age of 65, or less if there are significant comorbidities, supportive care should be offered as for low-risk patients. Immunosuppression with ATG and ciclosporin should be considered for cytopenic patients who are otherwise deemed unfit for intensive chemotherapy, particularly if the marrow is hypocellular with no excess of blasts or adverse cytogenetics. For younger patients below the age of 50 who have either a sibling or unrelated donor available, allogeneic transplantation should be offered as a potentially curative procedure. Whether the conditioning regimen should be myeloablative or non-myeloablative is unclear and should be at the discretion of the local transplant unit. For patients between 50 and 65 years of age, the optimal management is less straightforward given the significant TRM associated with allogeneic SCT and the predicted median survival of 5.2 years for patients less than 60. The impressive data emerging for patients treated with RIC transplantation makes this an attractive treatment option, especially when a sibling donor is available, although unrelated donor transplants are also feasible. While trials demonstrate better outcomes if the transplantation is performed prior to disease progression, this is not always a straightforward decision and some patients may reasonably elect to reserve this option for when there is evidence of clonal evolution or early transformation. Iron overload should be avoided in those patients who remain transplant candidates, either by managing anaemia with erythropoietin with or without G-CSF or by using iron chelation for those who are transfusion-dependent.

IPSS intermediate-2/high

Patients in these poor prognostic categories are known to have median survivals of less than 2 years for intermediate-2 to only a few months for high-risk individuals. Patients below the age of 65 years and without significant comorbidities, particularly where a sibling donor is available, should be offered intensive chemotherapy and RIC transplantation, with myeloablative conditioning reserved for younger fitter patients below 50 years at the discretion of the local transplant unit. However, if the patient fails to achieve at least a good partial remission following intensive chemotherapy, then the prospects of successful outcome from allogeneic transplantation are minimal and palliative treatment with supportive care may be a preferable option, although a FLAMSA-conditioned RIC transplant could be considered in some cases.

For patients over the age of 65 years, the best recommendation is not straightforward. The NCRI AML 16 trial is open for patients over 60 with high-risk MDS and AML, allowing randomization to various treatment options on either intensive or non-intensive arms. However, this will depend on the patient's performance status, comorbidities and own wishes. It is reasonable to await the result of cytogenetic analysis, as patients with

poor-risk karyotypes have low response rates to intensive AML-type induction chemotherapy. For such patients, and particularly those with chromosome 7 abnormalities, azacitidine should be considered as an alternative low-intensive treatment option.

With the advent of further novel agents in the future, the most appropriate treatment option is likely to become more complex. However, as with all investigational therapies, patients should be treated within the context of clinical research trials.

Myelodysplastic/myeloproliferative diseases

The WHO classification established a new diagnostic entity for those diseases that share features characteristic of both the myelodysplastic syndromes and the myeloproliferative neoplasms. This overlap category comprises disorders that at the time of initial presentation share clinical, laboratory or morphological findings indicative of underlying dysplastic and proliferative processes. They are usually characterized by hypercellularity of the bone marrow due to proliferation in one or more of the myeloid lineages, with increased numbers of circulating cells that may be morphologically dysplastic. Simultaneously, one or more of the other lineages may exhibit ineffective proliferation so that cytopenias may also be present. The presence of excess blasts is closely correlated with the risk of leukaemic transformation.

The WHO recognizes three distinct entities, namely chronic myelomonocytic leukaemia, atypical chronic myeloid leukaemia and juvenile myelomonocytic leukaemia, and one provisional entity of refractory anaemia with ring sideroblasts and thrombocytosis, with the remainder categorized as myelodysplastic/myeloproliferative neoplasms unclassifiable.

Chronic myelomonocytic leukaemia (see also Chapter 27)

CMML constitutes 20–30% of cases of MDS. The hallmark feature is peripheral blood monocytosis accompanied by morphological dysplasia of other lineages. CMML is a clonal malignancy that has a male predominance and a median age of presentation of approximately 70 years; only 10% of CMML cases occur in individuals less than 60 years. While the aetiology is largely unknown, therapy-related cases of CMML are very rare.

Clinical and laboratory features

There is a spectrum of clinical and laboratory features found in CMML. The majority of patients present with a leucocytosis that is often accompanied by mild anaemia and thrombocytopenia. Reactive causes due to infection, notably tuberculosis, must be excluded. By definition, the monocyte count must be

greater than $1 \times 10^9/L$ and is usually in the range $2\text{--}5 \times 10^9/L$, but may exceed $80 \times 10^9/L$. The monocytes generally appear mature and morphologically unremarkable but may have agranular cytoplasm and/or abnormal nuclear lobulation. Promonocytes and monoblasts may also be seen but if they comprise more than 20%, then the diagnosis is AML rather than CMML. Evidence of dysgranulopoiesis is commonly present, including hypogranular and hypolobated neutrophils that are sometimes difficult to distinguish from dysplastic monocytes. The bone marrow is generally hypercellular, usually with striking granulocytic proliferation and invariably monocytic proliferation that can be distinguished using cytochemical studies. Typical features of dysplasia can be identified in all three lineages in over 80% of patients.

Cytogenetic analysis is important for confirming clonality, although abnormalities are only found in 30–40% of cases, notably +8, -7/del(7q) and del(12p), and none is specific for CMML. Up to 40% of patients have point mutations of *RAS* genes, which is higher than for other forms of MDS. Hypermethylation of the *CDKN2B* gene (which encodes the tumour suppressor p15INK4b), resulting in reduced expression, can be demonstrated in approximately 50% of patients. Recently, the *CBL* gene, which encodes the E3 ubiquitin ligase, has been implicated in progressive CMML by its presence within a region of UPD on chromosome 11q. It is important to exclude certain chromosomal translocations, by cytogenetic and polymerase chain reaction (PCR) analysis, that are indicative of alternative diagnoses. These include chronic myeloid leukaemia diagnosed by the *BCR-ABL1* rearrangement and eosinophilia-related disorders associated with abnormalities of *PDGFRA*, *PDGFRB* and *FGFR1*. Mutations of the *JAK2* gene should also be excluded.

Approximately half of patients have splenomegaly, and often hepatomegaly, at diagnosis. Individuals with high monocyte counts may develop a maculopapular skin infiltration, gum infiltration, and monocytic pleural and pericardial effusions. Lymphadenopathy is uncommon but when it occurs it may signal a more acute phase with infiltration of lymph nodes by myeloblasts. Weight loss, fevers and night sweats may occur in symptomatic patients. The number of blast cells plus promonocytes should account for less than 5% of peripheral blood leucocytes and less than 10% of nucleated marrow cells to give a diagnosis of CMML-1. If the blast/promonocyte count is higher than this but less than 20% in either the peripheral blood or bone marrow, or if Auer rods are present, then the diagnosis is CMML-2. This identifies a group of patients who have a worse prognosis and higher risk of transformation to AML, which is diagnosed when the blast/promonocyte count exceeds 20%. Immunophenotyping may be helpful for identifying myelomonocytic populations but can also give prognostic information such as reduced CD14 expression indicating monocytic immaturity, aberrant expression of CD2 and CD56, and the CD34-positive cell percentage.

Natural history and prognosis

The clinical course of CMML is highly variable, with a median survival of approximately 2 years though occasional patients surviving beyond 8 years. There is an age-dependent prognosis that can be calculated using the IPSS according to the blast percentage, number of cytopenias, and karyotypic abnormalities. The distinction between dysplastic and proliferative forms of the disease is unreliable and unhelpful but the separation between CMML-1 and CMML-2, which reflects the marrow blast percentage (<10% and 10–19% respectively), is important and prognostically relevant. Similarly, anaemia and thrombocytopenia are adverse prognostic factors, especially if the patient is transfusion-dependent. A rising lactate dehydrogenase level often reflects a rising blast count, indicating progression to AML with leukaemic transformation occurring in approximately 15–30% of cases.

Management and treatment

Therapy of CMML is unsatisfactory with the vast majority of patients being elderly (>60 years). Supportive care by way of blood transfusions and antibiotics for infections are the mainstay of management. When the proliferative phase prevails, causing symptomatic organomegaly, infiltrative disease or escalating monocytosis, then oral chemotherapy with hydroxycarbamide (hydroxyurea) is the treatment of choice. A European randomized study comparing hydroxycarbamide with etoposide gave a response rate and survival, respectively, of 60% and 20 months for hydroxycarbamide and 36% and 9 months for etoposide. Intensive chemotherapy alone is of little benefit in this age group.

In younger patients, particularly with adverse features, intensive treatment and allogeneic transplantation represent the only possibility of cure. However, the EBMT data for adults with CMML shows poor long-term outcomes with this approach, with 5-year overall survival after transplant (both related and unrelated) of only 21%. As with other forms of MDS, outcomes are better if the patient is transplanted before significant disease progression but this must be weighed against the considerable TRM rate. AML-type induction chemotherapy regimens are unlikely to achieve long-lasting remission on their own unless consolidated with a transplant procedure. A deeper understanding of the biological basis of CMML may lead to targeted therapies analogous to that for chronic myeloid leukaemia and there is a strong case for entering younger patients into clinical trials that seek to test such drugs.

Atypical chronic myeloid leukaemia

Atypical chronic myeloid leukaemia is a poorly defined entity. Importantly, it is negative for the *BCR-ABL1* fusion gene associated with the t(9;22) translocation diagnostic of typical chronic myeloid leukaemia (see Chapter 27). It is a leukaemic disorder with myelodysplastic and myeloproliferative features principally involving the neutrophil lineage. Myeloid precursors

often comprise more than 10% of cells but blasts are rarely more than 5%. Dysgranulopoiesis is prominent but multilineage dysplasia is also seen.

Patients usually present with anaemia and/or thrombocytopenia that accompany the leucocytosis. Splenomegaly is common and often causes symptoms because of its massive enlargement. Cytogenetic abnormalities can be identified in 80% of cases although none is specific. The outlook is generally poorer for atypical chronic myeloid leukaemia than for CMML, with a median survival of less than 20 months. The response to intensive chemotherapy is poor and the mainstay of management is supportive care and hydroxycarbamide to control proliferative elements of the disease.

Juvenile myelomonocytic leukaemia (see also Chapter 27)

Juvenile myelomonocytic leukaemia (JMML) is a clonal haemopoietic disorder of childhood characterized principally by proliferation of the granulocytic and monocytic lineages. It occurs with an incidence of 1.2 per million, comprising approximately 2–3% of all childhood leukaemias but 40% of childhood MDS. The majority of cases of JMML occur in children under 3 years of age and twice as commonly in boys than girls. There are associations with neurofibromatosis type 1 and Noonan syndrome due to germline mutations in the *NF1* and *PTPN11* or *KRAS* genes respectively. There is marked *in vitro* hypersensitivity of myeloid progenitors to granulocyte/macrophage colony-stimulating factor that is a hallmark feature of JMML and suggestive of defective RAS–MAP kinase signalling that is often attributable to *RAS* mutations. Monosomy 7 is the most common chromosomal abnormality, found in 25% of cases. A marked increase in the synthesis of HbF is a recurrent finding that has poor prognostic implications.

Clinically, most patients present with constitutional symptoms or evidence of infection and are found to have marked hepatosplenomegaly. Lymphoid and tonsillar enlargement is also common. Typically, there is a leucocytosis comprising neutrophils, myeloid precursors and monocytes, with blasts constituting less than 5% of cells. The marrow is hypercellular and dysplastic features are minimal. The prognosis of JMML is variable with a median survival of 1 year. It is usually rapidly fatal without treatment, causing organ failure, especially respiratory failure due to leukaemic infiltration, while blast transformation occurs infrequently. Although responses are seen to cytarabine-containing regimens, allogeneic transplantation offers the only possibility of cure but with relapse rates of up to 50% in some series.

Refractory anaemia with ring sideroblasts and thrombocytosis

The precise nature of refractory anaemia with ring sideroblasts and thrombocytosis (RARS-T) is a controversial and unre-

solved issue. These patients meet the criteria for RARS but also have persistently elevated platelet counts over $450 \times 10^9/L$. The majority (50–60% of cases) carry the V617F mutation of the *JAK2* gene that is more commonly associated with myeloproliferative disorders. Whether RARS-T represents a *JAK2*-positive myeloproliferative neoplasm with acquired dysplastic features or, conversely, a form of MDS with an acquired proliferative mutation remains partly a question of semantics and partly one of biology. For this reason, RARS-T exists as a provisional entity in the current version of the WHO classification.

Myelodysplasia of childhood

Childhood MDS is recognized as an entity of its own in the current version of the WHO classification but excludes JMML, which is grouped within the myelodysplastic/myeloproliferative category. MDS associated with Down syndrome, which previously accounted for up to 25% of paediatric MDS, is now grouped within a new entity of Down syndrome-related myeloid leukaemia. Most remaining cases of childhood MDS fall within one of the subgroups of conventional MDS, namely RA, RARS, RCMD or RAEB-1/RAEB-2. The term ‘refractory cytopenia of childhood’ is reserved for cases of MDS associated with persistent cytopenia and less than 5% blasts in the marrow and less than 2% blasts in peripheral blood. About 75% of children with RCC show considerable hypocellularity of the bone marrow, making it difficult to differentiate from congenital bone marrow failure syndromes that can lead to secondary myelodysplasia in affected children. These congenital syndromes include disorders such as Fanconi anaemia, dyskeratosis congenita, Schwachman–Diamond syndrome, amegakaryocytic thrombocytopenia, and pancytopenia with radioulnar synostosis. Understanding the mechanism by which they predispose children to developing MDS has helped shed light on the aetiology of acquired MDS in adulthood. However, a discussion of the biology of these disorders is beyond the scope of this chapter.

Future directions

Traditionally, MDS has been viewed as an awkward collection of biologically related disorders mainly affecting elderly patients for whom treatment options were largely unsatisfactory. The last decade has completely changed this landscape. Today, the molecular pathogenesis of MDS is being revealed through newer technologies that allow better understanding of the biology of this clonal disease and its stem cell origin. The revised WHO classification has helped resolve points of diagnostic ambiguity while large retrospective studies of patients have refined our ability to make accurate predictions about prognosis and survival. As for therapy, two new drug treatments, lena-

lidomide and azacitidine, have shown significant clinical benefit in Phase III trials, including improved survival and quality of life. In addition, increasing numbers of patients are receiving allogeneic transplants made possible through the use of RIC regimens that hold the potential for long-term remission or disease control through donor lymphocyte infusions. We still have a long way to go, but recent developments clearly show that better risk stratification, novel targeted therapies and expanded transplant eligibility are all likely to significantly improve the prospects for patients with MDS in the future.

Introduction

Within the broad category of B-cell lymphoproliferative disorders we include a number of disease entities arising from mature B lymphocytes and which involve primarily the blood, bone marrow and other lymphoid organs such as the lymph nodes and spleen. All these disorders are classified by the World Health Organization (WHO) (see Chapter 33) on the basis of their histopathological features. Their clinical course is often chronic and they affect mainly adults. A constant finding in all these entities is the presence in peripheral blood of leukaemic cells in various degrees. Some of these conditions could be considered as primary leukaemias and these are dealt with in this chapter. Others represent the leukaemic phase of indolent non-Hodgkin lymphomas (NHL) and their recognition is important for differential diagnosis and patient management.

The study of lymphoid leukaemias has been enriched with the advent of monoclonal antibodies that define antigenic determinants specific for the B- and T-cell lineages. Characterization of these malignancies is not possible without the use of these reagents, which help define the cell lineage and the maturation stage of the leukaemic cell. DNA analysis for the detection of immunoglobulin and T-cell receptor gene rearrangements has been incorporated as another diagnostic test for

cell lineage and clonality and for monitoring minimal residual disease (MRD) after therapy. Chromosome abnormalities that characterize some of the genetic changes in the lymphoid leukaemias are also important for diagnostic and prognostic purposes and are routinely studied by fluorescence *in situ* hybridization (FISH) as it is not easy to obtain metaphases in slowly dividing lymphocytes.

The primary B-cell leukaemias include chronic lymphocytic leukaemia (CLL), which is by far the most common, the rare B-prolymphocytic leukaemia (B-PLL) and hairy cell leukaemia (HCL). The B-cell NHLs that most frequently affect the blood and bone marrow include splenic marginal zone lymphoma (SMZL), mantle cell lymphoma (MCL), particularly the splenomegalic form, and follicular lymphoma which, in its generalized or systemic form, regularly involves the bone marrow and may spill over to the peripheral blood.

Methodology for diagnosis

Examination of the morphology of leukaemic cells in well-prepared peripheral blood and bone marrow films stained with Romanowsky dyes is still the first diagnostic procedure and cannot be replaced by any of the newer, more modern diagnostic techniques.

The second element for the diagnosis of any type of lymphocytosis is to use a small battery of membrane markers to define the immunophenotype (B or T) and whether the process is clonal or polyclonal. Once a monoclonal B-cell proliferation

is established by light-chain restriction (e.g. κ or λ), one can clarify the problem further by using a panel of monoclonal antibodies to define a particular disease immunophenotype. The typical immunophenotype of CLL, as elaborated by the group of one of the authors, is shown in Table 29.1. The original proposal by Matutes and colleagues was revised by replacing CD22 with CD79b, which is one of the components of the B-cell antigen receptor molecule. In Table 29.1, the symbols in parentheses after each of the five markers indicates the expected result in CLL. Figure 29.1 illustrates the contrast between the flow cytometry profile of a case of CLL and one of follicular lymphoma.

Table 29.2 summarizes the results of applying the panel of markers used for the CLL score to the other B-cell disorders in peripheral blood samples. High scores are expected in CLL; low scores are the feature in the other B-cell leukaemias and B-cell NHL. Figure 29.2 illustrates the almost complete lack of overlap between CLL and B-cell NHL evolving with lymphocytosis. However, there are a number of issues that may present problems. First, as shown in Table 29.2, some cases of CLL with atypical morphology (e.g. clefted nucleus, plasmacytoid features) or more than 10% prolymphocytes (CLL/PL) may have scores lower than 4. Rare cases of NHL may approach scores of

Table 29.1 Immunophenotype of CLL: tests used as basis for a scoring system.

Marker (result)	Score
SmIg (weak)	1
CD5 (+)	1
CD23 (+)	1
FMC7 (– or weak)*	1
CD79b (– or weak)	1
Total	5

*Epitope of CD20 but CD20 not useful for scoring.

Table 29.2 CLL score in B-cell disorders evolving with lymphocytosis.

Disease	Score
CLL	
Typical	4–5
Atypical; CLL/PL	3–5
B-prolymphocytic leukaemia	0–1
Hairy cell leukaemia	0–1
NHL with leukaemia*	0–2

*Follicular lymphoma, MCL, SMZL.

2 or 3; thus reliance only on the immunophenotype may be misleading. Second, the important distinction between CLL and MCL, another CD5-positive disease, may require other tests such as FISH (see below). MCL rarely shows an immunophenotypic score above 2.

An important consideration when using membrane markers is the distinction between CD20 and FMC7. FMC7 has now been recognized as binding to a conformational epitope of CD20, but FMC7 does not correlate with CD20 staining in CLL. Most cases of CLL and other B-cell disorders express CD20, hence its value as a broad B-cell marker and as a target for the monoclonal antibody rituximab. Analysis of the use of CD20 instead of FMC7 for the scoring of CLL in close to 1000 cases has shown that FMC7 is of greater diagnostic value for distinguishing CLL, where it is negative or weak, from the other B-cell disorders, in which it is strongly expressed. The findings with CD20 and FMC7 are similar only in the non-CLL B-cell disorders.

When considering the possibility of a diagnosis of NHL, it is essential to obtain tissue for histology to confirm this suspicion and facilitate the classification of the disease. When the white blood cell (WBC) count is high (e.g. $>50 \times 10^9/L$) and the blood film shows unequivocal features of CLL or B-PLL, lymph node histology is not required.

Bone marrow trephine biopsies are needed to provide important diagnostic and prognostic information (see below) and can confirm a diagnosis of CLL or NHL, provide indications about the mechanism of anaemia or thrombocytopenia and predict the outcome of splenectomy. For disorders with an enlarged spleen, such as B-PLL and HCL, SMZL and some forms of MCL, spleen histology may be of diagnostic value.

The difficulties in eliciting metaphases for cytogenetic analysis in CLL and other small lymphocytic disorders have emphasized the value of FISH analysis, which can be assessed on interphase cells. However, there is no specific genetic abnormality in CLL, but the current FISH studies are valuable as prognostic indicators (see below). FISH is important for excluding the two NHLs that have characteristic abnormalities, MCL with t(11;14)(q13;q32) and follicular lymphoma with t(14;18)(q32;q21).

Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia accounts for about 25% of all leukaemias. In adults over the age of 50 years it is the most common form, particularly in the West. In the Far East, its incidence is low. CLL affects twice as many males as females, with a peak incidence between 60 and 80 years. The median age of patients at diagnosis is around 70 years. In the MRC CLL trials, 70% of patients entered were aged 60 years or over, and 15% were below 50 years. There is a tendency for older patients to present with less advanced disease. CLL is rarely diagnosed

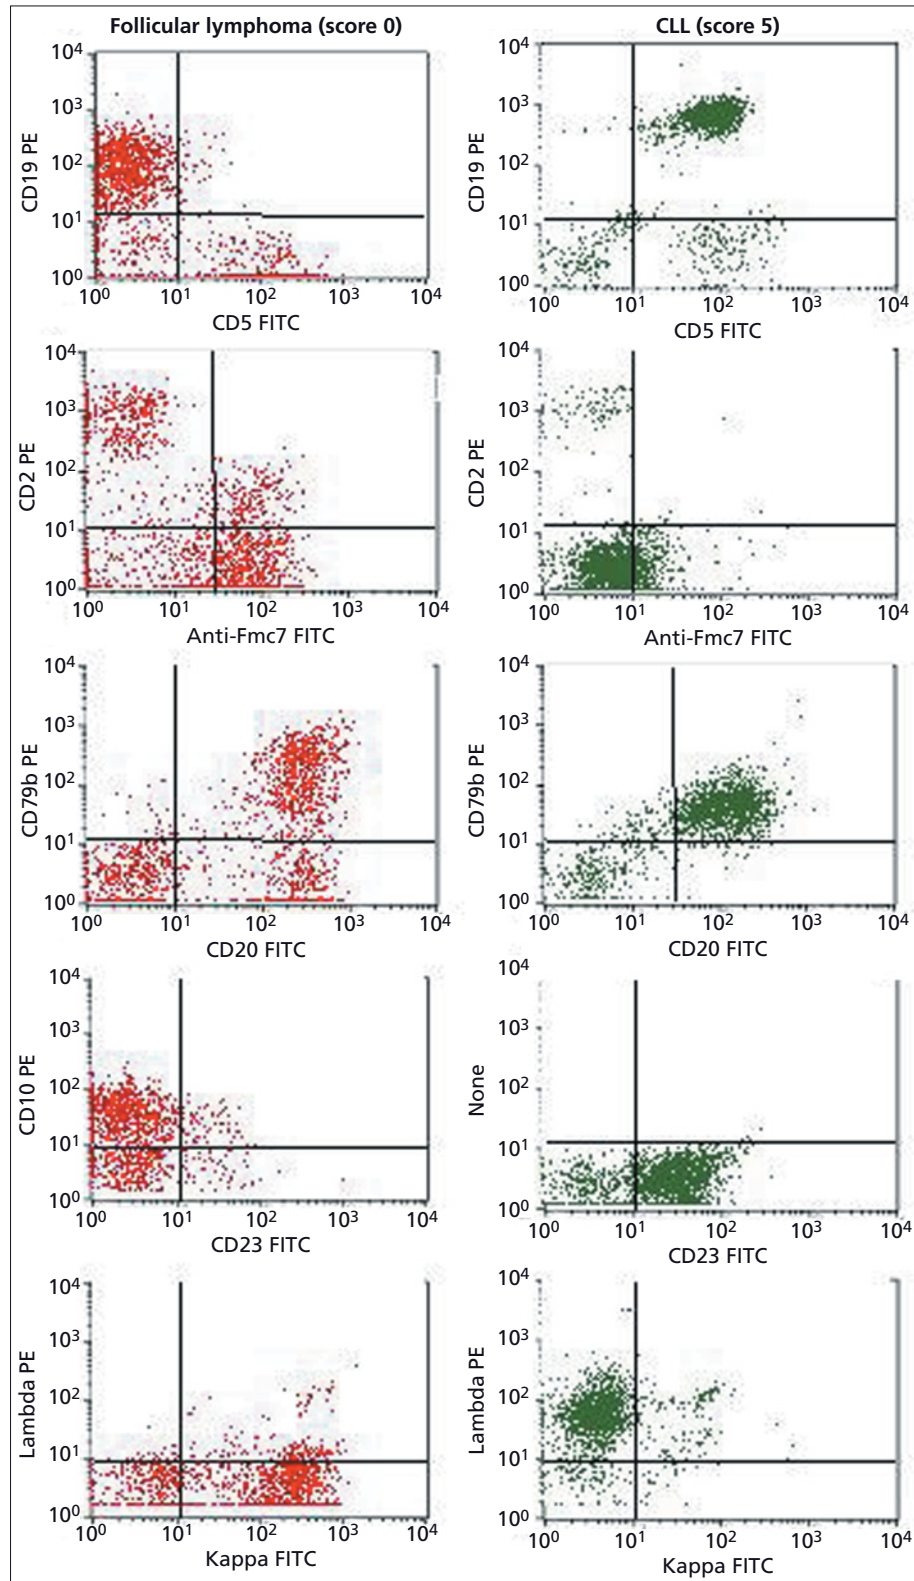

Figure 29.1 Flow cytometry analysis of peripheral blood samples from a case of follicular lymphoma with lymphocytosis (score 0) compared with a case of CLL (score 5) using the antibodies listed in Table 29.1.

Figure 29.2 Distribution frequency of scores in CLL (high scores) compared with cases of B-cell non-Hodgkin lymphoma (B-NHL) with circulating lymphoma cells (low scores).

below the age of 40 years and is even more rare below 30. Of all the leukaemias, CLL has the highest familial incidence, which can be documented in about 10% of patients (see below).

Pioneering work independently developed by Dameshek and Galton in the 1960s introduced the concept of CLL as a progressive accumulation of immunologically incompetent lymphocytes, starting in lymph nodes and/or the bone marrow and gradually expanding to most haemopoietic organs. This concept of slow progression was the basis of the clinical staging systems and explains the gradual abnormalities of the immune system that result in hypogammaglobulinaemia and, not infrequently, autoimmune complications. The bone marrow also reflects the progression of CLL from early interstitial and nodular infiltration to late diffuse lymphocytic replacement of normal haemopoietic elements.

Pathogenesis

Several factors are involved in the pathogenesis of CLL, including antigen stimulation within specific microenvironments and failure to undergo apoptosis. In the past, CLL was considered to be derived from CD5-positive naive B cells. Now there is significant evidence that these B cells are antigen experienced, expressing CD23, CD25, CD27, CD69 and CD71. After VDJ rearrangement the cells may undergo somatic hypermutation, which can be demonstrated by the lack of homology with germline DNA. In half of cases the immunoglobulin variable region heavy chain (*IGHV*) gene is mutated, but in the rest is unmutated. These changes and subsequent complex interactions between the B-cell receptor (BCR), which comprises the immunoglobulin heavy and light chains, and the microenvironment drive the pathogenesis of CLL. The immunoglobulin gene repertoire in CLL shows biased (non-random) V_H usage compared with normal B cells. This restricted V_H usage is linked to the

Table 29.3 Frequency of *IGHV* usage in CLL by mutation status.

<i>IGHV</i> gene	Unmutated cases (%)	Mutated cases (%)
<i>IGHV1-69</i>	28	1
<i>IGHV3-21</i>	6	19
<i>IGHV4-34</i>	5	13
<i>IGHV3-30</i>	4	10
<i>IGHV1-2</i>	7	4
<i>IGHV3-23</i>	1	10

degree of somatic hypermutation. For example, unmutated cases often use *IGHV1-69*, while mutated cases use preferentially *IGHV3-21*, *IGHV4-34*, etc. (Table 29.3). The immunoglobulin repertoire in CLL may be shaped by antigens as yet unknown. This phenomenon, the over-representation of some *IGHV* genes, is not unique to CLL and, in the case of *IGHV1-69* and *IGHV4-34*, is also a feature of other indolent lymphomas.

Approximately 20% of immunoglobulin subsets show similar (homologous) patterns of the complementarity-determining region (CDR)3 in both heavy and light chains, designated 'stereotypes'. These are more common in unmutated cases and provide further evidence for antigen selection in the pathogenesis of CLL. Unmutated cases are associated with autoreactivity and polyreactivity to certain molecules and have a more proliferative pattern of disease with a more aggressive clinical course. Determination of the *IGHV* mutation status as mutated or unmutated is also an important prognostic marker (see below). There are some exceptions, notably *IGHV3-21*, which is more often mutated (see Table 29.3) and is associated with poor outcome (comparable to unmutated cases) and has predominantly light chain expression. The reasons for the different clinical behaviour between unmutated and mutated cases may relate to continuous response to antigen stimulation in the unmutated cases eventually leading to genetic instability, while mutated cases minimize cell division by becoming anergic.

CLL B lymphocytes are long-lived and resistant to apoptosis, as shown by upregulation of the anti-apoptotic proteins BCL2, MCL1, Survivin, Toso. This BCL-2 family of proteins share a BH3 motif that is the target of small molecules currently being tested as new therapies. Gene expression profiling in CLL cells suggests that the disease originates from the transformation of a specific common precursor, likely to be an antigen-experienced memory B lymphocyte. This is supported by the constant expression of CD27. There is no evidence that CLL represents two distinct diseases, although detailed gene expression profiling may show some differences between mutated and unmutated cases, notably, the expression of ZAP-70.

Complex interactions between the BCR and the bone marrow and lymph node microenvironment drive the pathogenesis of CLL. These interactions involve stromal cells, including 'nurse' cells, T cells, cytokines, and pro- and anti-apoptotic factors.

Proliferating centres or pseudofollicles, as seen in histological sections, are the tissue hallmark of CLL and the nerve centre for these interactions. In them, B cells are activated and divide and are in close contact with CD4⁺ T cells. One important cytokine is tumour necrosis factor (TNF)- α ; this is consistently expressed in CLL cells, which also express the TNF- α receptor, suggesting that it may act as a growth factor. Abnormal angiogenesis is also associated with tumour progression and this is modulated by vascular endothelial growth factor. The relevance of the micro-environment is underlined by the therapeutic activity shown recently by immunomodulating and anti-angiogenic agents such as thalidomide and lenalidomide.

Clinical and laboratory features

In at least 50% of patients, the disease is diagnosed by chance, following a routine blood examination. In others, the presentation is prompted by symptoms of anaemia or by the discovery of painless lymph node enlargement. Systemic symptoms such as pyrexia, sweating or weight loss are rare. Not infrequently, a prolonged chest infection or pneumonia is the first manifestation of CLL.

Lymph node enlargement is symmetrical and involves the neck, axillae and inguinal regions. Splenomegaly of variable degree is present in two-thirds of cases. Significant hepatomegaly is less frequent. It is possible to document lymph node enlargement in the hilar regions on routine radiography or in the retroperitoneal regions by ultrasound or computed tomography (CT). Although the latter investigations may not add significant prognostic information and are not used for staging purposes (see below), they are often useful for follow-up after treatment. An abdominal CT scan is important in documenting the extent of abdominal lymphadenopathy in patients presenting with palpable nodes. It is rare to find large para-aortic nodes in patients presenting without peripheral lymphadenopathy. Late in the disease process, however, this is not uncommon, and abdominal CT may be necessary to document progression.

New diagnostic criteria

The International Workshop on CLL (IWCLL) and the WHO recommend that at least $5 \times 10^9/L$ monoclonal B lymphocytes (CD19⁺CD20⁺) should be demonstrated in the blood and that they should fulfil the characteristic CLL phenotype, i.e. CD5⁺, CD23⁺, weak or negative staining with FMC7 and CD79b, and weak expression of monoclonal surface membrane immunoglobulin (staining for κ or λ) (see Table 29.1). This, and the characteristic peripheral blood morphology, suffices for the diagnosis of CLL and helps exclude other B-cell disorders, chiefly lymphomas presenting with lymphocytosis (see section Differential diagnosis). A bone marrow aspirate and trephine biopsy is not required for diagnosis if the above findings are typical and the CLL immunophenotypic score is 4–5 (see Table

Figure 29.3 Blood film of a typical case of CLL.

29.2). A bone marrow test is required to assess the nature of cytopenias in order to exclude indolent lymphomas in cases scoring 3 or less, and before initiating therapy as a baseline for assessment of response and to interpret the development of cytopenia after therapy. One exception is small lymphocytic lymphoma (SLL), a condition identical to CLL according to the new WHO classification. SLL requires the presence of lymphadenopathy and/or splenomegaly and requires histopathology confirmation by lymph node biopsy. In contrast to CLL, SLL has less than $5 \times 10^9/L$ B lymphocytes in the peripheral blood. Cases with less than $5 \times 10^9/L$ B lymphocytes in the peripheral blood and not fulfilling the criteria for SLL are categorized as monoclonal B-cell lymphocytosis (see below).

Morphologically, the lymphocytes in blood films are small and show scanty cytoplasm and a characteristic pattern of nuclear chromatin clumping; the nucleolus is inconspicuous and azurophil granules are seen only in a minority of normal T cells (Figure 29.3). The presence of smudge cells, which correlates with the WBC count, is of diagnostic value. A proportion of prolymphocytes (1–5%) are nearly always seen with counts in excess of $30 \times 10^9/L$. If the proportion of prolymphocytes is greater than 10%, it represents a variant designated CLL/PL (Figure 29.4). Some patients have a mixed pattern of small and large cells and others have lymphoplasmacytoid features or even cells with nuclear clefts. These are often associated with other atypical features (see below).

Other haematological features

Anaemia and thrombocytopenia are important prognostic features in CLL and form part of the information used for staging. In advanced CLL, there is heavy lymphocytic infiltration resulting in bone marrow failure. The trephine biopsy shows heavy replacement of fat spaces and haemopoietic cells by lymphocytes (Figures 29.5 and 29.6). In an ageing population it is important always to exclude nutritional deficiencies (iron, folate), which

can easily be corrected by appropriate supplements. The possible causes of anaemia in CLL are listed in Table 29.4. The current staging systems do not clearly distinguish the causes of anaemia as having different prognostic significance. This is probably because marrow failure is by far the most common

cause and there is an assumption that most haematologists will be able to detect anaemias not strictly related to the disease.

Hypogammaglobulinaemia is the rule in advanced CLL and is considered to be responsible for the high incidence of upper respiratory tract infections. Small monoclonal bands, often IgM, are seen in less than 10% of cases. The appearance of a monoclonal band during the evolution of the disease or the discovery of free light chains in the urine (Bence Jones proteinuria) may indicate disease transformation (see below, Richter syndrome).

Figure 29.4 Blood film from a case of CLL/PL. Note the dual population of small lymphocytes and larger nucleolated prolymphocytes.

Immune cytopenias

There is evidence that autoimmune complications, e.g. anaemia or thrombocytopenia, which are rare at presentation (10% and 3%, respectively) do not necessarily confer a poor prognosis if adequately treated. It is important always to carry out the direct antiglobulin test (DAT), or Coombs test, at diagnosis in each patient. The importance of the DAT is twofold: to document

Figure 29.5 Low magnification of a trephine biopsy from a patient with CLL and heavy (packed) lymphocytic infiltration.

Figure 29.6 Higher magnification of the same case as in Figure 29.5 showing scanty fat spaces and diffuse lymphocytic infiltration.

Table 29.4 Causes of anaemia in CLL and their management.

<i>Cause</i>	<i>Diagnostic test</i>	<i>Treatment</i>	<i>Significance</i>
Bone marrow (BM) failure	BM aspirate and/or trephine biopsy	Corticosteroids, CLL therapy	Advanced CLL: stage III (Rai), stage C (Binet)
Haemolytic anaemia	DAT (Coombs test)	Corticosteroids, immunosuppression, splenectomy	Does not affect prognosis but more frequent in active CLL
Red cell aplasia	BM examination	(See text)	Uncertain
Hypersplenism	BM, spleen size	Splenectomy, CLL therapy	Prognosis depends on stage after splenectomy
Folate or iron deficiency	Indices, Fe and folate levels	Appropriate supplements	None; restage when anaemia corrected

autoimmune haemolytic anaemia (AIHA) and to detect its triggering after therapy. Not infrequently, patients have a positive DAT at presentation without overt haemolysis (e.g. no reticulocytosis or raised bilirubin).

The LRF CLL4 trial provided an opportunity to examine in detail the clinical significance of a DAT for the development of AIHA. The findings are only applicable to patients who require therapy, i.e. those with Binet stages A-progressive, B and C. At trial entry 14% were DAT positive, and this was associated with Binet stage C and high β_2 -microglobulin. A positive DAT was a predictor of the subsequent development of AIHA after treatment in 28%; when negative, it predicted that 93% of patients would not develop AIHA. Those who were DAT positive at entry achieved lower complete remission (CR) rates and had worse progression-free survival (PFS) and overall survival (OS), suggesting indirectly that DAT status may be a useful prognostic factor. Overall, 10% of patients developed AIHA during or after therapy; again, this was linked to stage C, high β_2 -microglobulin and positive DAT at entry, and worse outcome. The trial also established that those randomized to fludarabine and cyclophosphamide (FC) had a lower incidence of AIHA (5%) than those randomized to fludarabine alone (11%) and chlorambucil (12%) ($P = 0.01$). Similar data for the comparison between fludarabine and FC were recorded in a German trial. Of note is that AIHA after single-agent fludarabine may be more severe.

The development of autoimmune thrombocytopenic purpura (ITP) is less common and is often associated with positive DAT and AIHA and unmutated *IGHV* genes. The documentation of ITP requires the demonstration of platelet-associated immunoglobulin. If this is not possible, one can still suspect peripheral destruction of platelets by examination of the bone marrow (see below).

A study from the Mayo Clinic which looked retrospectively at the cause of cytopenia in a large cohort showed that those with immune cytopenias did better than those in whom the cytopenia was a result of bone marrow failure, which is not surprising since most of the latter patients would have presented with stage C disease.

Bone marrow examination

Bone marrow aspirates are not as informative as the core biopsy regarding overall cellularity and degree of infiltration. A trephine needs to be at least 2 cm in length (Figure 29.5) to be informative. The value of the biopsy is summarized in Table 29.5. The degree of infiltration provides prognostic information: a densely packed bone marrow (diffuse pattern) with little or no residual fat spaces (Figure 29.6) correlates with advanced CLL: stage C (Binet) or III–IV (Rai). Other bone marrow patterns are interstitial, with relatively abundant fat spaces (Figure 29.7), and nodular (Figure 29.8). Both of these are seen alone or in combination (mixed pattern) in relatively early stages of

Table 29.5 The value of bone marrow trephine biopsies in CLL.*

<i>Prognostic feature</i>
Diffuse pattern: packed bone marrow has poor prognosis
<i>Clarify the nature of cytopenias (before and after therapy)</i>
Low platelets > megakaryocytes
Red cell aplasia
Myelodysplastic changes
<i>Differential diagnosis from low-grade NHL</i>
Paratrabeular pattern not seen in CLL
More proliferation centres in CLL/PL
<i>To assess response to treatment</i>
Nodular partial remission seen only on biopsy (needs immunostaining)
Hypocellular bone marrow, without CLL infiltrates, and low blood counts

*A bone marrow test (aspirate or trephine) is not required for diagnosis.

Figure 29.7 Interstitial lymphocytic infiltration in a case of early CLL with preserved haemopoiesis and abundant fat spaces.

the disease. An increased number of megakaryocytes in the presence of low platelets may suggest ITP (Figure 29.9). Absence of red cell precursors and a low reticulocyte count suggest red cell aplasia. When this is due to parvovirus infection, large basophilic erythroid precursors can be seen in the bone marrow aspirates. Paratrabeular deposits are common in follicular lymphoma and may be seen in SMZL and MCL, but not in CLL. Proliferation centres are a unique feature of CLL and SLL. They are seen in lymph node biopsies and, in very active CLL, also in the bone marrow. Proliferating centres have a high labelling index, as detected by immunocytochemistry with Ki-67 or MIB-1, and show polymorphocytes and para-immunoblasts.

Figure 29.8 Nodular pattern of infiltration in CLL, early in the disease. A similar pattern described as nodular partial remission may be seen after chemotherapy in patients with previously diffuse involvement.

Figure 29.9 Diffuse infiltration in the bone marrow in a patient with CLL, a large spleen and thrombocytopenia. Note the large number of megakaryocytes, which indicated that splenectomy will improve the low platelet count.

There is also a higher expression of CD20 and CD23 in the proliferating centres of lymph nodes and spleen than in the small lymphocytes outside them. This may explain the high levels of soluble CD20 and CD23 in the serum of patients with active CLL.

Bone marrow biopsies are important for assessing response. In particular, a nodular partial remission (PR), which is a good clinical response, can only be defined by a biopsy and not an aspirate. In such cases, the aspirate may show less than 30% lymphocytes which, by the old criteria of response, could have been considered as CR. Immunostaining of the nodules is also important to assess response. If they are composed mainly of B cells (stained with CD20), they reflect residual CLL. If they are mainly T cells (stained with CD3), they may not represent

residual CLL and are consistent with a true CR. When assessing responses, it is always useful to compare the pre-treatment bone marrow with the one at the end of therapy.

Staging systems

The two widely accepted systems are those of Rai (1975) and Binet (1981). Rai's staging system takes the view that CLL cells accumulate first in the blood and bone marrow, then in lymph nodes and spleen, finally leading to bone marrow failure. The chances of a patient surviving will depend largely on the stage at which he or she presents to the physician's attention. The original Rai system has five stages: 0, no anaemia, thrombocytopenia or physical signs; I, lymphadenopathy only; II, splenomegaly and/or hepatomegaly with or without lymph node enlargement and without anaemia or thrombocytopenia; III, anaemia (Hb < 11 g/dL), irrespective of physical signs; and IV, thrombocytopenia (platelets < $100 \times 10^9/L$), with or without any of the above features. Binet modified this system following extensive multivariate analysis from two French studies. This system has only three stages (A, B and C) and is probably more accurate with respect to prognosis for patients with Rai stages I and II. The Binet system groups together patients with anaemia (Hb < 10 g/dL) and thrombocytopenia (platelets < $100 \times 10^9/L$) as group C. The remaining patients are staged according to the number of lymphoid organs involved, considering as one each of the following areas: neck, axillae and inguinal regions, spleen and liver. Group A patients have no organ enlargement or up to two areas; group B patients have three to five involved areas. Thus stage A may correspond to Rai 0, I or II. Recently, the Rai staging has also been simplified and used in trials as follows: stages 0 (low grade), I and II (intermediate), and III and IV (advanced stage). Except for the difference in the level of haemoglobin (10 or 11 g/dL), Rai stages III and IV are the same as Binet C.

In practice, staging is necessary to predict prognosis, make decisions about clinical management and facilitate allocation in randomized trials. Although only patients showing signs of symptoms of disease activity (i.e. upward trend in WBC count, decreasing haemoglobin or platelet levels due to bone marrow infiltration, lymph node or spleen enlargement causing compressive problems, general 'B' symptoms), most stage C and also stage B patients present with some of these features and therefore need therapy.

Because of the increasing practice of routine blood analysis, the presentation patterns of patients with CLL have changed over the last decade. At present, most patients are diagnosed in early phases of the disease (Rai stage 0, Binet stage A), thus undermining the prognostic value of clinical stages as a whole. Moreover, one of the important issues regarding clinical stages, in particular stage A, is that the pace of the disease (i.e. whether it will remain stable or progress) cannot be readily predicted. The Spanish group has shown that a short lymphocyte doubling

time (<12 months) in stage A correlates with poor prognosis. Similarly, the French group showed that those with haemoglobin below 12 g/dL and/or lymphocyte count greater than $30 \times 10^9/L$ fared worse than those with haemoglobin above 12 g/dL and lymphocytes under $30 \times 10^9/L$. The MRC examined both these factors in an observational study, MRC CLL3A, and found that both were indicators of prognosis and that the two criteria were independent of each other. As a result, the MRC uses a definition for stage A-progressive for patients with short doubling times, downward trend in haemoglobin and/or platelets, increasing organomegaly and systemic symptoms. Using these criteria, it has been shown in both the CLL3 and CLL4 trials that patients with stage A-progressive disease fared the same as those with stage B, confirming the validity of the clinical criteria used. Patients with both A-progressive and B disease fared better than those with stage C. Using biomarkers such as CD38, ZAP-70 or *IGHV* mutation status, it is possible to predict those patients who will have a short time from diagnosis to progression and will need treatment. However, as advised by the 2008 IWCLL guidelines, these factors should not be used to initiate therapy outside clinical trials.

Numerous new prognostic factors have now emerged in CLL (see below), and these are being tested against the well-established parameters. These are relevant in particular to stage A, but also perhaps for identifying prognosis and good responders in the other stages. While these new tests are incorporated and tested in the clinic, the simple clinical observations, blood counts, symptoms and physical examination will remain as the best guideline on outcome. With the caveat indicated above (i.e. increasing proportion of patients diagnosed in asymptomatic phase of the disease), clinical stages are still very important as a starting point and, when considering the whole population with CLL, remains the best prognostic indicator. However, for randomized trials in which stage A non-progressive patients will not be entered, the prognostic value of staging loses its strength and other measures which assess the biology of the disease have now become more relevant.

Prognostic factors

The median survival of patients with CLL is around 7 years but the individual prognosis is extremely variable. As previously indicated, the clinical staging systems are still the backbone for assessing prognosis. Patients with low-risk disease (Rai 0, Binet A) have a median survival greater than 10 years, those with intermediate-risk disease (Rai I, II; Binet B) have a median survival of 5–7 years, and patients with high-risk disease (Rai III, IV; Binet C) have a median life expectancy of less than 3–4 years. In addition to clinical stages, many other prognostic factors have been proposed, the most extensively investigated and validated being cytogenetics, *IGHV* mutational status, ZAP-70 and CD38 expression in leukaemic lymphocytes, and serum β_2 -microglobulin levels.

Once patients require therapy, prognostic factors are overcome by effective treatments. Indeed, response to therapy is, as in all cancers, the most important predictor of survival in patients with CLL. Predictors of response to therapy are being actively investigated. The most reliable are del(17p) and del(11q), reflecting, respectively, abnormalities of the *TP53* and *ATM* genes. Patients with these abnormalities do not respond to conventional fludarabine-based therapy or have a short-lived response. Recently, low expression of the microRNA 34a has also been found to predict poor response. The association between *IGHV* mutations, CD38 and ZAP-70 expression and response is not completely settled, but response duration seems to be shorter in patients with these biomarkers, particularly when they are found together.

Age is relevant in as much as it is associated with causes of death other than the disease itself. The effect of age is greater in stage A, in which up to 50% of patients may die of causes unrelated to CLL, such as other cancers or cardiovascular events. Another adverse prognostic factor that has emerged in all UK CLL trials over the last 30 years is male gender (see below).

Response to treatment has also emerged as an important prognostic variable. However, although it is associated with PFS, an association with OS has not been shown in randomized trials. One reason is that although treatment response matters, a patient not responding to first-line treatment, e.g. chlorambucil, may respond to a second treatment, e.g. FC with or without rituximab (FCR). There is increasing evidence that achieving MRD negativity (see below) is clinically important. Patients in CR with no detectable MRD have a longer PFS and OS than those with persistent MRD. However, MRD negativity is an arbitrary concept that depends on the technique used to assess MRD. In addition, patients who achieve MRD-negative status could be those with biologically less aggressive disease and hence with an intrinsically better prognosis. Another important point is that increasing or prolonging treatment to reach MRD-negative status may convey unnecessary risks such as myelotoxicity and infections. There is also the risk of developing secondary myelodysplastic syndrome (MDS)/acute myeloid leukaemia (AML). Furthermore, patients with aggressive disease, such as those with del(17p), do not usually respond to chemoimmunotherapy, yet these patients are those who could benefit most by achieving MRD-negative CR. Because of all these reasons, MRD eradication as a treatment end point is only justified within clinical trials.

Cytogenetics

There are no specific translocations in CLL. Most abnormalities are deletions, or extra copies such as trisomy of chromosome 12. Translocations have been reported in a few cases, e.g. t(14;19) (see below) or t(14;18), but whether these represent typical cases is equivocal. It was well known that analysis of the karyotype of CLL lymphocytes stimulated to divide by a variety of mitogens elicited positive results in less than 50% of cases.

Table 29.6 Hierarchical model of chromosomal abnormalities in CLL.

Karyotype	Döhner	LRF CLL4
Number of patients	352	579
17p13 deletion	7%	6%
11q22–23 deletion	17%	20%
6q21–23 deletion	8%	8%
12q trisomy	14%	15%
Normal karyotype	18%	15%
13q14 deletion as sole abnormality	36%	36%

This is due to normal metaphases, which reflected the karyotype of the normal T cells, and the frequent lack of metaphases in cases with high WBC count. Newer techniques are now available that are able to elicit metaphases in a higher proportion of cases. FISH analysis uses specific probes to detect the most common genetic changes on interphase cells. There is now a panel of at least five probes for studying the most frequent abnormalities, which can be detected in 80% of cases. Thus, we are now in a position in CLL similar to that of the acute leukaemias where distinct chromosome abnormalities of prognostic significance can be detected in most patients. However, it is important to state that none of the abnormalities found are unique or specific for CLL and can be found in other B-cell disorders.

The most important contribution to the subject has been that of Dohner, who in 2000 proposed a hierarchical model for prognosis based on the genetic aberrations found in CLL (Table 29.6). This model is based on the prognostic value of such markers and it is necessary because some patients have more than one abnormality, but the one which counts is the one listed higher in Table 29.6. It should be noted that deletions of 13q14 (Figure 29.10) confer a good prognosis (even better than no abnormality), but only provided they are found as the only change. Table 29.6 also shows the incidence of abnormalities in cases from the LRF CLL4 trial.

The 17p deletion (Figure 29.11) has a much higher incidence (three or four times) in patients with advanced CLL, particularly after multiple treatments, than in those requiring treatment for the first time. The result of the 17p13 deletion at the *TP53* locus often correlates with a point mutation in the other allele and this results in total inactivation of the *TP53* suppressor gene, the most common molecular change in cancer. Although the usual method for detecting *TP53* abnormalities is to use FISH to detect deletion of 17p, overexpression of the *TP53* gene can be demonstrated by flow cytometry and immunohistochemistry. The significance of *TP53* overexpression is probably the same, but these methods are often used mainly in histological section of bone marrow and lymph nodes. As

**Figure 29.10** FISH analysis with a 13q14 probe showing missing red dots in several cells denoting 13q deletion; all the cells are disomic for chromosome 12 (normal pattern).**Figure 29.11** FISH analysis with a *TP53* probe (red) and a control 17 probe. Note many cells with only one (instead of two) red dot, indicating *TP53* deletion.

stated above, *TP53* mutations can be detected by polymerase chain reaction (PCR) and carry similar adverse prognosis. A cautionary note was issued in a report from the M.D. Anderson Center and the Mayo Clinic. A study of 99 previously untreated patients with 17p deletion showed significant clinical heterogeneity, with some patients not showing progression for up to 5 years.

The group with deletion of 6q21–23 represents 8% of cases both in Dohner's series and LRF CLL4. These patients tend to present with high lymphocyte counts but apparently have an overall good prognosis. The deletion at 11q22–23 involves the *ATM* gene and it has been suggested that survival in del(11q)

cases may depend on whether the gene in the other allele is mutated (seen in 12% of cases). Cytogenetic clonal evolution has been reported in 17% of cases, which tend to be unmutated.

Biological prognostic markers

Numerous biomarkers have emerged in recent studies of CLL. These prognostic factors include genetic markers, mutational status of the *IGHV* gene, V_H gene usage, serum levels of β_2 -microglobulin and CD38 and ZAP-70 expression, the latter measured by flow cytometry. A list of these markers is given in Table 29.7. These biological markers have helped to unravel the clinical heterogeneity of CLL. The focus now is on new reproducible markers that relate to the underlying biology, proliferative potential and responsiveness to therapy. Some of these are predictive of time to disease progression from diagnosis; others predict also response to treatment, PFS and OS.

Early work suggested that CD38 expression correlates with unmutated status. Similarly, ZAP-70 emerged from gene expression studies as overexpressed in unmutated cases. The correlation of CD38 and ZAP-70 expression with *IGHV* mutation status is close but not complete and both of these markers assessed by flow cytometry are good predictors of time to disease progression. This may be important information in newly diagnosed patients, especially those with stage A. FISH analysis, which identifies common genetic abnormalities in CLL such as del(6q), trisomy 12, del(13q), del(11q) and del(17p), has been extensively studied in clinical trials, including LRF CLL4 and the German trials. Dohner's hierarchical model for analysis of the cytogenetic abnormalities (see above) has been shown to be reproducible and reliable. FISH has identified two groups of cases associated with aggressive CLL and resistance to conventional chemotherapy. The first group, deletion of 11q22, involves the *ATM* gene and is seen in 20% of those who need

therapy and identifies younger patients, particularly males, who often have significant lymphadenopathy. Although the outcome in del(11q) cases is worse than with other types of cytogenetic abnormality, current combinations such as FC and FCR have significantly improved their response rate and PFS. The other group is defined by the deletion of 17p13, which involves the *TP53* gene and is associated in 85% of cases with a mutation of the *TP53* gene in the other allele. Whether defined by deletion or mutation, the outcome of this group is poor, with a low response rate and very short PFS and OS. A number of recent studies and data from LRF CLL4 suggest that one needs to test for both 17p deletion and mutation to detect all the cases with *TP53* loss of function.

Studies first reported by the group from the M.D. Anderson Center and confirmed in the LRF CLL4 trial have shown the value of measuring β_2 -microglobulin, high levels of which are associated with poor treatment response and short PFS. V_H usage has identified the group with *IGHV3-21* as of poor prognosis regardless of their mutational status (mutated in two-thirds of cases). By combining *IGHV* status, V_H usage, FISH results and β_2 -microglobulin, it is possible to separate cases that have been entered into LRF CLL4 (therefore requiring therapy, i.e. Binet stage A-progressive, B and C) into three distinct prognostic groups: poor risk (6% of cases), defined by 17p deletion; intermediate risk (72% of cases), defined by unmutated *IGHV* genes or del(11q) or *IGHV3-21* usage or β_2 -microglobulin above 4 mg/L; and good risk (22% of cases), defined by mutated *IGHV* genes, but excluding those with *IGHV3-21* usage and/or the other abnormalities that define the intermediate group. These groups are clearly distinguished with respect to PFS and OS.

The IWCLL guidelines do not recommend these tests for diagnosis or for assessment of new patients, but they seem very important once treatment is indicated and for risk assessment when entered into clinical trials.

Table 29.7 Prognostic biomarkers in CLL.

<i>CD38</i> , <i>ZAP-70</i> , <i>CD49b</i> (flow cytometry)
<i>IGHV</i> mutational status (PCR)
<i>IGHV</i> usage (PCR)

<i>TP53</i> mutations (DNA based)
Telomere length (DNA based)
<i>CLLU1</i> (RNA based)
Lipoprotein lipase (RNA based)
Serum factors
β_2 -microglobulin
Soluble CD23
Circulating VEGF
Thymidine kinase

VEGF, vascular endothelial growth factor.

Chromosome translocations involving the *IGH* locus

It is debatable whether translocations of the *IGH* locus are a feature of CLL. Nevertheless, systematic interphase FISH with an *IGH* probe can detect up to 5% of cases with such translocations. Excluding t(11;14), a feature of MCL, some apparently genuine cases of CLL have been reported with t(14;18)(q32;q21) or *IGH/BCL2*, t(14;19)(q32;q13) or *IGH/BCL3*, and very rarely t(8;14)(q24.1;q32) involving the *MYC* gene. The latter cases were described as CLL/PL and some as typical B-PLL. *IGH* translocations have often been described as atypical and associated with poor prognosis. Cases with t(14;19), although rare, have been more extensively characterized. This translocation has been reported in a heterogeneous group of B-cell malignancies including marginal zone lymphomas and, in about half of cases, with a diagnosis of CLL frequently associated with trisomy 12, unmutated *IGHV* genes and low frequency of 13q14 deletion.

IGHV mutation analysis

The most interesting and exciting new findings that relate to prognosis and which may underlie the clinical heterogeneity of CLL are mutational status of the *IGHV* gene and the expression of CD38 and of ZAP-70. Somatic hypermutation is the process by which B cells, after the initial recombination of immunoglobulin genes, undergo further change in order to produce high-affinity antibodies. This event occurs within the germinal centre and gives rise to memory B cells and plasma cells.

CLL was for many years thought to be a disease of early or immature CD5-positive B cells with unmutated *IGHV* genes. More recent studies showed heterogeneity, and this was consolidated by two landmark papers in 1999 by Damle and Hamblin, demonstrating that just over half of the patients had mutated *IGHV* genes (Table 29.8), defined by convention as less than 98% homology to the nearest germline sequence.

Many studies have confirmed the original finding, which suggested initially that there were two forms of CLL: the unmutated type, associated with all the features of poor prognosis; and the mutated type, associated with stable disease and good prognosis (Table 29.8). Of interest is the finding that many of the poor prognostic features, such as stages B and C, male gender, atypical morphology, trisomy 12 and 11q deletion, are seen predominantly in unmutated cases, whereas the opposite is true for the mutated ones.

Data based on gene expression profiling has shown unequivocally that CLL has a characteristic pattern of expression (or signature) that is independent of *IGHV* mutation and is distinct from that of other B-cell lymphomas such as MCL, follicular lymphoma and diffuse large B-cell NHL. The genotype of CLL was defined by a common pattern of expression of 12 000 genes, with only between 23 and 200 differentially expressed in

mutated versus unmutated cases. One notable difference is the high expression (four to five times higher) of ZAP-70 in unmutated cases.

CD38 and ZAP-70

Early studies showed that unmutated cases correlated with higher expression of the transmembrane glycoprotein CD38. This correlation is seen in only two-thirds of cases. Therefore CD38 could not be regarded as a surrogate marker for *IGHV* mutational status. Nevertheless, many studies have now shown that CD38 is an important prognostic marker. Low percentages correlate with stable disease, while a high percentage of CD38-positive cells predicts a short time to disease progression and worse OS.

There are several caveats for the determination of CD38. Although assessed by flow cytometry and simpler than PCR and sequencing, which are used for *IGHV* mutations, CD38 should only be tested on CLL B lymphocytes and should exclude T cells, which strongly express this antigen. This is currently done by triple labelling with CD5, CD19 and CD38 and appropriate gating. Another issue is the best threshold for CD38 positivity. Early reports suggested 30%, but more recent studies recommend a lower figure (7%) as being more likely to be clinically relevant. This relatively simple determination seems to add to the constellation of markers useful for assessing prognosis in individual patients and predicting time to disease progression.

ZAP-70 is a protein tyrosine kinase and is of relevance in T-cell signalling. ZAP-70 can be demonstrated by flow cytometry, immunocytochemistry and Western blotting, and several studies have now shown a high concordance with the mutation status (~90%). Thus, ZAP-70 may be a better surrogate marker than CD38 for establishing *IGHV* mutational status without having recourse to molecular methodology. Studies using ZAP-70 have confirmed its prognostic value, particularly in patients with stage A disease, in whom early assessment of the need for future therapy may be desirable. The assessment of ZAP-70 by flow cytometry (Figure 29.12) requires the exclusion not only of T cells (as for CD38) but also of natural killer (NK) cells, as both cell types express this cytoplasmic protein strongly. Thus, the determination of ZAP-70 requires cell permeabilization procedures and staining for CD3 and CD56 (for T and NK cells), CD19 and CD5 (for CLL cells) and ZAP-70.

Role of microRNAs in CLL

MicroRNAs are a large family of short, non-coding, single-stranded molecules that regulate almost one-third of human genes. They are involved in a variety of normal and pathological processes and have recently been implicated in the pathogenesis of CLL. Two microRNAs, *MIR15* and *MIR16*, are located at 13q14, a region frequently deleted in CLL (see above). Both genes are deleted or downregulated in about two-thirds of cases and have been linked to initiation and progression of the

Table 29.8 Mutational status of *IGHV* genes in CLL (broad differences).

	<i>Unmutated</i>	<i>Mutated</i>
Incidence	45%	55%
Male/female ratio	10:1	1.1:1
Trisomy 12	Frequent	Infrequent
Abnormal 13q14	Rare	Common
Stage (Binet)	B and C (2/3)	Stage A (2/3)
Disease course	Progressive	Stable
CD38/ZAP-70	Frequently expressed	More often negative
Therapy*	Often required	Not always needed
Response	Less than optimal	Better
Survival/PFS	Short	Long

*When indicated on clinical grounds.

PFS, progression-free survival.

Figure 29.12 Flow cytometry plots of ZAP-70 in CLL. Top left: ZAP-70⁺CD19⁺ lymphocytes. Top right: control ZAP-70⁺ T and NK lymphocytes (CD2⁺). Bottom left: a ZAP-70⁻ case and the positive control T/NK cells (bottom right).

disease. Both microRNAs target *BCL2* which, as a result, is overexpressed in CLL. The expression profiles of microRNAs were investigated by Croce's group in close to 100 cases. They reported a unique microRNA signature that distinguished CLL according to *IGHV* mutation status and ZAP-70 expression. The mouse homologues of *MIR15* and *MIR16* are also deleted in the *TCL1A* transgenic mouse model, which develops a disease very similar to CLL, confirming their relevance in pathogenesis.

Another microRNA that may be important in CLL is *MIR34a*, which has very low expression in cases refractory to chemotherapy and with impaired DNA damage response, irrespective of whether such cases have deletions and/or mutations of *TP53*. If these findings are confirmed, they may provide a new tool for identifying drug-resistant cases and avoiding unnecessary use of non-effective drugs. Other microRNAs that may have relevance to CLL and its prognosis are *MIR29c* and *MIR223*, which were shown to have low expression in poor prognostic cases and to predict treatment-free and overall survival.

Gender differences

In CLL, female patients survive longer than males. The male to female ratio in CLL is 2:1 but in younger patients it is often higher. The proportion of cases with stage A is higher in women than in men, i.e. 40% versus 28%, while in men the proportion with stages B and C is higher. Despite women being older, gender remained an independent prognostic factor for response, PFS and OS in patients entered into UK clinical trials as shown in a number of consecutive MRC trials. This difference might be due at least in part to biological differences since, in a study

of over 900 cases, 51% of men and 37% of women had no *IGHV* mutations; in contrast, 63% of women versus 49% of men did have *IGHV* mutations ($P < 0.0001$).

Differential diagnosis

This has been partly discussed above in the methodology for diagnosis. One problem is when CLL has atypical morphology and another when the CLL immunophenotypic score is below 3. The most common morphological change is the increased proportion of larger nucleolated prolymphocytes. When there are more than 10% of these cells in blood films, the disease is described as CLL/PL.

CLL/PL is a proliferative form of CLL, not infrequently associated with trisomy 12 or *TP53* deletion, high rate of cell divisions (as shown with the antibody Ki-67) and histologically by many proliferating centres in lymph nodes and bone marrow sections. Occasionally, lymph nodes seem totally replaced by prolymphocyte-like cells, a situation that can provisionally be described as 'accelerated' CLL. Peripheral blood films always show a dual population of small lymphocytes and prolymphocytes. CLL does not transform to B-PLL, which is a distinct clinicopathological entity (see below).

When atypical features are present, including those of CLL/PL, it is important to consider the differential diagnosis with NHL evolving with lymphocytosis, notably MCL which, like CLL, is CD5 positive. The best method to exclude (or confirm) MCL is to test for t(11;14) by FISH and/or to demonstrate expression of cyclin D1 by immunohistochemistry. Other NHLs can be excluded by histological criteria (see Chapter 33)

and the combination of immunophenotype and peripheral blood morphology (see below).

Genetic predisposition to CLL

Evidence from epidemiological and family studies supports the view that there is inherited susceptibility to CLL in a significant subset of patients. Case reports of leukaemia families and case-control and case cohort studies all showed that the relative risk of developing CLL in patients' relatives is three to eight times higher than in the normal population. The molecular basis of familial CLL is currently being unravelled by means of genome-wide association studies, including both families and sporadic cases. Familial CLL often cosegregates with other B-cell disorders, chiefly Hodgkin lymphoma and lymphoplasmacytic lymphoma, suggesting that the predisposition to CLL is mediated through pleiotropic genes.

The search for the genetic basis of CLL has been active in the last few years with the possibility of collecting DNA samples from familial cases. Figure 29.13 illustrates families with several affected members. There is a strong rationale for searching for moderate- to high-risk mutations in linkage studies. The largest of these included 206 families and suggested a possible disease locus at 2q21. However, subsequent studies in two large multi-generational families failed to confirm this finding. Therefore the possibility that a single gene mutation is involved in the predisposition to CLL is now considered unlikely, the current hypothesis being that susceptibility to CLL is a consequence of the co-inheritance of several low-penetrance gene variants. This 'common-disease, common-variant hypothesis' concept can only be ascertained by large genome-wide association studies based on the analysis of SNPs. Such a study, conducted at the Institute of Cancer Research, identified for the first time six

previously unreported CLL risk loci. The most significant statistical association was at 6p25.3, which is the locus for the gene for interferon regulatory factor 4 (*IRF4*), previously known as *MUM1* (multiple myeloma oncogene 1). *IRF4* is a key regulatory transcription factor involved in lymphocyte development, proliferation and regulation of the immune response.

Monoclonal B-cell lymphocytosis

Recent studies have demonstrated a higher incidence of monoclonal B-cell lymphocytosis (MBL) in 'normal' relatives of patients with familial CLL. Small B-cell clones can be detected by very sensitive flow cytometry assays using CD5, CD19, CD20 and CD79b. The incidence of MBL in these individuals is four times greater than in the general population. The incidence is even higher when looking at people under 40 years of age.

MBL is now defined as the presence of less than $5 \times 10^9/L$ monoclonal B lymphocytes in the peripheral blood, in the absence of lymphadenopathy, splenomegaly, cytopenias or disease-related symptoms. Patients with MBL may have a moderate absolute lymphocytosis ($>4 \times 10^9/L$) or a completely normal lymphocyte count. In the majority of cases the immunophenotype is identical to that of CLL, i.e. CD5⁺ and CD23⁺ monoclonal B lymphocytes. MBL represents either a precursor state for CLL or a distinct entity, in the same way that monoclonal gammopathy of unknown significance (MGUS) relates to myeloma. MBL could be detected in 5% of subjects (aged 60–80 years) with a normal WBC count and in a higher proportion of those presenting with lymphocytosis. MBL may progress to frank CLL at a rate of 1–2% per year. Studies by the Leeds group showed that in those presenting with lymphocytosis, CLL may develop in 15% and that half of them may eventually require treatment. Of interest too is that the 13q14 deletion,

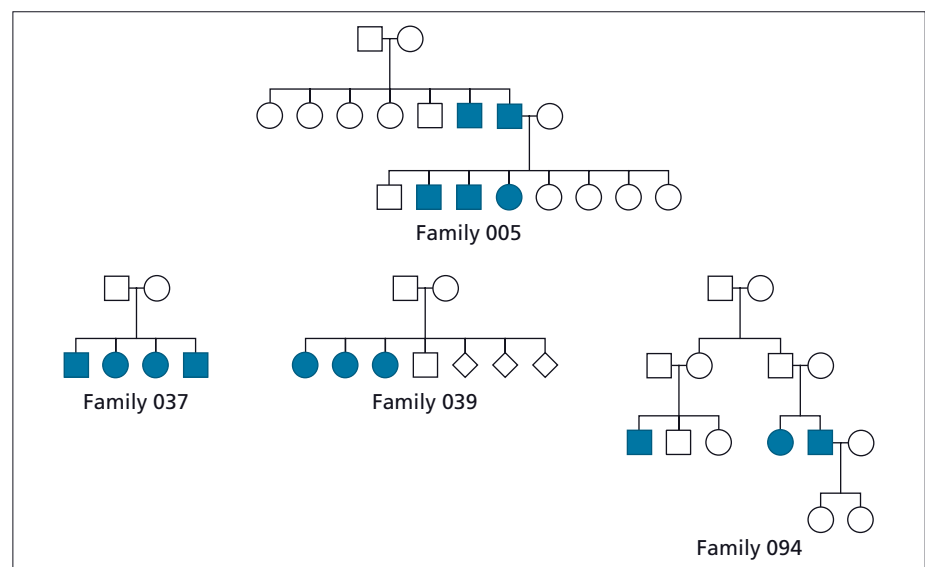

Figure 29.13 Four pedigrees of familial CLL cases with three or more affected per family.

which characterizes benign cases of CLL, is often seen in MBL. Data on *IGHV* usage are still inconclusive but those with higher B-lymphocyte counts tend to show the same biased usage as in CLL.

In a large retrospective study of patients who were found subsequently to have developed CLL (up to 6 years later), a prediagnostic B-cell clone, consistent with MBL, was demonstrated in the majority (98%). This strongly suggests that CLL may always be preceded by MBL, but it does not mean that MBL will always lead to CLL. A Spanish group has shown, using highly sensitive eight-colour flow cytometry instead of the standard four-colour method, that the frequency of MBL (or at least small B-cell clones) was higher than previously reported in healthy individuals, also increasing with age.

Polyclonal B-cell lymphocytosis

In contrast to MBL, a rare abnormality described as polyclonal B-cell lymphocytosis has been recognized. The absolute number of B cells is increased in affected patients, but staining with anti-light chain antibodies shows lack of clonality and normal proportions of κ - and λ -staining cells. For several reasons this entity, which appears not to be malignant, needs to be recognized, not least because in some patients it may mimic CLL or other B-cell disorders. Disease features are median age 40 years, lymphocyte count $3\text{--}15 \times 10^9/\text{L}$ (median 6.5), splenomegaly (15%) and mild bone marrow infiltration, sometimes showing intrasinusoidal distribution; 95% of patients are smokers and 90% have HLA-DR7 in their genotype. The cell markers are non-clonal, CD19⁺, FMC7⁺, CD5⁻, CD23⁻, CD27⁺ and the patients have elevated levels of serum IgM (polyclonal). Despite the benign and non-clonal nature, distinct abnormalities have been shown in the B lymphocytes: an extra copy of the long arm of chromosome 3 in the form of iso(3q) and also the presence of *IGH/BCL2* rearrangements. A minority of patients (~3%) may develop NHL. The blood picture is pleomorphic and frequently shows binucleated lymphocytes (Figure 29.14), which are characteristic of this condition. It is important to follow these patients closely and it is even more important not to institute any treatment.

Management

The indications for active treatment depend on the stage of the disease. For patients with stage A (Binet) or stages 0, I and II (Rai), a period of observation may be necessary to decide whether the pattern of the disease is stable or progressive. Most patients with stage B and two-thirds of those with Rai stage II will show progression within the first year or two after diagnosis. This is manifested by further organ enlargement, a downward trend in haemoglobin and/or platelets and a slowly rising WBC count. As responses are better with less disease, some trials have compared early versus delayed therapy to see whether

Figure 29.14 Blood film from a case of polyclonal B-cell lymphocytosis showing a binucleated cell characteristic of this condition.

survival improves. A number of trials showed that early treatment with chlorambucil was, if anything, deleterious, with more deaths due to progression in the group treated early. This was confirmed in a large overview. Thus, the old wisdom of watch and wait should continue to prevail for stage A patients, at least for the time being.

Nevertheless, the issue of early treatment in stage A patients may need to be revised, for two main reasons. First, it is now possible to better identify the patients likely to progress using some of the new prognostic factors defined above, for example unmutated *IGHV* genes, CD38/ZAP-70 expression, short lymphocyte doubling time, 17p or 11q deletions. It is in this group that randomized studies are currently being carried out to see whether early therapy may improve survival. Second, the combination of purine analogues with monoclonal antibodies increases the proportion of remitters and the quality of the responses; therefore, there may be of potential benefit early in high-risk cases.

Spontaneous regression

Spontaneous clinical remissions may occur in CLL but these are usually not complete. Based on patients entered in MRC CLL trials, 1.5% of stage A patients may undergo a spontaneous reduction of the lymphocyte count greater than 50%. The remission is rarely complete, most patients having persistent disease by flow cytometry and the remission is usually transient. The mechanisms behind spontaneous remissions are poorly understood but could be triggered by immune-mediated reactions.

Criteria for response

The definitions of response used in the UK for CLL3 and CLL4 trials were broadly similar to the National Cancer Institute (NCI) 1996 guidelines. These definitions have been updated and clarified in the 2008 IWCLL guidelines (see below). A bone

marrow biopsy is required to define the category of nodular PR by the presence of discrete or moderately large nodules of residual CLL. In this context, it is important to carry out immunohistochemistry as in some patients the nodules may contain mainly T cells rather than B cells. CR requires normalization of blood counts and the bone marrow, whereas a PR requires the regression of at least 50% of organomegaly and lymphocyte counts. A bone marrow aspirate is required also to assess MRD by flow cytometry (see below).

New IWCLL definition of response

The new IWCLL guidelines include minor changes from the 1996 NCI guidelines. They propose more stringent recommendations for use in clinical trials than in general practice. This is to stress the need to collect useful data in clinical trials rather than to downgrade the care given to patients outside trials. The criteria for CR require less than $4 \times 10^9/L$ lymphocytes in the peripheral blood and, ideally, without residual CLL cells as tested for MRD by flow cytometry. The definition of CR is otherwise the same as in 1996. For clinical trials the new recommendation is to test for MRD in bone marrow aspirates; thus there are two types of CR: MRD negative and MRD positive (see below). Immunohistochemistry should always be performed if residual nodules are present in the biopsies (see above) and the bone marrow needs to be tested at least 2 months after the end of therapy. CT should be repeated only if it was abnormal at the start of therapy. A new term, incomplete CR, is now used to describe patients with persistent anaemia, thrombocytopenia or neutropenia, due to myelotoxicity, who otherwise fulfil the criteria for CR. If the bone marrow is hypocellular, it is recommended that the biopsy be repeated once the blood counts have recovered.

Assessment of minimal residual disease

Refinements in flow cytometry now contribute to the definition of MRD with the same level of sensitivity as molecular methods. MRD positivity (i.e. $>0.05\%$ bone marrow cells) predicts a shorter event-free survival and a shorter remission. The standard method adopted by most international groups is four-colour flow cytometry, which has a level of sensitivity similar to that of allele-specific oligonucleotide PCR (i.e. 1 in 10 000 leucocytes). Thus, CR may now be defined as MRD negative depending on whether there is less than one leukaemic cell per 10 000 leucocytes. Methods have now been standardized and published in a report from the ERIC group. These are based on the CD5/CD19 combination, always with two other reagents such as κ and λ , CD20 and CD38, CD43 and CD79b, CD22 and CD81, and CD45 and CD14. If the first four tubes contain CD5/CD19/ κ/λ and all the B cells are CD5⁺ with restricted light-chain expression, there is no need to test the other MRD combinations. It is likely that the end point of new clinical studies in CLL will be to achieve CR with negative MRD. The sensitivity of the method used to evaluate MRD should always be reported.

MRD should be investigated in the bone marrow, as peripheral blood cells may be MRD negative for some months after treatment using monoclonal antibodies and are thus less reliable at that point.

Treatment

In the last few years, important progress has been made in the treatment of CLL. However, there is not yet a curative therapy for this form of leukaemia. Because of this, and the variable impact of the disease on patient survival, treatment needs to be adapted to the patient's risk. Importantly, the diagnosis of CLL is not equivalent to the necessity for starting therapy. Treatment is only indicated when any of the following features is present: (i) fever without evidence of infection, extreme fatigue, night sweats or weight loss; (ii) increasing anaemia or thrombocytopenia due to bone marrow infiltration by leukaemic cells; (iii) bulky or progressive lymphadenopathy; (iv) massive or progressive splenomegaly; (v) autoimmune cytopenias, which do not respond to corticosteroids; and (vi) rapid lymphocyte doubling time (e.g. <6 months). Hypogammaglobulinaemia or increased WBC counts, in the absence of any of the above criteria, are not enough to initiate treatment. Likewise, younger age, the mere availability of a bone marrow donor, or poor-prognosis biomarkers such as *IGHV* unmutated status or high ZAP-70 expression are not per se criteria to initiate treatment.

Treatment of patients in early-stage disease (Binet A, Rai 0) with chlorambucil or other alkylating agents delays disease progression rate but does not prolong survival. The impact of recent and more effective therapies in the natural history of patients in early stage as a whole has not been investigated. A proportion of patients in intermediate stage (Rai I and II, Binet B) have indolent disease; these patients may be followed with no therapy, like those in early stage. However, most patients with intermediate-stage disease and nearly all patients with advanced-stage disease (Rai III and IV, Binet C) need therapy.

Factors to be considered before indicating treatment include patient's age, performance status and associated diseases as well as the patient's expectations; also important are the characteristics of the disease, including biomarkers such as del(17p) or del(11q). Corticosteroids as initial treatment for stage C patients have been used in UK trials for many years. These are given at 30 mg/m² daily for 3 weeks, and reduced gradually for another week. Platelets rise within 4–6 weeks, as does the haemoglobin, and the WBC count follows a characteristic curve, rising after 3 or 4 weeks, sometimes doubling the initial count and then gradually coming down. This is nearly always accompanied by a decrease in size and softening of lymph nodes and spleen. This effect may facilitate subsequent therapy with agents that affect normal haemopoietic cells, and it seems more important when used before chlorambucil. It is not clear whether steroids are useful before combinations using fludarabine (e.g. FC or FCR).

For many years chlorambucil has been the treatment of choice for CLL. Chlorambucil yields a small proportion of complete responses (5–10%) and although it improves symptoms, survival is only slightly, if at all, affected. Because of this, chlorambucil is usually given to patients not able to tolerate more effective therapies. It should be noted that the doses of chlorambucil (and of cyclophosphamide) have varied widely in different studies and there is a clear indication of a dose–response curve. For example, the CALGB trial and the German CLL5 trial used chlorambucil at a dose equivalent to 40 mg/m² monthly and the reported CR rates were 3% and 5%, whereas the UK CLL3 and CLL4 trials used 60 mg/m² and 70 mg/m² (given as 10 mg/m² for 7 days every 4 weeks) and the CR rate was higher (7% in CLL4). Chlorambucil is still used as the standard comparator in many current trials. Because of its relative safety it is still recommended for patients over the age of 70 years or those with comorbidities.

A number of randomized studies conducted in the 1970s and 1980s showed that anthracycline-based therapy, such as cyclophosphamide, doxorubicin, vincristine and prednisolone (CHOP), produced a higher response rate than chlorambucil but that survival was not improved. Despite this, CHOP in combination with rituximab (R-CHOP) may be of some efficacy in patients with progressive disease who are poor responders to chlorambucil or fludarabine and, particularly, in those who develop Richter syndrome.

The greatest advance in the treatment of CLL in the last decade has been the development of monoclonal antibodies (Table 29.9) and the advent of the purine analogues (fludarabine, cladribine, pentostatin). Fludarabine's mode of action includes inhibition of DNA synthesis and DNA repair and activation of the apoptotic pathways. These mechanisms significantly enhance the effect of this agent when used in combination with other drugs (e.g. cyclophosphamide and mitoxantrone) and antibodies (e.g. rituximab). Treatment with fludarabine results in a higher CR rate than that achieved with chlorambucil or alkylating-based chemotherapies (20–40% vs. 10%) and a longer disease-free interval, although survival and PFS are not prolonged. The efficacy of fludarabine is improved by combining it with other agents (e.g. cyclophosphamide, mitoxantrone, rituximab). Using fludarabine in combination with other agents the CR rates have increased, for example from 20–35% when

Table 29.9 Monoclonal antibodies in clinical use for CLL.

Alemtuzumab (anti-CD52)
Rituximab (anti-CD20)
Ofatumumab (anti-CD20)
GA101 (anti-CD20)
Lumiliximab (anti-CD23)
Epratuzumab (anti-CD22)

used alone in previously untreated patients to 30–45% with cyclophosphamide (FC), 45% with rituximab and 65% with the FCR combination in the experience of the M.D. Anderson Center and confirmed in the CLL4 German trial. FCMR (adding mitoxantrone to FCR) may be an even more powerful combination, currently used in Spanish and UK trials.

The issue of first-line fludarabine and/or its combination with cyclophosphamide has been clarified in randomized controlled trials (Table 29.10). Taken together, current results indicate that FCR not only results in a response rate superior to fludarabine or FC, but a longer freedom from progression. In addition, new evidence from the German CLL8 trial comparing FCR and FC suggests, for the first time in a randomized trial, an improvement in OS. As a result, rituximab-based chemoimmunotherapy is now considered as the best upfront therapy for patients with CLL, particularly for those patients in whom, as discussed above, achieving MRD-negative CR is deemed a worthwhile target.

The FC component of FCR can be given by the intravenous or oral route. Using the intravenous route, fludarabine is given at 25 mg/m² and cyclophosphamide at 250 mg/m², both over 3 days. Orally, fludarabine is given at 24 mg/m² and cyclophosphamide at 150 mg/m², both over 5 days. Rituximab is given at 375 mg/m² on day one (or over 2 days) with the first course of FC, and then at 500 mg/m² on day one for the remaining five courses (courses 2–6), which are given at 4-week intervals.

Two other purine analogues with activity in CLL are cladribine (2-chlorodeoxyadenosine) and pentostatin (2-deoxycoformycin). Cladribine in particular can achieve as good a response as fludarabine and, in previously untreated CLL, the CR rate of the combination cladribine plus cyclophosphamide has been reported as 29% and nodular PR 24%. Although cladribine and fludarabine have not been compared directly, cladribine appears to be the more myelotoxic of the two. Pentostatin has been used

Table 29.10 Results with the combinations FC and FCR in randomized trials.

Study	No. of patients	Therapy	CR (%)	Median PFS (months)
Flinn <i>et al.</i> (US Intergroup Trial E2997)	278	FC	23	32
Catovsky <i>et al.</i> (LRF CLL4)	390	FC	38	43
Eichhorst <i>et al.</i> (German CLL4)	375	FC	24	48
Hallek <i>et al.</i> (German CLL8)	371	FC	27	32
	390	FCR	52	43

in combination with cyclophosphamide (PC) and rituximab (PCR). Another older agent, bendamustine, has rekindled interest because it combines the properties of an alkylating agent and a purine analogue. Bendamustine may be more effective than chlorambucil and is currently undergoing trials in combination with rituximab.

The downside of using combinations with fludarabine or other purine analogues is that they are more myelotoxic (manifested as neutropenia) and immunosuppressive (manifested as lymphopenia) and care should be taken to use prophylactic measures, such as co-trimoxazole to prevent *Pneumocystis jirovecii* pneumonia and aciclovir to prevent herpesvirus reactivations.

The introduction of alemtuzumab (Campath-1H), rituximab and other antibodies (Table 29.9) has opened the door for more targeted biological agents with little or no myelotoxicity. Alemtuzumab (anti-CD52) acts through antibody- and complement-mediated cytotoxicity. It has potent activity in previously untreated CLL but requires prolonged periods (18 weeks) of treatment to achieve CR. In fludarabine-resistant CLL, the CR rate is 2% but 31% achieve a PR. Its role in the management of CLL continues in active investigation, whether as first line, as consolidation to improve the quality of remission and MRD and/or as salvage therapy to rescue resistant cases. Alemtuzumab can be given intravenously or by subcutaneous injection. The standard dose is 30 mg three times a week (normally Monday, Wednesday and Friday), but this dose is reached over 5 days, starting with 5 mg and increasing gradually to 30 mg. The course duration depends on the indication: for eradication of MRD-positive disease it is 4–6 weeks; for the treatment of relapsed/refractory CLL it is 12–18 weeks. Currently, alemtuzumab is being tested in combination with fludarabine, high-dose methylprednisolone and rituximab. Alemtuzumab has activity in del(17p) cases when used alone and in combination with high-dose methylprednisolone. Toxicity of alemtuzumab includes rigors, chills, fever, immunosuppression and lymphocytopenia. Opportunistic infections can be observed. Cytomegalovirus (CMV) reactivation is a problem that deserves close monitoring and pre-emptive therapy. Responses to alemtuzumab vary in different disease sites, being higher in peripheral blood and bone marrow than in spleen or lymph nodes.

Rituximab (anti-CD20) has potent activity in high- and low-grade NHL and CLL when used in combination with fludarabine, FC, FCM, chlorambucil and high-dose methylprednisolone. Its mechanism of action is by complement-dependent cytotoxicity, activation of the intrinsic pathway of apoptosis and membrane-associated kinases. The lack of T-cell immunosuppression and its good tolerability makes it ideal for older individuals. Several studies are ongoing but it is likely that all will be positive, the limiting factor remaining its high cost. Unlike Campath, rituximab has limited activity on its own, unless used in very high doses, therefore remaining as an effective potentiator of apoptosis in combination with cytotoxic drugs.

Of particular interest are other monoclonal antibodies such as ofatumumab (Humax anti-CD20), lumiliximab (anti-CD23) and epratuzumab (anti-CD22) (Table 29.9). Two of the monoclonal antibodies against CD20, ofatumumab and GA101, may have a higher therapeutic index than rituximab. Other new treatments are being actively investigated in CLL, such as the *BCL2* antisense oligonucleotide Genasense (oblimersen). Two new drugs, lenalidomide and flavopiridol, might add to the list of agents active in CLL with del(17p) (such as alemtuzumab and high-dose methylprednisolone), although this notion needs further investigation. At the same time, treatment strategies are becoming more complex, targeting not only leukaemic cells but also the microenvironment, T-cell dysfunction and immune disturbances that are part of the CLL neoplastic process. Lenalidomide (Revlimid; see also Chapter 31) is currently being tested in two Phase III trials: (i) as first-line therapy versus chlorambucil; and (ii) as maintenance after second-line therapy (at least a PR) versus a placebo.

Role of splenectomy

Splenectomy is now rarely indicated for patients with a large spleen and in whom initial treatment achieves only a moderate reduction in spleen size. Patients with features of hypersplenism (peripheral cytopenias and an active bone marrow), as well as those with ITP and AIHA refractory to therapy, may benefit from splenectomy. This has low morbidity and mortality and may benefit patients with a large spleen and low blood counts, even if only as part of a debulking procedure. Prophylaxis with pneumococcal vaccines may not be effective in advanced CLL where antibody formation is reduced; thus patients require long-term penicillin or amoxicillin. Splenectomy may improve quality of life by raising haemoglobin levels and improving platelet counts in about 50% of cases. Although a rise in the lymphocyte count is often seen after splenectomy, one-third of patients still do not require therapy for long periods.

Stem cell transplantation

The number of stem cell transplantation (SCT) procedures for CLL has increased dramatically in Europe in the last decade. Three modalities are currently considered: autologous SCT, conventional allogeneic SCT with high-intensity therapy, and allogeneic SCT with low-intensity procedures or 'mini' allografts.

The necessary condition for the success of an autologous transplant is to achieve CR before the procedure, which is extremely unlikely in patients refractory to the chemoimmunotherapy regimens. Moreover, unfavourable prognostic factors for response to conventional chemotherapy, for example del(17p) and del(11q), also predict poor results with autologous transplantation. Autologous transplantation does not cure CLL but might prolong survival in selected patients (i.e. those responding to salvage therapy, without unfavourable prognostic factors, and transplanted early in the course of the disease).

The feasibility of autologous SCT in CLL was tested in an MRC pilot study, which registered over 100 patients between 1996 and 2001. After remission with fludarabine and priming with cyclophosphamide, a peripheral blood stem cell harvest was planned in the good remitters (CR, nodular PR). Only two-thirds of patients were transplanted after high-dose cyclophosphamide and total body irradiation. Failure to do so was because of inadequate remission in 20% and failure to harvest enough stem cells (CD34⁺ cells) in those achieving remission. The question of long-term benefits has been tested in a randomized European intergroup study. Preliminary data from this study indicate a prolonged PFS in those who received an autograft, but no difference in OS. A German study showed that patients with unmutated *IGHV* genes do significantly less well than those with mutated *IGHV* genes, but comparison of unmutated cases with a matched group treated without autograft suggests that this therapy may be more beneficial to the unmutated or poor-prognostic cases than to the mutated ones. A problem of major concern with autotransplants is the risk of secondary MDS/AML (2–5%), particularly in patients conditioned with total body irradiation.

Allogeneic transplantation in CLL may offer the chance of cure in a minority of patients. Allogeneic SCT should be particularly considered in those cases refractory to, or who relapse shortly (<12 months) after, modern chemoimmunotherapy. The effect of allografts relies on the graft-versus-tumour effect that notably overcomes poor prognostic features such as 17p deletions. Both family related and unrelated donors are used, the experience with cord blood as a stem cell source being scarce. In unselected registry series, the transplant-related mortality can be as high as 40%, whereas in selected series from experienced centres it is 25–35%. Reduced intensity or ‘mini’ allografts has lower transplant-related mortality of around 15–25%, but is still higher than with autografts (<5%). In all allograft series there is a plateau in disease-free and overall survival (40–60%), although late relapses (>7 years after transplant) can be observed. Treatment results are better in younger patients, not heavily pretreated and still showing some degree of response to therapy. Allografts should be performed within clinical studies and never as a last desperate attempt in extensively pretreated patients in poor clinical condition, and refractory disease.

Management of autoimmune complications

The most common immune complications in CLL are AIHA, ITP and pure red cell aplasia. Control of haemolysis can be achieved by corticosteroids (prednisolone or dexamethasone), but long-term management requires the DAT to become negative. This can be achieved with the addition of another agent, usually daily cyclophosphamide (100 mg/day), ciclosporin (150 mg twice daily) or mycophenolate mofetil (1 g twice daily). Rarely, in resistant cases, these agents may be used in combina-

tion. The advantage of cyclophosphamide is that it may provide a degree of control of the CLL. Rituximab has been reported to have beneficial effect when used in combination with cyclophosphamide and dexamethasone. AIHA often needs long-term treatment and may require a splenectomy. When the DAT remains positive, the risk of haemolysis continues. Achievement of a CR may be the best way to control AIHA and prevent recurrence. Alemtuzumab has also been shown to be useful for this indication.

ITP, although less common, also requires active treatment, as for AIHA. In those cases not responding to corticosteroids, high-dose γ -globulin infusions over 5 days may improve the platelet count and are often a good guide as to the subsequent benefit of splenectomy. Ciclosporin and rituximab are both effective in refractory ITP. ITP is usually more difficult to manage than AIHA and, more often than in the latter, one needs to resort to splenectomy.

Pure red cell aplasia is an uncommon but well-recognized complication. Some cases are secondary to parvovirus B19 infection. Ciclosporin, with or without corticosteroids, may resolve this complication. Rituximab and alemtuzumab have been reported to be able to reverse this process, which is sometimes very acute. It is paradoxical that rituximab and alemtuzumab have occasionally been reported to facilitate parvovirus infection and cause pure red cell aplasia. Rituximab has also been associated with delayed-onset neutropenia. The exact mechanism of the immune complications in CLL is still poorly understood and this explains the unusual, but well-documented, reports of the same agents causing or correcting these complications.

Richter transformation

‘Immunoblastic’ or large-cell transformation (Richter syndrome) is the most common form of transformation in CLL. The change occurs usually in one or several lymph nodes which show the features of diffuse large B-cell lymphoma (DLBCL). Richter syndrome is associated with systemic symptoms (fever and weight loss), increased serum lactate dehydrogenase levels and unexpected unilateral lymph node enlargement, not rare in the retroperitoneal area. Richter syndrome occurs in around 7% of CLL cases, but the incidence may be higher if lymph node biopsies are performed when unexplained systemic symptoms (e.g. fever) develop in a patient with previously well-controlled disease. In rare cases, transformation takes place in the bone marrow and is therefore seen in trephine biopsies. In such cases the large blast-like cells spill over to the peripheral blood and the morphology may resemble that of an acute leukaemia (Figure 29.15). Richter syndrome is often associated with monoclonal proteins in the serum or free light chains in the urine. Studies with immunoglobulin gene rearrangements are useful for demonstrating if the new malignant clone arose from a pre-existing CLL B cell or whether it is a new clone. The latter is

Figure 29.15 Blood film of a patient with Richter syndrome with circulating large blast cells that were positive for surface membrane immunoglobulin.

seen in at least one-third of cases. Genetic imbalances are frequent in Richter syndrome, the most common being *TP53* abnormalities.

Current evidence suggests that intense immunosuppression with agents such as fludarabine and alemtuzumab and the subsequent CD4 lymphopenia may trigger Richter transformation in some cases. Not infrequently, evidence of involvement of Epstein–Barr virus (EBV) in the pathogenesis has been shown by demonstration of EBV latent membrane protein by immunohistology or of EBV-encoded RNA by *in situ* hybridization. A role for EBV in the pathogenesis of Richter syndrome has been reported in close to 15–20% of cases. It is likely that this phenomenon is seen more often in heavily treated patients. In a minority, the large-cell transformation induced by EBV has scattered CD30⁺CD15⁺ Reed–Sternberg-like cells, and in others the histology is identical to that of classical Hodgkin lymphoma.

The rare cases of Hodgkin lymphoma are often clonally unrelated to the original CLL clone. Clonally unrelated transformation is more likely to be related to EBV infection. Cases of Hodgkin lymphoma and those with scattered Reed–Sternberg cells show mutated *IGHV* genes, while the majority of DLBCL show identical *IGHV* sequences in the CLL and lymphoma cells. Also, the clonally related DLBCL often carry unmutated *IGHV* genes. It has also been suggested that the risk of Richter transformation is higher in cases using *IGHV4-39* and stereotyped *CDR3* sequences.

Increasingly, positron emission tomography and CT have a role in the diagnosis of Richter syndrome, as in other lymphomas (see Chapters 34 and 35). Similarly, the treatment now involves protocols used in large-cell lymphomas, such as the combination CHOP-R (see also Chapter 35).

Hypercalcaemia with or without obvious osteolytic lesions is a well-recognized but rare finding in very advanced CLL. It does not represent, in itself, transformation to a large-cell lymphoma as the histology is often that of heavy lymphocytic infiltration.

Supportive care

The main objective of treatment for CLL is to prolong survival with a good quality of life; therefore care should be taken to prevent and/or treat promptly any complications arising from the immunodeficiency associated with the disease or its treatment. Thus, prompt antibiotic treatment for seemingly benign upper respiratory tract infections and antiviral measures to prevent the spread of herpetic infections are as important as specific treatment for the disease. Patients with repeated infections and very low serum immunoglobulin levels may benefit from courses of intravenous γ -globulin injections, e.g. 400 mg/kg every 4 weeks, particularly during the winter months. Additional measures are the administration of allopurinol when starting therapy with a WBC count above $50 \times 10^9/L$, oral anti-fungals and histamine H₂ blockers or proton pump inhibitors when using corticosteroids.

Causes of infection in CLL are multifactorial. Neutropenic episodes during chemotherapy require the use of granulocyte colony-stimulating factor (G-CSF). Patients with long-term respiratory infections may require antibiotic prophylactic measures and active physiotherapy programmes. Cotrimoxazole is necessary to prevent infections, particularly *Pneumocystis jirovecii* pneumonia, when fludarabine or alemtuzumab are used. The latter requires regular monitoring for CMV and prompt treatment when such immunosuppressed patients, usually lymphopenic, become symptomatic and positive for CMV. The main factors predisposing to infections in CLL are the number of chemotherapy regimens and the activity of the disease more than the levels of serum immunoglobulins.

Erythropoietin is now an accepted treatment for anaemia associated with cancer therapy. Patients with CLL and persistent anaemia (Hb < 10 g/dL) will benefit from erythropoietin given according to guidelines. There is strong evidence for benefit, particularly an improvement in quality of life. Erythropoietin should be given for a minimum of 4 weeks before deciding that there is no response, and iron deposits need to be adequate. There is no evidence that erythropoietin is useful in pure red cell aplasia. Folic acid supplements are often useful in patients with macrocytic indices resulting from low folate levels. They should always be given in AIHA.

Secondary MDS/AML

The increased intensity of treatments, in particular combinations of alkylating agents and purine analogues, may be responsible for an increased incidence of secondary MDS/AML in CLL. Combinations with mitoxantrone and the use of total

body irradiation for SCT are also major risk factors for these secondary events. Single-agent therapy with chlorambucil or fludarabine is rarely associated with MDS/AML.

B-cell prolymphocytic leukaemia

It has become apparent in the last two decades that there are important clinical and laboratory differences between B-PLL and CLL, despite the existence of a group with CLL/PL discussed above. In fact B-PLL is a distinct, but rare, disorder. This is supported by differences in the morphology and cell markers (see Table 29.2) and clinical evolution. Furthermore, recent observations show significant differences in gene expression profiling between these two disorders (see below). The key for diagnosis is the recognition of the prolymphocyte as the predominant cell in well-prepared peripheral blood films. B-PLL is included in the WHO classification (see Chapter 33).

The mean age of patients presenting with B-PLL is 70 years and the main features are splenomegaly without lymphadenopathy and a high WBC count, usually over $100 \times 10^9/L$, at the time of presentation. Anaemia and thrombocytopenia are seen in at least 50% of cases. Other laboratory findings are no different from high-count CLL (increased uric acid, low serum immunoglobulins) but the incidence of a monoclonal band appears to be higher than in CLL.

Differential diagnosis

The main diagnostic criterion is the identification of prolymphocytes as the predominant population in blood films. Usually, 55% prolymphocytes is the figure that discriminates B-PLL from CLL and CLL/PL, although the percentage of prolymphocytes in B-PLL is usually greater than 70%. The prolymphocyte is twice the size of a small CLL lymphocyte, has moderately condensed nuclear chromatin, a prominent central nucleolus and a lower nucleus to cytoplasm ratio than CLL cells (Figure 29.16). Using the scoring system described in Table 29.1, most B-PLL score 0–1, rarely 2 or 3. One-third of cases of B-PLL may be CD5⁺; this and other features may present a diagnostic problem with MCL with leukaemia.

The issue of MCL was revisited by us in eight cases diagnosed in the past as B-PLL but bearing the translocation t(11;14) (q13;32) characteristic of MCL. Detailed histology review and comparison with 13 cases of B-PLL without t(11;14) led us to conclude that the cases with t(11;14) and overexpression of cyclin D1 represent a splenomegalic form of MCL rather than B-PLL.

Molecular studies

The mutational status of *IGHV* genes in B-PLL is heterogeneous, with 53% showing an unmutated pattern. In contrast to

Figure 29.16 Typical blood film from a case of B-prolymphocytic leukaemia with the characteristic large size, abundant cytoplasm and prominent nucleolus.

CLL and CLL/PL, V_H usage involved mainly the V_H3 and V_H4 family, predominantly *IGHV3-23*, *IGHV4-59* and *IGHV4-34*, regardless of mutational status. Another consistent finding in B-PLL is the deletion and/or mutation of *TP53* in just over 50% of cases. This may be one of the factors accounting for the poor prognosis. Gene expression profiling was investigated in 10 cases of B-PLL and compared with 10 cases of CLL (including CLL/PL). Detailed analysis showed significant differences, with close to 6000 genes differently expressed, most of them overexpressed in B-PLL. One of them, *MYC*, is of interest as this gene promotes cell proliferation. Comparison of findings showed a high probability of predicting a difference between CLL and CLL/PL on the one hand and B-PLL on the other, confirming the distinct biology of these two disorders.

Treatment

Alkylating agents are of little value in the management of B-PLL. Response rates (PRs and rare CRs) to splenic irradiation and/or CHOP have been recorded in up to one-third of cases. There are no published data with CHOP-R. Splenectomy is often used to remove a major proliferative focus and tumour bulk in order to relieve hypersplenism and facilitate further therapy. Considering the older age group affected, splenectomy is not a practical proposition in some patients. Some patients may respond to fludarabine, but there are insufficient data in B-PLL on the use of fludarabine combinations, including those using monoclonal antibodies, e.g. FCR, FCMR.

Hairy cell leukaemia

Hairy cell leukaemia is a well-recognized clinicopathological entity that affects males more frequently than females (male to

female ratio 4:1), usually over the age of 40 years. The disease was first described by Bouroncle and colleagues 50 years ago and has elicited great interest for different reasons: in the 1960s, to establish the diagnostic features of the newly described entity and, in the 1970s and 1980s, advances in immunology led to the identification of the hairy cell as a B cell by the demonstration of heavy- and light-chain immunoglobulin gene rearrangement. In the 1980s and 1990s, there were significant advances in treatment, first with interferon alfa, later with the purine analogues pentostatin and cladribine and, more recently, with the use of rituximab.

Clinical and laboratory findings

The main disease features result from the pancytopenia affecting most patients. Patients with HCL are moderately neutropenic and severely monocytopenic; thus, bacterial and opportunistic infections do occur. There is evidence that the incidence of typical and atypical mycobacterial infections is increased, but this was seen more frequently before the current treatments became available.

The main physical signs are splenomegaly and hepatomegaly. Lymphadenopathy is rare, but this has now been recognized in advanced HCL. Routine CT may show a higher incidence than hitherto suspected of large abdominal nodes. These are more common in relapsed patients and those with long-standing HCL and tend to correlate with bulky disease at presentation.

Anaemia results from reduced bone marrow production and splenic pooling. Haemolysis is exceptional. The WBC count may be low, normal or high (rarely above $20 \times 10^9/L$), but neutropenia and monocytopenia are constant. Patients with low WBC count and no circulating hairy cells present diagnostic problems. Platelet counts are below $100 \times 10^9/L$ in most cases.

Diagnosis

The recognition of typical hairy cells in peripheral blood films is useful for suggesting this diagnosis. Hairy cells are large, twice the size of a normal lymphocyte, and have abundant cytoplasm (low nucleus to cytoplasm ratio) that is characteristically villous in its outline (Figure 29.17). The nucleus is round, oval or slightly indented, and occasionally bilobed. A smooth nuclear chromatin, absence of a visible nucleolus and low nucleus to cytoplasm ratio are hallmarks of typical hairy cells. Cells from the rare HCL variant have similar cytoplasmic features but have a round nucleus with more condensed chromatin and a distinct nucleolus (Figure 29.18).

Bone marrow aspirates are unsuccessful as no fragments and few cells are obtained. Therefore, a trephine biopsy is essential. This shows diffuse interstitial infiltration of variable degree; occasionally the infiltration is focal. A typical feature is the arrangement of the cellular infiltrate, which is loose, leaving plenty of space between cells, often with a clear zone around

Figure 29.17 Individual hairy cells from blood films from two patients with HCL.

Figure 29.18 Blood film from a case of HCL variant showing large nucleolated villous cells, one of them binucleated.

each cell which is unique to this condition (Figures 29.19 and 29.20). Reticulin is always increased (Figure 29.21) and the cells stain strongly with anti-CD20 (Figure 29.22). The immunocytochemical staining for CD20 is important for demonstrating clusters of hairy cells following therapy, suggesting residual disease. This is otherwise difficult to assess on conventional sections (Figure 29.23). There is now a wider range of reagents that can be used for immunohistochemistry, including annexin A, DBA44 and CD11c.

Spleen histology shows distinct diagnostic features: infiltration by mononuclear cells with a blunt nucleus in the red pulp with little residual white pulp, and formation of pseudosinususes filled with erythrocytes. Tartrate-resistant acid phosphatase (TRAP) demonstrated on hairy cells corresponds to a unique isoenzyme 5 and is specific for HCL. This enzyme is now tested by means of a monoclonal antibody, which can be used in bone

Figure 29.19 Bone marrow trephine section of a case of HCL showing the typical clear zone around the hairy cells in a paraffin-embedded section.

Figure 29.21 Increased reticulin pattern in a case of HCL.

Figure 29.22 Staining for CD20 in a bone marrow section from HCL before treatment.

marrow biopsies. Electron microscopy reveals ribosome-lamella complexes in one-third of cases. Rarely, this intracytoplasmic inclusion can be seen on light microscopy.

Hairy cells are considered activated B cells with features of late maturation stages. Surface membrane immunoglobulin is usually strong and characteristically shows several heavy-chain isotopes, often including IgA and IgG and sharing a single light chain. The majority show mutated *IGHV* genes. HCL cells are strongly positive for FMC7, CD20 and CD22 but, in contrast to other B-cell disorders, they consistently express CD25, CD103 and CD123. In contrast to CLL, hairy cells are always CD5 negative and their score using the CLL panel is very low (see Table 29.2).

Figure 29.23 Staining for CD20 in a patient treated for HCL showing a cluster of residual CD20⁺ cells, suggesting that the remission is incomplete.

The HCL variant is very rare and is characterized by high WBC count ($50\text{--}80 \times 10^9/\text{L}$) and splenomegaly. The cells do not express CD25 and CD123. The main diagnostic difficulty in HCL variant is with SMZL, except for spleen histology, which in the former is mainly red pulp and in the latter predominantly white pulp. HCL variant is now included in the 2008 WHO classification as a splenic B-cell lymphoma/leukaemia unclassifiable, as one of two conditions involving diffusely the splenic red pulp (see also Chapter 33).

Treatment

The prime objectives of treatment should be the normalization of blood counts, as pancytopenia is the main source of complications, and to induce prolonged CR. Two purine analogues, cladribine and pentostatin, are widely used. Other treatments still used but for specific indications are splenectomy and interferon alfa.

Splenectomy is well established and has been shown to improve the quality of life and prolong survival. It should now be reserved for patients with very large spleens and a degree of bone marrow reserve. In about 20% of successfully splenectomized patients, the counts remain normal for many years and no other therapy is indicated; some of them may never relapse although they may remain with some bone marrow involvement.

Interferon alfa has been used widely since the first report by Quesada in 1984. It induces a gradual normalization of blood counts, reduction of hairy cells in the blood and bone marrow, return of monocytes and improvement of neutropenia. The improvements in the blood are not associated with clearance in the bone marrow, and CRs are seen in only 20–30% of cases. The duration of response once interferon alfa is discontinued is relatively short (median 15–18 months), although blood counts may remain normal for well over a year. The tendency once therapy has ceased is to relapse slowly. Interferon alfa is now reserved for problem cases and to help initial treatment in patients with severe cytopenias. Some groups consider that long-term maintenance therapy can be given with benefit to patients in whom purine analogues cannot be used or where they have become ineffective.

The two agents currently used in HCL, pentostatin and cladribine, achieve CR in 80–85% of patients, with the remainder being partial responders. True resistance is seldom seen at first treatment. Long-term results are excellent, with very few patients actually dying of HCL. About 42% relapse by 10 years and 47% by 15 years; 90% of all patients and 95% of those with CR are alive at 10 years if one excludes non-HCL causes of death.

We recently reported the long-term follow-up (median 16 years) of 233 patients treated with either purine analogue. The long-term outcome was similar with both pentostatin and cladribine. The overall CR rate was 80% and the median relapse-

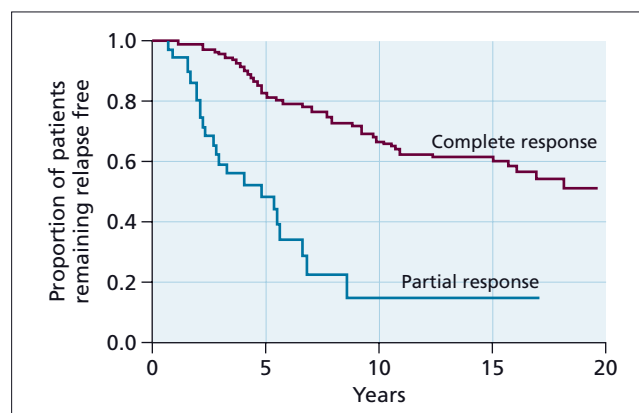

Figure 29.24 Relapse-free survival by response. Complete responders (186 patients) had significantly longer relapse-free survival than partial responders (37 patients) ($P < 0.0001$). (From Catovsky & Else 2009 with permission.)

free survival was 16 years. After relapse, the CR rate decreased with each successive treatment but, when CR was achieved, this was equally as durable as after first-line treatment. Patients with haemoglobin above 10 g/dL and platelets above $100 \times 10^9/\text{L}$ before treatment had the longest relapse-free survival. Patients still in CR at 5 years had only a 25% risk of relapse by 15 years. Complete responders to purine analogues always fare significantly better than partial responders (Figure 29.24). Achievement of CR seems therefore an important therapeutic end point in HCL, as these patients can expect a normal lifespan.

Monoclonal antibodies against CD20 (rituximab) and CD22 (coupled with an immunotoxin) have now shown activity in HCL. Hairy cells strongly express CD20 and CD22, and these antibodies seem to achieve good responses in the group of relapsing patients, although when rituximab is used alone in cladribine relapses the CR rate is low (~15%). Its main role may be, as in other B-cell disorders, when used in combination with one of the purine analogues and this has been our recent experience. Elderly patients may also benefit from antibodies like rituximab as they do not cause myelotoxicity.

Patients with HCL variant respond less well to cladribine and pentostatin and not at all to interferon alfa. Palliation of symptoms and improvement in blood counts can be achieved with splenectomy, which has been the most successful modality in this relatively resistant disease.

Supportive care for HCL is confined to patients undergoing therapy with nucleoside analogues, which can cause transient neutropenia in the early phases and prolonged lymphopenia later on. Long-term co-trimoxazole until lymphocyte counts rise above $1 \times 10^9/\text{L}$ and also long periods on aciclovir are recommended. Major infections are only seen in untreated patients or those responding poorly to therapy.

The leukaemic phase of indolent NHL

There are three types of NHL which not infrequently evolve with lymphocytosis that mimics, and can be confused with, CLL: follicular lymphoma, SMZL (formerly described as splenic lymphoma with circulating villous lymphocytes) and MCL (see also Chapter 33).

Follicular lymphoma

Of patients with follicular lymphoma, 15% may have circulating lymphoma cells ($5\text{--}20 \times 10^9/\text{L}$), and this correlates with bone marrow involvement. A minority may present with a WBC count in excess of $40 \times 10^9/\text{L}$ (up to $200 \times 10^9/\text{L}$) and extensive disease, generalized lymphadenopathy and hepatosplenomegaly. Usually the circulating cells are very small with almost no visible cytoplasm, the nuclear chromatin is smooth without clumps of heterochromatin and no visible nucleolus, and the nuclear shape is angular and has a small cleft (Figure 29.25), seen also at the ultrastructural level (Figure 29.26). The differential diagnosis from CLL is supported by the immunophenotype: follicular lymphoma cells usually score 0 or 1 (see Figure 29.1). Lymph node histology is essential for confirming a diagnosis of follicular lymphoma. Only patients with very high WBC counts may have poor prognosis; cases with a minor degree of spillover respond, as do cases without circulating cells. Late-stage follicular lymphoma may have circulating blasts (centroblasts) characterized by a peripherally located nucleolus and this corresponds with histological transformation to a large-cell lymphoma.

Figure 29.25 Blood film of a patient with follicular lymphoma presenting with significant lymphocytosis ($55 \times 10^9/\text{L}$). The cells show a cleaved nucleus, angular shape, homogeneous chromatin pattern, high nucleus to cytoplasm ratio and small size.

Splenic marginal zone lymphoma

SMZL has been recognized by the WHO classification as a distinct pathological entity (see Chapter 33). Close to two-thirds of patients with this lymphoma have circulating villous lymphocytes. A minority does not have frankly villous cells despite being clonal and in some the diagnosis can be suspected without circulating lymphocytes but can only be established after splenectomy. The true incidence of this condition without circulating villous cells is unknown.

The median age of patients is 69 years and the majority present with splenomegaly. Anaemia and/or thrombocytopenia are seen in 40% of cases. One-third have a serum monoclonal band, usually IgM below 30 g/L. Diagnosis is suspected on a typical blood film (Figure 29.27) showing small lymphocytes with an irregular membrane outline and short villi, often confined to one pole of the cells. The immunophenotype (see Table 29.2) is different from CLL. SMZL cells can be distinguished from HCL and the HCL variant (now separated as a form of splenic lymphoma) because they are negative for CD103 and CD123 but are always positive for CD11c.

Bone marrow aspirates may show the same cells as in the blood, with variable degrees of infiltration. A distinct pattern of intrasinusoidal infiltration (Figure 29.28) is characteristic of SMZL which can be highlighted with anti-B-cell antibodies (CD20, CD79a). This pattern of infiltration is less common in other types of NHL and is not seen in CLL. In addition, the

Figure 29.26 Electron microscopy of a circulating follicular centre lymphocyte showing a deep nuclear cleft.

Figure 29.27 Lymphocytes from a case of splenic lymphoma with circulating villous lymphocytes.

Figure 29.28 Bone marrow trephine biopsy from a case of splenic lymphoma with circulating villous lymphocytes showing the characteristic intrasinusoidal infiltration seen in this disease highlighted by anti-CD20 antibody.

pattern of bone marrow infiltration can be nodular, interstitial and/or paratrabecular.

The spleen histology shows a characteristic bizoned pattern in the white pulp, with a central zone of small lymphocytes with scanty cytoplasm and a peripheral zone of larger cells with more dispersed chromatin and more abundant cytoplasm. The red pulp is always infiltrated by both the smaller and larger cells. Plasmacytic differentiation may be seen.

There is no unique cytogenetic abnormality in SMZL, but unbalanced translocations and deletions of 7q22–32 have been described in about 30%; 50% of cases have a monoallelic deletion at 13q14. Trisomy 3, an abnormality seen in extranodal

Figure 29.29 Blood film from a patient with mantle cell lymphoma and lymphocytosis. The cells are medium size, slightly irregular in shape and have a speckled nuclear chromatin pattern.

marginal zone lymphoma, has been found in 17% of cases. Abnormalities of *TP53* (mainly deletions) are found in 17% and are associated with worse prognosis.

An association with hepatitis C has been reported but the incidence of this is unknown. Of interest is that interferon alfa has been reported to induce CR in some hepatitis C-positive SMZL patients. An association with hyperreactive malaria and tropical splenomegaly has been described in African cases. Large-cell transformation is seen in 10% of cases.

Splenectomy is the treatment of choice when the spleen is a prominent feature. Splenectomized patients fare significantly better than those treated with chemotherapy only. Fludarabine has been reported to induce remissions and recently rituximab has shown beneficial effect (see also Chapter 35). The median survival in our series is 13 years, with 72% of patients alive at 5 years.

Mantle cell lymphoma

Blood and bone marrow involvement are common in MCL. Close to 40% of cases evolving with splenomegaly have significant lymphocytosis, sometimes mimicking CLL, CLL/PL or B-PLL (see above).

Morphologically, the circulating cells are of medium size with a variable amount of cytoplasm, an irregular nucleus with nuclear cleft, a distinctly stippled chromatin pattern and an indistinct nucleolus (Figure 29.29). If small lymphocytes predominate or if there is a mixture of small and large cells, CLL/PL is suspected. A lymphoblastoid form with blast-like cells has been recognized.

Marker studies show that MCL cells are always positive for CD5, CD19 and CD20, thus raising the issue of CLL. In a series of over 60 cases which we studied, the majority (68%) scored 1

(CD5⁺CD23⁻, in contrast to CLL), 17% scored 0 (CD5⁻CD23⁻) and 15% scored 2 or 3 (CD5⁺CD23⁺).

The bone marrow trephine biopsy shows a rather monotonous infiltration by slightly irregular cells. In contrast with CLL, no proliferating centres are seen in MCL. The pattern of bone marrow infiltration is often diffuse in advanced cases, but in other cases is nodular and/or paratrabecular.

The characteristic translocation t(11;14)(q13;q32) is demonstrated in all cases by conventional cytogenetics or by FISH. The rearrangement of the *BCL1/PRAD1* (now called *CCND1*) gene at 11q13 results in the overexpression of cyclin D1, one of the proteins that controls the cell cycle. Cyclin D1 can be demonstrated in histological sections.

Therapy in MCL has been unsatisfactory, although improvements have been reported using fludarabine combinations such as FCMR, as reported by a German study. A significant proportion of MCL patients have *TP53* abnormalities, which underlie their poor response to therapy. New agents such as bortezomib and lenalidomide seem to be active in MCL (see also Chapter 35).

Conclusions, 575**Acknowledgements**, 575**Selected bibliography**, 575**Introduction and classification**

The mature T-cell lymphoproliferative disorders comprise a variety of entities that result from the clonal proliferation of post-thymic T lymphocytes. They should be distinguished from the thymus-derived T-cell neoplasms, i.e. T-cell acute lymphoblastic leukaemia (T-ALL) and lymphoblastic lymphomas, as the disease course and therapeutic approaches are different. The distinction between these two groups of T-cell malignancies is made on clinical grounds, morphology and immunophenotype, i.e. terminal deoxynucleotidyltransferase (TdT)-positive blasts in T-ALL compared with TdT-negative mature T lymphocytes in chronic T-cell disorders.

The incidence of the T-cell disorders varies around the world. Overall they are more common in eastern and rare in western countries, where they account for 15% of lymphoid malignancies. This distribution may relate to host and environmental factors. Advances in immunophenotyping and molecular cytogenetics together with detailed analysis of the morphology and histopathology have contributed to a more precise classification of the T-cell neoplasms. The role of viruses in T-cell malignancies, essentially Epstein–Barr virus (EBV) and human T-cell leukaemia/lymphoma virus (HTLV)-I, has been well recognized. HTLV-I is the aetiological agent of adult T-cell leukaemia lymphoma (ATLL), and EBV has been shown to be involved in the pathogenesis of certain lymphomas such as extranodal T/natural killer (NK) lymphomas.

These advances have shed some light onto the disease pathogenesis and in turn resulted in better therapeutic approaches. Information on gene expression profiling is still in its infancy and is known for few of these diseases. It is likely that in the future this information will have an impact by allowing novel targeted therapies to be devised and by helping to elucidate the genes involved in pathogenesis.

For classification of the T-lymphoproliferative disorders, it is essential to combine the clinical and laboratory features. The latter should include (i) morphology and tissue histology; (ii) immunophenotyping; (iii) molecular genetics using standard techniques such as fluorescence *in situ* hybridization (FISH) or polymerase chain reaction (PCR); (iv) analysis of the T-cell receptor (TCR) chain genes to demonstrate clonality of the T-cell population; and (v) detection of viruses such as HTLV-I and EBV. Some of these investigations are key diagnostic tests while others may have prognostic or therapeutic implications. Furthermore, molecular analysis to search for certain oncogenes such as *TCL1* and *TP53*, is relevant by providing clues to the pathogenesis and/or progression of the disease.

On the basis of the clinical manifestations and origin of the neoplasm, the T-lymphoid disorders can be classified into three main groups: (i) primary leukaemias that arise in the bone marrow and evolve with leukaemia; (ii) leukaemia/lymphoma syndromes or the leukaemic phase of T-cell non-Hodgkin lymphomas (T-NHLs) in which the tumour arises in lymphoid tissues but a leukaemic picture is common; and (iii) T-NHLs that originate in lymphoid tissues and rarely involve the blood. Each of these groups includes disease entities distinguishable by their clinical and laboratory features and all have been recognized as such by the WHO classification (Table 30.1).

The disease features of the T-cell malignancies, the basis for diagnosis, their prognosis and management as well as the pathogenic events involved in disease initiation and/or progression are described.

Primary leukaemias

This group includes T-prolymphocytic leukaemia (T-PLL) and T-cell large granular lymphocyte leukaemia (T-LGL leukaemia).

T-prolymphocytic leukaemia

T-PLL was first documented in a patient having clinical features similar to B-prolymphocytic leukaemia (B-PLL) but in whom

the cells had a T-cell phenotype. T-PLL is recognized in the WHO classification as a distinct entity with three morphological variants. Despite the morphological heterogeneity, all these variants have a similar clinical course and identical molecular genetics.

Aetiology

T-PLL is a rare disease accounting for 2% of all mature lymphoid leukaemias and is more frequent than B-PLL. T-PLL has been described in the West and East without geographical clustering. There is no evidence that radiation, carcinogenic agents and/or viruses play a role in its pathogenesis. However, there is a prevalence of T-PLL in patients with ataxia telangiectasia (AT) and it has been speculated, but not yet proven, that the AT mutated gene (*ATM*) may play a role in the development of T-PLL (see section Pathogenesis).

Clinical features

T-PLL affects adults (median age 65 years), predominantly males. Patients manifest with widespread disease and one-third with skin lesions. Main physical signs are hepatosplenomegaly and lymphadenopathy. Effusions are seen in 15% of patients but are frequent during terminal or relapse phases of the disease; central nervous system (CNS) involvement is rare (Table 30.2). Few patients are asymptomatic and they manifest with non-specific symptoms and a slowly progressive lymphocytosis resembling the picture seen in early chronic lymphocytic leukaemia (CLL). This 'smouldering' form of T-PLL progresses in months or rarely years. Lymphocyte counts range from $35 \times 10^9/L$ and one-third of cases have anaemia and/or thrombocytopenia. Serology and/or DNA analysis for HTLV-I/HTLV-II are negative. Liver function tests may be impaired and urate and sodium lactate dehydrogenase (LDH) raised. Bone

marrow shows a variable degree of involvement; the pattern of lymphoid infiltration in the trephine biopsy is mixed (interstitial plus diffuse) or diffuse with reticulin fibrosis.

Diagnosis

Morphology and immunophenotyping are the key diagnostic tests. In two-thirds of cases, the lymphocytes have condensed chromatin, regular or irregular nuclear outline, prominent nucleolus and a deeply basophilic cytoplasm with blebs (typical T-PLL) (Figure 30.1). In the remaining, the lymphocytes are smaller in size and the nucleolus is small or not visible by light microscopy (small-cell variant of T-PLL) and/or have a cerebriform nucleus resembling Sézary cells (cerebriform variant). Although small-cell T-PLL has been referred to as 'T-CLL', such designation may lead to confusion as patients with small-cell T-PLL have an aggressive course and the immunophenotype and cytogenetics are similar to typical T-PLL.

Tissue histology is not essential for diagnosis. The spleen histology shows red pulp lymphoid infiltrates with invasion of

(a)

(b)

Figure 30.1 (a, b) Peripheral blood films from two cases of T-PLL showing medium-size lymphoid cells with prominent nucleolus and basophilic cytoplasm.

the white pulp and spleen capsule. Skin histology is different from Sézary syndrome (SS) and shows dermal infiltration preferentially around the appendages without epidermotropism.

Immunophenotyping shows that T-prolymphocytes, unlike T-lymphoblasts, are negative for TdT and the thymic marker CD1a while expressing CD2, CD5 and CD7, the latter with strong intensity. CD3 and anti-TCR- α/β are negative in the cell membrane from 20% of patients but are always expressed in the cytoplasm. The most common phenotype is CD4⁺CD8⁻ (65% of cases); in about 10% the phenotype is CD4⁺CD8⁺, and in 25% it is CD4⁺CD8⁺. CD25 is negative or weak and CD52w (Campath-1H) is strongly expressed (Table 30.3). T-prolymphocytes are negative with monoclonal antibodies against NK cells, TIA-1 and HLA-DR but they may express the lectin NK immunoglobulin receptor CD161.

Cytogenetics and pathogenesis

Chromosomal abnormalities are complex. The abnormality inv(14)(q11;q32) is characteristic of T-PLL and is detected in greater than two-thirds of cases. This juxtaposes the TCR- α gene (*TRA@*, 14q11.2) to the oncogene *TCL1* (14q32.1) resulting in the activation of *TCL1*. Most cases have rearrangement of the *TCL1* gene and overexpression of the TCL-1 protein, supporting the hypothesis that this oncogene plays a role in the pathogenesis of this disease (Table 30.3). In some cases, *TRA@* is juxtaposed to the *MTCP1* gene (Xq28), resulting in the translocation t(X;14)(q28;q11). The *MTCP1* gene has homology with *TCL1* and it has been shown to be expressed in two T-PLL patients who developed the leukaemia following a preceding phase of AT. Transgenic mice with *TCL1* or *MTCP1* develop a T-cell leukaemia similar to T-PLL. Abnormalities of chromosome 8 involving both arms of this chromosome are frequent; although the *MYC* oncogene (8q24) is not rearranged, overexpression of the protein is found in cases with iso(8q). 11q23 abnormalities are rarely detected by cytogenetics, but missense mutations of the *ATM* gene (11q23) are common. There are genetic similarities between the sporadic T-PLL and circulating T lymphocytes from AT patients. These patients are at risk of developing lymphoid malignancies including T-PLL. T-cell clones in AT carry similar abnormalities to leukaemic T-prolymphocytes and expression of *TCL1* transcripts occurs in both the preleukaemic and leukaemic phases in AT patients, as it does in sporadic T-PLL. All these findings stress the relationship between T-PLL and the leukaemia that develops in AT patients. Gene expression profiling in a few T-PLL cases with inv(14) has revealed deregulation of genes involved in the cell cycle, apoptosis and DNA repair that likely play a role in its pathogenesis.

Differential diagnosis

The differential diagnosis of T-PLL arises with B-PLL, T-ALL and other mature T-cell malignancies. Distinction between T- and B-PLL and T-ALL can be made by immunophenotyping.

Table 30.3 Immunophenotype and genotype in T-cell disorders.*

<i>Disease</i>	<i>Immunophenotype</i>	<i>Genotype</i>

*Refers only to the most relevant and distinct features.

ATM, ataxia telangiectasia mutated gene; EBV, Epstein–Barr virus; EMA, epithelial membrane antigen; HTLV, human T-cell leukaemia/lymphoma virus; KIR, killer-cell immunoglobulin-like receptor; LGL, large granular lymphocyte; LMP, latent membrane protein; NHL, non-Hodgkin lymphoma; *NPM-ALK*, nucleolar phosphoprotein–anaplastic lymphoma tyrosine kinase gene.

Distinction between T-PLL and T-cell LGL leukaemia is not problematic except in cases of smouldering small-cell variant T-PLL. Immunophenotype, cytogenetics and morphology distinguish these two conditions. Morphology, clinical features, skin histology and HTLV-I status will differentiate T-PLL from ATLL and SS.

Disease course and therapy

T-PLL has an aggressive course and short survival, estimated to be 7 months in the historical series. Poor predictors for outcome include age, high lymphocyte count, high TCL-1 expression and lack of response to alemtuzumab (Campath-1H) or pentostatin (2'-deoxycoformycin). Patients are resistant or achieve transient responses to most chemotherapies. Pentostatin is effective, with response rates of 45%, 10% of which are complete responses (CRs) with survival improvement. At present, the best front-line treatment is alemtuzumab. Over two-thirds of patients respond to this agent, and most achieve a CR. However, most patients will eventually relapse, and therefore responses need to be consolidated with autologous or allogeneic stem cell transplantation (SCT). Autologous SCT increases disease-free survival, although up to two-thirds of patients will relapse. The chances of cure are higher with allogeneic SCT with non-myeloablative (reduced intensity) conditioning or intensive conditioning but morbidity and mortality are still high. Figure 30.2 illustrates the response to alemtuzumab in a patient with T-PLL.

Large granular lymphocyte leukaemia

LGL leukaemia was first described three decades ago and designated T-CLL to contrast with B-CLL. Names such as T γ lym-

phoproliferative disorder, chronic T-cell lymphocytosis with neutropenia, T8⁺/NK, cytotoxic and/or suppressor T-cell CLL were used until 1993 when Loughran coined the term of LGL leukaemia for this disease. Depending on the origin of the LGL cells, LGL leukaemia can be subdivided into two groups: one derived from T cells (CD3⁺) and another, uncommon, derived from NK cells (CD3⁻). In the WHO classification, NK-cell LGL is considered separate and designated chronic NK-LGL leukaemia. Here we strictly refer to T-cell LGL leukaemia, which includes cases that result from clonal expansion of a TCR- α/β -positive lymphocyte and a minority from a TCR- γ/δ -positive cell.

Aetiology

The aetiology of T-cell LGL leukaemia is unknown. There is compelling evidence that it results from persistent antigen (auto or foreign) stimulation that leads to the expansion of a memory effector cytotoxic T cell that is not eliminated due to impaired apoptosis. It is frequent in patients with autoimmune diseases, particularly rheumatoid arthritis. These patients, as those with T-cell LGL leukaemia, have a high frequency of the HLA-DR4 haplotype. This suggests a common immunogenetic basis for these two conditions. No infective agent has been shown to be involved in the pathogenesis of the most common form of CD8⁺ T-cell LGL leukaemia, while recent data indicate that persistent infection by cytomegalovirus (CMV) may be responsible in cases with a CD4⁺CD8^{-/+dim} phenotype.

Clinical features

T-cell LGL leukaemia affects preferentially adults. Patients are asymptomatic or manifest symptoms derived from cytopenias,

Figure 30.2 Flow chart from a patient with T-PLL illustrating complete response (CR) to alemtuzumab (Campath-1H) and subsequent consolidation with stem cell transplantation.

essentially recurrent infections, autoimmune disease or rarely pure red cell aplasia; it also may be associated with bone marrow failure due to myelodysplasia. The disease may evolve as a pure lymphomatous form in few cases. The CD4⁺ form is often associated with neoplasms, rarely with autoimmunity. Physical examination shows splenomegaly in two-thirds of patients and hepatomegaly in half; skin lesions may be present but lymphadenopathy is rare (see Table 30.2). The lymphocyte count is normal, low or slightly raised, usually under $15 \times 10^9/L$, with most cells being LGLs; neutropenia is common, and one-third of patients have anaemia and/or thrombocytopenia. In a few cases, a Coombs-positive haemolytic anaemia and autoimmune thrombocytopenia is detected. An autoimmune screen may reveal a positive rheumatoid factor, antinuclear antibodies, circulating immune complexes and hypogammaglobulinaemia or hypergammaglobulinaemia. Bone marrow shows mild lymphoid interstitial or intrasinusoidal infiltration; reactive nodules may be present. It is not uncommon that involvement is missed in the aspirates and trephine biopsies unless immunophenotyping or immunohistochemistry are done. There may be erythroid and myeloid hyperplasia with left shift and maturation arrest.

Diagnosis

Morphology, immunophenotyping, and molecular analysis of the configuration of the TCR β - or γ -chain genes are the key diagnostic tests. LGLs are medium in size, have an eccentric nucleus with mature chromatin, no visible nucleolus and abundant cytoplasm with azurophilic granules (Figure 30.3). These

contain hydrolases, perforin and cytokines involved in the function of these lymphocytes. At the ultrastructural level, some granules may display a special configuration designated ‘parallel tubular arrays’. The lymphocytes in T-cell LGL leukaemia cannot be distinguished morphologically from the minor blood circulating LGL population in normal individuals.

Tissue histology is rarely essential for diagnosis. The spleen histology shows red pulp expansion with an atrophic or reactive white pulp resembling the pattern seen in hairy cell leukaemia; unlike hairy cell leukaemia, the infiltrating cells have a T-cell phenotype and, unlike normal spleen red pulp cells, are CD5⁻CD45RO⁻. Sarcoid-like granulomas may be present. The liver shows sinusoidal infiltration extending to the portal tracts.

Immunophenotyping in T-cell LGL leukaemia shows that cells are positive for CD2, CD3, TCR- α/β and rarely TCR- γ/δ ; CD5 and CD7 are negative or weakly expressed. Cells negative for CD4 but positive for CD8, CD57, CD16, CD94, TIA-1, granzyme B and perforin is the most common phenotypic profile (Table 30.3 and Figure 30.4). A few cases have unusual phenotypes, i.e. coexpression of CD4 and CD8 or a CD4⁺CD8^{-/+dim} phenotype with or without coexpression of NK markers such as CD56 or CD161. T-cell activation markers such as HLA-DR determinants and CD38 are variably expressed. Although the p55 α -chain of the interleukin (IL)-2 receptor (CD25) is usually absent in the cell membrane, LGL cells express the p75 intermediate-affinity IL-2 receptor β -chain. A proportion of cases do express one or more killer-cell immunoglobulin-like receptors (KIRs), unlike normal T cells, and their overexpression is considered potentially diagnostic.

(a)

(b)

Figure 30.3 (a, b) Peripheral blood films from patients with T-cell LGL leukaemia showing lymphocytes with an eccentric nucleus, condensed chromatin and abundant pale cytoplasm with azurophilic granules.

Southern blot or PCR studies for the TCR demonstrate the clonal nature of the LGL population and distinguish them from polyclonal LGL proliferations. In T-cell LGL leukaemia, the cells have a rearranged TCR β -chain gene and/or TCR γ -chain gene (Figure 30.5). It is now possible to demonstrate clonality by flow cytometry using a range of monoclonal antibodies against the different variable regions of the TCR β -chain gene. Unlike reactive LGL proliferations, in which different proportions of cells will stain with various monoclonal antibodies, in LGL leukaemia the cells will stain with only one of them.

Pathogenesis

There is no evidence of a recurrent cytogenetic abnormality. It has been postulated that T-cell LGL leukaemia results from the

expansion of a terminal memory activated cytotoxic T lymphocyte that is triggered by persistent antigen (auto or foreign) stimulation. This lymphocyte does not undergo activated cell death because of an impaired apoptotic pathway. LGL cells express both Fas (CD95) and its ligand and do not have mutations of the gene. However, gene expression profiling has shown that clonal LGLs have a signature different from normal activated memory cells, with deregulation of genes involved in apoptosis, TCR signalling and immune response. In the group of cases with the phenotype $CD4^+/CD8^{-/+dim}$, it has been suggested that CMV is responsible for triggering and maintaining the LGL clone in an individual with a genetic predisposition.

Differential diagnosis

The differential diagnosis of T-cell LGL leukaemia arises with polyclonal T-cell lymphocytosis following splenectomy or as a reaction to viral infections, B-CLL and other T-cell disorders, particularly hepatosplenic lymphoma and T-PLL. DNA analysis allows differentiation between reactive and clonal LGL proliferations, as only in the former will the TCR chain genes be in germline configuration. Morphology and immunophenotyping distinguish T-cell LGL leukaemia from other B- and T-cell disorders.

Prognosis and therapy

The clinical course of T-cell LGL leukaemia is often stable; only few patients present with widespread/progressive disease. It has been suggested that cases whose cells express CD56 or CD26 behave more aggressively. Transformation into a large-cell lymphoma is exceedingly rare.

The prognosis of LGL leukaemia is good compared with other T-cell malignancies. Thus data based on large series of patients show that 80% of them survive at 4 years and the overall median survival is greater than 10 years. The main causes of death are infections and only in few patients is death associated with progressive disease.

A substantial proportion of patients, for example those without cytopenias and with stable blood counts, do not require treatment but only monitoring (i.e. 'watch and wait'), a policy similar to that adopted in stage A CLL. Treatment is indicated in those with severe cytopenias, recurrent infections or progressive lymphocytosis or organomegaly. There is no gold-standard therapy in LGL leukaemia. Therapeutic strategies are based on the use of immunosuppressive agents as there is no evidence that high-dose therapy will benefit these patients by eradicating the clone. These treatments include ciclosporin, low-dose cyclophosphamide (200–300 mg/week) or weekly pulses of methotrexate (10 mg/m²). Responses are seen in greater than two-thirds of patients. There are no data concerning disease features that will predict response to one or other immunosuppressive drug (Figure 30.6). Corticosteroids and haemopoietic growth factors, such as granulocyte/macrophage colony-stimulating factor, granulocyte colony-stimulating factor or

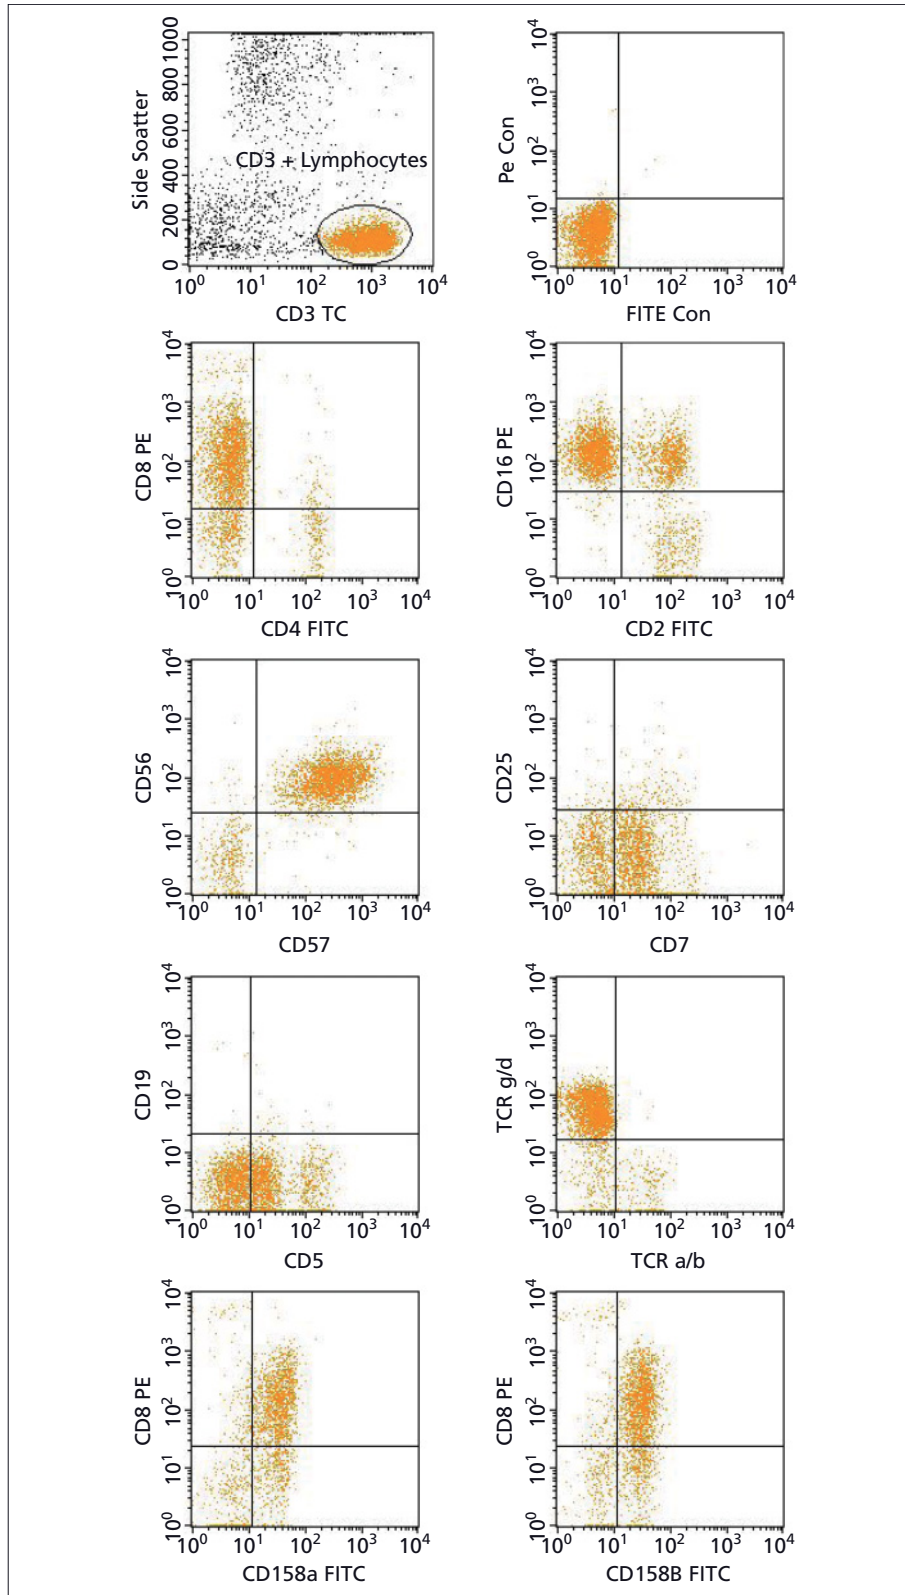

Figure 30.4 Flow cytometry plots of lymphocytes from a γ/δ -positive T-cell LGL leukaemia. The cells have been gated on $CD3^+$ cells. The majority of cells express TCR- γ/δ , CD8, CD16, CD56 and CD57 but are negative for TCR- α/β and CD4 and

have partial/weak expression of CD5 and CD7. The majority of cells express two killer-cell immunoglobulin-like receptors (CD158a and CD158b), unlike normal LGLs.

erythropoietin, may be useful adjuvants for maintaining or improving the blood cell counts. Few patients respond to pentostatin, although this drug has not been extensively used in LGL leukaemia. Splenectomy does not correct the cytopenias and usually results in an increase in circulating LGLs. Nevertheless, in patients with bulky spleen, this procedure may help by removing tumour burden. Patients with widespread disease (e.g. skin lesions, hepatosplenomegaly, rising white cell count) should be managed with combination chemotherapy. Newer agents such as the monoclonal antibodies anti-CD2 (siplizumab) and anti-CD122, a farnesyltransferase inhibitor and alemtuzumab are being incorporated in the therapeutic scenario.

Figure 30.5 PCR analysis of a case of T-cell LGL leukaemia showing a single rearranged band for the TCR γ -chain gene in the blood (second row) and bone marrow (third row). The first row is 1 kb ladder, the fourth a positive control and the fifth a negative control.

Leukaemia/lymphoma syndromes (see Table 30.1)

The leukaemia/lymphoma syndromes comprise neoplasms that arise in peripheral lymphoid tissues but a high frequency present with blood involvement mimicking T-cell leukaemias. These include SS and ATLL.

Sézary syndrome/mycosis fungoides

Aetiology

These are cutaneous T-cell lymphomas (CTCLs), with SS being considered the leukaemic manifestation of mycosis fungoides (MF). Their aetiology is unknown. Although some studies have suggested a link between SS/MF and HTLV-I/II on the basis of the detection of retroviral sequences in the tumour cells, there is no evidence for the involvement of these retroviruses in SS/MF. HTLV-I antibodies are not detected in the patient's serum and clonal integration of HTLV-I in the tumour cells has not been demonstrated in any case with bona fide SS/MF. A cooperative study in more than 100 cases of CTCL using sensitive molecular tests, serology and cell cultures failed to show a single CTCL harbouring HTLV-I/II.

A relationship between MF and other T-cell conditions, chiefly lymphomatoid papulosis, has been entertained. Lymphomatoid papulosis is a recurrent skin eruption characterized by the presence of nodules with evidence by histology of anaplastic Reed–Sternberg-like cells infiltrating the skin; it has a good prognosis. Despite the demonstration of T-cell clonality in two-thirds of the tumours, this condition is not considered malignant in the WHO classification and it is included in the subgroup of primary cutaneous lesions. Lymphomatoid

Figure 30.6 Flow chart from a patient with T-cell LGL leukaemia with profound neutropenia (neutrophils $0.1 \times 10^9/L$). The patient did not respond to ciclosporin, but the neutropenia improved (neutrophils $1 \times 10^9/L$) with weekly pulses of methotrexate.

papulosis may precede not only CTCL but also anaplastic lymphoma and/or Hodgkin disease. The association between lymphomatoid papulosis and CTCL was established in a patient who presented with lymphomatoid papulosis and subsequently developed Hodgkin disease and MF with evidence of the same clone in the three tumours.

Clinical features

SS and MF affect elderly patients and are more common in males. Patients present with pruritus and skin lesions, either localized, e.g. nodules or plaques, or a generalized rash (see Table 30.2). In early-stage disease, the diagnosis is not always made at presentation and the manifestations are considered to be reactive dermatitis. Physical examination shows erythroderma and/or nodules; organomegaly is rare. In SS, the white

cell count is normal or raised with circulating atypical lymphocytes. Cytopenias are uncommon and bone marrow is usually not involved. HTLV-I serology is negative even in cases originating from endemic regions for this virus. ISCL-EORTC has proposed a clinical staging system (grades I–IV) based on the extent of the disease, with SS falling into stages III/IV.

Diagnosis

The diagnosis is based on morphology, skin histology and immunophenotyping. The circulating blood lymphocytes are small to large in size and exhibit a cerebriform or hyperchromatic nucleus (Figure 30.7); the cytoplasm is scanty and, in some cases, vacuolation is prominent. According to cell size, two SS variants, small-cell and large-cell, have been recognized. A mixture of small and large cells is the predominant type in the blood. The nuclear configuration of Sézary cells is best defined by ultrastructural analysis, which reveals a serpentine nucleus with multiple indentations.

Skin histology is a key diagnostic test in SS and MF. This shows the presence of dermal lymphoid infiltrates that characteristically extend into the epidermis, a phenomenon designated epidermotropism. Pautrier microabscesses are typical but not unique to these conditions as they may be seen in T-NHL and ATLL.

Histology of other tissues is rarely available at diagnosis. The lymph nodes may show a reactive lymphadenitis or infiltration by lymphoma (Figure 30.8). Bone marrow, when involved, shows a mild interstitial infiltration.

Immunophenotyping demonstrates that circulating Sézary cells are positive for CD2, CD3 and CD5, but CD7 is negative in about 50% of cases (see Table 30.3). The most common phenotype is CD4⁺CD8⁻, but other unusual phenotypes, such

(a)

(b)

Figure 30.7 (a, b) Peripheral blood films from a patient with Sézary syndrome showing large and small cells with a convoluted hyperchromatic nucleus.

Figure 30.8 Lymph node section from a patient with Sézary syndrome showing diffuse infiltration by lymphoid cells, some with an irregular nucleus.

as CD4⁻CD8⁺ or CD4⁺CD8⁺, may be seen in rare cases. The neoplastic cells also express the cutaneous lymphocyte antigen (CLA) and the skin homing receptor CCRA. NK-associated markers are usually negative while expression of T-cell activation markers is variable. CD25 may be expressed in Sézary cells but the reactivity is weaker than in ATLL cells. In the skin, the interdigitating Langerhans cells admixed with the neoplastic lymphocytes are positive for CD1a and S-100. Cases transforming into a large T-cell lymphoma display aberrant phenotypes with loss of pan-T markers and often expression of T-cell activation antigens such as CD30, CD25 and HLA-DR.

Cytogenetics

Chromosomal abnormalities are complex and have variable ploidy. Hyperploidy is frequent in the large-cell variant and aneuploidy or hypoploidy in the small-cell form. There are also differences in the DNA content between these two forms when analysed by flow cytometry. There is no evidence for a recurrent chromosomal abnormality in SS, but chromosomes 1, 2, 6 and 17q are the most commonly involved. Clonal evolution may be seen, particularly in cases transforming into large-cell lymphoma. Abnormalities of chromosome 17p have been documented in some cases, as well as p53 protein overexpression and *TP53* gene deletion; however, *TP53* mutations are rare in SS and therefore it has been postulated that the *MDM2* gene may be responsible for *TP53* inactivation in SS.

Differential diagnosis

The differential diagnosis arises with reactive dermatitis, T-PLL presenting with skin lesions, ATLL and other cutaneous lymphomas. Cell morphology and immunological markers allow the distinction between SS and T-PLL and cutaneous B-NHL. HTLV-I serology is the key test for distinguishing SS from ATLL, essentially in cases presenting primarily with cutaneous forms of ATLL. The pattern and extent of skin infiltration and histochemistry allow the differentiation of SS from reactive dermatitis. However, in difficult cases, PCR analysis investigating the configuration of the TCR chain genes is needed; in SS this will show a rearranged T-cell band, unlike reactive dermatitis where the pattern is polyclonal.

Clinical course, prognosis and treatment

The clinical course of MF/SS is usually chronic. Thus, 87% of MF patients survive at 5 years, whereas SS follows a progressive course with shorter survival of around 15% at 5 years. The outcome for patients with abnormal clones seems to be worse than those with random heteroploidy. Transformation of SS or MF into a large-cell T-NHL is uncommon but documented in 8–19% of cases in retrospective studies. Transformation may be localized or systemic and is chiefly associated with advanced stages and a short survival. Only in a few cases has it been demonstrated that the tumour in the phase of transformation arises from the original clone. As SS/MF patients have an increased

risk of secondary malignancies, the non-haemopoietic nature of the tumour in these cases needs to be excluded.

A variety of treatments, including topical and systemic agents, have been used in SS/MF. In elderly patients and those with localized skin disease, PUVA (psoralen with UVA irradiation), electron beam irradiation and/or topical carmustine and steroids may alleviate and control the skin symptoms. Local radiotherapy is useful in patients with localized plaques. Systemic therapy is indicated in young patients and/or those with widespread disease. This is based on either single-agent therapy with methotrexate, cyclophosphamide or etoposide or a combination such as CHOP (cyclophosphamide, doxorubicin, vincristine and prednisolone). Over the last decade, new therapies have been employed, such as purine analogues, interferons, retinoids such as bexarotene or etretinate, and immunotherapy with an anti-IL-2 monoclonal antibody conjugated with the diphtheria toxin. Responses to purine analogues (pentostatin, cladribine or fludarabine) range from 30 to 62%. Interferon alfa alone or combined with etretinate appears effective in cases with cutaneous disease but not in systemic disease. Alemtuzumab has been used in some patients with relapsed and refractory disease with encouraging results.

Adult T-cell leukaemia lymphoma

Aetiology and epidemiology

ATLL is a unique malignancy in which the primary aetiological agent has been well established. This disease is caused by a retrovirus, HTLV-I, which is almost universally detected in all patients. ATLL was first described as a clinical entity in 1977. Its association with HTLV-I was demonstrated in the early 1980s almost simultaneously in the USA and Japan, based on seroepidemiological studies and the isolation of HTLV-I from ATLL cells. ATLL is clustered in HTLV-I endemic areas such as Japan, the Caribbean, Africa, South America and the Middle East, and among first/second-generation immigrants from these countries to Europe and the USA. In the UK, this disease is seen in immigrants of Afro-Caribbean descent. Familial cases of ATLL have been documented, and it has been suggested that a shared environment and perhaps a genetic predisposition influence the development of ATLL in these families.

Clinical features

ATLL affects adults without sex predominance. The disease manifests with leukaemia in over two-thirds of cases (leukaemia form), whereas approximately 25% have no blood involvement (lymphoma form). Within the leukaemia form, three subtypes are distinguished: acute, chronic and smouldering. Acute ATLL is the most common, accounting for 65% of cases. Patients present acutely with widespread disease, leucocytosis, opportunistic infections and/or hypercalcaemia. Physical examination shows lymphadenopathy, skin lesions and/or hepatosplenomegaly (see Table 30.2). Chronic ATLL (5% of cases)

presents with stable or slowly progressive lymphocytosis with the presence of atypical lymphocytes and minor or no lymphadenopathy or skin involvement. Smouldering ATLL (5% of cases) is characterized by normal blood counts with less than 4% atypical lymphocytes and recurrent skin lesions or lung infiltrates. Hypercalcaemia by definition is not detected in chronic and smouldering ATLL. Both these forms progress in terms of months or rarely years into acute ATLL. A haemophagocytic syndrome preceding this transformation has been documented in smouldering ATLL. A few patients have manifestations of conditions linked to HTLV-I infection such as tropical spastic paraparesis, arthritis and uveitis. These either manifest concomitantly with, or precede the onset of, the T-cell neoplasm. In addition to the symptoms derived from the leukaemia, patients are immunocompromised and develop severe opportunistic infections; infestation by *Strongyloides stercoralis* is frequent and may be fatal. Peripheral blood counts show a raised white cell count with lymphocytosis in the acute and chronic leukaemia forms. Anaemia and thrombocytopenia is seen in close to one-third of cases; eosinophilia and neutrophilia may be present. Biochemistry shows a markedly raised LDH and liver function tests may be abnormal. Hypercalcaemia is the most distinct biochemical abnormality, seen in 50% of cases at presentation and in up to two-thirds during the disease course. Rarely, it is associated with osteolytic lesions. The pathogenesis of hypercalcaemia is described below.

Diagnosis

The diagnosis of ATLL is based on cell morphology, immunophenotype and the demonstration of HTLV-I antibodies in the patient's serum or retrovirus sequences in the cell DNA.

Morphological analysis of peripheral blood films shows a pleomorphic picture with the presence of cells of different size and degree of nuclear irregularities in the acute and chronic leukaemia subtypes. The prototype cell, designated 'flower cell', is a medium-sized lymphocyte with condensed chromatin and a convoluted or polylobated nucleus (Figure 30.9); a few cells may have a cerebriform nucleus and a minority show features of immunoblasts.

Immunological markers show that ATLL cells have a mature activated T-cell phenotype ($CD2^+CD5^+$) and most cases are $CD7^-$. $CD3$ is expressed in the cytoplasm but, in some cases, cells lack expression of $CD3$ and $TCR-\alpha/\beta$ in the membrane. It has been suggested that the decreased numbers of $CD3$ and TCR molecules in ATLL cells results from cell activation by the retrovirus and that it might play a role in disease pathogenesis. Most ATLL cells have a $CD4^+CD8^-$ phenotype. Uncommon phenotypes such as $CD4^+CD8^+$ or $CD4^-CD8^+$ have been reported in Japan and these cases appear to have a more aggressive course. A distinct feature of ATLL cells is the strong expression of the p55 α -chain of the IL-2 receptor ($CD25$) in the cell membrane (Figure 30.10). Soluble IL-2 receptors are detected in the patient's serum and the levels correlate with tumour

Figure 30.9 Peripheral blood film from a patient with ATLL showing lymphocytes with a polylobed nucleus (flower cells).

burden and response to therapy. Other markers linked to T-cell activation such as HLA-DR determinants and $CD38$ are expressed in a variable proportion of cases but NK markers are negative.

Tissue histology is not essential for diagnosis in patients presenting with leukaemia. In the lymphoma forms, histology is an important diagnostic test; however, the histological pattern by itself is not sufficient for a diagnosis of ATLL as the pattern of infiltration might be similar in other T-NHLs. Often, there is diffuse infiltration by pleomorphic lymphoid cells of different sizes. ATLL does not fit into a single category in the WHO classification and it is only defined by the presence of HTLV-I. The pattern of skin infiltration is not specific either, as in half the cases it is identical to that in SS, with evidence of epidermotropism. Bone marrow biopsy shows mild or no lymphoid infiltration but bone resorption and proliferation of osteoclasts is not rare, particularly in patients with hypercalcaemia.

Demonstration of HTLV-I is the key test for the definitive diagnosis of ATLL. Serum antibodies to HTLV-I can be detected by ELISA or Western blot in virtually all cases. In a minority of patients who have a clinical and laboratory picture characteristic of ATLL, the retrovirus cannot be detected by either serology or molecular analysis. This suggests that in these cases the initiating event responsible for the development of ATLL is not HTLV-I. When findings are negative for HTLV-I, one should question the diagnosis of ATLL.

Cytogenetics and pathogenesis

ATLL has no distinct chromosomal abnormality but complex karyotypes and clonal evolution are frequent. Common abnormalities include +3, +7, +21, monosomy X, deletion of chromosome Y and rearrangements involving 6q and 14q. Rearrangements of chromosome 14 at breakpoints q11 and q32, characteristic of T-PLL, are rare. Mutations of the tumour-suppressor genes *TP53*, *CDKN2A* (encoding the p16INK4A

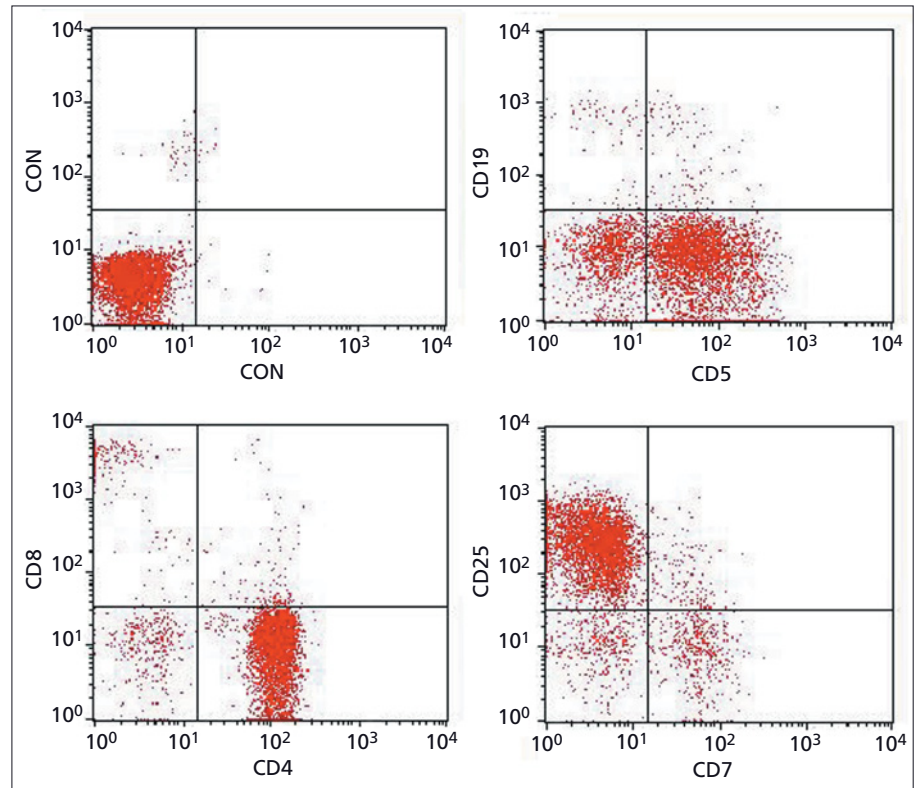

Figure 30.10 Flow cytometry plots of lymphocytes from a patient with ATLL showing reactivity with CD5, CD4 and CD25 while CD7 is negative.

protein) and *CDKN2B* (encoding the p15INK4B protein) have been documented and implicated in development of the disease. In smouldering ATLL, clonal and non-clonal abnormalities have been reported and occasional cases show clonal evolution from the smouldering to the acute phase. Sequential cytogenetic studies during the various phases of HTLV-I infection, from carrier to acute ATLL, might give some clues to the steps involved in leukaemogenesis, as the secondary factors involved in the neoplastic transformation of HTLV-I-infected lymphocytes are largely unknown.

IL-2 and its receptor have been implicated in the pathogenesis on the basis of the independent growth of some HTLV-I-positive cell lines, the continuous transcription of the IL-2 receptor gene, the increased levels of IL-2 receptor mRNA and the fact that HTLV-I induces IL-2 receptor expression in normal T lymphocytes when infected by this retrovirus. However, a role of IL-2 in pathogenesis is uncertain as ATLL cells do not secrete IL-2 nor have increased mRNA levels for this cytokine.

The mechanism of hypercalcaemia seems to relate to the release of cytokines, chiefly a parathyroid-like hormone, IL-1 and tumour necrosis factor (TNF)- β by the tumour cells. These lead to bone resorption and release of calcium into the serum.

It is well established that HTLV-I is the primary aetiological agent of ATLL, shown by the presence of monoclonal/oligo-clonal integration of HTLV-I sequences into the leukaemic cell's DNA. Although HTLV-I infection constitutes the first step

in the development of ATLL, it is not enough by itself to cause malignancy as only 0.5% of HTLV-I carriers will develop the disease and the life risk of developing ATLL in a carrier is estimated to be around 5%. Infection in early life seems to be a risk factor. HTLV-I does not carry an oncogene and the sites of integration vary from tumour to tumour. However, the retrovirus harbours various regulatory genes (e.g. *tax*) that code for proteins responsible for cell immortalization by activating genes relevant to proliferation and differentiation (*trans*-activation pathway).

Differential diagnosis

The differential diagnosis of ATLL arises with primary T-cell leukaemias and T-NHL not associated to HTLV-I. In addition, smouldering ATLL raises diagnostic problems with carriers of the retrovirus. T-cell leukaemias and T-NHL can be distinguished from ATLL by clinical features, morphology and the presence or absence of HTLV-I. The HTLV-I test is essential, as ATLL-type lymphoma, or its cutaneous form, cannot be distinguished from either T-NHL or MF/SS when only histology is available. In endemic areas and when the picture is not typical of ATLL, DNA analysis is needed in addition to serology to confirm that HTLV-I is clonally integrated in the leukaemic cells. The distinction between smouldering ATLL and carriers of the retrovirus is based on molecular analysis with probes specific for HTLV-I that will show a monoclonal/oligo-clonal

pattern of retroviral integration in smouldering ATLL versus a polyclonal pattern in the carriers.

Clinical course and therapy

ATLL is an aggressive malignancy for which no successful treatment is yet available, with a median survival of less than 12 months. Patients are refractory or transiently respond to chemotherapy or purine analogues. Smouldering and chronic ATLL pursue an indolent course until the disease progresses and becomes refractory to therapy. The poor outlook of ATLL relates to both chemotherapy resistance and complications (hypercalcaemia and opportunistic infections). Despite advances in disease pathogenesis, management of these patients remains a challenge. Most patients are refractory or achieve transient responses to CHOP, similar schedules and/or immunotherapy with monoclonal antibodies against the IL-2 receptor. Data with alemtuzumab is scanty. A major advance in treatment comes from the use of interferon alfa and the antiretroviral agents zidovudine and lamivudine, either alone or when used after, or combined with, chemotherapy. Following two initial Phase II trials, two prospective studies in France and England confirmed the efficacy of this combination and documented a response rate of 65–92%, of which half were CR, with improved survival. Although the mechanism of action of zidovudine is unknown, *in vitro* studies suggest that the drug inhibits telomerase function and leukaemic cells enter senescence. Consolidation with high-dose therapy and autologous or allogeneic SCT should be considered in young patients.

T-cell non-Hodgkin lymphomas

The tissue-based T-cell NHLs encompass a variety of entities that essentially affect lymphoid tissues and/or extranodal sites. Some of them are frequent in the East but very uncommon in Western countries. A minority of patients may develop or manifest a leukaemic picture and, when the circulating cells are large blasts (Figure 30.11), present problems of differential diagnosis with acute leukaemias. According to the WHO classification, the T-NHLs are classified as shown in Table 30.1.

Peripheral T-NHL not otherwise specified (see also Chapters 33 and 35)

This term includes T-NHL that does not correspond to specific T-NHL entities and most of these are referred to as non-lymphoblastic TdT-negative T-NHL. Patients present with organomegaly, 'B' symptoms and some with extranodal disease; haemophagocytosis and/or impairment of the immune system are not uncommon. Lymph node histology shows diffuse effacement of the architecture by atypical lymphocytes (Figure 30.12), or infiltration may be confined to interfollicular areas (T-zone variant) and/or the paracortical zone. There may be a

Figure 30.11 Bone marrow aspirate from a patient with T-NHL showing two large blasts.

Figure 30.12 Bone marrow trephine biopsy from a patient with peripheral T-cell lymphoma (unspecified) showing diffuse infiltration by pleomorphic lymphoid cells.

background of eosinophils and histiocytes in the lymphoepithelioid variant (Figure 30.13). The neoplastic cells express several T-cell markers (CD2, CD3, CD5, CD7), with variable expression of CD4 and CD8. Aberrant phenotypes with lack of expression of pan-T markers are common. CD52 may be negative in 60% of cases and the proliferative rate is usually high. Bone marrow is rarely involved. There is no consistent chromosomal abnormality but complex karyotypes are common. Gene expression profiling has shown a signature different from other T-NHLs and characterized by deregulation of genes involved in proliferation, apoptosis, transcription, cell adhesion and cytoskeleton organization. Most peripheral T-NHLs should be considered high grade; the 5-year survival is around 20%. Treatments are based on chemotherapy combinations such as intensified CHOP plus etoposide or given at shorter intervals (e.g. every 2 weeks), or gencitabine and platinum schedules followed or not by SCT.

Figure 30.13 Bone marrow trephine showing infiltration by lymphoid cells with marked eosinophilia in a patient with T-NHL.

Figure 30.14 Bone marrow trephine section from a patient with hepatosplenic lymphoma showing intrasinusoidal infiltration.

Peripheral T-NHL specific variants (see Table 30.1)

Several specific variants of T-NHL have been considered by the WHO as distinct entities on the basis of the clinical and laboratory features. The most relevant features of these lymphomas are described below.

Hepatosplenic T-NHL

This tumour usually derives from T cells positive for TCR- γ/δ and affects preferentially young males. It is more common in immunocompromised patients. Hepatosplenomegaly is the main feature, but extranodal sites (e.g. skin) may be involved (see Table 30.2). Cytopenias are common but bone marrow involvement is not frequent. A rare form of primary cutaneous γ/δ T-NHL is considered in the WHO classification but should be distinguished from the hepatosplenic T-NHL. The histology is distinct, with an intrasinusoidal pattern of infiltration in all tissues affected such as spleen, liver and bone marrow (Figures 30.14 and 30.15). This mimics the pattern of distribution of normal T γ/δ lymphocytes, which home preferentially in the spleen sinusoids. The neoplastic cells have a $CD2^+CD7^+CD3^{+/-}TCR-\gamma/\delta^+$ phenotype (Figure 30.16) and are usually negative with monoclonal antibodies against TCR- α/β , CD5, CD4 and CD8. Often, the cells are positive for the NK-associated markers CD16 and CD56, the cytotoxic granule-associated proteins TIA-1 and granzyme B, and may aberrantly express multiple KIRs. Molecular studies show rearrangement of the TCR γ - and δ -chain genes while the TCR α - and β -chain genes are in the germline. Cytogenetics have shown that some cases have iso(7q) and it has been suggested that this is a recurrent abnormality in this lymphoma (see Table 30.3). EBV does not play a pathogenic role. The clinical course is aggressive and median survival is less than 2 years. The most effective drugs are pentostatin and platinum-based regimens.

Figure 30.15 Immunohistochemistry of the bone marrow in Figure 30.14 showing that most lymphocytes in the sinusoids express cytoplasmic CD3.

Subcutaneous panniculitis-like T-NHL

This manifests with skin nodules resembling a benign panniculitis; haemophagocytic syndrome is frequent and may be fatal. It may be seen associated with autoimmune diseases, particularly lupus, and it has been speculated that autoimmunity plays a pathogenic role. Skin histology shows lymphoid infiltrates admixed with adipocytes in the subcutaneous tissue with extension to the dermis. Fat and connective tissue necrosis and granulomas are common; vascular invasion may be seen. The mitotic rate is high. The neoplastic cells are positive for CD2, CD3 and often CD8 and express granzyme B, perforin and TIA-1, suggesting that this lymphoma arises from cytotoxic T cells. Molecular analysis shows rearrangement of the TCR β -chain gene. There are limited data on outcome and response to therapy but cases with haemophagocytic syndrome appear to have the worst prognosis. Overall survival at 5 years is 80%.

Figure 30.16 Flow cytometry plots of bone marrow cells from a patient with hepatosplenic T-NHL showing that the lymphocytes express membrane TCR- γ/δ , cytoplasmic CD3 and CD8, but are negative for anti-TCR- α/β and CD4.

Angioimmunoblastic T-NHL

Angioimmunoblastic T-NHL had already been described in the 1970s. It affects adults and has an acute onset. 'B' symptoms, pruritus, cutaneous rash, organomegaly, effusions and immune disturbance, comprising autoimmune phenomena, immunodeficiency and/or dysproteinaemia, are common (see Table 30.2). Cases of clonal angioimmunoblastic T-NHL evolving from reactive hyperplasia have been described, and this may correlate with clinical progression. The diagnosis is based on clinical features and histology. The lymph node shows a pleomorphic infiltrate composed of lymphocytes, plasma cells, immunoblasts and eosinophils; proliferation of epithelioid post-capillary venules and increased numbers of follicular dendritic cell meshworks is common. There is obliteration of the follicular structure, described as 'burned-out' follicular centres. The bone marrow is often involved and aspirates may show reactive features with increase in polyclonal plasma cells. The lymphoma cells have a T-cell phenotype ($CD2^+CD5^+CD3^+$) and are often positive for CD4 and CD10; the proliferative rate is high. B immunoblasts may be present but usually are polyclonal. Complex karyotypes with multiple clones involving trisomy 3 or iso(3q), trisomy 5 and del(6q) are common. Most cases have rearrangement of TCR β - and/or γ -chain genes and, in a few cases, both immunoglobulin and TCR chain genes are rearranged; the latter correlates with the presence of an expanded EBV-positive B-cell clone which,

rarely, may progress to a diffuse B-cell lymphoma. The clinical course of angioimmunoblastic T-NHL is acute and prognosis is poor. Although transient spontaneous remissions have been documented, the lymphoma always recurs. Some patients initially respond to corticosteroids or combination chemotherapy but most relapse. Single case reports have documented responses to fludarabine and/or thalidomide. Combinations of gemcitabine and platinum appear to be more effective than CHOP. The median survival ranges from 13 to 17 months. It is likely that more aggressive regimens including SCT and/or combinations of chemotherapy with anti-T-cell monoclonal antibody will improve the dismal outcome of this lymphoma.

Extranodal T/NK lymphoma, nasal type

This type is significantly more frequent in China and Central/South America. Other designations for this lymphoma include lymphomatoid granulomatosis, polymorphic reticulosis, angiocentric immunoproliferative lesion or lethal midline granuloma. Patients are adults and present with systemic symptoms and extranodal disease, frequently involving the aerogastric tract and particularly the nasal cavity; other tissues that may be involved include skin, testes, CNS, lung, bowel and bone. The tumour histology shows lymphoid infiltrates admixed with histiocytes with marked angiocentricity, angiodestruction and ulceration (Figure 30.17).

Figure 30.17 Section from a nasal mass of a patient with extranodal T/NK lymphoma, nasal type, showing infiltration by lymphoid cells with angiocentricity.

Figure 30.18 Immunohistochemistry of the tissue in Figure 30.17 showing strong reactivity with CD56.

It has been suggested that necrosis relates to the release of TNF overexpressed by the tumour cells and induced by EBV. Immunophenotype shows that most cases have an NK phenotype ($CD2^+CD3e^+CD56^+mCD3^-$), while a small proportion have a cytotoxic T-cell phenotype ($mCD3^+$) with both subtypes expressing CD56 (Figure 30.18). The neoplastic cells express cytotoxic molecules such as perforin, TIA-1 and granzyme B. HLA-DR determinants, CD38, CD30 and CD25 may be positive, indicating that the tumour cells are activated lymphocytes. The EBV latent membrane protein (LMP)-1 can be demonstrated by immunohistochemistry in most cases. Cytogenetic abnormalities involving $iso(6p)$, $del(6q)$ and $iso(1q)$ are common; some cases may have *TP53* and/or *KIT* mutations

and/or partial deletion of the *FAS* gene. TCR chain genes are germline in cases with an NK phenotype but rearranged in the minority with a cytotoxic T-cell phenotype. Although the aetiology of this lymphoma is unknown, there is evidence of the pathogenic role of EBV by serology, a high titre of EBV DNA copies in the blood and molecular analysis showing single clonal episomal bands in the tumour cells. Detection of EBV-encoded RNA (EBER) is useful for distinguishing this lymphoma from benign or inflammatory nasal lymphoid infiltrates. The prognosis is variable. Unfavourable factors include advanced stages, high blood EBV copies and disease occurring outside the nasal cavity. Combination chemotherapy, especially including L-asparaginase, together with up-front local radiotherapy seems to be the best approach.

EBV-positive T-cell lymphoproliferative disorders in childhood

These have been incorporated in the new WHO classification. Two forms, systemic and cutaneous, are recognized with a different course and prognosis. They are more frequent in Asian and South American patients and EBV is consistently detected in the lesions, suggesting that the disease is triggered by this virus in an individual with a genetic predisposition. The systemic form corresponds to what was recognized as fatal haemophagocytic syndrome and affects liver, spleen and other organs, while the cutaneous form is confined to the skin particularly in sun-exposed areas. The tissues affected are infiltrated by pleomorphic lymphocytes with a cytotoxic phenotype: $CD2^+$, $CD3^+$, $CD56^-$, $TIA-1^+$ and often $CD8^+$. Haemophagocytosis may be prominent. All cases carry the type A EBV and EBERS can be detected in the neoplastic cells by FISH. The prognosis is poor in the systemic form.

Enteropathy-associated T-NHL

Intestinal lymphomas are often B-cell derived but a minority have a T-cell phenotype and these are designated 'enteropathy-associated T-NHL'. This lymphoma seems to arise from a $CD3^+CD8^+CD103^+$ T lymphocyte present in the normal epithelial intestinal mucosa. Some patients have a previous history of coeliac disease and/or gluten-sensitive enteropathy. The relationship between enteropathy-type T-NHL and coeliac disease is supported by the higher frequency of this lymphoma in geographical regions where gluten enteropathy is common such as northern Europe; diet may improve symptoms and patients have the HLA genotypes $DQA1^*0501$ and $DQB1^*0201$ seen in coeliac disease. It affects adults and the main manifestations are abdominal pain, chronic diarrhoea and/or weight loss; rarely bowel perforation or obstruction is the first manifestation. In some cases, the diagnosis is made concomitantly with coeliac disease. Histology shows intraepithelial and subepithelial lymphoid infiltration of the mucosa and villous atrophy with reactive eosinophils and histiocytes. Three histological subtypes with regard to the presence or absence of enteropathy have been

documented. These appear to correlate with outcome, which is worst for patients with associated enteropathy. The lymphoma cells express T-cell markers ($CD7^+CD3^{+/-}$), cytotoxic granule proteins and rarely are $CD8^+$ or $CD4^+$. The expression of HML-1 (CD103), a marker of normal intestinal lymphocytes, is a consistent finding supporting the theory that this lymphoma arises from intraepithelial mucosa T cells. The TCR β - and γ -chain genes are rearranged. Cytogenetics shows amplification of 9q31 or del(16q) and in some cases *MYC* amplification. A high prevalence of EBV has been documented in Mexican but not European patients. The clinical course is aggressive, with survival estimated to be less than 1 year. Patients with localized bowel disease have longer survival than those with generalized disease. Surgery is often the diagnostic procedure and the first therapeutic approach. Problems in the patient's management include intolerance to chemotherapy due to poor nutrition, low performance status and low albumin.

Anaplastic large-cell lymphoma

Anaplastic large-cell lymphoma (ALCL) is now considered a distinct clinicobiological entity with characteristic molecular features involving the *ALK* gene and expression of Ki-1 (CD30), a marker also present in Reed–Sternberg cells. It has a bimodal age of presentation (childhood and elderly) and shows a male predominance. Lymphadenopathy and cutaneous lesions are the most frequent manifestations but extranodal disease such as bone, lung and liver may be present (see Table 30.2). Systemic symptoms are common and most patients present with advanced stages. There are two forms, systemic and primarily cutaneous, and it is controversial whether these forms are biologically different. In the WHO classification, cutaneous CD30-positive ALCL is considered within the group of primary cutaneous CD30-positive T-cell disorders together with lymphomatoid papulosis and other rare subtypes. In addition, *ALK*-negative ALCL is also considered separately (see also Chapter 33).

Lymph node histology shows lymphoid infiltration of the T zone and paracortical areas, with or without intrasinusoidal involvement. Capsular thickening and fibrous tissue deposition are common. The skin shows infiltration of the dermis and subcutaneous tissue but epidermotropism is rare. Morphologically, ALCL is heterogeneous. The typical morphology is that of very large lymphoid cells, sometimes multinucleated, resembling Reed–Sternberg cells (Figure 30.19). Several morphological variants of ALCL have been recognized: monomorphic, Hodgkin-like, lymphohistiocytic or small cell. Despite this morphological heterogeneity, all these variants bear the t(2;5) translocation and express *ALK*. Most cases have a T-cell phenotype and often lack expression of some T-cell markers, particularly CD3; a few cases have a 'null' (non-B, non-T) phenotype, but molecular analysis demonstrates the T-cell nature of the lymphoma cells.

Figure 30.19 Bone marrow film from a patient with CD30-positive ALCL showing infiltration by large bizarre anaplastic cells.

ALCL cells always express CD30 (Ki-1), the hallmark of this lymphoma (see Table 30.3). Lymphocyte activation markers such as CD25, HLA-DR determinants and CD71 and the epithelial membrane antigen (EMA) are often positive while the cells are cytokeratin negative. Unlike Reed–Sternberg cells, ALCL cells are, as a rule, CD15 negative. This is important to consider as diagnostic confusion between this lymphoma and Hodgkin disease frequently arise. Some studies have shown that in most cases ALCL cells express TIA-1, perforin and granzyme B, molecules present in cytotoxic and NK cells, and thus suggested that ALCL cells derive from activated cytotoxic T cells. EBV is consistently negative. The chromosomal abnormality t(2;5)(p23;q35) is characteristic of ALCL. This leads to the rearrangement of the nucleolar phosphoprotein gene (*NPM*) on 5q35 with the anaplastic lymphoma tyrosine kinase (*ALK*) gene on 2p23 (see Table 30.3). This fusion generates a chimeric transcript, *NPM–ALK*, which can be detected by FISH or by reverse transcriptase PCR using specific primers and by immunohistochemistry with an antibody against the *ALK*-encoded p80 protein. A number of variant translocations involving *ALK* with other partner chromosomes have been described and all lead to the deregulation of *ALK*. The expression or absence of p80 protein appears to have prognostic impact. The *NPM–ALK* transcripts are detectable in most cases of nodal Ki-1-positive ALCL, but in only a few with the pure cutaneous form. This reinforces the fact that the latter represent a different entity, as regarded by the WHO classification.

The clinical course of ALCL is variable. Patients with early stages (I/II) and/or primary ALCL fare relatively well compared with those with advanced stages, bulky disease and/or secondary ALCL. The main prognostic factor in multivariate analysis is advanced stage (III/IV). There is no gold-standard therapy

for ALCL, which should be tailored according to age, performance status and extent of the disease. Localized skin lesions may respond to radiotherapy but in advanced stages combination chemotherapy should be recommended. Unlike other T-NHLs, patients with ALCL have sensitive disease and usually respond to chemotherapy, with an overall response rate of 55–100% in different series; however, most patients relapse. Autologous SCT has been successful in relapsed or newly diagnosed patients and this is the treatment of choice for young patients with advanced stages.

Differential diagnosis of peripheral T-NHLs

The differential diagnosis arises with (i) T-cell rich B-NHL; (ii) reactive non-neoplastic lymphadenitis; and (iii) rarely, Hodgkin disease or acute leukaemias. In difficult cases, markers should be complemented with TCR and immunoglobulin gene analysis. The latter, in addition, will exclude cases of reactive lymphadenitis with difficult histology. Immunophenotype allows the distinction between large-cell T-NHL and acute myeloid leukaemia.

Diagnostic problems with other diseases may also arise with specific T-NHL subtypes. For instance, subpanniculitis-like T-NHL should be distinguished from benign skin conditions or histiocytosis, angioimmunoblastic T-NHL from reactive disorders, CD30-positive ALCL from Hodgkin disease, and peripheral T-NHL, with marked haemophagocytic component, from histiocytic tumours or a reactive haemophagocytic syndrome. It is important to combine clinical features with histopathology and, if required, with molecular analysis of the TCR chain genes.

Conclusions

The mature or chronic T-cell lymphoproliferative disorders comprise a variety of disease entities with distinct clinical and laboratory features. They can be classified on the basis of the clinical presentation and disease manifestations into primary leukaemias, leukaemia/lymphoma syndromes and T-cell lymphomas. The precise diagnosis is important in terms of patient management, prognosis and therapy. Most of these disorders have an aggressive clinical course and are considered as high- to intermediate-grade lymphomas. The application of molecular techniques together with immunological markers has greatly helped the understanding of their pathogenesis by the identification of genes or oncogenes responsible for disease initiation or progression and has allowed the definition of disease entities. This, in turn, has provided the basis for the development of novel and specific therapies for certain conditions, with improvement in survival. However, further research is needed to define a number of disorders which at present have not emerged as distinct entities.

Definition

Multiple myeloma (MM) is characterized by the proliferation of a single clone of plasma cells that produce a monoclonal protein. The plasma cell proliferation results in extensive skeletal involvement, with osteolytic lesions, hypercalcaemia, anaemia and/or soft tissue plasmacytomas. In addition, the excessive production of nephrotoxic monoclonal immunoglobulin can result in renal failure and an increased risk of developing potentially life-threatening infections due to the lack of functional immunoglobulins. The clinical and laboratory manifestations of the disease, including their management, are discussed in this chapter.

Epidemiology and aetiology

The annual incidence of MM is 4 per 100 000. It represents approximately 1% of all malignant diseases and 15% of all haematological malignancies. The incidence of MM is lower in Asian populations and in blacks is twice that in whites; MM is slightly more frequent in men than in women. The median age

at diagnosis is 65–70 years. Only 15% and 2% of the patients are younger than 50 and 40 years, respectively.

The cause of MM is unknown. Radiation may play a role in some cases. An increased risk has been reported in farmers, particularly those who use herbicides and insecticides, and in people exposed to benzene and other organic solvents. However, the number of cases is small and more data are needed to establish a significant relationship. MM and monoclonal gammopathy of undetermined significance (MGUS) have been reported in familial clusters. A relationship between MM and pre-existing inflammatory diseases has been suggested, and plasma cell dyscrasias associated with protracted stimulation of the reticuloendothelial system have been reported in experimental studies. However, more recent case–control studies do not support a role for chronic antigenic stimulation in the aetiopathogenesis of MM.

Pathogenesis

MM is a B-cell malignancy characterized by the accumulation of terminally differentiated clonal plasma cells in the bone marrow, the production of a monoclonal immunoglobulin detectable in serum and/or urine and the presence of lytic bone lesions. In order to understand the pathogenesis of MM, it is important to review not only the molecular changes involved in the development of the malignant clone, but also the

mechanisms responsible for the interaction between the malignant plasma cells and their microenvironment, since they play a relevant role in bone destruction, tumour cell growth, survival, migration and drug resistance.

Cellular origin of myeloma cells

Normal differentiation from early B cells to plasma cells is characterized by three B-cell specific DNA remodelling mechanisms that modify immunoglobulin genes: VDJ rearrangement, somatic mutation and class switch recombination. Rearrangements of the immunoglobulin genes of B-cell precursors to form a B-cell receptor (BCR) occur in the bone marrow, while antigen recognition, selection, somatic hypermutation and class switch recombination take place in the germinal centre lymph node. Sequence analysis of the immunoglobulin V_H gene support the post-germinal origin of myeloma cells, which have successfully completed somatic hypermutation (without intracлонаl variation) and IgH switching before migrating to the bone marrow, where they will interact with stromal cells before finally differentiating into long-lived plasma cells.

Genetic abnormalities

Molecular cytogenetic investigations of myeloma cells have demonstrated that almost all cases of MM are cytogenetically abnormal. MM is characterized by marked karyotypic instability.

IGH translocations

A primary event in many kinds of B-cell tumour is dysregulation of an oncogene that, as a result of translocation to the *IGH* locus (14q32) or, somewhat less often, the *IGL* locus (κ 2p11 or λ 22q11), is juxtaposed near one of the potent immunoglobulin enhancers. In MM, *IGH* translocation may be classified into primary or secondary. Primary *IGH* translocations occur as initiating events during the pathogenesis of MM, whereas secondary translocations are involved in progression. Most primary *IGH* translocations result from errors in B-cell-specific DNA modification processes, mostly *IGH* switch recombination or less often somatic hypermutation. The breakpoints occur mainly within or immediately adjacent to *IGH* switch regions or J_H regions. In contrast, secondary translocations are mediated by other kinds of recombination mechanism that do not specifically target B-cell specific DNA modification processes. Unlike other B-cell tumours, in MM there is a marked diversity of chromosomal loci involved in *IGH* translocations. About 40% of MM tumours have *IGH* translocations involving five recurrent chromosomal patterns (Figure 31.1): 11q13 (*CCND1*), 4p16 (*FGFR3/MMSET*), 16q23 (*MAF*), 6p21 (*CCND3*) and 20q11 (*MAFB*).

The prevalence of t(11;14) according to interphase fluorescence *in situ* hybridization (FISH) analysis is 15–20% and is readily detectable by karyotyping. As result of the translocation, *CCND1* is juxtaposed to the powerful *IGH* 3' enhancer(s) on der(14), and its expression is dysregulated, as indicated by gene expression profiling and reverse transcriptase polymerase chain reaction (RT-PCR) in 100% of MM cases with t(11;14).

Figure 31.1 *IGH* translocations in multiple myeloma.

The t(4;14) translocation is identified in approximately 15% of MM cases using FISH analysis, but cannot be detected by karyotyping techniques. This translocation results in the simultaneous deregulation of the fibroblast growth factor receptor 3 (*FGFR3*) gene on der(14) and the multiple myeloma SET domain (*MMSET*) gene on der(4). *FGFR3* is one of the high-affinity tyrosine kinase receptors for the FGF family of ligands. Both *FGFR3* and *MMSET* genes are not normally expressed in plasma cells but are overexpressed as a result of t(4;14). However, gene expression profiling and RT-PCR analysis have shown that only 75% of MM cases with t(4;14) display simultaneous overexpression of *MMSET* and *FGFR3*. In the remaining 25% of cases, only *MMSET* is upregulated and the lack of *FGFR3* expression is linked in most cases to loss of the *FGFR3* gene on der(14). These data suggest that *MMSET* may be the critical transforming event in MM harbouring t(4;14), whereas *FGFR3* could be dispensable. In some cases (10%) the translocated *FGFR3* contains activating mutations that may be involved in MM progression.

The incidence of t(14;16) is 5–10%. The breakpoints on 16q23 occur over a region 550–1350 kb centromeric to *MAF*. Taking into account such a long distance, it is still an open question whether or not *IGH* may act as enhancer for *MAF* in this translocation. Moreover, overexpression of *MAF* is observed in half of myeloma cases, while the prevalence of t(14;16) is low. The t(6;14) translocation has been found in a low proportion (3%) of MM cases. Using microarray analyses, high levels of cyclin D3 mRNA have been shown in cases with t(6;14) detected by FISH. The t(14;20) translocation leads to deregulation of *MAFB* (20q23), which like *MAF* encodes a B-ZIP transcription factor, but in contrast to t(14;16), *MAFB* translocations have structural features that indicate they are secondary translocations.

It should be noted that several FISH studies have shown that MGUS display similar numerical and structural chromosomal abnormalities to those observed in MM. Thus, the prevalence of *IGH* translocations in MGUS is similar to that in MM, which favours the hypothesis that *IGH* rearrangements are early genetic events in the tumorigenic process leading to MM. Interestingly, the existence of MGUS cases with t(4;14) that remain stable for many years suggests that this chromosomal abnormality would be insufficient for further progression to MM.

Some of these molecular events represent potential therapeutic targets. Thus the t(4;14) translocation generates constitutive activation of the oncogenic receptor tyrosine kinase *FGFR3* with subsequent phosphorylation of the anti-apoptotic *STAT3* signalling pathway. Therefore, the use of inhibitors of the *FGFR3* tyrosine kinase, as well as inhibitors of cyclin-dependent kinases, could be attractive therapeutic targets. Similarly c-Maf, which is overexpressed in MM patients with t(14;16) as well as in some MM cases lacking this translocation, also represents a potential target.

Gains and losses of chromosomal material: monosomy 13, deletion of 17p and gains of 1q

Although *IGH* translocations are a hallmark in many cases of MM, there are other chromosomal abnormalities also involved in pathogenesis and prognosis that result in changes in chromosomal copy number. The loss of chromosome 13 is the most common monosomy in MM (40–50% of newly diagnosed patients). This abnormality shows a strong association with t(4;14) and t(14;16), deletion of 17p and gains on 1q. Chromosome 17p deletion, which includes loss of *TP53*, occurs at a lower frequency (5–10% of newly diagnosed MM), but its prognostic influence seems to be more important. Classical cytogenetics, FISH and comparative genomic hybridization analysis have all demonstrated that gains on 1q are some of the most common abnormalities in MM. Mostly they are the result of tandem duplications and jumping segmental duplications of the chromosome 1q band. The increased expression of *CKS1B* (1q21) detected in MM with gains of 1q has been suggested as the cause of increased proliferation in these cases.

Aneuploidy

Patients with MM may be grouped in two major categories according to ploidy status assessed by karyotyping: the hyperdiploid group (more than 46/47 chromosomes) and the non-hyperdiploid group, composed of hypodiploid (up to 44/45 chromosomes), pseudodiploid (44/45 to 46/47) and near tetraploid (more than 74). Non-hyperdiploid MM is characterized by a very high prevalence of *IGH* translocations involving the five recurrent partners. Likewise, monosomy/deletion 13 and gains on 1q occur predominantly in non-hyperdiploid MM. In contrast, the hyperdiploid group is associated with recurrent trisomies involving odd chromosomes (3, 5, 7, 9, 11, 15 and 19) and with a low incidence of structural chromosomal abnormalities. Similar associations have been observed on analysing DNA content by flow cytometry.

Late genetic events

Some genetic changes in MM, such as secondary translocations, mutations, deletions and epigenetic abnormalities, are considered late oncogenic events and are associated with disease progression. Dysregulation of *MYC* is a paradigm for secondary translocations in MM. Most karyotypic abnormalities involving *MYC* correspond to complex translocations and insertions that often are non-reciprocal and frequently involve three different chromosomes. Activating *RAS* mutations are considered molecular markers of disease progression. Thus, the prevalence of activating *KRAS* and *NRAS* mutations is over 75% in MM cases at relapse. *TP53* inactivation, via either deletion or mutation, seems to be more frequently associated with disease progression. Methylation is an epigenetic change that has been described in MM and acts as an inactivating mechanism of the tumour-suppressor genes *CDKN2B* and *CDKN2A*. Although it

has also been detected in MGUS, its prevalence is much higher in advanced MM and extramedullary forms of the disease.

Molecular classification of MM based on gene expression profiling

Gene expression analysis of MM has confirmed the huge genetic diversity of this tumour. Recently, the classification of MM into seven different groups has been proposed. Each group displays a specific genetic signature and some of them are associated with a particular *IGH* translocation or ploidy status and with a characteristic clinical behaviour. Table 31.1 summarizes this classification, which connects genetic abnormalities, cell transcriptome and clinical features of patients.

Dysregulation of cyclin D genes as a potential unifying event in MM pathogenesis

There is no common genetic mechanism to explain the pathogenesis of MM. However, it can be speculated that although *IGH* translocations induce upregulation of different oncogenes, it is possible that all *IGH* translocations involved in MM converge on a common pathway resulting in inhibition of differentiation and an increase in cell survival and proliferation. Gene expression profiling analysis has demonstrated that expression of *CCND1*, *CCND2* and *CCND3* is increased in virtually all MM patients, supporting the recent hypothesis of a potential unifying event in pathogenesis. Approximately 25% of MM cases

display overexpression of one of these cyclins, which may be triggered directly by an *IGH* translocation such as t(11;14) and t(6;14) that dysregulates *CCND1* and *CCND3* respectively, or indirectly by an *IGH* translocation involving *MAF* and *MAFB* genes which encode a transcription factor that targets cyclin D2. Nearly 40% of MM cases express increased cyclin D1 through biallelic dysregulation of *CCND1* and without apparent t(11;14); most of the remaining cases of MM, including those with t(4;14), have increased expression of cyclin D2. The expression level of cyclin D has also been incorporated into the molecular classification (Table 31.1).

Interaction between plasma cells and their microenvironment

As far as the pathogenesis of MM is concerned, interactions between the myelomatous plasma cells and their microenvironment can be as important as the genetic lesions. In the bone marrow, MM cells adhere to extracellular matrix proteins and bone marrow stromal cells through a series of adhesion molecules, for example the β_1 integrin family (VLA-4, VLA-5, VLA-6; also called CD49d, CD49e and CD49f), intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 (Figure 31.2). In addition, bone marrow stromal cells produce a stromal cell-derived factor (SDF)-1 that binds to CXCR4 on the surface of myeloma cells, inducing both

chemotaxis of plasma cells and upregulation of surface adhesion molecules such as VLA-4. Bone marrow homing of plasma cells is likely further facilitated through other adhesion molecules expressed by myeloma cells, such as CD138, CD38, CD44 and CD106.

Adhesion of myeloma cells to the bone marrow microenvironment induces a cell adhesion-mediated drug resistance phenotype via three mechanisms: (i) cell cycle arrest at G_1 (associated with upregulation of p27, an inhibitor of cyclin-dependent kinases); (ii) apoptosis inhibition via upregulation of FLIP-L, an endogenous inhibitor of FAS (CD95); and (iii) protection of tumour cells from initial drug-induced DNA damage (double-strand breaks) by reducing topoisomerase II activity. The binding of MM cells to the bone marrow microenvironment also induces the transcription and secretion of cytokines, such as tumour necrosis factor (TNF)- α , interleukin (IL)-6, insulin-like growth factor (IGF)-1, IL-21, SDF-1 α and vascular endothelial growth factor (VEGF), by both the plasma cells and the bone marrow stromal cells; this triggers signalling pathways (e.g. RAF/MEK/MAPK, PI3K/AKT and JAK/STAT) that promote cell proliferation and prevent apoptosis. These pathways are also potential targets for therapeutic intervention (Figure 31.3). In addition, cytokines modulate the production of additional adhesion molecules, which in a vicious circle enhance cell adhesion further.

In summary, it appears that the bone marrow microenvironment provides a sanctuary for myeloma cells by both promoting proliferation and blocking apoptosis, thereby allowing tumour progression and eventual emergence of drug resistance. Interruption by downregulating the interactions between the tumour cell and its microenvironment can potentially halt cell growth and proliferation and be of benefit to patients.

Figure 31.3 Signalling pathways involved in myeloma pathogenesis. See text for definition of abbreviations.

Influence of pathogenesis on the clinical features of MM and the development of bone lesions

The interaction between MM cells and the microenvironment not only favours tumour growth but is also responsible for the final myeloma portrait (see below). This interaction stimulates other cytokine cascades responsible for osteolytic lesions, which can result in bone pain, hypercalcaemia and neurological compression syndromes. Bone marrow infiltration also impairs normal haemopoiesis, leading to anaemia. MM cells secrete

monoclonal protein (M-protein) that increases plasma viscosity. In addition, M-protein, and particularly light chains, are responsible for the impairment of renal function, leading ultimately to renal failure. Hypercalcaemia due to osteolytic disease may also contribute to renal failure. Patients are also at increased risk of developing potentially life-threatening infections due to the lack of functional immunoglobulins.

Bone disease is one of the hallmarks of MM (see below). Osteolysis is mediated by an imbalance between osteoclast activity (increased) and osteoblast activity (decreased). Adhesion of MM cells to stromal cells induces the secretion of osteoclast-activating factors such as TNF- α , IL-6, IL-1, matrix metalloproteinases, hepatocyte growth factors, parathyroid hormone-related protein, RANK-L, VEGF, IGF and macrophage inflammatory protein (MIP)-1 α . Two of the most important are RANK-L (receptor activator of NF- κ B ligand) and MIP-1 α .

RANK-L is a transmembrane molecule, and is also called TRANCE (TNF-related activation-induced cytokine) or OPG-L (osteoprotegerin ligand). RANK-L binds to its functional receptor RANK (TNF receptor superfamily) on osteoclasts, stimulating osteoclastogenesis by inducing differentiation and maturation and stimulating resorption activity. Its activity can be blocked by osteoprotegerin (OPG), a receptor for OPG-L, which acts as a decoy receptor for RANK-L. Therefore osteoclastic activity is regulated by a delicate balance between RANK-L and OPG. In fact, under normal physiological conditions the levels of OPG are significantly higher than those of RANK-L. In contrast, in MM this balance is disrupted by increasing expression of RANK-L and decreasing expression of OPG. It has been suggested that the decline in OPG is mediated by myeloma cell uptake and degradation. MIP-1 α is a potent stimulator of osteoclast formation through a dual mechanism: (i) it enhances the activity of RANK-L and (ii) it directly stimulates osteoclast precursors to differentiate into mature forms. MIP-1 α gene expression is abnormally regulated in MM due to unbalanced expression of the acute myeloid leukaemia (AML)-1A and AML-1B transcription factors. This imbalance also induces IL-3, which stimulates osteoclast formation. In addition IL-3, as mentioned below, indirectly inhibits osteoblast formation.

In MM, in addition to the marked osteoclast activation, there is inhibition of osteoblast function. The WNT signalling pathway is critical for osteoblast differentiation. Indeed, the mesenchymal stem cell requires WNT signalling to differentiate into mature bone-forming osteoblasts. Myeloma cells produce DKK1, which inhibits the WNT pathway, and a soluble WNT inhibitor (sFRP-2) that suppresses osteoblast differentiation. Other relevant factors involved in osteoblast activity are RUNX2 and IL-3. The transcription factor RUNX2 is important in dividing mesenchymal stem cells to differentiated osteoblasts. MM patients with osteolytic lesions show a significant reduction of RUNX2, which may be the result of WNT signalling

inhibition by DKK1. IL-3 leads not only to increased osteoclast formation but also to inhibition of osteoblast differentiation. Bone marrow plasma from multiple myeloma patients, which exhibited high IL-3 levels, blocked osteoblast formation in human cultures, and this inhibition was partially reversed by the addition of a neutralizing antibody to human IL-3.

Differential diagnosis

The diagnostic criteria for the monoclonal gammopathies have been reviewed by the International Myeloma Working Group (IMWG). The main clinical entities are MGUS, primary systemic amyloidosis (see also Chapter 32), smouldering multiple myeloma and symptomatic multiple myeloma.

Monoclonal gammopathy of undetermined significance

MGUS has a high prevalence (3.2% and 5.8% in individuals over 50 and 70 years of age, respectively). MGUS is characterized by the presence of a serum M-protein (<30 g/L) and less than 10% plasma cells in the bone marrow with no evidence of other B-cell lymphoproliferative disorder and no symptoms or organ or tissue impairment due to the monoclonal gammopathy. The transformation rate to a malignant plasma cell disorder is about 1% per year, with an actuarial probability of malignant evolution of 30% at 25 years of follow-up. When the different causes of death are considered, the actuarial probability of malignant transformation at 25 years of follow-up is only 11%, much lower than the actuarial prediction. The main factors associated with MGUS progression include M-protein size, IgA isotype, abnormal free light-chain ratio and the 'evolving type' (rising M-protein during the first years of follow-up), and the presence of more than 95% phenotypically aberrant plasma cells within the bone marrow compartment.

When the proportion of bone marrow plasma cells is consistent with MGUS but the patient has a nephrotic syndrome, congestive heart failure, peripheral neuropathy, orthostatic hypotension or massive hepatomegaly, the most likely diagnosis is primary systemic amyloidosis resulting from the deposition of amyloidogenic light chains. On the other hand, in a patient with constitutional symptoms, lytic bone lesions, a small M-spike and less than 10% plasma cells in the bone marrow, the most likely diagnosis is metastatic carcinoma with coincidental MGUS.

Smouldering multiple myeloma

The term 'smouldering multiple myeloma' was first defined by Kyle and Greipp as the presence of a serum M-protein (>30 g/L) and 10% or more plasma cells in the bone marrow in the absence of lytic bone lesions or clinical manifestations due to

Table 31.2 Myeloma-related organ or tissue impairment (end-organ damage) due to the plasma cell proliferative process.

Increased serum calcium
Renal insufficiency
Anaemia: haemoglobin 2 g/dL below the lowest normal limit
Bone lesions: lytic lesions or osteoporosis with compression fractures (possibly confirmed by MRI or CT)
Other: symptomatic hyperviscosity (rare), amyloidosis, recurrent bacterial infections (more than 2 episodes in 12 months), extramedullary plasmacytomas

the monoclonal gammopathy. More recently, the IMWG considered that the term 'asymptomatic myeloma' could be more appropriate. This condition was defined as the presence of an M-protein (≥ 30 g/L) and/or 10% or greater bone marrow plasma cells in the absence of symptoms or organ or tissue impairment due to the monoclonal gammopathy. About 10% of patients diagnosed with MM have smouldering disease. This situation is clinically and biologically very close to that observed in MGUS. However, the plasma cell mass is much higher and most cases will eventually evolve into symptomatic MM.

The risk of transformation is 10% per year during the first 5 years and then decreases to 3% in the subsequent 5 years, with a cumulative probability of progression of 73% at 15 years. Risk factors for transformation include high M-component, IgA isotype, more than 20% plasma cells in the bone marrow, presence of urinary light chains, immunoparesis, abnormal free light-chain ratio, and the presence of more than 95% phenotypically aberrant plasma cells within the bone marrow compartment.

Symptomatic multiple myeloma

The diagnosis of symptomatic MM requires the presence of an M-protein in serum and/or urine, increased plasma cells in the bone marrow or plasmacytoma, and related-organ or tissue impairment (including bone lesions). The more common symptoms are fatigue from anaemia and bone pain due to the skeletal involvement. Some patients may have no symptoms but they can have related organ or tissue impairment. Clinical and laboratory features may include anaemia, skeletal involvement (lytic lesions and/or severe osteoporosis with or without compression fractures), renal failure, hypercalcaemia, recurrent bacterial infections, extramedullary plasmacytomas or associated amyloidosis (Table 31.2). The criteria agreed by the IMWG for the diagnosis of symptomatic MM are shown in Table 31.3. Of note, no serum or urine M-protein values were included, since about 40% of patients with symptomatic MM have a serum M-protein level lower than 30 g/L and 3% have non-secretory myeloma. In the same sense, no minimal proportion of bone marrow plasma cells was required because about 5% of

M-protein in serum and/or urine
Bone marrow (clonal) plasma cells or plasmacytoma [†]
Related organ or tissue impairment (end-organ damage, including bone lesions)

*Some patients may have no symptoms but have related organ or tissue impairment.

[†]If flow cytometry is performed, most plasma cells (>90%) will show a 'neoplastic' phenotype.

Table 31.4 Laboratory work-up for a patient with monoclonal gammopathy.

History and physical examination
Complete blood count and differential peripheral blood film
Chemistry including calcium and creatinine
Serum protein electrophoresis and immunofixation
Nephelometric quantification of immunoglobulins
24-hour urine collection for electrophoresis and immunofixation
Bone marrow aspirate (cytogenetics, immunophenotyping and plasma cell labelling index if available)
Radiological skeletal bone survey: CT or MRI may be helpful
β_2 -Microglobulin, C-reactive protein and lactate dehydrogenase
Measurement of free monoclonal light chains if available

patients with well-documented symptomatic MM have less than 10% plasma cells in their bone marrow. Table 31.4 illustrates the laboratory work-up for patients with monoclonal gammopathies.

Other special forms of plasma cell dyscrasia

Plasma cell leukaemia

Plasma cell leukaemia was initially described by Kyle in 1974 as a plasma cell disorder characterized by a relative peripheral blood plasmacytosis of more than 20% of total nucleated cells, or an absolute number of plasma cells greater than 2×10^9 /L. There are two forms of plasma cell leukaemia: the *de novo* presentation in leukaemic phase, and secondary cases corresponding to already diagnosed MM that evolve into a leukaemic phase. The clinical course of plasma cell leukaemia is usually very aggressive and resistant to conventional treatment and therefore new agents should be urgently investigated in these patients.

Solitary plasmacytoma of bone

The existence of a solitary plasmacytoma has been recognized in up to 3% of patients with a plasma cell dyscrasia, usually on the vertebral column. The diagnostic criteria require the existence of a solitary plasma cell tumour in which the biopsy confirms plasma cell histology, a negative skeletal survey, absence of plasma cell infiltration in a random bone sample (<10%), as well as no evidence of anaemia, hypercalcaemia or renal impairment. Some groups suggest that patients in whom a paraprotein persists after the eradication of plasmacytoma with local treatment should undergo a review of the diagnosis. The treatment of choice is local radiotherapy, but about two-thirds of patients with solitary bone plasmacytoma develop MM at 10 years' follow-up, with a median time to progression of 2 years.

Extramedullary plasmacytoma

Extramedullary plasmacytoma is a plasma cell tumour that arises outside the bone marrow, most frequently in the upper respiratory tract (nose, paranasal sinuses, nasopharynx and tonsils). Other sites include parathyroid gland, orbit, lung, spleen, gastrointestinal tract, testes and skin. In most cases the lesion is unique, although the presence of more lesions (multiple plasmacytomas) has also been reported. Diagnosis is based on the detection of the plasma cell tumour in an extramedullary site, in the absence of bone marrow plasma cell infiltration, bone lytic lesions and other signs of MM (end-organ damage).

Non-secretory multiple myeloma

This specific type of MM requires particular attention, since it is very difficult to diagnose. The only way to make a definitive diagnosis is to demonstrate the presence of tissue infiltration (usually bone marrow) by cells with plasma cell morphology. However, plasma cell infiltration must be greater than 10% and clonality must be assessed by immunophenotyping (demonstration of cytoplasmic immunoglobulins with restricted light chain: positive production without excretion). In addition, the serum free light chains are abnormal and this is a most useful parameter for the follow-up of these patients. However, exceptional cases exist in which no monoclonal protein can be observed within the plasma cells. In these cases, it is mandatory to demonstrate clonality by the study of the rearrangement status of the immunoglobulin genes. Additional detection of aneuploid DNA content by flow cytometry or an abnormal clone by cytogenetics may be helpful.

IgM multiple myeloma

This exceptional form of myeloma has been reported very rarely and must be distinguished from Waldenström macroglobulinaemia. The morphology and immunophenotype of the infil-

trating cells will give the definitive diagnosis, as well as the existence of osteolytic lesions, which are absent in Waldenström macroglobulinaemia.

Osteosclerotic myeloma (POEMS syndrome)

POEMS syndrome is characterized by polyneuropathy, organomegaly, endocrinopathy, M-protein and skin changes. The clinical picture consists of a chronic inflammatory demyelinating polyneuropathy, more motor than sensory, and osteosclerotic lesions. Hepatomegaly is observed in half of the patients. Hyperpigmentation, hypertrichosis, angiomatous lesions on the trunk, gynaecomastia and testicular atrophy may occur. Papilloedema is frequently present. The M-protein is commonly of IgA λ type (<30 g/L) and the bone marrow contains less than 5% plasma cells. Thrombocytosis is common. Castleman disease can be associated and VEGF is universally increased. Biopsy of an osteosclerotic lesion is generally necessary to confirm the diagnosis.

Disease complications and their management

Figure 31.4 illustrates the clinical manifestations of multiple myeloma.

Skeletal involvement

Bone involvement is the most frequent clinical complication in patients with MM. About 70% of patients have lytic bone lesions with or without osteoporosis and another 20% have severe osteoporosis without lytic lesions. The skeletal involvement leads to bone pain and can result in pathological fractures. The pathophysiology of bone disease has been described above. Some patients develop pathological fractures of long bones and require orthopaedic surgery. In the event of extensive lesions, surgery can be followed by radiation therapy. On the other hand, prophylactic orthopaedic intervention must be considered in patients with large lytic lesions at high risk of fracture. It is important to consider that patients with severe back pain due to vertebral compression fractures can benefit from vertebroplasty or kyphoplasty. Spinal cord compression caused by a vertebral fracture is very rare in patients with MM. This complication is usually caused by a plasmacytoma arising from a vertebral body.

Between 15 and 20% of patients with MM have hypercalcaemia at the time of diagnosis. A common complication of hypercalcaemia is renal impairment caused by interstitial nephritis. Treatment of hypercalcaemia with hydration and bisphosphonates is a medical emergency. Zoledronic acid is the bisphosphonate of choice (quicker response and significantly longer time to recurrence compared with pamidronate). With the

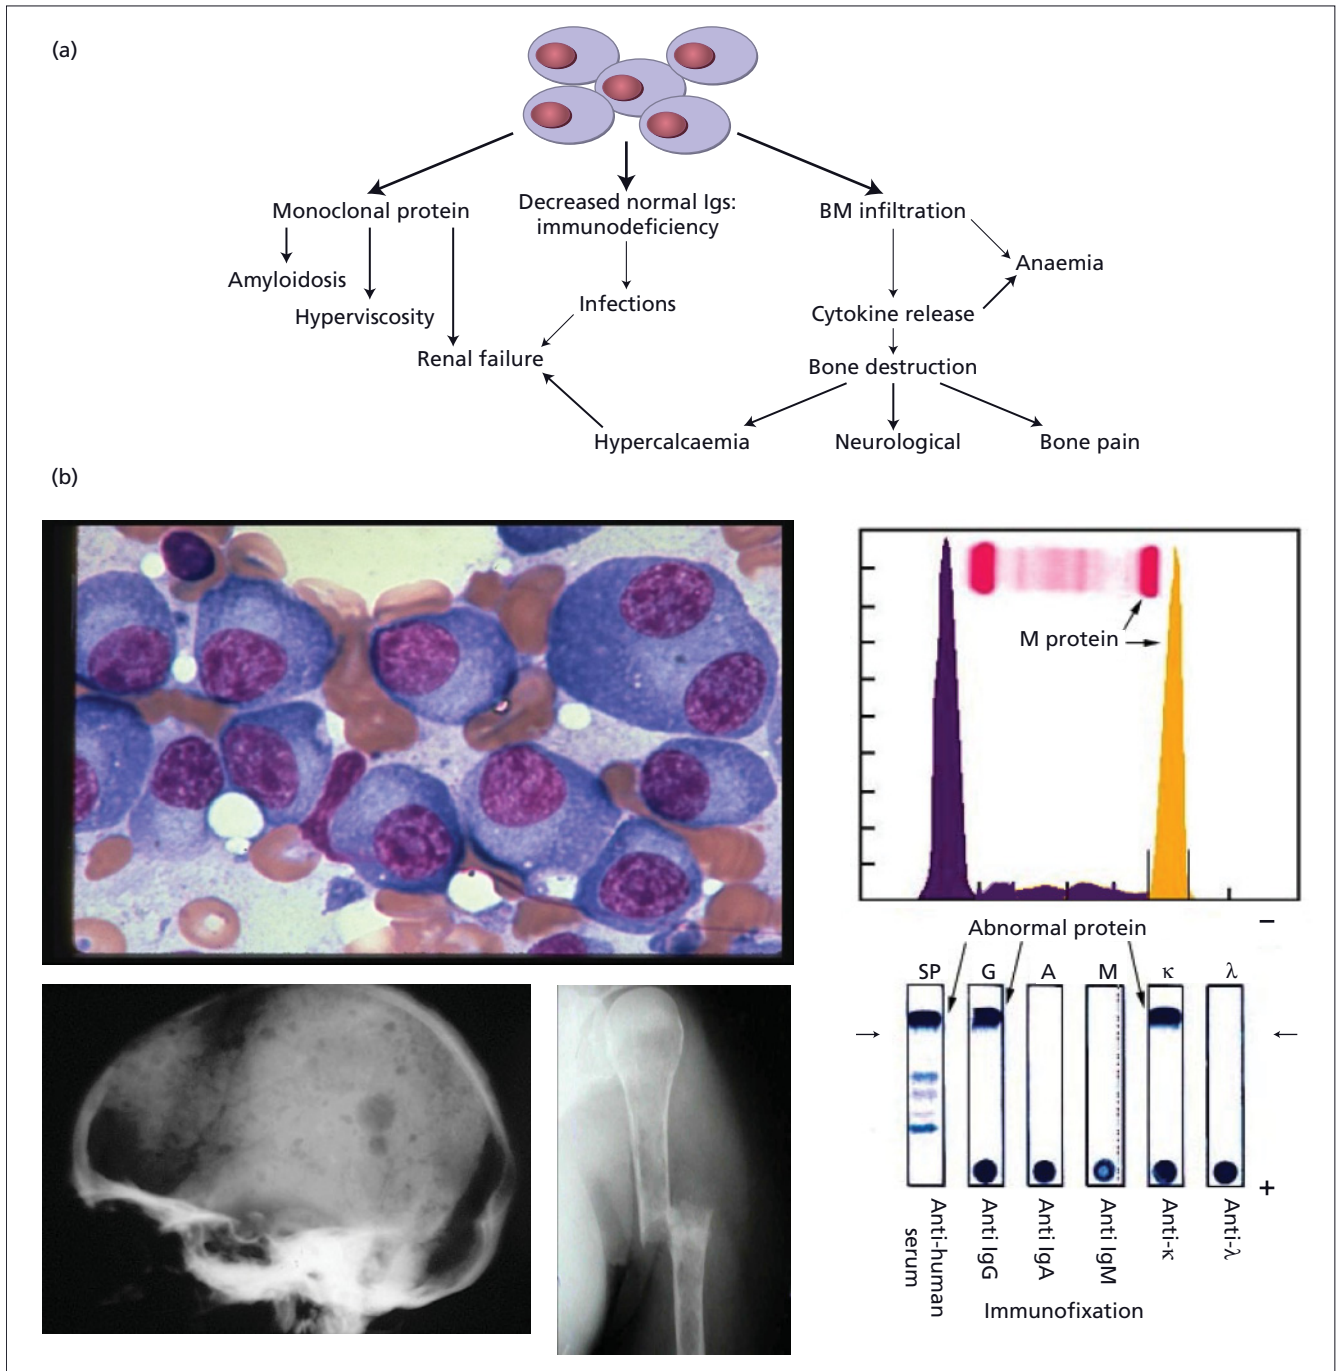

Figure 31.4 (a) Clinical manifestations in myeloma and (b) bone marrow infiltration, monoclonal band (IgGκ by immunofixation) osteolytic lesions resulting in a pathological fracture.

availability of zoledronic acid, forced diuresis and glucocorticoids are usually no longer necessary.

Oral clodronate and the intravenous agents pamidronate and zoledronic acid are of clinical benefit in the treatment of bone disease in patients with MM. For different reasons clodronate has not been extensively used in clinical practice outside the UK

and the Nordic countries. Pamidronate is administered at a monthly dose of 90 mg via a 2-hour intravenous infusion. Zoledronic acid, at a monthly dose of 4 mg, is at least as effective as pamidronate and has the advantage that it can be administered via a 15-min infusion. In patients with renal function impairment, the dose of zoledronic acid must be reduced to a

Figure 31.5 Pathogenesis of bone disease. (For abbreviations, see text)

maximum of 3 mg. A panel from the American Society of Clinical Oncology (ASCO) recommended the use of either pamidronate or zoledronic acid in patients with MM with either lytic bone lesions or osteoporosis. It was suggested that bisphosphonates should be used indefinitely once initiated. However, the appearance of severe late complications, such as osteonecrosis of the jaw, related to the duration of bisphosphonate exposure has resulted in a reconsideration of the initial recommendations. Osteonecrosis of the jaw is associated with the duration of bisphosphonate exposure, type of bisphosphonate (higher with zoledronic acid than with pamidronate) and history of recent dental procedure. The current recommendations for treatment with bisphosphonates in MM patients, based on a Mayo Clinic consensus statement as well as consensus panels from both the IMWG and the ASCO, do not recommend the initial use of bisphosphonates for more than 2 years. In relapsed patients treatment with bisphosphonates can be restarted and administered concomitantly with active therapy. Finally, in patients in whom the bone disease is a consequence of excess RANK-L activity, newer molecules such as denosumab might be of benefit. The pathogenesis of myeloma bone disease is summarized in Figure 31.5.

Renal failure

About 20% of patients with MM have a serum creatinine higher than $177\ \mu\text{mol/L}$ ($2\ \text{mg/dL}$) at diagnosis. The degree of renal failure is usually moderate, with a serum creatinine lower than $354\ \mu\text{mol/L}$ ($4\ \text{mg/dL}$). However, in some series up to 10% of patients with newly diagnosed MM have renal failure severe enough to require dialysis from the time of

diagnosis. The main causes of renal failure in MM are (i) light-chain excretion resulting in cast nephropathy (myeloma kidney) and (ii) glomerular deposition of immunoglobulin (light-chain amyloidosis or immunoglobulin deposition disease). In myeloma kidney, the typical feature consists of the presence of myeloma casts, mainly composed of light chains, in the distal tubules and collecting ducts. There is a correlation between the degree of cast formation and the severity of renal failure. Light-chain tissue deposition usually consists of glomerular deposits of immunoglobulins resulting in nephrotic syndrome. The amyloid deposits are fibrillar structures of light chains showing positive Congo red staining. In light-chain deposition disease, the deposit of light-chain immunoglobulins is non-fibrillar (Congo red negative). In contrast with amyloidosis, the light chain is usually of κ type. The characteristic clinical feature is a nephrotic syndrome, but renal function can rapidly deteriorate resembling glomerulonephritis (see also Chapter 32).

The median survival of patients with MM and renal insufficiency is less than 1 year. However, the prognosis mainly depends on the reversibility of renal function. Thus, the median survival of patients with reversible renal failure is similar to that of patients with normal renal function, whereas patients with non-reversible renal failure have a median survival of less than 6 months. The factors associated with renal function recovery include serum creatinine lower than $354\ \mu\text{mol/L}$ ($4\ \text{mg/dL}$), 24-hour urinary protein excretion lower than 1g, and serum calcium higher than $2.875\ \text{mmol/L}$ ($11.5\ \text{mg/dL}$).

Vincristine, doxorubicin (Adriamycin) and high-dose dexamethasone (VAD), or cyclophosphamide and dexamethasone, or even dexamethasone alone in very fragile patients, appear to

be better approaches than melphalan-containing regimens because of both lower myelosuppression and quicker action. Of these, the most frequently used has been VAD. However, it seems that the effect of vincristine and doxorubicin is only marginal, the efficacy of VAD mainly coming from high-dose dexamethasone. In addition, a randomized trial from the Nordic Myeloma Study Group has recently shown that the association of dexamethasone and cyclophosphamide was more convenient and as effective as VAD when given as up-front therapy. The novel drugs introduced for myeloma treatment may also be of great value in patients with renal failure. Taking into account that the action of bortezomib is very quick, it is probably an ideal agent for rapidly decreasing light chains in order to prevent the development of irreversible renal failure by avoiding further tubular light-chain damage. In a retrospective series of 24 patients with relapsed/refractory MM and dialysis-dependent renal failure, the overall response rate (RR) was 75%, with 30% complete remissions (CR) or near-CR. Hopefully, ongoing prospective studies will confirm the benefit of bortezomib-based therapies in patients with newly diagnosed myeloma and renal failure. The association of lenalidomide and dexamethasone could also be a good treatment option for patients with renal failure. However, the dose of lenalidomide must be adjusted to the degree of renal failure according to the guidelines for the use of lenalidomide in patients with renal function impairment. Although thalidomide has been used for more than 10 years, little information on its efficacy and toxicity in patients with renal failure is available, but it is also probably a useful agent for these patients.

With regard to the use of high-dose therapy/autologous stem cell transplantation (SCT) in patients with MM and renal failure, the largest experience comes from the Arkansas group, with a reversibility of renal failure of 43% but higher morbidity and mortality (6% and 13% after a single or tandem transplant, respectively) than in patients with normal renal function. Chemoresistant disease, low serum albumin and older age were associated with a poorer outcome. According to the results of a Spanish group, patients with serum creatinine above 442 $\mu\text{mol/L}$ (5 mg/dL), haemoglobin below 9.5 g/dL and/or poor performance status should be excluded from autologous SCT because of the high transplant-related mortality (TRM). In patients with no overt myeloma and low plasma cell mass in whom renal function impairment is due to glomerular light-chain deposition (light-chain deposition disease), the likelihood of response is higher than that in MM because of the low plasma cell mass at the time of transplantation. In this situation there is no need for tumour reduction with induction chemotherapy before stem cell mobilization and high-dose therapy.

Theoretically, the removal of nephrotoxic light chains with plasma exchange could avoid further renal failure and hopefully prevent irreversible renal failure. The Mayo Clinic group, in a small controlled trial, compared chemotherapy with chemotherapy plus plasma exchange and found only a trend in favour

of the group including plasma exchange. Similarly, in a large randomized trial there was no conclusive evidence that plasma exchange improved the outcome of patients with MM and acute renal failure. In our experience, patients with renal failure severe enough to require dialysis do not benefit from plasma exchange. However, it is our belief that in non-oliguric patients an early plasma exchange programme along with forced diuresis and chemotherapy could be of benefit. When excluding the patients who die in this early period, the median survival of patients with MM and non-reversible renal failure needing chronic dialysis is almost 2 years and 30% of them survive for more than 3 years. Thus, long-term dialysis is a worthwhile supportive measure for patients with MM and end-stage renal failure.

Anaemia and bone marrow failure

Approximately 35% of patients with newly diagnosed MM have a haemoglobin lower than 9 g/dL. In addition, severe anaemia is a frequent complication later in the course of the disease due to disease progression. Anaemia is associated with a significant loss in quality of life and poor prognosis. The main causes of anaemia in MM are bone marrow replacement by plasma cells, relative erythropoietin deficiency, renal insufficiency and chemotherapy with cytotoxic agents.

Severe granulocytopenia and thrombocytopenia at the time of diagnosis are unusual. About 10% of patients have a platelet count of less than $100 \times 10^9/\text{L}$, but platelet counts lower than $20 \times 10^9/\text{L}$ with risk of severe bleeding are very unusual. The development of an unexplained pancytopenia in patients previously treated with alkylating agents, particularly melphalan, is suspicious of myelodysplasia.

A number of trials have shown the beneficial effect of recombinant human erythropoietins and darbepoetin alfa in the treatment of myeloma-associated anaemia. The response to erythropoietin is associated with a significant improvement in quality of life. An important aspect is that the most significant improvement in quality of life is reached when the haemoglobin increases from 11 to 12 g/dL, but levels above 14 g/dL should be avoided due to its association with a higher risk of thrombosis. Thus, the goal should be maintenance of the haemoglobin around 12 g/dL, with careful dose titration in order to achieve a good quality of life while minimizing severe complications such as thrombotic events. The major cause of erythropoietin failure is iron deficiency. Iron repletion should be indicated when there is evidence of functional iron deficiency measured by an increased soluble transferrin receptor. The efficacy of oral iron is limited. It seems that the best iron supplemental therapy is the administration of iron saccharate. Treatment with granulocyte colony-stimulating factor (G-CSF) may be required to treat chemotherapy-induced severe granulocytopenia. Patients treated with lenalidomide may occasionally require G-CSF therapy.

Infection

Infectious complications are the major cause of morbidity and mortality in patients with MM. The highest risk of infection is observed during the first 2 months of starting therapy, in patients with severe chemotherapy-induced granulocytopenia and in those with relapsed and refractory disease. The main cause of infection in MM is the impaired antibody production, leading to a decrease in the uninvolved immunoglobulins. Other important causes include chemotherapy-induced granulocytopenia, renal function impairment and glucocorticoid treatment, particularly high-dose dexamethasone. Most infections in newly diagnosed patients and during the first cycles of chemotherapy are caused by *Streptococcus pneumoniae*, *Staphylococcus aureus* and *Haemophilus influenzae*, while in patients with renal failure, as well as in those with relapsed and/or refractory advanced disease, more than 90% of the infectious episodes are caused by Gram-negative bacilli or *Staph. aureus*.

An infectious episode in a patient with MM should be managed as a potentially serious complication requiring immediate therapy. In case of suspected severe infection and before the identification of the causal agent, treatment against encapsulated bacteria and Gram-negative microorganisms should be initiated. Although prophylaxis of infection in patients with MM is a controversial issue, some general guidelines can be offered. Intravenous immunoglobulin prophylaxis is not recommended. Pneumococcal vaccination is recommended, particularly in patients with IgG myeloma with high-serum M-protein levels, which are usually associated with very low levels of uninvolved immunoglobulins. Antibiotic prophylaxis is likely of benefit within the first 2 months of initiation of therapy, especially in patients at high risk of infection (recent past history of serious infections, such as recurrent pneumonia, or renal failure).

Nervous system involvement

Spinal cord compression from a plasmacytoma, which occurs in about 10% of patients, is the most frequent and serious neurological complication in MM. The dorsal spine is the most common site of involvement, followed by the lumbar region. The clinical picture of spinal cord compression consists of back pain and paraparesis. Although it can evolve for several days or even a few weeks, the onset can be abrupt, resulting in severe paraparesis or paraplegia in a few hours. The picture is usually accompanied by a sensitive level. Lumbar involvement can cause a cauda equina syndrome (low back pain with radicular distribution and leg weakness).

Spinal cord compression is an emergency requiring immediate medical action. When suspected, urgent magnetic resonance imaging (MRI) should be performed. If confirmed, treatment

with high-dose dexamethasone must be started immediately at a loading dose of 100 mg followed by 25 mg every 6 hours followed by progressive tapering. Local radiation therapy should be started as soon as possible, simultaneously with high-dose dexamethasone. If the spinal cord compression is caused by a vertebral collapse or by spinal instability rather than a plasmacytoma (which is very rare), urgent surgical decompression followed by fixation of a prosthesis of bone graft or methacrylate is required.

Nerve root compression can cause back pain that follows a radicular metameric distribution with or without radicular sensory involvement. Treatment with radiation therapy is helpful, allowing time for the action of systemic chemotherapy. Clinically significant peripheral neuropathy is very uncommon in newly diagnosed patients with MM. Leptomeningeal involvement in the central nervous system (CNS) with detection of plasma cells in the cerebrospinal fluid (CSF) is exceedingly rare. The frequency of CNS involvement is roughly 1%, the most frequent presenting features being paraparesis, symptoms from increased intracranial pressure, cranial nerves palsies and confusion. The CSF examination frequently shows plasma cells of plasmablastic morphology as well as an increased protein concentration with positive immunofixation for the myeloma protein. Unfortunately, despite active treatment measures such as intrathecal therapy (methotrexate, cytarabine, glucocorticoids), cranial or even craniospinal irradiation along with systemic therapy, the prognosis is extremely poor with a median survival of 3 months from the diagnosis of CNS involvement.

Prognostic factors

The outcome for patients with MM is highly heterogeneous, with survival duration ranging from a few months to more than 10 years. This heterogeneity relates to (i) specific characteristics of the tumour itself, (ii) host factors and (iii) a series of factors resulting from the interaction between the tumour clone and the host, which mainly reflect tumour burden and disease complications (Table 31.5).

Host factors

The favourable influence of a good performance status (ECOG ≥ 2) and young age (<65–70 years) is well established. In contrast, neither sex nor race has prognostic influence. Immune surveillance, by T and natural killer (NK) cells, plays a relevant role in most malignancies, and low numbers of mature NK and CD4 cells have been reported in advanced-stage MM. In addition, patients who develop expanded T-cell clones (CD8⁺CD57⁺CD28⁻), which can recognize autologous idiotypic immunoglobulin structures, display favourable outcome.

Table 31.5 Prognostic factors in MM.

<i>Prognostic factors</i>	<i>Tumour related</i>	<i>Host related</i>	<i>Tumour burden</i>
Essential	Cytogenetics/FISH: t(4;14), t(14;16), <i>TP53</i> , <i>RB</i>	Age Performance status	International Staging System (β_2 -microglobulin/albumin)
Additional	Plasma cell proliferation Immunophenotyping markers		
New and promising	Gene molecular markers: <i>PSMD9</i> (p27), <i>CKS1B</i> (1q21)	Immune status	Circulating clonotypic plasma cells sRANK-L

Malignant clone factors

The second cohort of prognostic factors are those that reflect specific characteristics of myelomatous plasma cells and include morphology, immunophenotyping, cytogenetics, oncogenes, multidrug resistance and proliferative activity of plasma cells. Immature/plasmablastic morphology is associated with poor outcome. With regard to antigen expression, we have observed that downregulation of CD117 (c-Kit) and CD56, and expression of CD28 and CD19, are associated with poor prognosis. As occurs with acute leukaemia, cytogenetics is emerging as one of the most important prognostic tools for MM. Therefore, investigation of cytogenetic changes (mainly by FISH, since cells from MM patients frequently do not yield mitoses in conventional karyotyping) should be mandatory in all newly diagnosed MM patients. Among *IGH* translocations, t(4;14) and t(14;16) have been consistently associated with unfavourable prognosis, whereas t(11;14) does not have a negative influence on survival. Initial studies indicated that monosomy 13/del(13) was associated with poor outcome; however, recent analyses based on large series of MM patients have revealed that the presence of monosomy 13/del(13) as a unique abnormality, without concomitant *IGH* abnormalities, is probably not indicative of unfavourable prognosis. In contrast, del(17p) (with deletion of the *TP53* gene) is one of the most, if not the most, adverse prognostic factor in MM. It has also been reported that amplifications on 1q and del(22) are associated with poor outcome, although this requires confirmation in larger series of patients. Moreover, the presence of complex as well as non-hyperdiploid karyotypes also predict treatment failure. Similarly, patients with chromosome losses detected by comparative genomic hybridization display very short survival. In contrast, hyperdiploid tumours with multiple trisomies involving chromosomes 3, 5, 7, 9, 11, 15, 19 and 21 tend to have a favourable prognosis. In line with this latter observation, we have shown that patients with hyperdiploid DNA cell content (defined by flow cytometry) have a favourable outcome. Finally, the proliferative activity of the malignant plasma cells, as assessed either by the labelling index with bromodeoxyuridine

or by flow cytometry, is one of the most important prognostic markers.

Tumour burden and disease complications

A high proportion of plasma cells in the bone marrow, diffuse bone marrow infiltration and the presence of circulating plasma cells reflect a high tumour burden, but their prognostic influence is modest. Similarly, the impact of skeletal lesions, evaluated by radiography or bone resorption markers, is not clear. In contrast, disease complications such as anaemia, thrombocytopenia and particularly renal insufficiency have a major influence. Nevertheless, the most important factor is the concentration of β_2 -microglobulin, which increases as a result of both growth of tumour burden and deterioration in renal function. The higher the value, the worse the prognosis. In contrast, β_2 -microglobulin is not helpful for disease monitoring. C-reactive protein is a surrogate marker for IL-6 (a major plasma cell growth factor), which also correlates with outcome. In contrast to hypoalbuminaemia, neither the amount of paraprotein nor its isotype influences prognosis.

Only a few of the prognostic factors have real independent value. A summary of the most important is shown below.

- 1 Two host factors (*age* and *performance status*) reflect the ability of the patient to tolerate chemotherapy.
- 2 Two intrinsic characteristics of the malignant clone (*cytogenetics* and *plasma cell proliferative activity*).
- 3 One biochemical marker that reflects tumour burden (*β_2 -microglobulin*).

A new International Staging System (ISS), derived from more than 11 000 patients, has shown that β_2 -microglobulin and albumin are the best combination of easily available markers for discriminating prognostic subgroups: stage I (β_2 -microglobulin <3.5 mg/dL, albumin >3.5 mg/dL); stage III (β_2 -microglobulin >5.5 mg/dL); stage II (the rest). This substitutes for the Durie and Salmon classification, which affords little prognostic information. In the next few years improved staging systems using cytogenetics and S-phase analysis should be

developed for use by reference centres and eventually for all patients with myeloma.

Response to therapy as a prognostic factor

In addition to all the variables that can be measured at diagnosis and which have already been mentioned, response to front-line therapy represents one of the most important prognostic factors in most haematological malignancies. In the case of MM there is still open debate about the importance of the depth of response on patient outcome. The reason for this controversy is probably that, historically, until the introduction of high-dose chemotherapy, CR was extremely rare and the only available comparison was between responding patients (achieving partial or minor responses) and non-responding patients, with the former having a better outcome. A recently published meta-analysis including 21 reports with independent datasets for which outcome data were reported has shown a very significant association between the maximal response obtained after treatment and the two main long-term-outcome parameters, i.e. overall survival (OS) and time to progression-related events. However, it is clear that more sensitive techniques (e.g. multiparametric immunophenotyping, molecular analysis of bone marrow plasma cells by PCR, serum free light chain test, and imaging techniques such as MRI or positron emission tomography to detect myeloma activity outside the bone marrow) are needed to evaluate response in MM and these may contribute to a better assessment of the impact of response in final outcome. We have shown that when transplanted MM patients show undetectable residual myelomatous plasma cells by immunophenotyping, progression-free survival (PFS) and OS are significantly longer, and this parameter is significantly more powerful than negative immunofixation.

Criteria of response

Response criteria were initially developed by the Chronic Leukaemia and Myeloma Task Force (CLMTF) in 1968. The main response parameter was a minimum 50% reduction in the M-protein. In 1972 the Southwest Oncology Group (SWOG) defined partial response (PR) as a reduction of at least 75% in the calculated serum paraprotein synthetic rate and/or a decrease of at least 90% in urinary light chain urine protein excretion sustained for at least 2 months. The Medical Research Council (MRC) introduced the concept of plateau phase, defined as a period of stability after chemotherapy in which tumour progression does not occur despite the presence of measurable disease. The minimum period of stability required for definition of plateau phase was 3 months. Since CRs were rarely observed with the classical conventional dose chemotherapy, neither the CLMTF nor the SWOG response criteria included a definition of CR. In addition there were no definitions for relapse and progression.

EBMT criteria for response, relapse and progression

With the introduction of high-dose therapy/SCT, the M-protein disappears in a significant number of patients, a fact that is associated with a significant prolongation of survival. In this context, the European Group for Blood and Marrow Transplantation (EBMT) developed new criteria defining CR (negative immunofixation in serum and urine and less than 5% bone marrow plasma cells), PR ($\geq 50\%$ reduction in serum M-component and $\geq 90\%$ in 24-hour urine Bence Jones proteinuria), minimal response (MR) (25–49% decrease in M-component), as well as criteria for relapse (reappearance of M-protein by immunofixation in patient who had achieved CR, and progression from PR or MR). Any type of response should be maintained for a minimum of 6 weeks. These criteria have been shown to be useful and reproducible in both transplant and non-transplant series as well as in prospective clinical trials.

Uniform response criteria

The IMWG has expanded the EBMT criteria by adding the categories of stringent CR (sCR) and very good partial response (VGPR) (Table 31.6). Patients with negative immunofixation in serum and urine and with a normal free light-chain ratio are considered in sCR. The free light-chain measurement has also been included for the evaluation of response in patients with non-secretory and oligosecretory disease. VGPR requires a decrease in the M-protein size of at least 90%. In addition, time to event, duration of response, clinical relapse and time to

Table 31.6 International uniform response criteria for multiple myeloma (IMWG response criteria).

Response category*	Criteria
Complete remission (CR)	Negative immunofixation (serum and urine) <5% bone marrow plasma cells No soft tissue plasmacytomas
Stringent CR	As above, <i>plus</i> Normal free light-chain ratio Absence of clonal plasma cells [†]
Very good partial response	$\geq 90\%$ decrease in serum M-protein Urine M-protein <100 mg per 24 hours
Partial response	$\geq 50\%$ decrease in serum M-protein $\geq 90\%$ decrease in urine M-protein or <200 mg per 24 hours $\geq 50\%$ decrease in soft tissue plasmacytomas

*All response categories require two consecutive measurements made at any time.

[†]Determined by immunohistochemistry or immunofluorescence.

alternative therapy are emphasized as critical end points. More recently, the IMWG has considered the possibility of also adding the parameters 'CR by immunophenotyping' and 'CR by molecular techniques', as well as the reintroduction of minor responses for treatment evaluation of relapse/refractory patients.

Treatment

In this section we focus on the treatment of the malignant clone, since the management of disease complications (anaemia, renal insufficiency, bone disease) has been discussed above.

Melphalan–prednisone (MP) was introduced for the treatment of MM in the late 1960s. In the subsequent 30 years treatment improvements remained stagnant, since more complex chemotherapy combinations (e.g. VCMP, VBAD, VAD) only led to small increases in the overall RR but without differences in survival, as assessed in a large meta-analysis that included over 6000 patients. The next step forward was the use of high-dose melphalan followed by stem cell support (autologous SCT) for young myeloma patients, which resulted in a significant improvement in disease-free survival and OS. However, for elderly patients, MP remained the standard of care. From 2000, there was a revolution in the treatment of MM with the availability of new agents with distinct mechanisms of action: the immunomodulatory drugs thalidomide and lenalidomide (Revlimid) and the proteasome inhibitor bortezomib (Velcade).

In this section we first discuss the treatment of newly diagnosed patients stratified according to age (above or below 65–70 years), which categorizes the patients as transplant or non-transplant candidates, and then analyse the options for relapse/refractory patients, as well as emerging novel agents.

Treatment of newly diagnosed transplant candidate patients

Currently, treatment in this setting usually includes three to six cycles of induction therapy, consolidation with autologous SCT and the possibility of maintenance therapy.

Induction

The VAD combination has long been the gold standard as a preparatory regimen for young newly diagnosed MM patients who are candidates for autologous SCT, with PR rates ranging from 52 to 63% and CR rates from 3 to 13%. However, novel drug combinations appear to be superior to VAD-like regimens for decreasing tumour burden before transplantation. As shown in Table 31.7, three randomized trials have compared thalidomide (T)-based regimens (TD or TAD or TVAD) versus either high-dose dexamethasone or VAD as initial therapy in transplant-eligible patients. In all studies, thalidomide combinations

were superior to conventional induction treatment, although the response rate (PR or greater) obtained with thalidomide plus dexamethasone (63%) was lower than that achieved with TAD or TVAD (80%, with CR rates usually <10%). The MRC group has compared cyclophosphamide (C) plus thalidomide and dexamethasone with CVAD as induction regimen before transplantation; the thalidomide arm was significantly superior (RR 87% vs. 75%; CR 20% vs. 12%). In studies evaluating bortezomib combination therapy, data from a French randomized trial that compared bortezomib plus dexamethasone with VAD show the superiority of bortezomib plus dexamethasone, both before and after transplantation (Table 31.7). The Italian group has reported similar results on comparing bortezomib, thalidomide and dexamethasone with thalidomide and dexamethasone (Table 31.7). The high efficacy of bortezomib-based regimens as induction treatment is consistent with several pilot studies using either bortezomib plus dexamethasone alone or in combination with doxorubicin (Adriamycin/Doxil) or thalidomide, with RRs usually over 80% and CR rates of 18–32%. With regard to lenalidomide, two large randomized studies have shown that the majority of patients (>85%) respond to lenalidomide plus dexamethasone induction, but a minimum of four to six cycles would probably be required to achieve a substantial number of CRs. Thalidomide or bortezomib combinations did not affect stem cell collection or granulocyte and platelet recovery after transplantation. For lenalidomide, three recent reports indicate a decrease in CD34-positive cells collected and recommended harvesting early in the course of induction with lenalidomide and/or using cyclophosphamide along with G-CSF. Although these novel induction regimens appear to be clearly superior to VAD, a longer follow-up is still required.

Autologous stem cell transplantation

High-dose therapy (usually melphalan 200 mg/m²) followed by autologous SCT prolonged OS compared with standard-dose therapy in prospective randomized trials conducted by the French (IFM) and English (MRC) groups and has provided evidence for more than 10-year survivorship in at least a subset of patients. Nevertheless, although the SWOG 9321 study in the USA, the French MAG91 study and the Spanish PETHEMA-94 trial confirmed the benefit of autologous SCT in terms of RR and event-free survival (EFS), they did not find superiority in terms of survival compared with standard-dose therapy. These discrepancies can be partly explained by differences in study design (the Spanish study randomized patients responding to initial therapy, while in the others randomization was performed up-front), differences in the conditioning regimens and, particularly, differences in the intensity and duration of the chemotherapy arm (the dose of alkylating agents and steroids was higher in the SWOG and Spanish trials, which may explain why OS for conventionally treated patients was longer in these two studies compared with the IFM and MRC trials).

Table 31.7 Response to induction treatment in transplant candidate patients: results from Phase III front-line trials.*

Regimen	Patients	PR or better (%)	CR + n-CR (%)	Study

Table 31.8 Result of randomized trials comparing autologous SCT with chemotherapy.

	Patients	CR (%)	EFS (months)	OS (months)
IFM90 (Attal <i>et al.</i> 1996)	200	22/5	28/18	57/44
MRC 03 (Child <i>et al.</i> 2003)	401	44/8	31/19	54/42
PETHEMA 95 (Bladé <i>et al.</i> 2005)	185	30/11	42/33	61/66
US-Intergroup (Barlogie <i>et al.</i> 2006)	516	11/11	25/21	58/53

CR, complete remission; EFS, event-free survival; OS, overall survival.

Despite these discrepancies, high-dose therapy is currently considered standard of care for younger patients with MM, mainly based on the benefit on RR and EFS.

In the setting of novel agents, it is also important to define whether autologous SCT enhances the RRs obtained with these new induction regimens. As mentioned above, studies based on bortezomib combinations, including two randomized trials, have shown that the CR rate was improved following autologous SCT (Table 31.8), suggesting that induction with novel agents and autologous SCT are complementary rather than alternative treatment approaches. Nevertheless, the benefit in terms of EFS and OS remains to be seen. With regard to thalidomide, it appears that the initial advantage of thalidomide-based regimens (TAD) compared with VAD is not so evident after autologous SCT. Data on lenalidomide are very encouraging, though still scanty. Nevertheless, some investigators argue that this approach may be challenged by the optimal results obtained with ‘long-term’ treatment with novel combinations (i.e. lenalidomide plus dexamethasone). Although a randomized trial comparing these two approaches would be most interesting, the transplant approach induces a very high CR rate (a goal in all haematological malignancies) and patients enjoy a long-term period free of treatment.

With regard to tandem autologous SCT, its use will decrease for two reasons: (i) according to the French and Italian experience, only patients achieving less than a VGPR with the first transplant benefit from the second; and (ii) a similar benefit is obtained on using thalidomide as consolidation/maintenance therapy. In contrast, a second transplant at relapse may be increasingly used, providing that the duration of the response to the first transplant has lasted for more than 2–3 years.

Maintenance

The third step in the sequence of treatment is maintenance. Interferon and/or corticosteroids have shown little benefit and have been abandoned. The availability of novel agents (particularly thalidomide and lenalidomide, which are available in oral formulations) has transformed the concept of maintenance in an attempt to prolong the duration of responses after transplantation. The IFM group has shown that thalidomide maintenance after tandem autologous SCT is significantly superior to no maintenance or pamidronate alone in terms of EFS (52%, 36% and 37% at 3 years) and OS (87% vs. 74% at 4 years). This superiority has been confirmed by an Australian study that compared thalidomide plus prednisone with prednisone alone. Of note, the Arkansas group has also observed that the use of

thalidomide as part of the induction and maintenance phases was associated with longer EFS, although this does not translate into a prolonged OS. This raises an important concern about whether the continuous use of novel agents may induce more resistant relapses. Moreover, the benefit of thalidomide maintenance for patients who are already in CR as well as for those with poor cytogenetics is not well established. Accordingly, although randomized trials are required to define the role of long-term maintenance (>1 year), a short treatment with thalidomide would be justified in patients who have not achieved CR after autologous SCT. It is possible that the better tolerance of lenalidomide will facilitate its use in maintenance programmes.

Allogeneic stem cell transplantation

Allogeneic SCT remains the only curative therapeutic approach in MM. However, it is associated with a high TRM (up to 30–50%) and high morbidity mainly due to chronic graft-versus-host disease (GVHD). Accordingly, it should be used in carefully defined situations and preferably within the context of clinical trials. In order to decrease TRM, different reduced-intensity conditioning regimens (allo-RIC), mainly based on fludarabine and melphalan or fludarabine plus radiotherapy (2 Gy) have been introduced. The TRM decreases by 25–25% but this is associated with a higher incidence of relapses. In a prospective randomized trial, the French group compared double autologous SCT with autologous SCT followed by allo-RIC among patients displaying poor prognostic features (high β_2 -microglobulin and monosomy 13). Unfortunately, there were no event-free survivors at 5 years after either double autologous SCT or autologous SCT followed by allo-RIC. In contrast, the Italian group, using a similar approach, has described an improvement in terms of OS among patients receiving autologous SCT followed by allo-RIC compared with double autologous SCT. The Spanish group has recently reported a comparison between double autologous SCT and autologous SCT followed by allo-RIC in patients failing to achieve at least near CR after a first autologous SCT. Although there was a higher increase in CR rate and a trend towards a longer PFS in favour of allo-RIC, this was associated with a trend towards a higher TRM (16% vs. 5%; $P = 0.07$) and no statistical difference in EFS and OS. Differences in patient characteristics, GVHD prophylaxis and conditioning regimens could contribute to these discrepant results. Moreover, unfortunately, a high proportion of patients developed extramedullary relapses without bone marrow involvement, indicating that although the disease may be under control in the bone marrow milieu, extramedullary spread may occur.

With regard to the use of allogeneic SCT as rescue therapy, a prerequisite is to obtain a CR or VGPR before the transplant since most patients with active disease will not benefit from this procedure. Once again these transplants should be performed by experienced groups and within clinical trials. Donor lym-

phocyte infusions given for relapsed myeloma following allogeneic transplantation induce responses in 30–50% of patients, but unfortunately the long-term efficacy is limited.

Treatment of newly diagnosed elderly and non-transplant candidate patients

MP has been the gold standard for over 40 years, although recent results based on the combination of MP with either thalidomide or bortezomib, and probably also with lenalidomide, indicate that there are now new standards of care for elderly MM patients. As shown in Table 31.9, five randomized trials have compared thalidomide plus MP (MPT) with MP. In all studies both the RRs and CRs were significantly higher in the MPT arm (RR 57–76% for MPT vs. 31–48% for MP; CR 7–16% for MPT vs. 1–4% for MP). Moreover, the five studies showed a significant advantage of MPT treatment in terms of PFS/time to progression (TTP) (prolongation in PFS ranging from 2 to 9 months). However, only in the two French studies was MPT treatment associated with a significant prolongation in OS. The toxicity associated with the high dose of thalidomide used in some of these trials may explain the survival discrepancies. Preliminary data from the MRC Myeloma IX trial show that the combination of cyclophosphamide, thalidomide and dexamethasone is superior to MP in terms of RR (82% vs. 49%) and CR (22% vs. 6%). The proteasome inhibitor bortezomib has been tested in combination with MP (BMP) in a pilot study conducted by the Spanish group; the positive results have been recently confirmed in a large (682 patients) randomized study (VISTA) that showed the superiority of BMP over MP (RR 71% vs. 35%; CR 30% vs. 4%). BMP treatment was associated with a 52% reduction in risk of progression, with a median TTP of 24 compared with 16.6 months ($P < 0.0001$) and a 36% reduction in risk of death, which translates into an OS at 3 years of 72% for BMP and 59% for MP. This benefit was present despite 45% of MP patients receiving bortezomib on progression. In addition, time to next therapy and treatment-free interval were significantly prolonged in patients treated with BMP and the benefit of this combination was observed across all patient subgroups, including those with advanced age, renal insufficiency and high-risk cytogenetics.

Lenalidomide has also been combined with MP. A pilot study showed an RR of 81%, a CR of 17% and an EFS of 87% at 16 months, and it is currently being tested in a randomized trial comparing lenalidomide plus MP with MP. Nevertheless, these MP combinations are being challenged by the recent results reported with lenalidomide plus dexamethasone, particularly using low-dose dexamethasone, with a 2-year survival probability of 82% in patients 65 years or older.

A final controversial issue is whether there is a preference for any one of the three novel MP combinations.

Table 31.9 Results from randomized Phase III trials in newly diagnosed elderly patients.

Study	Regimen	No. of patients	CR with negative immunofixation	TTP/PFS (months)	Overall survival
GIMEMA (Palumbo <i>et al.</i> 2006, 2008)	MPT	129	15.5%	29.2	NS (45 vs. 47 months)

- 1 The most mature data are with MPT and BMP.
- 2 For patients with antecedent, or risk of, deep venous thrombosis (DVT), BMP could be the preferred option.
- 3 In patients with antecedent peripheral neuropathy, lenalidomide plus MP should be the choice.
- 4 In patients with renal insufficiency, BMP is safe.
- 5 In patients living long distances from hospital, oral treatment (MPT, or lenalidomide plus MP) would be preferable.
- 6 In patients with poor compliance with treatment, BMP could be better.
- 7 If costs are a concern, MPT is less expensive.

An individualized treatment approach would probably be valuable. The toxicity profile of novel agents is discussed at the end of the treatment section.

In patients over 75 years of age or in fragile condition, the recommendation is to use modified regimens, with a lower dose of thalidomide (100 mg) and lenalidomide (15–20 mg) or bortezomib 1 mg/m² (or a weekly schedule). One additional possibility in these patients is to substitute melphalan with cyclophosphamide (50 mg/day or 1 g every 21 days), since this latter agent is less myelotoxic. In very elderly patients, special attention must be paid to infectious episodes (require active treatment) and renal function (appropriate hydration), particularly during the first 3 months of treatment when they are responsible for the high incidence of early deaths.

Treatment at relapse

It is important to separate the young (<55 years) from the elderly (>55 years) patients. In patients relapsing after transplantation, we discriminate three cohorts of patients: early

relapse (<1 year), intermediate relapse (1–3 years) and late relapse (>3 years). If the relapse occurs within the first year after transplantation, patients should be immediately considered high risk and, in order to overcome drug resistance, rescued with either a combination of all potentially effective drugs (e.g. BTM plus cisplatin, Adriamycin, cyclophosphamide and etoposide; or bortezomib, lenalidomide and dexamethasone) or alternating cycles of two combinations of non-cross-resistant agents (BCD alternating with lenalidomide or TAD). Nevertheless, it must be pointed out that these types of combinations should ideally be conducted within controlled clinical trials. If CR is achieved, the patient could proceed to allogeneic SCT with RIC, although this must still be considered an investigational approach.

If relapse occurs 1–3 years after autologous SCT, we would favour rescue with novel agents used in a sequential (not simultaneous) manner, starting with one line of treatment (different from the one used as induction) and shifting to the second and subsequent lines only when disease progression occurs. Within this category of patients, those under 55 years old with an HLA-identical sibling and a suboptimal response to the first line of treatment should be considered for allogeneic SCT with RIC. Finally, if relapse occurs more than 3 years after the first autologous SCT, an attractive possibility is reinduction with the initial treatment or other novel-agent combination followed by a second autologous SCT.

In the elderly patients, treatment decisions at relapse must take into account the general condition of the patient. Once the patient relapses, after up-front treatment, the durations of subsequent responses to rescue therapies are progressively shortened. Therefore, the current goal in relapsed MM is to optimize

the efficacy of novel drugs through their most appropriate combinations, to establish optimal sequences of treatment and to promote active clinical research on experimental agents that have already shown promising activity in *in vitro* and animal models.

At first relapse, a regimen based on novel drugs (thalidomide, lenalidomide or bortezomib) and different from that used as

induction should be instituted. Table 31.10 summarizes the most relevant results and combinations reported in relapsed patients. Thalidomide has been widely used, although few randomized studies have been conducted; the RR ranges between 25 and 70% depending on whether it has been used as a single agent or in combination with alkylating agents and corticosteroids. Bortezomib as a single agent has been shown to be

significantly superior to high-dose dexamethasone in relapsed/refractory patients (RR 43% vs. 18%; CR 16% vs. 1%; TTP 6 vs. 3 months). The addition of pegylated doxorubicin increased EFS to 9.3 months. With regard to lenalidomide, a large randomized trial has shown that lenalidomide plus dexamethasone is significantly superior to dexamethasone alone (RR 60% vs. 20%; CR 15% vs. 2%; TTP 11.1 vs. 4.7 months). The most widely used regimens at relapse include:

- thalidomide/dexamethasone or thalidomide/cyclophosphamide/dexamethasone;
- lenalidomide/dexamethasone or lenalidomide/dexamethasone/doxorubicin;
- bortezomib/dexamethasone or bortezomib/liposomal doxorubicin with or without dexamethasone or bortezomib/cyclophosphamide/dexamethasone (Table 31.10).

At second or subsequent relapse, usually after the patient has already failed bortezomib and at least one immunomodulator, a clinical trial with experimental agents should be encouraged. If the patient is not a candidate for active therapy, palliative treatment with oral cyclophosphamide (50 mg/day) and prednisone (30 mg on alternating days) can be considered.

Side-effects associated with novel agents

Because of the previous history of thalidomide a major concern was its toxicity profile. The side-effects are dose related and the most common include constipation, weakness, somnolence and neuropathy. Peripheral neuropathy is a common adverse event with thalidomide therapy and often limits the dose and duration of treatment. The use of combination therapy has raised concern about an increased risk of DVT. Apparently the major risk of DVT occurs when tumour load is high and thalidomide is combined with chemotherapy, especially Adriamycin (30% incidence vs. 4% when thalidomide is used alone). Accordingly, in this setting, anticoagulant prophylaxis with low-molecular-weight heparin (LMWH) or aspirin is mandatory. Current data suggest that lenalidomide is better tolerated than thalidomide in several aspects: it does not usually produce clinically significant somnolence, constipation or neuropathy, although the incidence of myelosuppression is higher, mainly neutropenia (grade 3 in 17–30%) and thrombocytopenia, which are manageable with dose reduction and growth factor support. Similarly to thalidomide, lenalidomide is associated with a higher risk of DVT (5–25%) and the risk increases in patients with comorbidities, previous history of DVT, concomitant use of erythropoietin, high-dose dexamethasone, anthracyclines or high tumour mass. For these reasons, anticoagulant prophylaxis with LMWH or aspirin is mandatory. The most frequent toxicities of bortezomib include fatigue, gastrointestinal symptoms (grade 3 in 15–25%), cyclical thrombocytopenia and, particularly, peripheral neuropathy. This latter side-effect, classified as grade 3 in 9–20% of patients, is the main reason for treatment discontinuation, and the early detection of peripheral neuropathy

is most important in order to reduce the dose or frequency of injections. Nevertheless, it resolved or improved in two-thirds of patients after completion or discontinuation of therapy.

Promising new drugs

Some of the molecular events responsible for the transformation of a normal into a malignant plasma cell represent potential therapeutic targets. Thus the t(4;14) translocation leads to constitutive activation of the oncogenic tyrosine kinase receptor FGFR3, with subsequent phosphorylation of the anti-apoptotic STAT3 signalling pathway. Moreover, several *IGH* translocations lead to cyclin D deregulation, and represent a common pathogenic event in MM. Therefore, the use of inhibitors of cyclin-dependent kinases, aurora kinase inhibitors and inhibitors of the FGFR3 tyrosine kinase could be attractive therapeutic targets. Although *in vitro* studies have shown that FGFR3 tyrosine kinase inhibitors such as CHIR-258/TKI or AB1010 inhibit FGFR3 autophosphorylation in cells carrying the translocation, resulting in cell growth arrest and apoptosis, preliminary clinical data show very limited activity as single agents.

The second area of MM pathogenesis that has important implications for treatment is the interaction between the malignant cell and the bone marrow microenvironment, which promotes MM cell growth and proliferation. As mentioned in the section on pathogenesis, adhesion of myeloma cells to bone marrow microenvironment induces a drug-resistant plasma cell phenotype. Moreover, this binding also induces the transcription and secretion of cytokines (TNF- α , IL-6, IGF-1, SDF-1 α , VEGF), by both the plasma cells and bone marrow stromal cells, that on interacting with their corresponding receptors trigger signalling pathways (e.g. RAF/MEK/MAPK, PI3K/AKT and JAK/STAT) that promote cell proliferation and prevent apoptosis. Several drugs that affect these pathways are already in the early phases of clinical investigation, including the following.

1 Agents against receptors present in plasma cells, which can be targeted by specific drugs or monoclonal antibodies, including death receptors (e.g. DR4-6 and FAS), tyrosine kinase receptors, VEGF-R, TACI, IL6-R, IGF-1R or the CD56 or CD40 antigens.

2 Several clinical trials are being conducted with inhibitors directed at signalling pathways, including farnesyltransferase (tipifarnib), RAF (RAF 265), STAT3 (atiprimod), mTOR (everolimus) or AKT (perifosine).

3 Drugs that interfere with the unfolded protein response and epigenetics, such as the new proteasome inhibitors (NPI-0052 and carfilzomib), Hsp90 inhibitors or histone deacetylase inhibitors.

Unfortunately, the expectations raised by some of these agents have not been confirmed in the clinic as yet. It is prob-

able that these targeted therapies will be more effective in combinations with other agents that have already shown clear efficacy in MM.

Introduction

Amyloidosis is a disorder of protein folding in which normally soluble proteins are deposited in the extracellular space as insoluble fibrils that progressively disrupt tissue structure and function. Some 25 different unrelated proteins can form amyloid *in vivo*, and clinical amyloidosis is classified according to the fibril protein type (Table 32.1). Of interest, although the term 'amyloid' is derived from the Greek for 'starch-like', the misnomer was recognized over 100 years ago and has remained unchallenged.

Amyloid deposition is remarkable in its diversity; it can be systemic or localized, acquired or hereditary, life-threatening or merely an incidental finding. Clinical consequences are seen when the accumulation of amyloid fibrils is sufficiently substantial to cause structural disruption of tissues or organs, leading to their impairment or failure. The pattern of organ involvement varies within and between fibril types and clinical phenotypes overlap greatly. In systemic amyloidosis, virtually any tissue may be involved and the disease is often fatal, although its prognosis has been improved by increasingly effective treatments for some of the conditions that underlie it. Greater understanding of the pathogenesis of the disease, allowing improved subtyping and appropriate targeted therapies, with improved supportive care including haemodialysis and solid organ transplantation in selected patients have also influenced the prognosis of this disorder. In localized amyloidosis, deposits are confined to a particular organ or tissue and are usually clinically silent, although they can cause serious consequences such

as haemorrhage in local respiratory or urogenital tracts. In addition to the amyloidoses, local amyloid deposition is a pathological feature of uncertain significance in other important diseases including Alzheimer disease, the prion disorders and type 2 diabetes mellitus.

The chapter is devoted mainly to describing the clinical features, diagnosis and management of AL (monoclonal immunoglobulin light chain) amyloidosis, which is the most common and serious form of systemic amyloidosis in industrialized societies. The differential diagnosis and other amyloid fibril types that can mimic AL type, including their diagnosis and management, are also discussed.

Pathogenesis of amyloid

Amyloidosis challenges the dogma that the tertiary structure of proteins is determined solely by their primary amino acid sequence. Amyloid-forming proteins can exist in two completely different stable structures, the transformation evidently involving massive refolding of the native form into one that can autoaggregate in a highly ordered manner to produce the characteristic predominantly β -sheet, rigid, non-branching fibrils of 10–15 nm in diameter and of indeterminate length. Acquired biophysical properties common to all amyloid fibrils include insolubility in physiological solutions, relative resistance to proteolysis, and ability to bind Congo red dye in an ordered manner that gives the diagnostic green birefringence under cross-polarized light.

Amyloid deposition can occur in three circumstances.

1 When there is a sustained abnormally high concentration of certain normal proteins, such as serum amyloid A (SAA) protein in chronic inflammation and β_2 -microglobulin in renal

Table 32.1 Classification of amyloidosis.*

Type	Fibril precursor protein	Clinical syndrome
AA	Serum amyloid A protein	Systemic amyloidosis associated with acquired or hereditary chronic inflammatory diseases. Formerly known as secondary or reactive amyloidosis
AL	Monoclonal immunoglobulin light chains	Systemic amyloidosis associated with myeloma, monoclonal gammopathy, occult B-cell dyscrasia. Formerly known as primary amyloidosis
ATTR	Normal plasma transthyretin	Senile systemic amyloidosis with predominant cardiac involvement
ATTR	Genetic variants of transthyretin (e.g. ATTR Met30, Ala60, Ile122)	Familial amyloid polyneuropathy (FAP), with systemic amyloidosis and often prominent amyloid cardiomyopathy
A β_2 M	β_2 -Microglobulin	Dialysis-related amyloidosis (DRA) associated with renal failure and long-term dialysis. Predominantly musculoskeletal symptoms
A β	β -Protein precursor (and rare genetic variants)	Cerebrovascular and intracerebral plaque amyloid in Alzheimer disease. Occasional familial cases
AApoAI	Genetic variants of apolipoprotein A-I (e.g. AApoAI Arg26, Arg60)	Autosomal dominant systemic amyloidosis. Predominantly non-neuropathic with prominent visceral involvement, especially nephropathy. Minor wild-type ApoAI amyloid deposits may occur in the aorta
AApoAII	Genetic variants of apolipoprotein A-II	Autosomal dominant systemic amyloidosis with predominant renal involvement
AFib	Genetic variants of fibrinogen α chain (e.g. AFib Val526)	Autosomal dominant systemic amyloidosis. Non-neuropathic usually with prominent nephropathy
ALys	Genetic variants of lysozyme (e.g. ALys His67)	Autosomal dominant systemic amyloidosis. Non-neuropathic with prominent renal and gastrointestinal involvement
ACys	Genetic variant of cystatin C (Gln68)	Hereditary cerebral haemorrhage with cerebral and systemic amyloidosis
AGel	Genetic variants of gelsolin (e.g. Asn187)	Autosomal dominant systemic amyloidosis. Predominant cranial nerve involvement with lattice corneal dystrophy
AIAPP	Islet amyloid polypeptide	Amyloid in islets of Langerhans in type 2 diabetes mellitus and insulinoma
ALECT2	Leukocyte chemotactic factor II	Systemic amyloidosis with predominant renal involvement

*Amyloid composed of peptide hormones, prion protein and unknown proteins not included.

failure, which underlie susceptibility to AA and β_2 -microglobulin amyloidosis respectively.

2 When there is a normal concentration of a normal, but inherently amyloidogenic, protein over a very prolonged period, such as transthyretin (TTR) in senile amyloidosis and β -protein in Alzheimer disease.

3 When there is production of an acquired or inherited variant protein with an abnormal structure, such as amyloidogenic monoclonal immunoglobulin light chains in AL amyloidosis or the hereditary amyloidogenic variants of TTR, lysozyme, apolipoprotein A-I and fibrinogen A α chain.

The genetic and environmental factors that influence individual susceptibility to and timing of amyloid deposition are unclear, but once the process has begun, amyloid deposition is unremitting as long as the supply of the respective precursor protein remains undiminished.

Amyloid deposits consist mainly of amyloid fibrils but they also contain some common minor constituents, including certain glycosaminoglycans (GAGs) and the normal circulating plasma protein serum amyloid P component (SAP), as well as various other trace proteins. SAP binds in a specific calcium-dependent manner to a ligand that is present on all amyloid fibrils but not on their precursor proteins. This phenomenon is the basis for the use of SAP scintigraphy in some centres for imaging and monitoring amyloid deposits. Studies in knockout mice indicate that SAP contributes to amyloidogenesis.

Amyloid fibril-associated GAGs mainly comprise heparan and dermatan sulphates. Their universal presence, restricted heterogeneity and intimate relationship with the fibrils suggest that they may also contribute to the development or stability of amyloid deposits, a possibility that has lately been supported by the inhibitory effect of low-molecular-weight GAG ana-

logues on the experimental induction of AA amyloidosis in mice.

Many of the pathological effects of amyloid can be attributed to its physical presence. Extensive deposits, which may amount to kilograms, are structurally disruptive and incompatible with normal function, as are strategically located smaller deposits, for example in glomeruli or nerves. Amyloid fibrils may also be directly cytotoxic but they appear to evoke little or no local inflammatory reaction in the tissues. However, the relationship between the quantity of amyloid and degree of associated organ dysfunction differs greatly between individuals, and there is a strong impression that the rate of new amyloid deposition may be as important a determinant of progressive organ failure as the amyloid load itself.

Treatments that substantially reduce the supply of amyloidogenic precursor protein frequently result in stabilization or regression of existing amyloid deposits, and are often associated with preservation or improvement in the function of organs infiltrated by amyloid.

Systemic AL amyloidosis

Systemic AL (formerly known as ‘primary’) amyloidosis occurs in a small proportion of individuals with monoclonal B-cell dyscrasia. AL fibrils are derived from monoclonal immunoglobulin light chains, which are unique in each patient. It is this uniqueness of an individual’s light chains that helps to explain the considerable heterogeneity in the way AL amyloidosis affects individual organs and its clinical outcome. Virtually any organ other than the brain may be directly affected. The kidneys, heart, liver and peripheral nervous system are the organs most often involved and most often associated with clinical consequences. Early symptoms are often non-specific. Screening techniques can fail to detect any underlying monoclonal gammopathy, leading to a delay in diagnosis, by which time the deposits are often extensive and the prognosis poor. This emphasizes the need to consider AL amyloidosis as a potential diagnosis in a range of vague clinical presentations, and the need for prompt appropriate investigations, such as biopsy of the affected organ and serum free light chain (SFLC) analysis.

AL fibrils and monoclonal light chains

AL amyloid fibrils are derived from the N-terminal region of monoclonal immunoglobulin light chains and consist of the whole or part of the variable (V_L) domain. The molecular mass of the fibril subunit protein therefore varies between about 8 and 30 kDa. All monoclonal light chains are structurally unique and the propensity for certain ones to form amyloid fibrils is an inherent property related to their particular structure. Only a small proportion of monoclonal light chains are

amyloidogenic, but it is not possible to identify these from their class or abundance. Monoclonal light chains that form amyloid are able to exist in partly unfolded states, involving loss of tertiary or higher order structure. These readily aggregate, with retention of β -sheet secondary structure, into protofilaments and fibrils.

The inherent ‘amyloidogenicity’ of certain monoclonal light chains has been demonstrated in an *in vivo* model in which purified Bence Jones proteins were injected into mice. Animals receiving light chains from patients with AL amyloidosis developed typical amyloid deposits composed of the human protein, whereas animals receiving light chains from myeloma patients without amyloid did not. AL fibrils are more commonly derived from λ than κ light chains, despite the fact that κ isotypes predominate among both normal immunoglobulins and monoclonal gammopathies. Some amyloidogenic light chains have distinctive amino acid replacements or insertions compared with non-amyloid monoclonal light chains, including replacement of hydrophilic framework residues by hydrophobic ones, changes that can promote aggregation and insolubility. Certain light-chain isotypes, notably $V_{\lambda V1}$, are especially amyloidogenic, and there is a degree of concordance between some isotypes and their tropism for being deposited as amyloid in particular organ systems. For example, the $V_{\lambda V1}$ isotype often presents with dominant renal involvement, whereas the $V_{\lambda II}$ isotype frequently involves the heart.

The plasma cell dyscrasia

Although almost any dyscrasia of differentiated B lymphocytes, including multiple myeloma, Waldenström macroglobulinaemia and other malignant lymphomas/leukaemias, may produce a monoclonal immunoglobulin that can form AL amyloid, well over 80% of cases are associated with low-grade and otherwise ‘benign’ monoclonal gammopathies. Histological studies indicate that amyloid deposition occurs in up to 15% of cases of myeloma, but usually in small and clinically insignificant amounts, and that it probably occurs in less than 5% of patients with ‘benign’ monoclonal gammopathy of undetermined significance (MGUS). The cytogenetic abnormalities that commonly occur in multiple myeloma and MGUS, such as 14q translocations and 13q deletion, have also been observed in AL amyloidosis, but their prognostic significance has not been fully elucidated.

Clinical features

AL amyloidosis accounts for 1 in 1500 deaths in the UK and occurs equally in men and women. The age-adjusted incidence of AL amyloidosis in the USA is estimated to be 5.1–12.8 per million persons per year, which is equivalent to approximately 600 new cases per year in the UK. The median age at presentation is 65 years, but it can occur in young adults and is most

likely underdiagnosed in the elderly, in whom it would be expected to have the highest incidence. AL amyloidosis is the most serious and commonly diagnosed form of systemic amyloidosis, and presently outnumbers referrals of AA amyloidosis to the UK National Amyloidosis Centre by a factor of 4:1.

Commonly, presenting features are non-specific and can be as vague as decreased exercise tolerance, fatigue, anorexia, weight loss and malaise. Not infrequently, patients are misdiagnosed with cardiac failure with symptoms and signs such as worsening pedal oedema and/or exertional dyspnoea. All these symptoms can be manifestations of amyloid infiltration resulting in nephrotic syndrome with or without renal impairment, cardiac involvement, neuropathy and hepatomegaly. Dysfunction of a single organ may dominate the clinical picture. The heart is affected in more than 50% of patients and in 30% a restrictive cardiomyopathy is a presenting feature. Rarer cardiac presentations include arrhythmias and angina, the latter sometimes due to coronary amyloid angiopathy. Dominant renal amyloid is the presenting feature in one-third of patients, typically presenting with nephrotic syndrome and/or renal impairment. Gut involvement may cause motility disturbances, which can also be secondary to autonomic neuropathy, and malabsorption, perforation, haemorrhage or obstruction. Macroglossia occurs in 5–10% but is almost pathognomonic of AL amyloidosis (Figure 32.1). Hyposplenism is not infrequent in both AA and AL amyloidosis but is rarely documented or clinically significant. Painful sensory polyneuropathy with

Figure 32.1 Macroglossia in AL amyloidosis.

changes in pain and temperature sensation followed later by motor deficits occur in 10–20% of cases and carpal tunnel syndrome occurs in 20%. Autonomic neuropathy leading to impotence, orthostatic hypotension and gastrointestinal disturbances may occur alone or together with peripheral neuropathy, and has a poor prognosis. Involvement of dermal blood vessels is common and may cause purpura, most distinctively in a peri-orbital distribution ('raccoon eyes'). Direct skin involvement takes the form of papules, nodules and plaques, usually on the face and upper trunk. Articular amyloid is rare but the symptoms can be severe and superficially mimic an inflammatory polyarthritis. Soft-tissue infiltration may occur, characteristically involving the submandibular region or the glenohumeral joints and surrounding tissues to produce the 'shoulder pad' sign, or lymph nodes themselves can be infiltrated. Thyroid infiltration with amyloid, occasionally resulting in hypothyroidism, has been reported. An uncommon but serious manifestation of AL amyloidosis is an acquired bleeding diathesis that may be associated with deficiency of factor X and sometimes also factor IX, or with increased fibrinolysis. It does not occur in other amyloidoses, although in both AL and AA disease there may be serious bleeding in the absence of any identifiable factor deficiency.

Diagnosis and investigation of AL amyloidosis

Amyloid should be considered in the differential diagnosis of renal failure, nephrotic syndrome, restrictive cardiomyopathy, peripheral or autonomic neuropathy and hepatomegaly, but early symptoms are often very non-specific and insidious, such as malaise or weight loss. The index of suspicion should be high in patients known to have clonal B-cell dyscrasias, but in practice the diagnosis of amyloidosis is usually an unexpected finding following biopsy of an organ with disturbed function. The approach to diagnosis is outlined in Table 32.2, and essentially comprises confirmation of the presence of amyloid, determination of fibril type, characterization of the underlying plasma cell dyscrasia, and evaluation of the extent, distribution and function of involved organs.

Confirming the presence of amyloid

Histology

In systemic forms of amyloidosis, deposits occur in blood vessels and as small interstitial foci throughout the body. This provides the basis for 'screening' biopsies, such as of the rectum by flexible sigmoidoscopy or of abdominal fat by needle aspiration, both of which are diagnostic in 50–80% of cases. Bone marrow trephine biopsies performed to differentiate MGUS from myeloma in a newly diagnosed plasma cell dyscrasia can also be used to diagnose amyloidosis and are almost pathognomonic of the AL type, hence routine Congo red staining should

Table 32.2 Suggested approach to the investigation and monitoring of suspected AL amyloidosis.

	<i>Confirmation of amyloid</i>	<i>Determination of amyloid type</i>	<i>Evaluation of organ involvement</i>	<i>Investigation of plasma cell dyscrasia</i>	<i>Monitoring</i>
Pathology	Biopsy and Congo red histology of affected organ, screening tissue (e.g. rectum or fat aspirate) or any available specimen	Immunohistochemical staining of tissue sections with a panel of antibodies to amyloid fibril proteins (often not definitive in AL amyloidosis)	Biopsy of affected organ (but subsequent biopsies merely to determine the extent of amyloid involvement are not recommended)	Bone marrow aspirate and trephine biopsy with immunophenotyping	Follow-up biopsies usually not helpful in monitoring amyloid load
Haematology, biochemistry, immunology		Identification of a monoclonal gammopathy supports AL type, but may be an incidental finding	Serum creatinine and creatinine clearance, albumin, 24-hour urine protein Liver function tests Coagulation screen NT-pro-BNP, troponin, thyroid function tests	Full blood count, urea and electrolytes, creatinine, calcium Immunoglobulins Electrophoresis and immunofixation of serum and urine Quantitative serum free light chain assay	Quantitative serum free light chain assay (every month or two) NT-pro-BNP (3–6 monthly) Electrophoresis and immunofixation of serum and urine (3–6 monthly)
Imaging	SAP scintigraphy	SAP scintigraphy (evidence of marrow involvement is indicative of AL type)	Echocardiogram, ECG, SAP scintigraphy	Skeletal survey	SAP scintigraphy (6–12 monthly)
Other		DNA analysis for hereditary forms of amyloidosis Amyloid fibril protein sequencing	As otherwise indicated, e.g. nerve conduction studies, cardiac MRI		Serial assessment of organ function, e.g. liver and renal function tests, including 24-hour proteinuria estimations, echocardiography and other investigations as indicated

NT-pro-BNP, N-terminal pro-brain natriuretic peptide.

be considered in these instances. Diffuse parenchymal amyloid deposits may occur in few or many organs, and biopsy of a clinically affected organ, for example the kidney, heart, liver or gastrointestinal tract, is likely to give positive results in more than 95% of cases. The appearance on haematoxylin and eosin-stained tissue of pink amorphous material should raise suspicion of amyloid and prompt further more specific stains. Many cotton dyes, fluorochromes and metachromatic stains are used, but Congo red stains that produce green birefringence under cross-polarized light is generally accepted to be the diagnostic gold standard in amyloidosis (Figure 32.2). False-positive and false-negative interpretation of the Congo red stain is not rare but can be minimized by using the alkaline-alcohol method

(a)

(b)

Figure 32.2 Appearance of amyloid in a bone marrow biopsy ($\times 40$, 6- μm section). (a) Congo red stain showing amorphous pink material in the interstitium and small blood vessel (arrow). (b) Same section under high-intensity cross-polarized light showing diagnostic apple-green birefringence.

(described by Puchtler and colleagues), fresh reagents, tissue sections of optimal 5–10 μm thickness, inclusion of positive control tissue and high-quality polarizing filters. Some Congo red techniques stain connective tissues quite strongly and produce white or very pale-green birefringence that can cause diagnostic errors.

The histological appearance of light chain deposition disease (LCDD) can mimic AL amyloidosis and can initially cause a diagnostic challenge. However, unlike AL amyloidosis, LCDD deposits lack the fibrillar configuration, with no affinity for Congo red stain and do not produce the characteristic green birefringence of amyloid under cross-polarized light.

Electron microscopy

Electron microscopy is helpful in distinguishing between AL amyloidosis and LCDD. Amyloid deposits are fibrillar, whereas LCDD deposits are granular. However, amyloid fibrils cannot always be convincingly identified ultrastructurally, and a diagnosis of amyloidosis made through electron microscopy alone should be regarded with caution since other pathological processes involve deposition of fibrillar material.

SAP scintigraphy

Radiolabelled SAP scintigraphy is a specific nuclear medicine imaging technique that demonstrates the presence and distribution of amyloid deposits *in vivo* in a quantitative manner. It was developed, and is used routinely, at the UK National Amyloidosis Centre. ^{123}I -labelled SAP localizes rapidly and specifically to amyloid deposits of all fibril types, in proportion to the amount of amyloid present. SAP scintigraphy confirms the presence of amyloid in most patients with AL type and virtually all with AA type, as well as most hereditary forms. The scans provide information that is different and complementary to biopsy histology, including whole-body and individual organ amyloid load both at diagnosis and in serial follow-up studies, for example following chemotherapy in AL amyloidosis (Figure 32.3). It is a particularly good imaging modality for detecting amyloid deposition in the liver, spleen, kidneys, bone marrow and adrenal glands. The organ distribution of amyloid on SAP scintigraphy can be indicative of the fibril type, for example bone uptake essentially occurs only in AL amyloidosis. Unfortunately, amyloid in the moving heart and in small or diffuse hollow structures such as nerves, the gastrointestinal tract and the lungs is not adequately visualized by SAP scintigraphy. Various other tracers, including conventional bone-seeking agents and radiolabelled aprotinin, sometimes localize non-specifically to amyloid deposits but do not have any defined clinical role.

Identifying fibril type

It has been common practice to diagnose apparently 'primary' cases of amyloidosis as AL in type, especially when a monoclonal gammopathy can be demonstrated. However, the under-

Figure 32.3 Radiolabelled ^{123}I -SAP whole-body scintigraphy, anterior images. (a) The tracer has localized virtually exclusively to amyloid deposits in the bones in this particular patient, a distribution that is almost pathognomonic for amyloid of AL type. (b, c) Serial scintigraphs in a 56-year-old woman with AL

amyloidosis. At presentation in 1998 (b) she had massive uptake in the spleen and liver, obscuring any renal signal. She underwent high-dose chemotherapy, and the follow-up scan in 2002 (c) shows that the deposits have regressed substantially.

lying chronic inflammatory disease process is clinically covert in 5–10% of patients with AA amyloidosis, and a family history is quite often absent in patients with hereditary amyloidosis, due to variable penetrance and late onset of symptoms. The coincidental presence of a monoclonal gammopathy can therefore be gravely misleading and lead to misdiagnosis of AL amyloidosis and inappropriate use of cytotoxic agents. The combination of immunohistochemical staining and DNA analysis is vital to aid confirmation of amyloid fibril type and exclusion of hereditary forms of amyloidosis.

Immunohistochemistry

Immunohistochemical staining of amyloid-containing tissue sections using a panel of antibodies against known amyloid proteins is the most accessible method for characterizing fibril type. However, definitive results are often not obtained in AL

amyloidosis due to a combination of background staining of normal immunoglobulin and failure of antibodies to bind to κ or λ light chains in their abnormal amyloid conformation. In contrast, antibodies against serum amyloid A protein can confirm or exclude AA amyloidosis in virtually all cases and, with optimization, immunohistochemical staining is usually definitive in hereditary forms involving TTR, fibrinogen and apolipoprotein A-I. Reliable interpretation of immunohistochemical stains is not possible unless positive and negative controls have been used, and the specificity of staining by absorption with appropriate antigens has been demonstrated in each run.

DNA analysis

The clinical features in hereditary systemic amyloidosis are often indistinguishable from those in AL amyloidosis. Sequencing of the genes associated with hereditary amyloidosis

should be performed routinely to exclude hereditary amyloidosis when the AL type cannot be confirmed with absolute certainty by immunohistochemistry as well as in all patients in whom familial disease is suspected. DNA analysis for mutations in the genes coding for TTR, fibrinogen A α chain, lysozyme, apolipoprotein A-I, apolipoprotein A-II and gelsolin are now available at major amyloid centres, including the UK National Amyloidosis Centre. Importantly, hereditary TTR and fibrinogen A α chain amyloidosis are much more common than previously thought. Compounding this, a family history of amyloidosis may be absent due to incomplete penetrance. In a British series of 350 cases, 34 patients were initially misdiagnosed as having AL amyloidosis until genetic sequencing demonstrated the alternative hereditary types. Hereditary TTR amyloidosis can present with polyneuropathy and/or amyloid cardiomyopathy, and there should be a low threshold for sequencing the gene for TTR in patients with this phenotype. Hereditary fibrinogen A α -chain amyloidosis should be considered in any patient with an exclusive renal presentation and has a distinctive appearance on renal biopsy, with extensive glomerular involvement and notable absence of extraglomerular amyloid. Corroboration by immunohistochemistry and clinical features is necessary to confirm that identified mutations are indeed the cause of the amyloid. It is often only possible therefore to be confident of the diagnosis of AL amyloidosis after exclusion of AA and hereditary types by immunohistochemistry and genetic sequencing respectively.

Mass spectrometry

Amyloid fibril proteins can also be characterized by various proteomic analyses including mass spectrometry, although these techniques are not yet routinely available.

Assessment of the plasma cell dyscrasia

A monoclonal whole paraprotein or free light chains can be identified by electrophoresis and immunofixation of serum and urine in only 80% of patients with systemic AL amyloidosis. However, SFLC analysis (Freelite, The Binding Site, Birmingham, UK) can demonstrate a clonal excess of SFLCs in over 90% of cases and can be used to quantitatively monitor the effects of chemotherapy on the underlying plasma cell clone on a frequent basis. Unlike whole intact paraproteins, which have a half-life of 5–20 days, SFLCs have half-lives of only 2–6 hours, which means that they are ideal for gauging response to chemotherapy and have become the standard of care in AL amyloidosis. In patients with renal failure, κ and λ free light chains are retained in the serum, leading to higher than normal individual light chain levels, but the ratio of free κ to free λ continues to enable the clonal disease to be followed.

Bone marrow aspiration and trephine biopsy are required to characterize the underlying B-cell dyscrasia, which comprises a subtle plasma cell infiltrate in about 80% of cases. The presence of amyloid in a bone marrow specimen other than blood vessels

is highly suggestive of AL type. Immunophenotyping and cytogenetic findings in AL amyloidosis are similar to those in myeloma. Immunoparesis occurs frequently in AL amyloidosis. Lytic lesions or hypercalcaemia are diagnostic of myeloma and so skeletal surveys are routinely recommended in new cases of AL amyloidosis to help distinguish myeloma from MGUS.

Assessment of organ involvement

There are now international consensus criteria, detailed by Gertz and colleagues in 2005, for defining organ involvement in AL amyloidosis (Table 32.3). Organ involvement by amyloid is variously defined clinically, histologically, according to organ function and by SAP scintigraphy where available. ECG and two-dimensional Doppler echocardiography are vital tools for evaluating cardiac involvement. In cardiac amyloidosis, ECG may demonstrate reduced QRS voltages in the limb leads and

Table 32.3 Non-invasive diagnostic criteria for amyloid-related major organ involvement.

Heart

Echocardiogram demonstrates mean wall thickness >12 mm, no other cardiac cause found

Kidney

Proteinuria >0.5 g per 24 hours, predominantly albumin

Liver

Total liver span >15 cm in the absence of heart failure or alkaline phosphatase >1.5 times the institutional upper limit of normal

Nerve

Peripheral: clinical; symmetric lower extremity sensorimotor peripheral neuropathy
Autonomic: gastric emptying disorder, pseudo-obstruction, voiding dysfunction not related to direct organ infiltration

Gastrointestinal tract

Direct biopsy verification with symptoms

Lung

Direct biopsy verification with symptoms
Interstitial radiographic pattern

Soft tissue

Tongue enlargement, clinical
Arthropathy
Claudication, presumed vascular amyloid
Skin
Myopathy by biopsy or pseudohypertrophy
Lymph node (may be localized)
Carpal tunnel syndrome

poor R-wave progression in the chest leads ('pseudo-infarct pattern'). Echocardiography typically reveals concentrically thickened and echogenic heart valves. Cardiac amyloidosis is a restrictive cardiomyopathy and diastolic dysfunction is easily missed and difficult to quantify. Cardiac magnetic resonance imaging (MRI) is emerging as a useful tool for identifying cardiac amyloidosis and distinguishing it from other restrictive cardiomyopathies. The status of other organs can be assessed either through routine tests of organ function, such as liver function tests, serum creatinine and 24-hour urine measurements, or by specialist investigations as indicated, for example autonomic function and nerve conduction tests and high-resolution pulmonary computed tomography (CT).

Glomerular proteinuria (predominantly albuminuria) is present in about 90% of patients with renal involvement. Abnormalities in liver function tests are unusual and do not occur until liver amyloidosis is substantial, and are most commonly obstructive in nature. Right-sided heart failure due to amyloid cardiomyopathy may cause obstructive liver function tests in the absence of liver involvement by amyloid. Anaemia is uncommon unless amyloidosis is associated with myeloma, bleeding or chronic kidney disease. An abnormal clotting screen is relatively common. A prolonged thrombin time is the most frequent abnormality, but is generally of no clinical consequence. A prolonged prothrombin time due to acquired factor X deficiency is the most likely coagulation abnormality to be associated with clinically significant bleeding.

Elevation of N-terminal pro-brain natriuretic peptide (NT-pro-BNP) and cardiac troponin concentrations occur in a wide variety of cardiac conditions and in chronic kidney disease. However, significant myocardial AL amyloidosis is excluded by NT-pro-BNP concentrations below 30 pmol/L. Cardiac troponin and NT-pro-BNP concentrations appear to be powerful predictors of prognosis and survival after chemotherapy. A staging system for patients with newly diagnosed AL amyloidosis using these two biomarkers has been proposed but requires further validation.

Differential diagnosis

Alternative diagnoses that frequently need to be considered include amyloidosis of non-AL types (principally AA and hereditary forms), localized forms of AL amyloidosis, and non-amyloid diseases such as LCDD and paraprotein-associated neuropathies including POEMS syndrome and treatment-related toxicities.

Natural history

Systemic AL amyloidosis is a progressive systemic disease that left untreated has a prognosis far worse than AA and hereditary amyloidoses. Median survival without treatment in historical series is only 12–15 months. Half of deaths are due to cardiac

involvement, and in patients in whom heart failure is evident at presentation, median survival is 6 months.

Until recently, amyloid deposition has been thought to be inexorably progressive and irreversible. It is now clear that amyloid deposits usually exist in a slowly dynamic state, and that they often gradually regress if the supply of amyloid fibril precursor protein can be reduced. However, the turnover of amyloid varies substantially between different individuals and organs and the factors that may influence this are not yet understood. The knowledge that amyloid can regress has encouraged a much more aggressive approach to patient management in recent years.

Prognostic factors

Prognosis varies in AL amyloidosis but is generally poor if the disease is left untreated. With adequate suppression of amyloidogenic light chains, and under favourable circumstances, amyloid may stabilize or regress, organ function may improve gradually and prolonged survival is not infrequent. Proteinuria often improves over 12–24 months with adequate suppression of the underlying clone, but improvement in renal function, soft-tissue involvement including macroglossia, and cardiac amyloidosis is generally very slow indeed after a haematological response. Therefore, patients should be informed that treatment is aimed at preventing disease progression while being encouraged that survival has steadily improved from a median of 1–2 years in the 1980s and 1990s to more than 4 years currently.

Various factors help to predict survival at diagnosis. Symptomatic or substantial echocardiographic evidence of cardiac amyloid is associated with a prognosis of only 6–12 months. Patients with liver involvement and hyperbilirubinaemia (bilirubin > 35 µmol/L) rarely survive more than 4 months. Significant autonomic neuropathy, progressive clonal disease unresponsive to chemotherapy and a bone marrow plasmacytosis of over 20% are also associated with poor outcomes. A large whole-body amyloid load on SAP scintigraphy and evidence of accumulation of amyloid on follow-up SAP scans are also poor prognostic features.

A better prognosis is associated with proteinuria or peripheral neuropathy as the dominant clinical feature, substantial suppression of underlying clonal disease by chemotherapy and regression of amyloid deposits on serial SAP scintigraphy. More recently, NT-pro-BNP concentration has been introduced as a prognostic marker, with raised values at diagnosis associated with a poorer prognosis and a fall in concentration >30% after chemotherapy associated with improved survival.

Management

Specific therapies that inhibit formation of amyloid or enhance its clearance are not yet available, although both strategies are

being rigorously pursued. Currently, the objective of treatment in AL amyloidosis is to suppress production of the amyloidogenic monoclonal light chains in the hope that progression of the disease will be slowed, halted or reversed. However, many patients have advanced multisystem disease at diagnosis and tolerate chemotherapy poorly.

Quantitative measurements of SFLCs are usually the most effective means for guiding ongoing treatment in individual patients. Although it is generally desirable to suppress the underlying clonal disease as rapidly and as extensively as possible, reduction in the concentration of the amyloidogenic free light chain by just 50–75% can be sufficient to halt disease progression in the majority of patients and confer substantial survival benefit, regardless of the chemotherapy used. Hence, more intensive suppression of the clonal disease beyond this may be unnecessary. This is particularly important given the broad range of organ involvement and impairment in AL amyloidosis that is associated with higher rates of treatment-related toxicities than in myeloma. Chemotherapy must be tailored to the individual patient, balancing the need for complete remission with the need to minimize treatment toxicity.

Certain organs affected by amyloid tend to fare better than others following treatment. Proteinuria and liver function often improve when the clonal disease is adequately suppressed, whereas cardiac disease, macroglossia and peripheral nerve function tend to improve extremely slowly if at all. International consensus criteria on the definitions of clonal and organ responses and progression were described by Gertz and colleagues in 2005.

Autologous peripheral blood stem cell transplantation

Use of high-dose melphalan therapy and autologous stem cell transplantation (SCT) in AL amyloidosis was first reported in 1996, and several series have reported clinical benefit in up to 80% of patients who survived the procedure. In the largest reported series, consisting of 394 patients, a complete clonal response occurred in 41%. Of those alive and in clonal response 1 year after autologous SCT, median survival has not been reached after 10 years of follow-up. However, treatment-related mortality (TRM) with autologous SCT has been consistently and substantially higher than in multiple myeloma, ranging from 5 to 43%, reflecting the compromised function of multiple organ systems by amyloid. Even stem cell mobilization has significant risks in AL amyloidosis. Causes of death include cardiac arrhythmias, intractable hypotension, multiple organ failure and gastrointestinal bleeding. Patient selection has since been refined and criteria for eligibility for autologous SCT developed, with the main exclusion criteria being overt cardiac involvement, more than two vital organ systems involved, a history of gastrointestinal bleeding and age over 65 years. Improvements in TRM have gradually resulted from better patient selection with improved supportive care and physician experience.

The exact role of SCT in AL amyloidosis remains controversial and its apparently good outcome may reflect selection of fitter good-prognosis patients. Regardless, because of its special problems in AL amyloidosis, it is recommended that such patients are treated in units with expertise in this particular disease. In eligible patients, autologous SCT with melphalan 200 mg/m² is often recommended as first-line therapy without induction chemotherapy except in those with underlying myeloma. Lower doses of melphalan appear to compromise the efficacy of transplantation. Stem-cell mobilization is often achieved with the use of granulocyte colony-stimulating factor (G-CSF) alone, as the underlying plasma cell burden is usually relatively small. The French group compared autologous SCT with oral melphalan and dexamethasone in a randomized study and found no difference in response rates between the two arms but a significantly higher TRM for the autologous SCT arm (24%) and a longer overall survival in the melphalan/dexamethasone arm, throwing into question the routine use of autologous SCT in AL amyloidosis. However, the trial has attracted some controversy, with higher than expected rates of TRM in autologous SCT compared with other case series and the use of lower doses of melphalan (140 mg/m²) in some of the patients undergoing SCT, prompting calls for further study in this area.

Melphalan and dexamethasone

Since 1999, melphalan and dexamethasone have been widely used in Europe and been found to be a well-tolerated and effective oral chemotherapy, with clonal response rates of 67% including complete responses in 37%, organ response rates of 50% and median overall survival of about 5 years. However, median time to response is slow at 4.5 months, and the problem of stem-cell toxicity makes it a less attractive regimen for patients who may subsequently be eligible for autologous SCT. Renal dose adjustment is required and the long-term leukaemogenesis of this regimen has yet to be established.

Cyclophosphamide, thalidomide and dexamethasone

Thalidomide has been used extensively in combination therapies for plasma cell disorders but doses above 200 mg daily are poorly tolerated in AL amyloidosis. Amyloid-related cardiac involvement or peripheral neuropathy results in increased sensitivity to the adverse effects of thalidomide, such as fluid retention fatigue, constipation and neuropathy. Lower doses of single-agent thalidomide reduce toxicity but also markedly reduce response rates. The use of thalidomide as maintenance treatment in AL amyloidosis has not yet been established. Addition of dexamethasone to intermediate-dose thalidomide improves the response rate to about 50%, with a median time to response of less than 4 months, but is associated with significant toxicity in 60% of patients. The cyclophosphamide, thalidomide and dexamethasone (CTD) regimen has been used extensively in the treatment of AL amyloidosis in the UK since

2002 and incorporates the addition of weekly oral cyclophosphamide 500 mg to low-dose thalidomide (100–200 mg) and two pulses of dexamethasone over a 21-day cycle. A risk-adapted approach using even lower doses of both thalidomide (50–100 mg) and dexamethasone in high-risk patients maintains good clonal response rates while decreasing the incidence of severe toxicity to around 20%. Overall SFLC response rates are around 75%, with an SFLC clonal response rate of 37%. Organ responses occur in approximately 50%. Median duration of response is 32 months. Fatigue and fluid retention requiring increased diuretic use remain the most troublesome toxicities of this regimen. Patients with severe nephrotic syndrome are at particular risk of venous and arterial thrombosis and should receive thromboprophylaxis. However, CTD has the advantage of being a stem cell-sparing oral regimen that does not require dose adjustment in renal impairment and is rapidly acting, the majority of patients achieving at least a partial (>50%) SFLC response after only 1 month of treatment.

Bortezomib

The proteasome inhibitor bortezomib is emerging as one of the most effective and rapidly acting therapies in the treatment of AL amyloidosis. In a recent multicentre study of 94 patients, most of whom had relapsed following previous treatments, clonal responses with bortezomib-based therapy occurred in 70% including complete remission CR in 25%, and the median time to clonal response was only 1 month. Organ responses occurred in 30%, and median time to progression was 14 months; major toxicities included peripheral and autonomic neuropathy. However, unlike in myeloma, cytopenias were rare with bortezomib, most likely due to the smaller plasma cell burden in the bone marrow. Its optimal dosing, long-term efficacy and use with dexamethasone, alkylators and other agents are the subject of ongoing clinical studies.

Lenalidomide

The thalidomide analogue lenalidomide has lately also been reported in several small studies in AL amyloidosis. Maximum tolerated dose is typically about 15 mg. Efficacy is markedly improved when administered with dexamethasone, and is associated with clonal response rates of about 50%, including complete remission in 20%. Organ responses were reported as approximately 22%. Toxicity from infections, even without neutropenia, appears to be surprisingly high, especially in patients with severe renal or cardiac impairment. Time to response is relatively slow, with a median in one study of 6 months when lenalidomide was used alone. However, lenalidomide remains an attractive treatment option in patients with severe neuropathy in whom thalidomide or bortezomib are relatively contraindicated. Use of lenalidomide in combination regimens and its role as maintenance therapy are currently under investigation.

Vincristine, doxorubicin and dexamethasone

Vincristine, doxorubicin (Adriamycin) and dexamethasone (VAD) and similar regimens have been well established as infusional induction regimens in myeloma (see Chapter 31), associated with response rates of 60–80%, complete response rates of 10–25% and rapid reduction in tumour burden. They do not deplete stem-cell reserve, keeping open the option for subsequent autologous SCT. Problems with the use of VAD in AL amyloidosis include exacerbation of peripheral and autonomic neuropathy by vincristine, and induction or worsening of fluid retention in renal or cardiac amyloidosis by dexamethasone. Doxorubicin has not been shown to exacerbate amyloid cardiomyopathy. The SFLC response rate is approximately 65%, and organ responses are seen in 50%. However, like in myeloma, the inconvenience of this regimen relative to newer oral therapies has led to a decline in its use.

Melphalan and prednisolone

In the early 1990s, cyclical oral melphalan with or without prednisolone was the first chemotherapy to be demonstrated in a randomized controlled trial as effective in the treatment of AL amyloidosis. However, benefits of treatment were typically not observed for at least 6 months and were substantial in only 20% of cases. As such, the use of melphalan was a breakthrough in the treatment of AL amyloidosis, but it is now no longer routinely recommended in low doses either as a single agent or with prednisolone.

Intermediate-dose intravenous melphalan

The variable absorption of melphalan from the gastrointestinal tract led investigators to trial intravenous intermediate-dose melphalan (25 mg/m²) and oral dexamethasone in patients with untreated multiple myeloma. This regimen has also been used as first-line therapy in patients with AL amyloidosis, who were selected on the basis that they were not fit enough to receive VAD-based treatment because of age, poor performance status, severe amyloid cardiomyopathy or neuropathy. Dexamethasone was omitted in patients with significant fluid retention. Efficacy, in terms of both clonal disease and organ response, was similar to that of VAD. However, this regimen was found to be associated with an unacceptably high rate of TRM (12%) and is now little used.

Allogeneic bone marrow transplantation

A case of successful allogeneic bone marrow transplantation in AL amyloidosis was reported in 1998 and since then a European study has reported on allogeneic and syngeneic haemopoietic cell transplantation in 19 patients with AL amyloidosis. Overall TRM was 40% and haematological response occurred in eight patients, with only one relapse after 31 months of follow-up. This treatment option is thus rarely exercised at present.

Supportive treatment

Supportive therapy remains a critical component of management of AL amyloidosis. For cardiac amyloidosis, the mainstay of treatment is diuretics. Vasodilating drugs and beta-blockers are generally best avoided as they often worsen symptoms significantly. Fluid overload should be treated with fluid restriction, loop diuretics and a low-salt diet. Refractory oedema may respond well to the addition of spironolactone. Salt-poor albumin infusions can occasionally be helpful. Dysrhythmias may respond to amiodarone or to pacing.

In renal amyloidosis, rigorous control of hypertension is vital, and inhibition of angiotensin-converting enzyme and/or angiotensin II is often recommended in the context of proteinuria. Renal dialysis may be necessary, and is usually both feasible and acceptably tolerated. In autonomic neuropathy, fludrocortisone 100–200 µg/day can be helpful in some patients, but may cause or exacerbate fluid retention. Midodrine is an effective pressor agent, starting at 2.5–15 mg thrice daily. Midodrine causes activation of the α -adrenergic receptors of the arteriolar and venous vasculature, producing an increase in vascular tone and elevation of blood pressure. Its chief adverse effect is supine hypertension, and other pressor agents must be coadministered with caution. Gastroparesis causing symptoms of early satiety and nausea can be managed with prokinetic agents such as metaclopramide, along with advice about small frequent meals that are of soft consistency. Diarrhoea due to amyloid gut involvement or autonomic neuropathy may respond to loperamide and codeine phosphate. Malnutrition is not uncommon and is often underestimated. Significant weight loss should be treated with protein and vitamin supplementation and the patient should be reviewed by an experienced dietitian. Feeding via a percutaneous endoscopic gastrostomy may occasionally be required. Amyloid- and treatment-related peripheral neuropathy can be disabling and difficult to treat. Analgesia including opioids and non-steroidal anti-inflammatory drugs, amitriptyline, venlafaxine, antiepileptics, TENS and/or gabapentin/pregabalin have all been used, although anecdotal reports suggest limited efficacy. Withdrawal or dose reduction of any neurotoxic chemotherapies, such as thalidomide or bortezomib, should be considered.

Surgical resection of amyloidotic tissue is occasionally beneficial but, in general, a conservative approach to surgery, anaesthesia and other invasive procedures is advised. Should any such procedure be undertaken, meticulous attention to blood pressure and fluid balance is essential, especially in patients with renal and/or cardiac involvement. Amyloidotic tissues may heal poorly and are liable to haemorrhage.

Solid organ transplantation

Renal and cardiac transplantation have been used in selected patients with AL amyloidosis for over 25 years. Renal transplantation should be considered in relatively young patients with

otherwise well-preserved extrarenal organ function who have chemotherapy-responsive disease. Cardiac transplantation should be considered in patients with isolated end-stage cardiac failure who would otherwise be eligible for autologous SCT. In such patients, cardiac transplantation must be followed by chemotherapy to prevent recurrence of cardiac amyloid or its accumulation in other organ systems. Liver transplantation has been performed in only a very small number of patients with generally disappointing results.

Localized AL amyloidosis

Localized deposits of AL amyloid can occur almost anywhere in the body, with characteristic sites including the skin, airways, conjunctiva and urogenital tract. They may be nodular or confluent and are associated with a usually inconspicuous focal infiltrate of clonal B cell-producing amyloidogenic light chains. Progression of localized AL amyloid into a truly systemic disease is exceedingly rare, and conservative management is usually appropriate. Orbital AL amyloid presents as mass lesions that can disrupt eye movement and the structure of the orbit. Localized laryngeal AL amyloidosis is a well-recognized syndrome that is often amenable to direct or laser excision, but hereditary systemic apolipoprotein A-I amyloidosis can also present in this manner. Amyloidosis in the bronchial tree is virtually always of localized AL type, as are solitary or multiple amyloid nodules within the lung tissue. If accessible, bronchoscopic lasering of stenosing lesions can bring symptom relief. In contrast, diffuse alveolar septal parenchymal deposition is commonly a manifestation of systemic AL amyloidosis. There are anecdotal reports that inhaled steroids may benefit pulmonary symptoms. Breast amyloidosis has been associated with Sjögren disease in some cases, and mucosa-associated lymphoid tissue (MALT) lymphoma should be excluded. Lichenoid and macular forms of cutaneous amyloid are thought to be derived from keratin or related proteins, whereas nodular cutaneous amyloid deposits are generally of AL type and can sometimes be a manifestation of systemic AL amyloidosis. Localized urogenital AL amyloid deposits are often incidental findings but may present with haematuria or, less commonly, obstruction. They can occur anywhere from the renal collecting system to the urethra, although are most usually identified within the bladder. Management is conservative or with transurethral laser resection when symptoms occur; cystectomy is rarely required.

Other forms of systemic amyloidosis

Among more than 3000 patients with systemic amyloidosis who have been referred for evaluation at the National Amyloidosis

Centre, approximately 55% have had AL type, 15% AA (reactive systemic) type, and the remainder have had a variety of hereditary, localized and other types. Although some features of systemic AL amyloidosis are very characteristic of this particular type, such as macroglossia, periorbital purpura and certain permutations of organ involvement, the clinical phenotypes of AA, AL and hereditary systemic amyloidosis can be indistinguishable. Furthermore, the underlying chronic inflammatory disease process is clinically covert in 5–10% of patients with AA amyloidosis, and a family history is often absent in patients with hereditary TTR and fibrinogen A α -chain amyloidosis, which are the most common familial forms.

AA amyloidosis

Reactive systemic AA (secondary) amyloidosis occurs in 1–5% of patients with chronic inflammatory diseases that evoke a substantial acute-phase response, after a median latency of about 15–20 years. AA amyloid fibrils are derived from the circulating acute-phase reactant SAA, the serum concentration of which can increase from the healthy reference range of less than 10 mg/L to over 1000 mg/L during active inflammation. The commonest associated diseases in the developed world include rheumatoid arthritis, juvenile idiopathic arthritis and Crohn's disease. Familial Mediterranean fever and other rare periodic fever syndromes can result in AA amyloidosis. Chronic infections remain important causes in some parts of world. Castleman disease of the solitary plasma cell type should be considered among the underlying conditions that remain clinically covert.

Most patients present with nephropathy, particularly proteinuria, but liver and gastrointestinal involvement may occur at a late stage. Clinical involvement of the heart and nerves occurs very rarely. Diagnosis of AA amyloid is usually achieved by renal (or rectal) biopsy, and the AA fibril type can be confirmed immunohistochemically using anti-SAA antibodies in almost all cases. SAP scintigraphy virtually always shows involvement of the spleen and kidneys; hepatic involvement is a late feature associated with a poor prognosis. Treatment in AA amyloidosis should decrease the underlying inflammation so that SAA levels remain well controlled, preferably below 10 mg/L. The exact nature of the treatment will depend on the underlying inflammatory disease, and ranges from inhibitors of tumour necrosis factor in rheumatoid arthritis and colchicine in familial Mediterranean fever to surgical resection of Castleman disease tumours. Any therapy that reduces SAA production to healthy baseline levels prevents further deposition of AA amyloid, frequently leads to the regression of existing amyloid deposits with improvement in amyloid-related organ dysfunction, and significantly improves long-term survival. Kidney transplantation generally has excellent outcomes in AA amyloidosis.

β_2 -Microglobulin amyloidosis

β_2 -Microglobulin amyloidosis, also known as dialysis-related amyloidosis, occurs because of the accumulation of β_2 -microglobulin in renal failure and predominantly affects articular and periarticular structures in patients with end-stage renal failure who have been on dialysis for at least 7–10 years. Susceptibility factors include older age and the use of non-biocompatible dialysis membranes. Carpal tunnel syndrome is often the first clinical manifestation, and large-joint arthralgias, tenosynovitis, spondyloarthropathies and periarticular bone cysts are common. Although β_2 -microglobulin amyloidosis is a systemic form of amyloidosis, deposits outside the musculoskeletal system are seldom of clinical significance. The disabling arthralgia may respond partially to non-steroidal anti-inflammatory drugs or corticosteroids, but the only really effective treatment for this condition is normalization of β_2 -microglobulin levels through renal transplantation. Carpal tunnel syndrome is amenable to surgery but may recur.

Transthyretin amyloidosis

Normal TTR is inherently but weakly amyloidogenic, and minor TTR amyloid deposits are common in elderly individuals. Clinically significant involvement is almost completely restricted to the heart and carpal tunnel, and senile cardiac amyloid derived from wild-type TTR occurs in up to 25% of subjects over 80 years of age and is most likely under-recognized by physicians. This syndrome is extremely rare before 65 years of age. Patients may survive for many years with reasonably good quality of life managed with diuretics alone; specific therapies are currently being tested.

Hereditary systemic amyloidoses

Hereditary systemic amyloidosis is caused by deposition of genetically variant proteins as amyloid fibrils, and is associated with mutations in the genes for TTR, fibrinogen A α chain, cystatin C, gelsolin, apolipoprotein A-I, apolipoprotein A-II and lysozyme. These disorders are all inherited in an autosomal dominant manner with variable penetrance, and usually present in adult life.

Familial amyloidotic polyneuropathy (FAP) associated with mutations in the gene for TTR is the most common type of hereditary amyloidosis. It is characterized by progressive and disabling peripheral and autonomic neuropathy, often with cardiac involvement. Vitreous amyloid deposits may also occur and are virtually pathognomonic of the syndrome. Symptoms typically present between the third and seventh decades. More than 100 TTR variants are associated with FAP, the most frequent of which is the substitution of methionine for valine at residue 30 (TTR Met30). There are well-recognized foci of this

in Portugal, Japan and Sweden, but FAP has been reported in most ethnic groups. TTR Ala60 is the most frequent cause of FAP in the British and Irish population, typically presenting after 50 years of age and usually with marked cardiac involvement. TTR Ile122 occurs in 3–4% of black Africans and is associated with a phenotype indistinguishable from senile (wild-type) cardiac amyloidosis. The majority of TTR is produced by hepatocytes, and liver transplantation is the only effective treatment for this disorder. Although the visceral amyloid deposits frequently regress following liver transplantation, the neuropathy is often irreversible and established cardiac amyloidosis may paradoxically progress due to ongoing fibril formation by wild-type TTR in this particular organ. Combined heart and liver transplantation has been performed successfully in a small number of cases.

The syndrome of non-neuropathic hereditary systemic amyloidosis is caused by mutations in the genes for fibrinogen A α chain, lysozyme, apolipoprotein A-I and apolipoprotein A-II. Most such patients present with renal impairment and/or proteinuria, but substantial deposits in the liver and spleen are frequent in hereditary lysozyme and apolipoprotein A-I amyloidosis, and the heart may be involved in hereditary apolipoprotein A-I amyloidosis. Prominent neuropathy occurs in some patients with apolipoprotein A-I Arg26. Although kindreds with hereditary amyloidosis are rare, 5–10% of patients referred to the National Amyloidosis Centre with apparently sporadic amyloidosis do in fact have hereditary forms of the disease. About half of these are associated with TTR mutations, and most of the remainder are associated with variant fibrinogen A α chain Val526. Penetrance of this particular mutation is extremely low in most families, thus obscuring the genetic aetiology, but the renal histology is characteristic, showing substantial accumulation of amyloid within enlarged glomeruli but none in blood vessels or the interstitium. Renal impairment is often noted in the fourth or fifth decade, and end-stage renal failure is managed with dialysis or renal transplantation. Variant fibrinogen A α -chain amyloidosis can recur in the transplanted graft and median survival of kidney transplants in patients attending our centre has been 7 years though this can be much longer. Combined liver–kidney transplants have been performed in this condition though with notable mortality. Hereditary cystatin C amyloidosis manifests in Icelandic families as cerebral amyloid angiopathy with recurrent cerebral haemorrhage, and gelsolin variants are associated with corneal lattice dystrophy and cranial neuropathy, most often in Finnish patients.

DNA analysis should now be performed routinely on patients with systemic amyloidosis in whom AA or AL fibril type cannot be definitively verified. The newly described leukocyte chemotactic factor II (LECT2) form of amyloidosis can also mimic AL, AA and hereditary forms of amyloid-related kidney disease but usually manifests as isolated, stable or slowly progressive renal impairment, often with positive kidney and adrenal gland

signalling on SAP scintigraphy; currently it can only be reliably identified with mass spectrometry.

Conclusion and future directions

Improved understanding of the aetiology and pathogenesis of amyloid has led to numerous recent advances in the characterization and management of amyloidosis. Chemotherapy in systemic AL amyloidosis can now be guided by its early effect on SFLC concentration, and routine DNA analysis can prevent patients with otherwise unrecognized hereditary amyloidosis from receiving inappropriate cytotoxic treatment. Clinical improvement following successful treatment of the various conditions that underlie amyloidosis is always delayed, and supportive measures are of great importance.

Novel therapeutic strategies include small molecules, monoclonal antibodies, peptides and GAG analogues that bind to fibril precursors and stabilize their native fold, or which interfere with refolding and/or aggregation into the common amyloid conformation or SAP depletion. Immunotherapy approaches are being explored as specific therapies directed at promoting regression of amyloid. Several of these new therapeutic approaches are already being tested in patients with the hope that they may be effective in a diverse spectrum of amyloid-related disorders in the near future.

Introduction

The classification of lymphoid neoplasms in the World Health Organization (WHO) proposal is based on two major principles: stratification of the neoplasms according to their cell lineage and the definition of non-overlapping distinct diseases that are clinically relevant. The identification of these diseases is based on a combination of morphology, immunophenotype, genetic and molecular features and clinical manifestations.

The 2001 WHO classification of lymphoid neoplasms was based on the Revised European–American Classification of Lymphoid Neoplasms (REAL) published by the International Lymphoma Study Group (ILSG) in 1994. The validation of this proposal in a large series of tumours and the publication of the third edition of the WHO classification ended a long history of controversy between different classification schemes that used different terminologies and concepts among pathologists and clinicians in different parts of the world.

The revision of the current WHO classification in 2008 has integrated concepts and criteria developed in the last few years by different working groups (IWCLL, EORTC among others) and has refined definitions of well-established diseases, incorporated new entities and developed new concepts and ideas related to the biology of lymphomas. However, the classification still has contentious aspects, such as provisional entities corresponding to categories for which the WHO Working Group felt there was insufficient evidence to recognize as distinct diseases at this time (Table 33.1).

Mature B-cell neoplasms

Chronic lymphocytic leukaemia/small lymphocytic lymphoma

Chronic lymphocytic leukaemia/small lymphocytic lymphoma (CLL/SLL) is a neoplasm of mature small B-cell lymphocytes that commonly express CD5 and CD23 and have dim expression of surface IgM/IgD. The tumour usually involves the peripheral blood and bone marrow but also lymph nodes, spleen, liver and other extranodal sites. The new WHO classi-

Table 33.1 WHO classification of mature lymphoid neoplasms.

<i>Mature B-cell neoplasms</i>	B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma
Chronic lymphocytic leukaemia/small lymphocytic lymphoma	
B-cell prolymphocytic leukaemia	<i>Mature T-cell and NK-cell neoplasms</i>
Splenic B-cell marginal zone lymphoma	T-cell prolymphocytic leukaemia
Hairy cell leukaemia	T-cell large granular lymphocytic leukaemia
Splenic lymphoma/leukaemia unclassifiable	Chronic lymphoproliferative disorder of NK cells
Splenic diffuse red pulp small B-cell lymphoma	Aggressive NK-cell leukaemia
Hairy cell leukaemia variant	Systemic EBV-positive T-cell lymphoproliferative disease of childhood
Lymphoplasmacytic lymphoma/Waldenström macroglobulinaemia	Hydroa vacciniforme-like lymphoma
Heavy chain diseases	Adult T-cell leukaemia/lymphoma
Plasma cell myeloma	Extranodal NK/T-cell lymphoma, nasal type
Solitary plasmacytoma of bone	Enteropathy-associated T-cell lymphoma
Extraosseous plasmacytoma	Hepatosplenic T-cell lymphoma
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)	Subcutaneous panniculitis-like T-cell lymphoma
Nodal marginal zone lymphoma	Mycosis fungoides
Paediatric nodal marginal zone lymphoma	Sézary syndrome
Follicular lymphoma	Primary cutaneous CD30-positive T-cell lymphoproliferative disorders
Paediatric follicular lymphoma	Lymphomatoid papulosis
Primary cutaneous follicle centre lymphoma	Primary cutaneous anaplastic large-cell lymphoma
Mantle cell lymphoma	Primary cutaneous $\gamma\delta$ T-cell lymphoma
Diffuse large B-cell lymphoma (DLBCL), not otherwise specified	Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma
T-cell/histiocyte-rich large B-cell lymphoma	Primary cutaneous CD4-positive small/medium T-cell lymphoma
Primary DLBCL of the CNS	Peripheral T-cell lymphoma, unspecified
Primary cutaneous DLBCL, leg type	Angioimmunoblastic T-cell lymphoma
EBV-positive DLBCL of the elderly	Anaplastic large-cell lymphoma, ALK positive
DLBCL associated with chronic inflammation	Anaplastic large-cell lymphoma, ALK negative
Lymphomatoid granulomatosis	
Primary mediastinal (thymic) large B-cell lymphoma	<i>Hodgkin lymphoma</i>
Intravascular large B-cell lymphoma	Nodular lymphocyte predominant Hodgkin lymphoma
ALK-positive large B-cell lymphoma	Classical Hodgkin lymphoma
Plasmablastic lymphoma	Nodular sclerosis classical Hodgkin lymphoma
Large B-cell lymphomas arising in HHV8-associated multicentric Castleman disease	Lymphocyte-rich classical Hodgkin lymphoma
Primary effusion lymphoma	Mixed cellularity classical Hodgkin lymphoma
Burkitt lymphoma	Lymphocyte-depleted classical Hodgkin lymphoma
B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma

fication has adopted the definition of the disease proposed by the International Workshop on CLL (IWCLL): this requires, in the absence of extramedullary tissue involvement, the presence of $5 \times 10^9/L$ monoclonal B lymphocytes with a CLL phenotype in the blood. The diagnosis of CLL may be established with lower cell counts when the patient has cytopenias or disease-related symptoms. The term 'small lymphocytic lymphoma' refers to non-leukaemic neoplasms with the same morphology

and phenotype. This new definition of CLL expands the number of patients who will be categorized as having monoclonal B-cell lymphocytosis (MBL).

The bone marrow is infiltrated in virtually all cases with an interstitial, nodular or diffuse pattern. The lymph nodes show effacement of the architecture by a diffuse infiltration. Aggregates of prolymphocytes and para-immunoblasts, called proliferation centres, are an almost constant feature in the

lymph nodes (Figure 33.1). The proliferative cells tend to accumulate in these areas and are also associated with some follicular dendritic cells and increased numbers of CD4⁺ T cells. The detection of ZAP-70 by flow cytometry is an important prognostic marker of the disease that correlates well with the mutational status of the immunoglobulin genes. CD38 expression is also considered a prognostic marker (see also Chapter 29).

Molecular studies have recognized two major subtypes based on the mutational status of the immunoglobulin genes. Thus,

(a)

(b)

Figure 33.1 Lymph node involved by chronic lymphocytic leukaemia. (a) At low power the lymph node shows diffuse effacement of the architecture with vaguely nodular pale areas that correspond to the proliferation centres. (b) At higher magnification the proliferation centre contains larger cells with nuclei that have a central nucleolus (prolymphocytes and para-immunoblasts).

40–50% of cases have unmutated immunoglobulin genes (>98% homology with the germline), whereas 50–60% have hypermutated genes. Patients with unmutated CLL have a more aggressive disease. Analysis of immunoglobulin gene sequences has revealed a marked bias in use of the different regions, suggesting an influence of certain antigens in the selection of tumour cells. The most common genetic alterations in CLL are deletions of chromosome 13q (50%), trisomy 12 (20%), 11q deletions (15%) and 17p deletions (10%); 13q deletions are more common in mutated CLL whereas 11q and 17p deletions are more frequent in unmutated CLL and are associated with a worse prognosis.

Transformation into a more aggressive tumour occurs in 2–10% of patients (Richter syndrome). The two most common forms of transformation are diffuse large B-cell lymphoma (DLBCL) and, less frequently, Hodgkin lymphoma (HL). DLBCL arising in unmutated CLL usually corresponds to the clonal evolution of the preceding CLL, whereas in mutated CLL it frequently corresponds to a different lymphoid neoplasm.

B-cell prolymphocytic leukaemia (see also Chapter 29)

B-cell prolymphocytic leukaemia (B-PLL) is a malignancy of B prolymphocytes that affects the blood, bone marrow and spleen and is characterized by more than 55% prolymphocytes in the blood. B-PLL does not include transformed CLL, CLL with increased prolymphocytes, and blastoid mantle cell lymphoma with t(11;14)(q13;q32), which should be excluded. B-PLL is an uncommon disease of old patients (median age 65–69 years) and similar male/female distribution. Patients have 'B' symptoms, massive splenomegaly, absent or minimal lymphadenopathy and a rapidly rising lymphocyte count, usually over $100 \times 10^9/L$. Anaemia and thrombocytopenia are seen in 50%.

The cells strongly express surface IgM with or without IgD and mature B-cell antigens. CD5 and CD23 are only positive in 20–30% and 10–20% of cases, respectively. Complex karyotypes are common and 17p deletions associated with *TP53* gene mutations are detected in 50% of cases.

Median survival is 30–50 months. *IGHV* mutations, ZAP-70 and CD38 expression are heterogeneous and, contrary to CLL, lack precise clinical prognostic value.

Splenic marginal zone lymphoma

Splenic marginal zone lymphoma (SMZL) is a B-cell neoplasm composed of small lymphocytes that surround and replace the germinal centres and mantle of the reactive follicles in the white pulp, and merge with a peripheral (marginal) zone of larger cells including scattered transformed blasts. Both small and larger cells infiltrate the red pulp. The patients usually have a leukaemic and splenomegaly presentation with villous lym-

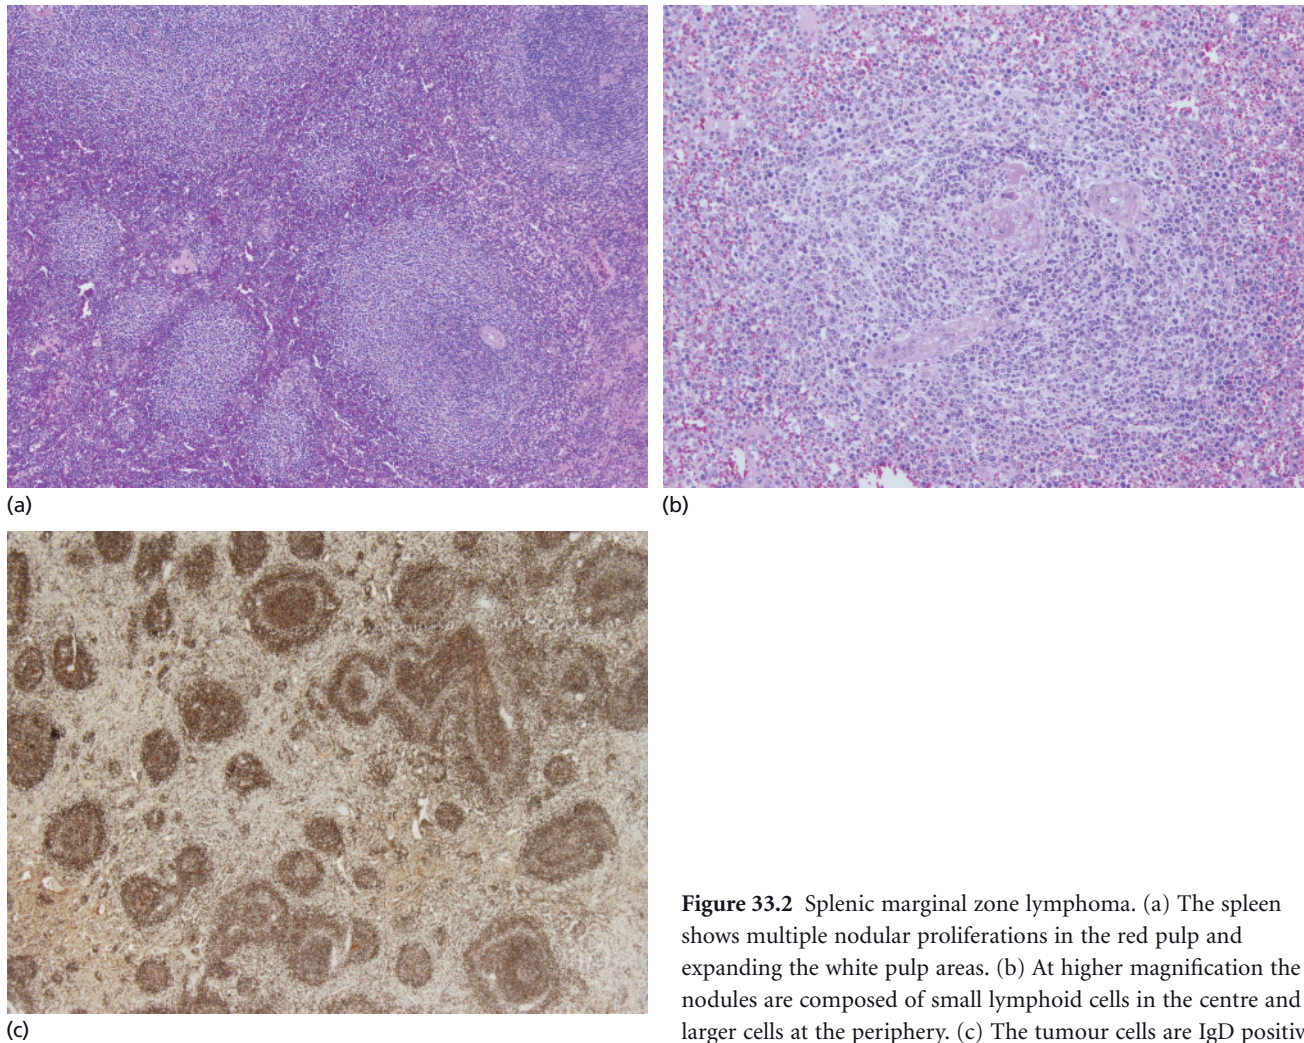

Figure 33.2 Splenic marginal zone lymphoma. (a) The spleen shows multiple nodular proliferations in the red pulp and expanding the white pulp areas. (b) At higher magnification the nodules are composed of small lymphoid cells in the centre and larger cells at the periphery. (c) The tumour cells are IgD positive.

phocytes in the blood. The disease also involves the splenic hilar lymph nodes and bone marrow but extension to peripheral lymph nodes is uncommon (Figure 33.2).

There are no distinctive phenotypic markers for SMZL, whose diagnosis requires the exclusion of other lymphoma types. Most cases exhibit IgM/IgD and a mature B-cell phenotype but other markers are usually negative (Figure 33.2). The immunoglobulin genes are unmutated in approximately half of the cases, which also tend to have deletions of chromosome 7q31–32 and a more unfavourable evolution. Some cases are positive for hepatitis C virus and may respond to antiviral treatment. The clinical course is usually indolent but some patients may have progressive disease and transformation to a large-cell lymphoma may occur. The hairy cell leukaemia variant and lymphomas with a diffuse infiltrate of the red pulp are included in a provisional category termed ‘splenic B-cell lymphoma/leukaemia, unclassifiable’.

Lymphoplasmacytic lymphoma/Waldenström macroglobulinaemia

Lymphoplasmacytic lymphoma (LPL) and Waldenström macroglobulinaemia have been redefined in the new classification. LPL is a B-cell neoplasm composed of small lymphocytes, plasmacytoid lymphocytes and plasma cells usually involving the bone marrow and sometimes lymph nodes and spleen that does not fulfil the criteria for any other B-cell neoplasm which may have plasmacytic differentiation. Although the detection of a paraprotein is common, it is not required for the diagnosis. Waldenström macroglobulinaemia is an LPL with bone marrow involvement and an IgM monoclonal gammopathy of any concentration. Because these entities do not have specific markers, it is essential to exclude the presence of any other B-cell neoplasm that may have a plasmacytic differentiation.

Table 33.2 Plasma cell neoplasms.

Monoclonal gammopathy of undetermined significance
Plasma cell myeloma
Asymptomatic (smouldering) myeloma
Non-secretory myeloma
Plasma cell leukaemia
Plasmacytoma
Solitary plasmacytoma of bone
Extrasosseous (extramedullary) plasmacytoma
Immunoglobulin deposition diseases
Osteosclerotic myeloma (POEMS syndrome)

Plasma cell neoplasms (see also Chapter 31)

Plasma cell neoplasms encompass a spectrum of lesions characterized by the clonal expansion of terminally differentiated B cells that usually secrete a class-switched immunoglobulin (Table 33.2).

Monoclonal gammopathy of undetermined significance

Monoclonal gammopathy of undetermined significance (MGUS) is defined by less than 10% clonal plasma cells in the bone marrow and less than 30 g/L of an M-protein and absence of end-organ damage. This condition is considered a preneoplastic process since evolution to overt plasma cell malignancy does not always occur.

Plasma cell myeloma

Plasma cell myeloma is a bone marrow neoplasm characterized by multifocal proliferation of plasma cells associated with a serum M-protein and symptomatic disease related to different organ dysfunction or lytic bone lesions. The plasma cells in the bone marrow expand in small or large clusters. Some cases may present asymptotically, whereas in others the tumour cells spread to the peripheral blood in the form of a plasma cell leukaemia. The phenotype of these cells is aberrant, with expression of CD19 and CD56 in 75% of cases and other markers such as CD117, CD20, CD52 and CD10. Chromosomal translocations involving the 14q32 region occur in 40% of cases; the partner translocations include *CCND1* (cyclin D1) at 11q13, *MAF* at 16q23, *FGFR3* at 4p16, *CCND3* (cyclin D3) at 6p21 and *MAFB* at 20q11. Tumours lacking these alterations are usually hyperdiploid.

Plasmacytoma

Plasmacytoma is a solitary tumour lesion composed of clonal plasma cells that may occur in bones or extrasosseous tissues (Figure 33.3). Bone plasmacytomas evolve to plasma cell myeloma in two-thirds of patients. In contrast, extrasosseous

(a)

(b)

Figure 33.3 Plasmacytoma of the nasal cavity. (a) Atypical plasma cells embedded in fibrous stroma. (b) Plasma cells are CD138 positive

localized lesions have a relatively indolent behaviour without bone marrow involvement, suggesting a closer relationship to MALT lymphomas than bone marrow plasma cell neoplasms.

Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)

MALT lymphomas are extranodal B-cell neoplasms composed of a heterogeneous population of small lymphocytes, marginal zone lymphocytes with cleaved nuclei (centrocyte-like), cells with clear cytoplasm resembling monocytoid B cells, cells with plasmacytic differentiation and occasional large transformed cells. All these cells expand the marginal zone of reactive

follicles and in some cases may colonize the germinal centres but preserve the mantle zone area. In epithelial tissues the neoplastic cells infiltrate the epithelium forming lymphoepithelial lesions (Figure 33.4). These tumours occur most commonly in the gastrointestinal tract, salivary gland, lung, head and neck, ocular adnexa, skin and less frequently thyroid and breast.

The lymphoma cells express mature B-cell markers, IgM and less often IgG or IgA, but IgD is usually negative. CD5, CD10 and CD23 are negative, although some CD5-positive cases have been described. Four major translocations have been associated

(a)

(b)

Figure 33.4 Gastric marginal zone lymphoma of the mucosa-associated lymphoid tissue (MALT lymphoma). The gastric mucosa is infiltrated by a monotonous population of lymphoid cells that surrounds a residual germinal centre (a) and destroys the glands, creating lymphoepithelial lesions clearly observed with cyokeratin staining (Cam 5.2 immunoperoxidase staining) (b).

with these lymphomas, t(11;18), t(1;14), t(14;18) and t(3;14), that generate the chimeric gene *BIRC3-MALT1* or activate *BCL10*, *MALT1* and *FOXP1*, respectively. The t(11;18) translocation tends to occur more frequently in gastric and lung lymphomas, whereas the t(14;18) translocation is more often seen in salivary gland and ocular adnexa tumours. Interestingly, *MALT1* and *BCL10* participate in activation of the same NF- κ B pathway.

These lymphomas arise in topographic sites with a pre-existing chronic inflammatory lesion induced by infectious, immunological or unknown stimuli. Thus gastric lesions are associated with *Helicobacter pylori*, *Campylobacter jejuni* is detected in the immunoproliferative small intestinal disease, *Chlamydia psittaci* in ocular adnexa tumours of certain geographic regions, and *Borrelia burgdorferi* in some cutaneous MALT lymphomas. Autoimmune disorders of the salivary gland (Sjögren syndrome) and thyroid (Hashimoto disease) are the preceding lesions of MALT lymphomas in these locations.

The lymphoma responds to control of the underlying infectious disease and local treatments but may relapse in extranodal territories after many years. Nodal dissemination may precede clinically the detection of extranodal involvement. Tumours with the translocations described appear to be resistant to antibiotic therapy. Transformation to large-cell lymphomas may occur.

Nodal marginal zone lymphoma

Nodal marginal zone lymphoma (NMZL) is a primary lymphoma of the lymph nodes that resembles extranodal MALT lymphomas (Figure 33.5). An extranodal or splenic lymphoma should be ruled out before this diagnosis is established. Although the morphology and phenotype is similar to MALT lymphoma, primary NMZL does not exhibit the typical translocations of these tumours. Patients may present with disseminated disease and 60–80% survive more than 5 years. Some cases may evolve to large B-cell lymphomas.

NMZLs in the paediatric age group seem to have distinctive clinical and morphological features. Thus they present predominantly in males as asymptomatic localized tumours and morphologically the residual follicles may have features of progressive transformed germinal centres with eroded mantle zones by the tumour cell infiltration. The prognosis of these patients seems excellent with conservative therapy.

Follicular lymphoma

Follicular lymphoma (FL) is a neoplasm composed of cells of the germinal centres, with different proportions of small centrocytes and large centroblasts, that usually has a follicular growth pattern (Figure 33.6). These tumours are common in Western countries, accounting for around 20–30% of all lymphomas.

(a)

(b)

Figure 33.5 Nodal marginal zone lymphoma. (a) Tumour cells with a clear appearance infiltrate the node, with partial preservation of the architecture. (b) Higher magnification reveals the clear cytoplasm of the tumour cells.

These tumours have been graded according to the number of large cells as follows: grade 1 (0–5 large cells per high-power field), grade 2 (6–15 large cells) and grade 3 (>15 large cells). The new WHO classification considers that grades 1 and 2 represent a morphological continuum that is not associated with relevant clinical or biological differences and therefore this distinction is not encouraged. However, grade 3 tumours are further distinguished into grades 3a and 3b according to the presence of intermingled small centrocytes in grade 3a whereas grade 3b is composed entirely of large cells. According to the genetic and phenotypic features, FL grade 3a seems more related to FL grade 1–2, whereas FL grade 3b may be closer to DLBCL. Any diffuse area composed of more than 15 large cells should

be reported as DLBCL, and the percentage of the respective DLBCL and FL components indicated.

FL has a mature B-cell phenotype with coexpression of the germinal-centre markers CD10 and BCL-6 (Figure 33.6). CD5, CD43 and CD23 are negative. IRF4/MUM1, an antigen related to plasma cell differentiation, is also usually negative. BCL-2 is positive in 85–90% of FL grade 1–2 but only in 50% of grade 3. BCL-2 staining is very useful because reactive germinal centres are negative (Figure 33.6). This expression reflects the presence of the t(14;18) translocation that is the genetic hallmark of this lymphoma and which targets the *BCL2* gene. FL grade 3b is less frequently positive for CD10 and BCL-2 protein and the t(14;18) translocation is only detected in 5–40% of cases. In contrast, these lymphomas express IRF4/MUM1 in 40% of the cases and carry 3q27 and *BCL6* rearrangements in 30–50% of cases, whereas these aberrations are rare in FL grades 1–3a.

The tumour cells are associated with a rich microenvironment of different types of T cells and histiocytes that seem to play a major role in determining the biological behaviour of the lymphoma.

***In situ* follicular lymphoma or intrafollicular neoplasia**

In situ FL or intrafollicular neoplasia is a variant in which the tumour cells are limited to the germinal centres of the follicles. Usually, only a number of the lymph node follicles are involved whereas others are reactive. The tumour cells are recognized by their strong BCL-2 expression inside the germinal centres and absence of CD10- and BCL-6-positive tumour cells outside the follicles. The BCL-2-positive cells in the follicle carry the t(14;18) translocation. Some of these cases may correspond to early involvement of a lymph node by a disseminated tumour. A second group of patients may develop overt FL during follow-up but most patients remain free of lymphoma elsewhere after many years of follow-up.

Paediatric follicular lymphoma

Paediatric FL occurs in children and young adults, usually involving the head and neck region but also the testis with localized disease. The lymphomas are BCL-2 negative, do not carry the t(14;18) translocation and are grade 3. These cases have a relatively good evolution.

Primary intestinal follicular lymphoma

Primary intestinal FL occurs frequently in the duodenum as an incidental finding (Figure 33.7). These cases have a conventional morphology, phenotype and genetic findings. However, the tumours express IgA and remain localized, with an excellent prognosis even without treatment.

Primary cutaneous follicle centre lymphoma

Primary cutaneous follicle centre lymphoma generally presents in the skin of the head and trunk. The tumour cells may grow

Figure 33.6 Follicular lymphoma. (a) The tumour grows in a follicular pattern with expanded germinal centres without macrophages. The tumour cells are positive for CD10 (b) and BCL-2 (c).

Figure 33.7 Follicular lymphoma of the duodenum.

with a follicular or more diffuse pattern. The cells express B-cell markers and BCL-6, whereas CD10 is positive in cases with a follicular pattern but tend to be lost in the diffuse component. BCL-2 expression and the t(14;18) translocation are usually negative. The tumours may relapse but have a good outcome without extracutaneous dissemination even with only localized therapy.

Mantle cell lymphoma

Mantle cell lymphoma (MCL) is a B-cell neoplasm generally composed of monomorphous small to medium-sized lymphoid cells with irregular nuclear contours and cyclin D1 overexpression secondary to *CCND1* translocation (Figures 33.8 and 33.9). This tumour comprises 3–10% of non-Hodgkin lymphomas and occurs mainly in males, with a median age around 60 years. Most MCLs are diagnosed as disseminated nodal disease but a

(a)

(b)

Figure 33.9 Mantle cell lymphoma is positive for cyclin D1.

number of patients are initially seen with leukaemic disease, bone marrow involvement and frequently splenomegaly, but without lymphadenopathy. Extranodal involvement is very common. Some tumours may have a blastoid or pleomorphic cytology resembling lymphoblasts or DLBCL, respectively. These cytological variants are associated with higher proliferative activity, more complex karyotypes and worse prognosis. The tumour cells grow with a vaguely nodular, diffuse or mantle zone pattern. Some cases may show restricted infiltration to the inner mantle zones of otherwise reactive follicles, a situation that has been named *in situ* MCL. The tumour cells express mature B-cell markers, with intense CD20 and surface immunoglobulin, and coexpress CD5 and CD43. CD23 and germinal-centre markers are negative.

MCL exhibits the t(11;14) translocation that targets cyclin D1. Complex karyotypes with many secondary aberrations are common. Cyclin D1-negative cases are exceptional, and their diagnosis requires strict morphological and phenotypic criteria. These cases have high expression of cyclin D2 or cyclin D3 and some of them carry a t(2;12) translocation that fuses cyclin D2 to the κ light chain immunoglobulin gene locus. SOX11, a transcription factor expressed in conventional MCL, is also expressed in cyclin D1-negative tumours and therefore its detection may be of help in recognizing this variant.

In general MCL has an aggressive clinical course, with poor response to chemotherapy and a median survival of 3–5 years. Proliferation is considered the best prognostic parameter. Patients presenting with disease limited to the blood, bone marrow and sometimes the spleen, without lymphadenopathy, have been reported to have a better prognosis. These tumours seem to have a distinct expression profile and simple karyotypes.

Diffuse large B-cell lymphoma not otherwise specified

DLBCL is a neoplasm of large B lymphocytes with a diffuse growth pattern. These lymphomas are heterogeneous and several morphological variants, phenotypical and molecular subtypes and different entities have been recognized (Table 33.3). DLBCL is very common and accounts for 25–30% of adult non-Hodgkin lymphomas. Usually, these cases present as primary tumours but they can also represent the transformation of a less aggressive B-cell lymphoma.

Morphologically, DLBCL not otherwise specified may have centroblastic, immunoblastic or anaplastic cytology (Figures 33.10 and 33.11). These variants are related to biological and genetic features of the tumour but they have poor reproducibility and broad overlap that prevent their use as major classifiers. Phenotypically, DLBCL not otherwise specified expresses mature B-cell markers. CD5 is detected in a subset of these tumours that seem to have a more aggressive behaviour, particularly in Eastern populations. The expression of the germi-

nal-centre markers CD10 and BCL-6 has been related to a germinal-centre origin of the tumours, whereas the expression of IRF4/MUM1 antigen has been associated with an origin in non-germinal centre activated B cells (Figures 33.10 and 33.11). These two immunophenotypic subgroups of DLBCL have a clear correlation with the two subtypes of germinal-centre and activated B-cell DLBCL recognized by gene expression profiling. However, the controversial results obtained in different studies on the prognostic significance of these phenotypic subgroups preclude their use in clinical practice.

Genetically, 20–30% of DLBCL not otherwise specified exhibit the t(14;18) translocation and *BCL2* gene rearrange-

(a)

(b)

Figure 33.10 Diffuse large B-cell lymphoma (a) positive for CD10 (b) suggests a germinal centre cell origin.

ment. These cases are associated with CD10 expression and a germinal-centre origin. Translocation of the 3q27 region and *BCL6* rearrangements are found up to 30% of cases. *MYC* translocations have been observed in up to 10% of cases and are usually associated with complex karyotypes. Contrary to Burkitt lymphoma in which *MYC* is rearranged with immunoglobulin genes in virtually all cases, in DLBCL around 40% of these translocations involve a non-immunoglobulin gene.

Gene expression profiling of DLBCL not otherwise specified has identified two major subtypes, germinal-centre B cell-like (GCB) and activated B cell-like (ABC) DLBCL, that express genes related to germinal-centre cells or activated B cells with a secretory function, respectively. ABC but not GCB DLBCL exhibits constitutive activation of the NF- κ B pathway. These subtypes of DLBCL differ in genetic and molecular aspects, suggesting that they correspond to different clinical entities.

(a)

(b)

Figure 33.11 Diffuse large B-cell lymphoma with immunoblastic morphology (a) and positivity for MUM1/IRF4 (b) suggesting a non-germinal centre cell origin.

The clinical outcome is also different, with 5-year survival rates of 59% and 30% in GCB and ABC DLBCL, respectively. In addition, the clinical phenomenon of late relapse or relapse as FL occurs in patients with GCB DLBCL. The prognostic value of these molecular subtypes has been retained in patients treated with rituximab-containing regimens.

T-cell/histiocyte-rich large B-cell lymphoma

T-cell/histiocyte-rich large B-cell lymphoma is characterized by a limited number of scattered large B cells immersed in a rich background of T cells and frequently histiocytes. The tumour cells express mature B-cell markers and frequently BCL-2 and EMA, although CD30, CD15 and CD138 are negative. The background is composed of CD3 and CD4 T cells and CD68-

positive histiocytes. T-cell rosettes surrounding tumour B cells are not seen. Cases positive for Epstein–Barr virus (EBV) and a similar morphology would be better classified as EBV-positive DLBCL. This tumour presents with disseminated disease involving lymph nodes but also spleen, liver and bone marrow. Failure to therapy and International Prognostic Index (IPI) score are predictors of survival.

DLBCL with a predominant extranodal location

The WHO classification recognizes a series of DLBCL subtypes and entities characterized by predominantly extranodal presentation (Table 33.3).

Primary mediastinal (thymic) large B-cell lymphoma

Primary mediastinal (thymic) large B-cell lymphoma (PMBL) seems to originate in a thymic B cell and predominates in young women presenting with a large mediastinal mass that frequently invades adjacent structures. Progression outside the mediastinum frequently involves extranodal sites such as kidney, liver, adrenal or central nervous system (CNS). The tumour is mainly composed of large cells with abundant pale cytoplasm that express mature B-cell markers but usually lack surface immunoglobulin. CD30 is positive in 80% of cases, although not as uniformly as in HL. CD15 is negative. Genetically, PMBL has frequent gains and amplifications of 9p24 and inactivating mutations of *SOCS1*. These tumours have a distinctive expression profile relatively similar to that of HL, confirming the pathological evidence of the relationship between these two tumours. In fact, some patients may present with combined HL and PMBL at diagnosis or relapse or have tumours with intermediate features of both (see below). The outcome of these tumours is more favourable than other DLBCL, with a 5-year survival of 65%.

Intravascular large B-cell lymphoma

Intravascular large B-cell lymphoma is a distinctive lymphoma characterized by the growth of large B cells within the lumina of small to medium-sized vessels and capillaries (Figure 33.12). It is relatively rare in Western countries but more common in Eastern populations. This lymphoma is very aggressive and frequently diagnosed only at post-mortem. An isolated cutaneous variant with better prognosis has been identified, mainly in women.

Primary cutaneous DLBCL, leg type

Primary cutaneous DLBCL, leg type, is a primary cutaneous lymphoma composed almost exclusively of atypical large B cells that commonly presents in the lower extremities. These tumours express an activated B-cell phenotype with positivity for IRF4/MUM1 and CD10 negativity. BCL-6 is frequently positive and BCL-2 is strongly expressed. The genetic and molecular profiles are relatively similar to those found in ABC DLBCL. The prog-

Figure 33.12 Intravascular lymphoma in the brain.

nosis is poor and the tumour tends to disseminate to extracranial sites.

Large-cell lymphomas of terminally differentiated B cells

The updated WHO classification has included different lymphoma entities that have in common the proliferation of large lymphoid cells with a terminally differentiated B-cell phenotype characterized by variable or total lack of CD20 expression, and less frequently CD79a, but which express plasma cell-associated antigens such as CD38 and CD138. Most of these tumours are infected with EBV or human herpesvirus (HHV)-8 and occur in patients with a certain immunodeficiency status.

ALK-positive large B-cell lymphoma

ALK-positive large B-cell lymphoma is a distinctive disease characterized by proliferation of large B cells with plasmablastic differentiation that express ALK and which are EBV negative. These tumours present in young immunocompetent patients, usually with nodal involvement and aggressive behaviour. ALK expression is due to *ALK* rearrangements, particularly with clathrin [t(2;17)] or less frequently nucleophosmin [t(2;5)]. Contrary to other lymphomas in this group, viral infection and immunodeficiency are absent.

Plasmablastic lymphoma

Plasmablastic lymphoma is a large B-cell lymphoma with immunoblastic morphology and plasma cell immunophenotype that present mainly in extranodal sites such as oral mucosa and gastrointestinal tract of immunosuppressed patients. HIV infection is the main cause but post-transplant or immunosuppressive treatments are also common causes. Most of the tumours are EBV positive and latent membrane protein (LMP)-

Figure 33.13 Primary effusion lymphoma. The tumour cells were present in the pleura and have a large plasmablastic morphology.

1 negative. The clinical behaviour is aggressive with poor response to therapy.

Primary effusion lymphoma

Primary effusion lymphoma occurs mainly in immunosuppressed patients associated with HHV-8 and, frequently, EBV infection. It is characterized by proliferation of large pleomorphic B cells that lack expression of B-cell markers and immunoglobulin but which express plasma cell-associated antigens and CD30 (Figure 33.13). These tumours usually present as effusion lymphomas with no involvement of tissues. However, some patients may present with, or later develop, a solid tumour in extranodal sites.

Burkitt lymphoma

Burkitt lymphoma (BL) is mainly a tumour of children and young adults and is characterized by monotonous proliferation of medium-sized B cells with a mature B and germinal-centre phenotype, negative or very weak BCL-2 expression, high proliferation (Ki-67 > 95%) and the t(8;14) translocation with *MYC* rearrangement. These tumours occur endemically in equatorial Africa and other geographic areas and sporadically throughout the world. BL is also seen associated with immunodeficiency, particularly HIV infection. The tumour mainly involves extranodal sites, particularly the abdominal cavity, and in endemic areas jaws and facial bones. The tumour may infiltrate the CNS. A leukaemic phase may be seen in patients with bulky disease and occasional patients may present with a pure leukaemic disease (Burkitt leukaemia variant). The tumour is clinically aggressive but potentially curable with current protocols.

Morphologically, the tumour cells are very monomorphic. The high proliferation is typically associated with a 'starry sky'

(a)

(b)

Figure 33.14 Burkitt lymphoma. (a) 'Starry sky' pattern due to the abundant histiocytes with apoptotic bodies. (b) Monotonous medium-sized cells with high proliferation.

pattern because of the high number of histiocytes phagocytosing apoptotic bodies (Figure 33.14). Genetically, the t(8;14) translocation is found in most tumours with very few if any additional genetic alterations. However, up to 10% of cases with typical morphology and phenotype may lack this translocation. On the other hand, DLBCL may have high proliferation and may also exhibit *MYC* rearrangements that make the differential diagnosis between BL and DLBCL difficult.

Two recent studies using microarray technology have described the gene expression profile of BL that refines the differential diagnosis with DLBCL. This BL signature is composed of a group of genes that are targets of the *MYC* gene, high expression of germinal centre-related genes and low expression of NF- κ B target genes and MHC class I genes.

B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma

Borderline cases between DLBCL and BL comprise tumours with a morphology that resembles BL but which have an atypical phenotype such as strong BCL-2 protein expression, tumours with blastic nuclear morphology but negative for terminal deoxynucleotidyltransferase and cyclin D1, or tumours with a BL phenotype but with more irregular nuclei than acceptable for this lymphoma. Some of these cases were diagnosed previously as Burkitt-like lymphomas. These tumours express a mature B-cell phenotype with a high proliferative index. Strong expression of BCL-2 protein should suggest the presence of t(14;18) in addition to t(8;14) ('double hit'). *MYC* rearrangements may occur with a non-immunoglobulin gene and may be associated with complex karyotypes. Lymphomas with typical morphology of DLBCL with high proliferative activity and/or t(8;14) should not be included in this category. Clinically, the patients are older than those with conventional BL, the disease is usually disseminated and the bone marrow and peripheral blood may be involved. The clinical evolution is very aggressive with poor response to therapy. These cases are not considered a specific entity but a working category. Some cases may represent transformed FL, evolving DLBCL activating particular molecular pathways, and some of them may perhaps represent some specific entity not well recognized yet. However, independent of the possible biological significance, these patients should be recognized and studied separately from conventional DLBCL and BL.

B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma

These tumours are B-cell lymphomas that have clinical, morphological and/or immunophenotypic features that overlap those of DLBCL, particularly PMBL, and HL. These cases are diagnosed frequently in young men presenting with a large mediastinal mass that is sometimes associated with supraclavicular lymph nodes. Most of these cases are composed of sheets of large cells with a pleomorphic aspect, sometimes lacunar appearance, associated with some inflammatory infiltrate. The phenotype combines strong expression of a complete B-cell programme (CD20, CD79a, BOB-1, OCT2, PAX5) with CD30 and CD15 positivity. Some cases resembling classical nodular sclerosis HL with uniform expression of CD20 and other B-cell markers and lack of CD15 may also be included in this category. In contrast, cases resembling PMBL that lack CD20 and which are positive for CD15 or EBV may also be diagnosed in this category. Composite lymphomas with clear areas of PMBL and HL should not be included in this group and both components should be mentioned in the diagnosis. The overlapping mor-

phological and phenotypical features of these tumours have been validated as authentic biological characteristics by microarray expression profiling studies that have demonstrated the similarities between PMBL and HL. These tumours probably represent evidence of plasticity in the differentiation pathways of B cells.

Mature NK-cell/T-cell neoplasms

These tumours derive from natural killer (NK) cells and T cells of peripheral lymphoid organs and can be roughly subdivided into three groups: leukaemic, extranodal and nodal. These are discussed in the following sections, with the exception of T-cell prolymphocytic leukaemia, T-cell large granular lymphocyte leukaemia and chronic lymphoproliferative disorders of NK cells, which are considered in Chapter 30.

Aggressive NK-cell leukaemia

This is a rare neoplasm, mainly observed among Asians, and exhibits systemic proliferation of NK cells almost always associated with EBV and an aggressive clinical course. Patients are usually middle-aged of either sex. The most commonly involved sites are the peripheral blood, bone marrow, liver and spleen (Figure 33.15). Fever and constitutional symptoms are common. Frequent complications are coagulopathy, haemophagocytic syndrome (HPS) or multiorgan failure. A specific overlap with extranodal NK/T-cell lymphoma may exist. Circulating leukaemic cells exhibit a morphological spectrum, from 'normal LGL' to elements with atypical infolded nuclei, open chromatin and distinct nucleoli. They express CD2, CD3 ϵ , CD56 and cytotoxic molecules. Surface CD3 is absent. T-cell receptor (TCR) genes

Figure 33.15 Cytospin from the peripheral blood of a patient with aggressive NK-cell leukaemia, stained for CD56 (alkaline phosphatase anti-alkaline phosphatase technique).

are in germline configuration. Most cases pursue a fulminant clinical course.

EBV-positive T-cell lymphoproliferative disorders of childhood

Systemic EBV-positive T-cell lymphoproliferative disease of childhood and hydroa vacciniforme-like lymphoma are the prototypes of these diseases. Both are prevalent in Asia and Central and South America with no sex predilection. EBV-positive T-cell lymphoproliferative disease of childhood can develop shortly after primary EBV infection or in the setting of chronic active EBV infection. It may have a rapid evolution with fatal outcome. Hydroa vacciniforme-like lymphoma is associated with sensitivity to insect bites and sun exposure and behaves indolently. In both conditions, there is strong suggestion of a genetic defect in the host immune response to EBV. The infiltrating T cells are usually small and lack significant cytological atypia, but at times are pleomorphic, medium/large with irregular nuclei and frequent mitoses (Figure 33.16). They are positive for CD2, CD3, TIA and EBV but negative for CD56, and have monoclonally rearranged TCR genes.

Adult T-cell leukaemia/lymphoma (see also Chapter 30)

Adult T-cell leukaemia/lymphoma (ATLL) is endemic in southwestern Japan, the Caribbean basin and parts of Central Africa, its distribution resembling that of human T-cell leukaemia/lymphoma virus (HTLV)-I. The disease has a long latency with exposure of affected individuals to the virus very early in life. Although causally linked to ATLL, HTLV-I itself is insufficient to cause neoplastic transformation, additional genetic events being required. Most patients present with widespread lymph node and peripheral blood involvement, the skin being affected in more than 50%. ATLL is characterized by variable clinical and histological features. In particular, the behaviour varies from acute (with usual hypercalcaemia and possible lytic bone

Figure 33.16 Bone-marrow involvement by EBV-positive lymphoproliferative disorder in a 16-year-old boy.

Figure 33.17 Lymph node infiltration in a patient with adult T-cell leukaemia/lymphoma.

lesions) to lymphomatous, chronic or smouldering, while the growth may consist of small to large-sized pleomorphic cells or display anaplastic or even angioimmunoblastic-like morphology (Figure 33.17). Tumour elements are usually CD2⁺CD3⁺CD5⁺CD25⁺CD7⁻. Most cases are CD4⁺CD8⁻, a few CD4⁻CD8⁺ or CD4⁺CD8⁺. CCR4 and FoxP3 are frequently expressed, CD30 may be positive and cytotoxic molecules are absent. TCR genes are clonally rearranged. Clinical subtypes, age, performance status, serum calcium and lactate dehydrogenase levels are major prognostic indicators. The acute and lymphomatous variants have a short survival (2 weeks to more than 1 year), while the chronic and smouldering forms behave more indolently but can progress to an acute phase (see also Chapter 30).

Extranodal NK/T-cell lymphoma, nasal type

Extranodal NK/T-cell lymphoma, nasal type, more often occurs in adult males from Asia, Mexico and Central and South America. The tumour is EBV positive with type II latency, although LMP-1 expression is variable. Usually, these lymphomas affect the nasal cavity, nasopharynx, paranasal sinuses and palate. Extranodal locations include the skin, soft tissue, gastrointestinal tract and testis. Patients with nasal disease suffer from nasal obstruction or epistaxis, or extensive mid-facial destruction (so-called lethal midline granuloma). Irrespective of the site of presentation, the lymphomatous infiltrate is diffuse with angiocentric and angiodestructive features and frequent necrosis. Neoplastic cells may be small, medium-sized, large or anaplastic with numerous mitotic figures and azurophilic granules in Giemsa-stained touch preparations (Figure 33.18). Phenotypically, they are positive for CD2, CD56, CD3ε and cytotoxic markers but negative for CD3. Occasional cases are CD7⁺ or CD30⁺. It is noteworthy that CD56 is not specific for these lymphomas, being detected in other peripheral T-cell

Figure 33.18 Destructive lesion of the nasal cavities in the course of extranodal NK/T-cell lymphoma, nasal type.

lymphomas, mainly carrying $\gamma\delta$ -TCR. A diagnosis of extranodal NK/T-cell lymphoma, nasal type should be accepted with scepticism if EBV-encoded RNA *in situ* hybridization is negative. TCR and *IGHV* genes are usually in germline configuration, the former being clonally rearranged in a few instances. The prognosis of extranodal NK/T-cell lymphoma, nasal type is variable, being always poor for cases occurring outside the nasal cavity. It is noteworthy that survival has recently been improved with more intensive regimens including up-front radiotherapy and L-asparaginase.

Enteropathy-associated T-cell lymphoma

Enteropathy-associated T-cell lymphoma (EATL) is an intestinal tumour of intraepithelial T lymphocytes, usually consisting of large lymphoid cells admixed with numerous histiocytes and eosinophils and associated with necrosis. The adjacent small intestinal mucosa shows villous atrophy, crypt hyperplasia, increased lamina propria lymphocytes and plasma cells, and intraepithelial lymphocytosis (Figure 33.19). The disease occurs more often in areas with a high prevalence of coeliac disease (i.e. northern Europe). In 10–20% of cases, EATL is composed of monomorphic medium-sized cells with no inflammatory background and rare necrosis. Such monomorphic variant (type II) EATL may occur sporadically, without risk factors for coeliac disease, and has a broader geographic distribution. Patients (usually adults) present with abdominal pain, frequently associated with intestinal perforation. The tumour forms one or more ulcerating mucosal masses that invade the wall of the intestine (frequently jejunum or ileum). Neoplastic cells are positive for CD3, CD7, CD103, TCR- β and cytotoxic molecules, negative for CD4 and CD5, with variable expression of CD8 and CD30. Type II EATL has a distinctive immunophenotype (CD3⁺CD4⁻CD8⁺CD56⁺TCR- β ⁺). TCR β and γ genes are always clonally rearranged. The prognosis is poor, with death frequently resulting from abdominal complications.

Figure 33.19 Enteropathy-associated T-cell lymphoma. Remnants of the mucosa are seen on the left-hand side.

Figure 33.21 Example of subcutaneous panniculitis-like T-cell lymphoma. Features of 'rimming' are easily seen.

Figure 33.20 Splenic red pulp involvement by hepatosplenic T-cell lymphoma.

Hepatosplenic T-cell lymphoma

Hepatosplenic T-cell lymphoma is a rare neoplasm derived from cytotoxic T cells, mostly of the $\gamma\delta$ type. It affects adolescents and young adults, with male predominance. Up to 20% of these lymphomas arise in the setting of chronic immunosuppression, usually for solid organ transplantation or prolonged antigenic stimulation. It may also occur in patients, especially children, treated with azathioprine and infliximab for Crohn's disease. Clinically, it is characterized by hepatosplenomegaly, systemic symptoms and marked thrombocytopenia. Morphologically, neoplastic cells are monotonous, with medium-sized nuclei, loosely condensed nuclear chromatin, inconspicuous nucleoli and a rim of pale cytoplasm. In the spleen, they infiltrate the red pulp cords and sinuses with atrophy of the white pulp, while in the liver and bone marrow they show intrasinusoidal diffusion (Figure 33.20). Phenotypically, most cases are positive for CD3 and TCR- $\delta 1$,

partly positive for CD56 and CD8, and negative for TCR- $\alpha\beta$, CD4 and CD5. A minority carries the α/β dimer. The cells express TIA1 and granzyme-M, but not granzyme-B and perforin. They have rearranged TCR- γ genes. Cases of $\gamma\delta$ origin show biallelic rearrangement of TCR- δ genes. Isochromosome 7q is present in most instances. Trisomy 8 and loss of a sex chromosome may also be present. The course is aggressive, with initial response to chemotherapy but rapid relapse. The median survival is less than 2 years.

Subcutaneous panniculitis-like T-cell lymphoma

Subcutaneous panniculitis-like T-cell lymphoma is a rare cytotoxic T-cell lymphoma that preferentially infiltrates subcutaneous tissue, is slightly commoner in females and has a broad age spectrum. In the new WHO classification, cases expressing TCR- $\gamma\delta$ are classified as primary cutaneous $\gamma\delta$ T-cell lymphoma. About 20% of patients have an associated autoimmune disease, mostly systemic lupus erythematosus. Patients present with multiple subcutaneous nodules, usually in the absence of other involved sites. Systemic symptoms are recorded in more than 50% of patients. Cytopenias and elevated liver function tests are common, and frank HPS is seen in 15–20%. The infiltrate involves the fat lobules with rimming around individual fat cells and usually spares septa as well as the overlying dermis and epidermis (Figure 33.21). Vascular invasion is seen occasionally, while necrosis and karyorrhexis are common. The cells have a mature $\alpha\beta$ T-cell phenotype ($\beta F1^+$), usually CD8⁺ with expression of cytotoxic molecules and negative for CD56. The neoplastic cells show rearrangement of TCR genes, and are negative for EBV. Dissemination to lymph nodes and other organs is rare. The 5-year overall survival (OS) is 80%; however, if HPS occurs, the prognosis is poor.

Figure 33.22 Mycosis fungoides. The epidermis is infiltrated by neoplastic T cells with cerebriform nuclei and strong CD3 expression.

Mycosis fungoides and Sézary syndrome (see also Chapter 30)

Mycosis fungoides is the commonest primary cutaneous T-cell lymphoma (CTCL) and is characterized by epidermotropic infiltrates of small to medium-sized T lymphocytes with cerebriform nuclei (Figure 33.22). It usually affects adults or the elderly with a male predominance, but can also occur in children and adolescents. The disease is limited to the skin, with classical evolution of patches, plaques and tumours. Extracutaneous dissemination occurs in advanced stages. Mycosis fungoides slowly progresses over years or sometimes decades. Histological transformation (i.e. >25% blasts in the dermal infiltrates) occurs mainly in the tumour stages. The typical phenotype is $CD2^+CD3^+TCR-\beta^+CD5^+CD4^+CD8^-CD7^-$. TCR genes are clonally rearranged in a proportion of cases. The single most important prognostic factor is the clinical stage. In the more advanced stages, the prognosis is poor as it is in the case of histological transformation. Rare clinical–morphological variants include folliculotropic mycosis fungoides, pagetoid reticulosis and granulomatous slack skin.

Sézary syndrome is defined by erythroderma, generalized lymphadenopathy and presence of neoplastic T cells with cerebriform nuclei (so-called Sézary cells) in skin, lymph nodes and blood. This is a rare disease accounting for less than 5% of CTCLs. It occurs in adults with a male predominance. The histological and phenotypic features in Sézary syndrome may be similar to those of mycosis fungoides. TCR genes are clonally rearranged. The 5-year OS is 10–20%.

Primary cutaneous CD30-positive T-cell lymphoproliferative disorders

These lesions include primary cutaneous anaplastic large-cell lymphoma (C-ALCL) and lymphomatoid papulosis, which

form a spectrum with overlapping histopathological and phenotypic features. Their appearance and course are therefore critical for the diagnosis.

Primary cutaneous anaplastic large-cell lymphoma

C-ALCL is composed of large cells with an anaplastic, pleomorphic or immunoblastic morphology, the vast majority of which express CD30. By definition, C-ALCL should not be preceded by or coincide with mycosis fungoides. It must also be distinguished from systemic ALCL, which is a different entity. Most patients present with solitary or localized nodules or tumours, and sometimes papules located on the trunk, face, extremities or buttocks, that often undergo ulceration and sometimes show partial or complete spontaneous regression, as in lymphomatoid papulosis. Besides CD30 positivity, the neoplastic cells display an activated $CD4^+$ T-cell phenotype with variable loss of CD2, CD5 and/or CD3. Unlike systemic ALCL, C-ALCL expresses CLA but not EMA or ALK. Unlike Hodgkin and Reed–Sternberg cells, staining for CD15 is generally negative. Most cases show clonal TCR gene rearrangement. The prognosis is favourable, with a 10-year OS of approximately 90%, although local relapses are frequent.

Lymphomatoid papulosis

Lymphomatoid papulosis is a chronic, recurrent, self-healing skin disease that most often occurs in adults with male preponderance, affects trunk and extremities and is characterized by paradoxical eruptions of papular, papulonecrotic and/or nodular lesions that tend to disappear within 3–12 weeks possibly leaving a scar. The duration of the disease may vary from several months to over 40 years. The prognosis is excellent. Morphologically, the large CD30-positive cells may be intermingled with a variable number of inflammatory cells or predominate as a monotonous population. The phenotype is similar to that of C-ALCL. Clonally rearranged TCR genes are detected in about 60% of lesions.

Primary cutaneous $\gamma\delta$ T-cell lymphoma

This tumour consists of a clonal proliferation of activated $\gamma\delta$ T cells with a cytotoxic phenotype. A possibly related condition may affect mucosal sites. Primary cutaneous $\gamma\delta$ T-cell lymphoma is rare (1% of CTCLs) and more often observed in the extremities of adults with no sex predilection. It may be predominantly epidermotropic with patches/plaques or may give rise to deep dermal or subcutaneous tumours, with or without epidermal necrosis and ulceration. Dissemination to mucosal and other extranodal sites is frequent. HPS may occur. 'B' symptoms are seen in most patients. The tumour cells characteristically exhibit a $\beta F1^-CD3^+CD2^+CD5^-CD7^{+/-}CD56^+$ phenotype with strong expression of cytotoxic proteins. The cells are strongly positive for TCR- δ with appropriate detection methods. The cells show clonal rearrangement of the TCR- γ and TCR- δ

genes. TCR- β may be rearranged or deleted, but is not expressed. Primary cutaneous $\gamma\delta$ T-cell lymphoma is resistant to multi-agent chemotherapy and/or radiation and has a poor prognosis, with a median survival of approximately 15 months.

Peripheral T-cell lymphoma not otherwise specified

Peripheral T-cell lymphoma not otherwise specified is a heterogeneous group of tumours that corresponds with none of the T-cell entities defined in the WHO classification. It accounts for approximately 30% of peripheral T-cell lymphomas in Western countries. Most patients are adults with a slight male predominance, and show peripheral lymphadenopathy and 'B' symptoms. Generalized disease is often encountered, with bone marrow, liver, spleen and extranodal tissue involvement. Leukaemic spread is uncommon. The cytological spectrum is extremely broad, from highly polymorphous to monotonous. Clear cells and Reed–Sternberg-like elements can be seen and high endothelial venules increased. An inflammatory background is often present (Figure 33.23). The differential diagnosis with angioimmunoblastic T-cell lymphoma may require extensive immunophenotyping. Peripheral T-cell lymphoma not otherwise specified usually displays an aberrant T-cell phenotype, with frequent loss of CD5 and CD7. A CD4⁺CD8⁻ profile predominates in nodal cases. CD4⁺CD8⁺ or CD4⁻CD8⁻ is sometimes seen, as is CD8, CD30, CD56 and/or cytotoxic granule expression. CD52 is absent in 60% of cases. Aberrant CD20 and/or CD79a expression is occasionally encountered. Proliferation is high and Ki-67 rates over 80% are associated with poor outcome. TCR genes are clonally rearranged. Gene expression profiling has revealed deregulation of genes involved in matrix deposition, cytoskeleton organization, cell adhesion, apoptosis, proliferation, transcription and signal transduction. The products of these genes might have therapeutic relevance. EBV integration is found in some cases. Peripheral T-cell lymphoma not otherwise specified is highly aggressive with poor response to therapy, frequent relapses and 5-year OS of 20–30%. The IPI is the only factor consistently associated with prognosis. New scoring systems have recently been proposed.

Angioimmunoblastic T-cell lymphoma

Angioimmunoblastic T-cell lymphoma is characterized by a polymorphous infiltrate constantly involving lymph nodes with prominent proliferation of high endothelial venules and follicular dendritic cells (Figure 33.24). Spleen, liver, skin and bone marrow are also frequently affected. It occurs in middle-aged/elderly individuals of either sex and accounts for approximately 15–20% of peripheral T-cell lymphomas. Virtually all patients present with advanced-stage disease, systemic symptoms, polyclonal hypergammaglobulinaemia, circulating immune

complexes, cold agglutinins with haemolytic anaemia, positive rheumatoid factor and anti-smooth muscle antibodies. Skin rash is frequently observed. Other common findings are pleural effusion, arthritis and ascites. Angioimmunoblastic T-cell lymphoma is characterized by partial effacement of the lymph node architecture with sparing of the peripheral cortical sinuses. The neoplastic infiltrate is composed of small to medium-sized lymphocytes, with clear to pale cytoplasm and mild cytological atypia. They often form small clusters around hyperplastic high endothelial venules and follicular dendritic cells, and are admixed with small reactive lymphocytes, eosinophils, plasma cells and histiocytes. An expansion of EBV-positive B immunoblasts is usually present. The neoplastic cells have the phenotype of follicular T-helper cells positive for mature T-cell markers,

Figure 33.24 Angioimmunoblastic T-cell lymphoma (a) Low-power view: note the amount of high endothelial venules as well as the cellular pleomorphism. (b) At higher magnification, neoplastic cells display irregular nuclear contours and a rim of clear cytoplasm. (c) Hyperplasia of follicular dendritic cells recognized with CD21 staining. The tumour cells are positive for CD10 (d) and CXCL13 (e).

i.e. CD4, CD10, CXCL13, PD1, SAP and ICOS (Figure 33.24). TCR genes are clonally rearranged in most cases. Clonal *IGHV* gene rearrangements are found in about 25–30% of cases, and correlate with expanded EBV-positive B cells. The clinical course is aggressive with a median survival of less than 3 years. Patients often succumb to infectious complications. Supervening large B-cell lymphoma (often but not invariably EBV positive) can occur.

Anaplastic large-cell lymphoma, ALK⁺

ALCL ALK⁺ is characterized by large neoplastic cells with abundant cytoplasm and kidney/horseshoe-shaped nuclei (so-called hallmark cells), with a translocation involving the *ALK* gene and expression of both ALK protein and CD30. ALCL with similar morphology and phenotype, but lacking *ALK* rearrangement and ALK protein, is considered as a separate category (ALCL ALK⁻). ALCL ALK⁺ shows a higher prevalence in the first three decades of life and a male predominance and frequently involves both lymph nodes and extranodal sites. Most patients present with stage III–IV disease and ‘B’ symptoms. The morphology

may be variable. The ‘common’ appearance (60% of cases) consists of large tumour cells, frequently with hallmark appearance, that tend to grow within the sinuses, resembling a metastatic tumour (Figure 33.25). Some cases may have a lymphohistiocytic pattern (10%) characterized by few tumour cells overwhelmed by reactive histiocytes. A small-cell variant (5–10%) has been recognized that seems to have a worse prognosis. Some cases (3%) may mimic HL but the cells are ALK positive and CD15 negative. Relapses may reveal morphological features different from those seen initially. The tumour cells are CD30 positive. In cases with t(2;5)/*NPM-ALK* translocation, ALK staining is both cytoplasmic and nuclear. In cases with variant translocations, ALK staining may be membranous or cytoplasmic. Most ALCL ALK⁺ are positive for EMA, express cytotoxic markers and bear one or more T-cell antigens, although some may have null phenotype. EBV is negative. TCR gene is rearranged. The most frequent genetic alteration is t(2;5)(p23;q35) involving the *ALK* and nucleophosmin (*NPM*) genes. Variant translocations lead to fusion of the *ALK* gene with other partners on chromosomes 1, 2, 3, 17, 19, 22 and X. All these aberrations result in upregulation and different subcellular

distribution of ALK protein but do not have clinical relevance. ALCL ALK⁺, ALCL ALK⁻ and peripheral T-cell lymphoma not otherwise specified have different chromosomal and gene expression profiles. The IPI predicts the clinical outcome. The 5-year OS is about 80%.

Anaplastic large-cell lymphoma, ALK⁻

In the new WHO Classification, ALCL ALK⁻ is a provisional entity. Most cases express both T-cell-associated and cytotoxic markers (Figure 33.26). The tumour must be distinguished from C-ALCL, other CD30-positive T- or B-cell lymphomas with anaplastic features, and classical HL. ALCL ALK⁻ affects adults with a slight male predominance, involves lymph nodes and, less frequently, extranodal sites. Most patients are staged III–IV, with 'B' symptoms. Usually, the organ architecture is effaced by solid cohesive sheets of neoplastic cells. In the lymph node, the latter tend to diffuse through sinuses, mimicking metastatic carcinoma. The main differential diagnosis is with peripheral T-cell lymphoma not otherwise specified and classical HL but immunophenotypic and molecular studies can distinguish these entities in most cases. In this regard, BSAP/PAX5 staining is useful: classical HL shows weak positivity in most

cases, a finding not observed in ALCL ALK⁻. In contrast, the distinction between peripheral T-cell lymphoma not otherwise specified and ALCL ALK⁻ is not always clear-cut, although recent gene expression profiling studies have definitely shown distinct signatures. Homogeneous strong CD30 staining on the cell membrane and Golgi area of all neoplastic cells favours the diagnosis of ALCL ALK⁻, as does complete loss of T-cell markers. Most cases show clonal TCR gene rearrangement and EBV is negative. ALCL ALK⁻ has a 5-year OS poorer than that of ALCL ALK⁺ (49% vs. 80%), but definitively better than peripheral T-cell lymphoma not otherwise specified (49% vs. 32%).

Hodgkin lymphoma

HL accounts for about 10% of lymphoid tumours. Irrespective of the histotype, HL is characterized by the following features: (i) usual onset in the lymph nodes, preferentially cervical ones; (ii) predilection for young adults; and (iii) small number of mononucleated and multinucleated tumour cells (Hodgkin and Reed–Sternberg cells) within an exuberant inflammatory milieu and often ringed by rosettes of T lymphocytes. Biological and clinical studies have shown that HL comprises two disease enti-

(a)

ties: nodular lymphocyte predominant HL (NLPHL) and classical HL.

Nodular lymphocyte predominant Hodgkin lymphoma

NLPHL is a monoclonal B-cell tumour characterized by a nodular or a nodular and diffuse proliferation of scattered large multilobated neoplastic cells, known as 'popcorn' or LP cells (Figure 33.27). These reside in a follicular background with large follicular dendritic cell meshworks filled with non-neoplastic lymphocytes and histiocytes. One-third of the cases diagnosed in the past as NLPHL were lymphocyte-rich classical HL. It is currently unclear whether a diffuse NLPHL exists, its borders with T-cell/histiocyte-rich large B-cell lymphoma being not always sharp. NLPHL represents approximately 5% of HL cases. Patients are predominantly males in the fourth decade of life. LP cells are regularly positive for CD20, CD79a, EMA, BCL-6 and CD45. In contrast to Hodgkin and Reed–Sternberg cells of classical HL, tumor cells are positive for Oct-2, BOB.1 and immunoglobulin light and/or heavy chains but lack CD15,

CD30 and EBV infection. The tumour cells are ringed by T-follicular helper cells that are positive for CD3, CD4, PD-1 and (to a lesser extent) CD57. LP cells show clonal *IGHV* gene rearrangement, with a high load of somatic mutations that may be ongoing. Aberrant somatic hypermutations of *PAX5*, *PIM1*, *RhoH/TTF* (now called *RHOH*) and *MYC* genes are recorded in 80% of cases. NLPHL is an indolent disease with frequent relapses that usually remains responsive to therapy. Advanced stages have an unfavourable prognosis. Progression to large B-cell lymphoma-like lesions is seen in 3–5% of cases.

Classical Hodgkin lymphoma

Classical Hodgkin lymphoma is a monoclonal lymphoid neoplasm (mostly derived from B cells) composed of Hodgkin and Reed–Sternberg cells within a variable mixture of reactive lymphocytes, eosinophils, neutrophils, histiocytes, plasma cells, fibroblasts and collagen fibres (Figure 33.28). Based on the characteristics of the inflammatory background, and to a certain extent on the morphology of Hodgkin and Reed–Sternberg cells (i.e. lacunar cells), four histological subtypes are distinguished:

Figure 33.28 Classical Hodgkin lymphoma. (a) Mixed cellularity type. (b) Nodular sclerosing type (H&E, ×100). (c, d) Neoplastic cells positive for CD30 (c) and CD15 (d).

lymphocyte rich, nodular sclerosis, mixed cellularity and lymphocyte depleted. The immunophenotypic and genetic features of Hodgkin and Reed–Sternberg cells are identical in these histological subtypes, whereas clinical features and EBV association vary. Classical HL accounts for 95% of HLs, with a bimodal age curve in resource-rich countries, showing a peak at 15–35 years and a second peak in late life. Classical HL most often involves cervical lymph nodes and in approximately 60% of patients (usually with the nodular sclerosis subtype) causes a mediastinal mass. Hodgkin and Reed–Sternberg cells typically represent 0.1–10% of the cellular infiltrate. The composition of the reactive milieu varies according to the subtype. Hodgkin and Reed–Sternberg cells are CD30 positive in nearly all cases, and CD15 positive in most. In 30–40% of cases CD20 may be detected, usually of varied intensity and in a minority of Hodgkin and Reed–Sternberg cells. The B-cell nature of neoplastic cells is sustained in about 95% of cases by their expression of BSAP/PAX5, though weaker than that of reactive B cells. EBV-positive Hodgkin and Reed–Sternberg cells show a latency II pattern (LMP1⁺, EBNA-2⁻). Characteristically, the transcription factors Oct-2 and BOB.1 are absent in about 90% of cases, while PU.1 is consistently absent. Reed–Sternberg cells contain clonal *IGHV* gene rearrangements in more than 98% of cases, and clonal TCR gene rearrangements in rare instances. The rearranged *IGHV* genes harbour a high load of somatic hypermutations, usually not ongoing.

Hodgkin lymphoma is an uncommon tumour, although it is one of the more frequent malignancies in young people. Traditionally, radiotherapy was the primary therapeutic approach, and the first successful combination chemotherapy regimen was introduced in the 1960s. Since then, combined modality therapy has developed allowing reduction of both chemotherapy and radiotherapy doses. The outcome of patients with Hodgkin lymphoma has improved greatly over the last few decades such that it should now be considered curable in the large majority of cases. With the excellent cure rates now attainable, the late effects of treatment have become more apparent. Current therapeutic strategies must aim to maintain these high cure rates while minimizing these late effects.

Epidemiology

Hodgkin lymphoma is a relatively uncommon malignancy, with an incidence in the UK of about 2.4 per 100 000 per annum, and an overall male to female ratio of 1.4:1. It is a disease that affects young adults, and is the third most commonly diagnosed cancer in people aged 15–29 years. The previously described second peak in older age groups is partly an artefact, due to

misreporting of non-Hodgkin (mainly anaplastic) lymphomas in this age group. The overall incidence is stable in comparison to that of non-Hodgkin lymphomas, which appears to be rising. Worldwide prevalence rates vary, with more than 5.5 per 100 000 in Yemen and Lebanon and less than 1 per 100 000 in China and Japan. At least some of this variation, and that of the proportions of histological subtypes, appears to relate to the degree of industrialization. As a consequence of the excellent responses to treatment, mortality rates are low (0.4 per 100 000 per annum in the UK). Mortality increases with age and in countries with less access to treatment.

Aetiology

Although no clear-cut aetiological agent has been identified for Hodgkin lymphoma, Epstein–Barr virus (EBV) has long been theorized to play a causative role. EBV nucleic acids and proteins have been detected in 25–50% of cases, and patients with Hodgkin lymphoma have different serological profiles of antibodies to EBV-associated antigens prior to diagnosis compared with healthy controls. However, differences remain between histological subtypes, age groups and geographical locations, and a precise causative role has not been definitively identified. No other infectious agents have shown a consistent association.

Immunosuppression is associated with an increased risk of developing Hodgkin lymphoma, especially in HIV infection, which increases the risk by 7–14 times. However, in contrast to non-Hodgkin lymphomas, the incidence is not directly correlated with a low CD4 count, and the prevalence has actually

increased with better viral control since the introduction of highly active antiretroviral therapy.

Histological classification (see also Chapter 33)

Hodgkin lymphoma is broadly classified into two distinct entities: classical Hodgkin lymphoma (CHL) and nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL). Both types are characterized by the histological appearance of only a small number of neoplastic Hodgkin/Reed–Sternberg (HRS) cells in an inflammatory background of reactive T cells and eosinophils, with varying degrees of fibrosis.

CHL is divided into four subtypes (Table 34.1). In the developed world, nodular sclerosing Hodgkin lymphoma accounts for the majority of cases. Although the HRS cell has now been identified as being of B-cell lineage, the mature B-cell antigen expression pattern is often low or absent (Table 34.2 and Figures 34.1–34.4).

NLPHL has a distinct histological appearance, with HRS cells having a lymphocytic and histiocytic or ‘popcorn’ appearance. The immunophenotype is more typical for a B cell, being positive for CD20 and immunoglobulin expression (Figures 34.5–34.8).

Figure 34.1 Low-power view of lymph node biopsy of classical Hodgkin lymphoma showing nodularity and sclerosis.

Figure 34.2 High-power view of classical Hodgkin lymphoma showing abundant Reed–Sternberg cells and occasional eosinophils.

Pathogenesis

Nature of malignant cell

The pathogenesis of Hodgkin lymphoma is still not completely understood. Indeed, the nature of the underlying neoplastic cell was only confirmed relatively recently, when single-cell studies from microdissected specimens were performed. These confirmed that the HRS cell of CHL is of B-cell origin, probably of a germinal or post-germinal centre type, with clonal rearrange-

Figure 34.3 CD30 immunostain of classical Hodgkin lymphoma showing clear membranous and Golgi apparatus staining of the Hodgkin/Reed–Sternberg cells.

Figure 34.4 CD15 immunostain of classical Hodgkin lymphoma.

ments in the V, D and J segments of the IgH chain locus in the majority of patients. There is absent immunoglobulin expression in HRS cells, indicative of crippling mutations in the immunoglobulin gene or defective expression of the transcription factor(s) that regulate the B-cell differentiation programme. In contrast, the malignant lymphocytic and histiocytic cells of NLPHL have both the genotype and immunophenotype of typical post-germinal centre B cells (Table 34.2). Whereas there is markedly reduced or absent expression of the transcription factor Oct2 or its coactivator BOB1 in HRS cells of CHL, these factors are highly expressed in the malignant cells of NLPHL.

Figure 34.5 Low-power view of lymph node biopsy of nodular lymphocyte-predominant Hodgkin lymphoma showing nodular features and slight mottled appearance of the follicles.

Figure 34.6 High-power view of nodular lymphocyte-predominant Hodgkin lymphoma showing many convoluted lymphocytic and histiocytic or ‘popcorn’ cells.

Mechanism of tumorigenesis

Information on the mechanisms leading to development of a malignant phenotype is limited, and the inability to perform functional studies on cells purified from tissue specimens means that almost all data are derived from cultured cell lines.

Several pathways have been identified as being linked to the growth and survival of HRS cells. NF- κ B signalling is increased, caused by a number of upstream mechanisms, such as reduced levels of I κ B, which normally acts as an inhibitor. The inactiva-

Figure 34.7 CD20 staining of nodular lymphocyte-predominant Hodgkin lymphoma. Note that the lymphocytic and histiocytic cells are typically surrounded by a rosette of CD20-negative reactive T cells.

Figure 34.8 J-chain immunostaining of nodular lymphocyte-predominant Hodgkin lymphoma demonstrating immunoglobulin production of lymphocytic and histiocytic cells, a feature not seen in classical Hodgkin lymphoma.

tion of I κ B is caused by, among other factors, the EBV-derived latent membrane protein (LMP)-1. This is one of the mechanisms by which EBV may act as a viral aetiological agent for the development of Hodgkin lymphoma. Other pathways implicated in tumorigenesis include activated protein (AP)-1, the JAK/STAT and NOTCH signalling pathway, and autocrine effects from interleukin (IL)-13 activity.

Unlike some other haematological neoplasms, no specific chromosomal translocation has been identified on cytogenetic analysis, but the presence of aneuploidy with widespread chromosomal abnormalities suggests underlying genomic instability.

Mechanism of surrounding tissue reaction

The characteristic surrounding inflammatory tissue of Hodgkin lymphoma is a mixture of T cells (mainly CD4⁺ T-regulatory cells), histiocytes, plasma cells, eosinophils and neutrophils. The background is thought to be cytokine-induced, for example eotaxin released from fibroblasts causing eosinophil infiltration. This cytokine release may also account for the characteristic blood abnormalities associated with Hodgkin lymphoma, and the systemic 'B' symptoms.

Clinical presentation

Hodgkin lymphoma can present in a variety of ways. Most commonly, however, it arises within a lymph node, presenting as an enlarged but painless lump, usually in the neck or supra-clavicular region. Mediastinal nodes are involved in up to 60% of cases at presentation and retroperitoneal nodes in 25%. Presentation in the subdiaphragmatic nodes alone is less common.

A mediastinal mass detected on chest radiography is also common, either after investigation for pulmonary symptoms (e.g. chest discomfort, cough or dyspnoea) or as an incidental finding (Figure 34.9). Other presentations, such as bone marrow infiltration, cholestasis and autoimmune phenomena, are well documented but much rarer.

An important feature of Hodgkin lymphoma is the initial contiguous pattern of spread through adjacent lymph nodes; only later does haematogenous spread to more distant organs take place. Splenomegaly may occur without direct disease involvement, although hepatosplenomegaly almost invariably indicates disease infiltration. Peripheral blood manifestations are common but non-specific, with lymphocytopenia and anaemia being indicators of advanced disease. The prognostic significance of eosinophilia is unclear.

Systemic 'B' symptoms are found in approximately 25% of patients at presentation. An 'A' staging merely represents the absence of 'B' symptoms. These consist of weight loss, night sweats and fevers. The so-called Pel-Ebstein fever describes a characteristic intermittent fever associated with Hodgkin lymphoma. However, its specificity and indeed existence has been called into question. Other systemic symptoms include pruritus, alcohol-induced pain at the site of affected lymph nodes and skin lesions.

NLPHL tends to present with chronic asymptomatic peripheral lymphadenopathy; 80% of cases present with early-stage

Figure 34.9 Chest radiograph showing enlarged superior mediastinum.

disease and, compared with CHL, mediastinal involvement and 'B' symptoms are less common. NLPHL tends to relapse late as a large-cell lymphoma, in keeping with its phenotype being more similar to non-Hodgkin lymphomas.

Diagnosis and staging

The diagnosis of Hodgkin lymphoma is made histologically, usually from an affected lymph node. Routine light microscopy is almost always augmented by immunohistochemical staining (see Figures 34.3, 34.4, 34.7 and 34.8).

Once the diagnosis has been confirmed, full staging is carried out by computed tomography (CT) from neck to pelvis, and bone marrow biopsy where indicated. Staging is still based on the Ann Arbor system (Table 34.3), which was developed over 30 years ago primarily to define who would benefit from radiotherapy. The Cotswolds modification, made in 1989, takes into account the importance of bulky disease and the fact that laparotomy and diagnostic splenectomy are no longer recommended due to the associated morbidity and mortality (Figure 34.10).

Functional imaging plays an increasing role, with gallium scanning now effectively superseded by ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET) (Figure 34.11). Hodgkin lymphoma is usually FDG-avid, and so is assumed to be positive on presentation. PET is beginning to form part of standard initial staging investigations, especially where FDG-avidity on PET will alter the stage and the treatment strategy employed.

Figure 34.10 CT scan of the chest showing large anterior mediastinal mass with area of probable necrosis.

Table 34.3 Ann Arbor staging system with Cotswolds modifications for Hodgkin lymphoma.

Stage	
I	Involvement of a single lymph-node region or lymphoid structure (e.g. spleen, thymus, Waldeyer ring)
II	Two or more lymph node regions on the same side of the diaphragm
III	Lymph nodes on both sides of the diaphragm
III1	With splenic hilar, coeliac or portal nodes
III2	With para-aortic, iliac, mesenteric nodes
IV	Involvement of extranodal site(s) beyond that designated 'E'
Modifying features	
A	No symptoms
B	Fever, drenching night sweats, weight loss >10% in 6 months
X	Bulky disease: more than one-third widening of mediastinum, >10 cm maximum diameter of nodal mass
E	Involvement of single, contiguous or proximal extranodal site
CS	Clinical stage
PS	Pathological stage

Bone marrow infiltration is only found in around 6% of cases (and even less in NLPHL), and bone marrow biopsy is only indicated in advanced-stage disease (IIB to IV), in the presence of cytopenias, or if mandated by a clinical trial. In otherwise localized disease, the pick-up rate for upstaging by bone marrow involvement is very low. PET positivity of infiltrated bone marrow has some concordance with histological analysis but

Figure 34.11 FDG-PET scan showing FDG avidity of large mediastinal mass.

has not been shown to correlate strongly enough to supersede its use.

Magnetic resonance imaging (MRI) is largely restricted to the evaluation of specific situations such as bony involvement or spinal cord compression.

Prognostic factors

Several attempts have been made to identify clinically relevant prognostic factors and combine them to allow risk stratification. Limited-stage disease (I and II) has been subdivided into favourable and unfavourable groups by the European Organization for Research and Treatment of Cancer (EORTC) on the basis of the number of nodal areas, age, systemic symptoms and large mediastinal adenopathy (Table 34.4). This stratification was first developed in the era when radiotherapy was the mainstay of treatment, but the EORTC H7 trial on limited-stage disease demonstrated the ongoing validity of this approach in defining favourable and unfavourable patient groups. However, the implications for treatment are still not clear, and in the UK and the USA all early-stage patients are usually managed the same way.

In advanced-stage disease, the International Prognostic Index (IPI) or Hasenclever score was developed based on an analysis of over 5000 patients treated initially with an anthracycline-containing chemotherapy regimen. Seven factors were identified, each of which reduced the 5-year freedom from progression rate by around 8% (Table 34.5).

NLPHL has a slightly better prognosis than CHL, although its potential for late relapse as a large-cell lymphoma necessitates ongoing post-treatment surveillance. A recent retrospec-

Table 34.4 EORTC risk factors in localized disease.

Favourable

Patients must have all of the following features:

- Clinical stage I and II
- Maximum of three nodal areas involved
- Age < 50 years
- ESR < 50 mm/hour without 'B' symptoms or ESR < 30 mm/hour with 'B' symptoms
- Mediastinal/thoracic ratio < 0.35

Unfavourable

Patients have any of the following features:

- Clinical stage II with involvement of at least four nodal areas
- Age > 50 years
- ESR > 50 mm/hour if asymptomatic or ESR > 30 mm/hour if 'B' symptoms
- Mediastinal/thoracic ratio > 0.35

ESR, erythrocyte sedimentation rate.

Table 34.5 Hasenclever index.

- Age > 45 years
- Male gender
- Serum albumin < 40 g/L
- Haemoglobin < 10.5 g/dL
- Stage IV disease
- Leucocytosis (white cell count $\geq 15 \times 10^9/L$)
- Lymphopenia ($< 0.6 \times 10^9/L$ or $< 8\%$ of the white cell count)

tive analysis at 4 years showed freedom from treatment failure rates for CHL and NLPHL patients of 88% and 82%, respectively, and overall survival rates of 96% and 92%. Poor prognostic factors in NLPHL have been identified as advanced stage, anaemia and lymphopenia.

Response assessment

Assessment of disease response requires repeat imaging (Figure 34.12) and, if infiltrated on staging investigations, repeat bone marrow biopsy. The utility of PET is increasingly well understood, and in any case of residual disease it can help differentiate between active disease and fibrotic material. In view of this, the previous CR(u) (unconfirmed) classification to describe residual masses of uncertain significance on CT has been eliminated. Responses to treatment are now classified as complete response (CR), partial response (PR), stable disease or progressive/relapsed disease (Table 34.6).

False-positive PET results can occur after treatment, so imaging is recommended at 3 or 6 weeks after chemotherapy

Figure 34.12 CT scan of the chest showing large residual mass at end of treatment.

Figure 34.13 PET/CT scan of same patient as in Figure 34.12 showing FDG avidity of large residual mass.

and radiotherapy, respectively. Other causes of false-positive PET results include rebound thymic hyperplasia, infection, inflammation, brown fat and extramedullary haemopoiesis. In the event of uncertainty as to the nature of the PET-positive lesion, biopsy is recommended. PET is also used in NLPHL, but it may be less reliably FDG-avid, making interpretation more difficult (Figures 34.13 and 34.14).

Interim PET to assess response and guide prognosis (e.g. after two to four cycles of treatment, after salvage treatment or before consideration of autograft or allograft) has been assessed for its value in predicting long-term response. There is evidence that negative PET at this stage can be predictive of outcome, but

Figure 34.14 PET/CT scan showing FDG-‘cold’ residual mass.

recent data from non-Hodgkin lymphomas have raised concerns about both the extent of predictive value and the degree of interobserver agreement in the interpretation of scans. Future strategies may employ a more quantitative approach, incorporating standard uptake values rather than qualitative interpretations as simple positive or negative.

At present, PET response-adapted therapies are not recommended outside of clinical trials. Post-remission surveillance with either CT or PET has not been shown to be useful in guiding treatment.

Treatment

The treatment of Hodgkin lymphoma is often called one of the success stories of cancer treatment. What was once an invariably terminal condition is now considered curable in the majority of cases. Early treatment strategies were based exclusively on radiotherapy, and the staging and prognostic systems still reflect this to an extent. Although radiotherapy resulted in high rates of remission in localized disease, relapse rates were high. Subsequent developments in field size have focused on balancing the benefits of lower relapse rates associated with larger fields with the reduced toxicity from smaller ones.

Starting in the 1940s, cytotoxic chemotherapy was introduced, initially with single agents, before the development of combination regimens. The first of these was the MOPP regimen in the 1960s, comprising mustine, vincristine (Oncovin), procarbazine and prednisolone, which was gradually adjusted to maintain efficacy but reduce toxicities. In the 1970s, an

Table 34.6 Response definitions for clinical trials.

<i>Response</i>	<i>Definition</i>	<i>Nodal masses</i>	<i>Spleen, liver</i>	<i>Bone marrow</i>
CR	Disappearance of all evidence of disease	(a) FDG-avid or PET positive prior to therapy; mass of any size permitted if PET negative (b) Variably FDG-avid or PET negative; regression to normal size on CT	Not palpable, nodules disappeared	Infiltrate cleared on repeat biopsy; if indeterminate by morphology, immunohistochemistry should be negative
PR	Regression of measurable disease and no new sites	≥50% decrease in SPD of up to six largest dominant masses; no increase in size of other nodes (a) FDG-avid or PET positive prior to therapy; one or more PET positive at previously involved site (b) Variably FDG-avid or PET negative; regression on CT	≥50% decrease in SPD of nodules (for single nodule in greatest transverse diameter); no increase in size of liver or spleen	Irrelevant if positive prior to therapy; cell type should be specified
SD	Failure to attain CR/PR or PD	(a) FDG-avid or PET positive prior to therapy; PET positive at prior sites of disease and no new sites on CT or PET (b) Variably FDG-avid or PET negative; no change in size of previous lesions on CT		
Relapsed disease or PD	Any new lesion or increase by ≥50% of previously involved sites from nadir	Appearance of a new lesion(s) >1.5 cm in any axis, ≥50% increase in SPD of more than one node, or ≥50% increase in longest diameter of a previously identified node >1 cm in short axis Lesions PET positive if FDG-avid lymphoma or PET positive prior to therapy	>50% increase from nadir in the SPD of any previous lesions	New or recurrent involvement

CR, complete remission; CT, computed tomography; FDG, [¹⁸F]fluorodeoxyglucose; PD, progressive disease; PET, positron emission tomography; PR, partial remission; SD, stable disease; SPD, sum of the product of the diameters.

alternative regimen comprising doxorubicin (Adriamycin), bleomycin, vinblastine and dacarbazine (ABVD) was developed, originally as salvage treatment for patients who had failed MOPP chemotherapy, and was designed as far as possible to contain non-cross-resistant drugs to those in MOPP. ABVD was subsequently shown to be as effective as MOPP, with lower rates of infertility and secondary leukaemias, and has become the first-line regimen of choice in most situations.

Recent trends in treatment strategy have focused on the combination of chemotherapy and radiotherapy in early-stage disease and better risk stratification in all patients. The aim is

to minimize toxicities where possible, but allow escalation of treatment in those in poorer-risk groups. A further factor is that many patients who relapse or fail to respond to initial therapy may be cured with subsequent salvage treatment, such as combination chemotherapy in relapse after radiotherapy or high-dose chemotherapy supported by stem cell autograft. This again raises issues about treatment selection, such as whether it is better to use more aggressive treatment strategies up front to minimize relapse risk or try to minimize toxicities with less intensive treatment, with the expectation that salvage treatment can be used in those who relapse.

Table 34.7 Chemotherapy regimens.

ABVD	Doxorubicin, bleomycin, vinblastine, dacarbazine
BEACOPP	Bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone
BEAM	Carmustine, etoposide, cytarabine, melphalan
ChlVPP	Chlorambucil, vinblastine, procarbazine, prednisolone
ChlVPP/PABIOE	Chlorambucil, vinblastine, procarbazine, prednisone alternating with prednisolone, doxorubicin, bleomycin, vincristine, etoposide
ChlVPP/EVA	Chlorambucil, vinblastine, procarbazine, prednisone, etoposide, vincristine, doxorubicin
ESHAP	Etoposide, cytarabine, cisplatin, methylprednisolone
GEM-P	Gemcitabine, cisplatin, methylprednisolone
ICE	Ifosfamide, carboplatin, etoposide
MOPP	Mechlorethamine, vincristine, procarbazine, prednisone
MOPP/ABV	Mechlorethamine, vincristine, procarbazine, prednisone, doxorubicin, bleomycin, vinblastine
MOPP/EBV/CAD	Mechlorethamine, vincristine, procarbazine, prednisone, epirubicin, bleomycin, vinblastine, lomustine, doxorubicin, vindesine
Stanford-V	Bleomycin, doxorubicin, etoposide, mechlorethamine, prednisone, vinblastine, vincristine

The number of different treatment options (Table 34.7) and ability to treat relapse disease has also made interpretation of trial data more complicated. Risk stratification and treatments vary widely, and long follow-up periods are required to assess long-term advantages in terms of overall survival benefit. Paradoxically, many of the best trials with robust data on long-term outcomes are hampered by the fact that treatments under investigation have often become obsolete by the time of final analysis.

Nodular lymphocyte-predominant Hodgkin lymphoma (Table 34.8)

As discussed above, NLPHL is a distinct entity and needs to be considered separately from a therapeutic standpoint. There are

no prospective randomized trials carried out specifically in NLPHL, so treatment recommendations have been more difficult to make.

Its better prognosis and tendency to present in early stage means that local treatment such as radiotherapy or even just surgical resection is often used. Surgery alone has been shown to confer an excellent overall survival rate, but there is a substantial relapse rate necessitating further treatment in many patients. A recent trial of surgery and observation alone produced a 4-year overall survival rate of 100% but progression-free survival of only 57%. Advanced disease is treated in the same way as CHL, with combination chemotherapy.

Use of the anti-CD20 monoclonal antibody rituximab is an attractive therapeutic option, and recent Phase II trials indicate response rates of 94–100% in newly diagnosed, relapsed and refractory disease, with complete response rates of around 50%. Its precise role has yet to be defined, and in the absence of Phase III trial data its use is highly variable from centre to centre.

Classical Hodgkin lymphoma: early stage

As noted above, treatment of Hodgkin lymphoma is constantly developing, and as disease control has improved, much of the emphasis is on reduction of toxicities.

Treatment of early-stage disease was traditionally with radiotherapy, but despite the impressive response rates two important problems were evident. Firstly, even the largest fields were associated with relapse rates of 20–30%, usually outside the treatment field, indicating the presence of occult metastatic disease at the time of presentation. Secondly, there were clinically significant toxicities, particularly secondary cancers and cardiac damage. In view of this, combined modality treatment was developed to try to gain the maximum benefits of both chemotherapy and radiotherapy, while minimizing the toxicities associated with both. Radiotherapy alone is nowadays only recommended for early-stage NLPHL.

Combined modality treatment (CMT) has been shown in a number of trials to give a superior progression-free survival compared with radiotherapy alone. The most recent EORTC H8 trial has also demonstrated an overall survival benefit in favourable-risk patients of 97% at 10 years compared with 92% with radiotherapy alone, albeit with a chemotherapy regimen (MOPP/ABV) that has been superseded by ABVD. Reduced rates of secondary cancers with CMT compared with radiotherapy alone were noted in a retrospective analysis of 181 favourable-group patients. This was assumed to be due to the reduced-dose radiotherapy in the CMT group.

Further trials have attempted to reduce the amount of radiotherapy by reducing dose and field size. Radiotherapy is now usually given as involved fields (as opposed to extended) and at a maximum of 30 Gy in the combined modality setting. Attempts

Table 34.8 Selected randomized trials in early-stage disease.

Study	Disease stage and treatment	Number of patients	Failure-free survival (%)	Overall survival (%)	Time (years)	Conclusion
<i>Radiotherapy (RT) vs. combined modality treatment (CMT)</i>

are ongoing to define the optimum treatment and to determine whether sites of bulky disease require additional radiotherapy boosts.

Chemotherapy regimens vary, but based on outcomes in trials of patients with advanced disease, ABVD is usually the treatment of choice. The number of cycles used at present is usually three or four, but there may be the potential to reduce this to two. There are also attempts to reduce the toxicity of the drug regimen, for example by omitting dacarbazine.

Trials have examined whether radiotherapy can be omitted completely by treating with chemotherapy alone. In two trials comparing CMT with chemotherapy alone, both following patients for 5 years, freedom from progression and overall survival rates were similar. This has led some to suggest that treating with chemotherapy alone may eventually prove to provide the best results in such patients but, in the absence of clear evidence or expert consensus, CMT remains the most widely used treatment. The ongoing UK-based RAPID trial in early-stage disease should give further guidance on the value of interim PET in guiding treatment.

Classical Hodgkin lymphoma: advanced stage (Table 34.9)

Since it was developed in the 1970s, originally as a salvage regimen for relapsed disease after MOPP, ABVD has remained the treatment of choice for most cases of advanced disease, with eight cycles of treatment standard in Europe. Canelos and colleagues demonstrated its superiority to MOPP in terms of response rate (82% vs. 67%) and 5-year failure-free survival (61% vs. 50%), although the 5-year overall survival rates were similar (73% vs. 66%). Significantly, long-term serious toxicities such as infertility and secondary cancers were reduced with ABVD, which contains no alkylating agent. ABVD has subsequently been compared with various other treatments, including alternating regimens such as MOPP/ABV, ChlVPP/PABIOE and hybrids such as ChlVPP/EVA and MOPP/EBV/CAD. In all cases, ABVD has been shown superior in terms of the balance of response and treatment toxicities.

Recently, attempts have been made to develop more intensive regimens to improve outcomes in poor-risk disease. The most

BNLI, British National Lymphoma Investigation; CALGB, Cancer and Leukaemia Group B; CR, complete remission; DFS, disease-free survival; EFS, event-free survival; EORTC, European Organization for the Research and Treatment of Cancer; FFP, freedom from progression; FFS, failure-free survival; FFTF, freedom from treatment failure; GELA, Groupe d'Etudes de Lymphomes d'Adulte; PR, partial remission.

promising of these appears to be escalated BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine and prednisone). This regimen was developed by the German Hodgkin Lymphoma Study Group, based on mathematical modelling showing a greater benefit from escalating drug doses than reducing the time interval between cycles. Increased myelosuppression was offset by the use of granulocyte colony-stimulating factor (G-CSF). Initial results in trials comparing BEACOPP with COPP/ABVD showed significantly improved outcomes in both freedom from treatment failure and overall survival. Increased toxicities have led to attempts for risk stratification in order to assess which patients required escalated BEACOPP and which could have the less-intensive BEACOPP or ABVD. This approach may well prove to be the most sensible way to proceed, especially using PET to assess initial response, but precise validated risk groups have still to be established.

The role for consolidation radiotherapy in advanced disease remains controversial. The EORTC 20884 trial showed no apparent benefit of adjuvant radiotherapy for patients who have achieved a CR with chemotherapy alone, and direct comparison of adjuvant radiotherapy with two extra cycles of chemotherapy also showed no advantage at 10-year follow-up for both disease-free survival and overall survival (GELA H89 trial). Radiotherapy may well have a role to play after less extensive chemotherapy treatment, and in patients who have only achieved a PR. It should be noted that both escalated BEACOPP and Stanford V (another more intensive regimen) make substantial use of radiotherapy as part of the treatment. For example, 85% of patients in the original Stanford trials received radiotherapy. In the 2003 escalated BEACOPP data, over 60% of all patients received radiotherapy.

The role of interim PET to guide treatment is being increasingly well understood. The German HD15 trial has demonstrated good negative predictive value of interim PET in advanced disease treated with BEACOPP chemotherapy. The impact on overall survival is not yet evaluable, but the authors have suggested that consolidation with radiotherapy could be omitted on the basis of a negative PET scan.

Relapsed and progressive disease

A proportion of patients receiving chemotherapy, either *de novo* or after radiation failure, will have refractory disease or will relapse after remission. Occasional patients can be cured by radiotherapy if the persistent or relapsed disease is localized, but the majority of patients will require systemic therapy. In patients with long first remissions, a significant proportion of patients may be cured by further standard-dose chemotherapy, but the results of such approaches are poor if the remission has been short or the disease was refractory to initial chemotherapy. In the report of the long-term follow-up of the initial cohort of patients treated with MOPP at the National Cancer Institute,

there were no survivors beyond 10 years in those who had not achieved a remission.

High-dose chemotherapy and autologous stem cell transplantation was first pioneered in relapsed Hodgkin lymphoma 50 years ago, but it is only in the last two decades that it has become an established modality of treatment. In the last decade, peripheral blood stem cells have replaced the use of bone marrow as the source of haemopoietic stem cells. In the early 1980s, the procedure-related mortality associated with an autograft was in the order of 10%, but with improved patient selection and better supportive care this has fallen to 3% or less. In large single-centre series and in registry reviews, the overall survival rates of patients receiving autologous transplantation for relapsed or resistant disease are approximately 40–50%. A number of different conditioning regimens have been used, and high-dose chemotherapy is generally preferred to total body irradiation. This is because chemotherapy is logistically easier to administer, appears as effective as total body irradiation and may be associated with less pneumonitis, particularly in patients who have received mediastinal radiation in the preceding year. Following high-dose therapy it is common practice to irradiate persistent masses or sites of previous high-volume disease, although there are no trial data to substantiate this practice.

Prior to high-dose therapy, standard-dose salvage chemotherapy is usually given to reduce disease bulk and demonstrate chemosensitivity. Regimens vary, but will consist of an alkylating agent-containing combination, with different drugs from the initial ABVD treatment (e.g. DHAP, ESHAP, IVE, ICE, GemP). In patients with progressive disease despite standard-dose chemotherapy or who have persistent 'B' symptoms or a raised lactate dehydrogenase, the risks of high-dose therapy are probably too high to justify proceeding to this course of action. However, it must be noted that in some cases a mass will not immediately shrink in size, and failure to achieve a formal response (complete or partial remission) as defined by CT should not automatically disqualify a patient from receiving an autograft.

The British National Lymphoma Investigation (BNLI) carried out a small randomized trial of treatment with carmustine (BCNU), etoposide, cytarabine and melphalan (BEAM) followed by autologous stem cell transplantation or mini-BEAM (the same drugs at lower doses) in patients with refractory or relapsed disease. There was a highly significant progression-free survival advantage in the group receiving high-dose therapy, and similar results have subsequently been reported from a larger German study. Neither study demonstrated an overall survival benefit, and this may be partly due to the small size of the trials, but may also be because some patients failing standard-dose salvage therapy can still be rescued by high-dose therapy at a later time. This raises the issue of the optimal time to consider an autograft procedure. It is widely recommended for all patients below the age of 65 years

who fail first-line chemotherapy, although this may not be appropriate if there has been a first complete remission lasting more than 3 years.

The role of allogeneic transplantation has become clearer over the last few years, with much of the evidence suggesting a move from myeloablative to reduced intensity conditioning regimens, which rely heavily on the graft-versus-Hodgkin effect. Transplant-related mortality with reduced intensity conditioning appears to be of the order of 15–25% compared with 40–60% in the older reports of myeloablative treatment. The long-term outcomes are also encouraging, with a 4-year progression-free survival of 39% and overall survival of 55%. There also appears to be a benefit from donor lymphocyte infusions: 56% of patients with progression post allograft showed a response to this treatment. At present an allograft is indicated for patients who have relapsed after an autograft. The possibility has been raised that reduced-intensity allografts should also be considered in those patients predicted to do poorly with an autograft (e.g. those who are PET-positive after salvage therapy). This approach requires further investigation.

Alternative approaches that may prove useful in selected patients are salvage radiotherapy and repeat autologous transplantation.

Treatment of Hodgkin lymphoma in childhood

Hodgkin lymphoma in children and adolescents is curable in over 90% of cases. With rising numbers of long-term survivors, the impact of long-term effects becomes increasingly important. A number of specific childhood regimens have been developed that aim to maintain these excellent remission rates but which reduce the likelihood of developing late effects.

Chemotherapy is usually combined with radiotherapy to minimize the toxicity from either modality, and risk stratification is used to avoid over-treatment of good-risk disease. Fertility can be damaged by both chemotherapy and radiotherapy, and strategies to avoid this include sperm storage (where possible) and avoidance of procarbazine in boys and moving ovaries out of radiation fields by oophoropexy in girls. Radiation can also have direct effects on bone and soft tissue, and minimizing the dose and field size can reduce the impact on growth and on the final height a developing child will reach. Reduction of anthracycline exposure can minimize cardiac toxicity in later life.

Treatment of Hodgkin lymphoma in pregnancy

Hodgkin lymphoma in pregnancy is rare, but the common presentation during adolescence and young adulthood is a sign that cases can and do arise (one estimate is 1 in 6000 pregnancies). Its treatment in pregnancy presents unique challenges in

that the well-being of the fetus as well as the mother will be affected. Pregnancy does not seem to affect outcome in treated disease, with 48 cases of Hodgkin lymphoma during pregnancy showing similar 20-year outcomes to matched controls.

Staging investigations should be limited to avoid radiation exposure; abdominal and pelvic CT is avoided if possible and PET is not recommended. All cytotoxic chemotherapy is potentially teratogenic, with the highest risks of fetal malformations in the first trimester. In the second and third trimesters the risk is lower, but there is an increased incidence of fetal or neonatal death, intrauterine growth retardation, preterm delivery and low birth weight. Radiotherapy should also be avoided during the first trimester, with uterine shielding used to reduce fetal radiation exposure.

Presentation during the first trimester is difficult to combine with a risk-free pregnancy. In these cases early delivery or termination is usually recommended, followed by standard treatment. Treatment in the second and third trimesters can be managed with normal treatment regimens, with careful monitoring of the pregnancy and ensuring delivery does not coincide with cytopenias. Occasionally in early-stage or low-risk disease, it may be possible to treat partially during the pregnancy, or even delay treatment until after delivery, to allow adequate disease control and normal pregnancy. Breast-feeding is contraindicated during staging and treatment, as drugs and contrast and nuclear imaging agents can all concentrate in breast milk.

Late effects of treatment

As the cure rate for Hodgkin lymphoma has increased and longer-term follow-up data have become available, the significance of the late effects of treatment have become more apparent. In a study of young adults aged 29 years or less at diagnosis and who achieved a stable complete remission after first- or second-line therapy, the actuarial overall survival at 20 years was 93% and 85% respectively, compared with 98.5% in the age-matched general population. In some patients treated for favourable-risk disease it has been shown that, at 12–15 years after therapy, the mortality risk related to therapy exceeds the risk of dying from Hodgkin lymphoma. The two most frequent causes of excess deaths are second malignancies and ischaemic heart disease. Patients who are hyposplenic following either splenectomy or irradiation should be on a vaccination programme and receive prophylactic antibiotics.

The overall increased risk of secondary cancers in patients with Hodgkin lymphoma is estimated at 0.4–0.7% per year. This cumulative effect explains the cancer risk rising with time after treatment. (The exception to this is secondary myelodysplastic syndrome and acute myeloid leukaemia, which peaks at 5–9 years after exposure to chemotherapy.) The commonest second malignancy is lung cancer. This is mainly attributable to radiotherapy although chemotherapy also contributes to the

risk. Patients who have had thoracic irradiation must be warned of the risk of developing secondary lung cancer and should be strongly discouraged from smoking. The risk of developing secondary acute myeloid leukaemia is related to the accumulated dose of alkylating agents received and therefore occurs predominantly in patients who have had a remitting and relapsing disease course.

The risk of secondary breast cancer is greatest in women who have received mediastinal or axillary radiation at less than 35 years of age. The risk of such patients ever developing breast cancer was as high as one in four in some series. There is also a clear dose–response relationship, emphasizing the need to use the minimal radiation dose required for tumour control. Other malignancies that occur in excess in patients treated for Hodgkin lymphoma include non-Hodgkin lymphomas, cancers of the colon, stomach, head and neck and thyroid, and malignant melanoma.

In view of these risks, it is recommended that screening for secondary malignancies is carried out as part of routine post-treatment review. Patients who received radiotherapy or alkylating agents should have annual chest radiography, and younger women should be enrolled on a breast cancer screening programme. In the UK, women who received radiotherapy that impinged on the breasts when they were under the age of 35 years are invited to attend screening from 10 years after the radiotherapy. Mammography is used in most patients but MRI is preferable in younger women and in those with denser breast tissue.

The Stanford group reported a threefold increase in relative risk of cardiac death in Hodgkin lymphoma survivors, representing a major risk given that the incidence of cardiac disease in the general population is already so high. The major contributory factor is mediastinal irradiation, especially if a dose in excess of 30 Gy is used. Chemotherapy is also associated with accelerated coronary artery disease. It is not clear which drugs cause this but anthracyclines and vincristine have both been implicated. Bleomycin exposure (as in ABVD) is associated with an 18% risk of pulmonary fibrosis, and was associated with reduction in overall survival, especially in older patients. Radiotherapy fields that included the lungs are an additional risk factor for lung injury.

The most common endocrine disorders are hypothyroidism following radiotherapy to the lower neck, and infertility. Around half of patients receiving neck irradiation will develop hypothyroidism and will need to be monitored and treated accordingly. Infertility is caused both by irradiation of the gonads and the use of cytotoxic drugs such as procarbazine and alkylating agents. It is their repeated use that is most damaging, and young female patients receiving an autologous transplant will often remain fertile if they are still menstruating prior to high-dose therapy. Sperm cryopreservation prior to chemotherapy should be offered to men who have not completed their families. Of the multidrug regimens, escalated BEACOPP causes

more infertility in both men and women than ABVD. Artificial insemination has a relatively low success rate per cycle, although intracytoplasmic sperm injection may be more successful. Hodgkin lymphoma may be sufficiently slow-growing to allow harvesting of eggs, *in vitro* fertilization and embryo storage in those young women who have an established partner. Oocyte preservation and ovarian tissue banking are currently in development and remain experimental.

The psychological trauma associated with contracting a malignant disease, receiving radiotherapy and chemotherapy, and coping with the risk of eventual relapse is considerable. A significant proportion of patients report lower perceived levels of overall health, dissatisfaction in their personal relationships, and difficulties in obtaining life assurance and financial loans as a result of the disease and its treatment. Chronic fatigue is also increased, with a raised incidence over and above that explicable by cardiovascular or thyroid toxicity.

Novel therapies

Cytotoxic drugs

Gemcitabine, an analogue of cytarabine, has been found to have antitumour activity in Hodgkin lymphoma, and of the cytotoxic drugs appears to have the most potential for augmenting the efficacy of current treatments. It is well tolerated, and response rates in excess of 35% in heavily pretreated patients have been achieved with use as a single agent. Combination regimens have been developed, including GEM-P (gemcitabine, cisplatin and methylprednisolone) which produces response rates of 60–65%.

The proteasome inhibitor bortezomib appears to be a good candidate drug based on *in vitro* studies, although it has not yet demonstrated a significant benefit in clinical trials.

Immunotherapy

As in many fields of cancer treatment, immune modulation has great potential for treatment. Monoclonal antibodies have been developed against the cell membrane proteins CD25 and CD30, including conjugates with radioisotopes (e.g. ¹³¹I). The graft-versus-lymphoma effect of donor lymphocytes seen in allogeneic transplantation has demonstrated the potential benefits of cytotoxic T lymphocytes. Attempts are being made to develop clonal populations of T lymphocytes that would target HRS cells expressing EBV-derived antigens.

Conclusion

Much progress has been made in recent years regarding both the cellular aspects of the HRS cell and the treatment of the resultant tumour. The results of therapy are extremely good, and attention must be paid to minimizing late effects of treatment. In many cases the same ultimate survival outcome can

be achieved using different therapeutic approaches. The choice depends on an appreciation of the short- and long-term side-effects, and increasingly the patient must be involved in an informed decision-making process.

Epidemiology

Frequency

The incidence of non-Hodgkin lymphoma (NHL) has increased in the Western world over recent decades, rising by 3–5% per annum. The rate of increase exceeds that of most malignancies and the reason for this is unclear. This is partially explained by the higher incidence of NHL in immunosuppressed patients but the role of environmental factors is suggested. NHL has become

the fifth most common cancer in the USA, occurring at a frequency of approximately 17.4 per 100 000.

NHL is slightly more common in males than in females, and in the USA it is more common in white people than in black people. Although NHL can occur at any age, the incidence rises considerably with age. As life expectancy increases there is a consequent increased frequency of NHL.

Geographical variations

The proportions of cases in different histological categories vary markedly from one country to another and among different racial groups. Although some of these variations may be spurious, reflecting local medical practice, real differences undoubtedly exist. For example, follicular lymphoma (FL), one of the

most common NHLs in Europe and the USA, is rare in Japan and other Far Eastern countries. In contrast, human T-cell leukaemia/lymphoma virus (HTLV)-I is much more common in the Far East (Japan) and the Caribbean islands than in Western countries.

These differences are perhaps not surprising, given the role of the immune system (from which these neoplasms arise) in constantly monitoring and reacting to antigenic factors in the environment. This must cause variations between different parts of the world in the degree to which individual cell populations in lymphoid tissue are activated, which is likely to be reflected in the frequency variations of different lymphomas.

Aetiology

In the majority of cases of NHL, the cause is not identified, although several factors are known to play a role in lymphomagenesis. A small number of lymphomas originate from chronic antigenic stimulation; for example, *Helicobacter pylori* infection appears to be a possible causative agent for the development of gastric mucosa-associated lymphoid tissue (MALT) lymphoma. Eradication of *H. pylori* with antibiotics appears to be initial effective therapy for localized gastric MALT lymphoma. Similarly, infection with *Campylobacter jejuni* has been suggested recently to be associated with the development of immunoproliferative small intestinal disease.

Viruses

Several viruses have been implicated in lymphoma pathogenesis, although none of them is directly causative in the same way as the oncogenic viruses that induce neoplasia in animals.

Epstein–Barr virus

Epstein–Barr virus (EBV) was first thought to be associated with lymphomagenesis following its isolation from endemic Burkitt lymphoma tissue, but it is now known to be a major factor causing development of NHL in immunosuppressed individuals, for example HIV-infected patients or those recovering after solid-organ/allogeneic haemopoietic stem cell transplantation (allogeneic SCT), in whom it is called post-transplant lymphoproliferative disease (PTLD). There are two forms of cellular infection by EBV: latent and replicative. In latent infection, the virus enters the cell and remains in the DNA; B cells become immortalized and acquire neoplastic potential. In replicative infection, viral particles are released from cells, whereas the cells themselves die.

It is the latent type of infection that transforms infected resting B cells into proliferating blasts. The mechanism of this remarkable effect depends on the expression of several viral latent proteins that are under the control of a master transcription factor, EBV nuclear antigen (EBNA)-2. The pattern of viral gene expression that drives this process is called the growth programme (Table 35.1).

This process can occur in the presence of the following conditions: (i) the EBV-infected cells that express the growth programme must be unable to exit the cell cycle and become resting memory B cells; and (ii) the cytotoxic T-cell response must be impeded, so that lymphoblasts would not be killed. PTLD may therefore develop when B cells (other than naive B cells) become infected and express the growth programme without being able to exit it, and continue to proliferate in the absence of effective cytotoxic T-cell response.

EBV is also associated with the development of the endemic (African) type of Burkitt lymphoma (BL), in which it is expressed by 98%. However, the exact mechanism of EBV involvement in the development of BL is unclear. None of the

Table 35.1 Transcriptional programmes used by EBV to establish and maintain infection.

Type of infected B cells*	Programme	Genes expressed	Function of the programme
Naive cell	Growth	EBNA-1 through EBNA-6, LMP-1, LMP-2A, LMP-3B	Activated B cell
Germinal centre cell	Default	EBNA-1, LMP-1, LMP-2A	Differentiate activated B cells into memory cells
Peripheral blood memory cell	Latency	None	Allows lifetime persistence
Dividing peripheral blood memory cell		EBNA-1 only	Allows viral DNA in latency programme cell to divide
Plasma cell	Lytic	All lytic genes	Replicates virus in plasma cell

*Except where indicated, the types of cell are primarily restricted to the lymphoid tissues of the Waldeyer ring.

EBNA, EBV nuclear antigen; LMP, latent membrane protein.

t(14;18)(q32;q21)	<i>BCL2</i> and IgH	Follicular lymphoma
t(3;4)(q27;q32) and variants	<i>BCL6</i> and various partners	Large B-cell lymphoma
t(2;5)(p23;q35)	<i>NPM</i> and <i>ALK</i>	T-cell anaplastic large-cell lymphoma

growth-promoting latent genes is expressed, whereas the only detected latent protein of the virus is EBNA-1. BL is characterized by deregulated activation of *MYC* oncogene (Table 35.2), resulting in a sustained proliferation mode in which cells express EBNA-1 only. EBV may therefore have a role in the development of BL. However, given the multistep process of tumorigenesis, it is actually impossible to be sure whether the final cellular or viral phenotype of BL is related to the original infected precursor.

Human T-cell leukaemia/lymphoma virus type I

HTLV-I infection affects 15–20 million individuals worldwide, although 95% of these are likely to remain asymptomatic carriers. Adult T-cell leukaemia lymphoma (ATLL) is a T-cell malignancy that occurs after a 40- to 60-year period of clinical latency in about 3–5% of HTLV-I-infected individuals. ATLL cells are monoclonally expanded and harbour an integrated provirus. Persistent oligoclonal/polyclonal expansion of HTLV-I-bearing cells has been shown to precede ATLL, supporting the fact that in ATLL tumour cells arise from a clonally expanding non-malignant cell (see also Chapter 30).

Human herpesvirus 8 (Kaposi sarcoma-associated virus)

Human herpesvirus (HHV)-8 is the causative agent of both Kaposi sarcoma (KS) and primary effusion lymphoma. It is also detected in 100% and 50% of patients with multicentric Castlemann disease who are HIV positive and HIV negative respectively. HHV-8, called also Kaposi sarcoma-associated virus (KSHV), appears to have an important role in the pathogenesis of both KS and primary effusion lymphoma, elaborating

growth factors and cytokines that promote tumour growth. It encodes putative oncogenes and genes that stimulate angiogenesis and cell proliferation, including G protein-coupled receptor promoting cell transformation and angiogenesis and ‘interleukin (IL)-6 homologous cytokine’, preventing cell apoptosis in IL-6-dependent cell lines.

The KSHV G-protein-coupled receptor (vGPCR) is a homologue of the human IL-8 receptor that signals constitutively, activates mitogen- and stress-activated kinases, and induces transcription via multiple transcription factors, including AP-1 and nuclear factor (NF)-κB. Furthermore, vGPCR causes cellular transformation *in vitro* and leads to KS-like tumours in transgenic mouse models.

KSHV also encodes a cyclin D homologue, K cyclin, which is thought to promote viral oncogenesis. The expression of K cyclin in cultured cells not only triggers cell cycle progression but also engages the p53 tumour-suppressor pathway, which probably restricts the oncogenic potential of K cyclin.

Hepatitis C virus

Hepatitis C virus (HCV) infection is associated with the development of essential mixed cryoglobulinaemia, a low-grade lymphoproliferative disorder that can progress to NHL. HCV may induce lymphoproliferation by binding to the CD81 receptor on the surface of B lymphocytes, which could lower the threshold for antigen response or induce DNA mutations and is associated with markers of lymphoproliferation. Furthermore, HCV-infected individuals have an elevated prevalence of circulating lymphocytes with abnormal chromosomal translocations associated with NHL, e.g. t(14;18).

An association between HCV infection and NHL has been examined in many retrospective case–control studies. Notably, however, there has been substantial heterogeneity in the magnitude of association across studies, with odds ratios (ORs) ranging from 2 to 10. A large cohort study of US military veterans (including 146 394 HCV-infected individuals and 572 293 uninfected individuals) demonstrated that HCV infection precedes the development of NHL and is associated with an increased NHL risk over a period of at least 7 years [hazard ratio (HR) 1.28, 95% CI 1.12–1.45]. Whether HCV is associated with an increased risk of all NHL subtypes or only certain subtypes has not been resolved. A pooled analysis of data from seven case–control studies showed associations between HCV and diffuse large B-cell lymphoma (DLBCL), lymphoplasmacytic NHL and marginal zone NHL.

Among HCV-infected patients with splenic marginal zone NHL, treatment of the HCV infection with interferon alpha-based regimens can lead to resolution of HCV and, simultaneously, regression of NHL. This observation also suggests that HCV directly contributes to lymphoproliferation in at least a subset of NHL cases. Clearance of the virus should be considered in the therapeutic algorithm for this rare lymphoma.

Immunosuppression

HIV-infected patients are at increased risk of developing NHL, and AIDS-related lymphoma is an AIDS-defining illness. This is the second most common tumour in individuals with HIV and although studies show a decline in incidence in the era of highly active antiretroviral therapy (HAART), AIDS-related lymphomas have increased as a percentage of first AIDS-defining illness. The development of AIDS-related lymphoma has been shown to be related to age, low CD4 cell count and no prior treatment with HAART. The pathogenesis is almost certainly multifactorial. The increased risk of infections with viruses such as EBV, chronic antigen exposure and cytokine stimulation arising from repeated infections result in polyclonal B-cell activation and therefore a greater chance of mutations that develop randomly during mitosis. Almost all cases of central nervous system (CNS) lymphomas and Hodgkin lymphoma diagnosed in immunosuppressed patients are EBV positive.

Lymphomas develop in less than 1% of allogeneic SCT recipients, although the risk is higher in patients receiving rigorous T-cell-depleted transplants followed by heavy post-graft immunosuppression, for example with antithymocyte globulins for graft-versus-host disease (GVHD). In heart or lung transplants, the incidence of lymphomas is as high as 4–7%. Most post-transplant lymphomas are EBV related (see above on EBV-related lymphomas). At early stages, they may be polyclonal or oligoclonal and only later become monoclonal, but the clonal nature of the proliferation does not appear to predict closely the response to immunosuppression withdrawal, which may result in spontaneous remission.

Genetic and occupational factors

Several studies have reported an increased risk of NHL in first-degree relatives of lymphoma probands compared with the general population. The temporal proximity of sibling pairs argues for environmental as well as genetic aetiology.

An increased incidence of NHL has been reported in people working in agriculture, forestry and logging industries, as well as in those involved in the metalworking, machinery, printing and publishing industry, motor vehicles and telephone communications. The risk seems to increase with employment duration and vary by histological type.

Personal use of hair dye has been inconsistently linked to risk of NHL. A study of 4461 NHL cases and 5799 controls from the International Lymphoma Epidemiology Consortium 1988–2003 has recently been reported. An increased risk of NHL (OR 1.3, 95% CI 1.1, 1.4) associated with hair-dye use was observed among women who began using hair dye before 1980. Analyses by NHL subtype showed increased risk for FL (OR 1.4, 95% CI 1.1, 1.9) and chronic lymphocytic leukaemia/small lymphocytic lymphoma (OR 1.5, 95% CI 1.1, 2.0). Occupational

exposure to specific chemicals, such as benzidine, mineral, cutting or lubricating oil, pesticides, herbicides and wood dust seem to play an important role in the development of NHL. However, the exact impact of these factors is still debated and their contribution to pre-existing genetic factors is not totally clear.

Cytogenetics and oncogenes

Cytogenetic analysis in NHL can be difficult, given the problem of isolating neoplastic cells from tissue biopsy samples for karyotypic analysis. However, several large studies suggest that nearly all cases have a cytogenetic abnormality. It may be either numerical or structural but a number of translocations are particularly interesting because of their association with specific types of lymphoma and the insights they have provided into the process of lymphomagenesis. Rearrangements frequently involve T-cell receptor (TCR) or immunoglobulin genes, which rearrange as part of the normal process of lymphoid differentiation (see Chapter 19). In some cases, the aberrant recombination may be due to structural similarities between the regions close to the breakpoints and the heptamer/nonamer recombinase-recognition sequences bordering the normally rearranging genes. The rearrangements typically cause deregulation (usually upregulation) of oncogenes brought under the influence of immunoglobulin TCR promoter and enhancer sequences (see Table 35.2).

There is some disagreement concerning the frequency of the t(14;18) translocation in FLs, but most studies report its presence in about 85% of patients. Some of the discrepancies may reflect true geographical variation, for instance in Japan the reported incidence is only 33%. The breakpoints on chromosome 18 occur at two sites, approximately 20kb apart, within or near the transcriptional unit of the *BCL2* gene. Approximately two-thirds of the breakpoints occur within 150bp, known as the major breakpoint region, in the 5'-untranslated region of the *BCL2* gene, and most of the remaining breakpoints occur 3' to this in the minor cluster region. The *BCL2* gene codes for a protein localized in the inner mitochondrial membrane, which is involved in the inhibition of apoptosis rather than the induction of proliferation. This blockade of cell death in neoplastic germinal centre cells may account for the fact that the FLs are, at least initially, slow-growing.

The usual cytogenetic abnormality in BL is a translocation involving the *MYC* gene on chromosome 8 and the immunoglobulin heavy-chain gene on chromosome 14, which is found in over 80% of cases. Although both the endemic and sporadic forms of BL have the same gross translocations, there are subtle differences at the molecular level. Variant translocations involve chromosome 8 and either chromosome 2 or 22, where the breakpoints involve, respectively, κ and λ light-chain genes. In all cases, there is upregulation of *c-Myc*, a nuclear

transcription factor involved in cell proliferation and the control of apoptosis.

The t(11;14) translocation is found in mantle cell lymphomas (MCLs). The oncogene on chromosome 11 is known as *BCL1/PRAD1* (now called *CCND1*), and encodes a D-cyclin involved in cell cycle control (Table 35.2).

The *BCL6* gene encodes a transcription factor of the zinc finger family whose precise function is unknown. It has recently been suggested that it maintains B cells in a germinal centre-like state, inhibiting B-cell differentiation. Rearrangements of *BCL6* occur in over one-third of large-cell lymphomas, and in an even higher number of cases mutations within the gene are found. The presence of *BCL6* rearrangement has been suggested to predict favourable prognosis, although not confirmed in all studies (Table 35.2).

T-cell lymphomas are less frequent than B-cell lymphomas and have been less extensively studied at the molecular level. T-cell lymphoblastic lymphomas may have abnormalities similar to those found in T-cell acute lymphoblastic leukaemia (ALL), such as abnormalities of the *TAL1* gene on chromosome 1, the *HOX11* gene on chromosome 10 and the *LMO2* gene on chromosome 11.

Anaplastic Ki-1 (CD30)-positive large-cell lymphomas are usually of T-cell origin, and in at least half of the cases there is a t(2;5)(p23;q35) translocation (see Table 35.2). The genes involved in this translocation encode a receptor tyrosine kinase called anaplastic lymphoma kinase (ALK) on chromosome 2, and nucleophosmin on chromosome 5. The resulting hybrid gene (*NPM-ALK*) encodes a hybrid protein in which about 40% of nucleophosmin is fused to the entire cytoplasmic portion of ALK. The nucleophosmin moiety not only induces ALK expression (as nucleophosmin is a ubiquitously expressed nuclear protein) but also activates the kinase through cross-linking with subsequent mitogenic activity, promoting T-cell transformation and tumour growth.

When a chromosomal translocation is found frequently in a particular lymphoma type, e.g. t(14;18) in FL, and if the breakpoint falls within a well-defined and limited region(s), polymerase chain reaction (PCR) analysis may be used to either assist in diagnosis or detect minimal residual disease. However, the clinical significance and value of such studies have yet to be determined, as it is not completely clear what the prognostic importance may be of small numbers of cells carrying this translocation in patients who are in clinical remission.

Recently, DNA microarray technology has opened new avenues for the understanding of lymphomas. By hybridization of cDNA to arrays containing more than 10 000 different DNA fragments, this approach allows simultaneous evaluation of the mRNA expression of thousands of genes in a single experiment. These data can then be used for identification of lymphoma subgroups, with a defined gene expression pattern, not previously identified by morphology, cytogenetics or molecular techniques. This approach has already provided novel insights into

different entities of B-cell NHLs; measurement of the expression of only six genes was found to be predictive of OS in DLBCL and the prognosis of FL has been related to the molecular features of tumour-infiltrating cells.

Clinical features

The median age of presentation of low-grade lymphomas and large-cell lymphomas is around 55–60 years, with a slight male predominance. In FL, the marrow is involved in about 50% of cases at diagnosis. BL often presents with extranodal disease, appearing in the jaw in Africa and as gastrointestinal disease or in other intra-abdominal sites in the West. Hypercalcaemia is frequent.

Widespread painless lymphadenopathy is more common at presentation in NHL than in Hodgkin disease and contiguous spread is not so apparent. Superior vena cava syndrome caused by a bulky mediastinal mass is also more frequent in NHL than in Hodgkin lymphoma. Hepatosplenomegaly is frequent at diagnosis.

Patients with indolent histology are less likely to have 'B' symptoms (unexplained fever of 38°C or higher, night sweats and loss of more than 10% of body weight in 6 months) than those with an aggressive histology, but this is not invariable. Some patients present with systemic symptoms without peripheral lymphadenopathy, which can result in considerable delay in diagnosis. Symptoms and signs may be due to the involvement of particular organs (e.g. skin, gastrointestinal tract, salivary glands, lungs, renal tract and CNS).

Lymphoblastic lymphoma usually occurs in children and young adults, often with thymic mass, systemic symptoms and bone marrow failure.

Laboratory investigations

Histological diagnosis from either excision or core biopsy of a lymph node, bone marrow or extranodal mass is essential (Figures 35.1–35.8). Fine-needle aspiration has been used to exclude an infection (i.e. mycobacterial) or suggest lymphoma but can lead to delay in establishing a diagnosis. Fine-needle aspiration should not be performed except in suspected cases of T-lymphoblastic lymphoma or BL, when a diagnosis can be made on the morphology and immunophenotype, and therapy can be urgent. Immunocytochemistry is now performed routinely, with cytogenetic and immunoglobulin or TCR rearrangement analysis and, more recently, DNA microarray testing in specialized units.

Anaemia at diagnosis is usually indicative of widespread disease and may reflect a non-specific manifestation of malignancy. However, it can also be due to hypersplenism or bone marrow infiltration. Occasional patients, most often those with

Figure 35.1 Anaplastic large-cell lymphoma of T-cell type.

Figure 35.2 Large B-cell lymphoma. The cells are larger than normal lymphocytes and have a round nucleus with prominent nucleoli, some adjacent to the nuclear membrane ('centroblasts').

indolent histology, have an autoimmune haemolysis. The white count is variable. Overspill of lymphoma cells into the blood is relatively frequent in late stages of indolent lymphoma and can infrequently be seen by light microscopy at diagnosis. It can be detected much more frequently using PCR. Hypoalbuminaemia is another non-specific feature associated with a systemic disturbance and is indicative of a poor prognosis. A raised lactate dehydrogenase (LDH) level is usually associated with advanced disease and is an important independent prognostic factor (Tables 35.3–35.5). Paraproteins are found in about 15% of indolent lymphomas and in a little less than 5% of histologically

aggressive lymphomas. Levels of β_2 -microglobulin have been shown to be of prognostic value in some low-grade lymphomas.

Staging

The Ann Arbor staging system, initially developed for Hodgkin disease, is used in adults with NHL (Table 35.6). Inspection of the Waldeyer ring is particularly important, and a bone marrow biopsy should be performed in all patients. Radiography, computed tomography (CT), magnetic resonance imaging (MRI) or positron emission tomography (PET) are used for initial staging of the disease and are of value in monitoring response to therapy and detection of residual disease or relapse. Using PET, fluorodeoxyglucose (FDG)-avid lymphomas include DLBCL, Hodgkin lymphoma, FL and MCL, while variably FDG-avid lymphomas include other aggressive and indolent lymphomas. As treatment differs for patients with stage I disease (DLBCL and FL) and more advanced stages, PET at diagnosis can have significant therapeutic implications. Staging laparotomy is no longer routinely performed. At the end of therapy, PET has been incorporated into the revised response criteria.

Cerebrospinal fluid (CSF) examination should be considered if there are clinical signs of CNS disease, or for patients presenting with high-grade NHL at certain anatomical sites such as paranasal sinus, breast, epidural area or testis. Cytological assessment by cytopsin and immunophenotyping should be

Table 35.6 Ann Arbor staging system.

Stage I	Involvement in a single lymph node region or single extralymphatic site
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm; localized contiguous involvement of only one extralymphatic site and lymph node region (stage IIE)
Stage III	Involvement of lymph node regions on both sides of the diaphragm; may include spleen
Stage IV	Disseminated involvement of one or more extralymphatic organs with or without lymph node involvement

considered. Intrathecal prophylaxis should be administered at the time of first CSF examination in these patients. Serology for HIV and hepatitis B virus (HBsAg, HBcAb and HBsAb) and HCV should be performed in all patients as appropriate concomitant antiviral therapy may be indicated during and after therapy.

Treatment

Treatment of NHL is mainly based on the histological findings, although therapeutic decisions are influenced by the patient's age, performance status and disease extension. The two main subtypes comprise over two-thirds of cases in the Western world: DLBCL, an aggressive lymphoma, and FL, which follows a more indolent course. There are also a number of subtypes of lymphoma with distinct clinical and pathological features and therapeutic strategies that are discussed separately. Some of the NHLs are potentially curable and thus access to timely sophisticated diagnostic services and expert clinical opinion is necessary to ensure accurate diagnosis and tailored therapy.

Particular considerations prior to therapy should include a formal assessment of cardiac function for older patients and those with a previous history of diabetes or cardiac disease if anthracycline therapy is considered. Accurate analysis of renal function is necessary before the administration of high-dose methotrexate and platinum-containing regimens.

Follicular lymphoma

Localized disease

Approximately 10–20% of patients with FL present with non-bulky localized (stage I/IIA) disease. Localized radiotherapy can cure approximately half of patients with stage I and one-quarter of those with stage IIA. Although the addition of chemotherapy

may produce better results, local radiotherapy is currently considered an appropriate approach for these cases and represents the treatment of choice in most centres. Accurate definition of the truly localized forms is therefore crucial in ensuring an appropriate treatment design for such patients. PET/CT is increasingly performed at presentation in order to help clarify stage, as FL is uniformly an FDG-avid lymphoma.

Using very sensitive tests such as PCR for the t(14;18) translocation, the majority of patients with localized disease have been shown to have low-level involvement in the bone marrow or peripheral blood. However, after treatment with involved-field radiotherapy, durable disappearance of Bcl-2/IgH-positive cells has been observed in a significant proportion of cases. Patients with localized disease, confirmed on PET/CT (and a negative bone marrow biopsy), should therefore receive involved-field radiation without undue delay, aiming not only to eliminate their symptoms but also to achieve disease cure.

Adding adjuvant chemotherapy to radiotherapy for localized disease

As most relapses following radiotherapy occur outside the radiation field, it has been postulated that a reasonable approach may be to combine radiotherapy with systemic chemotherapy, aiming to reduce relapse risk and improve cure rate.

The British National Lymphoma Investigation (BNLI) prospectively compared the outcome of patients with localized low-grade lymphoma treated with radiotherapy, with or without adjuvant continuous chlorambucil. There were no significant differences in either overall survival (OS) or disease-free survival (DFS) between the two treatment groups (maximal follow-up 18 years). Intensification of chemotherapy (e.g. CHOP; Table 35.7) also failed to improve patient outcome. Although there have been some retrospective and prospective non-randomized trials that have reported improved progression-free survival (PFS) in patients given combined modality treatment compared with radiotherapy alone, at present there are no proven data to support the addition of chemotherapy. Chemotherapy should therefore be used in such patients only after relapse.

Is there any place for radiotherapy in relapsed localized disease?

Low-dose (4 Gy) involved-field radiotherapy appears to provide a high response rate (92% overall response rate, with 61% complete responses) with durable remissions (>1 year) in patients with relapsed disease. Low-dose radiotherapy should therefore be considered in patients with recurrent localized disease, irrespective of their initial presentation.

Advanced disease

Patients with FL tend to have a highly variable outcome. Although some patients experience early progression and die of

Table 35.7 Chemotherapy protocols used in NHL.

CVP	Cyclophosphamide, vincristine, prednisolone
FMC	Fludarabine, cyclophosphamide, mitoxantrone

Hyper-CVAD	Hyperfractionated cyclophosphamide, vincristine, doxorubicin, dexamethasone
ACVBP	Doxorubicin, cyclophosphamide, vindesine, bleomycin, prednisolone

their disease in less than 5 years, others may have an indolent course and live for 15 years or longer. Conventional chemotherapy has not been shown to prolong long-term survival compared with observation. For some patients management is mainly targeted to reducing symptoms and prolonging time to progression (TTP) rather than prolonging survival. Previously FL was considered an incurable disease but it is possible that novel approaches (immunochemotherapy, radioimmunotherapy, transplantation strategies) and their combination will lead to prolonged survival and potential cure in some patients.

Patient quality of life and treatment-related side-effects should be carefully considered, especially in the background of a disease with a median survival of 10–15 years and which occurs mainly in elderly patients, whose life expectancy irrespective of disease may be less than 20 years. However, there is a risk of transformation to high-grade lymphoma of approximately 3% per annum that has significant impact on outcome.

Management therefore ranges from a ‘watch-and-wait’ approach to different kinds of chemotherapy regimens (monoclonal antibodies applied in symptomatic patients) to the experimental intensive therapies considered in younger patients that aim to prolong survival and achieve cure, for example autologous or allogeneic SCT.

What is required is a series of complementary structured randomized studies that will give proper data over a number of years. Unfortunately, newer modalities such as monoclonal antibodies with some sort of SCT will inevitably be introduced during the lifetime of an incidental patient’s disease and thus ‘skew’ the findings. It is almost impossible to study a patient over 10–15 years without allowing him or her to potentially benefit from new treatments emerging during that period.

Patients with the histological subtype FL grade 3b follow a more aggressive course and should be treated according to practice for aggressive large-cell lymphomas.

Chemotherapy for follicular lymphoma

As mentioned above, historically treatment has been unable to prolong long-term survival. Therefore, it is mainly offered to reduce symptoms and signs of the disease and improve quality of life.

A large number of patients are asymptomatic at diagnosis. Deferral of treatment in such patients seems to have no adverse impact on survival. The BNLI reported the outcome of patients with asymptomatic advanced stage III/IV low-grade lymphoma who were randomly assigned to receive oral chlorambucil 10 mg/m² continuously ($N = 158$) versus observation until disease progression ($N = 151$) (local radiotherapy to symptomatic enlarged lymph nodes was permitted in both arms). There was no significant difference in OS and cause-specific survival between the two arms. However, age below 60 years and stage III versus IV conferred a significant survival advantage. The actuarial chance of not requiring chemotherapy at 10 years was almost 20%, supporting the strategy of ‘watch and wait’ in these ‘advanced’ patients. Similarly, the Groupe d’Étude des Lymphomes Folliculaires (GELF) found no differences in OS between patients with low tumour burden randomized to prednimustine/interferon versus observation only. Results from the UK NCRI ‘Watch and Wait’ study, in which asymptomatic patients with low-volume disease are randomized between rituximab and observation, are awaited. As a rule, conservative management should be considered in asymptomatic patients in order to maintain their quality of life without unnecessary toxicity.

First-line chemotherapy for advanced-stage follicular lymphoma

Those individuals who have symptoms can receive either oral or intravenous therapies. Oral chlorambucil and cyclophosphamide, both alkylating agents, remain good therapies for those

who do not need rapid debulking of their tumour mass. The combination chemotherapeutic regimens CVP (cyclophosphamide, vincristine, prednisolone) and CHOP (cyclophosphamide, vincristine, Adriamycin, prednisolone) with rituximab (R-CHOP) are widely used. Rituximab/bendamustine has been shown to be efficacious in a randomized non-inferiority study (vs. R-CHOP) and well tolerated, with similar haematological and infectious complications but without inducing alopecia.

The role of doxorubicin-containing regimens for indolent lymphoma is controversial. There has been no direct randomized comparison between R-CHOP and R-CVP. Comparison of outcome from up-front Phase II/III studies demonstrates prolongation of response duration and higher overall response rate (ORR) and complete responses (CR) following R-CHOP, although it is not known whether this will translate into overall survival benefit. There is some evidence from retrospective studies that risk of transformation may be lower with anthracycline-based therapy though this needs confirmation. However, haematological and non-haematological (alopecia, cardiac) toxicity are greater with R-CHOP.

Nevertheless, there are some patients for whom doxorubicin-containing regimens may be appropriate, although the data to support this approach remain controversial. Grade IIIB FL is a definite indication, while those who present with constitutional symptoms, high tumour burden and elevated LDH (all parameters suggesting more aggressive disease, despite the indolent histology) may be more appropriate for doxorubicin-containing combinations.

Seven randomized controlled trials involving 1943 patients with indolent lymphomas (1480 with FL) have been included in a recent meta-analysis comparing the outcome after radiochemotherapy with chemotherapy alone. In five of the trials patients had no prior therapy. Patients treated with radiochemotherapy had better OS (HR for mortality 0.65, 95% CI 0.54–0.78), overall response (relative risk of tumour response 1.21, 95% CI 1.16–1.27) and disease control (HR of disease event 0.62, 95% CI 0.55–0.71) than patients treated with chemotherapy alone.

Purine analogues

The more recent purine analogues, fludarabine, 2-chlorodeoxyadenosine (cladribine) and deoxycoformycin (pentostatin), represent a group of potentially lymphotoxic antimetabolite agents, non-cross-resistant to alkylating agent therapy. Their activity in the indolent NHLs, particularly in the follicular subtype, may be due to their unique ability as antimetabolites to inhibit resting as well as dividing cells.

Several retrospective studies suggested a higher response rate with single-agent fludarabine compared with alkylating agent-based regimens. However, prospective randomized trials failed to confirm these results, suggesting CVP/CHVP plus interferon to be as good as single-agent fludarabine. Several retrospective/Phase I studies have suggested that fludarabine-containing

combinations (e.g. fludarabine/cyclophosphamide, fludarabine/mitoxantrone/dexamethasone) are superior to traditional alkylating agent regimens or fludarabine only, providing a higher CR rate in both therapy-naïve and relapsed patients. However, other studies failed to repeat these results, emphasizing the need for prospective randomized trials.

Fludarabine does cause immunosuppression, resulting in increased incidence of opportunistic infection necessitating prophylaxis against *Pneumocystis jirovecii*. It may also cause myelosuppression and adversely affect stem cell harvesting. However, it is usually well tolerated and its use has become much easier since the introduction of an oral formulation. Several studies performed in patients with chronic lymphocytic leukaemia and low-grade lymphoma confirmed oral fludarabine to be as effective as the intravenous formulation.

Side-effects of chemotherapy

Chemotherapy-related side-effects should be considered seriously, taking into account the historical inability of chemotherapy to improve patient survival. Chemotherapy may adversely affect quality of life, causing myelosuppression and immunosuppression with increased risk of infections. Myelodysplastic changes and increased risk of leukaemia were mainly reported with alkylating agents, although these may also be associated with fludarabine. For young patients, infertility may be a primary concern of treatment.

Interferon

Recombinant interferon alfa has been used simultaneously with initial cytotoxic chemotherapy or as maintenance therapy in patients who responded to initial chemotherapy, aiming to enhance immunological response and prolong survival. Interferon has been shown to improve DFS but the benefit did not appear to translate into improved OS, unless an anthracycline regimen was used. Benefit has not been proven in the rituximab era and therefore it is not widely used at present.

Monoclonal antibodies

The addition of the monoclonal antibody rituximab to chemotherapy regimens has been associated with improvements in response rates, PFS and OS, although it is unclear whether advanced indolent NHL can be cured without allogeneic SCT.

Rituximab is an anti-CD20 chimeric monoclonal antibody that was the first approved for NHL treatment. The cell-surface antigen CD20 is in many ways an ideal target as it is expressed by 95% of B cells in NHL but not by haemopoietic stem cells; it has a functional role in B-cell growth and also does not normally circulate as a free antigen in plasma, so the free antigen does not compete for antibody binding. Response is achieved via several mechanisms, including complement-dependent cytotoxicity, antibody-dependent cellular cytotoxicity and induction of apoptosis. Rituximab is also able to sensitize lymphoma cells to the cytotoxic activity of chemotherapy.

Table 35.8 Monoclonal antibodies in NHL.

<i>Antibody</i>	<i>Antigen</i>	<i>Conjugate</i>
Rituximab (IDEC-C2B8, Rituxan)	CD20	None
Alemtuzumab (Campath-1H)	CD52	None
Epratuzumab (hLL2)	CD22	None
Apolizumab (Hu1D10, Remitogen)	HLA-DR	None
Ibritumomab tiuxetan (IDEC-Y2B8, Zevalin)	CD20	⁹⁰ Y
Tositumomab (Bexxar)	CD20	¹³¹ I
Immunotoxins	CD19, CD22	<i>Pseudomonas</i> exotoxin A (PE38), ricin A, Shiga toxin

The efficacy and tolerability of monoclonal antibodies targeted against CD20 and other antigens expressed by lymphoma cells are also being explored (Table 35.8).

Previously untreated low-grade lymphoma

Single-agent therapy with rituximab appears to be effective in previously untreated low-grade NHL, yielding a high response rate of 62–73%, including 20–44% CRs.

A number of Phase II studies have suggested that extending therapy with rituximab maintenance schedules is associated with improved outcomes compared with rituximab induction alone. A Phase III trial comparing rituximab maintenance therapy with observation only (following rituximab induction) showed a significantly improved PFS in those who received rituximab maintenance, with no increase in treatment-related adverse events. Whether maintenance with rituximab to these complete responders can prolong survival remains to be seen and studies are addressing this.

The single-agent activity of rituximab, coupled with its distinct mechanisms of action, non-overlapping toxicity and ability to sensitize lymphoma cells to cytotoxic activity, has encouraged researchers to evaluate its combinations with chemotherapy. In a number of large Phase III trials, rituximab plus chemotherapy (CHOP or CVP) has demonstrated significant activity, achieving improvements in ORR (81% vs. 57%, with CRs of 40% vs. 10% respectively; $P < 0.0001$) and prolongation of time to treatment failure and TTP and OS compared with CVP alone ($P < 0.0001$ for both parameters).

A characteristic chromosomal translocation, t(14;18), leading to overexpression of *BCL2*, an anti-apoptotic gene that may

serve as a survival factor for lymphoma cells, is carried by 85% of patients with FL and can be detected by PCR. Achievement of molecular remission after therapy (clearance of *BCL2*-positive cells) appears to be associated with prolonged PFS and may even predict a longer OS. Various chemotherapy regimens (e.g. FND-R, CHOP-R) have yielded similar results, reporting molecular remissions with prolonged PFS. Rituximab-containing chemotherapy regimens appear to increase both clinical and molecular remission rates when compared with those usually achieved with chemotherapy only, giving grounds for optimism.

Relapsed low-grade lymphoma

Single-agent rituximab has limited efficacy in relapsed disease, providing responses in 38–59% of patients, including CR in up to 28%. However, responses are not durable and patients eventually relapse. Many studies now suggest that combination immunochemotherapy may be more effective than single-agent rituximab or chemotherapy alone and thus this treatment may be offered to patients with relapsed disease who can tolerate a combined regimen. However, results of prospective comparative trials are still needed to confirm the superiority of this strategy, especially in the setting of first-line chemoimmunotherapy. Concerns regarding the ability to mobilize stem cells after fludarabine should be taken into account if subsequent autologous SCT is considered.

A study by the German Low-grade Lymphoma Study Group compared the combination of fludarabine, cyclophosphamide and mitoxantrone (FCM) with rituximab plus FCM in patients with relapsed FL and MCL. This study was stopped early after 147 patients had been randomized when R-FCM treatment revealed a significant improvement in response rates, response duration, and survival over that of FCM alone.

Rituximab maintenance

A recent meta-analysis of randomized controlled trials that compared rituximab maintenance therapy with observation or treatment at relapse (no maintenance) has recently been published. Five trials including 1143 adult patients were included in this meta-analysis. Data for 985 patients with FL were available for the meta-analysis of OS. Patients treated with maintenance rituximab had statistically significantly better OS than patients in the observation arm or patients treated at relapse (HR for death 0.60, 95% CI 0.45–0.79). The rate of infection-related adverse events was higher with rituximab maintenance treatment (HR 1.99, 95% CI 1.21–3.27). Patients with refractory or relapsed (i.e. previously treated) FL had a survival benefit with maintenance rituximab therapy (HR for death 0.58, 95% CI 0.42–0.79), whereas previously untreated patients did not (HR for death 0.68, 95% CI 0.37–1.25). Maintenance therapy with rituximab was offered either as four weekly infusions every 6 months or as a single infusion every 2–3 months. Open questions still exist regarding the effect of rituximab

maintenance on the outcome of patients with FL, some of which are currently being evaluated in randomized clinical trials. These questions include the effects of rituximab maintenance therapy compared with rituximab at disease progression, effects of rituximab maintenance therapy in previously untreated patients with advanced FL, effects of rituximab maintenance therapy in patients with FL following rituximab and chemotherapy induction, the optimal duration of rituximab maintenance therapy, and the optimal schedule of rituximab maintenance.

Presently it is felt to be reasonable to offer rituximab maintenance to patients responding to reinduction with chemotherapy with or without rituximab regardless of whether they received rituximab with initial chemotherapy. There has been no direct comparison of rituximab maintenance with autologous or allogeneic SCT but any of these treatment options for patients who have responded to second-line chemotherapy may be considered. There are many factors to consider, such as response duration, morbidity, survival, quality of life, potential of 'cure' and financial criteria. The multidisciplinary team meeting is a venue to discuss such options but clearly involving the patient in such treatment choices is recommended.

New unconjugated antibodies and combinations of monoclonal antibodies

New monoclonal antibodies directed at different antigens expressed by lymphoma cells are being investigated, for example anti-CD22 (hLL2, epratuzumab), anti-HLA-DR (Hu1D10, apolizumab, Remitogen) and anti-CD19 monoclonal antibodies (see Table 35.8). New monoclonal antibodies directed against CD20 include ofatumumab (HuMax CD20), IMMU-106 (hA20) which has a greater than 90% humanized framework, and GA-101, a novel third-generation fully humanized and optimized monoclonal antibody. These agents are highly cytotoxic against B-cell lymphoid cells and are currently being evaluated. Veltuzumab is a humanized anti-CD20 monoclonal antibody that has significantly reduced off-rates and increased complement-dependent cytotoxicity in lymphoma cell lines.

Greater efficacy than rituximab *in vivo* has been demonstrated in preclinical lymphoma models and this agent is being assessed clinically. The combination of epratuzumab (anti-CD22) and rituximab has been shown to induce durable responses in patients with recurrent indolent NHL in an international multicenter trial. Apolizumab is a humanized IgG1 antibody specific for a polymorphic determinant found on the HLA-DR β -chain expressed by normal and malignant B cells. It has been shown to be well tolerated and effective in a proportion of patients with rituximab-refractory FL. Alemtuzumab (Campath-1H), directed against CD52, may be used in both T-cell and B-cell NHL. An increased risk of opportunistic infection (related to T-cell depletion) may limit its use and its efficacy is described separately in the relevant sections.

Combinations of monoclonal antibodies directed at different antigens may have a synergistic effect, leading to increased response rates. Various combinations are being investigated (e.g. rituximab and alemtuzumab, rituximab and epratuzumab). Data are still too limited to draw final conclusions about their potential toxicity and efficacy. In summary, there is little doubt about the efficacy of rituximab in FL, but there is still doubt as to whether any treatment significantly modifies the ultimate duration of disease.

Radioimmunoconjugates

FL is a radiosensitive malignancy and a targeted strategy using radiotherapy involves the use of radiolabelled monoclonal antibodies such as ^{131}I -labelled or ^{90}Y -labelled anti-CD20 antibodies. ^{90}Y -ibritumomab tiuxetan (Zevalin; Bayer Schering Pharma AG, Berlin, Germany) is an immunoconjugate comprising murine IgG1 and the anti-CD20 monoclonal antibody ibritumomab covalently bound to the chelator tiuxetan, which provides stable linkage to the radioisotope. Radioimmunoconjugates kill tumour cells predominantly by radioactive emission and can therefore be effective in patients who do not respond to unconjugated antibodies (e.g. rituximab). The most common radioisotopes are ^{131}I (β/γ -emitter) and ^{90}Y (a pure β -emitter) (Table 35.9). The β -particles emitted

Table 35.9 Characteristics of currently available radioimmunoconjugates used in NHL.

Characteristics	^{131}I	^{90}Y
Emission	β and γ	β
Half-life	8 days	2.5 days
Energy	–	$\times 5$
Imaging	Can be used for radioimmunoscinigraphy	Cannot be used for radioimmunoscinigraphy by conventional methods*
Stability	Rapid degradation after endocytosis	Retained stable by tumour cells after endocytosis
Hospitalization	Hospitalization	Outpatient*

*As a result of having no γ emission.

Table 35.10 Potential problems when using radioimmunoconjugates.

Requires special knowledge and can be given by an expert only
Treatment with ^{131}I (emitting γ -particles) requires hospitalization for isolation
Accumulative toxicity may limit future stem cell harvesting
Long-term toxicity unknown (possibility of secondary malignancies)

by ^{131}I and ^{90}Y radioisotopes have high penetration (over many cell diameters), allowing eradication of tumour cells that are not expressing the targeted antigen but which are adjacent to target CD20-positive cells; this is known as the 'crossfire' effect. Although ^{131}I is inexpensive and easily conjugated, ^{90}Y has five times more energy, a longer path length and a shorter half-life than ^{131}I (2.5 days vs. 8 days). A potential problem with pure β -emitters such as ^{90}Y is that dosimetry is relatively complicated. However, pure β -emitters can be given to outpatients, as there is no radiation risk for those who come into contact with them. This risk is substantially higher with γ -emitters such as ^{131}I (Table 35.10).

Radioimmunoconjugates in patients with relapsed disease

During the past decade, two products directed against the CD20 antigen, ^{131}I -labelled tositumomab and ^{90}Y -labelled ibritumomab tiuxetan, have been studied. Both products have produced response rates of 70–80% in patients with relapsed/treatment-naïve low-grade lymphoma, and 50–60% in low-grade lymphoma that has transformed into an intermediate or high-grade lymphoma. Median duration of response to a single course of treatment approached 1 year. The treatment was well tolerated. However, prolonged myelosuppression with a potential risk of long-term myelodysplastic syndrome/myeloid leukaemia was noted. A Phase III trial comparing rituximab with ^{90}Y -labelled ibritumomab tiuxetan in patients with relapsed/refractory low-grade lymphoma/transformed B-cell NHL confirmed the efficacy of radioimmunoconjugates, showing a higher response rate in those who received ^{90}Y -labelled ibritumomab tiuxetan. There was no difference in median TTP, but durable responses (≥ 6 months) were more frequent in the radioimmunotherapy arm. A recent meta-analysis demonstrated that response rates, response duration and safety profile of ^{90}Y -ibritumomab tiuxetan in elderly patients (>70 years) were similar to those of younger patients.

These agents have been used in patients prior to transplantation, with the aim of reducing disease bulk, and in some cases establishing CR before consolidation with high-dose therapy. Whether patients can achieve a similar outcome from radioimmunotherapy without proceeding to a transplant procedure is unknown.

Radioimmunoconjugates in therapy-naïve patients

Radioimmunoconjugates are particularly effective when used earlier in the disease course and in less bulky (<5 cm diameter) disease. The recently published First-Line Indolent Trial (FIT), an international randomized controlled Phase III trial, evaluated the safety and efficacy of consolidation therapy with a single dose of ^{90}Y -ibritumomab tiuxetan in 414 patients with advanced-stage FL who achieved a partial response (PR) or better with first-line induction treatment. Consolidation of first remission with ^{90}Y -ibritumomab tiuxetan was highly effective with no unexpected toxicities, prolonging PFS by 2 years and resulting in high PR-to-CR conversion rates regardless of type of first-line induction treatment (although only 15% of patients received rituximab-containing chemotherapy). Median PFS with consolidation was prolonged in all IPI risk subgroups. The most common toxicity with ^{90}Y -ibritumomab tiuxetan was haematological, and grade 3 or 4 infections occurred in 8% of patients. Whether such benefit will be seen after radiochemotherapy remains to be evaluated.

Immunotoxins

Immunotoxins are specific antibodies connected to toxins through a linker that is easily cleavable on the malignant cell surface but which is stable while the toxin circulates in the blood. For the immunotoxin to be effective, the antigen should be expressed extensively on the surface of the targeted cell, and should be able to be internalized in response to antibody binding so that the toxin can kill the cell. The most commonly used toxins (ricin A, diphtheria, *Pseudomonas* exotoxin A and Shiga-like toxin-1) kill by inhibiting protein synthesis. The efficacy and safety of most of these immunotoxins have yet to be proven. However, an anti-CD22 immunotoxin called RFB4(dsFv)-PE38 (BL22) has been recently reported to be extremely potent in patients with hairy cell leukaemia who failed cladribine (see also Chapter 29). The CD22 antigen is expressed by other lymphoproliferative disorders (i.e. MCL and DLBCL) and the BL22 immunotoxin may also be applied in these patients.

Stem cell transplantation in low-grade NHL

Autologous stem cell transplantation

Autologous SCT can prolong OS in relapsed disease and can extend PFS in first remission. With more than 10 years of follow-up, the survival curves demonstrate a plateau indicating a potential cure in certain patients. A recently published retrospective analysis by the European Group for Blood and Marrow Transplantation (EBMT) of 693 patients with follicular lymphoma who underwent autologous SCT between 1979 and 1995 reported a 15-year PFS and OS of 27 and 47% respectively. Notably, the PFS curve begins to plateau after 10 years, suggesting that some patients may be cured. Combined data from St Bartholomew's Hospital and the Dana-Farber Cancer Institute

in 121 recipients of autologous SCT in second, third or fourth complete remission also support this observation, with a survival plateau after 13 years. At 10 and 15 years, PFS of 48 and 47% and OS of 54 and 44%, respectively, were reported. A comparison of second complete remission age-matched controls showed superior OS with autologous SCT compared with conventional therapy (61% vs. 41% at 10 years; 54% vs. 30% at 15 years).

Second malignancies are the most common cause of late non-relapse mortality after autologous SCT. Although recipient age, number of prior chemotherapeutic regimens, and use of fludarabine, etoposide and alkylating agents may predispose patients to myelodysplastic syndrome (MDS)/acute myeloid leukaemia (AML), it is now clear that haemopoietic SCT independently adds to the overall risk. The inclusion of total body irradiation (TBI) into the conditioning regimen markedly increases the risk of MDS/AML. The EBMT analysis noted a fourfold increased risk of secondary malignancies at 10 years. The Dana-Farber group, who used a TBI-containing conditioning regimen, demonstrated a 16% risk of second malignancy at 10 years, even though patients underwent autologous SCT in first remission and therefore were exposed only to one prior regimen. An increased incidence of hypothyroidism, hypogonadism, infections, anxiety, depression and cardiac dysfunction were also reported.

In contrast, three studies comparing the outcome after TBI-based autologous SCT compared with further conventional-dose chemotherapy in patients responding to first-line induction chemotherapy have shown no difference in OS between the arms. The PFS benefit, seen for patients autografted in two of these studies, is balanced by an increased risk of second cancers in the autograft arm. Autografting in first complete remission is not therefore generally recommended.

Non-conjugated monoclonal antibodies, radioimmunoconjugates and autologous stem cell transplantation

It is well established that conventional chemotherapy does not prolong survival in patients with low-grade lymphoma. However, autologous SCT may improve PFS, and most patients with FL will eventually relapse due to contamination of the harvest product with lymphoma cells or regrowth of malignant cells that survived the transplantation procedure. Molecular remission before transplantation appears to be linked to increased PFS. Therefore, it is tempting to try to purge the stem cells before transplantation in order to minimize harvest contamination and reduce relapse risk. Similarly, it might be a reasonable approach to add rituximab post transplant ('mopping up'), aiming to eradicate residual cells that survived high-dose chemotherapy (ongoing EBMT Lym1 study). The efficacy of both stem cell purging/post-transplant 'mopping-up' is still debated, and results from prospective randomized trials are awaited.

Radioimmunoconjugates may also be used as part of autologous SCT in NHL, enabling the delivery of higher radiotherapy doses without significantly increasing treatment-related toxicity. Phase I and II studies have demonstrated the addition of a radioimmunoconjugate to standard conditioning regimens to be well tolerated and associated with a potential increase in efficacy. Randomized studies are ongoing and long-term follow-up will be important, given the potential for these agents to increase rates of treatment-related MDS and AML.

Allogeneic stem cell transplantation in low-grade lymphoma

Advanced low-grade lymphomas are usually incurable with conventional-dose chemotherapy. It is uncertain whether cures are possible with autologous SCT and bone marrow transplantation from a human leucocyte antigen (HLA)-identical sibling. Earlier studies suggested that allogeneic SCT using myeloablative conditioning was potentially curative, although the transplant-related mortality (TRM) was high. This strategy combines the cytoreductive effect of the conditioning agents with the alloreactive donor T cells to eliminate residual lymphoma. The problems of tumour contamination of the graft and secondary MDS/AML are not concerns compared with autologous SCT.

Reduced-intensity SCT is being increasingly used for various kinds of haematological malignancies, aiming to exploit the curative potential of this modality by inducing a graft-versus-tumour effect without the morbidity and mortality associated with conventional transplantation. Several retrospective studies have suggested this approach to be less toxic and potentially curative in patients with low-grade lymphoma. At 2–5 years of follow-up, OS rates are at least comparable to those obtained with myeloablative regimens. In an Italian multicentre study a relapse risk of 14% and 3-year OS of 88% were observed for patients with FL. This outcome is similar to that described by a UK group, although different rates of acute and chronic GVHD reflect differences in prophylaxis (T-cell depletion).

Treatment of transformed follicular lymphoma

There is approximately a 3% per annum risk of transformation of FL to a more aggressive phenotype. In the pre-rituximab era the outcome after chemotherapy was generally poor, with median survival of 1.2–1.8 years reported. Consideration for autologous SCT after chemotherapy was thus advocated and in small Phase II studies 30% survival at 5 years has been described. Although published data are scant, outcome appears to be improved after rituximab, CHOP or other combination chemotherapy regimens, especially for patients who had received no prior therapy for their low-grade disease and who achieve complete remission following treatment of the transformed disease. Thus autologous SCT is commonly withheld in this subgroup. Allografting using reduced-intensity conditioning is another option and its efficacy described in small series, with a 60% OS at 4 years observed in chemosensitive patients.

Suggested algorithm for therapy of low-grade NHL (mostly follicular lymphoma)

Localized disease

- Use of involved-field radiation

Disseminated disease (stage III/IV)

- *Asymptomatic patient.* In asymptomatic patients a 'watch and wait' policy is generally appropriate. Younger patients with advanced asymptomatic disease may be considered for clinical trials (e.g. BNLI trial: rituximab in patients with stage III/IV asymptomatic low-volume FL).
- *Symptomatic patient.* Use of chemotherapy and/or immunotherapy to relieve symptoms. Treatment regimen should be chosen according to patient's performance status and age. The efficacy of maintenance rituximab is presently being evaluated.
- *Relapsed disease.* At the time of relapse it is important to evaluate the patient's symptoms and rule out biological progression as identified by histological evidence of progression, asynchronous growth in prior disease sites, appearance of 'B' symptoms and high LDH. Patients who have previously achieved a prolonged response to alkylating agents may be retreated, whereas those who failed to respond or progressed quickly may benefit from purine analogue-based therapies, with the concomitant administration of monoclonal antibodies. The addition of maintenance rituximab has improved results even further. Histological evidence of transformation or clinical suspicion of more aggressive disease indicates the need for anthracycline-containing regimens.
- *Further intensification of treatment.* Autologous SCT may be valuable in patients beyond CR1, providing a prolonged DFS and OS. Autologous SCT may be considered for patients who have histological evidence of transformation and who had received prior therapy for low-grade disease. Younger patients with progressive disease may be considered for allogeneic SCT, the only potentially curative therapy for patients with advanced disease. Useful outcomes have been seen in patients undergoing reduced-intensity allogeneic SCT.

Marginal zone B-cell lymphoma

The term 'marginal zone lymphoma' refers to three closely related lymphoma subtypes: nodal, primary splenic and extranodal lymphomas of mucosa-associated lymphoid tissue (MALT) (see Chapter 33). MALT lymphomas are the most common, representing about 7% of NHLs, of which at least one-third present as primary gastric lymphoma. These lymphomas are characterized by mature B cells lacking expression of CD5 and CD10.

MALT lymphoma

Staging

Up to 25% and 46% of patients with gastric and non-gastric MALT lymphoma respectively have disseminated disease at presentation so more extensive staging is indicated, including gastroduodenal endoscopy with multiple biopsies. For patients presenting with gastric MALT lymphoma, consideration should be given to endoscopic ultrasound for evaluation of depth of infiltration if this is not evaluable by CT. It is essential to assess the *H. pylori* status in all cases (see below). Wherever possible, the t(11;18) status, which is positive in about 30–40% of cases, should also be determined as this is of prognostic and therapeutic value.

Treatment

Helicobacter pylori infection appears to be a possible causative agent for development of gastric MALT lymphoma. Eradication of *H. pylori* with antibiotics appears to be initial effective therapy for localized gastric MALT lymphoma. Preliminary analysis of the LY03 trial (International Extranodal Lymphoma Study Group, the United Kingdom Lymphoma Group and the Groupe d'Etude des Lymphomes de l'Adulte) confirmed that at least half of the cases treated with antibiotics achieve histological complete remission. Median time for optimal response is 6 months, but some patients require 24 months to achieve complete remission. Response rate is highest in those whose disease is restricted to the mucosa (78%) and in those who have no nodal involvement by endoscopic ultrasonography. The extent of tumour penetration into the gastric wall is inversely correlated with complete remission rate.

Based on these data it seems reasonable to treat localized disease with antibiotic therapy, followed by strict endoscopic follow-up, including multiple biopsies 2 months after therapy to confirm eradication of bacteria, with repeated endoscopies and biopsies at least twice per year for 2 years to confirm histological regression of the tumour.

Histological complete remission does not necessarily predict cure: PCR for the detection of monoclonality remains positive in approximately half of those who achieve histological complete remission, suggesting suppression but not eradication of the lymphoma clone. In cases of unsuccessful eradication of *H. pylori* (PR/resistance disease), a second-line high-dose antibiotic regimen containing three or four drugs, one of which should be omeprazole (e.g. omeprazole, bismuth citrate, metronidazole, tetracycline), should be administered. Those patients whose tumour fails to regress despite second-line therapy frequently express t(11;18) or t(1;14) and those who present with *H. pylori*-negative localized gastric lymphoma may still respond to chemotherapy (e.g. oral cyclophosphamide/chlorambucil), immunotherapy (monoclonal antibodies), radiotherapy or more rarely surgery, or combinations of these treat-

ments. Data from small series suggest low-dose radiotherapy to be highly effective for patients with stage I/II disease, providing a 5-year DFS of 93%. At present there are no prospective randomized trials comparing these modalities.

Surgical resection is not recommended because the frequent multicentric nature of MALT lymphomas necessitates radical surgery with its attendant morbidity. Patients with advanced-stage disease are unlikely to be cured with antibiotics only and are therefore treated with systemic chemotherapy/immunotherapy up-front.

Splenic marginal zone lymphoma (with or without villous lymphocytes) and nodal variant

Splenic marginal zone lymphoma (SMZL) often presents as splenomegaly with bone marrow and peripheral blood involvement, with associated cytopenias, whereas lymph nodes/extranodal sites are usually spared. SMZL is characterized by micronodular infiltration of the spleen with marginal-zone differentiation; the immunophenotype usually shows cells positive for IgM and pan B antigens and negative for CD5, CD10, CD23 and cyclin D1, with variable expression of IgD, cytoplasmic immunoglobulin and CD43 (described further in Chapter 33).

It generally tends to have an indolent course; however, autoimmune complications are often associated with tumour progression, with increase of blastic forms and shorter survival. The median survival is around 10 years and more than 60% of patients are alive at 5 years. Approximately 10% of cases undergo transformation to DLBCL. To date no definitive curative therapy has been established and thus therapeutic intervention is generally reserved for patients with symptomatic active disease.

Splenectomy is considered to be the treatment of choice for symptomatic patients (pain, cytopenias), resulting in correction of pancytopenia and improvement in quality of life. Up to half of patients do not require further therapy. Retrospective studies have reported better OS in splenectomized patients than those treated with chemotherapy, although this may reflect selection bias. In the majority of evaluable cases a worsening of both the degree and pattern of bone marrow infiltration after splenectomy has been observed. A change in intrasinusoidal to nodular infiltration has been reported.

The utility of purine analogues with or without anti-CD20 antibodies has to be clarified in prospective trials, although retrospective data suggest these modalities to be effective.

Non-gastric MALT lymphoma

MALT lymphoma can also occur in salivary glands, skin, thyroid, conjunctiva, orbit, larynx, lung, breast, kidney, liver

and prostate; in these cases it tends to have an indolent course. Treatment should be tailored to the patient, considering the site of disease and the patient's symptoms. Management therefore ranges from a 'watch-and-wait' policy, through various kinds of therapy, including chemotherapy, monoclonal antibodies (e.g. rituximab) and radiotherapy, to surgery.

A number of reports have suggested an association between ocular adnexal MALT lymphoma and *Chlamydia psittaci*, although this has precipitated much debate. However, there is wide variability (0–80%) in the seroprevalence of *C. psittaci* in series of ocular adnexal lymphomas, which may partly reflect methodological differences among published studies. Responses to doxycycline have been documented in the treatment of ocular MALT lymphoma and this agent may be considered, although the time to response may be prolonged.

Waldenström macroglobulinaemia

Waldenström macroglobulinaemia (WM) is a clinical syndrome occurring in most patients with a lymphoplasmacytic lymphoma, rather than a specific pathological diagnosis. WM represents a clonal expansion of post-germinal centre lymphoid cells expressing IgM, CD19 and CD20. The morphological, immunophenotypic and genetic features are described in Chapter 33.

High IgM levels may cause hyperviscosity syndrome, manifested as fatigue, headache, blurred vision, mucosal bleeding, impaired cognition or coma. Other clinical manifestations include haemostatic abnormalities, polyneuropathies (which may be related to anti-myelin-associated glycoprotein antibodies), cryoglobulinaemias, cold agglutinin haemolytic anaemia and the consequences of tissue deposition such as amyloidosis. Depending on the degree of marrow infiltration, patients may present with mild anaemia or with severe pancytopenia. Progressive anaemia is the most common indication for initiation of treatment. Approximately one-third of patients present with lymphadenopathy, splenomegaly or hepatomegaly.

Factors predictive of poor prognosis include age over 65 years, anaemia, thrombocytopenia, serum monoclonal protein concentration above 70 g/L and raised levels of β_2 -microglobulin. These factors form the basis of the International Prognostic Staging System for WM (IPSSWM).

Patient management ranges from 'watch and wait' for asymptomatic patients, through various types of chemotherapy (e.g. alkylating agents with or without steroids, CHOP, purine nucleoside analogues), monoclonal antibodies (e.g. rituximab) and immunomodulators (e.g. thalidomide), to autologous/allogeneic SCT. Patients presenting with hyperviscosity also need adjuvant plasmapheresis.

Chemotherapy

Alkylating agents (e.g. chlorambucil) with or without prednisolone have been the mainstay of treatment for patients with symptomatic WM, producing remissions in 50–75% of patients. Responses are usually slow and toxicity minimal provided the dose is adjusted for cytopenias. Response rates of 60% and median survival of about 60 months have been observed. Combination chemotherapy (CHOP or CVP) produces comparable response rates to single-agent alkylating agents and more rapid responses, but with greater toxicity. The advantages of regimens such as CHOP include the rapidity of response and the lack of compromise to subsequent stem cell harvesting.

Purine analogues (e.g. fludarabine and cladribine) appear to be active in both previously untreated patients and those who fail to respond to alkylating agents/relapsed disease, providing response rates of 38–85% and 30–50% respectively. One disadvantage of purine analogue therapy is the prolonged lymphopenia that results, with consequent risk of opportunistic infections. Prophylaxis against opportunistic infections (acyclovir and co-trimoxazole or pentamidine) during therapy and for approximately 6 months following completion of treatment is essential. Another concern is the recent reports suggesting an increased incidence of Richter transformation and development of secondary MDS/AML in WM patients treated with nucleoside analogue-containing regimens. These data favour limiting exposure of WM patients to nucleoside analogues, particularly younger patients.

Monoclonal antibodies

Several studies have shown rituximab to be active in WM, providing responses in up to 35% of previously untreated patients. However, rituximab can cause a sudden rise in serum IgM and viscosity in certain patients, which may lead to complications; therefore, close monitoring of these parameters and symptoms of hyperviscosity is recommended during therapy. Similarly, ⁹⁰Y-ibritumomab tiuxetan (Zevalin) is likely to be effective and a Phase I trial evaluating this monoclonal antibody in patients with WM is ongoing. Rituximab is commonly added to chemotherapy schedules with reported improvement in outcome.

Stem cell transplantation for Waldenström macroglobulinaemia

Several small studies have reported encouraging results with autologous SCT in heavily pretreated patients, providing high response rates (95%), with improved PFS in some patients. However, at least half of these patients relapse, and the impact of this approach on long-term survival is not known. Allogeneic SCT does produce prolonged remissions with potential cures compared with autologous SCT, but TRM approaches 40%. Future strategies in WM will include a plan to evaluate the role

of autologous SCT along with biological agents (e.g. rituximab purging), maintenance strategies (including immunotherapy) and evaluation of non-myeloablative regimens containing fludarabine to achieve higher response rates and improve survival.

Novel therapies

Agents with efficacy include bortezomib, immunomodulatory drugs (thalidomide, lenalidomide), sildenafil (Viagra), Akt inhibitors and novel monoclonal antibodies and have been described in a number of small studies. A combination of these agents with chemotherapy may increase treatment efficacy, inhibiting diverse pathways that are important for tumour growth and survival.

Guidelines for Waldenström macroglobulinaemia

The Fourth International Workshop on WM, a consensus panel, published its recommendations for the treatment of patients with WM in 2009.

- 1 First-line combinations such as rituximab with nucleoside analogues with or without alkylating agents or with cyclophosphamide-based therapies (CHOP) or the combination of rituximab with thalidomide are recommended. Limiting exposure to nucleoside analogues is recommended in younger patients because of the reports of the associated increase in incidence of Richter transformation and development of secondary MDS/AML.
- 2 Patients with relapsed disease can be treated with an alternative first-line agent or with the same agent again. Thalidomide with or without chemotherapy can also be considered at relapse. In the salvage setting, reuse of a first-line regimen or use of a different regimen should be considered along with bortezomib or alemtuzumab.
- 3 Autologous SCT may be considered for patients with refractory or relapsing disease. However, patients considered for autologous SCT may fail mobilization following treatment with alkylating agents or nucleoside analogues.
- 4 Allogeneic transplantation should only be undertaken in the context of a clinical trial.
- 5 Plasmapheresis should be considered as interim therapy until definitive therapy can be initiated.
- 6 The panel reaffirmed its encouragement of the active enrolment of patients with WM onto innovative clinical trials whenever possible.
- 7 Patients should be stratified according to the IPSSWM.

Mantle cell lymphoma

This represents approximately 5–10% of NHLs, with a median age at presentation of 60 years. The majority of patients have

advanced-stage disease at the time of diagnosis, with approximately 80% having stage IV disease, 50% having gastrointestinal involvement and 70% bone marrow involvement. The MIPI score (see Table 35.5) is a combined clinical and biological score devised by the European MCL Network after a retrospective analysis of 350 patients.

Typically, patients have a short response to treatment with frequent relapses and a median survival of 3–5 years. However, a minority (10–15%) of patients appear to have more indolent disease and are long-term survivors, suggesting a ‘watch-and-wait’ approach should be considered at diagnosis.

Conventional chemotherapy regimens do improve PFS, but rarely lead to cure. None of the following chemotherapeutic regimens – CVP, CHOP, MCP, fludarabine, bendamustine – seem to be significantly better than any other, providing an OS of only 3–5 years. The addition of rituximab to these regimens appears to improve remission rates but does not influence PFS or OS. A number of studies are addressing the merit of rituximab maintenance but this is unproven to date.

An alternative approach for patients who are fit for more intensive strategies is the Hyper-CVAD multidrug regimen, which incorporates high doses of methotrexate and cytarabine, and rituximab. Efficacy with this regimen was first described by the group at the M.D. Anderson Cancer Center who have recently reported a 7-year OS of 68% for patients under 65 years. Multicentre Phase II trials using this regimen performed by the Southwestern Oncology Group (SWOG) and researchers in Italy have not reproduced these impressive results, with 22–42% of patients not completing treatment due to toxicity.

The efficacy of another intensive approach has recently been described by the Nordic group in their MCL2 study. This incorporates intensive immunochemotherapy using ‘maxi-CHOP’, high-dose cytarabine and rituximab, and is consolidated by *in vivo* purged SCT. A 5-year OS of 74% was reported although the follow-up is short. A majority of patients achieved PCR negativity after SCT, which was associated with prolonged response duration.

Similar efficacy of up-front autologous SCT after chemoimmunotherapy (CHOP, high-dose cytarabine and rituximab) and *in vivo* purging has also been described recently in Phase II studies by the Groupe de l’Etude des Lymphomes de l’Adulte (GELA) and an Italian multicentre report. Prolonged follow-up of 10 years in the latter has shown that 71% of 28 patients are alive, with 50% of patients disease-free. A number of groups are also assessing the efficacy of maintenance rituximab after autologous SCT. The European MCL network has also identified that the achievement of molecular remission, after immunochemotherapy with or without autologous SCT, is a strong prognostic factor in patients with MCL.

Allogeneic transplantation is also considered for patients with MCL, although it is not standard practice to perform this up-front and is generally reserved for patients with relapsed disease. A retrospective analysis of reduced-intensity allogeneic

SCT for MCL reported to the EBMT identified 279 patients transplanted between 1998 and 2006. At 1 and 3 years OS was 60% and 43% and PFS 49% and 29% respectively. Survival was significantly worse for patients with a poor performance status, refractory disease or those transplanted before 2002. The M.D. Anderson Cancer Center has recently reported the outcome of 30 patients, with disease beyond first remission, undergoing an allograft using fludarabine, cyclophosphamide and rituximab as a preparative regimen. Durable remissions were observed and a PFS of 5–9 years described. Donor chimerism of 95% or more was associated with disease control, while chronic GVHD was a major cause of TRM.

For patients who have previously received standard salvage regimens, novel agents such as mTOR inhibitors, bortezomib, immunomodulatory agents (lenalidomide and thalidomide) and flavopiridol have been used with reports of efficacy. Multicentre Phase II and III studies of the mTOR inhibitor temsirolimus (CCI-779) involving patients with relapsed or refractory MCL have been recently reported. ORRs of 22–38% have been described. Median duration of response of 7.1 months and median OS of 13.6 months were reported. Adverse effects were predominantly haematological and thrombocytopenia was the most frequent cause of dose reduction. Other mTOR inhibitors are being evaluated in Phase II studies. Whether the outcome of patients can be improved by combining an mTOR inhibitor with other agents while maintaining an acceptable safety profile is the subject of ongoing and future clinical trials.

A number of multicentre Phase II studies of bortezomib in patients with relapsed or refractory MCL have reported ORR of 33–47%. A median duration of response of 9 months and median time to progression of 6.2 months have been described. The most common adverse effects are peripheral neuropathy, fatigue and thrombocytopenia. Lenalidomide, an agent with antineoplastic, anti-angiogenic, pro-erythropoietic and immunomodulatory properties, has also been used for patients with relapsed and refractory MCL. A Phase II trial involving 15 MCL patients described an ORR of 53%, median duration of response of 13.7 months and median PFS of 5.6 months. The toxicities of therapy were predominantly haematological, but manageable with dose reduction or dose interruption. Flavopiridol, a cyclin inhibitor, and other specific cyclin-dependent kinase inhibitors have been shown to be biologically active and are being evaluated in MCL patients.

Aggressive B-cell NHL

Treatment of DLBCL is mainly based on anthracycline-containing combinations, with or without adjuvant radiotherapy. However, there are some variations in treatment related to patient age, performance status, stage, disease bulk (<10 cm vs. ≥10 cm), IPI risk group and presence of primary extranodal

disease (see Table 35.3). The other histological entities, anaplastic large-cell lymphoma and grade 3b FL, are treated similarly.

A large international trial has suggested that in patients under 60 years of age, the presence of two of the following risk factors – raised LDH, stage III or IV and poor performance status – predicts a lower chance to achieve CR and increased risk of relapse (see Table 35.3).

Localized disease: non-bulky stage I, with no additional risk factors

The BNLI reported a 10-year DFS and OS of 35% and 67%, respectively, in 243 patients who were treated with local radiotherapy for stage I/IE disease. In patients younger than 60 years ($N = 140$), the actuarial cause-specific death approached 80%. It is therefore quite clear that local radiotherapy is insufficient and systemic treatment such as chemotherapy is necessary.

A significantly improved DFS and OS in patients who received combined modality treatment with a brief chemotherapy course (three cycles of anthracycline-containing regimen) followed by radiotherapy has been reported in a prospective randomized trial. Patients with non-bulky stage I disease with no additional risk factors (age >60 years, elevated serum LDH, performance status 2–4) have a 5-year OS of 94%. Patients with at least one of the above adverse risk factors have a 5-year OS of around 70%. One randomized study has shown that the outcome for patients older than 60 years with limited-stage disease and no risk factors is equivalent after four courses of R-CHOP chemotherapy to that after four courses of CHOP chemotherapy and involved-field radiotherapy. Consideration of this approach may be appropriate if radiotherapy is not thought feasible.

Stage II–IV disease

Patients with more advanced-stage disease should receive combination chemotherapy. It is now over 30 years since the doxorubicin-containing CHOP regimen was first introduced. Despite a CR rate of 60–70%, less than 40% remain disease-free at 5 years from diagnosis. Since that time, different chemotherapy regimens have been introduced (e.g. MACOP-B, m-BACOD; see Table 35.7), although none of them has proved superior to CHOP. Several prospective studies have failed to show any advantage of intensified regimens over CHOP, supporting the continued use of CHOP in DLBCL. A collaborative study by SWOG/Eastern Cooperative Oncology Group (ECOG), comparing CHOP with three different intensified regimens (MACOP-B, m-BACOD and Pro-MACECytabom), showed no survival advantage of any of these regimens compared with CHOP. However, it should be noted that most of the Phase III studies have compared CHOP with various chemotherapy regimens that contained a lower dose of doxorubicin and/or cyclophosphamide, two of the most potent drugs in DLBCL

therapy, which may partially explain the inferiority of these combinations.

Adjuvant immunotherapy has been shown to significantly improve patient outcomes. A prospective randomized trial performed by GELA in 399 elderly patients with previously untreated DLBCL demonstrated a significant advantage for CHOP-R over CHOP alone. Patients in the CHOP-R group had a higher CR rate (75% vs. 63%, $P < 0.005$), improved PFS (2-year disease progression of 9% vs. 22%, $P < 0.007$; 2-year relapse rate of 14% vs. 25%, $P = 0.002$) and increased OS (2-year OS 70% vs. 57%, $P < 0.007$), with no significant increase in treatment-related toxicity. This study identified CHOP-R as the gold-standard therapy in elderly patients with DLBCL. These results were corroborated in young patients with good-prognosis DLBCL in the MInT study.

The German High-Grade NHL Study Group (Deutsche Studiengruppe Hochmaligne Lymphome; DSHNHL) also demonstrated the efficacy of shortening intervals between CHOP from 3 weeks to 2 weeks (CHOP-14). This approach was also shown to improve the outcome of patients, notably without relevant additional toxicity. More recently, the RICOVER-60 study, performed by the DSHNHL, demonstrated that six cycles of R-CHOP-14 significantly improved event-free survival (EFS), PFS and OS over six cycles of CHOP-14 treatment for patients over 60 years with DLBCL. No further benefit was observed after eight cycles of chemoimmunotherapy.

Prophylactic therapy to the central nervous system

Patients with DLBCL who present with a high IPI score (particularly those with high LDH and/or extranodal disease) are at higher risk for CNS relapse and should therefore receive CNS prophylactic therapy (see CNS prophylaxis, p. 681).

Adjuvant radiotherapy

The role of adjuvant radiotherapy in DLBCL remains controversial. Although this kind of radiotherapy is recommended at present for patients with stage I/II disease, it is unclear if adjuvant radiotherapy has any benefit in patients with advanced (stage III–IV) bulky disease, who have completed six to eight cycles of systemic combination chemotherapy.

The maximum tumour (bulk) diameter (MTD) has been shown to be an adverse factor affecting outcome in many studies. Arbitrary cut-off points for bulky disease have been set between 5 cm and 10 cm, depending on clinical considerations, although a recent study in the rituximab era has identified a cut-off point of 10 cm to delineate those patients with bulky disease. The addition of rituximab decreased but did not eliminate the adverse prognostic effect of MTD in this study performed in young patients with good-prognosis DLBCL (MInT study).

Radiation may cause short- and long-term side-effects and therefore minimal effective doses should be delivered, aiming to minimize toxicity (e.g. salivary glands, orbital structures, lung, heart).

Up-front autologous stem cell transplantation

The merit of up-front (performed in CR1) autologous SCT is unproven. A meta-analysis of 15 randomized controlled trials including 3079 patients has recently been published. Overall treatment-related mortality was 6% in the group receiving autologous SCT and was not significantly different from that of the group receiving conventional chemotherapy (OR 1.33, 95% CI 0.91–1.93; $P = 0.14$). Thirteen studies including 2018 patients showed significantly higher CR rates in the group receiving autologous SCT (OR 1.32, 95% CI 1.09–1.59; $P = 0.004$). Despite higher CR rates after autologous SCT there was no OS or EFS benefit compared with conventional chemotherapy. The pooled HRs were 1.04 (95% CI 0.91–1.18; $P = 0.58$) and 0.93 (95% CI 0.81–1.07; $P = 0.31$) respectively. Subgroup analysis of prognostic groups according to the IPI did not show any survival difference between those receiving autologous SCT and controls in 12 trials, although there was suggestive but inconclusive evidence that poor-risk patients may benefit from autologous SCT. Whether the response of histological subtypes ('activated B cell subtype' vs. 'germinal centre') is different is unclear at present and may warrant evaluation. Further assessment of the role of autologous SCT for high-risk patients should be conducted in large trials with harmonized procedures and definitions, which would facilitate the comparability of results and improve the assessment of its value.

Autologous stem cell transplantation in relapsed and primary refractory disease

Once a patient has failed initial chemotherapy, the prognosis is poor and long-term OS is less than 10%. The prospective randomized multinational Parma trial demonstrated the superiority of intensified treatment in patients with sensitive relapse, providing a significantly longer EFS than those treated with chemotherapy. However, high-dose therapy followed by autologous SCT is effective only in those who have shown some response to conventional-dose second-line (salvage) chemotherapy prior to autologous SCT (PR or chemoresponsive relapse). A retrospective UK study of 57 lymphoma patients (26 with histologically aggressive NHL) identified that of 16 patients with progressive disease after first-line salvage, only one patient (4%) subsequently responded to second-line salvage regimens. The PFS and OS at 3 years in this subgroup was only 4%. Since patients who progress on first-line salvage therapy have a very low chance of responding to a second-line salvage regimen, they should therefore be considered instead for experimental therapies.

The subgroup of patients that fails to respond to induction is defined as 'primary refractory disease'. Attempts to overcome this biological resistance, by early autologous SCT, have failed to achieve better results than conventional chemotherapy. Autologous SCT should therefore be limited to those who respond to second-line chemotherapy.

The role of PET following second-line chemotherapy prior to autologous SCT has been evaluated in a number of studies. A positive FDG-PET scan before autologous SCT has been correlated with inferior PFS and OS and an increased risk for relapse.

Allogeneic stem cell transplantation in aggressive NHL

Some patients are likely to have a very poor prognosis with conventional therapy, including those who failed autologous SCT, those presenting with a very high IPI and those with special subtypes of aggressive NHL (e.g. $\gamma\delta$ T-cell NHL). Such patients may be considered for allogeneic SCT. Several reports have suggested allogeneic SCT to be potentially curative in high-risk patients with chemosensitive disease. There is no certainty regarding the existence of a strong graft-versus-leukaemia effect in intermediate/high grade of the disease, whereas mortality following transplantation remains high, indicating that this treatment should be reserved for selected patients only.

There are scant data available at present regarding the role of low-intensity SCT in aggressive NHL, although a number of recent reports suggest there is a role for this approach. Although a relatively high TRM (32%) and a high relapse rate (33%) have been reported, the 4-year OS was 44% for patients with *de novo* DLBCL that was chemotherapy sensitive before reduced intensity transplantation. Chemotherapy-refractory patients had a poor outcome. The majority of patients included in these studies had very advanced disease, received multiple lines of therapy and failed a prior autologous transplantation procedure, which might have adversely affected results. There is little evidence to support a clinically relevant anti-DLBCL effect secondary to donor lymphocyte infusions from these series. Further studies that explore low-intensity SCT in earlier stages are ongoing.

Primary mediastinal B-cell lymphoma

Primary mediastinal B-cell lymphoma (PMBL) is a discrete clinicopathological entity, representing less than 3% of all non-NHL cases. The disease affects females more frequently than men, and peaks in incidence in the third and fourth decades. Molecular analyses have revealed it to be distinct from other types of large B-cell lymphoma. PMBL typically presents with a bulky mass in the anterior mediastinum and symptoms related to local compressive effects are not uncommon.

Initial therapy is critical in treating PMBL as salvage therapy for recurrence or progressive disease is of limited efficacy. However, this creates a challenge in delivering the most effective therapy while minimizing the long-term sequelae in a young patient population. Retrospective analyses suggest patients with PMBL may respond better to third-generation multiagent chemotherapy regimens (i.e. MACOP-B and VACOP-B) than to CHOP. The addition of rituximab may mitigate such differences and may also diminish the role of consolidation radiotherapy.

Intravascular large B-cell lymphoma

Intravascular large B-cell lymphoma is an extremely rare form of NHL and is characterized by an accumulation of large neoplastic B cells within blood vessel lumina. These lymphomas preferentially affect the elderly and involve the CNS, reported in approximately 30% of patients, lungs and skin. Prognosis is generally poor. Patients presenting with only skin lesions appear to have a significantly better survival than patients with other clinical presentations (3-year OS 56% vs. 22%). Multiagent chemotherapy using agents with higher CNS bioavailability is the preferred mode of treatment. The role of autologous SCT in younger patients with unfavourable features is being explored.

Extranodal lymphomas

At least 25% of NHLs arise from tissues other than lymph nodes, including sites that normally contain no lymphatic tissue. The incidence of NHL, particularly primary extranodal lymphoma, is gradually increasing (e.g. primary CNS/gastrointestinal/breast), most probably due to the increase in viral infections, especially HIV, and exposure to environmental factors.

Primary gastrointestinal lymphoma

Gastrointestinal lymphoma is the most common form of extranodal lymphoma, accounting for 30–40% of cases and 4–20% of all NHL cases.

Diffuse large-cell lymphoma of the stomach

Advanced gastrointestinal DLBCL tends to behave primarily like nodal advanced disease. These tumours were traditionally treated with gastrectomy; however, recent data suggest that this strategy is unnecessary in most cases, where combination chemioimmunotherapy (six to eight courses of R-CHOP) with or without adjuvant radiotherapy provides high response and cure rates. For patients with localized gastric diffuse large-cell lymphoma, short-course chemioimmunotherapy (three to four courses of R-CHOP) followed by involved-field radiotherapy has been shown to be effective.

In some cases, histological transformation of MALT lymphoma may have occurred and therefore it is reasonable to add anti-*H. pylori* therapy, aiming to eradicate the bacteria and avoid potential relapses. Furthermore, anti-*H. pylori* therapy applied in these '*H. pylori*-positive' cases yields a high response rate, suggesting that an antigenic drive may be present in a subset of aggressive gastric lymphomas.

Diffuse large-cell lymphoma of the intestine

At present, there are no studies that demonstrate surgery to be unnecessary, and management is therefore based on surgical resection followed by systemic chemotherapy.

Immunoproliferative small intestinal disease

Immunoproliferative small intestinal disease (IPSID), also known as α -chain disease, arises in small intestinal MALT and is characterized by the expression of a monotypic truncated immunoglobulin α -heavy chain without an associated light chain. IPSID is mostly found in young adults of low socioeconomic class in developing countries. The aetiology of this disease is unclear, although various causative pathogens (e.g. *Campylobacter jejuni*) and genetic and toxic mechanisms have been proposed.

Half of all IPSID patients present with concurrent intestinal B-cell lymphoma, whereas most of the remaining patients develop frank lymphoma within a few years. Whereas patients with early-stage disease may respond to antibiotics, those who present with more advanced disease should be treated with chemotherapy.

Primary CNS lymphoma

Primary CNS lymphoma is defined as lymphoma arising in the craniospinal axis (brain, spinal cord, leptomeninges and eye). It is usually disseminated within the nervous system at presentation (in 50% of immunocompetent patients and in nearly 100% of HIV-positive patients). The histology in most cases is compatible with diffuse large-cell lymphoma (90%) or non-cleaved cell lymphoma. Age, poor performance status, involvement of deep structures, high LDH level and a high protein level in the CSF have been shown to predict poor prognosis.

Previously, the traditional therapy was based on whole-brain irradiation. Unfortunately, the median survival was 12–18 months and 5-year survival less than 10%, suggesting that radiotherapy is insufficient. The combination of high-dose methotrexate (>3 g/m² over 2–3 hours) and radiotherapy appears to be more effective, providing a 5-year OS of 30–50%, but may cause delayed neurotoxicity, especially in patients older than 60 years. Many groups avoid radiotherapy up-front in these older patients and defer radiotherapy until relapse. A recent randomized study has shown that the efficacy of high-dose methotrexate is improved by using it in combination with cytarabine. Other protocols that include combinations of other CNS-

penetrating agents have been evaluated but their efficacy has not been directly compared.

Further attempts to reduce long-term neurotoxicity in this group, delivering lower doses of radiotherapy or omitting radiotherapy, by providing intensified chemotherapy regimens such as up-front autologous SCT have been described and are being explored further.

Treatment of secondary CNS lymphoma

Secondary CNS lymphoma may present as cranial nerve palsies, headache, cognitive disturbance or spinal cord compression. It may occur concurrently with a systemic lymphoma, during therapy or may present as a late relapse.

There is no consensus on how best to treat secondary CNS lymphoma and scant data regarding the effects of treatment on survival, quality of life and cognitive function. Whether the CNS relapse is confined to brain parenchyma or the leptomeninges alters the approach. Options for the former include chemotherapy (high-dose methotrexate or combination chemotherapy), immunotherapy, cranial radiotherapy and autologous SCT. These approaches are often combined. A large retrospective analysis of 113 cases with isolated CNS relapse involving brain parenchyma reported a median OS of 1.6 years (95% CI 0.9–2.6 years), although this does not reflect the outcome of all patients. Other studies have described a median survival of less than 6–12 months with no survival difference in patients with leptomeningeal, parenchymal or combined parenchymal/leptomeningeal disease. Treatment of isolated leptomeningeal involvement commonly includes intrathecal methotrexate or cytarabine. The latter agent is also available as a liposomal product and cytotoxic levels are maintained for at least 14 days in the CSF.

Nodal peripheral T-cell NHL (see also Chapter 30)

Peripheral T-cell lymphomas (PTCLs) are a biologically and clinically heterogeneous group of rare disorders that result from clonal proliferation of mature post-thymic lymphocytes. There is geographical variation in the frequency of the different subtypes and in Europe, PTCL unspecified, anaplastic large-cell lymphoma (ALCL) and angioimmunoblastic T-cell lymphoma (AITL) account for about three-quarters of all cases. PTCL unspecified, and particularly natural killer (NK)-cell lymphomas, are more common in Asia and the Far East.

Extranodal presentation is common in PTCL. Paraneoplastic features are well described, including eosinophilia, haemophagocytic syndrome and autoimmune phenomena (particularly seen in AITL). Most patients present with unfavourable IPI scores (>3) and poor performance status. A number of T-cell-specific IPI features have been described, including age,

performance status, LDH, bone marrow involvement and Ki-67 expression.

Excluding anaplastic lymphoma kinase (ALK)-positive ALCL, which has a good outcome, 5-year survival for other nodal and extranodal T-cell lymphomas is about 30%. Treatment of T-cell lymphomas is commonly based on multi-agent chemotherapy (e.g. CHOP), although patient outcome remains disappointing and the majority of patients die of their disease. A number of small Phase II studies have assessed (and are assessing) the efficacy and toxicity of combining CHOP chemotherapy with alemtuzumab. Whether outcome is improved is unclear although infectious toxicity is greater. CD52 expression in PTCL is unclear, with some groups reporting a high rate of CD52 negativity. Gemcitabine-containing combination chemotherapy regimens (gemcitabine, cisplatin and methylprednisolone: GEM-P, PEGS, CHOP-EG) have been shown to be efficacious, although no comparative study has been performed. At present, no chemotherapy regimens have been found to be superior to CHOP.

The similarity in PFS and OS is an indication of the poor response to second-line therapies. Consideration for up-front autologous SCT (performed in first CR) is recommended (except for ALK-positive ALCL) as improvements in long-term outcome have been reported in prospective and retrospective analyses. However, approximately 25% of patients show disease progression during first-line chemotherapy and thus are not candidates for autologous SCT.

Initial treatment of refractory disease is usually with platinum-based combination chemotherapy prior to consolidation with a transplant. Alternatively, purine analogue or gemcitabine-containing combination chemotherapy regimens may be considered. There are also a number of experimental agents that have shown promise and patients should also be considered for inclusion in suitable clinical trials where available. Early data regarding the efficacy of histone deacetylase inhibitors (Depsipeptide), pralatrexate (a novel antifolate agent) and antibodies to CD52, CD25 and the IL-2–toxin conjugate dinileukin difitox (ONTAK) have been reported. Patients with chemosensitive relapsed disease may be considered subsequently for allograft. In addition, a number of agents, including ciclosporin, thalidomide, rituximab and bevacizumab (MAb to VEGF-A), are being assessed for the treatment of AITL in Phase II trials.

Enteropathy-associated T-cell lymphoma

Enteropathy-associated T-cell lymphoma is an aggressive tumour of the small bowel that is strongly associated with coeliac disease, of which it may be the presenting feature in adults. A gluten-free diet appears to markedly reduce the risk for lymphoma. The outcome is poor, partly due to the biology of the disease and partly the performance status of patients in the setting of malabsorption and malnutrition. Conventional

chemotherapy gives poor results but there are some long-term survivors (~10%). Dose intensification is often attempted, using salvage-type chemotherapy with or without high-dose methotrexate, as is up-front autologous SCT but has yet to be confirmed as beneficial in adequate trials and must be seen as experimental.

Anaplastic large-cell lymphoma

The WHO classification recognizes two distinct subtypes of ALCL, primary systemic and primary cutaneous types, which exhibit differences in immunophenotype, genetics and clinical behaviour (see Chapter 33). It is now known that approximately 60% of cases of systemic ALCL express the ALK protein (ALK⁺) and have a significantly superior survival to ALK-negative cases. Since cases of ALK-negative ALCL appear to have a prognosis similar to that of PTCL unspecified, it has been suggested that they should be treated similarly.

Systemic ALK-positive ALCL occurs at a young age (median <30 years) and shows a male predominance. The majority of patients present with 'B' symptoms, advanced-stage disease and involvement of multiple extranodal sites. However, the majority of patients fall into lower IPI categories because of good performance status, younger age and a normal LDH. Combination anthracycline-based chemotherapy (e.g. CHOP) is associated with a 5-year OS of 60–93%. Prognosis is so good in this group of patients that transplantation should only be considered at relapse. Platinum-based chemotherapy is standard for patients with relapsed disease, although monoclonal antibodies directed against CD30 and/or specific inhibitors of NPM-ALK are under investigation. Patients with ALK-positive ALCL autografted at relapse have a 3-year EFS/PFS/OS of 67–100%.

Hepatosplenic T-cell lymphoma

This is a rare entity, affecting mainly younger men. It is a distinctive and aggressive disease with a characteristic presentation (liver, spleen and bone marrow involvement but rarely lymphadenopathy) and clinical course. Most patients exhibit a characteristic phenotype (typical histology showing sinusoidal infiltration with tumour cells in the affected tissues), expression of the $\gamma\delta$ TCR and an isochromosome 7q abnormality (described in Chapter 33).

The outlook is very poor with scant data regarding effective therapies and a number of single case reports concerning treatment with CHOP, alemtuzumab, purine analogues (fludarabine, pentostatin or cladribine) or their combination. However, responses are often transient and there is increasing enthusiasm for early allogeneic SCT, although its efficacy is also unclear due to the small number of patients in published reports. A recent literature review identified 7 of 17 (40%) patients who had been treated with allogeneic SCT and who were alive and in CR. Thus

prolonged remission duration is observed in some patients after allogeneic SCT and the outcome appears to be superior compared with chemotherapy.

Extranodal NK/T-cell lymphoma, nasal type

This is an aggressive, largely extranodal lymphoma, usually of NK-cell type but with recognized T-cell phenotypic variants. These are very rare in the Western world but commoner in Asia and South America. It is usually associated with EBV and often presents as localized disease in and around the nasal structures. Local extension and dissemination is frequent, usually to regional nodes and distant extranodal structures such as skin, testis and gut. An association with the haemophagocytic syndrome has been described.

Survival at 5 years ranges from 20 to 35% in different series but most of the cases included in these figures are localized stage I/II nasal presentations, and when considered separately the patients with disseminated disease almost all die, mostly within a few months. Involved-field radiotherapy produces excellent initial control for patients with stage I/II disease, and may be followed by CHOP-based chemotherapy, although its merit is unclear.

Adult T-cell leukaemia lymphoma (see also Chapter 30)

ATLL is divided into four different clinical subtypes, with the acute (leukaemic) and lymphomatous subtypes being more common than the chronic and smouldering forms. Lymphadenopathy, hepatosplenomegaly, skin lesions and hypercalcaemia are observed in the majority of patients. The prognosis for acute and lymphoma subtypes is poor, with a median survival of only 6.2 and 10.2 months respectively. Patients are immunocompromised and opportunistic infections are common, including *Pneumocystis jirovecii* pneumonia, aspergillosis or candidiasis, *Strongyloides stercoralis* and cytomegalovirus.

Despite significant advances in understanding the pathogenesis of ATLL, results of treatment remain disappointing. Responses to conventional chemotherapy are poor. A number of Phase II studies of the combination of the antiretroviral drug zidovudine and interferon alfa have reported significant activity in patients with ATLL and have been administered successively with chemotherapeutic regimens such as CHOP. Conjugated and unconjugated monoclonal antibodies (anti-CD25, anti-CD4, anti-CD52) have all been tested in small numbers of patients. Other agents being evaluated include arsenic trioxide and bortezomib.

There appears to be minimal long-term benefit in autografting patients with ATLL, with the majority of patients relapsing within 1 year of transplantation. Prolonged DFS has been

described after allogeneic SCT, with many of the reports derived from retrospective analyses of the Japanese Registry Data. Age and remission status at transplantation have been identified as significant predictors of survival and since the median age at presentation with ATLL is approximately 60 years, reduced-intensity conditioning is generally favoured. The estimated 3-year overall and relapse-free survival rates have been reported as approximately 45% and 35% respectively.

Histiocytic and dendritic cell neoplasms

Precursor haematological neoplasm: CD4⁺CD56⁺ haematodermic neoplasm

The derivation of this clinically aggressive neoplasm (previously called blastic NK-cell lymphoma), with a high incidence of cutaneous involvement and risk of leukaemic dissemination, is thought to be a plasmacytoid dendritic cell precursor. Although patients typically present with cutaneous manifestations, about half have nodal or bone marrow involvement at presentation and many rapidly develop extracutaneous spread. The coexistence of myelodysplasia has been described in approximately 15–20% of cases.

The prognosis is very poor, with most patients dying from their disease within 2 years. Remissions achieved by systemic chemotherapy are rarely maintained and resistance to subsequent chemotherapy is common. Whether patients should be treated with regimens used in acute leukaemias or aggressive lymphomas is unclear.

High-grade lymphoma

Burkitt lymphoma and small non-cleaved Burkitt-like lymphoma

These are highly aggressive forms of NHL, frequently involving extranodal organs (e.g. CNS in 20%) but usually without tumour cells detected in the peripheral blood and characterized by dysregulation of the *MYC* oncogene. BL is a distinct entity that includes endemic and sporadic types and cases associated with immunodeficiency or immunosuppression. Transcriptional and genomic profiling has defined BL, an entity with a favourable outcome, more precisely. Mature aggressive B-cell lymphomas with chromosomal breakpoints at the *MYC* locus but without a gene signature for BL conversely have an adverse clinical outcome.

Effective treatment of patients with BL is based on multidrug combination chemotherapy (e.g. CODOX-M/IVAC, Hyper-CVAD; see Table 35.7) that includes drugs such as methotrexate and cytarabine, which penetrate the CNS extremely well.

Rituximab is commonly added to such regimens, although randomized trials demonstrating its efficacy have not been performed. Approximately 50–80% of adult patients can be cured with these intensive chemotherapy regimens, and in paediatric populations the cure rate is even higher.

The risk of tumour lysis syndrome, especially after initiating chemotherapy, is relatively high, reflecting the high proliferation rate of tumour cells. Vigorous hydration with alkalinization, accompanied by administration of recombinant urate oxidase (rasburicase), or a uric acid synthesis inhibitor such as allopurinol, are very important in preventing/reducing the severity of this complication (see also Chapter 26). Hypercalcaemia is also frequent at presentation and needs appropriate therapy with hydration and bisphosphonates.

Lymphoblastic lymphoma

Lymphoblastic lymphoma is a lymphoproliferative disorder derived from early B/T cells and patients should therefore be treated as for ALL (see Chapters 24 and 25) using protocols such as UKALL 2003, UKALL XII, Hyper-CVAD or German NHL-BFM 90. These generally use multidrug induction followed by high-dose methotrexate, with or without consolidation chemotherapy blocks (depending on stage).

Autologous SCT (with or without TBI) in first remission gives as good an outcome as extended chemotherapy and both treatment modalities are followed. Most adult studies show EFS of 30–50%, which is inferior to outcome in paediatric studies. Allogeneic SCT provides a lower relapse rate compared with autologous SCT; however, long-term survival is not necessarily higher due to increased TRM as observed with allograft. Allogeneic SCT is commonly deferred for the relapsed patients with chemosensitive disease.

Tumour regression in lymphoblastic lymphoma is often incomplete and has not been shown to be predictive for relapse. The role for consolidative mediastinal radiotherapy in those with residual masses is contentious. In children it appears to add to toxicity without leading to improved outcome. Consequently, paediatric studies reserve local radiotherapy for 'high-risk' patients, such as those with suboptimal volume response of a mediastinal mass during induction chemotherapy. In adults, a proportion (12–47%) of patients who subsequently relapse had undergone previous radiotherapy, often to the site of subsequent relapse, suggesting doubtful benefit. One study suggested that higher radiotherapy doses (36 Gy) were associated with reduced local relapse rates but such doses are associated with increased toxicity.

The efficacy of nelarabine, a nucleoside analogue prodrug of 9-β-D-arabinofuranosylguanine, for the treatment of patients with T-cell lymphoblastic lymphoma whose disease has not responded to, or has relapsed after, treatment has been described. The most common adverse events associated with nelarabine are neurotoxic and have been dose-limiting.

Lymphomatoid granulomatosis

Lymphomatoid granulomatosis is a rare angiocentric and angiodestructive lymphoreticular proliferation that usually primarily affects the lungs, although other sites such as skin, CNS and kidney may be involved. The immunophenotype has been described as a T-cell-rich, EBV-associated, B-cell lymphoproliferative disorder. However, primary CNS lymphomatoid granulomatosis appears to be derived from clonal T cells in some cases and appears not to be associated with EBV.

Treatment is currently not well established. Spontaneous remission has been reported. The therapeutic approach ranges from immunomodulatory agents (corticosteroids, interferon, ciclosporin), chemotherapy (cyclophosphamide, CHOP) or immunotherapy (rituximab). A number of case reports have described the efficacy of autografting. The prognosis of this disorder has been considered to be poor, with a 5-year survival in less than 50% of cases and with progression to lymphoma in 13% of cases. Primary CNS lymphomatoid granulomatosis appears to have a better prognosis.

Castleman disease

Castleman disease is a rare atypical lymphoproliferative disorder classified according to the histopathology of the affected lymph nodes as hyaline-vascular, plasma-cell type or a mixed variant of the two (discussed in more detail in Chapter 33). Classification may also be based on whether the disease is localized or multifocal, the latter often associated with systemic features and abnormal laboratory findings.

Localized Castleman disease

Localized Castleman disease is commonly of the hyaline-vascular variant and patients are usually asymptomatic. It usually presents in young adults with isolated masses in the mediastinum (60–75%), neck (20%) or less commonly the abdomen (10%). Excision of the affected lymph node results in subsequent cure in a majority of cases. Patients with the plasma-cell type or the mixed-type variant frequently have systemic manifestations and the disease is multifocal with widespread adenopathy and multiorgan involvement (see below).

Multicentric Castleman disease

Multicentric Castleman disease (MCD) is a relatively rare lymphoproliferative disorder that occurs in the fourth or fifth decade of life but at younger ages in people who are HIV positive. Today, MCD is most commonly diagnosed in individuals

infected with HIV, although the effect of HAART on incidence and prognosis is unclear.

MCD typically presents with fevers, multifocal lymphadenopathy, hepatosplenomegaly, polyneuropathies, effusions and weight loss. Laboratory investigations may reveal thrombocytopenia, anaemia, raised serum C-reactive protein, hypoalbuminaemia and hypergammaglobulinaemia. Not only is MCD itself potentially fatal due to organ failure but it is also associated with an increased incidence of NHL. HHV-8 has been found to be present in 100% and 50% of cases of HIV-positive and HIV-negative MCD respectively.

The diagnosis is established on lymph node biopsy and the characteristic features of HIV-associated MCD are interfollicular plasmablasts that express the HHV-8 latent nuclear antigen. These plasmablasts also express high levels of λ light-chain-restricted IgM, but are polyclonal and do not contain somatic mutations in their *IGV* genes, suggesting that they arise from naive B lymphocytes.

There are no definitive gold-standard treatments for MCD. No randomized trials have been conducted on account of the infrequency of the diagnosis and often only case reports have appeared in the literature. Resolution of systemic symptoms can be achieved with chemotherapy (etoposide or vinblastine) but relapse occurs and many patients remain dependent on chemotherapy for life. Lymphoma schedules such as CHOP or immunomodulatory therapy with thalidomide or interferon alfa have also been used, with efficacy described. The initiation of HAART in HIV-positive patients, often in combination with chemotherapy, appears to be well tolerated and is associated with immune reconstitution. The role of antiviral agents (ganciclovir, cidofovir, foscarnet) is unclear. Administration of the humanized anti-IL-6 receptor antibody to patients with MCD has been associated with improvements in inflammatory parameters, fatigue and lymphadenopathy. This likely reflects that dysregulated overproduction of IL-6 underlies at least some of the clinical abnormalities. However, benefit was not sustained and recurrence was observed.

A number of small studies have shown that rituximab can induce impressive clinical, biochemical and radiological sustained response in HIV-related MCD. Its efficacy as initial therapy and for relapsed patients has been described. Exacerbation of Kaposi sarcoma lesions after rituximab has been described.

CNS prophylaxis in aggressive NHL

There is a 5% incidence of CNS relapse in most large studies of aggressive NHL. These include DLBCL, PTCL, the blastoid variant of MCL, ATLL, NK-cell lymphoma and primary mediastinal B-cell lymphoma. The factors of importance include high IPI score, elevated LDH, involvement of more than one

Table 35.11 Risk factors for CNS involvement.

High IPI score
Extranodal sites involved (0 or 1 vs. >1)
Raised LDH level
Age < 60 years
Specific involvement of the following organs: bone marrow, testis, paranasal sinuses, Waldeyer ring
Low albumin level
Retroperitoneal glands

extranodal site and specific sites such as bone marrow, testis, breast, epidural space, paranasal sinuses and Waldeyer ring (Table 35.11).

The use of rituximab has recently been shown to be associated with a significantly lower incidence of CNS disease in elderly patients with aggressive CD20-positive lymphoma treated in the RICOVER-60 trial. Patients treated with R-CHOP-14 had a relative risk for CNS disease of 0.58 (95% CI 0.3, 1.0; $P = 0.046$) compared with patients treated with CHOP-14. CNS prophylaxis with intrathecal methotrexate was offered to patients with involvement of bone marrow, testes, upper neck, or head. The estimated 2-year incidence of CNS disease was 6.9% (CI 4.5, 9.3) after CHOP-14 and 4.1% (CI 2.3, 5.9) after R-CHOP-14.

The outcome of those who develop CNS relapse is extremely poor, with a median survival of less than 6 months (discussed later). Thus intrathecal chemotherapy is routinely administered to patients considered at high risk. However, agreement regarding the optimal regimen, the frequency of administration and whether high-dose systemic (methotrexate, cytarabine) chemotherapy should also be offered is lacking.

All patients with BL or lymphoblastic lymphoma should receive CNS prophylaxis with both intrathecal and high-dose systemic chemotherapy, as the observed incidence of CNS relapse without prophylaxis is about 20%. Standard treatment incorporates both intrathecal therapy and high-dose systemic chemotherapy with methotrexate and cytarabine.

There is no evidence to support routine use of CNS prophylaxis in any patient with low-grade lymphoma.

Suggested algorithm for therapy of aggressive NHL

At diagnosis

- Anthracycline-containing combination chemotherapy with rituximab (CHOP-R) is already proven to be superior to CHOP in patients who are more than 60 years old.
- Patients with intermediate-high/high IPI score (particularly those who present with raised LDH and/or extranodal involvement) should receive CNS prophylactic therapy.

- Adjuvant radiotherapy may be considered in patients with bulky disease.
- No clear role for up-front autologous SCT (performed in CR1).

At relapse

- Second-line regimens (e.g. ESHAP, DVIP, DHAP, mini-BEAM), followed by autologous SCT.
- Allogeneic SCT may be considered in patients who have failed autologous SCT or in those with special subtypes of NHL (e.g. $\gamma\delta$ lymphoma).

Lymphoma in the immunocompromised patient

Most frequently, the disease is diagnosed in patients with acquired immunodeficiency caused by HIV infection (AIDS-related lymphoma) or immunosuppressive drugs (e.g. PTLD).

AIDS-related NHL

The histological diagnosis in the majority of such patients is diffuse large-cell lymphoma (60%) or BL (30%). Patients tend to present with advanced-stage disease, 'B' symptoms, extranodal sites of disease and bone marrow involvement. Prior to the introduction of HAART (highly active antiretroviral therapy), treatment with standard-dose chemotherapy induced high levels of toxicity and a high incidence of opportunistic infections. Since the regular use of HAART, the immunological function and haemopoietic reserve of these patients has improved dramatically. This is associated with a reduction in the incidence of infections and an outcome similar to that of non-HIV-infected patients. Increasingly, similar treatment strategies adopted for HIV-negative patients (e.g. CHOP, m-BACOD, CDE, EPOCH, CODOX-M/IVAC) with or without rituximab are used. The use of rituximab has been associated with a significant reduction in progression of lymphoma on treatment, and in death due to lymphoma. However, an increase in infectious deaths has been described in patients with CD4 cell counts less than $50 \times 10^6/L$ and thus caution or more vigilant antimicrobial prophylaxis and surveillance is advocated in this cohort.

Improvements in the immune function and haematological reserves of HAART-treated patients, and better supportive care, have made stem cell mobilization and high-dose chemotherapy approaches possible in HIV-infected patients. The feasibility and efficacy of autologous SCT for HIV-positive patients with relapsed lymphoma has been widely described by single centres and cooperative groups. In a recently published retrospective study performed by the EBMT, a similar outcome for HIV-negative and HIV-positive lymphoma patients undergoing autologous SCT has been described.

HIV-positive patients with BL should also receive intensive regimens used in the HIV-negative setting, such as CODOX-M/IVAC with or without rituximab, as the outcome has been shown to be equivalent to that in HIV-negative patients in small studies.

Post-transplant lymphoproliferative disorder

PTLD ranges from polyclonal plasmacytic hyperplasia to monoclonal B-cell proliferation, polymorphic hyperplasia/lymphoma, immunoblastic lymphoma or myeloma. EBV causes the majority of these disorders: impaired T-cell function leads to proliferation of latently EBV-infected polyclonal B cells, whereas subsequent genomic mutations result in monoclonal PTLD. Prevention of EBV infection/reactivation may therefore be essential. Antiviral agents (e.g. aciclovir, ganciclovir), passive immunotherapy and pre-emptive immunotherapy, using cytotoxic T lymphocytes targeted against EBV, are all applied to prevent PTLDs, with variable success.

The optimal treatment of PTLD is still not clearly defined due to lack of randomized Phase III trials. Most published data are in the form of case series. Therapeutic options in PTLD include immunosuppression reduction, transplant organ resection, radiotherapy, chemotherapy and immunotherapy. Patients may respond to reduction in immunosuppressive therapy, especially those who develop PTLD within 1 year from transplant (ORR 80% vs. 10% in patients who developed PTLD beyond 1 year). Case series and Phase II studies of rituximab monotherapy following failure of reduction of immunosuppression have confirmed efficacy in inducing remission in a proportion of patients (44–65%) with PTLD. Toxicity appears to be low, but significant numbers of patients progressed on therapy or relapsed after rituximab, some died of lymphoma and many required intensification to chemotherapy. A risk score for identifying patients with PTLD most likely to respond to rituximab monotherapy has been proposed, using age over 60 years, performance status ECOG 2–4 and raised LDH as poor risk markers. Chemotherapy (i.e. CHOP) is usually reserved for those patients who have failed to respond to previous modalities. Adoptive immunotherapy following allogeneic SCT may also be effective. Donor lymphocyte infusion may cause severe GVHD, limiting its use. In contrast, anti-EBV cytotoxic T lymphocytes do provide a more specific effect, but are less available, being produced over weeks to months by expert laboratories and their infusion is associated with regulatory challenges.

Cutaneous lymphomas

Primary cutaneous T-cell lymphoma

Primary cutaneous T-cell lymphoma (CTCL) comprises a heterogeneous group of extranodal NHLs, of which mycosis

fungoides/Sézary syndrome are the most common clinicopathological subtypes (see also Chapter 30). Mycosis fungoides is characterized by distinct clinical stages of cutaneous disease consisting of patches/plaques, tumours and erythroderma in which the whole skin is involved. Sézary syndrome is defined by the presence of erythroderma, peripheral lymphadenopathy and a minimum number of Sézary cells within the peripheral blood. These clinicopathological entities are closely related pathogenetically but are distinct from other less common types of primary CTCL, including primary cutaneous CD30-positive lymphoproliferative disorders, which have an excellent prognosis, and other CTCL variants which generally have intermediate or poor prognosis and are more closely related to peripheral T-cell lymphomas.

For mycosis fungoides, two staging systems are in regular use, including a TNM (primary tumour, regional nodes, metastasis) system and a clinical staging system specifically designed for CTCL. Most cases of primary CTCL are not curable but patients with very early stage disease (IA) are highly unlikely to die of their disease. The 5-year and 10-year OS are 80% and 57%, respectively, with disease-specific survival rates of 89% and 75% at 5 and 10 years respectively. Patients with folliculotropic variants of mycosis fungoides have a worse prognosis. Therapy is based on 'skin-targeted modalities', including PUVA (psoralen with UVA irradiation), electron beam radiation, narrowband UVA (NB-UVA), topical steroids, nitrogen mustard, carmustine and vitamin D. PUVA and NB-UVA remain the gold-standard therapies at early stages (IA/IIA), whereas systemic therapies are reserved for more advanced stages. Treatment options in these cases may include chlorambucil, methotrexate, doxorubicin, etoposide, retinoids, rexinoids, interferon, extracorporeal photopheresis, interferon alfa/gamma, or conjugated monoclonal antibodies (e.g. anti-CD52) and immunotoxins (e.g. IL-2 receptor-specific fusion protein combined with diphtheria toxin, which selectively targets the IL-2 receptor on malignant and activated T cells). Systemic therapies are frequently combined with topical agents. Interferon alfa with or without phototherapy appears to be highly effective in advanced disease, providing responses in up to 80% of patients. Other immunomodulatory agents, such as recombinant human IL-2, anti-idiotypic vaccines and gene therapies, are under investigation.

Young patients with biologically aggressive mycosis fungoides who have failed conventional therapies may be considered for allogeneic SCT. There is increasing enthusiasm for reduced-intensity approaches for a number of reasons: the average age of patients with CTCL is 60 years, many patients have chronically infected skin ulcers and the risk of life-threatening sepsis is lower. Efficacy of reduced-intensity allogeneic SCT has been reported by a number of groups.

Sézary syndrome is an aggressive CTCL, characterized by erythroderma, lymphadenopathy and circulating malignant T cells with cerebriform nuclei. Therapy is usually based on a

combination of systemic and topical therapy: chemotherapy (e.g. alkylating agents, including temozolomide), IL-2–diphtheria toxin, anti-CD52 monoclonal antibodies, retinoids/rexinoid, accompanied with topical steroids or PUVA. Extracorporeal photopheresis may also be effective, especially in those who present with a low number of circulating Sézary cells. Patients with Sézary syndrome have an 11% 5-year survival, with a median survival of 32 months from diagnosis.

CD30-positive large-cell lymphoma is the most common form of non-mycosis fungoides primary CTCL that appears to have an indolent course, with 5-year survival in 90% of cases. These patients are usually treated successfully with spot radiation or surgical excision, and only those who progress are considered for systemic treatment. On the other hand, patients with CD30-negative large T-cell lymphoma tend to have aggressive disease with poor prognosis and should therefore receive multiagent systemic chemotherapy at diagnosis, irrespective of disease stage.

Cutaneous B-cell lymphoma

Primary cutaneous B-cell lymphoma (CBCL) comprises a group of lymphomas characterized by dominant infiltration of clonal B cells in the skin. Primary cutaneous follicle centre lymphoma, the most frequent CBCL, is characterized by a localized slowly progressive lesion in the neck/head or trunk and is associated with an excellent prognosis (5-year OS >95%). In most cases the tumour cells do not express Bcl-2 and MUM-1. Local radiation remains the preferred therapy for patients with localized disease (localized with regional satellites), whereas those who present with disseminated skin disease may be observed or treated with systemic chemotherapy with or without monoclonal antibodies (e.g. rituximab). Primary cutaneous marginal zone lymphoma, the second most common CBCL, is also considered to have an indolent course, with a 5-year OS approaching 100%. Patient management is similar to that of patients with primary cutaneous follicle centre lymphoma.

A more aggressive type of CBCL, primary cutaneous large B-cell lymphoma leg-type, typically presents with nodules/tumours on one or both legs, although other anatomical sites may be involved. Elderly patients, particularly females, are most commonly affected. The lesions commonly demonstrate strong expression of Bcl-2, MUM-1 and Bcl-6. Despite its less indolent nature, the treatment of choice for early stages remains local (local radiation or excision), whereas those who present with disseminated disease are treated with systemic chemotherapy with or without adjuvant monoclonal antibodies. The 5-year disease-specific survival is approximately 50%. The extent of skin lesions has been associated with prognosis.

In summary, primary cutaneous lymphomas comprise a heterogeneous group of B- and T-cell lymphomas with a variety of clinical presentations and prognoses. Accurate diagnosis and assessment of prognostic factors determine patient manage-

ment. The majority of patients should be considered for conservative palliative therapy (e.g. local or topical treatments), unless they present with histologically aggressive lymphoma (e.g. large-cell CTCL) or disseminated stage of an ‘indolent’ disease (extracutaneous involvement), for which they should receive systemic therapy. New emerging therapies (monoclonal antibodies, topical and systemic retinoids, recombinant toxins and immunomodulators) may succeed in improving long-term outcome, although further studies are needed.

Lymphoma in elderly patients

Diffuse large-cell lymphoma accounts for 50% of lymphomas in patients older than 60 years. Unfortunately, the outcome in this population is worse than that observed in younger adults, partly because of the high incidence of coexisting medical problems affecting organ function. Attempts to improve patient outcome, providing intensified chemotherapy regimens (compared with CHOP), ended with increased toxicity without improvement in survival, whereas less toxic regimens were often less effective. However, the prospective randomized GELA study, comparing CHOP with CHOP plus rituximab (CHOP-R), reported an improved DFS and OS in elderly patients (>60 years) treated with CHOP-R, with no increase in treatment-related toxicity.

The addition of granulocyte colony-stimulating factors can shorten duration of neutropenia, enabling the delivery of chemotherapy at the planned time and dose intensity. Several studies have recently reported encouraging results with autologous SCT in patients older than 60 years (4-year OS in patients with chemosensitive relapsed disease approached 40%), indicating the feasibility of this treatment in selected patients.

Introduction

For the purposes of this chapter, the term ‘myeloproliferative neoplasm’ (MPN) refers to clonal disorders of haemopoiesis that lead to an increase in the numbers of one or more mature blood cell progeny. The chronic myeloid leukaemias would fit this definition and share pathogenetic features with some of the MPNs, but have historically (since the discovery of the Philadelphia chromosome) been studied separately from the MPNs and are described in another chapter. Myelodysplastic syndrome (MDS) can also, in a minority of cases, fit our working definition of MPN, in being associated with increased numbers of mature cell progeny, but dysplasia is a major feature and there are, usually, coexisting cytopenias. Not surprisingly, a small number of patients do not fit neatly into a single category and exhibit features of both MPN and MDS.

This chapter focuses on the classical MPNs: polycythaemia (rubra) vera (PV), essential thrombocythaemia (ET) and primary myelofibrosis (PMF), three related disorders originally grouped together by William Dameshek in 1951. They share clinical, morphological and molecular features and can transform, in their course, into one another. They are clonal disorders of the pluripotent haemopoietic stem cell and have, to varying degrees, the potential to transform into acute myeloid leukaemia (AML). Secondary (non-clonal) polycythaemias and

thrombocytoses are also discussed in this chapter, as they often enter the differential diagnosis of their clonal counterparts.

In addition, some of the less common MPNs are described, namely mastocytosis and its variants, the clonal eosinophilic syndromes and chronic neutrophilic leukaemia. The ontogeny of the target cell for transformation is less well established in these disorders, but there is accumulating evidence implicating the pluripotent haemopoietic stem cell in at least some cases.

The polycythaemias

True polycythaemia refers to an absolute increase in total body red cell volume (or mass), which usually manifests itself as a raised haemoglobin concentration (Hb) and/or packed cell volume (PCV). A raised Hb (or PCV) can also be secondary to a reduction in plasma volume, without an increase in total red cell volume; this is known as apparent (or relative) polycythaemia.

True polycythaemia is further subdivided into primary polycythaemia (namely PV), a clonal haematological disorder, and secondary polycythaemia, which results from an increased erythropoietin drive, either in the presence or absence of hypoxia (Figure 36.1).

Polycythaemia vera

The central pathological feature of PV is an expansion in the total red cell mass, although elevations in the platelet and/or neutrophil counts are relatively common. The first description

of PV was by Vaquez in 1892. Osler, in 1903, published the first series of patients, identifying salient clinical features setting PV apart from other erythrocytoses. Considerable information has been gathered about PV since the work of these pioneers, much of it due to the work of the Polycythaemia Vera Study Group (PVSG), which was set up in 1967 with the aim of optimizing diagnosis and management of PV. The recent discovery of the V617F mutation in the pseudokinase domain of the tyrosine kinase JAK2, in nearly all cases of PV, represents a major advance in our understanding of this disorder.

Pathophysiology

PV is a stem cell disorder characterized by hyperplasia of all three major myeloid cell lineages. The first line of evidence in support of the stem cell origin of PV came in the form of clonality studies. Using X-chromosome inactivation patterns in the mid-1970s Fialkow and colleagues showed that neutrophils, erythrocytes and platelets originated from the same clone. Large studies have since confirmed these findings.

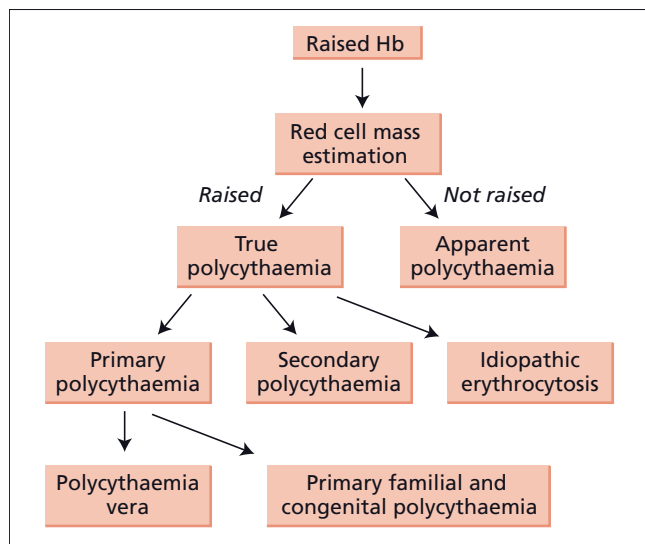

Figure 36.1 An aetiological classification of polycythaemia.

Figure 36.2 Diagrammatic representation of JAK2 indicating the location of valine 617 and the very high degree of cross-species amino acid homology in its JH2 domain. The JH2 domain

normally acts to repress the kinase activity of JAK2, but its ability to do so is impaired in the presence of the JAK2 V617F mutation. (Modified from Baxter *et al.* 2005 with permission.)

Erythropoiesis in PV is autonomous and does not rely on erythropoietin (Epo). Plasma levels of this hormone are reduced in PV patients, and PV progenitor cells, unlike normal ones, can survive *in vitro* and give rise to erythroid colonies (BFU-E) in the absence of added Epo (endogenous erythroid colonies). PV erythroid progenitors show increased sensitivity to Epo but also to several other growth factors, including insulin-like growth factor (IGF)-1, thrombopoietin, interleukin (IL)-3 and granulocyte/monocyte colony-stimulating factor. Germline mutations in the Epo receptor (EpoR) are known to occur in inherited polycythaemia, but such mutations are absent in patients with PV.

In 2005, several groups identified a unique acquired mutation in the cytoplasmic tyrosine kinase JAK2 in myeloid cells from the great majority of patients with PV. JAK2 lies downstream of several cell surface receptors including EpoR. Upon Epo binding to EpoR, JAK2 becomes phosphorylated and in turn phosphorylates downstream targets, most important of which are the STATs (signal transducers and activators of transcription), leading to stimulation of erythropoiesis. Valine 617 is located in the JH2 domain of JAK2, which acts to repress its kinase activity (Figure 36.2). The V617F mutation leads to increased kinase activity, confers cytokine independence and results in erythrocytosis in a mouse transplant model. The mutation appears to be fairly specific to the classical MPNs and although it has been reported in small numbers of patients with related myeloid neoplasms, it is not present in lymphoid or non-haemopoietic cancers. Intriguingly, the mutation is homozygous in a large proportion of patients with PV and PMF but this is rare in ET. It appears that the moderate familial predisposition to MPNs can be largely attributed to an inherited haplotype block surrounding the *JAK2* gene, although the mechanism underlying this interaction between somatic and germline genetics has not been identified.

When appropriately sensitive methods are used for the detection of the V617F mutation, about 95% of PV patients are positive. Recently, mutations elsewhere in *JAK2* have been described in most of the V617F-negative patients who have PV by strict diagnostic criteria. These mutations cluster in exon 12,

and can be of several different types, but all seem to affect the pseudokinase domain, leading to constitutive activation of the JAK2 kinase. Interestingly, compared with PV patients with the V617F mutation, those carrying exon 12 mutations tend to be younger and have a more isolated erythrocytosis, with less frequent thrombocytosis and leucocytosis. The molecular basis for these differences in phenotype has not been identified.

Recently, mutations in a novel tumour-suppressor gene, *TET2*, have been identified in myeloid disorders of all types, including MPNs. In particular, 20–25% of patients with MDS, 50% of patients with chronic myelomonocytic leukaemia, 12–15% of patients with MPN and about 20% of patients with AML carry somatically acquired mutations of the gene. Little is known about how the gene functions in normal cells, nor how disruption of the gene promotes myeloid disorders. However, the mutation is found in early haemopoietic progenitors, can either pre-date or post-date *JAK2* V617F mutation, and allows stable engraftment of haemopoietic cells in immunodeficient mice.

Clinical features

Epidemiology

The annual incidence of PV is reported to be around 2–3 per 100 000 population with a male to female ratio of 1.2:1. The median age at onset is 55–60 years and although incidence increases with age, PV can occur at any age even, rarely, in childhood.

Thrombotic complications

Thrombosis is the most common serious complication of PV. Untreated PV patients run a greatly increased risk of thrombosis, which can be arterial, venous or microvascular. The increased PCV leads to an increased blood viscosity, rheological abnormalities and abnormal platelet–endothelial contact. Additionally, procoagulant changes in platelets (e.g. decreased response to prostaglandin D_2), thrombocytosis and pre-existing vascular disease can all conspire to dramatically increase thrombotic risk.

Arterial occlusions can lead to myocardial infarcts, strokes, transient ischaemic attacks, amaurosis, scotomata, and mesenteric and limb ischaemia. Less commonly, microvascular occlusions affecting the extremities and erythromelalgia can occur.

In the venous circulation, unusual sites such as the splanchnic vessels can be involved. As a result, mesenteric, splenic and hepatoportal thromboses (Figure 36.3) are recognized presenting features of PV. Recent data indicate that this propensity to venous thrombosis in atypical sites is particularly strongly correlated with presence of the *JAK2* V617F mutation, and indeed patients presenting with otherwise unexplained splanchnic vein thrombosis will often be found to have the mutation, even in the absence of an overt MPN. Superficial thrombophlebitis,

Figure 36.3 Polycythaemia vera presenting with Budd–Chiari syndrome in a 28-year-old man: contrast computed tomography showing reduced enhancement of the right lobe of the liver (arrow) with characteristic sparing of the caudate lobe (arrowhead). On this occasion, the left lobe was also relatively spared. Marked ascites and a bulky spleen are also seen.

conventional deep venous thromboses and pulmonary emboli are also seen.

Neurological features

Over and above the consequences of occlusive vascular lesions, the sluggish cerebral blood flow secondary to the increased PCV is thought to underlie features such as headaches, drowsiness, insomnia, amnesia, tinnitus, vertigo, chorea and even depression. Transient visual disturbances also occur.

Pruritus

This symptom occurs in about one-quarter of PV patients and in some it may be severe. It is characteristically aquagenic, precipitated by warm baths, and can be associated with erythema, swelling or even pain. Pruritus is often relieved by controlling the PCV, but its aetiology remains elusive. Basophilia, hyperhistaminaemia and iron deficiency may have a role and there is an increased incidence in patients with a lower mean corpuscular volume.

Skin

Plethora, dilated conjunctival vessels and rosacea-like facial skin changes are not uncommon at presentation. Brown discoloration of the skin, erythromelalgia and, rarely, Sweet syndrome may be seen.

Splenomegaly

Palpable splenomegaly is seen in 30–50% of cases of PV. It is unclear if its presence affects prognosis, but it may be associated with an increased risk of progression to myelofibrosis.

Hypertension and gout

Hypertension is probably more common in patients with PV as is hyperuricaemia, with gout seen in about 5% of cases.

Leukaemic transformation

This is perhaps the most feared complication of PV, but the risk of developing acute leukaemia in PV patients treated only with venesection is very small (1–3%). However, this risk increases dramatically (more than 10-fold) when radioactive phosphorus (^{32}P), chlorambucil or irradiation are used as treatment. The median time interval between first starting such therapy and developing acute leukaemia is 5–8 years. Interestingly, in about half of patients transforming to acute leukaemia from a preceding *JAK2*-positive MPN, the leukaemia is *JAK2* negative.

Myelofibrosis

Progression to myelofibrosis (Figure 36.4) occurs in around 10–20% of PV cases at 15 years after diagnosis. This figure is approximate, not least because different studies have used distinct criteria to define myelofibrotic transformation. Transformation often occurs gradually over many years and is thought to be associated with an increased risk of leukaemic conversion. The management of these patients is similar to that of PMF.

Investigations

The diagnosis of PV requires both the identification of features in support of this diagnosis and the exclusion of secondary and apparent polycythaemia. The original set of diagnostic criteria was formulated by the PVSG in the 1970s. The British Committee for Standards in Haematology (BCSH) guidelines

Figure 36.4 Blood film from a case of post-polycythaemic myelofibrosis after splenectomy. Note the presence of nucleated erythrocytes, giant platelets and features of splenectomy including target cells, spherocytes and acanthocytes.

for diagnosing PV, taking into account the latest advances in the molecular understanding of these disorders, are shown in Table 36.1.

Most patients can now be diagnosed on the basis of a raised haematocrit together with the presence of the *JAK2* V617F mutation. It is also important to emphasize that the V617F mutation has been identified in a small proportion of other hematological malignancies (e.g. AML, chronic myelomonocytic leukaemia and myelodysplasia). However, none of these disorders is associated with a raised red cell mass and clinical distinction from PV is rarely an issue. The role of bone marrow biopsy in the evaluation of PV remains controversial, but it may be useful as a baseline investigation for later comparison in younger patients with the disorder, or if there are atypical clinical and laboratory features at presentation.

A minority of patients with clinical PV is negative for the V617F mutation, even when tested using sensitive detection methods. Many reference laboratories now offer highly sensitive molecular testing for *JAK2* exon 12 mutations, and this should be considered in patients who have a typical clinical and laboratory presentation of PV but who are negative for the V617F mutation. Rarely, patients will be negative for both

Table 36.1 Diagnostic criteria for polycythaemia vera, as recommended in the BCSH guidelines.

JAK2-positive polycythaemia vera

A1 High haematocrit (>0.52 in men, >0.48 in women) or raised red cell mass (>25% above predicted)*

A2 Mutation in *JAK2*

Diagnosis requires both criteria to be present

JAK2-negative polycythaemia vera

A1 Raised red cell mass (>25% above predicted) or haematocrit >0.60 in men, >0.56 in women.

A2 Absence of mutation in *JAK2*

A3 No cause of secondary erythrocytosis

A4 Palpable splenomegaly

A5 Presence of an acquired genetic abnormality (excluding *BCR-ABL1*) in haemopoietic cells

B1 Thrombocytosis (platelet count >450 × 10⁹/L)

B2 Neutrophil leucocytosis (neutrophil count >10 × 10⁹/L in non-smokers, >12.5 × 10⁹/L in smokers)

B3 Radiological evidence of splenomegaly

B4 Endogenous erythroid colonies or low serum erythropoietin

Diagnosis requires A1 + A2 + A3 + either another A or two B criteria

*Dual pathology (coexistent secondary erythrocytosis or relative erythrocytosis) may rarely be present in patients with a *JAK2*-positive MPN. In this situation, it would be prudent to reduce the haematocrit to the same target as for polycythaemia vera.

V617F and exon 12 *JAK2* mutations. In these patients, the diagnosis of PV can be made if the other criteria set out in Table 36.1 are met, but it should be remembered that this group of truly *JAK2*-negative PV is very rare, and secondary erythrocytosis, idiopathic erythrocytosis and relative erythrocytosis are all much more likely diagnoses in this clinical setting.

Treatment

Identification of the *JAK2* V617F mutation has generated much interest in the development of therapeutic *JAK2* inhibitors. However, as patients with PV currently have a very good prognosis, new agents will have to display an excellent safety profile. For the time being, the treatment of PV should employ existing treatment modalities whose effectiveness has been validated, as described below.

In the absence of thrombocytosis, regular venesection remains the mainstay of treatment for PV in patients who can tolerate it. A target haematocrit of 0.45 or less is widely used, following the demonstration that in patients with PV, higher haematocrits are associated with a significantly increased risk of thrombosis. Venesection has little impact on the haematocrit in the short term: the purpose of regular venesection is to induce iron deficiency such that the haematocrit remains chronically below the target threshold of 0.45. Thus, typical venesection regimens start with phlebotomy every 2–3 weeks until the haematocrit is controlled, and thereafter phlebotomy is generally needed every 1–3 months, depending of factors such as dietary iron intake and erythropoietic activity.

Cytoreductive therapy is recommended for patients unable to undergo venesection and those with thrombocytosis, in view of the probable increased risk of thrombosis. Hydroxycarbamide (hydroxyurea) is the most commonly used drug. It is orally bioavailable and generally very well tolerated. It will reduce both the haematocrit and the platelet count. The commonest complications are leucopenia or thrombocytopenia, which are dose dependent and can usually be avoided by close monitoring of the blood count when the drug is first introduced. In susceptible patients it can cause photosensitivity, painful leg ulcers and gastrointestinal side-effects. The usual dose is 0.5–2 g daily.

It has been suggested that hydroxycarbamide may increase the inherent leukaemogenic risk associated with PV. This concern is largely based on studies involving small numbers of patients or patients who have also required other cytotoxic agents (and may therefore represent a subgroup with more aggressive disease). At present, there are no convincing data to show that hydroxycarbamide, when used as a single agent, significantly increases the risk of leukaemia, although a small effect cannot be excluded. Preliminary data from studies of hydroxycarbamide in sickle cell disease are reassuring, but longer follow-up is required.

Interferon alfa is effective in controlling both the platelet count and the PCV, and there are some data that it may induce impressive reductions in the burden of V617F-positive cells in

the blood. It is not widely used because of its cost, route of administration (subcutaneous injection) and its side-effects (including fatigue, flu-like symptoms and depression). However, it can be useful in young patients who are reluctant to take other cytotoxic agents, in pregnancy and in patients with intractable pruritus. The usual dose range is 3–5 million units three times per week.

Anagrelide is a newer agent that lowers the platelet count by inhibiting megakaryocyte differentiation. It can be useful in controlling the platelet count of patients being treated with venesection and can also be combined with hydroxycarbamide to allow the use of lower doses of both agents. Approximately 10% of patients are completely refractory to anagrelide. The usual dose is 1–2 mg daily, but occasional patients may require doses of up to 8 mg daily. Its side-effects are mainly secondary to its inotropic and vasodilatory properties and include headaches, palpitations and fluid retention.

Busulfan is sometimes used in elderly patients or when all other treatments are not tolerated. It is very convenient as it need only be administered intermittently, but may increase the risk of leukaemia. The usual dosage is 25–75 mg as a single dose every 2–3 months. Low-dose aspirin (75–100 mg daily) reduces thrombotic complications in PV and is used in most patients without contraindications to this drug. Pruritus often improves with control of the PCV but paroxetine, antihistamines and aspirin (in some cases) can help. There is also evidence that interferon can be useful in intractable cases.

In view of the age of most patients and the relatively benign natural history of treated PV, bone marrow transplantation is not advocated for stable disease. The role, if any, of transplantation employing reduced-intensity conditioning regimens is not yet clear.

Prognosis

In the first half of the 20th century, untreated polycythaemia had a dismal prognosis with a 50% survival of less than 2 years. However, adequately treated PV now has a relatively benign natural history with a life expectancy of over 11 years, bearing in mind that the average age of onset is 60 years. Factors predictive of poorer prognosis and increased complication rates in PV include *JAK2* mutation burden and white cell count at diagnosis, both factors probably serving as surrogate markers of disease activity.

Other causes of erythrocytosis

All disorders with an increased red cell mass that are not due to clonal proliferation of haemopoietic progenitors are included under this heading. They are most conveniently subclassified into primary and secondary causes. In primary polycythaemia, the defect is intrinsic to the red cell precursors, which are hypersensitive to Epo. In secondary polycythaemia, the defect is upstream of the red cell precursors. The latter group can be

Table 36.2 Causes of erythrocytosis other than polycythaemia vera.**Primary erythrocytosis**

Conn syndrome

Pheochromocytoma (rarely)

Bartter syndrome

Idiopathic erythrocytosis

further subdivided into polycythaemias in the presence or absence of systemic hypoxia. A small group of patients do not fall into any of these categories and are given the diagnosis of idiopathic erythrocytosis (Table 36.2). The clinical management of many of these syndromes is not well defined.

The term 'apparent polycythaemia' refers to a raised haematocrit in the absence of a raised red cell mass and is discussed later in this chapter.

Primary erythrocytosis**Inherited/congenital erythrocytosis**

Chuvash polycythaemia is an autosomal recessive condition that is endemic in the Russian mid-Volga river region of

Chuvashia. Patients have increased levels of circulating Epo but do not carry mutations of EpoR. Chuvash polycythaemia was recently shown to be associated with a C→T mutation at nucleotide 598 (leads to an Arg200Trp substitution) in the von Hippel–Lindau (*VHL*) gene. The *VHL* gene is pivotal for ubiquitination and subsequent degradation of HIF-1 transcription factor, which is central to the oxygen-sensing pathway. This *VHL* mutant leads to a reduced rate of degradation of HIF-1 and upregulation of downstream targets including Epo, leading to polycythaemia. Recently, some of the rare non-Russian families with inherited polycythaemia were also shown to carry *VHL* mutations, and occasional pedigrees with mutations elsewhere in the oxygen-sensing pathway have been described, including the *PHD2* and *HIF2A* genes.

Primary familial and congenital polycythaemia (PFCP) is a rare disorder in which erythropoiesis is intrinsically overactive. The disorder is usually transmitted in an autosomal dominant manner with some cases appearing sporadically. Clinical features include the presence of isolated erythrocytosis without evolution into leukaemia or other MPNs, absence of splenomegaly, normal white blood cell and platelet counts, low or normal plasma Epo levels, normal haemoglobin–oxygen dissociation curve/ P_{50} , and hypersensitivity of erythroid progenitors to Epo. Mutations in the gene encoding EpoR have been described in several (but not all) families with PFCP. In most cases, the mutations lead to a C-terminal truncation of the EpoR protein, with increased sensitivity to Epo.

Secondary erythrocytosis**Erythrocytosis in the presence of systemic hypoxia*****Chronic lung disease and hypopnoea***

Lung disease is the predominant cause of chronic systemic hypoxia at sea level. Hypoxaemic chronic obstructive pulmonary disease is the commonest syndrome, but any lung–airway disease leading to chronic hypoxia could cause polycythaemia. Syndromes such as obstructive sleep apnoea and hypoventilation due to muscle weakness or paralysis can also occasionally be associated with secondary erythrocytosis.

Where possible, hypoxia should be ameliorated by treating the lung disease or with home oxygen therapy. Erythrocytosis has opposing effects on oxygen delivery as it increases the oxygen-carrying capacity while also increasing blood viscosity. Unfortunately, there is little evidence from clinical trials to guide management. In practice, many specialists suggest that venesection should be performed for haematocrits above 0.55.

High altitude

Residents at altitudes above 4000 m compensate for the ambient hypoxia by multisystem adaptation, including mild erythrocytosis, increase in capillary perfusion and lung diffusion capacity as well as biochemical changes in metabolic enzymes and myoglobin. Excessive altitude polycythaemia (PCV \geq 0.65) is

seen in a proportion of cases and is often accompanied by hyperuricaemia and proteinuria. Some of these individuals eventually decompensate and develop chronic mountain sickness (Monge disease). Such people deteriorate steadily and develop extreme polycythaemia (sometimes PCV ≥ 0.75), arterial desaturation and right heart failure. Resettlement at lower altitudes halts disease progression and can partly reverse it. Treatment with angiotensin-converting enzyme (ACE) inhibitors has been shown in randomized studies to reduce the PCV and proteinuria seen in excessive altitude polycythaemia.

Congenital cyanotic heart disease

Congenital heart defects leading to a right-to-left shunt can cause dramatic erythrocytosis (up to PCV of 0.80). Surgery to correct the cardiac defect should be undertaken when possible. A few inoperable patients survive to adulthood and the management of their erythrocytosis is not straightforward. As in patients with chronic lung disease, the increase in oxygen-carrying capacity afforded by erythrocytosis is countered by an increased viscosity and associated haemodynamic changes. Here, however, we are often dealing with young patients with responsive vasculatures, which can usually accommodate such changes. Some experts advocate venesection when the PCV is greater than 0.60, whereas others allow the haematocrit to rise further and venesect for symptoms such as recurrent haemoptysis, marked fatigue or deteriorating exercise tolerance.

High-affinity haemoglobins

High-affinity haemoglobins release less oxygen for a given oxygen partial pressure, and may thus give rise to tissue hypoxia. This leads to an Epo-driven erythrocytosis, which tends to renormalize Epo levels. The pathognomonic anomaly is a left shift in the oxygen dissociation curve (Figure 36.5). The precise

Figure 36.5 Haemoglobin–oxygen dissociation curves from a 27-year-old man with a raised red cell mass and a normal person (HbA) showing the presence of a high-affinity haemoglobin ('left shift'). Mass spectrometric analysis showed the man to be heterozygous for Hb San Diego, a high-affinity β -chain variant.

variant can be identified by mutational screening of DNA or by protein mass spectrometry.

There are over 40 haemoglobin variants with an increased affinity for oxygen, all dominantly inherited. Most are due to mutations in β -globin, with a small number due to mutations in α -globin. Mutations are clustered in regions of the globin chains involved in the regulation of the transition between tense (T) and relaxed (R) states of haemoglobin. Normally, oxy-HbA is in the T state and has low affinity for oxygen, and deoxy-HbA is in the R state and has high affinity for oxygen. Thus, mutations at the $\alpha\beta$ contact site (e.g. Hb San Diego), the C-terminus (e.g. Hb Bethesda) and the 2,3-diphosphoglycerate (2,3-DPG)-binding site (e.g. Hb Helsinki) are the commonest.

Most people with a high-affinity haemoglobin are in good health and are either diagnosed coincidentally or after being noticed to be plethoric. Some experience excessive muscle fatigue after vigorous exercise. Hyperviscosity is rarely a problem and surveys have failed to identify increased cardiovascular morbidity or mortality. Pregnancy is not adversely affected, even in mothers with haemoglobin affinity that exceeds that of HbF. Generally, therefore, no management is required, unless symptomatic.

Red cell metabolic defects

Very rare cases of erythrocytosis are due to abnormalities in red cell metabolism that lead to a reduction in intraerythrocytic 2,3-DPG. The best characterized defect is a mutant 2,3-DPG mutase. The only well-characterized family with this disorder showed autosomal recessive inheritance, although heterozygous family members had a decreased P_{50} and, in some cases, a moderate erythrocytosis. This disorder is excluded by the finding of a normal P_{50} in a fresh blood sample.

Methaemoglobinaemia

Oxidation of haem iron converts it from its normal ferrous (Fe^{2+}) to the ferric (Fe^{3+}) form and, correspondingly, haemoglobin (HbA) becomes methaemoglobin (Met-HbA). This constitutes an important antioxidant mechanism for the red cell, and conversion of Met-HbA back to HbA requires the generation of NADH from glycolysis. The rate of HbA auto-oxidation is about 20 times slower under normal circumstances than the rate of Met-HbA reduction, thus preventing Met-HbA accumulation.

Methaemoglobin has an increased affinity for oxygen and a left-shifted oxygen dissociation curve. Pathological acquired methaemoglobinaemia can result from exposure to strong oxidants (e.g. dapsone, paraquat, benzocaine) and can be life-threatening when severe but is rarely sufficiently long-lived to give rise to polycythaemia.

Hereditary methaemoglobinaemias can be due to haemoglobin mutations involving amino acids around the haem pocket (HbM disease), or secondary to enzymatic deficiencies

that interfere with the generation of NADH, which is required for day-to-day methaemoglobin reduction (namely NADH reductase and cytochrome *b₅* reductase). In view of the chronic nature of the methaemoglobinaemia in these disorders, secondary erythrocytosis can develop in the same manner as for high-affinity haemoglobin mutants.

Heavy smoking

Heavy smoking can lead to mild polycythaemia in the absence of hypoxic lung disease. The underlying cause of this is a raised carboxyhaemoglobin (CO-Hb) level resulting from chronically raised carbon monoxide (CO) levels. CO-Hb levels in urban dwelling non-smokers are rarely higher than 2%, with levels ranging from 3 to 20% in smokers. The short half-life of CO in the body (3–5 hours) leads, in smokers, to a rise in CO-Hb during the day and a fall during sleep, making it difficult to compare measurements taken at different times. Binding of CO to Hb, as well as displacing oxygen, leads to a conformational change similar to that seen in methaemoglobinaemia, with a similar left shift in the oxygen dissociation curve and a fall in P_{50} .

Erythrocytosis in the absence of systemic hypoxia

Abnormal erythropoietin secretion

Abnormal Epo secretion is a well-recognized cause of secondary erythrocytosis and is most commonly secondary to renal pathologies such as renal tumours (benign and malignant), polycystic kidney disease and diseases associated with local hypoxia such as renal cysts, hydronephrosis and renal artery stenosis. The polycythaemia usually responds to treatment of the underlying renal pathology.

Erythrocytosis occurs in 20–30% of patients after renal transplantation. The biggest risk to such patients is hypertension, strokes and cardiovascular complications. In many cases, the erythrocytosis and associated hypertension respond to ACE inhibitors. Theophylline may also be effective in some cases. Patients who remain polycythaemic despite such therapy should be treated with repeated venesection to maintain their haematocrit below 45%; 30–40% of cases resolve spontaneously.

Non-renal tumours can rarely be associated with polycythaemia. The commonest reported ones are hepatocellular carcinoma, cerebellar and other haemangiomas and large uterine fibromyomas. Polycythaemia responds to removal of the tumour in most of these cases.

Endocrine disorders

The mechanism underlying the development of polycythaemia in most endocrine disorders lies in the overproduction of androgens, which can produce polycythaemia by increasing Epo levels and also, probably, through a direct action on bone marrow progenitors.

Idiopathic erythrocytosis

In a small proportion of patients with polycythaemia the criteria for the diagnosis of PV are not met and no other aetiology for the raised red cell mass can be identified. This group is heterogeneous and likely to include patients with germline mutations causing polycythaemia as well as some that will go on to develop overt PV. With the advent of increasingly sophisticated diagnostic tests and the identification of the molecular lesions in many inherited forms of polycythaemia, idiopathic erythrocytosis is becoming a rare entity.

Apparent polycythaemia

Apparent polycythaemia refers to a raised PCV in the presence of a normal red cell volume (<25% above the predicted mean normal value). The raised haematocrit is due to a reduction in the plasma volume. Smoking, hypertension, obesity, excessive alcohol and diuretic therapy have all been associated with apparent polycythaemia. Pathogenesis is uncertain and almost certainly heterogeneous.

It is not clear whether apparent polycythaemia is associated with increased rates of thrombosis, but it seems sensible to encourage affected individuals to avoid known predisposing factors. There are no convincing data that routine venesection is beneficial.

Essential thrombocythaemia

The fundamental pathological feature of ET is a persistent elevation in the platelet count. However, ET has been poorly understood largely because of a lack of positive diagnostic criteria together with the fact that cases labelled as ET are likely to be pathogenetically heterogeneous. In 1934 Epstein and Goedel first described a patient with persistent elevation of the platelet count in association with megakaryocyte hyperplasia and tendency for venous thromboses and haemorrhage. Subsequently, Ozer and Gunz independently described two series of patients in 1960, thus confirming ET as a specific clinical entity. The recent discovery that approximately half the cases of ET carry the *JAK2* V617F mutation, as do half the cases of PMF and nearly all cases of PV, has enhanced our understanding of the relationship between the three disorders.

Pathophysiology

X-chromosome inactivation patterns provided the first evidence that ET may be a clonal stem cell disorder involving granulocytes, platelets and red cells but not T cells. For about 60% of patients a molecular basis for the clonality can be found, with about 55% of ET patients positive for the *JAK2* V617F mutation, and a further 5% carrying activating mutations near the transmembrane domain of the thrombopoietin receptor gene *MPL*.

Clinical and pathological features vary significantly between patients with ET, suggesting that the disease is heterogeneous. Prospective data from over 800 patients with ET has demonstrated that the presence or absence of the *JAK2* V617F mutation divides ET into two biologically distinct disorders. Mutation-positive ET exists along a continuum with PV as it displays multiple features of the latter, with significantly increased haemoglobin levels, neutrophil counts and bone marrow erythropoiesis, more venous thromboses and a higher incidence of polycythaemic transformation. Mutation-negative patients do nonetheless exhibit many clinical and laboratory features characteristic of an MPN including the presence of endogenous erythroid colonies and a risk of transformation to acute leukaemia. Patients with *MPL*-positive ET appear to have a phenotype that more closely resembles *JAK2*-negative ET, with an isolated thrombocytosis and less hypercellular bone marrow.

Clinical features

Epidemiology

The annual incidence of ET is similar to that of PV at around 1.5–2.0 cases per 100 000 population. The median age at onset is 50–55 years and although it can occur at any age, it is rare in childhood.

Thrombotic complications

As with PV, thrombotic complications are the main cause of morbidity and mortality in ET. Thromboses are present in around 15–20% of patients at presentation and may be arterial or venous. The range of clinical syndromes is similar to PV, but the frequency of splanchnic thromboses is probably lower and strongly correlated with presence of the *JAK2* V617F mutation.

A number of risk factors are associated with an increase in the risk of thrombosis in patients with ET. The best characterized are age over 60 years and a prior history of thrombosis. Other risk factors for thrombosis in ET are likely to include diabetes, hyperlipidaemia, hypertension and cigarette smoking. More recently, it has been reported that white cell count and reticulिन levels at diagnosis have predictive value for thrombosis (and indeed other complications) in ET. The exact role these and other predictors have in individualizing treatment regimens remains unclear.

Haemorrhagic complications

Bleeding is less common and less well studied than thrombosis in ET, but can be dramatic when it happens. Efforts to correlate the thrombotic risk with platelet function abnormalities have generally been fruitless and this investigation is also unable to predict haemorrhagic risk. However, bleeding is more common in patients with platelet counts above $1000 \times 10^9/L$ and, in at least some cases, this is due to acquired von Willebrand

disease, with a decrease in circulating high-molecular-weight multimers caused by adsorption to the surface of the excessive platelets.

Splenomegaly and hyposplenism

Splenomegaly is present in about 5% of ET patients at diagnosis and is rarely more than mild. Progressive enlargement of the spleen during the course of ET should raise suspicion of evolving myelofibrosis. It has been suggested that, over time, some patients with ET develop splenic atrophy secondary to silent microinfarcts in the splenic microcirculation. However, frank hyposplenism and its complications are rare.

Transformation to myelofibrosis or polycythaemia vera

Transformation to myelofibrosis and, more rarely, to PV are recognized complications of ET. Some, but not all, cases of apparent polycythaemic transformation may represent resolution of prior iron deficiency, as can happen with iron supplementation and after the menopause. The insidious onset of myelofibrotic transformation and the reluctance to serially study bone marrow trephine biopsies have hampered attempts to define its nature and frequency. Nonetheless, recent studies have shown that progression of reticulिन levels over time shows extensive interindividual variability and can be influenced by choice of therapy, being more marked in patients treated with anagrelide (see below). From the available data, myelofibrotic transformation occurs in less than 10% and polycythaemic transformation in less than 1–2% of ET patients over 10 years.

Leukaemic transformation

ET can evolve into MDS or AML even in untreated cases, but only rarely. The presence of cytogenetic abnormalities and treatment with alkylating agents increase this risk. Approximately 3% of patients treated with hydroxycarbamide alone develop MDS or AML if followed for a median time of 8 years. As with PV, there are no data to demonstrate that hydroxycarbamide as a single agent significantly increases the risk of leukaemia inherent to this disease, but a small effect cannot be excluded.

Investigations

The lack of pathognomonic features and the existence of many other causes of a raised platelet count have posed significant hurdles in the diagnosis of ET. The identification of the *JAK2* V617F mutation now provides a very useful positive diagnostic criterion for approximately 50% of ET patients. However, for V617F-negative patients, ET remains a diagnosis of exclusion and can only be made after other clonal blood disorders and reactive thrombocytosis have been ruled out. A proposed diagnostic schema for ET, as outlined by the BCSH guidelines, is given in Table 36.3.

Table 36.3 Diagnostic criteria for essential thrombocythaemia as recommended in the BCSH guidelines.

A1	Sustained platelet count $>450 \times 10^9/L$
A2	Presence of an acquired pathogenetic mutation (e.g. in the <i>JAK2</i> or <i>MPL</i> genes)
A3	No other myeloid malignancy, especially PV*, PMF†, CML‡ or MDS§
A4	No reactive cause for thrombocytosis and normal iron stores
A5	Bone marrow aspirate and trephine biopsy showing increased megakaryocyte numbers displaying a spectrum of morphology with predominant large megakaryocytes with hyperlobated nuclei and abundant cytoplasm. Reticulin is generally not increased (grades 0–2/4 or grade 0/3)

Diagnosis requires A1–A3 or A1 + A3–A5

*Excluded by a normal haematocrit in an iron-replete patient.

†Indicated by presence of significant bone marrow fibrosis ($\geq 2/3$ or $3/4$ reticulin) and palpable splenomegaly, blood film abnormalities (circulating progenitors and teardrop cells) or unexplained anaemia.

‡Excluded by absence of *BCR-ABL1* fusion from bone marrow or peripheral blood.

§Excluded by absence of dysplasia on examination of blood film and bone marrow aspirate.

An alternative set of diagnostic criteria, based largely around salient bone marrow morphological features, have been proposed as part of the WHO classification of tumours. Included in these is the concept of ‘prefibrotic myelofibrosis’, a putative group of patients previously labelled as ET who reportedly have increased rates of transformation to myelofibrosis over time. These proposals remain highly controversial in the MPN literature. In particular, studies of interobserver reliability for the histological component of this classification have shown it to be poorly reproducible, and a prospective multicentre study of the prognostic discrimination achieved by such a label found it to be minimal. Nevertheless, bone marrow histological features such as giant multilobated megakaryocytes and megakaryocyte clustering (Figure 36.6) can be of value in making the diagnosis of ET.

Reactive thrombocytosis

Thrombocytosis is most commonly reactive and secondary to increased levels of circulating cytokines that stimulate thrombopoiesis. Inflammatory, vasculitic and allergic disorders, acute and chronic infections, malignancies, haemolysis, iron deficiency and blood loss can all lead to an increased platelet count (Table 36.4). Reactive thrombocytosis can sometimes be marked and, occasionally, the platelet count can be greater than

Table 36.4 Causes of a reactive thrombocytosis.

Iron deficiency
Blood loss (acute or chronic)
Hyposplenism/splenectomy
Surgery
Acute bacterial infection
Pneumonia, septicaemia, meningitis, diverticular abscess, etc.
Chronic inflammation

Recovery from chemotherapy
Drugs
Vincristine

Figure 36.6 Bone marrow trephine section (haematoxylin and eosin, H&E) from a 60-year-old man with essential thrombocythaemia. Note the hypercellularity and marked increase in megakaryocyte numbers, consisting largely of clusters of mature multilobated forms.

$1000 \times 10^9/L$. There is usually evidence of ongoing inflammation in the form of a raised erythrocyte sedimentation rate or C-reactive protein but this is not always the case.

Other clonal thrombocytoses

A number of other haematological malignancies can be associated with thrombocytosis. Chronic myeloid leukaemia (CML) can be excluded by demonstrating the absence of the

BCR-ABL1 fusion transcript. Iron deficiency can mask the typical raised red cell mass of PV, although the clinical utility of distinguishing iron-deficient PV from ET is probably minimal. Established PMF can be excluded by the absence of significant bone marrow fibrosis and other characteristic laboratory features such as leucoerythroblastic blood film and splenomegaly.

Lastly, MDS can also be associated with a thrombocytosis in a minority of cases, but there are usually coexisting cytopenias, dysplastic features or specific cytogenetic abnormalities (e.g. deletion 5q). Sometimes, refractory anaemia with ringed sideroblasts can be associated with thrombocytosis and the presence of the *JAK2* V617F mutation; this illustrates the overlap among these chronic myeloid disorders.

Treatment

When considering the management of patients with ET, it is helpful to stratify them into risk groups, according to their risk of vascular complications, and take treatment decisions on this basis. Patients may be assigned to a high-, intermediate- or low-risk category.

High-risk patients

High-risk patients are those over 60 years old or those with one or more high-risk features, i.e. a platelet count of $1500 \times 10^9/L$ or more, a prior history of thrombosis or significant thrombotic risk factors such as diabetes or hypertension. In high-risk patients, control of the platelet count with hydroxycarbamide reduces thrombotic events compared with no cytoreductive therapy. The MRC PT-1 trial has recently compared treatment with hydroxycarbamide plus low-dose aspirin to anagrelide plus low-dose aspirin. Patients receiving anagrelide plus aspirin were significantly more likely to reach the composite primary end point (arterial thrombosis, venous thrombosis or major haemorrhage) and more likely to discontinue their allocated treatment. Compared with hydroxycarbamide plus aspirin, treatment with anagrelide plus aspirin was associated with a significantly increased rate of arterial thrombosis, major haemorrhage and myelofibrotic transformation, but a decreased rate of venous thromboembolism. These results suggest that hydroxycarbamide plus aspirin should remain first-line therapy for high-risk patients. Anagrelide is a useful second-line agent but the decision to use concurrent aspirin should depend on the relative risks of arterial thrombosis and haemorrhage in the individual patient.

Analysis of patients from the PT-1 trial according to *JAK2* status has shown that compared with V617F-negative patients, mutation-positive patients share many features with PV including a higher risk of venous thrombosis. Moreover, V617F-positive patients were more sensitive to hydroxycarbamide than anagrelide, raising the possibility that hydroxycarbamide is particularly effective in these patients.

Interferon alfa can give good control of the platelet count in ET, but as discussed under PV, its significant side-effect profile, subcutaneous administration and cost prevent its widespread use. It has a clearer role in the management of ET in pregnancy (see later) and some favour it in young patients. Busulfan can achieve good control of the platelet count but is only rarely used because of concerns over its long-term leukaemogenic potential. This is true for other alkylating agents and for radioactive phosphorus (^{32}P).

Intermediate-risk patients

Intermediate-risk patients are those between 40 and 60 years old who lack any of the high-risk features listed above. It is not clear whether it is beneficial to lower the platelet count in this group. Most receive either aspirin alone, or hydroxycarbamide and aspirin.

Low-risk patients

Low-risk patients are those younger than 40 years old who lack any high-risk features. Low-risk patients are usually given low-dose aspirin alone unless there is a contraindication such as previous peptic ulceration or allergy to salicylates. Antiplatelet agents such as dipyridamole or clopidogrel should be considered in these cases. In the setting of ET-associated haemorrhage, it is probably best to avoid antiplatelet agents.

Prognosis

Few studies have directly addressed survival in ET and these have reached different conclusions. Some suggest that mortality at 10 years is that of age-matched controls, whereas others found it to be worse. In high-risk patients, hydroxycarbamide reduces vaso-occlusive events from 10.7 to 1.6 per 100 patient-years.

Essential thrombocythaemia and pregnancy

ET is the MPN encountered most frequently in women of child-bearing age. In pregnancy, the commonest complication of ET is first-trimester miscarriage, which occurs in up to 30% of pregnancies. This is thought to be secondary to placental microinfarcts and insufficiency. The reported increased incidence of antiphospholipid antibodies in ET may contribute to this. Other less frequent complications include intrauterine death, growth retardation, premature delivery and pre-eclampsia. The risk of maternal thrombosis and haemorrhage is higher than in normal pregnancy, although a successful outcome (live birth) is achieved in around 60% of cases and no maternal deaths were seen in a recent review of 220 pregnancies.

The optimal management of ET in pregnancy has not yet been fully defined. There is conflicting evidence about the effectiveness of aspirin but, given the good documentation of its safety in a large unrelated study of pre-eclampsia, it should

probably be given to most patients who are pregnant or planning a pregnancy. Pregnancies deemed at high risk of thrombosis either on the basis of a prior history of thrombosis or a platelet count over $1500 \times 10^9/L$ should be considered for therapy with a combination of interferon and aspirin. Hydroxycarbamide and anagrelide should not be used on account of their teratogenic potential. In addition to lowering the platelet count, cases at the highest risk of thrombosis, such as those with previous thrombosis, hypertension or diabetes, should be considered for antithrombotic prophylaxis, normally in the form of low-molecular-weight heparin.

The platelet count may rise dramatically in the postpartum period but can normally be controlled with hydroxycarbamide or anagrelide. Hydroxycarbamide and anagrelide are excreted in breast milk so that breast-feeding is contraindicated while a patient is receiving either of these agents. Although interferon alfa is also excreted in breast milk, it is unlikely to be absorbed intact by the baby and there are anecdotal reports of successful breast-feeding while the mother was receiving interferon.

Primary myelofibrosis

Also known as agnogenic myeloid metaplasia and idiopathic myelofibrosis, PMF has the poorest prognosis of the MPNs. PV and ET can develop into a condition that resembles PMF, usually after a latency of many years. The first reported case of PMF is probably that described by Hueck in 1879 as a 'peculiar leukaemia'. It was not until Dameshek's seminal work in 1951 that PMF was recognized as an MPN. The identification of the *JAK2* V617F mutation in approximately half the cases of PMF and ET and nearly all cases of PV has revolutionized our understanding of the relationship between the three disorders. In fact, analogous to the concept of chronic and accelerated phase in CML, it may well be that PMF represents an accelerated phase of MPN, associated with the acquisition of further genetic abnormalities. In this model, patients presenting with apparently *de novo* PMF may have had a preceding undiagnosed disorder such as ET or PV.

Pathophysiology

PMF is a clonal MPN of the pluripotent haemopoietic stem cell, in which the proliferation of multiple cell lineages is accompanied by progressive bone marrow fibrosis. This is true for both *JAK2* V617F-positive and -negative cases while the precise effect of the mutation on the PMF phenotype awaits further studies.

Marrow fibrosis is thought to be secondary to the release of proinflammatory cytokines from abnormal clonal cells (primarily megakaryocytes), which act to stimulate fibroblast proliferation and fibrosis. In support of this premise, transgenic mice expressing high levels of thrombopoietin rapidly develop mye-

lofibrosis in association with increased megakaryocyte numbers. Additionally, mice expressing reduced levels of the transcription factor GATA-1, which impairs the ability of their megakaryocytes to differentiate into platelets, also develop myelofibrosis in association with increased expression of cytokines such as transforming growth factor (TGF)- β 1, platelet-derived growth factor (PDGF) and vascular endothelial growth factor in the bone marrow.

In the peripheral circulation there is an increase in the number of CD34-positive cells together with increased numbers of progenitors capable of giving rise to a variety of haemopoietic colonies. As with PV and ET, erythroid and megakaryocytic colonies can also be derived in the absence of exogenous growth factors.

The same molecular abnormalities seen in chronic-phase MPNs, such as mutations in *JAK2*, *MPL* and *TET2*, are found in patients with PMF, underscoring the interrelated nature of these disorders. Nonetheless, other mutations and epigenetic abnormalities are more frequently found in PMF, in keeping with the more aggressive phenotype, poorer prognosis and later stage of the disease. For example, cytogenetic abnormalities are found in up to 60% of cases. The commonest are deletions of 20q and 13q, trisomy 8, and abnormalities of chromosomes 1, 5, 7 and 9. Oncogene mutations are not infrequently found, and include point mutations in the *RAS*, *KIT* and *TP53*.

Clinical features

Epidemiology

The estimated annual incidence of PMF is around 0.5–1.5 per 100 000 population, with most patients diagnosed in the sixth decade and roughly equal involvement of the two sexes. Up to one-third of patients are asymptomatic at diagnosis and many of these are discovered after unrelated blood tests show modest abnormalities such as anaemia and thrombocytopenia.

Splenomegaly

An enlarged spleen is found in almost all patients at presentation and splenic pain/discomfort is a common presenting symptom of PMF. Most cases develop moderate to marked splenomegaly during the course of the disease and about 10% of cases develop massive splenomegaly, with the spleen extending to the right iliac fossa (Figure 36.7). This dramatic increase in splenic mass (up to 20–30 times normal) can lead to a substantial increase in splenic blood flow which, in the most severe cases, can lead to portal hypertension with oesophageal varices and ascites. Painful and painless splenic infarcts are common sequelae of splenomegaly in PMF.

Extramedullary haemopoiesis

The spleen is the commonest site of extramedullary haemopoiesis in PMF. The liver is also usually involved and this can lead to significant hepatomegaly. Unusual sites can sometimes be

Figure 36.7 Massive splenomegaly in a 53-year-old man with an 8-year history of primary myelofibrosis.

affected, leading to haemopoietic tumours surrounded by a capsule of connective tissue. Such sites include lymph nodes, central nervous system, skin, pericardium, peritoneum, pleura, ovaries, kidneys, adrenals, gastrointestinal tract and lungs. Many such cases remain asymptomatic, but involvement of the central nervous system can be a cause of serious morbidity. Treatment with radiotherapy or surgery, when required, almost always leads to resolution of these masses.

Systemic symptoms

A hypermetabolic state presenting with fevers, anorexia, weight loss and night sweats develops in many cases of PMF, sometimes early in the disease. The presence of such symptoms is associated with a poor prognosis.

Anaemia

Mild to moderate anaemia is found in most patients at presentation and worsens as myelofibrosis progresses. The anaemia is in large part due to reduced erythropoiesis, but may be compounded by hypersplenism, bleeding and iron or folate deficiency. Acquired HbH disease is a rare complication.

Platelet abnormalities

Platelet counts are raised in up to half of the cases at presentation and can be associated with thrombotic complications. However, progressive thrombocytopenia is a frequent occurrence and becomes increasingly troublesome as the disease progresses. Dysmegakaryopoiesis and abnormal platelet function further add to the risk of haemorrhagic complications.

White cells and leukaemic transformation

The presence of immature myeloid as well as erythroid progenitors is a characteristic feature of PMF (Figure 36.8). Neutrophilia is common, as are modest elevations in basophil and eosinophil counts. As the disease progresses, leucopenia increases in frequency and is believed to be secondary to progressive hyper-

Figure 36.8 Peripheral blood film in primary myelofibrosis showing a blast, an abnormal myelocyte, teardrop red cells and marked anisopoikilocytosis.

splenism, dysmyelopoiesis and progressive replacement of the bone marrow by fibrotic tissue. In end-stage PMF, myeloid precursors become increasingly common relative to mature cells, as do circulating blasts. Transformation to AML occurs in 20–30% of cases of PMF and is usually rapidly fatal.

Investigations

Diagnostic criteria for PMF are shown in Table 36.5. Other causes of bone marrow fibrosis are listed in Table 36.6.

Peripheral blood

The presence of myeloid and erythroid precursors in the peripheral blood (leucoerythroblastic blood picture) is common in PMF (see Figure 36.8). Other causes of a leucoerythroblastic blood film include bone marrow infiltration, severe sepsis, severe haemolysis and a sick neonate. Teardrop poikilocytes (dacrocytes), basophilic stippling, macrocytosis (which may or may not be secondary to folate deficiency), giant platelets and megakaryocyte fragments may also be present.

Bone marrow

Attempts at bone marrow aspiration often yield a dry tap or a haemodilute sample, making aspirate morphology of limited diagnostic value. Sufficient material can often be obtained from either bone marrow or peripheral blood to assess the karyotype, which can help exclude diagnoses such as CML. Other chromosomal abnormalities may be found in up to 60% of cases as

Table 36.5 Diagnostic criteria for primary myelofibrosis.**JAK2-positive primary myelofibrosis**

A1	Reticulin \geq grade 3 (on a 0–4 scale)
A2	Mutation in <i>JAK2</i>
B1	Palpable splenomegaly
B2	Otherwise unexplained anaemia (Hb < 11.5 g/L for men, < 10 g/L for women)
B3	Teardrop red cells on peripheral blood film
B4	Leukoerythroblastic blood film (presence of at least two nucleated red cells or immature myeloid cells in peripheral blood film)
B5	Systemic symptoms (drenching night sweats, weight loss >10% over 6 months <i>or</i> diffuse bone pain)
B6	Histological evidence of extramedullary haemopoiesis

Diagnosis requires A1 + A2 and any two B criteria

JAK2-negative primary myelofibrosis

A1	Reticulin \geq grade 3 (on a 0–4 scale)
A2	Absence of mutation in <i>JAK2</i>
A3	Absence of <i>BCR-ABL1</i> fusion gene
B1	Palpable splenomegaly
B2	Otherwise unexplained anaemia (Hb < 11.5 g/L for men, < 10 g/L for women)
B3	Teardrop red cells on peripheral blood film
B4	Leukoerythroblastic blood film (presence of at least two nucleated red cells or immature myeloid cells in peripheral blood film)
B5	Systemic symptoms (drenching night sweats, weight loss >10% over 6 months <i>or</i> diffuse bone pain)
B6	Histological evidence of extramedullary haemopoiesis

Diagnosis requires A1 + A2 + A3 and any two B criteria

detailed above. Abnormalities of chromosomes 5 and 7 are usually found in patients with prior exposure to genotoxic agents and are associated with a poor prognosis.

Bone marrow trephine biopsy is essential to make a diagnosis of PMF. Initial stages are characterized by an increase in bone marrow cellularity in association with disorganization of marrow architecture and the presence of abnormal large megakaryocytes often occurring in clusters (Figure 36.9). Bone marrow fibrosis becomes increasingly dominant and progressively replaces haemopoiesis. Intrasinusoidal haemopoiesis can sometimes be seen at this stage (Figure 36.10). The degree of fibrosis is best demonstrated using silver impregnation, which stains reticulin fibres (Figure 36.9). Collagen fibres are best demonstrated using a trichrome stain. The degree of fibrosis can be graded from 0 to 4 according to severity. In a minority of cases of advanced PMF, osteosclerosis ensues with thickening of the trabecula and extensive deposition of osteoid. Such changes may be evident on plain radiography.

Treatment

The only curative treatment for PMF is allogeneic stem cell transplantation, but this is only appropriate for a small proportion of patients. In the remaining cases therapy remains supportive and aimed at alleviating symptoms, but has little impact on the relatively poor survival of PMF patients. It is for this reason that the future development of therapeutic JAK2 inhibitors is most eagerly awaited for these patients, rather than for those with PV or ET who have a much better prognosis.

Conventional allogeneic bone marrow transplantation is only a realistic option in young patients, who represent perhaps 10% of all cases. The decision to proceed to transplantation should always be made in light of the patient's specific prognosis, age and general fitness. Only small series have been reported and the long-term survival of patients 45 years and younger is approximately 50%, with a 30% transplant-related mortality. For patients 45 years and older, outcomes are much worse, with long-term survival of 10–20%. Small numbers of reduced-intensity transplants have been reported, which show that this

(b)

Figure 36.9 Bone marrow trephine sections from a patient with early-stage primary myelofibrosis. The H&E stain (a) shows hypercellularity, disorganized architecture, increase in megakaryocyte numbers and prominent sinusoids. The silver stain (b) also shows a marked increase in reticulin fibres.

modality is feasible and safe in patients over 50 years old, although its efficacy is not yet clear.

Anaemia responds to treatment with androgens in up to one-third of cases, with the best responses seen in patients without massive splenomegaly and with a normal karyotype. The drugs most commonly used are oxymetholone (50–150 mg daily) and danazol (400–600 mg daily). Both of these can have virilizing effects and can lead to abnormal liver function. Patients with a reduced red cell survival may respond to treatment with corticosteroids. Human recombinant Epo has recently shown promise in small clinical studies of anaemia in PMF. Splenectomy also has a role (see below). Despite these treatments, most patients become transfusion dependent eventually.

Figure 36.10 Bone marrow trephine section in primary myelofibrosis (H&E). Note the presence of two dilated sinusoids (arrows) containing immature haemopoietic cells, including megakaryocytes.

Cytoreductive therapy can be useful in the management of some aspects of PMF, such as hepatosplenomegaly, constitutional symptoms and troublesome thrombocytosis. Hydroxycarbamide is the most widely used agent but anagrelide has also been used for thrombocytosis.

The indications for splenectomy include splenic pain, constitutional symptoms, portal hypertension and transfusion-dependent anaemia. In contrast, there is no good evidence that thrombocytopenia responds to splenectomy. The procedure has significant mortality (around 10%) and morbidity, particularly in elderly patients. Problems include perioperative bleeding, infection and thrombosis as well as rebound thrombocytosis and progressive hepatomegaly. It is particularly important to correct any coagulation abnormalities prior to surgery.

Splenic irradiation is an alternative to splenectomy in some cases and can significantly reduce splenic size, albeit transiently. This procedure is not without complications as it can lead to life-threatening cytopenias. Radiotherapy can also be useful for treating pockets of extramedullary haemopoiesis involving vital organs or body cavities.

The anti-angiogenic drug thalidomide has been reported to improve anaemia, thrombocytopenia or splenomegaly in approximately one-third of patients, but these changes are clinically significant only in a small proportion (20%). Thalidomide is poorly tolerated at conventional doses (>100 mg daily) with more than half of the patients being unable to tolerate it beyond 3 months. Furthermore, thalidomide increases the risk of extreme thrombocytosis and probably that of venous thrombosis, and needs special precautions for use in view of its extreme teratogenicity. Trials of lower doses of the drug alone or in combination with prednisolone suggest that such doses are

Table 36.7 Prognostic scoring systems in myelofibrosis: the Lille scoring system.

better tolerated and may be similarly efficacious. Bisphosphonates can help with bone pain.

Prognosis

The median survival is 3–5 years, but the range is very wide. As a result, efforts have been made to devise algorithms to individualize prognosis. The two most widely used algorithms are shown in Tables 36.7 and 36.8. Recently, an elevation in CD34 cell count above 300 × 10⁶/L and the presence of *JAK2* V617F mutation were also identified as adverse prognostic features.

Mastocytosis

Mastocytosis comprises a rare group of disorders characterized by a pathological increase in mast cells in tissues including the skin, bone marrow, liver, spleen, lymph nodes and gastrointestinal tract. Mastocytosis can be an isolated finding or can form part of other haematological disorders, including MDS, MPNs or AML. Some cases involve just the skin (cutaneous mastocytosis) whereas others involve multiple tissues and are associated

with systemic symptoms (systemic mastocytosis). Paediatric mast cell disease is generally a reactive condition rather than a clonal MPN and is not further discussed here. A classification of mast cell diseases has been proposed (Table 36.9).

The first case of urticaria pigmentosa (a form of cutaneous mastocytosis) was described in 1869 by Nettleship, and systemic disease due to increased mast cells was first documented by Ellis in 1949. The observation that stem cell factor (SCF) is an essential growth factor for mast cell development has led to significant advances in our understanding of this group of diseases.

Pathophysiology

After a search for abnormalities of SCF failed to identify any pathological changes, researchers turned to c-Kit, the tyrosine kinase receptor for SCF. A point mutation in the *KIT* gene leading to a single amino acid substitution (Asp816Val) in c-Kit was thus identified. This mutation leads to ligand-independent phosphorylation of c-Kit and consequent clonal expansion of mast cells.

Asp816Val was originally identified in cases of mastocytosis with associated haematological disorders but is now known to be present in the majority of adults presenting with urticaria pigmentosa or indolent systemic mastocytosis. More recently, other activating mutations affecting the same codon have been identified in a minority of adult cases of cutaneous mastocytosis (Asp816Tyr, Asp816Phe). A different mutation has been reported in a small number of cases of paediatric mastocytosis, namely Lys839Glu, which surprisingly gives rise to a dominant-negative (inactivating) form of c-Kit; the significance of this observation remains unresolved.

Recent reports have suggested that in some cases of mastocytosis, the c-Kit mutation is found in other haemopoietic cells such as B cells, myeloid cells and T cells. These results suggest that mastocytosis, as with the classical MPNs, may be a clonal disorder of the haemopoietic stem cell.

Figure 36.11 Urticaria pigmentosa in a 55-year-old woman. Note the widespread pink or brownish macules that become confluent in areas.

Clinical features

Cutaneous manifestations

Urticaria pigmentosa is the usual presenting feature in children and adults with isolated mastocytosis. Yellowish-brown lesions, usually macular and sometimes papular, appear in a patchy distribution. Less commonly, there is diffuse involvement of the skin, which becomes thickened and darker brown (Figure 36.11). Pruritus is common, as is flushing, and some cases develop haemorrhagic bullous disease. Whealing of lesions on rubbing is known as the Darier sign.

Systemic disease

Systemic manifestations are very heterogeneous and are thought to be largely secondary to mast cell mediator release. Episodes of flushing, angio-oedema, or even anaphylaxis with or without any specific trigger, can arise as a result of systemic histamine release. Gastrointestinal symptoms include abdominal pain, diarrhoea, nausea and vomiting. Gastritis and peptic ulceration may occur secondary to hyperhistaminaemia and severe cases may develop malabsorption. Osteoporosis is well recognized and can sometimes lead to pathological fractures. Peripheral blood cytopenias may arise secondary to mast cell infiltration of the bone marrow. Hepatosplenomegaly is more common in cases associated with another clonal haematological disorder. Fever, fatigue and weight loss can sometimes ensue and may result from the release of cytokines such as tumour necrosis factor (TNF)- α and IL-1.

Symptoms of organ failure due to infiltration are characteristic of aggressive systemic mastocytosis. Depending on the organs involved, cytopenias, pathological fractures, impaired liver function, ascites and malabsorption can all be seen.

Investigations

Clinical features of mastocytosis can be highly suggestive of the disease but diagnosis usually requires histological and biochem-

ical confirmation. An algorithm has been proposed for the diagnosis of systemic mast cell disease and is shown in Table 36.10.

Routine investigations should include a full blood count, liver function tests and a random serum tryptase. Tests for histamine metabolites in 24-hour urine specimens are probably no more useful than measurements of serum tryptase. Plasma levels of soluble CD25 and CD117 (c-Kit) have shown promise as novel markers of mast cell disease.

Bone marrow aspiration and trephine biopsy allow assessment of bone marrow involvement. Mast cell aggregates can be visualized on conventional haematoxylin and eosin-stained sections (Figure 36.12) but stand out much more clearly with stains such as toluidine blue (Figure 36.13). Immunocytochemistry using anti-tryptase antibodies can also be very useful, being highly specific for mast cells. Flow cytometry for expression of CD2 and CD25 in bone marrow mast cells may be useful as this phenotype is not seen in normal mast cells.

Abdominal ultrasound or computed tomography should be performed to look for hepatosplenomegaly and lymphadenopathy. Plain radiography and bone densitometry can be used to determine if bone involvement and osteoporosis are present. Endoscopy and biopsy can be useful if gut involvement is suspected.

Treatment

Despite significant advances in the understanding of its pathophysiology, no curative treatment exists for mastocytosis, the management of which remains symptomatic. There are four main components to the management of mastocytosis:

1 avoidance of factors that can trigger mediator release from mast cells;

Figure 36.12 Systemic mastocytosis involving the bone marrow (H&E). Malignant whorls of rounded and spindle-shaped mast cells are seen infiltrating the bone marrow in a paratrabecular distribution (arrow). A lymphoid aggregate and areas of hypocellularity are seen interspersed between the mast cell infiltrate and neighbouring haemopoietic islands (arrowhead). (Courtesy of Dr Wendy Erber.)

- 2 treatment of acute mediator release;
- 3 treatment of chronic mediator release;
- 4 reduction of the mast cell burden/organ infiltration.

Avoidance of triggers of mast cell mediator release is primarily an exercise in patient education. Severe reactions due to systemic mast cell mediator release are difficult to predict in patients with mastocytosis and do not correlate well with disease category, mast cell burden or severity of other symptoms. All patients and relevant healthcare workers should be warned of particular triggers, including general anaesthesia, contrast radiography and insect stings. Known mast cell activators such as morphine and dextran should only be introduced with great caution. Patients with previous anaphylaxis or severe hypotension should carry injectable adrenaline and they, their family and friends should be instructed in its intramuscular administration. Local mediator release in cutaneous mastocytosis can be moderated by avoidance of triggering factors such as friction and heat.

Acute systemic mast cell mediator release should be treated in much the same way as other forms of anaphylaxis. Treatment with adrenaline and intravenous fluids should be started as soon as possible, with early involvement of intensive care specialists in severe cases. Antihistamines (H_1 and H_2 blockers) should be introduced and continued long term if the episode is particularly severe or recurrent.

Symptoms of chronic mediator release are the commonest clinical problem in mastocytosis. Symptomatic cutaneous disease should be managed with the help of a dermatologist. Treatments include H_1 and H_2 blockers, topical corticosteroids and PUVA (psoralen with UVA irradiation) for severe disease.

(a)

(b)

Figure 36.13 Toluidine blue stain of bone marrow aspirate (a) and trephine biopsy section (b) in systemic mastocytosis. Abnormal spindle-shaped mast cells containing metachromatic granules are seen.

Non-life-threatening systemic symptoms such as flushing, abdominal pain and diarrhoea should be treated with H_1 and H_2 blockers, sodium cromoglycate and corticosteroids. Inhibitors of prostaglandin synthesis, such as aspirin and non-steroidal anti-inflammatory drugs, can also be useful. Aspirin should always be started with caution as it can initially lead to acute mediator release. Such drugs can be used prophylactically if symptoms recur frequently. Gastrointestinal disease usually responds to the drugs used to treat chronic systemic symptoms.

Anecdotally, leukotriene antagonists help with abdominal cramps and diarrhoea. Peptic ulcer and reflux disease should be treated with proton pump inhibitors. Osteoporosis should be treated with bisphosphonates and may be prevented with bisphosphonates or calcium and vitamin D supplementation. Bone density should be recorded and monitored according to the severity of osteoporosis. Radiotherapy can help with severe localized pain.

For patients in whom adequate symptomatic control cannot be achieved and for those with aggressive mastocytosis, interferon alfa, usually given in combination with oral corticosteroids, should be considered. Splenectomy may help reduce the mast cell burden and associated systemic symptoms. Cladribine has been found effective in isolated cases of aggressive systemic mastocytosis.

Treatment with chemotherapy is usually reserved for cases of rapidly progressive aggressive mastocytosis, mast cell leukaemia and mast cell sarcoma, but published data are not encouraging. Mast cell sarcoma may also respond to local radiotherapy when appropriate. Allogeneic bone marrow transplantation should also be considered. Treatment of any associated haematological disorder should be undertaken as appropriate for that disorder and the overall prognosis is usually that of the latter.

Future treatments

Treatments that target the mutant c-Kit tyrosine kinase have attracted a lot of interest recently. Imatinib is known to inhibit wild-type c-Kit *in vitro* and to be active against juxtamembrane mutants of c-Kit found in gastrointestinal stromal tumours. In contrast, the drug does not have the same effect on malignant mast cells carrying codon 816 mutations, probably because the mutant c-Kit does not allow access of imatinib to the site, hence conferring resistance to this drug in a similar way to acquired imatinib resistance in CML. In keeping with this, there have been early reports of its lack of efficacy in the presence of codon 816 mutations. A recent report showing that imatinib was effective in patients with mastocytosis with associated eosinophilia but without demonstrable *KIT* mutations awaits confirmation, particularly as these cases may represent variants of chronic eosinophilic leukaemia (CEL). Novel tyrosine kinase inhibitors that can inhibit the Asp816Val mutant c-Kit *in vitro* are under investigation.

Prognosis

Age and disease category are the most important determinants of outcome. The most benign syndrome is paediatric mastocytoma, which disappears with time in over 50% of cases. Paediatric urticaria pigmentosa also has a good prognosis and resolves in about half of the cases.

In adult mastocytosis, urticaria pigmentosa is usually associated with mast cell deposits in the marrow or other tissues, making this a systemic syndrome. Indolent systemic mastocytosis carries a favourable prognosis and usually persists as a

chronic low-grade disorder, although it rarely progresses to aggressive mastocytosis or mastocytosis associated with another haematological malignancy. Aggressive systemic mastocytosis can show a slowly progressive or a rapid clinical course but its overall prognosis has not been well defined in clinical studies. Mast cell leukaemia is rare but has a grave prognosis, with a median survival of less than 6 months.

Clonal hypereosinophilic syndromes

The term 'hypereosinophilic syndrome' (HES) was coined by Hardy and Anderson in 1968, who gave it the definition still in use today. Recently, major progress has been made in elucidating the molecular pathogenesis of clonal eosinophilia as described below.

Pathophysiology

Eosinophilia can be divided into three categories: reactive, idiopathic and clonal (Table 36.11). Reactive eosinophilia, which is by far the most common, is discussed in Chapter 17.

Idiopathic eosinophilias are those in which the cause is obscure. Within this category, HES describes patients with an unexplained elevation of peripheral blood eosinophils ($>1.5 \times 10^9/L$) for more than 6 months associated with end-organ damage (see Chapter 17). Many of these are probably cases of CEL for which the molecular defect has not been identified.

Clonal eosinophilias are those in which the eosinophilia is part of a clonal haematological malignancy. CEL is defined as an eosinophil count in excess of $1.5 \times 10^9/L$, with evidence of eosinophil clonality or an increased blast count in blood or bone marrow. The distinction between this entity and HES is blurred as it relies on the availability of a clonal marker. Indeed it has been shown recently that 25–50% of cases labelled as HES in fact have a microdeletion on chromosome 4, which results in the fusion of the *FIP1L1* and *PDGFRA* genes and the generation of a constitutively active tyrosine kinase. Importantly, patients carrying this fusion respond well to the tyrosine kinase inhibitor imatinib. Some patients with HES who do not carry this fusion gene also respond to imatinib, suggesting that in such cases other tyrosine kinases may be dysregulated.

In addition to CEL, a number of other haematological malignancies may be associated with increased numbers of clonal eosinophils, and in many cases this reflects tyrosine kinase dysregulation. *PDGFRA* rearrangements (e.g. *TEL-PDGFRB*) may present as chronic myelomonocytic leukaemia or atypical CML. The 8p11 myeloproliferative syndrome (EMS) is associated with rearrangements in the *FGFR1* gene (e.g. *ZMYM2-FGFR1*) and leads to a chronic MPN that frequently presents with eosinophilia and associated T-cell lymphoblastic lymphoma. Hypereosinophilic syndrome

a consequence of the *BCR-ABL1* tyrosine kinase fusion protein, may also be associated with clonal eosinophilia.

Eosinophilia as part of the malignant clone also occurs in patients with AML associated with inversion of chromosome 16 and the *SMMHC-CBFB* rearrangement. It has been reported that rare cases of acute lymphoblastic leukaemia may be associated with clonal eosinophilia but in this disease the eosinophilia is more usually secondary to growth factor release. Growth factor release is also believed to underlie the reactive eosinophilia seen in Hodgkin disease and in cases with clonal T cells in the peripheral blood.

Sustained hypereosinophilia can lead to symptomatology and end-organ damage regardless of its aetiology, but does not always do so. The reasons for this are unclear but may lie in the heterogeneity of eosinophilia and genetic differences between individuals that affect the propensity of eosinophils and other granulocytes to inflict tissue damage.

Clinical features (see also Chapter 17)

Much of the tissue damage in eosinophilia is believed to be secondary to eosinophil degranulation and release of mediators such as eosinophil cationic protein and major basic protein. Eosinophil mediators act mainly locally in tissues infiltrated by eosinophils to cause tissue damage. The recent finding that a raised serum tryptase in a subset of cases with clonal eosinophilia hints at a role for other cells (mast cells) in some cases.

Patients can present with constitutional symptoms such as fatigue, muscle aches or fevers. Pruritus, angio-oedema, diarrhoea and cough may also be present. Many tissues can be involved, but cardiac disease is the major cause of mortality. The heart can be affected by endomyocardial fibrosis, pericarditis, myocarditis and intramural thrombus formation. Death is usually due to dilated cardiomyopathy.

Involvement of the central and peripheral nervous systems can result in mononeuritis multiplex, paraparesis, encephalopathy and even dementia. Pulmonary involvement can take the form of pulmonary infiltrates, fibrosis or pleural disease with effusions. Gastrointestinal involvement can manifest as diarrhoea, gastritis, colitis, hepatitis or Budd–Chiari syndrome. The skin can be affected by pruritus, angio-oedema, papules or plaques. Rarely, other tissues such as the kidneys and bones can be involved.

Investigations

There are two aims in the investigation of eosinophilia: one is to establish its aetiology and the other to look for evidence of end-organ damage. As regards the former, given the diverse nature of the aetiologies of eosinophilia, a full history including family history, drug history and travel history can provide valuable clues. Investigations will usually aim to exclude reactive causes and will be guided by the clinical picture.

Bone marrow aspiration will reveal morphological abnormalities associated with haematological malignancies and allows cytogenetic analysis. It is also important to look for clonal T-cell receptor (TCR) gene rearrangements, the *FIP1L1-PDGFR* and *BCR-ABL1* fusion genes, as well as rearrangements of the *PDGFRB* and *FGFR1* genes. It has been reported that serum tryptase is raised in patients with the *FIP1L1-PDGFR* fusion.

Investigations to assess end-organ damage will depend on the clinical presentation. However, echocardiography should be

Figure 36.14 Cardiac MRI scan in a 65-year-old man with hypereosinophilic syndrome showing a rim of subendocardial fibrosis (arrow).

performed and repeated annually in patients with sustained eosinophilia, particularly as cardiac disease correlates poorly with the eosinophil count. If there is strong clinical suspicion of cardiac damage, then cardiac magnetic resonance imaging (MRI) can be useful, as this is more sensitive in detecting early disease (Figure 36.14). If there is doubt as to the aetiology of cardiac disease, endomyocardial biopsy may demonstrate eosinophil infiltration. Serial monitoring of pulmonary function may be required if there is evidence of lung involvement.

Treatment

Treatment should be used to halt or reverse organ damage. Eosinophilia without evidence of end-organ damage does not usually require treatment. When underlying clonal or non-clonal disorders are identified they should be treated appropriately.

Patients with rearrangements of the *PDGFRA* or *PDGFRB* genes respond well to imatinib, with normalization of eosinophil counts within weeks. A trial of imatinib is also reasonable in patients with HES who lack a clonal marker, as a proportion of these patients also respond.

For patients who do not respond to imatinib, prednisolone is the initial treatment of choice. Steroids reduce blood eosinophilia and the inflammation resulting from tissue infiltration. Cardiac disease may respond even in the absence of a significant reduction in the eosinophil count. Hydroxycarbamide and interferon alfa may benefit patients resistant to steroids. Cladribine and ciclosporin were also found to be of use in some cases.

Figure 36.15 Abundance of mature neutrophils and band forms in a blood film from a patient with chronic neutrophilic leukaemia.

Prognosis

The reported prognoses of CEL and HES are highly variable, with estimates of 3-year survival ranging from 23 to 96%. This is likely to reflect heterogeneity within these two categories of patients. In patients with HES, indicators of a poor prognosis include lack of response to steroids, a markedly elevated eosinophil count, normal IgE levels, splenomegaly, dysplastic features and male sex. Many of these adverse prognostic indicators may simply be markers of clonal (versus reactive) eosinophilia.

Chronic neutrophilic leukaemia

Chronic neutrophilia is a very common entity, and is usually secondary to chronic infections, chronic inflammation or malignancy. A very small subgroup of patients with chronic neutrophilia have chronic neutrophilic leukaemia (CNL), a clonal haematological disorder (Figure 36.15). Given the absence of a specific marker for this disease, CNL, like ET, is a diagnosis of exclusion (see also Chapter 27).

Pathophysiology

Cases can be subdivided into two main groups: 'true' CNL and neutrophilic CML. The two groups are only distinguishable by the presence in the latter of a rare type of *BCR-ABL1* rearrangement that produces a 230-kDa fusion protein (p230). In addition, rare patients with MDS can closely mimic CNL but exhibit dysplastic features and there are anecdotal reports of PV evolving into a disorder indistinguishable from CNL. The literature also includes reports of what was thought to be clonal chronic neutrophilia in association with plasma cell dyscrasias. However, data are accumulating that this type of neutrophilia is non-

Table 36.12 Diagnostic features of chronic neutrophilic leukaemia.

Peripheral blood leucocytosis $>25 \times 10^9/L$
Segmented neutrophils and bands $>80\%$ of white blood cells
Immature granulocytes $< 10\%$ of white blood cells
Myeloblasts $< 1\%$ of white blood cells
Hypercellular bone marrow biopsy
Neutrophilic granulocytes increased in percentage and number
Myeloblasts $< 5\%$ of nucleated marrow cells
Normal neutrophil maturation pattern
Hepatosplenomegaly
No identifiable cause of reactive neutrophilia
No evidence of another haematological malignancy
No Philadelphia chromosome or <i>BCR-ABL1</i> fusion
No evidence of another myeloproliferative disorder (i.e. normal PCV, platelets $< 600 \times 10^9/L$, no bone marrow fibrosis or other features of PMF)
No evidence of a myelodysplastic syndrome (i.e. no dysplasia, monocytes $< 1 \times 10^9/L$)

Source: modified from Vardiman *et al.* (2001) with permission.

clonal and probably a result of cytokine release from clonal plasma cells.

Diagnostic features of CNL are shown in Table 36.12. Neutrophilic CML usually exhibits these features, save for its association with the p230 *BCR-ABL1* rearrangement.

Clinical features and treatment

A recent review of the literature identified only 33 cases that fulfilled criteria for CNL. These cases exhibited a male to female ratio of 2:1 and a median age at diagnosis of 62.5 years (range 15–86 years). The median survival was 30 months, with only 28% of patients surviving to 5 years. Transformation to AML ensued in 21% (7 of 33) and this was invariably lethal. Other causes of death included sepsis and haemorrhage.

Haemoglobin was normal with platelet counts above $100 \times 10^9/L$ in most cases. The mean leucocyte count at diagnosis was $54.3 \times 10^9/L$ with mature and band forms in the peripheral blood. Vitamin B₁₂ levels were raised and neutrophil alkaline phosphatase levels were not low in most cases. Hyperuricaemia and gout were common. The spleen may be moderately enlarged. Bone marrow biopsies were markedly hypercellular and showed marked granulocytic proliferation, as did the bone marrow aspirates. Cytogenetic abnormalities were seen in about one-third, with del(20q), del(11q), del(12p), +8, +9 and +21 being mentioned in the WHO classification of tumours. In a small number of cases, X-chromosome inactivation patterns were used to demonstrate the clonal nature of CNL in patients lacking a cytogenetic marker.

The optimal treatment of CNL remains unclear. Oral cytoreductive agents such as hydroxycarbamide and busulfan can control the neutrophil count, as can interferon. The only potentially curative modality is allogeneic bone marrow transplantation and this option should be considered in younger patients.

Neutrophilic chronic myeloid leukaemia

This entity is probably even more rare than CNL, with only a handful of documented cases in the literature. The reported cases followed a more benign course than conventional CML, with a lower white cell count, lower proportion of immature granulocytes, milder anaemia, less marked splenomegaly and a lower propensity to acute transformation. Given recent advances in the treatment of *BCR-ABL1*-related diseases, it is important to consider and exclude neutrophilic CML during the investigation of chronic neutrophilia.

Transient abnormal myelopoiesis of Down syndrome

Children born with Down syndrome show a 10- to 20-fold increased risk of leukaemia, despite not showing an increased incidence of other cancer types. One haematological disorder, characteristically found only in neonates with Down syndrome, is transient abnormal myelopoiesis (TAM), also known as transient myeloproliferative disorder or transient leukaemia.

Incidence, clinical features and treatment

About 10% of neonates with Down syndrome are thought to develop TAM, although this may be underestimated since many otherwise healthy babies with trisomy 21 do not routinely have blood tests performed. Additional problems with recognition arise from the fact that many normal neonates with Down syndrome show mild abnormalities of blood counts, including polycythaemia and thrombocytopenia. About 25% of neonates with TAM are asymptomatic, with the blood film showing sometimes significantly elevated numbers of circulating immature myeloid cells, including basophilic blasts, nucleated red cells, megakaryocyte fragments and thrombocytosis or thrombocytopenia. In symptomatic babies, the clinical features are variable but can include neonatal jaundice, bleeding problems, respiratory distress and rarely liver failure.

The natural history of TAM is intriguing. In the majority of babies, the disorder resolves spontaneously by 3 months of age, without the need for treatment. Severely symptomatic infants, especially those with respiratory or hepatic dysfunction, can be treated very effectively with low-dose cytarabine chemotherapy. About 20% of neonates with TAM will subsequently develop acute megakaryoblastic leukaemia (AMKL) before the age of 4

years, although sometimes the leukaemia develops without antecedent TAM.

Pathophysiology

The fact that TAM only occurs in neonates points to it being a disorder of fetal haemopoiesis, and this presumably also explains why it is self-limiting in most cases. The characteristic association between TAM and AMKL indicates that a multistep model of mutation is operative in this clinical progression. Firstly, the disorder only occurs in trisomy 21, suggesting that there are genes on this chromosome that somehow predispose to abnormal fetal haemopoiesis. Several ETS family members and *RUNX1* are found on chromosome 21, but the key molecular pathways here have not been identified. Secondly, the development of TAM is tightly linked with the acquisition of characteristic mutations in the gene for the transcription factor GATA-1, located on the X chromosome. These mutations cluster in the first two coding exons of the gene and tend to be disruptive (frameshift insertions or deletions, splice-site and nonsense mutations). They all have the end result of generating a transcript in which protein translation is initiated downstream of the usual start site, leading to a GATA-1 protein lacking the first 84 amino acids. This prevents its interaction with another transcription factor, FOG1, leading to the characteristic phenotype of TAM. Thirdly, the progression to AMKL is probably driven by acquisition of further mutation(s). In particular, *JAK3* activating mutations are found in a small percentage of patients with AMKL in Down syndrome, although the mutations for most cases have not yet been identified.

The major histocompatibility complex and human leucocyte antigens

In the 1950s three independent scientists, Jean Dausset, Rose Payne and Jon van Rood, described the presence of alloantibodies in the sera of individuals exposed to genetically non-identical tissues such as the fetus in pregnancy and/or blood cells after transfusion. These alloantibodies were subsequently shown to react against protein antigens, encoded by a genetic region called the major histocompatibility complex (MHC). The MHC had also been independently identified in animal models of skin transplantation and tumour immunology, where genetically different strains of mice were shown to reject transplants from one another. Genetically identical mice could accept such transplants without rejection.

These observations led to theories of self/non-self discrimination, and the elucidation of the genetics of MHC genes encoding the protein 'histocompatibility' (or transplantation) antigens. Analysis of the structure and function of histocompatibility antigens has led to the establishment of routine and successful transplant protocols for both solid organ and haemopoietic stem cells between genetically disparate individuals.

The MHC in humans is located on the short arm of chromosome 6 (6p21.3). This region of the genome has been extensively studied and fully sequenced as part of the Human Genome Project (www.sanger.ac.uk/HGP/Chr6/). The MHC is an extremely gene-dense region of the genome, and it can be divided into 'three' subregions based on the type of genes found.

The genes encoding histocompatibility antigens are located within the MHC class I and II regions (Figure 37.1). These genes are called HLA genes (defined as human leucocyte antigens, although originally called human locus-A). HLA genes found in the class I region differ in structure from those found in the class II region and as a result the encoded proteins also differ. HLA class I genes encode a polypeptide of about 340 amino acids. This polypeptide is found as a cell-surface transmembrane glycoprotein and is associated with the soluble protein β_2 -microglobulin encoded by a gene on chromosome 15.

There are three classical class I genes: HLA-A, HLA-B and HLA-C. Their encoded proteins are expressed on virtually all nucleated cells within the body and also on platelets. The expression of HLA class I proteins varies for different types of tissues. For example, expression is high on lymphocytes but low on hepatocytes and tissues comprising the nervous system. In addition there are class I genes encoding non-classical class I molecules called HLA-E, HLA-F and HLA-G. The tissue distribution of these molecules is more restricted than that of HLA-A, -B and -C, and this is a reflection of their differing function. These molecules are not considered as transplantation antigens.

HLA class II molecules are similar in structure to HLA class I molecules. They are composed of two MHC-encoded polypeptide chains (α and β). HLA class II molecules, unlike class I, have a restricted tissue distribution. They are mainly expressed on antigen-presenting cells such as B cells, dendritic cells, macrophages and also activated (but not resting) T cells. There are three classical class II molecules: HLA-DR, HLA-DQ and HLA-DP. In addition, there are other non-classical class II molecules encoded by the HLA-DM and HLA-DO genes. These non-classical class II molecules are not transplantation antigens but do contribute to the antigen-presenting function of class II molecules.

Figure 37.1 Diagrammatic representation of the major histocompatibility complex. Approximate location of HLA-A, -B, -C, -DRA, -DRB, -DQA, -DQB, -DPA and -DPB genes are indicated. Other related genes are also present.

The class III region of the MHC does not contain any HLA genes. This region contains genes encoding proteins with various different functions including proteins involved in the immune response such as tumour necrosis factor (TNF)- α and TNF- β and complement components C2, C4 and Bf.

Structure of HLA proteins

The X-ray crystallographic structure of the extracellular domains of several HLA class I and II proteins has been resolved. The structures are divided into four domains as illustrated in Figure 37.2. The two most membrane-distal domains, α_1 and α_2 for HLA class I and α_1 and β_1 for HLA class II, form a β -pleated sheet surrounded on both sides by two α -helices. In both class I and II structures a short peptide is found bound in the cleft. Thus both class I and class II proteins can be considered trimolecular proteins consisting of three subunits: HLA heavy chain, β_2 -microglobulin and peptide form class I molecules, and HLA α - and β -chains and peptide form class II molecules.

Antigen processing and presentation

Peptide binding to HLA class I and II proteins plays an important role in the function of these molecules. The way in which peptides are derived and the binding procedure differs for the two classes of molecules and this is reflected in their different function.

Figure 37.2 Diagrammatic representation of HLA class I and II molecules showing protein domains and bound peptide.

HLA class I molecules are assembled within the endoplasmic reticulum (ER). The heavy chain is directed to the ER via a leader peptide sequence. Within the lumen of the ER, the extracellular domains of the heavy chain associate with β_2 -microglobulin. This association is mediated by ER-resident chaperones including calnexin and calreticulum.

Association with peptide also occurs within the ER. Peptides are derived from the cytoplasmic degradation of molecules that takes place in the proteasome, a multicatalytic protein complex. Peptides produced by the proteasome are actively transported into the ER via a transmembrane peptide pump called TAP

(transporter associated with antigen processing). Association between HLA class I heavy chain/ β_2 -microglobulin complex and peptide is catalysed by another ER-resident chaperone called tapasin associated with the thiol oxidoreductase ERp57.

Once the class I trimolecular complex is formed, the molecule can leave the ER and complete its journey to the cell surface via the Golgi apparatus. The journey of a class II molecule differs from that of a class I molecule. Both α - and β -chains are directed to the ER, where a complex of three $\alpha\beta$ chains and three invariant chains is formed. The invariant chain is also a transmembrane protein. Association of HLA class II molecules with the invariant chain effectively blocks the peptide-binding site on the class II molecule, thus preventing binding of ER-resident peptides. Invariant chain cytoplasmic tail sequences direct the class II molecule through the Golgi apparatus, but unlike class I molecules the class II molecules take a detour to endosomal vesicles before arriving at the cell surface. The non-classical HLA-DM and HLA-DO molecules are located within endosomal vesicles and it is here that the invariant chain is cleaved, leaving a peptide, called CLIP, blocking the class II peptide binding cleft. Specific peptide binding is catalysed by HLA-DM, and may also be aided by HLA-DO. The peptides that bind to class II molecules are derived from proteins that have been processed by the endocytic pathway. These proteins can be derived from the internalization of cell surface or extracellular proteins, or from endogenous cytosolic proteins via processes of autophagocytosis. Thus the antigen presentation pathway for HLA class II molecules differs from that of HLA class I molecules by directing the class II molecules to a location where they can bind peptides that are in the majority, differently sourced from those presented by class I molecules.

Peptides derived from exogenous sources may also be presented by HLA class I molecules via cross-presentation pathways. The detailed mechanisms involved in these pathways are not fully elucidated but such events likely play a significant role in ensuring an adequate immune response is elicited by the ability to present antigenic peptides from the same source on both class I and II molecules.

HLA function

Once presented at the cell surface, HLA molecules, together with bound peptide, are subject to surveillance by circulating T cells and natural killer (NK) cells. Both these cell types possess receptors that recognize and interact with HLA molecules. Typically, T cells expressing the CD4 molecule recognize HLA class II molecules and T cells expressing CD8 recognize HLA class I molecules. The specificity of interaction is determined during development of T cells within the thymus, such that circulating T cells should not interact with HLA molecules presenting peptides derived from normally expressed self proteins. However, the presentation of non-self peptides, for example

peptides derived from viral or bacterial proteins, or aberrant expression of tumour antigens can initiate, in appropriate conditions, activatory signals mediated by the T-cell receptor and coreceptors, resulting in the generation of an immune response against the cells expressing the target HLA protein-peptide complex.

NK cells have a determining role in the immune response to tumours and viral infections. NK cells function in innate immune responses and also contribute to the development of adaptive immune responses. The interactions between HLA molecules and NK cell receptors also impact on alloimmune responses occurring after transplantation and pregnancy. NK cells express a highly diverse repertoire of receptors, including killer cell immunoglobulin-like receptors (KIRs), that elicit either activatory or inhibitory signals. Some HLA class I molecules have been identified as ligands recognized by KIRs. Thus the interaction between an NK cell and target cell is influenced by the interaction between HLA on the target cell and KIRs on the NK cell. Typically, an interaction between HLA class I molecule and corresponding KIR will result in a negative signal and this will outweigh any additional activatory signals; thus the NK cell will not attack the target cell. However, if a cell has lost expression of HLA molecules as a result of malignancy or viral infection, the absence of the inhibitory signal will result in activatory signals being dominant and allow NK cell-mediated attack on the target cell. Interactions between HLA and KIR have been implicated in various medical conditions, including infectious disease, autoimmunity, cancer, reproduction and transplantation. KIRs are encoded within a multigene complex on chromosome 19, the gene organization of which varies within different haplotypes. KIR genes are also functionally polymorphic, thus making analysis of KIRs as challenging as that of HLA, if not more so.

HLA polymorphism

The outstanding feature of HLA genes and the proteins encoded is the extensive polymorphism exhibited. At each of the genes there are multiple possible variants (Table 37.1). The variants are called alleles. The nucleotide sequence differences between HLA alleles at a given locus can be translated into the protein sequence and analyses of the polymorphism has demonstrated that most variation exists within the peptide-binding domains. Experimental data support this by showing that different HLA proteins bind peptides with different sequences. Thus one of the functions of HLA polymorphism is to allow the presentation of numerous different peptides to the immune system. As there are six antigen-presenting 'classical' HLA molecules (HLA-A, -B, -C, -DR, -DQ, -DP) and most individuals are heterozygous for these loci, potentially each individual has 12 different HLA molecules, each of which can bind thousands of different peptides. The existence of a polymorphic polygenic

Table 37.1 Number of HLA alleles and serologically defined antigens by April 2010.

<i>HLA gene</i>	<i>No. of alleles</i>	<i>No. of antigens</i>

antigen-presenting system gives each individual the capacity to elicit immune responses against a wide variety of protein antigens. A complete listing of currently defined HLA alleles is given at www.ebi.ac.uk/imgt/hla/.

HLA polymorphism also varies within different populations. Variation in climate, geography and infectious pathogens are factors considered to have influenced the evolution of HLA polymorphism. It is therefore not surprising to find that HLA allele frequencies vary for different ethnic groups. This has an impact on unrelated donor transplantation: an HLA-matched donor is most likely to be found within a donor pool of the same ethnicity as the patient.

HLA polymorphism therefore functions as an advantage at the level of both a single individual and a population in terms of defence against pathogens. The extreme diversity found makes it very likely that someone somewhere possesses an HLA molecule that can be effective in generating an immune response against any infectious agent. However, HLA polymorphism is a significant obstacle to finding a matched unrelated donor for transplantation.

HLA associations with disease

Because both HLA class I and class II molecules control the positive and negative selection of T-cell receptors in the thymus and modulate the activity of NK cells, it is not surprising to find many associations between HLA and immune system disorders such as autoimmune disease. The first strong association described was that of HLA-B27 with ankylosing spondylitis and related seronegative spondylarthropathies, where over 95% of affected individuals possess an HLA-B*27 allele. Despite tremendous effort to discover the immunological basis for the association between B27 and ankylosing spondylitis, the answer

is still unknown. Other factors must also be involved because only 3–4% of individuals with HLA-B27 will develop disease. HLA type has also been associated with susceptibility to, and protection from, infectious diseases. Individuals possessing *HLA-B*53:01*, an allele prevalent within African populations, are more likely to be resistant to severe malaria. This association is supported by experiments showing that the B53 allotype can present a peptide derived from the malaria parasite. With HIV infection, the HLA type of the infected individual can influence the rate of disease progression. HLA-B35 is associated with more rapid progression to AIDS, whereas HLA-B27 and HLA-B57 are associated with slower disease progression. These associations reflect the function of different HLA molecules in the presentation of HIV peptides to CD8⁺ T cells in order to evoke an immune response against HIV-infected cells.

HLA class II molecules are restricted in their tissue distribution. However, appropriate stimulation can induce the expression of class II molecules on tissues where they are not normally expressed. This aberrant HLA class II expression may contribute to an autoimmune reaction by providing HLA–peptide complexes not encountered during T-cell receptor education in the thymus. Among the many associations between HLA class II molecules and autoimmune and/or inflammatory disease is that between rheumatoid arthritis and HLA-DR4. This association has been linked to the presence of an epitope contributed by residues 67, 70, 71 and 74 of the β -chain that contributes to a pocket (P4) in the peptide-binding site, thus supporting the role of peptide binding in the disease.

For other associations between HLA and disease, the answer has been found. Haemochromatosis has been associated with haplotypes possessing *HLA-A*03*. Genetic mapping has identified the gene, *HFE*, responsible for this association. Thus associations between HLA and disease may not be directly related to the HLA allotype but may be due to the presence of other genes that are closely linked or which are hitch-hiking within particular HLA haplotypes.

Associations between HLA type and hypersensitivity to drugs have also been reported, leading to the application of HLA typing to patient treatment. *HLA-B*57:01* typing is used to identify HIV-infected patients at risk from life-threatening hypersensitivity to the drug abacavir, an inhibitor of HIV-1 reverse transcriptase. The mechanism of this interaction is thought to involve an interaction between the drug and a peptide normally presented by the *HLA-B*57:01* encoded protein, resulting in a highly immunogenic CD8⁺ T-cell immune response.

HLA nomenclature

The naming of HLA specificities falls under the remit of the WHO Nomenclature Committee for Factors of the HLA System. The Committee names HLA genes, alleles and serologically

defined antigenic specificities. The names of the antigens, which were originally defined using either serological or cellular techniques, are a combination of letters which indicate the gene encoding the antigen, and numbers assigned in chronological order of their description. An example of an individual's HLA type determined by cellular and serological methods is A1, A2; B7, B13; Cw6, Cw7; Dw1, Dw13; DR1, DR4; DR53; DQ5, DQ8; DPw1, DPw4.

The numbering of antigens encoded by HLA-A and -B genes is in a single series for historical reasons, as these antigens were originally believed to represent the products of a single gene. The use of a lower case 'w' between the gene name and antigen number indicates a provisional specificity, although in most cases these have been removed. The exceptions are Bw4 and Bw6, which represent public epitopes rather than distinct antigens, HLA-C antigens (e.g. Cw1), to distinguish them from complement factors, and the HLA-D and HLA-DP antigens defined by cellular techniques.

Many HLA antigens have been characterized by serological methods into two or more subtypes, which are called 'splits', with the parent antigen called 'broad'. Thus both A23 and A24 are splits of the broad antigen A9. It is convention to indicate the broad antigen specificity in parentheses following the designation of the split, for example A23(9) or A24(9). A full listing of all the serologically and cellularly defined HLA antigens is given in Table 37.2.

Since 1987 the WHO Nomenclature Committee for Factors of the HLA System has assigned official names to HLA allele sequences. It was recognized that a single antigenic specificity, such as HLA-A2, defined by serology could be subdivided still further by DNA sequencing. Each allele is given a numerical designation that may be up to eight digits in length. The gene name is followed by an asterisk (*) and then the numerical designation. Each allele name consists of at least two, and maximally four, fields. The first field indicates the allele group, which often corresponds to the broad serological antigen encoded by the allele. The second field is used to list subtypes, numbers

assigned in the order in which the DNA sequences have been determined. Alleles whose numbers differ in the first two fields must differ in one or more nucleotide substitutions that change the amino acid sequence of the encoded protein. The third field is used to name alleles that differ only by synonymous nucleotide substitutions (also called silent or non-coding). The fourth field is used to name alleles that differ in either intron, or 3' or 5' regions of the gene. Lastly, an allele may have a suffix indicating aberrant expression; for example N indicates that it is a null allele with no protein being expressed, L indicates low cell surface expression and S indicates that the molecule is expressed only in a soluble form. For example, the *A*24:02:01:01* and *A*24:02:01:02L* alleles differ only by a single nucleotide which lies within an intron at a splice site. *A*24:02:01:01* is expressed at normal levels on the cell surface, whereas *A*24:02:01:02L* is expressed at very low levels on the cell surface due to the splice mutation.

Many new HLA alleles are reported each year (Figure 37.3). Details of the most recent advances in HLA nomenclature can be found in the latest WHO Nomenclature Committee for Factors of the HLA System Report or by accessing the IMGT/HLA Sequence Database, the official database of the Nomenclature Committee (www.ebi.ac.uk/imgt/hla).

HLA matching in transplantation

The benefits of HLA polymorphism in allowing the generation of immune responses against a wide range of antigens is completely negated when transplantation of organs and cells between genetically disparate individuals is considered. Typically, an individual will possess T cells capable of reacting against a foreign antigen at a frequency of 1 in 10⁴–10⁵. However, if cells from two HLA disparate individuals are mixed, the frequency of responding cells can be as high as 1–10%. These responding cells are called alloreactive cells.

A	B	C	D	DR	DQ	DP

Figure 37.3 Increase in number of HLA alleles identified by year.

Alloreactions are responsible for the inability to transplant organs and cells between genetically different individuals. To overcome alloreactivity, it is necessary to define the HLA type of donor and recipient and to select an HLA-matched donor wherever possible. In solid organ transplantation, HLA matching is encouraged for kidney transplants, where outcome data support a beneficial role of HLA matching. However, immunosuppressive therapy is extremely effective in renal transplantation and this allows for imperfect matching to be performed and optimum usage of all available organs. Nevertheless, it is critical to avoid transplantation of mismatched donor kidneys possessing HLA types against which the patient has raised alloantibodies as a result of a previous mismatched transplant, pregnancy or blood transfusion. The presence of such alloantibodies can lead to hyperacute rejection, but immunodepletion protocols may be used to remove such donor-specific antibodies. HLA matching for other solid organs such as liver and heart and lung is not usually performed. The liver is an immunoprivileged site that tolerates HLA mismatches, whereas heart and lung transplants are usually performed on patients for whom no other chance of life is possible, thereby disallowing selection of HLA-matched donors. Allereactions mediated following solid organ transplantation are usually only directed at the transplanted organ and with effective post-transplant immune monitoring can be managed with appropriate immunosuppression.

Patients receiving blood products, for example random pooled platelets, can produce antibodies against the HLA molecules present on transfused platelets. The presence of HLA-specific antibodies can lead to platelet refractoriness, and for

these patients it is advisable to seek HLA-matched platelet donors.

Allereactions occurring after haemopoietic stem cell transplantation (SCT) can result in failure of the cells to engraft or graft-versus-host disease (GVHD), in which donor cells mediate attack on various tissues within the host's body. The risks of graft rejection and GVHD are significantly reduced if the donor cells are histocompatible with the patient. The perfect donor is an identical twin. However, this will only be the case for very few patients. The chances of finding an HLA-matched sibling donor for a patient is theoretically one in four (25%). Therefore, again, the majority of patients will not be able to find a suitable donor within their family.

Another source of HLA-matched donors are the various volunteer donor registries that exist throughout the world. The first volunteer donor register, the Anthony Nolan Trust, was established in London in 1974 at a time when unrelated donor transplants were viewed as experimental. Since this time, the outcome of unrelated donor transplantation has vastly improved and the use of unrelated volunteer donors is now accepted practice. There are now over 60 volunteer donor registries throughout the world. In addition, the successful use of cord blood-derived stem cells for transplantation has driven the establishment of cord blood banks in many countries. An advantage of using cord blood cells in clinical transplantation is that a reduced degree of HLA matching is acceptable. Thus patients who fail to find a matched unrelated donor may receive mismatched cord blood stem cells. There are a number of factors that may negate the use of cord blood stem cells, such as the number of nucleated cells to be infused, particularly for

adult patients, as these may be insufficient to enable engraftment, and the inability to obtain donor cells for future donor lymphocyte infusion. However, the use of double cord units in adults can overcome the problem of cell numbers and it is certain that cord blood will be an important player in widening the application of haemopoietic SCT.

There are over 13 million potential volunteer adult donors and cord blood units registered for use in haemopoietic SCT worldwide. Unrelated adult and cord blood donations take place as a result of the successful international networking of the worldwide adult donor registries and cord blood banks, under the auspices of the World Marrow Donor Association. In 2007, 42% of haemopoietic stem cell donations were sourced in a country different to that of the patient. Details on both volunteer donor and cord blood registries can be found on www.bmdw.org.

HLA matching required for haemopoietic stem cell transplantation

The importance of HLA matching in haemopoietic SCT is well accepted. However, the degree of resolution required at each locus for an optimum match is not fully understood. Data obtained from large multicentre registry studies support the importance of optimum matching, which consists of allele-level matching for HLA-A, HLA-B, HLA-C and HLA-DRB1. The role of HLA-DQB1 is still not defined. Mismatching for HLA-DQB1 does not appear detrimental in studies published by the National Marrow Donor Program; however, an HLA-DQB1 mismatch with another HLA mismatch (HLA-A, -B or -C) was more detrimental than a single HLA-A, -B or -C mismatch. Furthermore, a hierarchy of beneficial mismatching has not been proven in terms of antigen-level mismatching over allele-level mismatching. Any type of mismatch can have a negative effect on transplant outcome. Because HLA-B and HLA-C are in linkage disequilibrium (i.e. matching for HLA-B increases the chance that HLA-C will also be matched), it is more difficult to mismatch for one and not the other. Similarly, HLA-DRB1 and -DQB1 genes are in linkage disequilibrium. HLA-A is the most telomeric of the HLA genes and in less linkage disequilibrium with other HLA class I genes; therefore, when selecting an HLA-mismatched donor, HLA-A is usually the easiest locus to mismatch. Therefore most mismatching targets HLA-DQB1 and then HLA-A. However there are no data to support HLA-A mismatching as being clinically more acceptable than mismatching for other single loci. The role of HLA-DPB1 is emerging in analysis of large patient and donor cohorts, including the International Histocompatibility Workshop studies. In these studies, HLA-DPB1 mismatching is associated with reduced disease relapse, together with an increase in acute GVHD. The association between HLA-DPB1 and disease relapse suggests that HLA-DP molecules may mediate a functional role in a graft-versus-leukaemia response.

Histocompatibility testing procedures

Detection of HLA polymorphisms can be performed by either targeting the DNA sequence of the HLA gene or by analysis of the expressed protein.

Serology

Serology describes the use of antibodies to detect epitopes on target antigens. HLA polymorphism results in the presence of different antigenic epitopes on the protein molecule. Antibodies used to define these antigenic epitopes are usually obtained from multiparous women, and can also be created using monoclonal antibody technology. The latter has the advantage of being available in unlimited supply. Serology involves the incubation of peripheral blood mononuclear cells (PBMCs), or separated T and B cells for distinguishing HLA class I from class II, with serum containing antibodies of known anti-HLA specificity. If the PBMCs express the appropriate HLA molecules, then binding between the antibodies in the serum and the PBMCs will occur. This binding will result in lysis of the PBMCs after the addition of complement components. The cells can be stained in order to detect which cells are alive (no reaction) and which cells are dead (positive reaction). The pattern of positive and negative reactions is then interpreted to give an HLA type.

In order to obtain a full HLA type, panels of antisera have to be screened to cover the range of recognized HLA specificities. Despite the number of serological reagents that have been analysed, there are many HLA class I and II polymorphisms which remain undetected by serology (see Table 37.1). Many of these polymorphisms are not present on the surface of the HLA molecules but are found within the peptide-binding site, and could alter the peptide-binding specificity of the HLA molecule and hence the antigen presentation function of the molecule. Thus serological typing does not detect all the functional polymorphisms of HLA molecules.

DNA-based methods

The introduction of the polymerase chain reaction (PCR) for analysis of DNA has led to the establishment of rigorous DNA-based methodologies that can be applied for genetic diagnostics. DNA-based methods are now used routinely for histocompatibility typing.

The most frequent HLA class I antigen in white populations and the first HLA antigen to be defined, HLA-A2, encompasses three serological variants. Sequencing analyses have shown that at least 199 alleles encode the HLA-A2 specificity. Of these 199 alleles, 155 differ by substitutions that are predicted to influence the antigen presentation function of the HLA-A2 molecule, and 10 alleles (*A*02:15N*, *A*02:32N*, *A*02:43N*, *A*02:53N*, *A*02:82N*,

*A*02:83N*, *A*02:88N*, *A*02:94N*, *A*92:13N* and *A*92:25N*) contain mutations which prevent expression of the HLA-A2 antigen.

For HLA class I molecules the polymorphism is mostly localized within the $\alpha 1$ and $\alpha 2$ domains, which are encoded by exons 2 and 3 respectively of the class I gene. For HLA class II, the $\alpha 1$ domain of the β -chain, encoded by exon 2, is most polymorphic for DRB1, whereas for DQ and DP, the polymorphism extends to both the $\alpha 1$ and $\beta 1$ domains. Thus DNA methods for HLA class I typing focus predominantly on exons 2 and 3, whereas for HLA class II exon 2 is targeted.

Sequence-specific oligonucleotide and sequence-specific primer methods

The most widely used DNA-based methods for HLA typing are PCR sequence-specific primers (PCR-SSP) and PCR sequence-specific oligonucleotides (PCR-SSO). These methods use DNA primers (SSP) or DNA probes (SSO) that react with polymorphic sequence motifs present within the nucleotide sequence of HLA alleles. The presence of a positive reaction indicates that the polymorphism defined by the primer or probe is present in the DNA sample, whereas a negative reaction defines the absence of that particular sequence polymorphism.

For PCR-SSO typing, the target DNA molecule is amplified by locus-specific PCR (e.g. all HLA-A alleles are amplified in one PCR) or by group-specific PCR (e.g. all DRB1*04 alleles are amplified in one PCR). The PCR product is immobilized directly onto a solid-phase matrix containing pre-immobilized HLA-specific oligonucleotide probes, for example nylon membrane or Luminex xMAP microspheres. Interaction between the immobilized probes and HLA PCR product is measured as positive, whereas no binding between probe and PCR product is measured as negative. Most methods utilize specific software to measure positive and negative reactions and to assign the interpreted HLA type.

PCR-SSP typing (Figure 37.4) utilizes multiple PCR primer pairs all tested independently on the same sample DNA. The primer pairs are designed such that the 3' end defines the specificity of the primer with the target sequence. To obtain a full HLA type requires numerous primer pairs which have been designed to operate under identical PCR amplification conditions. If the target sequence for a primer pair is present in the sample DNA, a PCR product will be produced, whereas if the target sequence is not present there will be no PCR product. The presence and absence of PCR products can be visualized after agarose gel electrophoresis. Because of the extensive HLA polymorphism, specialized software is usually required to interpret results. PCR-SSP can be used to perform a full HLA type or to target a particular group of HLA alleles to obtain a high-resolution type (e.g. subtype *A*02*).

The resolution of the typing results obtained by PCR-SSO and PCR-SSP methods can vary depending on the number of probes or primer mixes utilized, with an increasing number required for higher resolution. As SSO methods utilize less PCR steps, this method is more useful for high-throughput HLA genotyping, for example as required by laboratories with large sample numbers, including unrelated haemopoietic donor registry laboratories. SSP methods are more suitable for smaller volumes and are reserved for quick turnaround typing or for achieving higher resolution on particular samples.

Regardless of the number of typing reagents used with PCR-SSP and PCR-SSO methods, the end result is the presence or absence of a reaction between a probe or primer of a known sequence and the target HLA sequence. Thus the data generated can be directly related to the DNA sequence of the HLA alleles possessed by an individual.

Direct sequencing

The generation of a database of known nucleotide sequences of HLA alleles has had a tremendous impact on the transfer of

Figure 37.4 Example of PCR-SSP test. Photograph of an ethidium bromide-stained agarose gel containing electrophoresed PCR products. In this example, 24 PCR primer mixes have been utilized to determine HLA-DRB1*11 subtype. Each lane on the gel contains the product from amplification of a non-polymorphic region of the genome. The presence of this product indicates successful amplification. A second band is observed in

lanes 1, 3, 6 and 9, where specific amplification of a polymorphic region from an HLA gene is achieved. If no second band is present, then the individual being tested does not possess the complementary HLA polymorphism. The pattern of positive and negative reactions (presence and absence of second bands) is interpreted to give the HLA type. (Courtesy of Franco Tavarozzi, The Anthony Nolan Trust.)

methodologies from serology to DNA-based techniques. Improvements in automated instrumentation for DNA sequencing has also made this methodology an affordable alternative for HLA typing. The sequencing techniques utilized for HLA typing involve PCR amplification and direct sequencing of the PCR product. The strategies developed have focused on the amplification of DNA fragments containing the polymorphic exons, which for the majority of class I alleles extends to a fragment containing exons 2 and 3 at a minimum. The overall size of an HLA class I gene is about 3.2 kb and therefore it is feasible to target all exons (and introns) within the gene to define the polymorphisms present; this additional information greatly increases the resolving power of sequencing methods.

HLA class II genes are much larger than HLA class I genes and the amount of sequence information available for exons outside exon 2 is limited. HLA class II sequencing methods minimally target exon 2, with additional data sought from exon 3 to resolve some exon 3 known polymorphisms. HLA-DQB1 also benefits from analysis of both exon 2 and exon 3.

As most loci are heterozygous, assignment of HLA type is dependent on the use of software capable of assigning heterozygous positions. In addition an up-to-date database of all known HLA sequences is required (Figure 37.5).

The advantages of DNA-based methods over serology are numerous and include the ease with which typing reagents (primers, probes) can be synthesized and the interpretation of the data as directly relating to nucleotide sequence, whereas the data obtained with polyclonal antisera requires extensive knowledge of cross-reactivities of sera with different HLA antigens. In addition, the storage of material is simplified for DNA typing, as live cells are not required.

Ambiguities

DNA typing methods can generate ambiguous results when both alleles in a heterozygous combination are analysed together. Therefore it can be difficult to determine whether a sequence motif is in the *cis* or *trans* orientation compared with a different motif. This problem is overcome by performing allele-specific amplifications on samples with ambiguities prior to analysis, usually by SSO or sequencing. Alternatively, sequencing primers can be designed to target particular polymorphisms, allowing separation of the two alleles in a heterozygous sample. Fewer ambiguities are obtained using PCR-SSP as the PCR primers used link *cis* polymorphisms.

Cellular assays

Cellular methods for assessing potential alloreactivity between patient and donor can also be utilized for the selection of the most appropriate stem cell donor. The mixed lymphocyte culture (MLC) assay has been used since the 1960s. MLC meas-

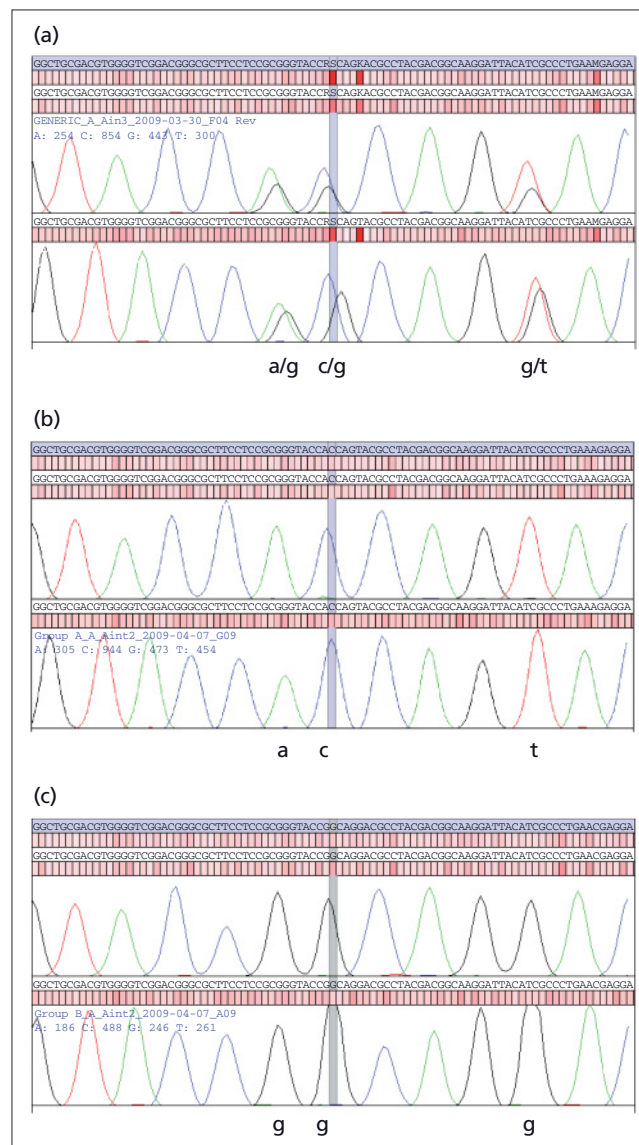

Figure 37.5 HLA sequencing electropherogram. The electropherograms are from ASSIGN software analysis of sequencing performed on an HLA-A PCR product containing exons 2, 3 and 4. (a) Heterozygous loci. The sequence is read from left to right. For this short stretch of nucleotides (12 from 822 analysed for HLA-A), eight different results are possible for the heterozygous nucleotides: ACG, ACT, AGG, AGT, GCG, GCT, GGG and GGT. Overall analysis of all 822 nucleotides gives an ambiguous result of A*03:01, *24:02 or A*03:07, *24:56 or A*03:08, *24:07 or A*03:15, *24:53 or A*03:17, *24:21. (b, c) Separated loci. By sequencing the two HLA-A alleles after separation using allele-specific PCR primers, the heterozygous ambiguities are resolved. The result for (b) gives ACT and for (c) gives GGG. The final result for this ambiguity, after analysis of all 822 nucleotides sequenced, is HLA-A*03:01, *24:02. (Courtesy of Shem Wallis-Jones, The Anthony Nolan Trust.)

ures the reactivity of donor T cells against alloantigens expressed by patient cells, i.e. graft versus host direction. By mixing both donor and patient cells together, any alloreactions that occur will cause the responding donor cells to proliferate and incorporate ^3H -thymidine, which can be measured. The patient cells are prevented from proliferating by being gamma-irradiated prior to the mixing of cells. However, since the introduction of DNA-based methods for HLA class II typing, the MLC reaction is infrequently used. Indeed studies have indicated that positive MLC reactions in the absence of detectable HLA class II mismatches are not predictors of the development of GVHD after bone marrow transplantation.

More sensitive cellular assays have been developed to measure HLA disparity. The cytotoxic T-lymphocyte precursor (CTLp) assay uses limiting dilution analysis to measure the frequency of donor CTLs responding to predominantly HLA class I mismatches on patient cells. High frequencies of CTLp have been shown to be strongly associated with HLA class I mismatches, which may have escaped detection by the low to medium level of resolution of conventional typings that were widely used for class I matching prior to the use of allele-level DNA typing. Similarly, the helper T-lymphocyte precursor (HTLp) assay measures the HTL response of the donor to HLA class II mismatches, with HLA-DR mismatches associated with high HTLp frequencies with no apparent contribution from HLA class I mismatches. Both CTLp and HTLp assays can be combined in a single limiting dilution analysis, thus minimizing the use of often valuable material.

The drawback of cellular assays is that they take up to 2 weeks to perform, and they require viable cells from both donor and patient. With more widespread use of high-resolution HLA typing techniques, the number of laboratories performing cellular assays has decreased significantly.

Other genetic polymorphisms

HLA polymorphisms clearly play an important role in determining the outcome of haemopoietic SCT. There are also other genetic polymorphisms that have been demonstrated to influence outcome. Minor histocompatibility antigens (mHA) are alloantigens that are also capable of initiating an immune response when their genes are mismatched for patient and donor, despite the presence of HLA matching. Minor histocompatibility antigens are peptides derived from normal self proteins that possess polymorphisms. A donor and patient may share HLA type, but differ in the polymorphism found in the mHA gene. Several human mHA have been defined, for example HA1, HA2, HA3. The genes encoding several of these mHA have been described and this has allowed the development of typing procedures for these genes using techniques such as PCR-SSP.

Single-nucleotide polymorphisms (SNPs) in other genes, particularly cytokines, have also been shown to have an impact

on the outcome of SCT. Recent studies have described the significant correlation between transplant outcome in patients suffering from acute leukaemias and three SNPs in the *CARD15* (caspase recruitment domain 15) gene, now called *NOD2* (nucleotide-binding oligomerization domain 2). These may be defined by a variety of techniques that are able to target single mutations within a gene.

There is therefore a choice of techniques that may be used for optimum donor selection for patients requiring SCT. Each methodology has its advantages and disadvantages. It is now accepted practice that DNA-based typing should be performed on all related and unrelated donors and patients. Serology and cellular assays may be used to complement the outcome of DNA typing. A major challenge for the future of histocompatibility typing for SCT will be to acquire a greater understanding of what types of mismatches are acceptable in that they do not result in adverse alloreactions, and also to know which mismatches are detrimental. It is likely that more sensitive and reproducible cellular assays may play a role in determining these mismatches. The use of ELISPOT assay and real-time PCR methods for detecting low numbers of cytokine-producing cells may in the future become additional tools for the histocompatibility laboratory, especially for the selection of best mismatched donors when no optimum matched donor is available.

Introduction

Haemopoietic stem cell transplantation (SCT) represents an important and increasingly utilized curative therapy in haematological malignancies and has an emerging role in the management of patients with haemoglobinopathies and bone marrow failure. Improvements in supportive care and treatment of post-transplant complications, a greater availability of alternative donors and advances in tissue typing have simultaneously improved transplant outcome and patient eligibility. The realization that an immunologically mediated graft-versus-leukaemia (GVL) effect makes a major contribution to the curative effect of an allograft has underpinned the concept that allogeneic transplantation can be used as a platform for antitumour immunotherapy. These advances have coincided with the advent of reduced-intensity conditioning (RIC) regimens, which have substantially reduced the morbidity and mortality of allografting and resulted in a marked increase in the number of stem cell transplants, particularly allografts, performed over this period in Europe and worldwide (Figure 38.1).

Immunological basis of stem cell transplantation

The major complications of allogeneic SCT are caused by the immunological responses triggered by the infusion of donor haemopoietic progenitors and lymphocytes into an immunosuppressed host. These can take the form of either a host-versus-graft (HVG) or a donor-derived graft-versus-host (GVH) response. Clinically, the HVG response can result in graft rejection, while a GVH response may manifest itself as either graft-versus-host disease (GVHD) or a GVL reaction. It is now possible to blunt the HVG reaction by optimizing the immunosuppressive properties of the conditioning regimen and consequently graft rejection is rare in most clinical settings. In contrast, GVHD and disease relapse remain the major complications of allogeneic transplantation and novel approaches that permit the induction of GVL without inducing host injury are required. Conversely, autologous SCT is a relatively unremarkable immunological event in which these allogeneic responses are absent.

Antigens and cellular effectors

The antigens against which HVG and GVH responses are directed include the products of highly polymorphic genes lying

Figure 38.1 Numbers of (a) allogeneic and (b) autologous stem cell transplants performed within Europe. (From Ljungman *et al.* 2010 with permission.)

within the major human leucocyte antigen (HLA) complex on chromosome 6 and minor histocompatibility antigens (minor H antigens) encoded by a number of disparate genes lying outside the HLA system. These antigens and the methods employed to identify them have been reviewed in Chapter 37.

In very general terms, the degree of difference or 'incompatibility' between the donor and recipient will define the risk of graft rejection and/or GVHD. Thus, in situations where the donor is genetically identical to the recipient (syngeneic transplantation), graft rejection or significant GVHD is not observed. For patients undergoing allogeneic transplantation using an HLA-identical sibling, the relevant antigens are minor H antigens, which are polymorphic proteins recognized by T cells as processed peptides in the context of a 'self' HLA molecule. To date, just over 20 such antigens have been identified and include antigens that are ubiquitously expressed on host tissue (e.g. HY antigens encoded by genes on the Y chromosome) or which have restricted tissue distribution (e.g. HA-1 or HA-2, which are only expressed by the haemopoietic system). Female donors, specifically multiparous individuals who have had male infants, may have been primed against HY antigens and as a consequence have circulating T cells that recognize male patient cells expressing these proteins. This is likely to underlie the increased risk of GVHD in male recipients of female grafts.

Where a patient has no HLA-identical sibling donor, an alternative donor may be considered. In this case, the transplant centre will generally seek a donor who is matched with the recipient at each of the HLA-A, -B, -C, -DRB1 and -DQB1 loci (the so-called '10/10 match'). Even with a complete 10/10 match, the risk of GVHD is higher than for an HLA-identical sibling, presumably because the number of polymorphic minor H antigen differences is likely to be greater. In the situation where the donor and recipient are mismatched for one or more class I or II HLA antigens, the risk of transplant complications

is higher since the adult T-cell repertoire contains a very high frequency of cells (~5%) with the potential to react or cross-react with mismatched HLA molecules. Although single HLA mismatches can be reasonably well tolerated clinically, greater degrees of mismatch are associated with increased rates of graft rejection or GVHD. There is a great deal of interest relating to the possibility of 'permissive' HLA mismatches that do not result in a worse transplant outcome. For example, it has been proposed recently that mismatches at HLA-DPB1 (a locus not usually considered in matching with unrelated donors) may actually be associated with an improved outcome because of a lower risk of disease relapse. The degree of HLA mismatch that can be tolerated is greater in patients transplanted using umbilical cord blood (UCB), possibly as a result of the cotransfer of naive donor T cells with less potential for cross-reactivity against HLA antigens.

More extensive HLA disparity, following for example haplo-identical transplantation, is only feasible under conditions in which the patient receives highly immunosuppressive conditioning and high doses of haemopoietic progenitor cells (to offset the risk of graft rejection) and where T cells are almost completely depleted from the graft (to prevent prohibitive rates of GVHD). In this setting, certain HLA class I mismatches may play an important role in activating donor natural killer (NK) cells. NK cells express inhibitory killer immunoglobulin-like receptors (inhibitory KIRs) that recognize certain classes of 'self' HLA class I molecules. Upon KIR interaction with a cognate class I ligand, NK functions are inhibited. Conversely, NK-mediated lysis will be triggered if the appropriate inhibitory KIR ligand (an HLA-C or HLA-B molecule) is not presented on the target cell (so-called 'missing self recognition'). While this is not sufficient to induce GVHD, it may result in killing of tumour cells in certain cancers such as acute myeloid leukaemia (AML).

Acute graft-versus-host disease

GVHD is a complex immunological disorder in which donor T cells with specificity for recipient antigens not expressed in the donor initiate tissue damage. The recipient, as a result of immunosuppression or immunodeficiency, is incapable of rejecting the T cells mediating the alloreactive response. Conditioning-induced tissue injury leads to the release of proinflammatory cytokines and altered chemokine or adhesion molecule expression. These changes impact on the developing GVH response leading to cytokine dysregulation and enhanced trafficking of cellular effectors to the organs targeted in GVHD.

Induction of GVHD (Figure 38.2) requires the interaction of donor T cells with host antigen-presenting cells (APCs), most probably dendritic cells within secondary lymphoid organs such as lymph nodes and gut-associated lymphoid tissue. Host APCs are activated by proinflammatory cytokines, such as tumour necrosis factor (TNF)- α or interleukin (IL)-1 β , which are released following tissue damage induced by the conditioning regimen. Activated APCs upregulate surface expression of HLA molecules and costimulatory (e.g. B-7 family) molecules and demonstrate increased secretion of inflammatory mediators (e.g. cytokines and inflammatory chemokines). Donor CD4 and CD8 T cells with anti-host specificity, activated on interaction with host APCs, proliferate and develop effector functions that lead to the secretion of effector cytokines (e.g. TNF- α , interferon- γ , IL-2, IL-17) or the induction of perforin/granzyme B pathways required for cellular cytotoxicity. 'Imprinting' of tissue-specific homing molecules (integrins or chemokine receptors) by APCs within certain locations (e.g. gut-draining lymph nodes) permits trafficking of alloreactive T cells from secondary lymphoid tissue to inflamed peripheral tissues. At these sites, T cells aid recruitment of other cellular effectors such as neutrophils, eosinophils, macrophages and NK cells, which together cause the epithelial injury resulting in the clinical manifestations of GVHD in gut, skin and liver. Importantly, GVHD at its initiation is an antigen-specific adaptive immune response but as the immune response develops it becomes less specific so that cells lacking the relevant antigens are targeted in the ensuing response. It follows that efforts designed to prevent or treat GVHD are likely to be more successful prior to, or at the point of induction of, the alloreactive response.

Chronic graft-versus-host disease

Chronic GVHD is a disorder associated with continuing host injury and profound immunodeficiency. The pathogenesis of this disorder is less well defined, partly as a result of the lack of preclinical models that fully recapitulate its onset and clinical features. However, it is clear that at least a component of the inflammatory process observed results from impairment of negative selection of auto-aggressive T cells within the thymus.

This may be consequent upon previous damage to the thymus as a result of acute GVHD and leads to a situation in which autoreactive T cells can enter the periphery and lead to tissue injury. This may help to explain why individuals with chronic GVHD develop some clinical features normally associated with autoimmunity (e.g. immune cytopenias). In contrast to acute GVHD, where CD8 cells are regarded as the most relevant effectors, CD4 cells are thought to be more important for the development of chronic GVHD. CD4 cells might provide helper functions for B cells leading to the production of antibodies against alloantigens or autoantigens or enhance macrophage generation of transforming growth factor (TGF)- β that leads to increased collagen deposition by fibroblasts.

Graft-versus-leukaemia effect

The importance of an immunologically mediated GVL effect in contributing to the curative effect of allogeneic SCT is supported by the observations that T-cell depletion (TCD) increases the risk of relapse and that patients who develop GVHD have a lower risk of disease relapse. Conclusive evidence was provided by the demonstration that infusion of donor lymphocytes can produce durable remissions in patients who have relapsed after allogeneic SCT. It has subsequently been shown that donor lymphocyte infusion (DLI) is a remarkably effective salvage therapy in chronic myeloid leukaemia (CML), with more than 80% of patients achieving a sustained molecular remission. Durable responses can also be achieved in patients transplanted for indolent lymphoma and Hodgkin lymphoma, with responses being observed less commonly in patients with aggressive lymphoma, myeloma or acute leukaemias. As would be predicted, DLI can be complicated by the development of GVHD, although the risk of this life-threatening complication is reduced if the lymphocytes are infused following a significant delay (>12 months) after transplantation or by using an escalating dose schedule rather than a single 'bulk' infusion. For the most part, the antigens recognized in a GVL reaction overlap with those recognized during GVHD. Clinical separation of GVL and GVHD may reflect increased sensitivity of normal or malignant haemopoietic tissue to an emerging GVH reaction compared with epithelial cells. Selective expression of antigenic targets of a GVH reaction on haemopoietic tissues (e.g. the minor H antigen HA-1, proteinase 3 or WT1) or leukaemic blasts (e.g. the product of the *BCR-ABL1* fusion gene) may also underlie the development of a GVL reaction in the absence of GVHD. This concept forms the basis of novel strategies to deliver a GVL effect without a concomitant risk of GVHD, such as peptide vaccination or gene transfer of T-cell receptors (TCRs) specific for leukaemic antigens.

Immune reconstitution

Allogeneic SCT is followed by a prolonged period of cellular and humoral immunodeficiency while donor-derived immune

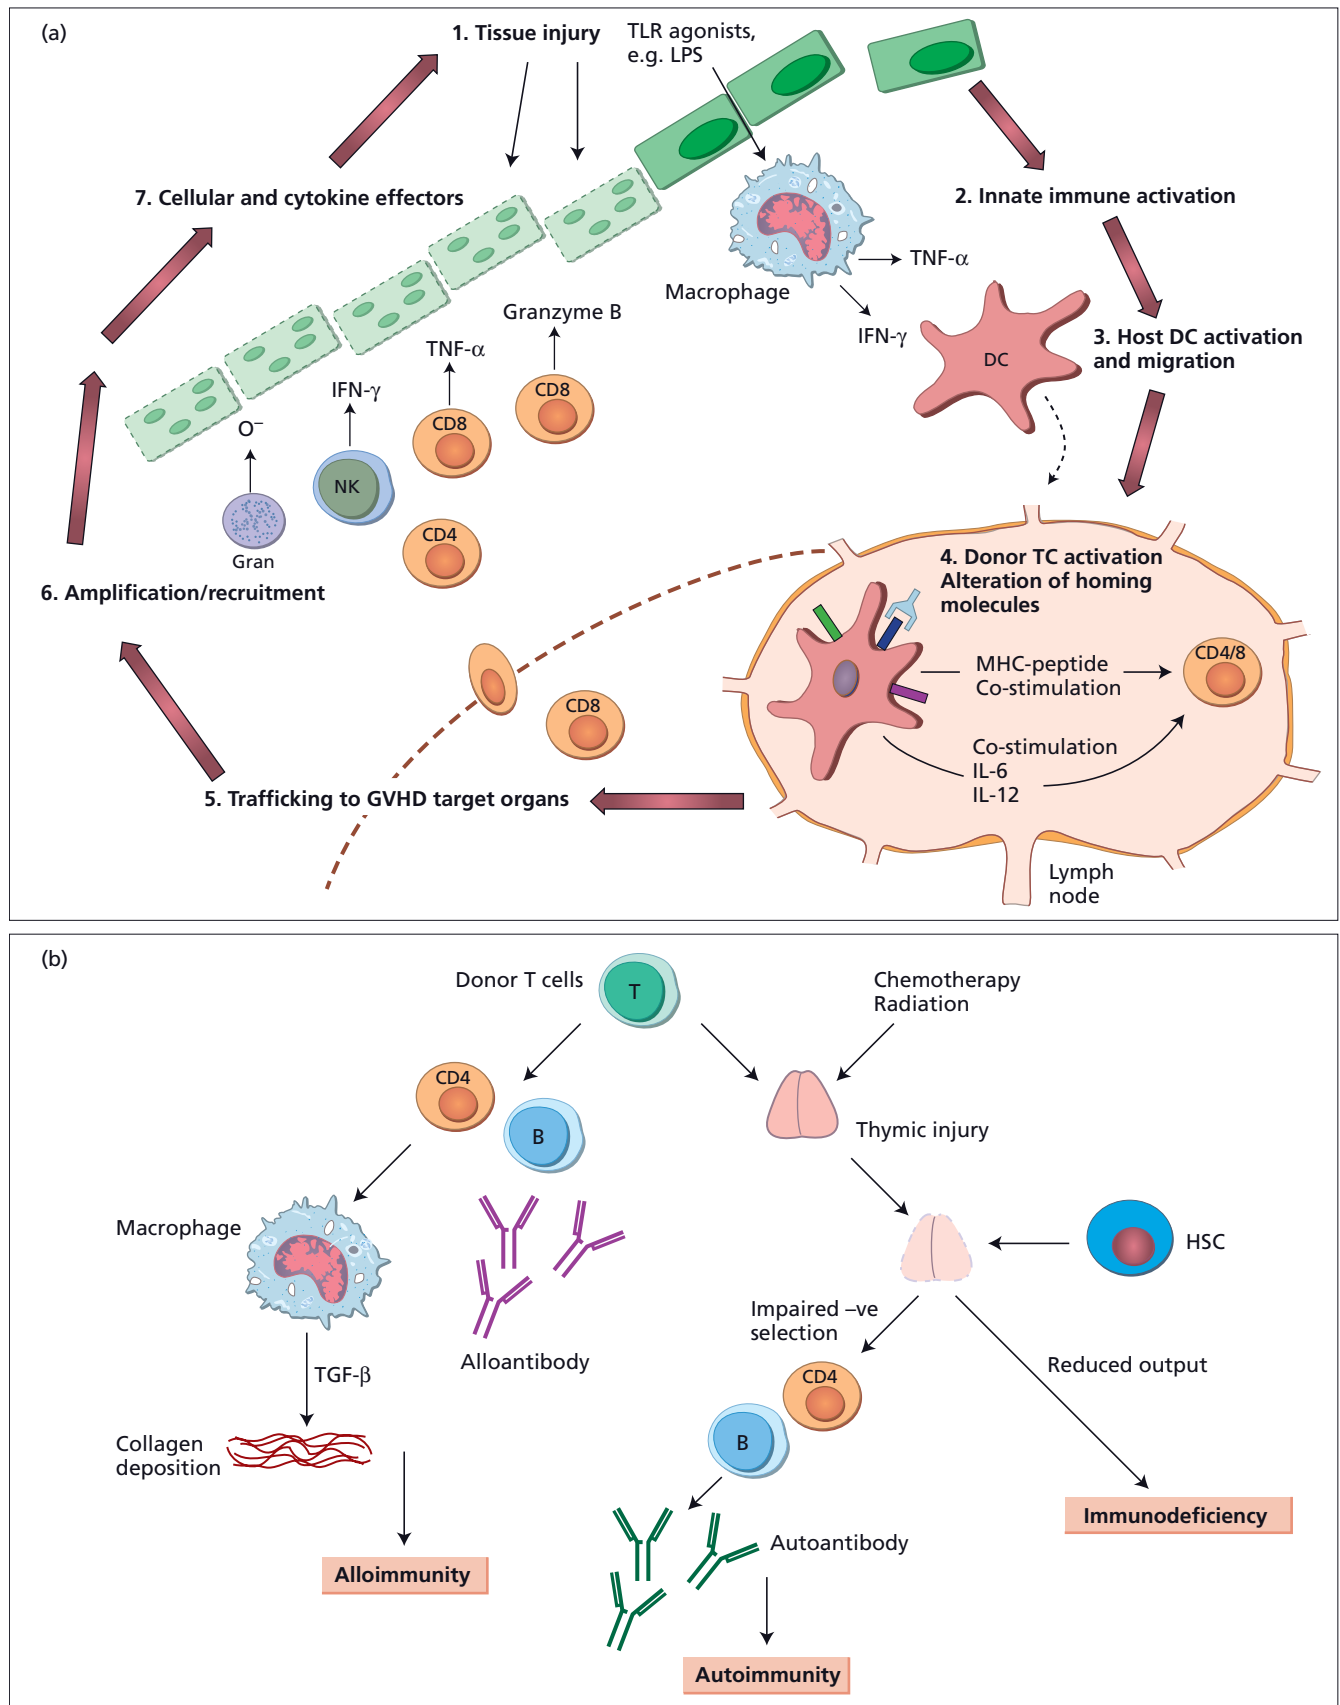

Figure 38.2 Pathophysiology of acute GVHD (a) and chronic GVHD (b). See text for explanation of abbreviations.

recovery occurs. Reconstitution of an immune response after transplantation can be evaluated in the clinic by monitoring the absolute numbers of T (CD4, CD8), B and NK cell numbers. NK cell numbers recover most rapidly while other subsets (especially CD4 cells and B cells) recover more slowly. In patients who have received a T-cell-depleted graft, T-cell recovery is substantially delayed. Analysis of thymic function after transplantation can be evaluated by measuring the episomal DNA excision circles of the TCR δ locus deleted during recombination of the TCR in functional $\alpha\beta$ T cells (known as TREC, for T-cell receptor excision DNA circles). TREC levels are low for the first 6 months following transplantation and recover thereafter. As a consequence, the T-cell repertoire is limited and mostly dependent on expansion of donor memory T cells. Thymic function is reduced in adults and may be further compromised by the effects of chemoradiotherapy and GVHD. Significant HLA mismatching between donor and recipient may also lead to 'holes' within the T-cell repertoire due to perturbations in thymic selection. These defects reflect a failure of donor-derived thymic emigrants to interact with peptides presented in the context of 'foreign' host HLA molecules.

Quantitative B-cell deficiency is present in virtually all patients in the first months after transplantation and may persist for a number of years post transplantation as a consequence of reductions in the number of marrow B-cell precursors, particularly in patients with chronic GVHD. This defect in B-cell production has multifactorial causes, including damage to the bone marrow stroma, the deleterious effect of inflammatory cytokines and the lympholytic effects of glucocorticoid therapy.

The source of stem cells also influences the kinetics of immune reconstitution. Thus, peripheral blood stem cell (PBSC) grafts, which contain higher numbers of haemopoietic progenitors and mature T cells, are associated with more rapid immune reconstitution than bone marrow grafts. Cord blood transplantation may be affected by poor immune reconstitution in adults since the number of haemopoietic progenitors is often limited and the transferred T cells are naive. Thus, patients are at heightened risk of reactivation of cytomegalovirus (CMV) or Epstein-Barr virus (EBV).

Stem cell engraftment

Biology of stem cell engraftment

The establishment of durable donor haemopoiesis after SCT depends on the engraftment of long-term reconstituting haemopoietic stem cells (HSCs) (see Chapter 1). These cells, defined by their capacity for self-renewal as well as their ability to differentiate into all haemopoietic lineages, are normally resident in the bone marrow at low frequency but can be mobilized into the peripheral blood by cytokines or chemotherapy. A high

frequency of haemopoietic stem and progenitor cells is also present in UCB. The cell surface glycoprotein CD34 is expressed on haemopoietic progenitors and HSCs and is currently widely used as a stem cell marker in clinical transplantation. However, it is important to remember that xenograft studies have demonstrated that HSCs reside within a CD34⁺CD38⁻ subpopulation and that many of the cells within the CD34⁺ population lack the properties of a long-term reconstituting stem cell.

Murine transplant studies have established that in a syngeneic setting, where there is no HVG reaction, transplantation of very small numbers of HSCs can result in durable engraftment of lethally irradiated recipients. In contrast, host immunosuppression is required to blunt an HVG reaction capable of rejecting the transplanted stem cell inoculum when there is donor-host HLA disparity, whether the donor is an HLA-identical sibling or an alternative donor.

Clinical factors determining stem cell engraftment

The sole determinant of durable engraftment after an autologous or syngeneic transplant is stem cell number and graft failure is exceedingly rare providing at least 2×10^6 CD34⁺ cells per kilogram are transplanted. Clinically durable engraftment in allograft recipients is determined by the degree of HLA disparity, the number of transplanted T cells and the size of the stem cell inoculum (Table 38.1). The immunosuppressive properties of the conditioning regimen play a critical role in blunting the HVG response and incorporation of total body irradiation (TBI) or drugs such as cyclophosphamide or fludarabine are highly effective in facilitating HSC engraftment. Historically, high rates of graft failure were observed when TCD was introduced as a form of GVHD prophylaxis in the late 1980s. However, the recognition that donor T cells play a critical role in facilitating engraftment led to redesign of conditioning regimens in patients receiving T-cell-depleted grafts so that their immunosuppressive properties were optimized. The widespread availability of PBSCs from sibling or unrelated donors (see below) allows transplantation of five to ten times more CD34-positive cells than if harvested bone marrow were used. Consequently, the use of PBSCs has played an important role in optimizing engraftment in settings such as TCD or trans-

plantation of a mismatched donor where a significant risk of graft failure rate would be expected were bone marrow to be used as the stem cell source. Incorporating these principles into clinical practice has markedly reduced the risk of graft failure such that it occurs in fewer than 1% of patients undergoing an HLA-identical sibling allograft and fewer than 5% of those transplanted from an unrelated donor. For a long time graft failure was a major complication of cord blood transplantation (CBT), particularly in adult recipients, and this likely reflected the low stem cell dose. The recent demonstration that the simultaneous transplantation of two cord blood units delivers durable rates of engraftment in the region of 95% has dramatically improved outcome of UCB transplants in adults.

Stem cell mobilization

Biology of stem cell trafficking

In steady-state haemopoiesis only very small numbers of haemopoietic stem and progenitor cells are present in the peripheral blood. The localization of haemopoietic stem and progenitor cells within the bone marrow cavity is mediated through the binding of a range of adhesion molecules, including CXCR4 and VLA4, with their cognate ligands on bone marrow stroma. Recent studies have demonstrated that administration of haemopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) disrupts the adhesion of progenitors to the bone marrow stroma resulting in their mobilization into the peripheral blood in large numbers. This has had a dramatic impact on transplant practice, resulting in peripheral blood replacing bone marrow as the commonest source of haemopoietic progenitors in both autologous and, more recently, allogeneic transplants. Antagonists to CXCR4 have now been shown to have the potential to significantly augment G-CSF-mediated stem cell mobilization and this promises to increase further the effectiveness of cytokine-mediated stem cell mobilization. Adhesive interactions between haemopoietic progenitors and the bone marrow stroma also play a critical role in the homing of transplanted HSCs and stem cell engraftment can be augmented in animal models by manipulation of the levels of adhesion molecule expression on haemopoietic progenitors and bone marrow stroma. As yet these observations have not been translated into clinical practice.

Stem cell mobilization in clinical practice

In patients undergoing autologous SCT, G-CSF administered alone or after myelosuppressive chemotherapy represents the commonest method of stem cell mobilization. Until recently G-CSF was only administered in conjunction with myelosuppressive doses of salvage chemotherapy or cyclophosphamide. While this represents a highly effective method of stem cell mobilization in the majority of patients, it is now clear that

administration of G-CSF alone, albeit at somewhat higher doses, can be equally effective and is substantially less toxic. As a result many units now utilize four daily subcutaneous injections of G-CSF, with stem cell harvesting on days 5 and 6. The minimum target cell dose of 2×10^6 CD34⁺ cells per kilogram can be harvested from more than 90% of patients using either G-CSF alone or G-CSF in combination with salvage chemotherapy or cyclophosphamide. In patients who fail to mobilize the target number of CD34⁺ cells, a number of possibilities exist. A second mobilization procedure can be performed using higher doses of G-CSF or, where appropriate, an additional chemotherapeutic drug such as cyclophosphamide or etoposide. Alternatively, the CXCR4 antagonist plerixafor can be used in conjunction with G-CSF. In the small minority of eligible patients who fail to mobilize adequate numbers of PBSCs using this approach, allogeneic transplantation should be considered.

G-CSF-mobilized PBSCs are increasingly used as a stem cell source in allogeneic SCT. The apparent safety of G-CSF doses in the range routinely used for autologous stem cell mobilization (10–15 µg/kg for 4–6 days) has resulted in all major unrelated donor panels offering this as an alternative to bone marrow harvest. However, it is important that all donors are counselled about the attendant side-effects in the form of myalgia, bone pain and headache. Other reactions are less common, and there are rare reports of splenic rupture. Consequently, donors should be advised to report immediately any pain in the left upper quadrant or shoulder tip. Although the effects of G-CSF on the fetus are not known, all female donors of childbearing age should have a negative pregnancy test prior to its administration. Donors also need to be aware of the 2–3% chance that an additional bone marrow harvest will be required if G-CSF fails to mobilize sufficient PBSC.

Choice of stem cell source and dose

Autologous transplantation

The use of PBSCs as a stem cell source is associated with more rapid engraftment than would be observed with harvested bone marrow and this, coupled with their ease of procurement, has secured their role as the standard stem cell source in autologous transplants. The generally accepted minimum number of haemopoietic progenitors required for engraftment after autologous SCT is 2×10^6 CD34⁺ cells per kilogram. While increasing the number of CD34⁺ cells transplanted hastens neutrophil and platelet engraftment, there is little evidence that transplantation of more than 5×10^6 CD34⁺ cells per kilogram is beneficial and there remain concerns that higher stem cell doses may be associated with an increased risk of tumour contamination. In patients with myeloma, many centres aim to harvest a minimum of 4×10^6 CD34-positive cells per kilogram in order that sufficient cells are available so that a tandem transplant, or second autograft at the time of relapse, is possible.

Sibling and unrelated donor transplantation

PBSCs are the most frequently used stem cell source for patients undergoing a sibling allograft and are increasingly used in unrelated donor transplant recipients. While PBSCs are established as the preferred stem cell source in reduced-intensity allografts, for the reasons discussed above, the relative merits of PBSCs and bone marrow in patients transplanted using a myeloablative regimen remains a matter of debate. Thus while transplantation of PBSCs results in earlier neutrophil and platelet engraftment, which may reduce transplant-related mortality (TRM), particularly in patients with advanced leukaemia, there are emerging registry data that demonstrate an increased incidence of chronic GVHD compared with patients transplanted with bone marrow. This is likely to be consequent on the five- to tenfold greater dose of T cells in a PBSC harvest compared with bone marrow (Table 38.2). As yet it remains unclear whether the increased risk of chronic GVHD associated with the use of PBSC results in a reduction in relapse rate. Thus while PBSCs are routinely used as a stem cell source in patients being allografted for advanced leukaemia, where TRM is a major cause of treatment failure, bone marrow is still preferred in diseases such as aplastic anaemia where chronic GVHD is an important cause of treatment failure. Long-term follow-up studies comparing the outcome of patients transplanted using bone marrow and PBSCs will clearly be important in order to define the optimal stem cell source in standard-risk leukaemias. In paediatric transplantation, bone marrow remains the preferred stem cell source and the use of PBSCs is less common.

Cell dose is an important factor determining outcome after both matched sibling and unrelated donor transplants and this effect is noted in recipients of both bone marrow and PBSCs. This effect is primarily mediated through a reduction in TRM consequent on accelerated immune reconstitution in recipients of a higher stem cell dose. The lowest acceptable stem cell dose to secure engraftment in an allogeneic setting is considered to be 2×10^6 CD34-positive cells per kilogram (2×10^8 mononuclear cells per kilogram if bone marrow is being used), although in practice the majority of patients transplanted using in excess of 1×10^6 CD34-positive cells per kilogram will engraft. Since outcome is improved with higher doses, most centres aim for a

Table 38.2 Comparison of the cellular composition of a typical bone marrow harvest compared with G-CSF-mobilized in a peripheral blood stem cell (PBSC) (after two aphereses).

	CD34 cells ($\times 10^6$)	CD34 cells ($\times 10^6/\text{kg}$)	CD3 cells ($\times 10^6$)	CD3 cells ($\times 10^6/\text{kg}$)

dose in the region of 4×10^6 CD34-positive cells per kilogram. In patients transplanted from an HLA-identical sibling using a T-replete myeloablative regimen, there is some evidence that the incidence of chronic GVHD is increased if the stem cell dose exceeds 8×10^6 CD34-positive cells per kilogram. In this setting it may therefore be reasonable to have a target dose of $4\text{--}8 \times 10^6$ CD34-positive cells per kilogram. However, there is no evidence, as yet, that there should be an upper limit on cell dose in patients transplanted using an RIC regimen or from an unrelated donor.

Cord blood transplantation

UCB contains a high proportion of haemopoietic progenitors and HSCs and is an increasingly important stem cell source in paediatric and adult transplantation. Importantly, HLA disparity appears better tolerated in recipients of UCB and as a consequence the incidence of severe GVHD is lower with mismatched UCB than would be expected using a comparably mismatched unrelated donor. This has important implications in terms of donor identification in patients with uncommon HLA types for whom a suitably matched unrelated donor cannot be readily identified. A major factor limiting the uptake of CBT has been delayed or failed engraftment, which has been a common problem particularly in adult recipients. The two most important factors determining the likelihood of neutrophil and platelet engraftment after CBT are nucleated cell dose and HLA disparity. More recently, it has been shown that transplantation of two cord blood units, harvested from two separate donors, increases the speed of engraftment and is associated with a decreased risk of primary graft failure. This observation has substantially increased the number of CBT procedures performed in adults and encouraging results have been reported in patients with high-risk leukaemia using both myeloablative and, more recently, RIC regimens. Selection of cord blood units remains a complex area and consideration must be given to both stem cell dose and HLA disparity in identification of suitable unit(s) (Figure 38.3). Immune reconstitution is markedly delayed after CBT and viral infections, particularly CMV and adenovirus, coupled with fungal infections result in a substantial TRM. For all these reasons it is recommended that cord blood unit selection and transplantation should be performed by physicians with experience in this field.

Stem cell manipulation and expansion

Immunophenotypic characterization of haemopoietic stem and progenitor cells has permitted the development of strategies by which PBSC grafts can be manipulated *ex vivo*. By conjugating antibodies that recognize CD34 with magnetic beads it is possible to achieve highly efficient enrichment of CD34⁺ cells from a PBSC or bone marrow harvest. This technology also allows, as a consequence of passive depletion of CD34⁻ cells, effective depletion of donor T cells in allogeneic stem cell harvests and

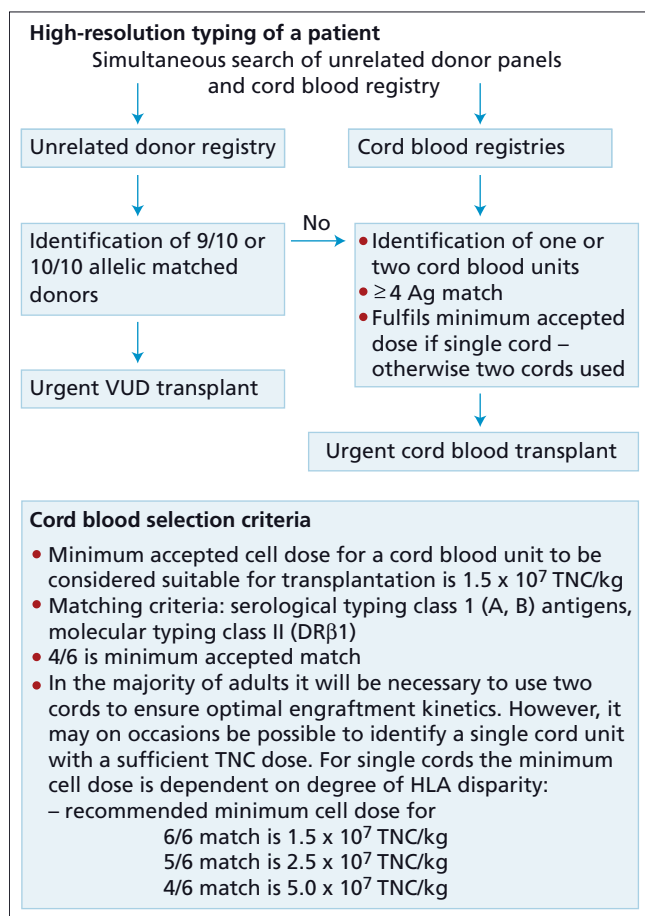

Figure 38.3 Possible algorithm for identification of alternative donors in patients requiring urgent allogeneic transplantation who lack a sibling donor. TNC, total nucleated cell dose; VUD, volunteer unrelated donor.

can be used to provide an effective form of GVHD prophylaxis. The importance of cell dose in determining engraftment and outcome after SCT has led to studies aimed at expanding either the stem cell or progenitor population prior to transplantation. In the autologous setting this strategy has not been widely adopted, if only because collection of adequate numbers of cells to ensure rapid engraftment can now be reliably achieved in the great majority of patients. There is, however, significantly more interest in allografting, particularly in CBT, where engraftment can be delayed because of suboptimal stem cell or progenitor numbers.

Conditioning regimens: basic principles

The combination of drugs and radiotherapy administered prior to stem cell infusion is termed the conditioning or preparative regimen. In autologous SCT, where there is no alloreactive

response, the sole purpose of the conditioning regimen is disease eradication. The most common conditioning regimens used in autologous transplantation utilize alkylating agents alone or in combination and other chemotherapeutic drugs.

In the setting of allogeneic SCT the conditioning regimen has conventionally served two purposes: immunosuppression designed to abrogate an HVG reaction thereby preventing graft rejection, and myeloablation in order to achieve tumour eradication. A number of refinements have been made over the past three decades to the design and delivery of myeloablative conditioning regimens. However, they are still associated with significant toxicity which precludes their use in patients older than 50–55 years (45–50 years for recipients of unrelated donor transplants). The recent demonstration that durable donor engraftment can be reliably achieved using a non-myeloablative preparative regimen, coupled with increased awareness of the potency of the GVL reaction, has led to the development of a range of reduced intensity regimens. These protocols are associated with a substantially reduced TRM, allowing allogeneic transplantation to be safely performed in patients in whom it would previously have been contraindicated on the grounds of age or comorbidity. However, experience with RIC regimens is still relatively limited and longer follow-up and, where possible, randomized trials are required before their role in the management of older patients with haematological malignancies can be defined with precision. The encouraging results to date in older patients suggest that there may potentially be a role for their use in younger patients in preference to myeloablative regimens because of their reduced early mortality and possible longer-term benefits such as preserved fertility.

Conditioning regimens in autologous SCT

Conditioning regimens in autologous SCT are designed with dose intensification in mind and are limited mainly by considerations of extramedullary toxicity. High-dose melphalan (200 mg/m^2) is the standard conditioning regimen in myeloma autografts. BEAM (carmustine, etoposide, cytarabine, melphalan) is widely used in patients with lymphoma. Autologous transplants are rarely indicated in the management of AML and acute lymphoblastic leukaemia (ALL) but both busulfan/cyclophosphamide and cyclophosphamide/TBI are effective preparative regimens in these diseases. A number of other drug combinations incorporating melphalan, busulfan and thiopeta are used in solid tumours. The major extramedullary toxicities of these regimens are mucositis and gastrointestinal toxicity. Disappointingly, there are few prospective randomized data on which to base the choice of conditioning regimen in autologous SCT. In myeloma a randomized comparison between a TBI-containing regimen and high-dose melphalan alone demonstrated that no benefit was associated with the use of TBI. However, there are no large randomized studies of preparative regimens in lymphoma.

Myeloablative conditioning regimens in allogeneic SCT

The two commonest myeloablative conditioning regimens used in allogeneic SCT employ combinations of cyclophosphamide and either TBI or busulfan.

TBI/cyclophosphamide

Cyclophosphamide is an alkylating agent that, when administered in the doses routinely used in myeloablative conditioning regimens (120–200 mg/kg), has both immunosuppressive and antileukaemic properties. It is a prodrug that must be metabolized by the cytochrome P450 system in the liver to produce metabolically active derivatives, principally phosphoramidate mustard, which exert their cytotoxic activity through the production of interstrand DNA links. The two major complications of cyclophosphamide at the doses employed in allogeneic transplantation are haemorrhagic cystitis and cardiac toxicity. Haemorrhagic cystitis results from the toxic effects of a cyclophosphamide metabolite, acrolein, on the uroepithelium and can be reduced by use of sodium 2-mercaptoethanesulfonate (MESNA), while cardiac toxicity is very rare at doses of cyclophosphamide below 150 mg/kg.

TBI has dual immunosuppressive and antileukaemic properties when administered in myeloablative doses (typically 12–14.4 Gy). Radiobiological principles predict that the toxicity of TBI can be reduced by either decreasing the overall dose of radiation or, as is now common, by giving it in fractionated form over a number of days (e.g. 14.4 Gy divided into eight fractions over 4 days). The degree of immunosuppression produced by TBI-containing regimens is related to the total dose of irradiation delivered. The use of higher TBI doses is therefore an effective method of optimizing engraftment in myeloablative allografts where there is use of TCD or an alternative donor and consequently an increased risk of graft failure. Haematological malignancies are highly radiosensitive and the risk of disease relapse is reduced if a higher dose of TBI is used, although this benefit is blunted by increased transplant toxicity (see below). Early complications associated with the use of TBI include nausea, vomiting, diarrhoea and parotitis which can usually be managed symptomatically. Increased doses of TBI are also associated with pneumonitis and veno-occlusive disease (VOD) of the liver, both of which may be life-threatening. Long-term complications include cataract formation, hypothyroidism, infertility and, in children, growth retardation.

Busulfan/cyclophosphamide

Busulfan/cyclophosphamide is a myeloablative preparative regimen that has the practical advantage of not requiring the presence of irradiation facilities on site. Busulfan is an alkylating agent with potent activity against leukaemic progenitors and is a core component of both allogeneic and autologous transplant regimens. Historically, busulfan has only been available as an oral preparation, used at a dose of 14–16 mg/kg delivered

6-hourly over a period of 4 days. In this formulation, VOD and pulmonary and central nervous system (CNS) toxicity represent major complications. The pharmacokinetics of oral busulfan are highly variable because it undergoes first-pass metabolism in the liver and there is therefore substantial interpatient variability in plasma drug levels using a standard dosing schedule. Because the incidence of VOD is closely correlated with higher plasma busulfan levels and patients with low busulfan levels also have an increased risk of relapse, oral preparations of busulfan are far from ideal. Two approaches have been used to overcome this problem. A number of groups use frequent (6-hourly) measurement of plasma busulfan levels during the first 24 hours of administration of an oral preparation followed by dose adjustment over the following 3 days in order to achieve a therapeutic busulfan level. Using such a targeted approach the Seattle group have achieved excellent results using busulfan/cyclophosphamide with a very low risk of VOD and reduced relapse rates compared with those achieved using oral busulfan. Alternatively, a recently developed intravenous formulation of busulfan delivers therapeutic drug levels predictably and is associated with markedly reduced toxicity. It should be remembered that with both preparations prophylactic phenytoin or clonazepam should be used to prevent seizures, a complication associated with the administration of high doses of busulfan.

Alternative myeloablative conditioning regimens

Fludarabine augments alkylator-induced cell killing *in vitro* and regimens combining fludarabine with intravenous busulfan appear to be active and well tolerated. Of note, the incidence of VOD using this combination appears to be low and further studies of this regimen are indicated. In patients undergoing a sibling allograft for ALL, etoposide is often substituted for cyclophosphamide and a TBI/etoposide regimen has been shown in some studies to be associated with improved outcome.

In non-malignant disorders, such as aplastic anaemia, cyclophosphamide alone can be used as a conditioning regimen and is sufficiently immunosuppressive to permit engraftment of allogeneic stem cells provided an adequate stem cell inoculum is transplanted. Addition of fludarabine is increasingly used in conjunction with cyclophosphamide in patients with sickle cell disease and thalassaemia.

Comparison of myeloablative conditioning regimens

Sibling allografts

There are two central questions in the design of myeloablative conditioning regimens: is there any survival benefit to be gained from intensifying the conditioning regimen and are cyclophosphamide/TBI and busulfan/cyclophosphamide equally effective preparative regimens?

Prospective randomized trials in patients undergoing a sibling allograft for AML have failed to show any improvement

in survival using an increased dose of TBI. Studies performed in the past two decades have shown that while increasing the TBI dose reduces the risk of leukaemic relapse, this benefit is offset by a concomitant increase in TRM. Similarly, there is no evidence that addition of busulfan to a cyclophosphamide/TBI regimen has any impact on disease-free survival.

The decision to use cyclophosphamide/TBI or busulfan/cyclophosphamide as a conditioning regimen in sibling allografts has been studied in a number of randomized studies, all of which used oral busulfan without plasma level targeting. Given the substantial toxicity associated with the use of oral busulfan, the results of these studies need to be interpreted with caution since they may well underestimate the potential benefit of a busulfan/cyclophosphamide regimen utilizing targeted or intravenous busulfan. However, it is of interest that both regimens appeared equally effective for patients undergoing a sibling allograft for CML in first chronic phase, while there appeared to be some benefit attached to the use of a TBI-based regimen in patients with advanced leukemia. The advent of new delivery strategies for busulfan makes it important to re-examine the optimal myeloablative preparative regimen in patients with AML and myelodysplastic syndrome (MDS) and such studies are underway. As noted above, preliminary results with a combination of fludarabine and intravenous busulfan are also promising.

Unrelated donor transplants

The optimal conditioning regimen in patients undergoing an unrelated donor transplant has not been determined and there are few randomized trials in this setting. The greater degree of HLA disparity associated with the use of an unrelated donor results in a higher risk of graft failure than that observed using an HLA-identical sibling. For this reason many groups elect to use a cyclophosphamide/TBI-based regimen, with its greater immunosuppressive properties, although it should be noted that equivalent results have been reported in a number of large series using a busulfan/cyclophosphamide regimen. The other important factor determining the choice of conditioning regimen in unrelated donor transplant is whether TCD is employed. Regimens utilizing rigorous *ex vivo* TCD are associated with a higher risk of graft failure and the use of *in vivo* approaches, using antithymocyte globulin (ATG) or alemtuzumab, is preferred if TCD is to be used. In all patients receiving a TCD unrelated donor transplant, it is important to ensure that the conditioning regimen is sufficiently immunosuppressive if primary graft failure is to be avoided.

Cord blood transplants

The increased HLA disparity and high rates of primary graft failure in CBT makes it critical to optimize the immunosuppressive properties of the preparative regimen. In adults undergoing transplantation using a myeloablative regimen, engraftment rates in the region of 90–95% can be achieved by

the addition of fludarabine to a cyclophosphamide/TBI regimen, providing an adequate stem cell inoculum is used. ATG was initially used as additional GVHD prophylaxis in myeloablative CBT but is less commonly used now because of delayed immune reconstitution and an increased risk of post-transplant lymphoproliferative disorders.

Strategies for GVHD prophylaxis in myeloablative regimens

Post-transplant immunosuppression using various combinations of ciclosporin, methotrexate, prednisolone and mycophenolate mofetil represent the commonest forms of GVHD prophylaxis in patients after a myeloablative sibling or unrelated donor transplant. Randomized trials from the Seattle group established the use of intravenous ciclosporin (2.5–5 mg/kg daily) and short-course methotrexate (administered on days 2, 4, 8 and 12 post transplant) as the most effective form of GVHD prophylaxis in patients transplanted undergoing a T-replete allograft using either an HLA-identical sibling or volunteer unrelated donor.

Rates of chronic extensive GVHD are in the region of 30% and 66% for recipients of T-replete sibling and unrelated donor transplants despite the use of ciclosporin/methotrexate GVHD prophylaxis. TCD is an additional, and highly effective method of reducing the risk of both acute and chronic GVHD. TCD can be achieved either by manipulating the stem cell inoculum *ex vivo* or by the *in vivo* administration of T-cell-depleting antibodies such as ATG or alemtuzumab (a humanized monoclonal antibody that recognizes CD52). Although a highly effective method of GVHD prophylaxis, TCD is associated with an increased risk of relapse and graft failure and delays immune reconstitution, increasing the risk of post-transplant infections such as CMV. There have been no randomized studies demonstrating a survival benefit for TCD. Clearly, the form of GVHD prophylaxis used for any particular patient should be selected with their individual risk of both GVHD and relapse in mind. Thus it may be desirable to avoid the use of TCD in patients with advanced leukaemia in whom the risk of relapse is high. In contrast, patients with a low risk of disease recurrence may benefit from more intensive GVHD prophylaxis. However, there remains no consensus concerning the use of TCD in allogeneic transplantation. Many UK and European groups, while performing T-replete sibling allografts, would choose to use *in vivo* TCD in unrelated donor transplant recipients. Compromise strategies in which TCD is used at the same time as further intensifying the conditioning regimen are of interest.

Reduced-intensity conditioning regimens in malignant and non-malignant disease

As recently as 10 years ago it was believed that a myeloablative conditioning regimen was essential if durable engraftment of donor stem cells was to be achieved. A decade's experience has

confirmed that reduced-intensity regimens that incorporate either fludarabine or low-dose (200 cGy) TBI as a core immunosuppressive component consistently result in long-term donor stem cell engraftment with a remarkable reduction in toxicity, particularly in older patients or patients with significant comorbidities. At the same time there is now convincing evidence that such regimens provide a platform for a potentially curative GVL effect. As a result, numerous Phase II trials have demonstrated long-term disease-free survival after RIC allografts in patients whose outcome with conventional chemotherapy would be extremely poor. Currently the most important unresolved questions are, firstly, whether low-dose TBI/fludarabine or fludarabine in combination with an alkylating agent represents the optimal conditioning regimen and, secondly, whether a T-replete stem cell inoculum or some form of TCD should be used. Although there is no universally accepted definition of what constitutes an RIC regimen, the European Group for Blood and Marrow Transplantation (EBMT) definition of a regimen incorporating fludarabine with low-dose TBI (4 Gy or less) or other immunosuppressive or chemotherapeutic drug such as cyclophosphamide or melphalan is generally accepted.

Choice of RIC regimen

Low-dose (200 cGy) TBI-based regimens

Pioneering work in a canine model by Storb's group demonstrated that durable engraftment could be achieved with a non-myeloablative conditioning regimen that used immunosuppressive doses of TBI (200–450 cGy) in conjunction with post-transplant immunosuppression in the form of ciclosporin and mycophenolate mofetil. In the late 1990s the Seattle group confirmed these results in patients with high-risk haematological malignancies and noted a substantial reduction in transplant toxicity compared with a myeloablative regimen. Early results from this group demonstrated a small but significant risk of graft failure with this regimen and fludarabine is now routinely incorporated into low-dose (200 cGy) TBI regimens. Accumulating data in the last decade confirms that this regimen now reliably achieves high rates of engraftment and full donor chimerism and is associated with a substantially reduced TRM compared with myeloablative preparative regimens. Its main drawback is a significant risk of acute and chronic GVHD. Recent data demonstrate that up to 66% of patients experience chronic extensive GVHD, the management of which is often very challenging, particularly in elderly and more frail patients.

Non-TBI-based regimens

At the same time as low-dose TBI regimens were being developed in Seattle, groups at the M.D. Anderson Cancer Center, Bethesda and Jerusalem demonstrated that durable engraftment of sibling and unrelated donor stem cells could be achieved with a similar reduction in transplant toxicity using a combination of fludarabine and an alkylating agent such as melphalan,

busulfan or cyclophosphamide. All groups reported a significant risk of severe acute and extensive chronic GVHD using ciclosporin with or without methotrexate as the sole form of GVHD prophylaxis. There are currently no data comparing the outcome of different RIC regimens. Given the significant risk of GVHD associated with the use of both regimens, a major area of research has focused on defining the optimal form of GVHD prophylaxis.

Strategies for GVHD prophylaxis in RIC regimens

Currently, two contrasting approaches are used for GVHD prophylaxis in patients undergoing an RIC allograft. The first uses combinations of ciclosporin, methotrexate and mycophenolate mofetil as the sole form of GVHD prophylaxis and is used in patients transplanted using a T-replete stem cell inoculum. The alternative approach uses ciclosporin alone and is most common in patients transplanted using either ATG or alemtuzumab as *in vivo* TCD. Supporters of a T-depleted approach argue that the incidence of acute, and particularly chronic, GVHD is otherwise unacceptably high, particularly in older patients transplanted using an unrelated donor. It can also be argued that this strategy generates an effective platform for the subsequent delivery of DLI with less GVHD-related toxicity. They point to the effectiveness of ATG and alemtuzumab in reducing the risk of GVHD while at the same time securing high rates of durable donor engraftment. Those favouring a T-replete strategy highlight potential abrogation of a GVL effect by TCD. They also cite the delay in immune reconstitution associated with the use of TCD and consequent increased risk of viral, particularly CMV, infection. As with many debates in transplantation there are no randomized data to support either approach. Substantial numbers of patients achieve durable remissions with both T-replete and TCD regimens. While there may be an increased risk of disease relapse with a T-cell-depleted regimen, much would appear to depend on the intensity of TCD and the form of post-transplant immunosuppression employed.

Clinical management of patients undergoing stem cell transplantation

The use of PBSCs coupled with improved supportive care has decreased the 100-day TRM of autologous transplantation to 1–3% in most centres. The morbidity and mortality of allogeneic SCT has also continued to fall over the last two decades but the 100-day TRM remains in the region of 10–20% depending on patient age, donor type, disease status and stem cell source. This progress reflects advances in supportive care and, in patients undergoing an unrelated donor transplant, more accurate tissue typing. Despite this organ toxicity, acute GVHD and

infections consequent on delayed immune reconstitution still represent major causes of morbidity and mortality in the first few months after allogeneic transplantation (Figure 38.4). In addition, chronic GVHD remains an increasing burden for patients and transplant services alike with the increasing use of mismatched unrelated and cord blood donors. The long-term complications of allogeneic transplantation, which can signifi-

cantly compromise a patient's quality of life, are also increasingly recognized and have led to the introduction of specific late-effects clinics where multidisciplinary input from transplant physicians, endocrinologists, gynaecologists, ophthalmologists and psychologists can be provided.

Practicalities of stem cell infusion and blood product support

Stem cell products are infused in the same way as other blood products except for the fact that online blood filters should not be used. Stem cell products must not be irradiated. They may either be infused once collected or, in the case of cryopreserved products, be infused immediately after being unfrozen, at the patient's bedside. The most common side-effect of the cryopreservative (dimethyl sulphoxide, DMSO) is nausea but since it is excreted by the lungs, a garlic-like odour is also observed for 2–3 days after stem cell infusion. Damage to red blood cells releases free haemoglobin, which can precipitate acute renal failure, and thus patients should be adequately hydrated prior to stem cell infusion and for the following hours. In all patients urine output must be monitored closely.

Patients will require red cell and platelet support during the immediate post-transplant period. In allograft recipients, particularly cord blood transplants and patients receiving myelo-toxic drugs such as ganciclovir, platelet transfusion may be required for a number of months after transplantation. All cellular blood products should be irradiated (25 Gy) prior to administration in order to prevent transfusion-related GVHD (see Chapter 26). This should be commenced 6 weeks prior to transplant and is continued for 6 months after an autologous transplant or indefinitely for allogeneic transplants. In patients undergoing allogeneic SCT where there is a major ABO incompatibility between donor and recipient (e.g. a group O recipient receiving group A bone marrow), the graft must be depleted of red cells prior to administration unless PBSCs are being transplanted in which case red blood cells are usually effectively depleted during leucapheresis. The subsequent choice of blood group for platelets or red cells depends on the precise nature of the ABO incompatibility, the time from SCT and the results of blood grouping. Delayed erythroid engraftment or haemolysis caused by continuing synthesis of iso-haemagglutinins by host lymphocytes may occur several weeks after stem cell infusion and is associated with the presence of a positive direct anti-globulin test and anti-donor red cell antibodies in serum or red cell eluates.

Figure 38.4 Causes of death after stem cell transplantation 2001–2006. (Courtesy of the International Bone Marrow Transplant Registry.)

Complications of allogeneic SCT

Early complications (days 0–90)

Graft failure

Primary graft failure is defined as failure to achieve a neutrophil count above $0.5 \times 10^9/L$ within 28 days of stem cell infusion and

in the great majority of cases is caused by failure of the conditioning regimen to blunt an HVG reaction. It is rare unless there is marked donor–host HLA disparity, such as the use of a mismatched unrelated or family donor, or *in vitro* TCD has been deployed. Primary graft failure should be suspected in patients who fail to demonstrate any evidence of neutrophil engraftment by day +21 and should be investigated urgently with a bone marrow aspirate and trephine (which must be processed urgently), chimerism studies and virology to exclude parvovirus B19 or human herpesvirus (HHV)-6 infection. Patients with no morphological evidence of engraftment and an absence of donor chimerism require urgent intervention in the form of a second transplant, from the same donor if available. Such patients require further conditioning, and fludarabine with or without low-dose TBI provides potent immunosuppression in this setting. If there is no evidence of engraftment but peripheral blood lymphocytes type as donor, then an infusion of CD34-positive selected PBSCs may be employed without prior conditioning therapy. Alternatively, cryopreserved autologous stem cells, if available, can be infused. The mortality of primary graft failure is in excess of 50% and it is therefore important to consider performing an autologous harvest in patients, such as unrelated donor recipients, where there is a significant risk of graft failure.

Secondary graft failure is defined as the occurrence of sustained neutropenia and thrombocytopenia after donor engraftment. It is rare after sibling allografts and occurs predominantly in recipients of mismatched or unrelated donor transplants. The aetiology of secondary graft failure is often complex but causes that need to be considered include late graft rejection, drugs (co-trimoxazole and ganciclovir), viral infection (CMV, HHV-6 and parvovirus B19), disease relapse and rarely hypersplenism. Secondary graft failure is associated with significant mortality related to fungal infections and must be investigated urgently with a bone marrow aspirate and trephine and urgent chimerism studies. In patients with a hypocellular marrow and evidence of donor T-cell engraftment, a second infusion of donor stem cells is required.

Acute graft-versus-host disease

Acute pattern GVHD usually occurs within the first 3 months post transplant, at or near the time of engraftment, and is characterized by the presence of rash, diarrhoea or abnormal liver function tests. Depending on the type of protocol employed, between 20% and 70% of patients will develop this disorder. Acute pattern GVHD occurring after 3 months, with no features of chronic GVHD, is also increasingly recognized in patients receiving RIC transplants, often following withdrawal of immunosuppression. Risk factors for the development of acute GVHD include increased recipient age, unrelated or HLA-mismatched donor transplantation and the use of a female donor. Children have a lower risk of acute GVHD and recipients of CBT may have a lower incidence of GVHD compared

with adult bone marrow transplantation with similar degrees of HLA disparity.

Skin GVHD typically presents as a maculopapular rash involving the face, neck, palms and soles but may extend to involve the whole body (Figure 38.5). In the worst cases it progresses to erythroderma, with bullae formation and painful blistering. Histology shows apoptosis at the base of dermal crypts, dyskeratosis, and evidence of lymphocytes in a perivas-

(a)

(b)

Figure 38.5 Acute skin GVHD: (a) acute cutaneous GVHD; (b) chronic oral GVHD.

cular distribution or adjacent to dyskeratotic keratinocytes. Gastrointestinal involvement presents with nausea, vomiting, secretory diarrhoea and/or abdominal pain. In more advanced disease, severe abdominal pain and distension in associated with voluminous, occasionally bloody, diarrhoea may occur. Gastric, antral and rectal biopsies have a high diagnostic yield, with diagnostic features including the presence of apoptotic cells in the base of crypts and a lymphocytic infiltrate. A well-defined manifestation of upper gut GVHD is the development of anorexia and nausea, both of which usually resolve rapidly if treated with low-dose methylprednisolone (1 mg/kg). A rising bilirubin and raised alkaline phosphatase are the initial features of liver GVHD, which typically develops later than skin or gut GVHD. Liver histology is diagnostic and demonstrates a portal tract lymphocytic infiltration, pericholangitis and bile duct loss.

Accurate and early diagnosis of acute GVHD is essential for effective management of this potentially life-threatening disorder. Where possible diagnostic biopsies should be taken to both confirm the presence of GVHD and assist in the exclusion of other aetiologies. It is also important to stage GVHD accurately and the criteria devised by Glucksberg (and recently updated by the International Bone Marrow Transplant Registry) are widely used (Table 38.3). This staging system is a reliable indicator of prognosis and guides the intensity of treatment required. Grade 2–4 acute GVHD should be treated with high-dose methylprednisolone (typically 2 mg/kg daily), which is tapered according to response. In the setting of limited skin GVHD and upper gut GVHD, topical or oral steroids (1 mg/kg) coupled with optimization of ciclosporin levels may be sufficient to control symp-

toms. Approximately 70% of patients will improve significantly with oral or intravenous corticosteroid therapy, but a number will either fail to respond or relapse when immunosuppression is tapered. Failure to respond to 7 days of intravenous corticosteroid therapy defines steroid-resistant acute GVHD and these patients require the use of second-line therapies. Unfortunately, individuals with steroid-refractory acute GVHD have a poor prognosis, with a non-relapse mortality in excess of 70% secondary to persistent GVHD or as a result of infectious complications. Currently, robust evidence supporting efficacy of second-line treatments is lacking. Some patients with acute pattern GVHD affecting skin may respond to phototherapy. Patients with predominant gut involvement may respond to oral non-absorbable steroids or the monoclonal antibody infliximab. In other patients, treatment with other monoclonal antibodies such as daclizumab or pentostatin may be of benefit. More recently, encouraging results have been reported with the use of donor or third-party mesenchymal stromal cells, with a response rate of 60–70%. Application of this approach will require evaluation in prospective randomized studies. Patients with acute severe GVHD often require intensive supportive measures including replacement of gastrointestinal losses, parenteral nutrition, pain control and infectious prophylaxis.

Infectious complications

Bacterial, fungal, protozoal and viral infections are a major cause of morbidity and mortality after allogeneic transplantation. Host factors include neutropenia, post-transplant immunosuppression and acute or chronic GVHD requiring steroid therapy. Numerous additional factors contribute to delayed

Table 38.3 Glucksberg staging of acute GVHD: (a) clinical staging; (b) clinical grading.

(a)

Stage	Skin	Liver bilirubin	Gut
+	Maculopapular rash <25% body surface	34–51 µmol/L	Diarrhoea 500–1000 mL/day or persistent nausea
++	Maculopapular rash 25–50% body surface	51–102 µmol/L	Diarrhoea 1000–1500 mL/day
+++	Generalized erythroderma	102–255 µmol/L	Diarrhoea >1500 mL/day

Figure 38.6 Temporal pattern of infectious complications after allogeneic stem cell transplantation.

immune reconstitution after an allograft and include thymic atrophy in adults, the use of TCD and a suboptimal stem cell inoculum. Infectious complications are a particular challenge after CBT. The temporal pattern of infectious complications after allogeneic SCT is shown in Figure 38.6.

Considerable progress has been made in the development of strategies to reduce the risk of infection after allogeneic SCT. All patients should be nursed in single rooms, preferably with laminar airflow or high-efficiency particulate air filtration. Evidence supports the use of triazole antifungals, such as fluconazole 400 mg daily, as an effective means of reducing *Candida* infection. Aciclovir (200–400 mg four times daily) is usually administered to prevent herpes simplex virus (HSV) reactivation. Quinolone antibiotics (e.g. ciprofloxacin 500 mg twice daily) are used by some units to reduce the risk of severe Gram-negative infections, although the evidence supporting this measure is inconclusive and practice should be guided by advice from local microbiologists concerning the prevalence and sensitivity of drug-resistant organisms. Patients should receive cotrimoxazole (480 mg twice daily three times per week) at the time of neutrophil engraftment (neutrophils $>1.0 \times 10^9/L$) to prevent *Pneumocystis jirovecii* infection. If allergic to cotrimoxazole, nebulized pentamidine (300 mg monthly) can be substituted, although it should be remembered that this provides incomplete protection from *Pneumocystis* pneumonia and for this reason some units prefer to use dapsone.

Allogeneic transplants, particularly recipients of TBI-containing regimens, continue to be at long-term risk from infections caused by encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* and require lifelong prophylaxis with penicillin (250 mg twice daily) or erythromycin (250 mg twice daily) if allergic to penicillin. Antibody titres to diseases for which childhood vaccination is performed decline after SCT. Revaccination is therefore recommended, particularly in allograft recipients, and most centres commence such a programme 12 months after transplantation.

Herpesvirus infection: CMV, HSV and varicella zoster

Human CMV is a ubiquitous herpesvirus present in up to 60% of the general population, which reactivates after allogeneic SCT giving rise to either asymptomatic infection or, less commonly, end-organ damage (CMV disease) and death. Patients at the highest risk of CMV reactivation are seropositive recipients, especially those who receive TCD or unrelated donor grafts, and patients who develop GVHD requiring steroid therapy. CMV reactivation occurs in 40–80% of at-risk patients and until recently a substantial number of such patients developed CMV disease. CMV disease most commonly manifests as pneumonitis but can rarely cause gastrointestinal ulceration, hepatitis and retinitis. Until recently CMV was the commonest cause of infectious death after allogeneic transplantation. It is now possible to detect low levels of CMV infection after transplantation, using either polymerase chain reaction (PCR)-based detection of CMV or detection of pp65 antigen in peripheral blood leucocytes (CMV antigenaemia). The introduction of these sensitive diagnostic techniques coupled with the development of effective antiviral drugs has markedly reduced the incidence of CMV disease. Primary infection of seronegative patients may occur as a result of the infusion of stem cell or blood products from a CMV-positive donor but is rare. For this reason seronegative transplant recipients should receive CMV-negative or leucodepleted blood products to limit the possibility of primary infection.

All patients at risk of CMV infection (all CMV-seropositive patients and any patient with a seropositive donor) should undergo weekly PCR or CMV antigenaemia testing from engraftment until 100 days after transplantation. Patients with CMV reactivation should be treated promptly with ganciclovir (5–10 mg/kg daily adjusted according to renal function), a nucleoside analogue that inhibits viral thymidine kinase. The major side-effect of ganciclovir is myelosuppression, which is especially problematic in patients transplanted using an unrelated or cord blood donor. Randomized studies have confirmed that this pre-emptive treatment strategy reduces the risk of CMV disease and death after sibling allogeneic transplantation. The use of prophylactic ganciclovir, which is administered regardless of whether there is evidence of CMV infection, does not improve outcome and is associated with significant bacterial and fungal infections consequent on high rates of myelotoxicity. For this reason a pre-emptive approach to prevention of CMV disease is generally preferred. Foscarnet, a DNA polymerase inhibitor, has less myelotoxicity than ganciclovir and is effective as part of a pre-emptive approach, although it is associated with significant nephrotoxicity.

The incidence of CMV pneumonitis after allogeneic transplantation has substantially reduced since the advent of effective screening and pre-emptive treatment strategies. It occurs in patients with evidence of CMV reactivation within the first 100 days after transplantation and typically presents with dyspnoea, hypoxaemia and pulmonary infiltrates. Ganciclovir and foscarnet

net are often ineffective in patients with established CMV pneumonitis. However, recent studies have demonstrated significant activity of cidofovir, which is considered in some units as first-line treatment in all patients with CMV pneumonitis. Cidofovir is nephrotoxic but can usually be safely administered if attention is paid to adequate hydration and other nephrotoxic drugs, particularly foscarnet, are discontinued. The role of high-titre CMV immunoglobulin in the treatment of CMV pneumonitis remains unclear, although it is still widely used, if available. The effective treatment of CMV infection delays the development of an immune response to CMV and as a result late (beyond 100 days post-transplant) CMV reactivation and disease is increasingly observed. Risk factors for late CMV infection include previous CMV reactivation, lymphopenia and the presence of active GVHD.

Other members of the herpesvirus family have the potential to cause significant morbidity after allogeneic SCT. The incidence of HSV, which used to be very common in the first 30 days after SCT, has been sharply reduced by the use of prophylactic aciclovir. Reactivation of varicella zoster virus (VZV) occurs in up to 50% of at-risk patients after allogeneic SCT and typically presents as shingles with severe pain and a dermatomal vesicular eruption. Less commonly, VZV reactivation presents with atypical pain (headache or undiagnosed abdominal pain) in the absence of a rash. Prompt treatment of VZV infections with high-dose intravenous aciclovir is indicated after allogeneic SCT to prevent dissemination but also to reduce the severity of post-herpetic neuralgia. HHV-6 is also increasingly being reported in association with a syndrome variously associated with delayed engraftment, encephalitis and hepatitis.

Fungal infections

Fungal infections remain a major complication after SCT, reflecting the absence of accurate diagnostic tests and the inadequacy of current therapies. A high index of clinical suspicion is therefore required in transplant patients, particularly allografts, and most units administer systemic antifungal therapy early in the management of neutropenic fever. Risk factors for the development of fungal infection include prolonged neutropenia after SCT, the use of high-dose corticosteroids for treatment of GVHD and a history of prior fungal infection.

Effective strategies exist for the prophylaxis and treatment of infection with yeasts (*Candida* spp.) but are lacking for infection with moulds such as *Aspergillus* spp. *Candida* infections typical manifest as oral thrush and less commonly as oesophageal candidiasis. Hepatosplenic candidiasis is seen occasionally, presenting with high spiking fevers at the time of engraftment in association with abnormal liver function tests. Ultrasound or computed tomography (CT) of the liver and spleen will confirm the diagnosis. Prophylactic use of fluconazole (400 mg daily) has proved effective in reducing the incidence of both superficial and invasive candidiasis. Patients who develop either hepatosplenic candidiasis or candidaemia should be treated with

systemic antifungals, usually liposomal amphotericin. All indwelling catheters must be removed. Emergence of fluconazole-resistant *Candida* species such as *Candida krusei* or *Candida glabrata* is of concern and sensitivity data must be requested in any patient with *Candida* infection.

Aspergillus infections usually present prior to or shortly after engraftment. The most common manifestation is as invasive pulmonary aspergillosis (IPA), which typically presents with an antibiotic-resistant fever, a significantly raised C-reactive protein, and abnormal chest radiography or high-resolution CT, often in the absence of respiratory symptoms. Rarely invasive *Aspergillus* infections can present with cerebral or hepatic disease. Accurate diagnosis of *Aspergillus* infections remains problematic since spores are only rarely cultured from lavage fluid or infected tissues and the sensitivity and specificity of other currently available diagnostic techniques is low. Contradictory results have been obtained using galactomannan detection assays and the initially encouraging results with PCR technology have not been confirmed by all groups. Operationally, the most helpful test in deciding whether IPA is a clinical possibility is high-resolution CT of the chest, which should be obtained in all patients with a neutropenic fever that has persisted for more than 72 hours. While the characteristic radiographic features of peripheral nodular shadows, with or without evidence of cavitation or a 'halo' sign, may take weeks to develop, the presence of any significant pulmonary infiltrate substantially increases the likelihood of *Aspergillus* infection and is an indication for the consideration of treatment doses of liposomal amphotericin or voriconazole. Importantly, the likelihood of IPA in a patient with a normal chest on high-resolution CT is low. Improved antifungal drugs now make it possible to contemplate allogeneic transplantation in patients with a previous proven or suspected invasive fungal infection. Risk factors for recrudescence of fungal disease in this setting include a short period (<6 weeks) of antifungal treatment prior to transplant, the use of bone marrow or cord blood cells as opposed to PBSCs, occurrence of grade 2 or greater acute GVHD, and CMV reactivation.

Organ toxicity

Gastrointestinal toxicity

Mucositis is frequently observed in patients transplanted using a myeloablative conditioning regimen but is less common in patients transplanted using an RIC regimen. Symptoms of oral pain and pain on swallowing typically develop in the first few days after stem cell infusion and peak approximately 8 days post transplant. The severity of mucositis is closely correlated with the intensity of the conditioning regimen, the use of higher doses of fractionated TBI and the inclusion of methotrexate as a component of the GVHD prophylaxis regimen. Patients with severe mucositis should receive adequate (often opiate) analgesia and be monitored for evidence of airway obstruction. In patients who develop symptoms of severe oesophagitis, the pos-

sibility of superadded infection with *Candida albicans* or HSV must be considered, the latter typically being associated with intractable vomiting.

Diarrhoea and/or abdominal pain are common manifestations of conditioning toxicity. Alternative causes of diarrhoea in the first 4 weeks after transplantation include enteritis due to *Clostridium difficile*, rotavirus or CMV, acute GVHD and pancreatitis. VZV reactivation can occasionally present with severe abdominal pain, often in association with markedly deranged liver function tests sometimes days in advance of, or even in the absence of, the development of classic vesicles.

Liver toxicity

Abnormalities in liver function tests are commonly observed after allogeneic SCT and causes include VOD, drugs, infectious complications, cholelithiasis, acute GVHD and transfusional iron overload (Table 38.4). VOD is a clinical syndrome characterized by a triad of hyperbilirubinaemia (bilirubin >34 µmol/L), weight gain (>5% over baseline), and painful hepatomegaly. It is associated with evidence of damage to sinusoidal endothelial cells and hepatocytes and subsequent damage to the central veins in zone 3 of the hepatic acinus. In severe cases hepatic venular occlusion and widespread zonal disruption may lead to portal hypertension, hepatorenal syndrome, multiorgan failure and death. Risk factors for the development of VOD include the use of conditioning regimens containing busulfan or higher doses of TBI, pretransplant abnormalities of liver function tests, previous abdominal irradiation and recent exposure to the anti-CD33 antibody gemtuzumab ozogamicin (Mylotarg). A diagnosis of VOD is most commonly made on clinical criteria.

Table 38.4 Causes of abnormal liver function tests after allogeneic SCT.

Precipitant	Clinical presentation
Veno-occlusive disease	Hyperbilirubinaemia associated with weight gain, ascites and painful hepatomegaly
Drugs	Ciclosporin (hyperbilirubinaemia), azole antifungals (raised AST)
Haemolysis	Fall in Hb associated with unconjugated hyperbilirubinaemia and positive Coombs test
Biliary obstruction	Dilated biliary tree associated with gallbladder ‘sludge’ or cholelithiasis
Infection	Viral hepatitis, fungal infection (disseminated aspergillosis or candidiasis), cholangitis lenta (progressive development of obstructive picture occurring days after an episode of sepsis)

Hepatic Doppler studies demonstrating evidence of reversal of portal flow support the diagnosis. Definitive diagnosis requires transjugular venous liver biopsy, which has significant morbidity in the early post-transplant period and is therefore often avoided. It is important to exclude other causes of hyperbilirubinaemia, particularly ciclosporin toxicity (which can present with a very similar clinical picture), haemolysis (typically consequent on donor–recipient ABO mismatch or transplantation-associated microangiopathic haemolytic anaemia) and the hepatitis of sepsis (cholangitis lenta). Management is supportive, consisting of careful fluid balance, the judicious use of diuretics and, where necessary, haemofiltration. There is now convincing evidence that defibrotide can effectively treat severe VOD. Because of the clinical similarities between VOD and ciclosporin toxicity, it is wise to discontinue ciclosporin for at least 48 hours in any patient in whom a diagnosis of VOD is suspected.

Renal toxicity

The importance of the daily monitoring of weight, fluid balance and renal function in the effective management of patients after SCT cannot be overestimated. Impairment of renal function is frequently observed after allogeneic SCT unless careful attention is paid to fluid balance and the nephrotoxic potential of drugs commonly used during SCT, especially ciclosporin, amphotericin, aminoglycosides and loop diuretics. Ciclosporin-related renal toxicity is usually easily reversible by temporary omission and dose reduction. Occasionally, ciclosporin toxicity manifests itself as a microangiopathic haemolytic anaemia with features of thrombotic thrombocytopenic purpura/haemolytic-uraemic syndrome. Withdrawal of the drug is mandatory. There is no convincing evidence that plasmapheresis is beneficial. Introduction of an alternative immunosuppressant (e.g. mycophenolate mofetil) should be considered. Late renal toxicity is observed in patients on long-term ciclosporin and patients who have undergone a TBI-based allograft.

Pulmonary infections and non-infectious complications

A range of pulmonary infections occurs after allogeneic SCT. In the first month after transplantation bacterial and fungal pneumonias are common. CMV, respiratory syncytial virus, influenza and parainfluenza are important causes of pneumonitis and typically occur in the first 90 days after transplantation. *Pneumocystis* pneumonia and *Toxoplasma* infection are still seen occasionally in the first few months after transplantation in patients who do not receive, or who are not compliant with, co-trimoxazole prophylaxis.

Non-infectious pulmonary complications occurring after allogeneic transplantation can be reversible but demand prompt diagnosis if treatment is to be effective. Pulmonary oedema consequent on either increased capillary hydrostatic pressure caused by fluid overload or increased capillary permeability due to irradiation or sepsis is frequently seen in the post-transplant

period. Idiopathic pneumonia syndrome, defined as diffuse lung injury occurring after SCT for which no infectious or non-infectious aetiology can be identified, typically occurs 30–50 days after transplantation. The classic presentation includes dyspnoea, non-productive cough, hypoxaemia and non-lobar infiltrates on chest radiography and can progress rapidly to acute respiratory distress syndrome. Treatment is supportive but frequently unsatisfactory, and steroids have little effect on outcome. Diffuse alveolar haemorrhage is seen predominantly in patients undergoing autologous SCT but can also be seen in allogeneic recipients. This complication usually occurs within the first 2–3 weeks of transplantation and presents with dyspnoea, non-productive cough and hypoxaemia. Radiographic changes include interstitial or alveolar shadowing. Definitive diagnosis requires bronchoscopy, which shows fresh blood on repeated lavage. Early recognition of this disorder is essential since early intervention with high-dose steroids may significantly improve survival.

Post-transplant lymphoproliferative disease

Post-transplant lymphoproliferative disease (PTLD) includes a spectrum of EBV-driven B-cell hyperproliferative states that range from polyclonal benign proliferations to life-threatening neoplastic disease. Most cases of PTLD involve EBV-seropositive donors and present with lymphadenopathy and fever. In contrast to the PTLDs that develop following solid organ transplantation, the majority of cases after SCT are of donor origin and arise as a result of inadequate T-cell control of proliferation of EBV-infected B cells. Risk factors for the development of PTLD include TCD, particularly the use of ATG, and increased HLA disparity. Recent reports suggest that the use of alemtuzumab for TCD may now also be associated with an increased risk of PTLD. Weekly PCR quantitation of EBV viraemia is indicated in patients undergoing allogeneic transplantation that incorporates ATG or alemtuzumab and in all CBT procedures. Patients with a rising EBV load may be managed by a reduction in immunosuppression or treated with pre-emptive anti-CD20 monoclonal antibody (rituximab), although the triggers for intervention have not been precisely defined. In patients with a documented PTLD, early treatment with rituximab and, where possible, cessation of immunosuppressive therapy are the key to treatment. DLI using EBV-specific cytotoxic T lymphocytes has also been used with effect.

Intensive care support

The likelihood of developing organ failure requiring admission to the intensive therapy unit (ITU) after SCT varies widely according to stem cell source (autologous vs. allogeneic), the intensity of the conditioning regimen and the presence of pretransplant comorbidities. While recent studies suggest a reduction in the proportion of transplant recipients requiring ITU admission, it remains the case that at least 10% of allografted patients, and in some institutions significantly more,

will require ITU admission at some stage during their treatment.

Analysis of outcome in patients admitted to ITU has identified factors determining survival at varying stages after transplantation, allowing rational decisions about the likelihood of benefit of sustained intensive care in patients with multiorgan failure. Further sophistication in defining who will benefit from admission to ITU has been provided by the application of scoring systems. These include the Acute Physiology and Chronic Health Evaluation (APACHE) II and III mortality prediction models and Simplified Acute Physiology Score (SAPS) prognostic systems. Application of these scores prior to admission to ITU and, where appropriate, after a 72-hour period on ITU is helpful in identifying patients who will benefit from institution or continuation of intensive support. A number of studies have indicated that the development of progressive organ failure or the presence of multiorgan failure 72 hours after admission to ITU predicts an extremely poor outcome. The careful integration of these data into discussion with relatives and, where possible, patients can spare many the indignity of prolonged and futile intervention.

Late complications

As the results of allogeneic SCT have improved, its long-term complications have come to be better recognized. Chronic GVHD, secondary malignancies, and growth and fertility disorders represent an increasingly important cause of morbidity in patients who have been cured of their underlying disease.

Chronic GVHD

Chronic GVHD refers to a complex syndrome occurring more than 3 months following allogeneic transplantation and is its commonest long-term complication. There is increasing recognition that its onset can be variable and that patients may present features of both acute and chronic GVHD (often referred to as overlap syndrome). Registry data show that chronic GVHD occurs in approximately one-third of patients undergoing T-replete transplants from HLA-identical siblings, rising to two-thirds of patients receiving T-replete grafts from unrelated donors. Risk factors for the development of chronic GVHD include increased recipient age, the use of PBSCs as opposed to bone marrow as stem cell source, transplantation from an unrelated or HLA-mismatched donor, the use of a T-replete stem cell inoculum and the presence of prior acute GVHD. Chronic GVHD may develop directly from acute GVHD (progressive), after the resolution of an episode of acute GVHD, or *de novo* in patients with no history of chronic GVHD. The clinical manifestations are characterized by features of both immunodeficiency and 'autoimmunity' (Figure 38.7). Previous grading systems for chronic GVHD have classified its severity as limited or extensive (Table 38.5), although the utility of this staging system has been questioned. Patients with progressive-type onset, extensive skin involvement, throm-

bocytopenia or bronchiolitis obliterans have a particularly poor prognosis. A new scoring system based on the number of organs involved and the severity within each affected organ is likely to be adopted, particularly in trials of novel therapies.

Current treatment options are unsatisfactory and in the first instance involve immunosuppression with ciclosporin or prednisolone prior to the institution of a gradual reduction in responding patients. In patients, who fail to respond or who show steroid dependency, second-line therapies including extracorporeal photopheresis, sirolimus and rituximab can be effective. Extracorporeal photopheresis is particularly beneficial in patients with sclerodermatous involvement and appears to be less effective in patients with visceral disease. Rituximab has been employed successfully in some patients, with responses observed particularly in patients with musculoskeletal involvement. Other treatments suggested include non-absorbable steroids for those with gut involvement, tacrolimus (FK506), thalidomide and imatinib. Definitive prospective randomized data supporting any of these strategies are lacking.

Secondary malignancies

The incidence of solid tumours in recipients of allogeneic SCT is increased compared with control populations and includes a higher rate of skin or buccal cavity squamous cell carcinoma and melanoma. In the largest study to date, the cumulative incidence of all solid tumours was 2.2% at 10 years and 6.7% at 15 years, although the latter figure may represent an overestimate. Risk factors for the development of secondary malignancies include the use of TBI in the conditioning regimen and the presence of chronic GVHD.

Growth, puberty and fertility

Retarded growth is seen predominantly in children who receive transplants at a younger age (<10 years) and in those who have received irradiation, particularly cranial irradiation. Growth retardation is multifactorial and although growth hormone levels may be diminished as a consequence of hypothalamic or pituitary irradiation, this does not entirely account for the observed reduction in height. Gonadal failure (both testicular and ovarian) is a common consequence of myeloablative conditioning regimens, particularly those which contain TBI or busulfan. While prepubertal females receiving cyclophosphamide alone (as for transplantation in severe aplastic anaemia) have a high probability of experiencing a normal puberty, most receiving other preparative regimens will fail to regain normal ovarian function and will require sex hormone replacement therapy for the induction of puberty. Thereafter sex hormone replacement is indicated to maintain the menstrual cycle and normal bone turnover/mineralization, but the optimal duration of therapy and the potential long-term risks of hormone replacement therapy in this setting are unknown. Although about 10% of women who receive TBI-containing regimens

Table 38.6 Immediate complications of autologous SCT.

<i>Organ</i>	<i>Complications</i>
Lung	Diffuse alveolar haemorrhage, interstitial pneumonitis especially in recipients of bleomycin/carmustine- and TBI-containing regimens
Gastrointestinal	Mucositis, nausea, diarrhoea
Hepatic	Asymptomatic elevation of bilirubin or AST, veno-occlusive disease (especially recipients of busulfan-containing regimens)
Renal	Prerenal acute renal failure, renal toxicity (nephrotoxic antibiotics), interstitial nephritis
Cardiac	Arrhythmias, cardiac failure (cyclophosphamide)

may have some recovery of gonadal function, the overall incidence of pregnancy is very low. The advent of RIC raises the prospect that some women may remain fertile after transplantation and in this case prior therapies and age will be additional factors determining fertility. In males, cryopreservation of sperm should be performed at diagnosis since chemotherapy and transplantation both result in a high rate of male infertility.

Complications of autologous SCT

The morbidity and mortality of autologous SCT is much lower than that observed in allogeneic transplantation. The major toxicities relate to immediate or delayed organ failure caused by the conditioning regimen or complications consequent on neutropenia or thrombocytopenia (Table 38.6). The major infectious complications are bacterial and fungal and occur in the main in the first 28 days after transplantation. Late complications are rare but include pulmonary fibrosis in patients who have received busulfan and carmustine and gonadal failure in recipients of TBI or busulfan-containing regimens. Female recipients of BEAM chemotherapy may recover some gonadal function. The development of myelodysplasia is a well-recognized late complication, particularly in patients transplanted using a TBI-based regimen. In general, treatment-related MDS or AML occurs within 12 months of transplantation and is most frequently associated with abnormalities of chromosome 5 or 7 or a complex karyotype. It appears that prior chemotherapy is the most important factor in the development of MDS or AML since the leukaemia-associated cytogenetic abnormality can be detected in the infused stem cell inoculum.

Table 38.7 Impact of pretransplant patient and donor characteristics on outcome after allogeneic SCT.

Patient age
Donor match (sibling vs. unrelated donor)
Donor sex (female; male is associated with worse outcome)
Disease stage
Time from diagnosis to transplant (applies to patients with CML in first CP)
Patient CMV serostatus (if undergoing volunteer unrelated donor transplant)

Patient factors determining outcome after allogeneic stem cell transplantation

The major causes of treatment failure after allogeneic transplantation are organ toxicity, infectious complications, GVHD and disease relapse (see Figure 38.4). TRM after allografting is determined by specific patient and donor characteristics and these can be used to calculate transplant risk, providing useful information in assessing whether an individual patient is likely to benefit from allogeneic transplantation (Table 38.7). The advent of RIC regimens and alternative stem cell sources has increased the importance of developing a robust estimate of TRM. Recent studies in patients allografted using an RIC regimen have allowed the development of a comorbidity scoring system that assists in prediction of TRM and overall survival. These important studies require validation in specific RIC regimens, particularly those incorporating alternative donors or TCD, but offer the prospect of developing a more rational basis of selecting candidates for allogeneic transplantation.

Indications for transplantation

SCT is now an essential constituent of the treatment strategy for many haematological malignancies. In the case of autologous transplantation current practice has been informed by the results of randomized controlled trials comparing the outcome of transplanted patients with those who have received standard chemotherapy. However, methodological challenges have made it much more challenging to perform randomized trials in the setting of allogeneic transplantation. Obstacles not only include randomization biases introduced because of the fixed perceptions of either physicians or patients but also the very real problem that the allograft arm may include a smaller proportion of patients with high-risk disease given the propensity of such patients to relapse before they reach transplantation. The only effective approach that allows these biases to be removed is the use of a 'donor versus no-donor' analysis, which exploits

Table 38.8 Indications for SCT.

	<i>Autologous SCT</i>		<i>Allogeneic SCT</i>	
			<i>Sibling transplant</i>	<i>VUD transplant</i>
AML first CR

ALL, acute lymphoblastic leukaemia; AML, acute myeloid leukaemia; CML, chronic myeloid leukaemia; CR, complete remission; D, developmental; DLBCL, diffuse large B-cell lymphoma; MDS, myelodysplastic syndrome; NHL, non-Hodgkin lymphoma; NR, not recommended; R, recommended; VUD, volunteer unrelated donor.

the availability of an HLA-identical sibling donor as a form of biological randomization. However, such an approach is hard to apply in rarer diseases and difficult to apply to recipients of alternative donor transplants. Consequently, many of the recommendations concerning the role of allogeneic transplantation in specific diseases will continue to be based on registry data or institutional Phase II studies.

In order to provide a robust framework for SCT, the EBMT publishes a regularly updated summary of indications for transplantation (Table 38.8), allowing a consistent approach to be adopted. This categorizes specific diseases according to whether autologous or allogeneic SCT is accepted as standard therapy, is a promising treatment modality requiring further evaluation, or is not indicated.

Factors determining the choice of an allogeneic stem cell donor: the donor algorithm

An HLA-identical sibling donor can be identified in fewer than one-third of patients eligible for an allogeneic transplant. In older patients, where potential sibling matches may have medical conditions precluding stem cell donation, the likeli-

hood of locating a suitable matched donor is significantly lower. Two potential donor options now exist for adults lacking a suitable sibling donor in the form of either an unrelated or cord blood donor.

Thanks to the rapid expansion of unrelated donor registries, approximately 12 million unrelated donors are now registered worldwide. As a result it is possible to identify a suitable donor in up to 70–80% of Caucasians, although this figure is much lower in other ethnic groups. Preferably the donor should be matched for HLA A, B, C; DRB1, and DQB 1 (10/10). Initial results with unrelated donor transplantation were associated with a high TRM and an increased incidence of severe GVHD. In the last decade there has been a marked improvement in outcome of unrelated donor SCT because of the availability of molecular typing at class I and II loci of the HLA complex. It is now clear that the presence of multiple disparities at class I or II loci are associated with a worse transplant outcome (see Chapter 37). As yet we lack sufficient information to allow us to identify whether specific allelic mismatches are of particular clinical significance. Although the recent growth in the size of unrelated donor registries internationally has increased the availability of volunteer unrelated donors, their unrepresentative ethnic composition limits the availability of donors for ethnic minorities. Consequently, the timely identification of a suitable alternative donor remains a challenge for a significant

number of patients, particularly those with high-risk acute leukaemia who require urgent transplantation.

UCB has long been known to be a rich source of haemopoietic progenitors and recent results have demonstrated that high rates of durable engraftment can be achieved in adults, comparable to those achieved in children, providing the cell dose is optimized. Importantly, it appears that greater degrees of HLA mismatch can be tolerated using UCB than with a volunteer unrelated donor. As a result it is possible to transplant a cord blood unit mismatched at two or fewer HLA-A, -B or -DRB1 antigens as long as an adequate cell dose is available. This, coupled with the speed of procurement of UCB units, has resulted in the emergence of cord blood as an increasingly important alternative stem cell source in both adults and children. Although initial results using UCB in adults were compromised by delayed engraftment and a high rate of primary graft failure, these problems have largely been overcome by ensuring the use of a high total nucleated cell dose or two cord blood units. As a result UCB is increasingly recognized as an important stem cell source in adults with high-risk leukaemia lacking a suitable unrelated donor, providing strict matching and cell dose requirements are adhered to, although its precise role needs to be defined in prospective clinical trials.

Until recently, haploidentical transplants were associated with unacceptable rates of graft failure and GVHD because of the presence of HLA disparity at all major HLA antigens. However, the ability to maximize the stem cell dose, using G-CSF-mobilized progenitors, coupled with the development of efficient methods of TCD, has significantly improved outcome and it is now an important treatment option in children lacking an unrelated donor. In adults many allograft centres now prefer UCB as a stem cell source in adults without an unrelated donor but a number of European centres now also report encouraging results in adults using haploidentical donors.

Management of disease relapse

Disease relapse remains a major cause of treatment failure after allogeneic transplantation and is caused by either resistance of tumour cells to the conditioning regimen or failure of the donor immune system to eradicate residual malignant haemopoiesis. Possible mechanisms for tumour cells evading a GVL effect include downregulation of HLA class I or II expression or absence of costimulatory molecules on leukaemic blasts or location of residual cells in privileged sites such as the CNS or testes. While it is possible to reduce the risk of disease relapse after a myeloablative allograft by increasing the intensity of the preparative regimen, this approach does not translate into improved overall survival because of the increased TRM associated with a more intense conditioning regimen. Consequently, optimization of the GVL effect represents the only mechanism by which

the antileukaemic activity of a myeloablative allograft can be augmented. In routine clinical practice the options for manipulating a GVL effect are limited and are restricted to modifying the intensity of post-transplant immunosuppression, for example through the institution of a rapid ciclosporin taper in patients at a high risk of disease relapse. While the prophylactic use of DLI in patients deemed at high risk of relapse is an attractive option, such an approach is difficult to effect in practice because many patients will relapse early while still on immunosuppression and before DLI can be administered. In those patients in whom a course of prophylactic DLI can be commenced before disease relapse, the risk of severe GVHD associated with its use in the first 12 months after transplantation represents a significant problem.

In patients transplanted using an RIC regimen, there is limited room for increasing the intensity of the conditioning regimen without increasing transplant toxicity. Maximizing a GVL effect can be achieved by limiting post-transplant immunosuppression. There remains considerable debate as to whether the presence of mixed T-cell chimerism after an RIC allograft is associated with an increased risk of disease relapse. On the basis that it is an indicator of bidirectional tolerance and therefore permissive for disease relapse, a number of units administer prophylactic DLI in patients who have been transplanted using an RIC regimen in whom mixed T-cell chimerism persists after the withdrawal of post-transplant immunosuppression. Definitive data concerning the effectiveness of this approach in improving outcome are not yet available.

The management of patients who relapse after allogeneic transplantation is complex and in many patients should probably be palliative. This particularly applies to patients transplanted for acute leukaemia who relapse within the first 12–18 months post transplant or patients with a history of severe acute or chronic extensive GVHD. However, there is now a significant population of patients in whom DLI or a second transplant should be considered. Two factors determine the use of DLI in clinical practice. Firstly, the ability of DLI to deliver durable remissions is highly dependent on the underlying haematological malignancy. Thus up to 80% of patients who have relapsed after an allograft for CML will achieve a durable molecular remission with DLI in contrast to patients transplanted for acute leukaemia or myeloma where response rates are much lower. Prior cytoreduction appears to increase the likelihood of patients with relapsed acute leukaemia achieving a durable response to DLI. The major complications of DLI are myelosuppression and GVHD. Myelosuppression is most commonly observed in patients with overt haematological relapse and may require treatment with G-CSF and occasionally transfusion of donor CD34-positive selected PBSCs. In early studies DLI was administered as a single bulk infusion and was associated with a significant risk of severe GVHD. However, the recognition that use of an escalating schedule of administration substantially reduces the risk of severe GVHD without compromising

its efficacy has markedly reduced the toxicity of DLI. The explanation why early DLI is associated with such a high risk of severe GVHD is unclear but may relate to more rapid expansion of donor alloreactive T cells in the profoundly lymphopenic environment present in the first few months after transplantation. An alternative approach in patients who relapse late and in whom there was no evidence of either acute or chronic GVHD is a second allograft using an RIC regimen. Although associated with an increased TRM, a number of studies now show a significant chance of long-term disease-free survival after a second allograft in a significant proportion of such patients.

Relapse after autologous SCT is caused by either resistance of the underlying haematological malignancy to the myeloablative conditioning regimen or infusion of contaminating tumour cells at the time of transplantation. Patients with myeloma in whom the duration of response to the first transplant was greater than 18 months may benefit from a second autograft, although whether this is superior to the outcome of treatment with one of the newer agents such as bortezomib or lenalidomide is unknown. Allogeneic transplantation using an RIC regimen is an important treatment option in patients with Hodgkin disease or non-Hodgkin lymphoma who have relapsed after an autologous transplant.

Future developments in stem cell transplantation

Autologous SCT

Relapse remains the commonest cause of treatment failure in patients after autografting. It is likely that the most important cause of disease recurrence after an autologous transplant is caused by tumour chemoresistance or radioresistance. Most of the drugs contained in preparative regimens are already administered at close to the limit of extramedullary toxicity and there is therefore little room for further dose escalation. Consequently, efforts to reduce relapse rate will depend on either altering the mode of delivery of currently used agents or the development of new forms of chemotherapy or radiotherapy. The recent advent of an intravenous preparation of busulfan is an example of how improved drug delivery can improve the pharmacokinetic profile of an antitumour agent, thereby reducing toxicity and increasing activity. Many haematological malignancies are highly radiosensitive and there is interest in the possibility of increasing the effective dose of irradiation delivered to the marrow without increasing organ toxicity using radiolabelled immunoconjugates. Early-phase clinical studies using α (^{131}I) or β (^{90}Y) emitters conjugated to haematopoietic antigens, such as CD45 or CD66, demonstrate that such an approach is feasible and Phase II studies in myeloma and lymphoma are ongoing. Alternatively, drugs that disrupt tumour cell binding to the bone marrow microenvironment, such as the CXCR4 antago-

nist plerixafor, may overcome cytoadhesion-mediated drug resistance and increase the activity of drugs such as melphalan. Although contamination of PBSC grafts by malignant cells can undoubtedly contribute to disease relapse after an autologous transplant, there is no evidence that purging of stem cell collections reduces relapse risk.

Allogeneic SCT

The major advances in allogeneic transplantation in the past decade have been the introduction of RIC regimens and the increased availability of alternative donors. As a result allogeneic transplantation is increasingly employed as a treatment option in patients with haematological malignancies. However, the challenges of allografting remain substantially unchanged: GVHD, infection and disease relapse. Since all three, to a greater or lesser extent, are consequent on a failure to regulate or harness the donor immune response appropriately, advances in their management are rarely made alone but are interlinked.

The development of novel strategies to prevent GVHD are dependent on whether they are to be employed in the context of TCD or not. In patients transplanted using a T-replete stem cell inoculum, drugs such as mycophenolate mofetil and sirolimus are being actively considered as alternatives for GVHD prophylaxis. In the setting of TCD, where the risk of GVHD is low, the emphasis is on minimizing the impairment in immune reconstitution and increased infectious complications caused by depletion of donor T cells. One promising approach by which this might be achieved is through the use of 'add backs' of antigen-specific T cells recognizing common post-transplant viral pathogens such as CMV, EBV or adenovirus. Such cells can be generated either by coculturing donor lymphocytes with APCs primed with candidate antigens followed by expansion or by early selection on the basis of interferon- γ secretion (a technique termed 'IFN- γ capture'). Alternatively, antigen-specific cells might be selected directly from peripheral blood using immunomagnetic techniques based on labelling of antigen-specific cells using HLA class I-peptide multimers. In situations where a donor has no relevant immunity (e.g. where a CMV-seropositive patient is transplanted from a seronegative donor), gene transfer of a TCR specific for the relevant viral antigen is under investigation. In order to improve coverage against multiple pathogens, infusion of donor lymphocytes from which alloreactive T cells have been depleted may hasten immune reconstitution without incurring the risk of GVHD normally associated with DLI. Such an 'allodepletion' strategy can be achieved by either directly removing donor CD8 cells from the infusion, given that CD8 cells are postulated to be the major effectors of GVHD, or alloreactive T cells can be depleted from the graft by incubating cells *ex vivo* with recipient APCs. Activated T cells capable of mediating

GVHD can be identified by their expression of CD25 or other activation markers and removed using magnetic selection techniques or an immunotoxin. Preclinical models have suggested that transfer of memory phenotype T cells may also permit more rapid immune recovery without inducing GVHD, although whether such cells are truly representative of human memory T cells remains to be determined. There is also substantial interest in the feasibility of transferring naturally occurring or *ex vivo* expanded CD4⁺FoxP3⁺ or IL-10-producing regulatory T cells as a means of preventing conventional T cells from inducing GVHD. The best approach for isolating and expanding these regulatory populations remains unknown, but the results from ongoing trials are keenly awaited.

From first principles, reducing the risk of relapse can be achieved by increasing the intensity of the conditioning regimen (ideally without increasing transplant toxicity), administering antileukaemic therapies in the post-transplant period or by optimizing the GVL effect. Incorporating radioimmunotherapy (e.g. with antibodies directed at antigens specific for haemopoietic cells or malignant cells) into the preparative regimen shows promise in the setting of allogeneic as well as autologous SCT and may prove of value in patients with advanced leukaemia, where relapse is the most important cause of treatment failure. Alternatively, patients judged to be at high risk of relapse may benefit from administration of adjunctive therapies after transplantation (e.g. tyrosine kinase inhibitors or demethylating agents), reducing the residual disease burden while a GVL response is established. Prophylactic DLI might be administered in high-risk patients following TCD transplantations with the aim of boosting a GVL response. Given the high rate of GVHD associated with this approach, particularly if an unrelated donor has been used, there has been interest in the use of CD8 depletion or allopepleted DLI. Alternatively, the use of donor T cells that have been expanded selectively to recognize tumour-associated antigens or lineage-restricted minor H antigens (e.g. by expanding donor cells in the presence of peptide mixes) may prove effective. Early clinical studies examining the use of lymphocytes generated against minor H antigens or leukaemia-specific antigens such as WT1 and proteinase 3 are currently ongoing. Gene transfer of TCRs specific for such antigens is also of promise. If successful such an approach, coupled with a TCD transplant, may offer the prospect of disassociating GVHD from GVL.

Haemostasis is one of a number of protective processes that have evolved in order to maintain a stable physiology. It has many features in common with (and to some extent interacts with) other defence mechanisms in the body, such as the immune system and the inflammatory response. These links are most clearly seen in ancient species such as the horseshoe crab (*Limulus polyphemus*), where a primitive ‘coagulation’ pathway is initiated by entry of endotoxin into the haemolymph. Vestiges of this process still exist in humans and may give rise to serious clinical consequences. For example, disseminated intravascular coagulation (DIC) can be initiated by Gram-negative septicaemia. However, consequent upon the development of a high-pressure blood circulatory system, extra components have evolved and have resulted in a complex, highly integrated process in all vertebrates (Figure 39.1). Indeed, analysis of the haemostatic network in bony fish suggests that the network in its entirety evolved over 430 million years ago, prior to the divergence of bony fish from tetrapods.

The high blood pressure generated on the arterial side of the vertebrate circulation requires a powerful, almost instantaneous

but strictly localized procoagulant response in order to minimize blood loss from sites of vascular injury without compromising blood flow generally. Systemic anticoagulant and clot-dissolving components have also evolved to prevent extension of the procoagulant response beyond the vicinity of vascular injury resulting in unwanted thrombus formation in the slow, sometimes intermittent, blood flow in the veins. The resultant haemostatic system is thus a complex mosaic of activating or inhibitory feedback or feed-forward pathways that integrates its five major components (blood vessels, blood platelets, coagulation factors, coagulation inhibitors and fibrinolytic elements). Furthermore, links between haemostasis and other elements of the body’s overall defence response, such as the complement and kinin-generating processes and inflammation, must also be considered.

This chapter reviews current concepts of haemostasis in humans and is aimed at providing a background for the understanding of the haemostatic disorders described in succeeding chapters. Attempting to understand these complex events is a considerable task, even to the expert; for the relative newcomer to the subject, it may first be useful to present an overview of events that follow damage to a blood vessel and which lead to effective haemostasis and subsequent restoration of vessel patency. Following this introduction, each of five main areas will be examined in relative isolation, while at the same time acknowledging points of interaction and overlap.

Figure 39.1 The haemostasis network. The network includes elements of coagulation initiation via TF–FVIIa interaction, amplification via the tenase (FVIIIa–FIXa) and prothrombinase (FVa–FXa) complexes, feedback inhibition through specific inhibitors, and clot dissolution by fibrinolysis. Module organization of proteins is indicated (see Figure 39.8) and all abbreviations are given in the text. Protein names are coloured as follows: functionally active proteins, red; inactivated or inhibited proteins, blue; precursors and fibrinogen-derived components, black. Lines and arrows are coloured as follows: dashed red lines, positive procoagulant feedback loops; dashed blue lines, negative feedback and inhibitory loops; solid black lines, interactions or processes. Cream boxes indicate assembly of macromolecular complexes on a cellular phospholipid surface. The process of blood coagulation is initiated by the exposure of cells expressing TF to flowing blood. Thrombin generation is propagated by a

series of positive feedback loops, leading to fibrin deposition. This process is controlled by a series of negative feedback steps: the initiation complex is inhibited by the formation of the quaternary complex TF–FVIIa–FXa–TFPI and the active proteases FIXa, FXa and thrombin are inactivated by the serpin AT. In addition, thrombin initiates a negative feedback pathway by activating PC, leading to the inhibition of FVa and FVIIIa. The generation of fibrin leads to activation of the fibrinolytic pathway through binding of tPA, which leads to plasminogen activation and fibrin degradation. This pathway is also subject to inhibition through the binding of the serpins PAI-1 and α_2 -antiplasmin (α_2 AP) to tPA and plasmin respectively. All these processes, plus platelet activation, occur simultaneously or with short lag times. (From McVey JH, Tuddenham EGD (2007) *Genomics of haemostasis*. In: *Genomics and Clinical Medicine* (D Kumar, ed.). Oxford University Press, Oxford with permission.)

Overview of haemostasis

In the most simplistic terms, blood coagulation occurs when the enzyme thrombin is generated and proteolyzes soluble plasma fibrinogen, forming the insoluble fibrin polymer, or clot; this provides the physical consolidation of vessel wound repair following injury. ‘Haemostasis’ refers more widely to the process whereby blood coagulation is initiated and terminated in a tightly regulated fashion, together with the removal (or fibrinolysis) of the clot as part of vascular remodelling; as such, haemostasis describes the global process by which vessel integrity and patency are maintained over the whole organism, for its lifetime.

Although it is pedagogically convenient to present the sub-systems of haemostasis as if they operate independently, the whole haemostatic mechanism is integrated *in vivo* so that thrombin generation is localized, limited and followed by fibrinolysis and tissue remodelling, which are also localized and

limited. Furthermore, thrombin generation is not a simple exponential cascade as was originally envisaged by Davie and Ratnoff when the ‘waterfall’ hypothesis was described in the 1950s. Rather, it is a complex network of interactions with positive and negative feedback loops. Thus the effects of varying the concentration of any component in such a system are not intuitively obvious. Figure 39.2 presents a version of the earlier cascade concept for intrinsic and extrinsic pathways of thrombin generation.

Although a tremendous improvement over previous ideas, obvious deficiencies of such a scheme include the following.

- No explanation for the variation in clinical phenotype resulting from deficiencies of the components of the intrinsic pathway. While deficiencies of factor (F)VIII and FIX can cause severe bleeding, FXI deficiency is generally a much milder disorder and deficiencies of FXII, prekallikrein and high-molecular-weight kininogen (HMWK) are not associated with any clearly defined phenotype.

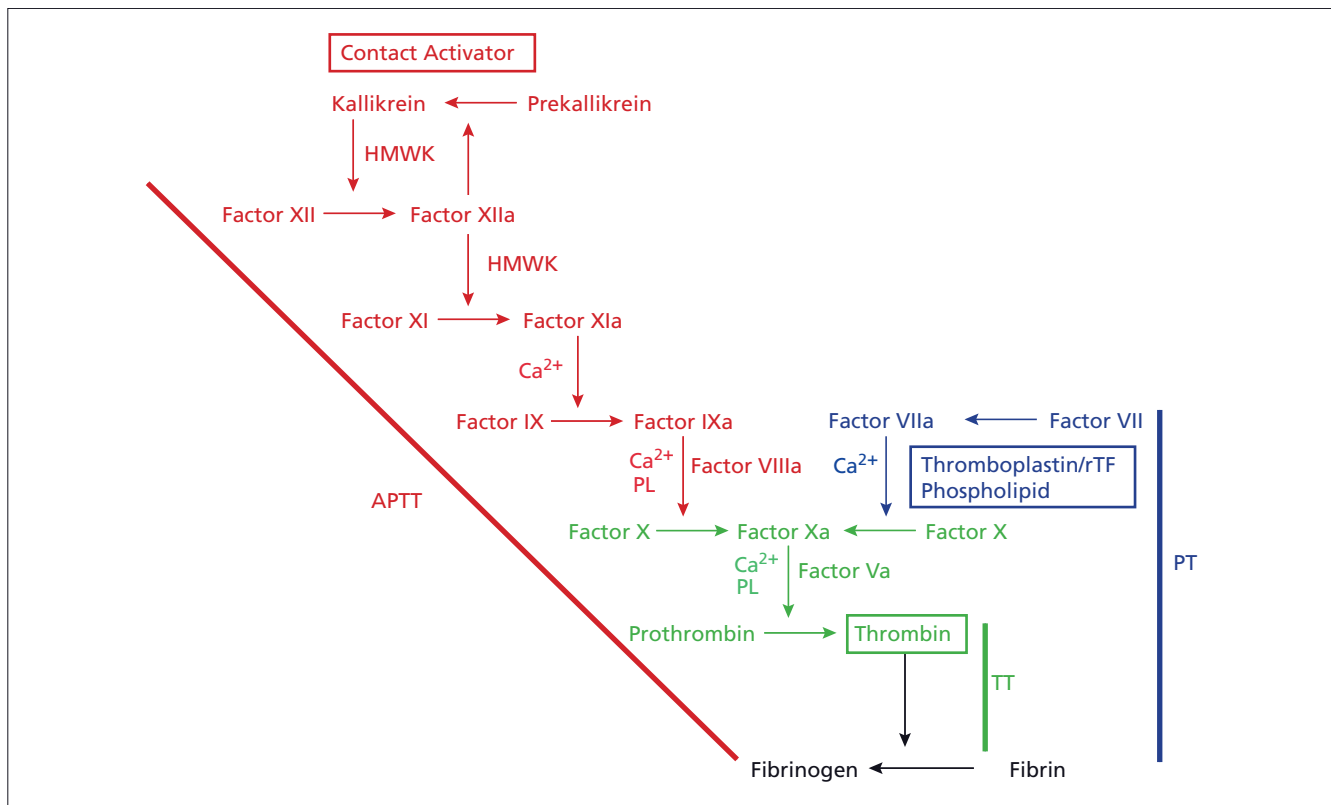

Figure 39.2 The coagulation cascade. The traditional concept of blood coagulation with separate intrinsic (red) and extrinsic (blue) pathways converging on the common pathway (green) with the generation of FXa. The activated partial thromboplastin time (APTT) is initiated by the addition of a contact activator (e.g. kaolin or silica) and tests for deficiencies in the intrinsic

pathway. The prothrombin time (PT) is initiated by addition of thromboplastin and phospholipids and tests for deficiencies in the intrinsic pathway. The thrombin time (TT) is initiated by addition of thrombin and tests for an inhibitor of thrombin (most commonly heparin) or a problem with fibrin cleavage. HMWK, high-molecular-weight kininogen; PL, phospholipid.

- No explanation for the variation in the rate of thrombin generation observed experimentally.
- Implies that clot formation can occur as a result of two independent pathways. In fact it is clear that the interaction between FVII and tissue factor (TF) is the initiator of all coagulation processes, both in normal haemostasis and pathological situations such as thrombosis.
- No recognition of the complex role of platelets in clot formation (see Chapter 40).

Despite these faults the waterfall hypothesis remains a valuable tool for understanding the common coagulations tests that are used in clinical practice today.

Tissue factor initiates blood coagulation

A major development over the past 10 years has been the realization that exposure of blood to cells expressing TF on their surface is both necessary and sufficient to initiate blood coagulation *in vivo*. The contact system (intrinsic pathway; see Figure 39.2) therefore does not appear to have a physiological role in haemostasis. Table 39.1 presents some other putative roles for the contact factors in body defence. TF is constitutively expressed at biological boundaries such as skin, organ surfaces, vascular adventitia and epithelial–mesenchymal surfaces, where it functions as a ‘haemostatic envelope’. This ensures that following disruption of vascular integrity blood is immediately exposed to cells expressing TF, leading to the initiation of blood coagulation. The primary control of haemostasis is therefore the anatomical segregation of cells expressing functional TF from other components of the coagulation network present in blood.

Table 39.1 Role of contact factors in integrating body defence mechanisms.

Pathway involved	Function	Comment
Coagulation	Prevention of blood loss	Not essential for normal haemostasis
Fibrinolysis	Maintenance of vessel patency	May be important
Complement	Contribution to immune response	Not essential
Kinin generation	Pain, capillary permeability, cardiovascular effects	May be important <i>in vivo</i>
Renin–angiotensin system	Blood pressure control	No demonstrated role <i>in vivo</i>
Chemotaxis	Phagocytosis, bactericidal activity	May be important <i>in vivo</i>

Amplification of the initial stimulus

An updated concept of TF-initiated thrombin generation, including the important feedback reactions of thrombin, is shown in Figure 39.3. As stated above, it is now clear from various *in vitro* and *in vivo* experiments that the physiological initiator of blood coagulation is exposure of the circulating zymogen FVII to membrane-bound TF. Activation of FVII to the protease FVIIa and formation of a very high affinity complex of TF with FVIIa results in the activation of FIX and FX by the TF–FVIIa complex. In the absence of its activated cofactor FVa, FXa generates only trace amounts of thrombin from prothrombin. Although insufficient to initiate significant fibrin polymerization, thrombin formed in this initiation stage of coagulation is able to back-activate FV, FVIII and FXI by limited proteolysis. In the amplification phase of coagulation, FXIa activates FIXa which forms a complex with FVIIIa. This is the tenase complex (FVIIIa–FIXa) that activates sufficient FXa to form a complex with FVa, the prothrombinase complex (FVa–FXa). This results in the explosive generation of thrombin that ultimately leads to generation of a fibrin clot.

A key feature of these processes is the assembly of multimolecular complexes on a phospholipid surface provided *in vivo* by cell membranes. For procoagulant complexes such as tenase and prothrombinase, this surface is provided by activated platelets. Each of these complexes consist of a cofactor (TF, FVa, FVIIIa), an enzyme (FVIIa, FIXa, FXa) and a substrate that is a zymogen (FIX, FX and prothrombin) of a serine protease. The product of one reaction becomes the enzyme in the next complex. The cofactors FV and FVIII are themselves activated by limited proteolytic digestion.

Feedback inhibition of the procoagulant response

The process of amplification occurs independently of the TF–FVIIa complex, which is rapidly inactivated by tissue factor pathway inhibitor (TFPI), released from thrombin-activated platelets or found on the surface of endothelial cells, by the formation of a quaternary inhibited complex (Figure 39.4). This explains the requirement for further activation of FX via FIXa–FVIIIa, and back-activation of FXI by thrombin, to permit further activation of FIX. Figure 39.4 also indicates the role of one of the other important inhibitors of the network, anti-thrombin (AT), which damps down thrombin generation by forming inactive complexes with FIX, FX, FXI and thrombin. The rate of inhibition by AT is substantially increased by binding a variety of polysulphated mucopolysaccharides known as glycosaminoglycans (GAGs) on the surface of endothelial cells.

Thrombin also proteolytically activates an anticoagulant pathway, the protein C (PC) pathway (Figure 39.4). Thrombomodulin (TM), an endothelial cell surface receptor,

Figure 39.3 The haemostasis network: fibrin generation. Following vascular damage blood coagulation is initiated by exposure of FVII to cells expressing the integral membrane protein TF. Activation of FVII to the protease FVIIa results in the activation of FIX and FX by the TF–FVIIa complex. In the absence of its activated cofactor FVa, FXa generates only trace amounts of thrombin. Although insufficient to initiate significant fibrin polymerization, trace amounts of thrombin formed in this

initiation stage of coagulation are able to back-activate FV and FVIII by limited proteolysis. In the amplification phase of coagulation, FVIIIa forms a complex with FIXa, activating sufficient FXa that (in complex with FVa) leads to the explosive generation of thrombin, ultimately leading to generation of a fibrin clot. The tenase (FVIIIa–FIXa) and prothrombinase (FVa–FXa) complexes assemble on phospholipid surfaces. Colours and symbols as in Figure 39.1.

plays a pivotal role in the activation of this anticoagulant pathway. TM binds thrombin and, by an allosteric mechanism, alters its substrate specificity. The procoagulant substrates of thrombin, including FV, FVIII and fibrinogen, are no longer

efficiently proteolysed. The preferred substrate of the thrombin–TM complex is PC, a zymogen that is proteolysed to activated PC (APC). The activation of PC can be augmented by another cellular receptor, endothelial cell protein C receptor (EPCR),

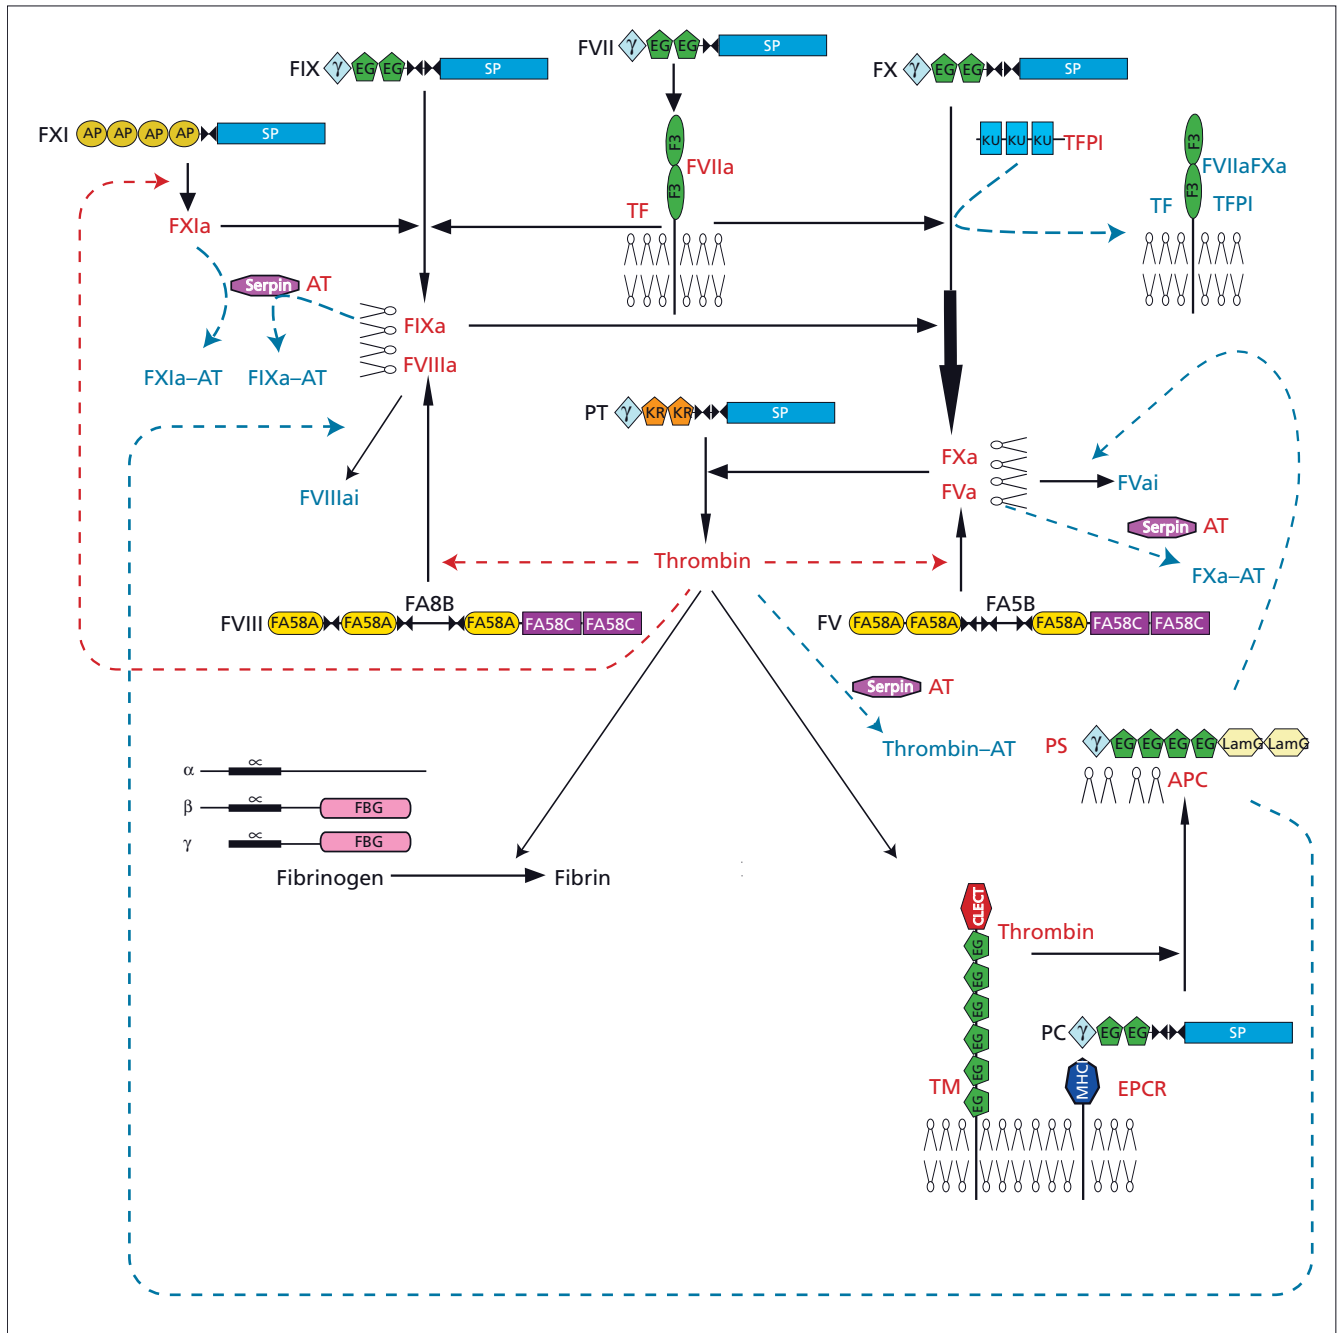

Figure 39.4 The haemostasis network: inhibition of thrombin generation. The initiation of blood coagulation via generation of FIXa and FXa by TF–FVIIa is shut down by the action of TFPI, which forms a quaternary complex with TF–FVIIa–FXa. Further generation of FIXa occurs following back-activation of FXI by thrombin. The serine proteases FIXa, FXa, FXI and thrombin are

all inhibited by AT. At the endothelial cell surface thrombin bound to TM activates PC bound to its receptor EPCR. APC in complex with its cofactor PS inactivates FVa and FVIIIa by further proteolytic cleavages. Colours and symbols as in Figure 39.1.

Figure 39.5 The haemostasis network: fibrinolysis. Both PLG and tPA bind to polymerized fibrin, promoting the cleavage of PLG by tPA to active plasmin, which then degrades cross-linked fibrin to soluble FDPs. Modulation of fibrinolysis is achieved by serpin

inhibition: PAI-1 inactivates tPA, while α_2 -antiplasmin (α_2 AP) inhibits plasmin. In addition, TAFIa removes Lys residues from fibrin, removing PLG and tPA binding sites. Colours and symbols as in Figure 39.1.

which provides a direct endothelial cell binding site for PC and thus increases the apparent affinity of the thrombin–TM complex for PC; however, not all endothelial cells coexpress TM and EPCR. In complex with its cofactor, protein S (PS), APC rapidly inactivates the procoagulant cofactors FVa and FVIIIa by specific proteolysis, forming a negative feedback loop. The PC pathway is most active in the microvasculature, where the relative concentration of EPCR is highest.

Fibrinolysis

The final step in the regulation of fibrin deposition is the prevention and/or rapid removal of insoluble fibrin by the fibrinolytic system (Figure 39.5) described more fully later in the chapter. Briefly, once sufficient fibrin is generated it binds tissue

plasminogen activator (tPA), leading to the increased activation of plasminogen (PLG). This results in the formation of plasmin at the site of the fibrin clot, which breaks down fibrin into soluble fibrin degradation products. The fibrinolytic system is also subject to inhibition through the action of inhibitors of tPA and plasmin, namely plasminogen activator inhibitor (PAI)-1 and α_2 -antiplasmin respectively.

Blood vessels

Blood vessel structure

The basic structure of blood vessels comprises three layers (Figure 39.6a): the intima, the media and the adventitia. It is

Figure 39.6 Blood vessel architecture and functions in haemostasis. (a) The anatomy of a generic vessel in the resting state. The layer thicknesses vary widely between arterial and venous circulation and between large and small vessels. In the absence of vessel damage, cells expressing TF are anatomically separated from components of the blood coagulation network, preventing initiation of coagulation. In addition, coagulation inhibitors present on the endothelial surface and inhibitors of platelet aggregation maintain vessel patency. (b) The localized haemostatic response to vessel injury: initiation of coagulation by TF exposure and platelet activation/aggregation by exposure of extravascular collagen to plasma VWF. Procoagulant responses away from lesion site are damped down by anticoagulant and antiplatelet factors derived from endothelium.

the components of these layers and the size of these layers themselves that differentiate arteries from veins, and indeed arteries or veins of different sizes. The intima is the innermost layer and the surface is covered with a single layer of endothelial cells (the endothelium), which rest on a basement membrane of subendothelial microfibrils composed of collagen fibres and some elastin. The media or middle layer contains mainly circularly arranged smooth muscle cells and collagen fibres, and is divided from the outer adventitia by the external elastic lamina. Contraction and relaxation of smooth muscle cells regulates intravascular pressure and the rate of blood flow. The elastin allows vessels to stretch and recoil, maintaining vascular tone. The adventitia or outermost layer is composed of collagen fibres and fibroblasts that protect the blood vessel and anchor it to surrounding structures.

The endothelium

The endothelium functions in a multitude of physiological processes including intracellular transport, the regulation of vasomotor tone and maintenance of blood flow. Endothelial cells possess surface receptors for a variety of physiological substances, for example thrombin and angiotensin II, which may influence vascular tone directly or indirectly through various haemostasis-related events. Once activated, endothelial cells express at their surface, and in some cases release into the plasma, a variety of intracellular adhesion molecules, for example vascular cell adhesion molecule (VCAM), E-selectin, P-selectin and von Willebrand factor (VWF), which modulate leucocyte and platelet adhesion, inflammation, phagocytosis and vascular permeability.

However, the endothelium should not be regarded as a simple homogeneous cell type. It would appear that endothelial cell phenotypes are differentially regulated. At any given point in time, structural and functional phenotypes may vary between segments of the vascular tree, and at any given location the endothelial phenotypes may change from one moment to the next. Endothelial cell heterogeneity occurs between different organs, within the vasculature of a given organ, and even between neighbouring endothelial cells of a single vessel.

The platelet–vessel wall interaction

Healthy unperturbed endothelial cells exert a powerful inhibitory influence on haemostasis by virtue of the factors they release or express on their surface (see Figure 39.6a). Two of these, prostaglandin (PG)₂ (or prostacyclin) and nitric oxide (NO), also known as endothelium-derived relaxing factor, have powerful vasodilator activity, acting on smooth muscle cells in the vessel wall (basal-directed secretion) and hence modulating blood flow. Both substances inhibit aggregation of

platelets and leucocytes (luminal-directed secretion) by raising intraplatelet levels of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) respectively (see below).

PGI₂ is the major prostaglandin synthesized by endothelial cells, a small amount also being produced by fibroblasts and smooth muscle cells. Its action on platelets involves binding to a specific G protein-coupled receptor (PTGIR) that activates adenylate cyclase, thus increasing the intraplatelet cAMP concentration. This promotes Ca²⁺ uptake into the dense tubular system and inhibits phosphatidylinositol metabolism, both of which prevent platelet aggregation and the consequent release of storage granules containing procoagulant molecules such as VWF and FV. The precursor of PGI₂ is arachidonic acid, derived from endothelial cell membrane phospholipids by phospholipases. Arachidonic acid is first converted to PGG₂ and PGH₂, the so-called cyclic endoperoxides, by cyclooxygenase, and then to PGI₂ by prostacyclin synthetase. Thrombin, and other agents (see above) that are generated at the site of injury, stimulate the synthesis of PGI₂ by adjacent endothelial cells, which counteracts the platelet-aggregating activity of the protease and thereby helps to localize platelet plug formation. Elevation of intravascular pressure and trauma, including venepuncture, also increase PGI₂ production and may be a source of artefactually high plasma levels. PGI₂ is rather unstable, with a half-life of only a few minutes in whole blood, and degrades spontaneously to 6-keto-PGF_{1α}. This degradation product is biologically inert, but in some tissues a variable proportion of PGI₂ may be enzymatically converted to 6-keto-PGF_{1α} or 6,15-diketo-13,14-dihydro-PGF_{1α}, which retain some platelet-inhibitory activity.

The once-held belief that PGI₂ is a circulating hormone that limits platelet–platelet interactions within the bloodstream is probably false, as plasma levels of PGI₂ are at least two orders of magnitude below that needed to inhibit platelet aggregation. Although in some settings, such as following severe trauma, it is possible that markedly raised systemic levels could occur transiently, it is more likely that PGI₂ serves mainly as a local hormone, principally concerned with vascular tone, but possibly also inhibiting the extension of the platelet plug beyond the immediate vicinity of any endothelial damage.

NO is synthesized in smooth muscle cells, macrophages and activated platelets, as well as by endothelial cells. Its synthesis and secretion may be constitutive (when it serves as a local hormone to ‘fine tune’ blood flow). Stimulated (inducible) synthesis of NO also occurs in endothelial cells exposed to cytokines such as interleukin (IL)-1, tumour necrosis factor (TNF) or endotoxin. This produces a slower but longer-lasting rise in NO and can have undesirable side-effects such as inflammation, cytotoxicity or prolonged hypotension. Like PGI₂, it has a very short half-life (3–5 s) and is rapidly oxidized to the inactive nitrite (NO₂⁻) or nitrate (NO₃⁻) forms.

In addition to PGI₂ and NO, endothelial cells also express an ecto-ADPase (CD39) on their cell surface, which rapidly metabolizes ATP and ADP released from activated platelets to AMP, thereby drastically reducing or abolishing platelet recruitment and aggregation in response to thrombin.

The 21-amino-acid peptide endothelin (ET)-1 is the predominant isoform of the endothelin peptide family, which includes ET-2, ET-3 and ET-4. It exerts various biological effects, including vasoconstriction and the stimulation of cell proliferation in tissues both within and outside the cardiovascular system. In the endothelium, ET-1 is predominantly released abluminally towards the vascular smooth muscle, where it acts as a potent vasoconstrictor and mitogen for smooth muscle cells. In addition, ET-1 stimulates the production of cytokines and growth factors. Furthermore, it stimulates neutrophil adhesion and platelet aggregation and is chemotactic for macrophages.

Thrombospondin (TSP)-1 is an abundant constituent of the α-granules of platelets and Weibel–Palade bodies of endothelial cells. TSP-1 was first identified as a thrombin-sensitive protein that was released in response to activation of platelets by thrombin. Upon release from platelets, TSP-1 binds to the platelet surface in a Ca²⁺-dependent manner and interacts with integrins α_{IIb}β₃ and α_vβ₃, CD36 and the integrin-associated protein (IAP), integrin-bound fibrinogen and fibronectin. TSP-1 activates α_{IIb}β₃ through its binding to IAP. This results in spreading of platelets and aggregation.

von Willebrand factor

VWF is a multimeric glycoprotein that plays an important role in primary haemostasis by promoting platelet adhesion to the subendothelium at sites of vascular injury under high shear-rate conditions. It is also a carrier of FVIII and this association protects FVIII from rapid proteolysis. Failure of FVIII to bind VWF, as occurs in type 2N von Willebrand disease (see Chapter 41), leads to its rapid turnover and resulting FVIII deficiency. VWF is synthesized by endothelial cells, megakaryocytes and platelets. In endothelial cells VWF may be secreted directly into the circulation or stored in Weibel–Palade bodies. The VWF produced in megakaryocytes and platelets is not secreted but stored in α-granules. Release of VWF from these stores occurs following activation of endothelial cells or platelets. Some therapeutic products, such as desmopressin, may work by stimulating release of stored VWF.

Mature VWF is composed of disulphide-linked subunits, each comprising 2050 amino acid residues and up to 22 carbohydrate side-chains. Each subunit has a molecular mass of approximately 278 kDa, of which 10–19% is carbohydrate. Two subunits joined at their C-termini by a disulphide bridge form a dimer. Additional disulphide bridges between dimers lead to the formation of larger multimers that range in size from

500 kDa to in excess of 10 000 kDa (Figure 39.7). The ultra-large VWF multimers are predominantly stored but when secreted by endothelial cells may appear as globular molecules or as thin filaments that are several microns long. These ultra-large VWF multimers can only be detected transiently in normal plasma because they are cleaved by a plasma metalloproteinase (ADAMTS-13). Deficiency or inhibition of ADAMTS-13 results in accumulation of ultra-large VWF multimers in plasma, leading to enhanced shear-induced platelet aggregation and microvascular thrombosis as seen in thrombotic thrombocytopenic purpura (TTP) (see Chapter 44).

VWF contains binding sites for collagen, fibrinogen and the platelet receptor, glycoprotein (GP)Ib. When vascular injury exposes subendothelial collagen, VWF binds and becomes unwound from its globular form (Figure 39.7c). This exposes more binding sites and allows the capture of platelets from the circulation. Thus VWF, and to some extent fibrinogen, act as bridges between the platelet and the injured vascular wall. Mutations in the genes encoding the GPIIb/IIIa complex that lead to loss of function cause the bleeding disorder Bernard–Soulier syndrome. Conversely, gain-of-function mutations in either VWF or GPIIb/IIIa that increase the interaction lead to type 2B von Willebrand disease or pseudo (platelet-type) von Willebrand disease (see Chapter 41).

Endothelial cell anticoagulant activities

Endothelial cells regulate coagulation by a number of mechanisms. The activity of the PC pathway is promoted by expression of two cellular receptors. TM is constitutively expressed on all endothelial cells with the exception of the brain. EPCR is expressed strongly in the endothelial cells of arteries and veins in heart and lung, less intensely in capillaries in the lung and skin, and not at all in the endothelium of small vessels of the liver and kidney. In addition, endothelial cells synthesize and secrete PS, the cofactor for APC in the inactivation of FVa and FVIIIa.

Endothelial cells regulate the initiation of coagulation by synthesizing and secreting the main physiological inhibitor of the FVIIa–TF initiating complex, namely TFPI. This is described in greater detail below. Endothelial cell-surface GAGs are important in binding TFPI and also modulate the activity of AT, which inhibits thrombin and FXa and to a lesser extent FIXa and FXIa.

Endothelium and vessel injury

Disruption of the vessel wall following injury leads to exposure of procoagulant stimuli (see Figure 39.6b). Cells of the adventitia or epithelial cells of the surrounding tissues express TF constitutively on their surfaces. Formation of a complex between TF and FVII present in blood flowing from the injured

vessel initiates coagulation, resulting in fibrin generation. Exposure of collagen within the subendothelial layers of the vessel wall leads to immobilization of plasma VWF, triggering platelet adhesion, aggregation and activation. Release of the contents of platelet α -granules increases the local VWF concentration and activation of endothelial cells results in release of Weibel–Palade bodies, further increasing the local concentration of VWF and expression of the cell adhesion molecule P-selectin, leading to further recruitment of platelets. In addition, release of ET-1 from the endothelium stimulates platelet aggregation and vasoconstriction, limiting blood loss. The anticoagulant activities of the endothelial cells discussed above serve to limit fibrin deposition and prevent vascular occlusion.

Endothelial cell-derived fibrinolytic factors

Three important fibrinolytic factors are detectable in the vessel wall: tPA and PAI-1 are synthesized primarily by endothelial cells, whereas urinary plasminogen activator (uPA, urokinase) is mainly derived from fibroblast-like cells in the kidney and gut. Unlike VWF and P-selectin, tPA and PAI-1 are not stored in Weibel–Palade bodies and, in the resting state, synthesis and secretion are slow, resulting in low circulating levels. However, stimulated synthesis and release occur in response to a variety of stimuli.

Platelets

Platelets play a vital role in the formation of an aggregate or primary plug that stems blood loss at the site of injury, but also by supplying a cellular surface tailored to the assembly of procoagulant complexes such as tenase and prothrombinase. Chapter 40 gives details of platelet biogenesis and function, including their specific roles in haemostasis.

Coagulation factors

Table 39.2 provides a summary of the characteristics of the proteins discussed, including gene location, number of exons, molecular mass, circulating concentration, plasma half-life and presumed function. The domain structure and modular nature of the proteins is shown in Figure 39.8. This demonstrates the similarity between coagulation factors that belong to the same protein family, such as the serine proteases (e.g. compare FVII, FIX, FX and PC).

Tissue factor

The formation of the FVIIa–TF complex is unambiguously regarded as the sole initiator of coagulation in both normal and

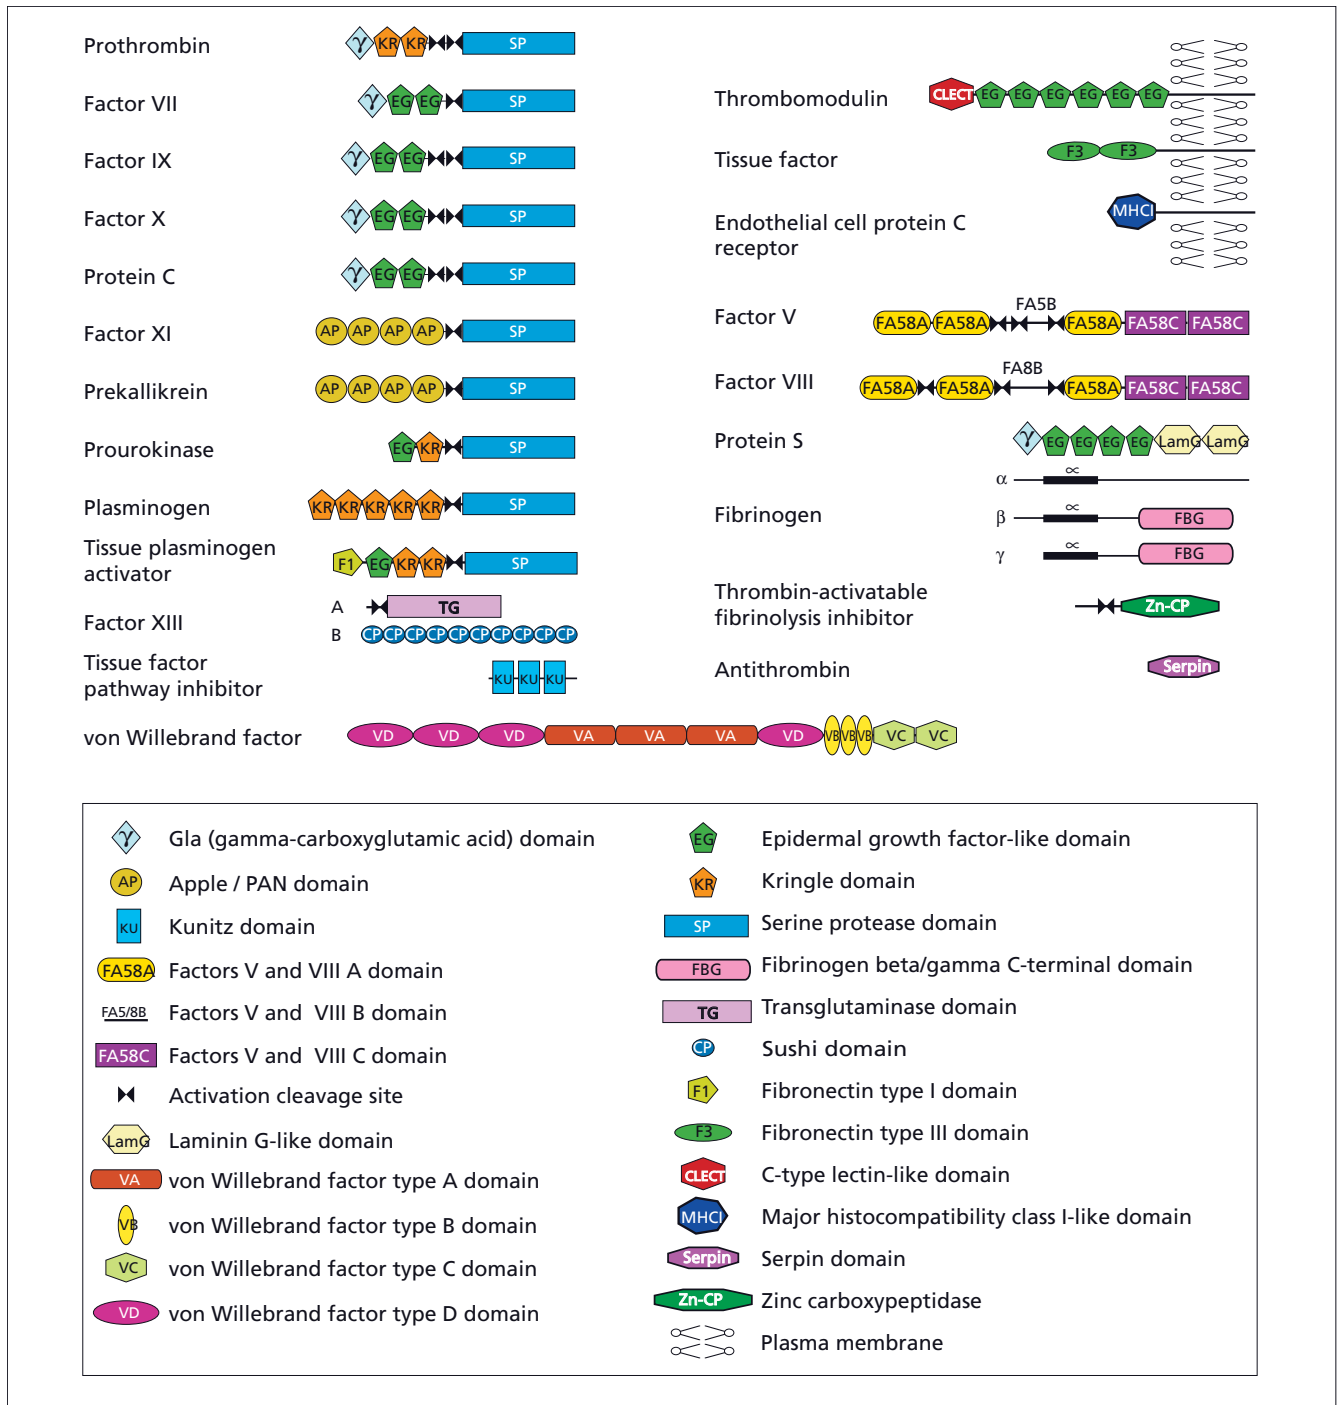

Figure 39.8 Modular organization of haemostasis proteins. The evolutionary relationship of many factors is suggested by their modular organization, represented as proposed by Bork and Bairoch (available at www.bork.embl-heidelberg.de/modules/).

Figure 39.7 Role of von Willebrand factor (VWF) in haemostasis. (a) VWF domain structure with important binding sites. Dimers are formed when individual monomers become joined through disulphide bonds at the C-terminus. Multiple dimers are then joined at the N-terminus to form high-molecular-weight multimers that take on a globular shape. When exposed to flowing blood under high shear stress the multimers become filamentous, exposing their binding sites. (b) In normal vasculature the ultra-high-molecular-weight VWF multimers

required for full VWF function are found only in the subendothelium. The circulation contains lower-molecular-weight multimers. After disruption of the endothelium (c), exposure of high-molecular-weight multimers to flowing blood applies shear stress, causing the multimers to unravel and capture activated platelets. The coagulation cascade forms on the surface of these platelets. Thus VWF acts to localize the process of clot formation to the site of vascular damage. EC, endothelial cell; IEL, internal elastic lamina; SMC, smooth muscle cell.

*FXI circulates as a 160-kDa homodimer of two 80-kDa monomers.

†FXIII circulates as a 326-kDa tetramer of two A- and two B-chains.

‡Fibrinogen circulates as a 340-kDa complex of two each of A-, B- and C-chains.

pathological coagulation. The processed mature TF protein is 263 amino acids in length after signal peptide cleavage. The 219-residue extracellular region consists of two fibronectin type III domains anchored into the cell membrane by a 23-residue transmembrane sequence. The extracellular region binds tightly to FVIIa to form a highly active procoagulant complex after exposure of cell surface TF to plasma FVII. The 21-residue cytoplasmic domain has been implicated in intracellular signalling; however, transgenic experiments in mice have shown that this domain is not required for either development or coagulant function, so its role is still unclear.

Vascular adventitial cells, neuroglia, vascular smooth muscle and epidermal cells express TF constitutively. It therefore forms a protective envelope around blood vessels and organs, ready to initiate clotting as soon as blood leaks out of vessels. TF is also expressed by monocytes and endothelium after activation by inflammatory cytokines or by endotoxin, as occurs in sepsis, and on cancerous tissues. Intravascular exposure of TF by any route, but particularly after atherosclerotic plaque rupture, can result in pathological thrombosis. Recent work has also focused on the novel hypothesis that functionally active TF can circulate in flowing blood on small procoagulant particles (microparticles), which may also be transferred from one blood cell type to another via specific receptor-mediated interactions.

Factor VII

Plasma FVII binds to TF, for example after vessel trauma or plaque rupture, to form a complex that initiates coagulation by directly activating FX and to a lesser extent FIX. The FVII gene (*F7*) lies adjacent to the factor X gene (*F10*), suggesting gene duplication during evolution, and close to that of protein Z (PZ) at 13q34. In common with the other serine proteases of the coagulation network (FIX, FX, prothrombin, PC), as well as PS and PZ, FVII has an N-terminal domain that contains a number (9–12) of glutamic acid residues that are post-translationally modified by the addition of a carboxyl group to the γ -carbon by a vitamin K-dependent carboxylase. This γ -carboxyglutamic acid (GLA) domain confers affinity to negatively charged phospholipid membranes such as those of activated platelets or endothelial cells, promoting the assembly of functional multiprotein complexes on these surfaces. Proteins containing GLA modules are commonly referred to as 'vitamin K-dependent factors' as this vitamin is a cofactor in the carboxylation reaction. Blocking this post-translational modification with coumarin derivatives such as warfarin represents the current therapy for the long-term treatment and prevention of thromboembolic events. FVII in common with other GLA domain-containing proteins has a primary translation product that contains a propeptide sequence encoded by exon 2 that directs the γ -carboxylation at 10 Glu residues within the GLA domain encoded by exon 3. The GLA domain is followed by

two epidermal growth factor (EGF)-like domains encoded by exons 4 and 5. Exon 6 encodes the connecting or activation peptide, and exons 7 and 8 the serine protease domain. FVII is activated by cleavage between residues Arg152 and Ile153, yielding a two-chain disulphide-linked FVIIa molecule; however, this has little catalytic activity until it is bound to TF. The half-life of FVII zymogen in plasma is 3 hours and, remarkably, the half-life of the FVIIa enzyme is 2.5 hours, probably because there is no plasma inhibitor capable of effectively neutralizing free FVIIa. In recent years, recombinant FVIIa has entered clinical use as a treatment, first, for haemophiliacs with inhibitors to exogenous FVIII and, second, for a wider range of bleeding problems and general surgical intervention.

Factor X

The gene and protein structures of FX closely resemble those of FVII. Unlike FVII, zymogen FX circulates as a two-chain disulphide-linked heterodimer due to excision of a tribasic peptide (Arg-Lys-Arg) at residues 139–141 during synthesis. The light chain of FX therefore consists of the GLA domain with 11 γ -carboxyglutamic acid residues, the amphipathic helix and two EGF-like domains. The half-life of FX in plasma is 36 hours. FX is activated by either FIXa–FVIIIa or TF–FVIIa on phospholipid surfaces in the presence of Ca^{2+} ions. FXa forms a phospholipid-bound complex with FVa, which efficiently activates prothrombin (prothrombinase complex).

Factor IX

The FIX gene (*F9*) is located at Xq26, about 15.2 Mb from the FVIII gene (*F8*); thus deficiencies of both factors are X-linked disorders. Deficiency of either FVIII or FIX results in clinical haemophilia (A or B respectively), as the main function of FIX is to participate in the tenase complex (FIXa–FVIIIa). The FIX promoter has been extensively studied and includes sites for liver-specific transcription factors and an androgen-responsive promoter element, which accounts for the haemophilia B Leiden phenotype (FIX deficiency which corrects spontaneously at puberty). The plasma half-life of FIX is 18 hours.

The mature protein is a single-chain molecule consisting of 415 amino acids and the GLA domain contains 12 γ -carboxyglutamic acid residues. Either TF–FVIIa or FXIa cleaves FIX within the connecting peptide (between residues 145–146 and 180–181). Unlike FVII and FX, FIX requires two proteolytic cleavages, releasing an activation peptide, in order to achieve full activation.

Factor XI

FXI is a zymogen of a serine protease that has four Apple (PAN1–4) domains and a serine protease domain in each monomer. The protein circulates as a homodimer, with the two

monomer subunits linked via a series of interactions between the two Apple four domains that includes a disulphide bridge. Activation of FXI is by a single cleavage performed by thrombin. It is clear that dimerization is required for full function of this factor presumably due to obstruction of essential binding sites in the monomer form. FXIa then activates FIX directly in free solution. FXI activation by the contact protein FXIIa was originally thought to be a relevant step in intrinsic or contact-activated coagulation (see Figure 39.2), but it is now considered that the feedback activation of FXI by trace thrombin provides a physiologically relevant route for generation of increased amounts of FIXa to assemble tenase during the amplification of the initial TF stimulus (see Figure 39.3).

Factor XIII

FXIII circulates as a tetramer of two A-chains and two B-chains. The B-chains function as carrier for the A-chains which, after activation by thrombin, function as a transglutaminase to cross-link fibrin and other proteins in the clot, resulting in a stable structure. FXIIIa contains a free sulphhydryl group at the active site. Platelets also contain FXIII A-chain dimers, which are fully functional after thrombin activation.

von Willebrand factor

The primary translation product of the VWF mRNA is a 2813 amino acid polypeptide that includes a 22 amino acid signal peptide and a 741 amino acid propeptide that is essential for multimerization. The mature protein contains four repeating domains termed A, B, C and D. During post-translational processing, monomer subunits dimerize and then multimerize with excision of the propeptide. VWF is synthesized in endothelial cells (where it is stored in Weibel–Palade bodies) and in megakaryocytes, where it is stored in the α -granules of platelets. Both Weibel–Palade body and α -granule VWF are released on stimulation by various agonists, including thrombin. Plasma also contains VWF, which is released from endothelial cells via a constitutive pathway. VWF serves two unique functions in haemostasis: as a carrier for FVIII and as the ligand mediating binding between platelets and the subendothelium.

Factor VIII

The FVIII gene (*F8*) spans 187kb of the X chromosome (Xq28) and encodes a protein of 2351 amino acids. After removal of the 19 amino acid signal sequence, a single chain of 2332 amino acids is transiently formed but is subsequently further processed prior to release as a series of heterodimers, due to variable cleavage within the B-domain sequence. Because of internal homology, the FVIII domain structure can be represented as A1–A2–B–A3–C1–C2. The B domain is not necessary for procoagulant function as B domain-deleted FVIII has

full activity. The B-domain sequences of FV and FVIII share little sequence identity, although their lengths are similar and both are heavily glycosylated. It is likely that the glycosylated B domain functions in promoting endoplasmic reticulum/Golgi transport since deficiency of LMAN1 (also known as ERGIC 53), a mannose-binding protein, results in combined deficiency of FV and FVIII. FVIII also has three short acidic interdomain peptides (a1, a2 and a3) that are closely implicated in FVIII function.

FVIII is the essential cofactor for activation of FX by FIXa in the tenase complex. It has no function until proteolysed to FVIIIa by thrombin or FXa at Arg372–Ser373 and Arg1689–Ser1690. FVIIIa is directly inactivated by APC cleavage at Arg336–Ser337 and Arg562–Ser563; however, functional activity of FVIIIa also decays rapidly by dissociation of the A2 subunit from FVIIIa. The crystal structure of FVIIIa has recently been solved by two groups.

Factor V

The mature protein product is 2196 amino acids in length after cleavage of a 28 amino acid signal peptide. The structure of FV, like that of FVIII, can be represented as A1–A2–B–A3–C1–C2. In contrast with FVIII the B domain is required for full procoagulant function. FV also differs from FVIII in that it lacks the three short acidic interdomain peptides (a1, a2 and a3) implicated in FVIII function.

FV is the cofactor for the activation of prothrombin by FXa. It has no cofactor activity until proteolysed by thrombin or FXa at Arg709–Ser710, Arg1018–Thr1019 and Arg1545–Ser1547. FVa is inactivated by APC through cleavages at Arg506–Ser507 and Arg1765–Leu1766. The initial (and rate-limiting) cleavage is at Arg506. This is the site of the mutation in FV Leiden (FV Arg506Gln) that is resistant to APC, leading to the most common form of familial thrombophilia.

Fibrinogen

The fibrinogen gene cluster is located on chromosome 4q32 in the order β – α – γ , with β transcribed in the opposite direction to α and γ . The three chains of fibrinogen are disulphide cross-linked and folded together in an intricate manner. The overall structure of fibrinogen is a symmetrical dimer, $\alpha_2\beta_2\gamma_2$. Viewed by electron microscopy, the molecule is trinodular, with the outer two globular domains (fragments D) containing the C-termini of all three chains connected to the central globular domain (fragment E), which contains the N-termini of all six chains tethered together by disulphide bonds. Coiled regions, forming α -helical ropes, connect the lateral and central globular domains.

Polymerization of fibrinogen occurs when thrombin cleaves two short negatively charged fibrinopeptides A and B from the N-termini of the α - and β -chains respectively. This reveals new

N-terminal sequences in the fragment E region (called knobs) that fit into holes in the fragment D regions. Polymerization then occurs spontaneously in a staggered half-overlap array, which can elongate indefinitely in either direction. Electron microscopy studies were and still are important in resolving the molecular architecture of fibrillar fibrin formation, but from 1997 elegant crystal structures of parts of the fibrin(ogen) molecule were successfully produced in a number of laboratories. These structures reveal the elegant mechanisms of fibrin polymerization.

Prothrombin

The mRNA encodes a preproleader sequence similar to that found in other vitamin K-dependent proteins, followed by a GLA domain, two kringle domains, an activation peptide and a serine protease domain. FXa complexed with FVa activates prothrombin zymogen to thrombin on a phospholipid surface (prothrombinase) on cleavage of two peptide bonds. The first, between Arg271 and Thr272, releases the protease domain from the GLA and kringle domains; the second, between Arg320 and Ile321, generates the catalytic site of thrombin by a typical trypsin-like conformational rearrangement. Cleavage at Arg320 yields the protease (meizothrombin) that retains membrane-binding properties. Cleavage at Arg271 yields thrombin and severs covalent linkage with the N-terminal domain known as fragment 1.2. Fully cleaved thrombin is termed α -thrombin, and is rapidly released from its site of production to participate in numerous haemostatic functions free in solution: acting as a procoagulant against many substrates including fibrinogen, FV, FVIII and FXI; acting in complex with TM as an anticoagulant against PC; and acting to activate cellular transmembrane protease-activated receptors. Thrombin also activates thrombin-activatable fibrinolytic inhibitor (TAFI), in complex with TM, inhibiting fibrinolysis.

Naturally occurring inhibitors of blood coagulation

In common with other defence mechanisms, such as those resulting in kinin release and complement activation, the blood coagulation process can be activated very rapidly when the need arises. This involves the generation of proteolytic enzymes, such as thrombin, that are potentially lethal if their action is not limited. For example, 10 mL of plasma can generate, in theory, sufficient thrombin to clot all of the fibrinogen in the body in 30 s. That it does not normally do so is due partly to the fact that the procoagulant response is most pronounced in the vicinity of the platelet plug forming at the point of vascular injury, while elsewhere coagulation is inhibited by substances in plasma or on the vascular surface that exhibit anticoagulant activity.

Classification of physiological anticoagulants

Physiological anticoagulants fall into two main groups: those that inhibit the serine proteases of the coagulation cascade (both Kunitz-type and serpins) and those involved in destruction of the activated coagulation cofactors FVa and FVIIIa (components of the PC system). These inhibitors assume great physiological significance: relatively minor deficiencies (50–70% of average levels) of some of these inhibitors, such as might be found in individuals heterozygous for a genetic defect, are associated with an increased incidence of thrombosis. Homozygous deficiencies are frequently either fatal in the first few years of life unless prophylactic replacement therapy is instituted, or are not found in nature, suggesting early fetal loss.

In addition to the specific inhibitors, there are some other inhibitory mechanisms that do not fit into either of the above categories, one of these being the detoxifying property of the liver, which plays an important role in removal of activated clotting factors, both directly and after their combination with natural inhibitors. Furthermore, the removal of free thrombin occurs as a result of its adsorption onto fibrin or onto fibrin(ogen) degradation products. The latter, which cannot themselves take part in a clot, may interfere with normal fibrin polymerization. Although less well defined than the others, this group appears to be physiologically important, as qualitative defects of fibrinogen (dysfibrinogenemias) that result in reduced thrombin binding may be associated with a thrombotic disorder (see Chapter 45).

Tissue factor pathway inhibitor: a Kunitz-type inhibitor

The various serpins found in blood (see below) probably play no physiological role in the inhibition of FVIIa in the initiating TF–FVIIa complex. Instead, the action of this serine protease-cofactor complex is modulated by TFPI, which is located on the endothelial cell surface, within platelets, in plasma and on monocytes. Two alternatively spliced isoforms of TFPI (α and β) have been identified in humans that differ in their domain structure and mechanism of cell surface binding. TFPI α has an acidic N-terminal region followed by three Kunitz-type protease inhibitory domains (K1–K3) and a basic C-terminal region. K2 is responsible for binding and direct inhibition of FXa and K1 inhibits FVIIa in a FXa-dependent manner. K3 and the C-terminal region do not directly inhibit proteolysis but they are necessary for rapid inhibition of FXa by K2. Recent data intriguingly suggest that this may be mediated through an interaction with PS acting as a cofactor in the formation of the TFPI–FXa complex. TFPI α indirectly associates with the endothelial cell surface through a non-covalent association with a glycosylphosphatidylinositol (GPI)-anchored coreceptor. It can also bind non-specifically to endothelial cell GAGs via the

basic C-terminal region; it is thought that this interaction is responsible for the twofold to fourfold increase in plasma TFPI following infusion of heparin. TFPI β has the N-terminal acidic region followed by K1 and K2 but lacks K3 and the C-terminal region of TFPI α . Instead it has a different C-terminal region encoding a GPI-anchor attachment sequence that allows it to directly associate with the cell surface.

Most TFPI in the vasculature (~ 85%) is associated with endothelial cells, particularly in the microcirculation, with a smaller amount (5–10%) being found in platelets and the rest in plasma. Virtually all circulating TFPI is associated with lipoproteins and has undergone variable amounts of proteolytic degradation within its C-terminal region. As a result plasma TFPI has reduced anticoagulant activity and is unlikely to play an important role as an *in vivo* inhibitor of blood coagulation.

Disruption of the murine *TFPI* gene is incompatible with normal development, suggesting that a deficiency of functional TFPI might lead to clinical thrombosis. However, as the bulk of intravascular TFPI is associated with the endothelial cell surface, simple measurement of plasma TFPI levels is not a clear indicator of a deficiency state. Moderately low plasma levels can occur in DIC, septicaemia and following major surgery, possibly due to increased utilization, but heparin infusion increases plasma TFPI in such patients. Whether congenital deficiency of TFPI is a risk factor for thrombosis remains uncertain: after several negative studies in this area, recently a case–control study found a relationship between low levels of free plasma TFPI (non-lipoprotein bound) and enhanced risk of deep vein thrombosis and myocardial infarction.

Serine protease inhibitors (serpins) and heparin

Human plasma contains at least seven inhibitors of serine protease coagulation factors. Apart from α_2 -macroglobulin, all are single-chain serpins of molecular mass 40–65 kDa. Specificity is imparted by their tertiary structure, which engenders high affinity for a defined substrate or small range of substrates. Of this group, only AT and heparin cofactor II (HCII) assume haemostatic significance, acting predominantly on proteases generated late in the coagulation cascade (i.e. thrombin and FXa). A deficiency of any of the other serpins (although sometimes giving rise to a clinical disorder due to the failure of neutralization of a serine protease not involved in coagulation pathways) is asymptomatic in terms of haemostasis.

Several serpins contain GAG-binding sites that, particularly in the case of AT and HCII but to a lesser extent for PAI-1 and APC inhibitor, greatly enhance the rate of interaction with (although not the affinity for) their specific protease(s). Since a major source of heparin-like material is heparan sulphate on the endothelial cell surface, another possible function of the heparin-binding site of these inhibitors (especially AT and

HCII) might be to allow them to exert a general and constitutive anticoagulant effect on intact vessels; this may also act to prevent extension of a procoagulant response beyond an area of damaged endothelium.

Antithrombin

AT (formerly ATIII) is a 58-kDa serpin that is synthesized principally in the liver, with a high plasma concentration of 2.4 $\mu\text{mol/L}$. The turnover of AT *in vivo* is complex, with a rapid initial clearance ($t_{1/2}$ 10 min) due to equilibration with endothelial cell-bound AT, a slower clearance ($t_{1/2}$ 3 hours) due to equilibration with the extravascular compartment, and a much slower linear phase with an overall $t_{1/2}$ of 90 hours.

Disruption of the murine AT gene results in death of all embryos shortly before birth due to severe cardiac and hepatic thrombosis. In humans, AT deficiency is associated with familial thrombosis.

AT forms a stable 1:1 complex with several serine protease coagulation factors, predominantly thrombin but also to some extent FIXa, FXIa, FXIIIa and kallikrein. Initially, the serine at the active centre of the protease cleaves a peptide bond (involving Arg393) in the 'reactive centre loop' near the C-terminus of AT: a conformational change in the serpin ensues resulting in irreversible trapping of the protease against the inhibitor. The inactivated enzyme–serpin complex is then cleared rapidly. Complex formation is progressive and only with thrombin and FXa is it rapid enough to be of physiological significance. In purified *in vitro* systems, the $t_{1/2}$ is around 30 s for free thrombin, 90 s for FXa and 10–25 min for the other enzymes. In each case, the inhibitor–protease complex is rapidly cleared ($t_{1/2}$ 3 min) from the circulation by the liver.

Heparin, without altering the stoichiometry, induces a more than 2000-fold increase in the rate of thrombin inactivation by AT, such that its action becomes almost instantaneous ($t_{1/2} < 0.01$ s). The unique mechanism of this activation involves release of the reactive centre loop from partial insertion in the β -sheet core of AT following heparin binding. Heparin also strongly enhances AT neutralization of FXa and, to a lesser extent, FIXa, particularly in the presence of Ca^{2+} . The enhancement of AT inhibition of thrombin and FXa by heparin is the basis of its use as a therapeutic anticoagulant to prevent thromboembolism. At therapeutic concentrations there is no significant effect on AT inhibition of FXIa and FIXa.

Anti-angiogenic and antitumour activities have also been described for the cleaved serpin in mouse models. This finding provides further evidence for the interrelationship of coagulation and angiogenic pathways.

Heparin cofactor II

This 65-kDa serpin is present in plasma at the high concentration of 90 mg/L (1.2 $\mu\text{mol/L}$). It appears to be a specific 1:1 inhibitor of thrombin and to have little or no anti-FXa activity. The rate of thrombin neutralization by HCII is increased

approximately 1000-fold by heparin, although because of its lower heparin affinity it requires five to ten times more heparin than does AT. Interaction seems to depend largely on the high anionic charge of heparin and related GAGs. Details of the molecular mechanism of HCII interaction with thrombin have recently been elucidated by X-ray crystallography.

That HCII has some physiological significance is suggested by the fact that it falls in parallel with AT in DIC. However, as AT is in twofold molar excess over HCII, the latter cannot altogether compensate for a deficiency of AT, which, as stated above, is a well-established cause of a thrombotic tendency. Whether HCII deficiency leads to a similar clinical picture remains to be established, as few cases have yet been described and only occasionally has concomitant thrombotic disease been present. Mice with HCII knockout develop normally and do not show spontaneous thrombosis; however, they show an enhanced propensity to carotid occlusion after deliberate injury to the endothelium, corrected by infusion of purified HCII, suggesting that HCII has a role in prevention of arterial thrombosis.

Heparin and heparin-like substances in plasma

Although the term 'heparin' implies a single compound, it in fact refers to a heterogeneous mixture of sulphated polysaccharides that are all members of the GAG group. The major pharmaceutical source is porcine intestinal mucosa. By virtue of its strong positive charge, heparin combines non-specifically with a number of cationic proteins such as albumin and reacts in a highly specific way with β -lipoproteins, fibrinogen, HCII and AT. It also mobilizes platelet factor (PF)4 and TFPI, which are bound to GAGs on the surface of endothelial cells, and releases lipoprotein lipase into plasma.

Unfractionated heparin (UFH) is an extremely heterogeneous polymer, being composed of between 10 and 100 saccharide units. Only about one-quarter of the polysaccharides has any anticoagulant activity *in vitro*. The pharmaceutical properties of heparin are unpredictable, because of its heterogeneity, with marked variation in pharmacokinetics and side-effects, the most serious of which is heparin-induced thrombocytopenia (see Chapter 46). The realization that the anticoagulant action of UFH was mostly delivered by short pentasaccharides has led to the use of more efficient fractionation procedures (including cleavage by nitrous acid, heparinase and oxidizing agents), yielding a number of low-molecular-weight heparin (LMWH) preparations. LMWHs contain 10–20 saccharide units (4–6 kDa) and because of their more uniform composition have much better pharmacokinetics and fewer side-effects. More recently, a synthetic pentasaccharide has come into therapeutic use, although whether this has any clear benefits over LMWH remains to be established.

UFH and the various LMWHs differ in their affinities for the plasma factors with which they interact and in the specific serine proteases that they inhibit. This, together with the timing of blood samples in relation to dosage interval, is critically

important in laboratory monitoring of the therapeutic effect (see Chapter 47). The major anticoagulant activity of both UFH and LMWH is attributed to the pentasaccharide sequence containing at its centre a 2,3,6-(SO₃) trisulphated glucosamine group. It is this that binds to lysine or tryptophan residues in AT in the region of the D helix, inducing the conformational change in the inhibitor. A second anticoagulant action of UFH (at least 20 saccharide units are required) involves direct binding between thrombin (but not FXa or other proteases) and a heparin sequence adjacent to the pentasaccharide. This brings thrombin and AT into close proximity and is necessary for the antithrombin activity. As LMWHs generally have fewer than 20 saccharide units, they have little or no antithrombin action and their anticoagulant action is mediated through inhibition of FXa. This explains why LMWHs have little effect on the activated partial thromboplastin time and are measured using an anti-FXa assay.

There is of course no detectable heparin in normal plasma. However, endogenous heparin-like molecules (e.g. dermatan sulphate and heparan sulphate) are present on the surface of endothelial cells and, by enhancing the action of AT and HCII, these would have antithrombotic effects. Such mechanisms seem to be of clinical importance, as recurrent thromboses have been reported in association with several dysfunctional AT molecules that inhibit thrombin normally in the absence of heparin but which do not show enhanced reactivity in its presence, presumably due to defects at the heparin-binding sites. At points of vascular injury, local accumulation of activated platelets provides a source of heparin-neutralizing activity that could overcome the anticoagulant effects of endothelial cell-bound heparinoids and permit the procoagulant response to proceed.

Protein Z and protein Z-dependent inhibitor

PZ is a 62-kDa vitamin K-dependent plasma protein that serves as a cofactor for the inhibition of FXa by PZ-dependent protease inhibitor (ZPI). Although PZ was first described in the 1970s, ZPI is a recently identified 72-kDa member of the serpin superfamily.

The organization of the PZ gene and the structure of the molecule are very similar to those of coagulation factors FVII, FIX, FX and PC; however, the PZ 'serine protease' domain lacks the canonical active-site His and Ser residues and therefore cannot function as a protease. PZ circulates in plasma in a complex with ZPI. Inhibition of FXa by ZPI in the presence of phospholipid and Ca²⁺ ions is enhanced 1000-fold by PZ, but ZPI also inhibits FXIa in a process that does not require PZ, phospholipid or Ca²⁺. ZPI activity is consumed during coagulation through proteolysis mediated by FXa (with PZ) and FXIa. PZ may serve to dampen the procoagulant response *in vivo* as PZ deficiency dramatically increases the severity of the prothrombotic phenotype of FV Leiden mice. Studies to determine the potential roles of PZ and ZPI deficiency in human thrombosis are in progress.

α_1 -Antitrypsin

This is a serpin whose primary targets are pancreatic and leucocyte elastases. In coagulation the major inhibitory activity is directed against FXIa and FXa, although the chief physiological inhibitor of FXIa is probably protease nexin 2. It has little effect on overall thrombin inhibition and a straightforward deficiency of α_1 -antitrypsin is not associated with hypercoagulability.

An abnormal molecular form of α_1 -antitrypsin in which there is a Met→Ser substitution at the active centre (antitrypsin Pittsburgh) has been described, resulting in a higher affinity for thrombin. At a plasma concentration of 25 $\mu\text{mol/L}$, the variant circulates at a 10-fold higher level than AT and gives rise to a clinical bleeding tendency. However, it is unaffected by heparin.

Protease nexin 2

This is a Kunitz-type serine protease inhibitor that is found in the α -granules of platelets. Normally, there is very little in plasma but it is released at sites of platelet activation, following which the single Kunitz domain enters into a tightly bound inhibitory complex with FXIa. It is one of several isoforms of Alzheimer β -amyloid protein precursor present in platelets. Deficiency of protease nexin 2 has not been described.

C1-esterase inhibitor

The primary target of this serpin is the activated form of the first component of complement, but it also contributes in a minor way to the neutralization of FXIa and plasmin. Deficiency of C1-esterase inhibitor, although of no haemostatic consequence, causes angioneurotic oedema, the characteristic lesions of which may sometimes be confused with haematomas.

 α_2 -Antiplasmin

This serpin is the principal inhibitor of the fibrinolytic enzyme plasmin. It also has weak activity against several coagulation proteases, especially the contact factors. However, any anticoagulant action against proteases late in the coagulation cascade (e.g. FXa) is only apparent at concentrations well in excess of those in normal plasma. Its mechanism of action and clinical importance are discussed further in the section on fibrinolysis.

 α_2 -Macroglobulin

α_2 -Macroglobulin is composed of four identical chains and has a molecular mass of 740 kDa. It is not a member of the serpin superfamily and its effects are not restricted to serine proteases. It binds to coagulation factors at a site away from the active site, the interaction involving the formation of a bond between cysteine and glutamate residues in the inhibitor and a lysine residue in the protease. Inhibition is produced by steric hindrance rather than by active site inactivation and indeed the proteases retain some esterolytic and amidolytic activity, particularly against small peptides, a fact that should be borne in mind when using chromogenic substrates to assay coagulation

inhibitors. It is responsible for approximately 50%, 20% and 10% of the inhibition of kallikrein, thrombin and FXa respectively.

Deficiency of α_2 -macroglobulin is not associated with a thrombotic tendency. However, it is an acute-phase reactant and it is possible that, when elevated under conditions of stress or when the other major antithrombins or antiplasmins are overwhelmed, it might become a significant inhibitor of coagulation or fibrinolysis. Moreover, it has been suggested that the raised level of α_2 -macroglobulin that exists in children (150–200% of adult values) may compensate for a low level of AT, and explain why thrombotic episodes do not usually occur before puberty in congenitally AT-deficient patients.

The protein C pathway: inhibition of cofactors FVa and FVIIIa

The activated forms of coagulation cofactors FV and FVIII (FVa and FVIIIa) are potent procoagulants that enormously enhance the activity of serine protease factors in the tenase and prothrombinase complexes (see above). It is not unexpected that these cofactors should be subject to a negative feedback mechanism that limits their procoagulant activity. This is achieved by a complex series of reactions collectively referred to as the protein C pathway. Four key factors are now known to be involved, and their role in the haemostatic network is shown in Figure 39.4.

Protein C

This vitamin K-dependent serine protease has an identical modular composition to the procoagulant factors FVII, FIX and FX. It circulates in blood as a two-chain disulphide-linked molecule. During biosynthesis, the primary translation product is proteolytically processed releasing the dipeptide Lys156Arg157. In order to exert its anticoagulant effect, PC must first be activated to APC. This is achieved by the action of thrombin, which cleaves the heavy chain to release a 12-residue (Gly158–Arg169) activation peptide, revealing the active site by the usual chymotrypsin-like mechanism. Thrombin activation of PC is slow in free solution but is markedly accelerated by specific endothelial cell receptors for both thrombin (TM) and PC (EPCR), which coordinate the assembly of a membrane complex for PC activation.

APC interacts with PS bound to the phospholipid surface of activated platelets, enhancing the anticoagulant activity of APC (see below) against FVa and FVIIIa. These procoagulant cofactors are inactivated by APC on the platelet surface by specific cleavage in their A domains, terminating the activity of the tenase and prothrombinase complex by disrupting their binding sites for FIXa and FXa respectively. In the absence of PS, this reaction is inefficient. The most common form of familial thrombosis is FV Leiden, which is caused by mutation of Arg506 to Gln, which makes the molecule resistant to cleavage by APC.

It appears that APC inactivation of FVa is a prerequisite for efficient inactivation of FVIIIa *in vivo*, as FVIIIa inactivation is also impaired in these patients, although there is no abnormality in the FVIII molecule. Since the discovery of FV Leiden other less common FV mutants have been found with a similar phenotype. None of the mutations reported in the FVIII molecule have been shown to cause a similar prothrombotic phenotype. PC is synthesized in the liver, and, being vitamin K dependent, is often low in the newborn. Even though its substrates (FV and FVIII) are normal at birth, this deficiency is compensated for by the reduction in plasma of the vitamin K-dependent procoagulant factors (prothrombin, FVII, FIX and FX). Because warfarin treatment initially decreases PC levels faster than FVII, FIX, FX and prothrombin levels, it can paradoxically increase the procoagulant tendency when anticoagulant treatment is first begun (many patients starting on warfarin are given heparin in parallel to combat this). Disruption of the murine PC gene results in lethal perinatal consumptive coagulopathy, whereas in humans homozygous PC deficiency is associated with lethal purpura fulminans (in the absence of PC replacement therapy) and heterozygous individuals have a high risk of venous thrombosis. There is increasing appreciation of the role of the PC pathway in regulation of inflammation and the concept of signalling mechanisms allowing 'cross-talk' between the haemostatic and inflammatory networks. This is well demonstrated by the protective effect of administration of APC concentrate to animals with induced sepsis. The survival benefits that APC concentrate provides in this situation has subsequently been seen in patients with sepsis and multiorgan failure. Recently, variant recombinant PC molecules have been produced that appear to have either anticoagulant or anti-inflammatory effects independent of each other.

Thrombomodulin

TM is an integral transmembrane receptor found on endothelial cells in virtually all body tissues. It appears to be absent in the brain vasculature and in hepatic sinusoids and lymph node venules. TM is essential for normal fetal development as shown by mouse knockout studies, although TM^{+/-} heterozygous mice appear to be completely healthy.

The protein has an extracellular region composed of an N terminal lectin-like or CLECT domain, six EGF-like domains, a transmembrane sequence and a small cytoplasmic region. TM forms a 1:1 complex with thrombin (via the protease's anion-binding exosite I and TM's EGF-like domains 4–6), preventing binding of the protease to its various procoagulant substrates (fibrinogen, FV, FVIII, FXIII and protease-activated receptors involved in platelet aggregation). TM also plays a part in binding of PC zymogen and, after formation of the TM–thrombin complex on the cell surface, there is a 20 000-fold increase in the rate of activation of PC, so that thrombin effectively becomes an anticoagulant. Binding of PC to TM is also enhanced by EPCR.

The TM–thrombin complex is short-lived, being endocytosed by endothelial cells, where the thrombin is taken up and degraded by lysosomes while TM recirculates to the cell membrane.

Endothelial protein C receptor

EPCR was cloned in 1994 as a novel transmembrane receptor on endothelial cells that was able to bind PC and promote its activation by the thrombin–TM complex. The extracellular portion of EPCR is related to the MHC class I/CD1 proteins; however, it lacks the $\alpha 3$ domain found in the extracellular portion of most of the family: there is good evidence that the $\alpha 1$ and $\alpha 2$ extracellular domains of EPCR interact with the GLA domain of PC. EPCR may function by localizing the PC molecule to the endothelial cell surface, moving laterally on the cell surface to locate a thrombin–TM complex, then presenting the PC molecule optimally for thrombin cleavage to form APC.

The essential role of EPCR was demonstrated recently by targeted deletion of the murine EPCR gene, resulting in early fetal death with evidence of thrombosis at the maternal–fetal interface. Abrogation of EPCR function *in vitro* reduces the rate of PC activation by thrombin–TM. In contrast, inhibition of EPCR action by a specific anti-EPCR monoclonal antibody in baboons given thrombin resulted in reduced APC levels amid evidence of excessive coagulopathy. Blockade of EPCR on challenge with *Escherichia coli* also led to worse outcomes in an animal model of sepsis, whereas administration of APC improved survival in experimental sepsis.

Protein S and C4b-binding protein

PS is a single-chain vitamin K-dependent glycoprotein chiefly synthesized in the liver by endothelial cells. Unlike the other vitamin K-dependent coagulation proteins it is not a serine protease, having two C-terminal LamG domains rather than a serine protease domain, and the N-terminal GLA domain is followed by four EGF-like domains rather than the two usually seen in the serine proteases (see Figure 39.8). About 40% of the PS in plasma is in the free form, whereas the remaining 60% is associated in a 1:1 complex with C4b-binding protein (C4bBP). Both forms bind strongly via the PS GLA domain to negatively charged phospholipids exposed on the surface of activated platelets. Free PS (although having no strong inhibitory effect on FVa or FVIIIa itself) forms a Ca²⁺-dependent complex with APC, helping to orient the APC active site above the phospholipid surface and enhancing its anticoagulant activity against both proteins. However, C4bBP-bound PS does not enhance PC function against FVa, suggesting a role for C4bBP in modulation of the APC pathway. Free thrombin cleaves PS N-terminal to the GLA domain, removing its ability to bind to both phospholipid and PC and thereby abolishing its PC cofactor activity.

C4bBP is a large molecule containing seven α -chains (each of which binds one molecule of the C4b component of comple-

Table 39.3 Haemostasis changes during pregnancy.

Platelet count	No consistent change but often falls
Platelet aggregation	Progressive enhancement
Fibrinogen	Progressive rise up to 400% basal
Prothrombin	No consistent change
Factor V	No consistent change
Factor VII	Progressive rise up to 300% basal
Factor VIII	Progressive rise up to 200% basal
von Willebrand factor	Progressive rise up to 250% basal
Factor IX	Variable, no consistent change
Factor X	No consistent change
Factor XI	Variable, no consistent change
Factor XIII	Progressive fall to 50% basal
Antithrombin	No consistent change
Tissue factor pathway inhibitor	Progressive rise
Protein C	No consistent change, but APC resistance increases
Protein S	Progressive fall to 50% basal
Plasminogen	Progressive rise up to 300% basal
tPA	No consistent change
α_2 -Antiplasmin	Progressive rise up to 300% basal
PAI-1	Progressive rise up to 300% basal
PAI-2	Progressive marked rise

ment) and a single β -chain (to which one molecule of PS attaches). It is an acute-phase reactant, which can increase by up to fourfold in severe inflammatory states. It is likely that such raised levels would disturb the equilibrium between free and bound PS, and result in a fall in the free (biologically active) form, predisposing to a hypercoagulable state.

Many haemostatic factors change during pregnancy. Free PS falls during pregnancy (Table 39.3) and to a lesser extent in women receiving estrogen supplements, but it is disputed whether this results from altered reactivity with C4bBP or if it contributes to hypercoagulability in pregnancy or during estrogen therapy. Total PS, like other vitamin K-dependent factors, is reduced in the newborn; levels as low as 20% of adult values can occur. However, this is compensated for by a marked reduction in C4bBP at birth (5–20% of adult levels), so that a relatively normal level of functional (free) PS is maintained.

The possibility that PS might have PC-independent functions in coagulation has been raised by the recent finding that PS binds to the K3 domain of TFPI. The full relevance of this finding is not yet known.

Protein C inhibitors

As with other serine proteases, APC is subject to inhibition by serpins (half-life of APC in plasma is 15–20 min), including

APC inhibitor (PCI), PAI-1 and α_1 -antitrypsin. The relative contributions of these *in vivo* are difficult to assess. PCI slowly but progressively blocks the action of APC (and, to a much lesser extent, thrombin and FXa), in each case forming a 1:1 complex: in addition PCI action is enhanced 20-fold by heparin and more weakly by other GAGs, but the physiological significance of this is uncertain. Despite the name, disruption of the murine PCI gene leads not to coagulopathy but to infertility due to lack of inhibition of another protease target of the serpin, the sperm protein acrosin.

Fibrinolysis

It is widely acknowledged that the principal functions of the fibrinolytic system are to ensure that excess fibrin deposition is either prevented or rapidly removed (i.e. that a localized pro-coagulant response is achieved without compromising blood circulation generally) and, following re-establishment of haemostasis, the fibrin mesh is removed during wound healing. The system of profibrinolytic and antifibrinolytic factors that has evolved to meet these requirements is closely coupled to that which results in fibrin clot formation. Fibrinolysis is essentially a localized, surface-bound phenomenon, with most events being catalysed by the presence of cross-linked fibrin itself, i.e. ‘fibrin orchestrates its own destruction’. For this reason, the assays of fibrinolytic factors carried out in the soluble phase, in particular in systemic blood, may be misleading and should be interpreted with great caution.

Components of the fibrinolytic system

These include PLG and plasmin, several endogenous (tissue or plasma derived) or exogenous (e.g. bacterial or venom derived) PLG activators, and a number of inhibitors of plasmin or of the PLG activators. Some basic features of the endogenous factors are shown in Table 39.2, and a simplified representation of their interaction in Figure 39.5. Both endogenous and exogenous fibrinolytic factors have been used clinically to treat venous and arterial thrombosis, with varying degrees of success (see Chapter 47).

Plasminogen and plasmin

PLG is a single-chain glycoprotein zymogen of the serine protease plasmin, which carries out the enzymatic degradation of cross-linked fibrin. Besides its active site serine, plasmin contains five kringle domains, four of which have a lysine-binding site, through which the molecule interacts with lysine residues in its substrates (e.g. fibrin), its activators (e.g. tissue PLG activator and urinary PLG activator) and its inhibitors (principally PLG activation inhibitor type 1). In its native form, it has a glutamic acid residue at its N-terminus and is known as

Glu-PLG. Conversion of PLG to plasmin can proceed via two routes. Most PLG activators (see below) cleave the Arg561–Val562 bond to form Glu-plasmin, a disulphide-linked two-chain molecule. The heavy chain is derived from the N-terminal region and bears the lysine-binding sites, whereas the C-terminal light chain contains the serine active centre. Glu-plasmin, despite being a serine protease, is functionally ineffective as its lysine-binding sites remain masked. It is converted autocatalytically to Lys-plasmin by N-terminal cleavage, chiefly between Lys76 and Lys77, which exposes the lysine-binding sites and thus markedly enhances its interaction with fibrin.

Both Glu- and Lys-plasmin also attack the same Lys76–Lys77 bond in Glu-PLG to form the zymogen Lys-PLG. This binds to fibrin before activation to the protease and is thus brought into close proximity with the physiological PLG activators (which also bind to fibrin) that convert it to Lys-plasmin. As a consequence, the conversion of PLG to plasmin by tPA is enhanced by two to three orders of magnitude; this serves to localize the fibrinolytic response to the fibrin clot, where plasmin is to some extent protected from the effects of circulating antiplasmins, which (as indicated below) would otherwise neutralize plasmin extremely rapidly (< 50 ms). The fact that Lys-PLG is potentially a much more effective agent in fibrinolysis than Glu-PLG is reflected in its half-life, which is around 20 hours compared with 50 hours for the latter.

Action of plasmin on fibrin and fibrinogen

Plasmin can hydrolyse a variety of substrates including FV and FVIII, but its major physiological targets are fibrin and fibrinogen, which are split progressively into a heterogeneous mixture of small soluble peptides (plasmin attacks at least 50 cleavage sites in fibrinogen) known collectively as fibrin degradation products (FDPs). The first stage in the proteolysis of fibrinogen involves the removal of several small peptides (fragments A, B and C) from the C-terminus of the A α -chains, each involving cleavage after a lysine residue. This is rapidly followed by removal of the first 42 amino acids from the N-terminal end of the B β -chain (the B β 1–42 fragment). The large residual portion, which is known as fragment X, and which still contains fibrinopeptide A, remains thrombin-clottable and will agglutinate some *Staphylococcus* spp. Assay of the B β 1–42 fragment released from fibrinogen by plasmin gives a sensitive index of fibrinogenolytic activity.

Asymmetrical digestion of all three pairs of chains of fibrin or fibrinogen then occurs with the release of the D fragment, in which the chains remained linked by disulphide bonds. The residue, known as fragment Y, is again attacked by plasmin, cleaving a second fragment D and leaving the disulphide-linked N-terminal ends of all six chains, which are referred to as fragment E. Fragments Y, D and E are not thrombin-clottable and do not agglutinate staphylococci. Their presence can be detected

immunologically using an antibody-coated latex bead agglutination assay, which provides a simple test for most FDPs, although carefully prepared serum must be used to prevent cross-reactivity of the antibody with fibrinogen in plasma. These assays detect the degradation products of both fibrin and fibrinogen indiscriminately.

Following thrombin generation and consequent activation of FXIII, intermolecular or intramolecular transamidation of the α - or β -chains by FXIIIa occurs and then the action of plasmin yields characteristic D-dimer, D-dimer–E fragments and oligomers of fragments X and Y (collectively known as cross-linked FDP or XDP), in addition to X, Y, D and E. These XDPs can be detected very simply using monoclonal antibody-coated latex beads. Because the monoclonal antibodies to XDPs do not cross-react with fibrinogen, they can be detected directly in citrated plasma. The presence of D-dimers in blood samples can be used in a clinical algorithm that predicts the likelihood of the presence of venous thrombosis (see Chapter 47).

Furthermore, plasmin-induced cleavage of the N-terminal end of the β -chain of fibrin (the B β 1–14 fibrinopeptide B fragment having been removed by thrombin) produces a β 15–42 fragment, the detection of which indicates fibrin (as opposed to fibrinogen) degradation. Consequently, assays for the B β 1–42 and β 15–42 fragments used in combination may be clinically useful by indicating whether fibrinogen or fibrin has been degraded, and thus whether fibrinolytic activity is primary or secondary to fibrin formation. However, clinically, FDP assays are used to detect DIC, when mixed fibrin/fibrinogen degradation products appear in the circulation.

Plasminogen activators

Tissue plasminogen activator

tPA is a serine protease secreted by endothelial cells. It is not synthesized by the liver or kidney but is found in most extravascular body fluids, including saliva, milk, bile, cerebrospinal fluid and urine. Intravascular tPA is quickly cleared by the liver or inactivated by the fast-acting tPA inhibitor (see below), the half-life of tPA in plasma being approximately 2 min. The resting level of tPA in plasma is around 70 pmol/L, most of which is in an inactive complex with tPA inhibitors (see below).

Several physical and biochemical stimuli, including venous occlusion, strenuous exercise, thrombin, adrenaline and vasopressin or its analogues such as DDAVP (see Chapter 41), markedly increase the rate of tPA release, although its biological activity remains negligible until it becomes bound to fibrin, whereupon its affinity for and action upon PLG is greatly potentiated. The activity of tPA is further enhanced by plasmin itself, which cleaves tPA at Arg275–Ile276 into a two-chain molecule, whose binding sites are exposed, thus enabling it to form a complex with PLG and fibrinogen more readily. The ability of

venous occlusion to stimulate tPA release from endothelial cells forms the basis of a test of fibrinolytic activity known as the 'cuff test'.

Both single-chain tPA and the two-chain form possess very little serine protease activity until they bind to fibrin, whereupon tPA affinity for, and activation of, fibrin-bound PLG is increased at least 100-fold. The principal interactions involve binding between the second kringle domain of tPA and lysine residues on the α - and β -chains of fibrin (in particular Lys157 on the α -chain of partly degraded fibrin). This association enhances cleavage of the Arg561–Val562 bond in adjacent PLG molecules, forming active plasmin.

Urinary plasminogen activator

So called because it was first extracted from urine, uPA is synthesized chiefly by the tubules and collecting ducts in the kidney and by fibroblast-like cells in the gastrointestinal tract. It is a serine protease secreted as an inactive single-chain zymogen (prourokinase) that is cleaved by activators in plasma (including kallikrein and plasmin) at Lys158–Ile159 to produce active two-chain uPA. The protease activity of uPA is associated with the heavy chain, which may dissociate from the light chain carrying the PLG-binding site. The isolated heavy chains, which are also known as low-molecular-weight urokinase, are therefore poorer PLG activators than the two-chain form.

uPA cleaves the same Arg561–Val562 bond in PLG as tPA. Although uPA contains a kringle domain, this does not impart high affinity for fibrin and it binds instead (via its EGF-like domain) to its cell-associated receptor. Thus it has been proposed that uPA may be preferentially involved in cellular events (such as differentiation and mitogenesis) rather than with dissolution of fibrin clots.

Exogenous plasminogen activators

These are derived from non-human sources, including animals (e.g. vampire bat saliva and some snake venoms) and certain plants and microorganisms. The best known of these is streptokinase (SK), which is derived from some strains of β -haemolytic streptococci and which has for many years been used, with moderate success, as a fibrinolytic agent for the treatment of life-threatening thrombotic states. SK is a non-enzymatic polypeptide that forms a stable 1:1 complex with PLG, as a result of which the latter undergoes a conformational change, unmasking its serine-active centre. The 'plasmin' that is formed remains associated with SK but can convert free PLG to plasmin.

Inhibitors of fibrinolysis

The plasmin-generating potential of plasma is sufficient to completely degrade all the fibrinogen in the body in a very short period of time. It is prevented from doing so by the PLG activa-

tor inhibitors or PAIs, most of which belong to the serpin family, and by a number of circulating inhibitors of plasmin itself (the antiplasmins).

Inhibitors of plasminogen activation

Plasminogen activator inhibitor type 1

PAI-1 is an important fast-acting serpin inhibitor of tPA, uPA and, to a small extent, plasmin, and is secreted by endothelial cells. It is also found in platelet α -granules. In plasma, it occurs in two forms: a functionally active 'free' form (that is stabilized by association with vitronectin) and as an inactive complex with tPA. Basal PAI-1 concentration in plasma is low at 0.5 nmol/L, of which at least 80% is in complex with tPA or uPA. It follows a diurnal rhythm, with an early morning peak that is around twice that in the late afternoon, and its activity is also increased by heparin. There is growing evidence that elevated levels of PAI-1 are associated with an increased incidence of venous and arterial thrombosis, and there is a suggested association between the early morning peak level of PAI-1 and a higher incidence of myocardial infarction at that time, the extent of this diurnal variation being associated with polymorphisms in the PAI-1 gene (*SERPINE1*).

The three main profibrinolytic serine proteases (tPA, uPA and plasmin) all cleave the same bond (Arg346–Met347) in the reactive centre loop of PAI-1, and are thus inhibited in the same way as described in the section on AT. PAI-1 binds non-covalently to fibrin, but although it can then complex with and inhibit fibrin-bound tPA (with most of the complexes remaining bound to the fibrin), it does so less effectively than with free tPA. Soluble tPA–PAI-1 complexes are rapidly removed by the liver ($t_{1/2}$ 4 min), as are uPA–PAI-1 complexes that have dissociated from fibrin.

Plasminogen activator inhibitor type 2

This serpin inhibitor of tPA is mainly produced by the placenta and may thus contribute to the inhibition of fibrinolysis that occurs during pregnancy. It is also synthesized in monocytes and epidermal cells, but is not usually found in the plasma of non-pregnant subjects. It is detectable in plasma from about the eighth week of pregnancy, rising to a peak at around 33 weeks and falling only slowly after delivery, the half-life being around 24 hours. Paradoxically, levels are often low in pre-eclampsia due to placental insufficiency. The inhibitory action of PAI-2 involves its Arg380–Thr381 residues and it is more effective against uPA than tPA, although for both the potency is at least 10-fold less than that of PAI-1.

Similarly, other protease inhibitors such as α_1 -antitrypsin, C1-esterase inhibitor, α_2 -antiplasmin (see below), α_2 -microglobulin and protease nexin 1 (one of a group of cell membrane-bound heparin-potentiated serpins) also neutralize tPA, but at a rate that is probably too slow to be of physiological

significance. However, α_2 -microglobulin is thought to be the major inhibitor of the SK–PLG complex.

Inhibitors of plasmin

As they do with thrombin and tPA, a number of the broad-spectrum inhibitors contribute to neutralization of plasmin. By far the most potent plasmin inhibitor is the serpin α_2 -antiplasmin, a single-chain glycoprotein synthesized by the liver, which has a half-life of about 60 hours and shows considerable sequence identity with AT and α_1 -antitrypsin. Its physiological importance is supported by the fact that a congenital deficiency (known as Miyasato disease) is associated with a clinically significant bleeding disorder due to uncontrolled fibrinolytic activity, and that levels are reduced in DIC and during thrombolytic therapy.

α_2 -Antiplasmin

This serpin is the predominant plasmin inhibitor. It forms a stable 1:1 complex with plasmin, in which the protease is completely inactivated. The reaction appears to involve the cleavage by plasmin of a specific Leu–Met bond in the inhibitor, exposing the reactive loop Arg364–Met365 peptide bond to the serine active centre on the light chain of plasmin. Plasmin-modified α_2 -antiplasmin can also bind to native Glu-PLG and to fibrin, the latter reaction being mediated by FXIIIa-mediated cross-linking. Thus, in addition to inactivating preformed plasmin, α_2 -antiplasmin retards fibrinolysis by reducing PLG activation and by ‘masking’ the lysine-binding sites through which plasmin(ogen) interacts with fibrin. However, these subsidiary mechanisms for inhibiting fibrinolysis are to some extent overcome by any Lys-plasmin(ogen) present, which has a higher affinity than Glu-PLG for fibrin, and is thus less susceptible to the action of α_2 -antiplasmin.

In plasma (as opposed to on fibrin strands), although the concentration of PLG (~ 2 μ mol/L) exceeds that of α_2 -antiplasmin (~ 1 μ mol/L), basal fibrinolytic activity is minimal because the tiny amounts of plasmin normally generated under physiological conditions are rapidly neutralized by the inhibitor. However, in certain pathological conditions (e.g. obstetric emergencies or snake bite) where extreme activation of fibrinolysis occurs, the latter may be swamped. Under these circumstances, other inhibitors, in particular α_2 -microglobulin and histidine-rich glycoprotein, may become clinically important. The action of α_2 -microglobulin on plasmin is similar to its effect on thrombin. Following the plasmin-induced cleavage of a specific Arg–Leu bond in the inhibitor, the latter forms a 1:1 complex with the light chain of plasmin. The serine active site of plasmin is not involved and the complex retains weak biological activity, albeit only briefly, until it is removed in the liver. Histidine-rich glycoprotein inhibits fibrinolysis by blocking the lysine-binding sites of PLG, thus preventing its interaction with fibrinogen.

Lipoprotein A

The protein portion of lipoprotein A is termed apo(a). It is synthesized in the liver and circulates in plasma. There is considerable structural homology with PLG, as it possesses both serine protease and kringle domains. It can compete with PLG for binding sites on fibrin(ogen) or tPA, and may also increase PAI-1 expression, both actions potentially inhibiting fibrinolysis. That lipoprotein A has some clinical importance is indicated by the finding that raised levels are associated with an increased incidence of thrombosis.

Thrombin-activated fibrinolytic inhibitor

In the presence of thrombomodulin, thrombin activates carboxypeptidase B, also called TAFI, and TAFIa in turn inhibits fibrinolysis; this provides another link between coagulation and the fibrinolytic pathway. TAFI removes the C-terminal lysine residues formed by limited plasmin proteolysis of fibrin, removing the binding sites for PLG and tPA. Thus the fibrin cofactor function in PLG activation is reduced, downregulating fibrinolysis. Mice with TAFI knockout have defective wound repair, and data from backcrossing against heterozygous PLG-deficient mice showed that TAFI modulates both fibrinolysis and cell migration *in vivo*.

Introduction

Platelets are small anucleate cells that play a critical role in haemostasis and thrombosis. Platelets ordinarily circulate in the bloodstream in a quiescent state but undergo 'explosive' activation following damage to the vessel wall, leading to the rapid formation of a platelet aggregate or vascular plug and occlusion of the site of damage. From a pragmatic viewpoint, the more rapid that vascular plug formation occurs, the lower the amount of blood that is lost. To facilitate a rapid response, platelets are enriched in signalling proteins and surface receptors, and activation is associated with the generation of the positive feedback or amplification mediators ADP and thromboxane (Tx)₂, and release of the adhesion proteins fibrinogen and von Willebrand factor (VWF), which support aggregate formation and the generation of thrombin through the coagulation cascade. The importance of platelets in haemostasis is illustrated by the excessive bleeding associated with defects in platelet function or platelet number. On the other hand, the activation of platelets in diseased blood vessels (e.g. at sites of plaque rupture) can lead to arterial thrombotic disorders such as stroke and myocardial infarction, two of the major causes of morbidity and mortality in the Western world.

It is essential that platelets circulate in the bloodstream in a quiescent state but that they undergo rapid activation as and when necessary. To achieve this balance, endothelial cells constitutively release nitric oxide (NO) and generate prostacyclin to inhibit platelet activation through elevation of the cyclic nucleotides cGMP and cAMP, respectively. In addition, endothelial cells express the ecto-ADPase CD39, which removes the feedback mediator ADP, and thrombomodulin, which converts the procoagulant action of thrombin to an anticoagulant action. Under normal circumstances, platelets are unable to form stable contacts on endothelial cells, but this can occur on diseased or activated endothelial cells or at sites of disturbed flow, including arterial bifurcations where plaques are commonly formed. Adhesion of platelets to endothelial cells promotes local inflammatory events that can initiate plaque formation, endothelial activation and damage. Lesions in the endothelial layer lead to exposure of subendothelial matrix proteins, particularly collagens and membrane surface-expressed tissue factor, which can initiate powerful platelet activation and coagulation, respectively.

Platelets have a wider role than solely supporting platelet aggregation (Figure 40.1). Platelet dense granules and α -granules are packed with a rich diversity of small molecules and proteins that play fundamental roles in many aspects of haemostasis, including vessel constriction, leucocyte recruitment and vessel repair. The ability to release such a diverse library of biological molecules may reflect the evolutionary relationship of the platelet to the haemocyte in lower organisms, which is

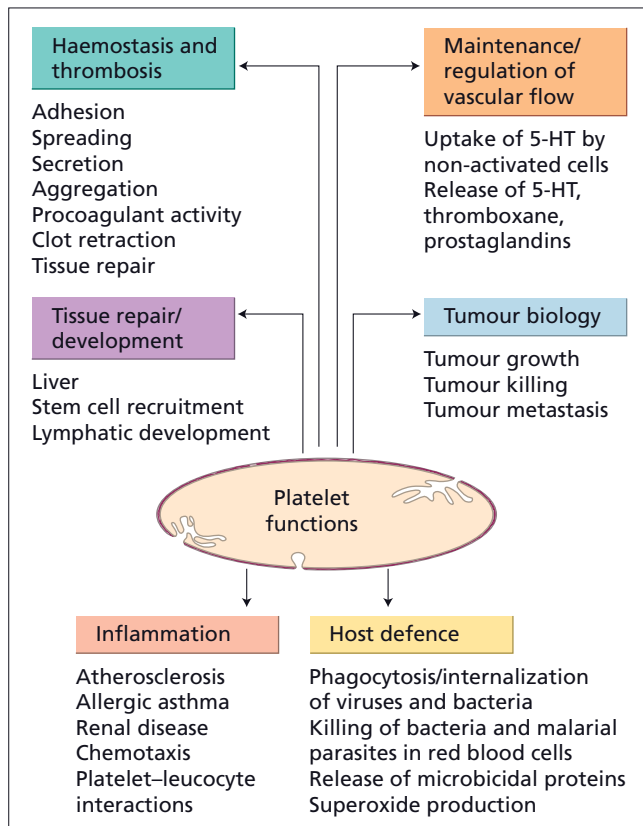

Figure 40.1 Functional roles of the platelet in the vasculature.

involved in both the innate defence system and the prevention of excessive blood loss. In higher organisms, two distinct sets of cells perform these functions, namely thrombocytes (or platelets) and leucocytes, and of course the function of the platelet has evolved to prevent excessive blood loss in a high-pressure arterial system. The contribution of platelets to many vascular responses is an area that is gaining increasing recognition, but one that is challenging to investigate because many mediators are released from other vascular cells.

Platelets are a major target in the treatment of individuals at risk of thrombosis. However, careful consideration is required as to whether a patient should receive antiplatelet therapy and for how long, bearing in mind that such treatment always carries a risk of increased bleeding. For the majority of individuals receiving the orally active antiplatelet drugs aspirin or clopidogrel this risk is extremely low, but it is not zero. In this context, the increasing tendency of otherwise healthy passengers to take aspirin as an antiplatelet therapy in long-haul flights should be viewed with concern as the major risk is venous thrombosis, which is minimally inhibited by treatment with aspirin. The small increase in risk of bleeding may therefore exceed any potential benefit.

The decision on whether a patient should receive antiplatelet therapy is based on the net sum of risk factors for arterial

thrombosis, such as age, stress, weight, sex, lifestyle, cholesterol level, blood pressure, smoking and previous thrombotic history, and the potential risk from excessive bleeding. It is now accepted that individuals judged to be at medium to high risk of thrombosis should receive some form of antiplatelet therapy (unless otherwise contraindicated), usually low-dose aspirin or clopidogrel, and nearly always in combination with other treatments such as statins and blood pressure-lowering drugs. There is also a small but significant advantage in using clopidogrel and aspirin in combination for the treatment of patients at high risk of thrombosis, although this also leads to an increase in significant bleeds. Stronger inhibitors of platelet integrin $\alpha_{IIb}\beta_3$, are used only in acute situations of thrombotic risk in the clinic, for example in cases of unstable angina or angioplasty and stenting, because of their narrow therapeutic window.

The aim of this short review is to describe the features of platelets that enable them to perform their physiological roles in the vasculature. More extensive information on all aspects of platelet function in health and disease can be found in the second edition of the excellent textbook *Platelets*, edited by Alan Michelson.

Platelet structure and organelles

Platelets have several unique features that enable them to efficiently perform their primary function, namely the rapid formation of a vascular plug following vessel injury. Platelets are extremely small and discoid in shape, with dimensions in the human of approximately $3.0 \times 0.5 \mu\text{m}$ and a mean volume of 7–11 fL. This shape and small size enables platelets to be 'marginated' by the red blood cells to the edge of the vessel, placing them next to the endothelial cells and therefore in the correct position to respond to vascular damage. Platelets are abundant in the circulation, with numbers in humans usually in the range $150\text{--}400 \times 10^9/\text{L}$. This relatively high count represents a considerable degree of redundancy, as individuals with platelet counts as low as $20 \times 10^9/\text{L}$ often exhibit only occasional major spontaneous bleeds, although they are at increased risk of excessive bleeding during major trauma and surgery.

The discoid shape of the platelet is formed by the platelet cytoskeleton, which consists of a spectrin-based membrane skeleton, circumferential bands of a single microtubule that lie beneath the plasma membrane and a rigid actin filament network that fills the cytoplasm of the cell. The disc shape is not essential for platelet function as mouse platelets that lack β_1 -tubulin, the major component of the microtubules, are spherical and yet undergo normal aggregation and secretion. The rigid structure and platelet strength is supported by 2 million copies of actin per platelet, of which approximately 40% in a non-stimulated cell are assembled into actin polymers. These polymers connect with each other and with the cytosolic tail of the

membrane glycoprotein (GP)Ib α via filamin in a lattice-like structure that gives the platelet its discoid shape.

Platelets lack a nucleus, which is consistent with their short lifespan of 10 days and their acute role in haemostasis. Platelets exhibit a very limited and specific degree of protein synthesis, as the result of residual mRNA that has been carried over from their precursor cell, the megakaryocyte, although interestingly the number of platelet/megakaryocyte genes is higher than any other blood cell lineage. However, although there is little historical evidence to suggest that the general capacity to synthesize new proteins is of major relevance, more recent evidence suggests that activated platelets can synthesize a small number of key proteins that may be of functional significance. The presence of low levels of platelet mRNA also provides an opportunity to perform a limited number of genetic studies, although concern over contamination from nucleated cells, which express several orders of magnitude higher levels of mRNA, necessitates the need for direct confirmation of protein expression. Potentially, many of these issues can be addressed at the level of the platelet precursor cell, the megakaryocyte, but these are present at low copy number in bone marrow and access to tissue is a problem particularly in humans. Despite these concerns, the application of both genomic and proteomic approaches have given an unprecedented insight into the protein composition of the platelet, although the challenge remains to identify the function and interplay of the key proteins, as many may be vestigial or have been carried over from the megakaryocyte.

Platelets contain four main types of storage granule, dense granules, α -granules, lysosomes and peroxisomes, although the significance of the latter two is unclear. There are between five and nine dense granules in platelets and these contain high levels of ADP, ATP, polyphosphates, 5-hydroxytryptamine (5-HT; also known as serotonin) and Ca²⁺. There are about 80 α -granules per platelet and these contain a rich diversity of proteins and membrane receptors that support haemostasis, vascular repair, inflammation and host defence (Table 40.1). Many of these proteins are made *de novo* in the megakaryocyte, such as platelet factor (PF)4 and VWF, whereas others are taken up from the plasma by receptor-mediated endocytosis, including fibrinogen. The major components of α -granules include fibrinogen and VWF, which support platelet adhesion and aggregation; factor (F)V, protein S and tissue factor pathway inhibitor (TFPI), which play key roles in regulating coagulation and fibrinolysis; the chemokines SDF-1 α , PF4, β -thromboglobulin, ENA-78 and RANTES, which attract haemopoietic stem cells and leucocytes; and the growth factors platelet-derived growth factor (PDGF) and vascular endothelial growth factor (VEGF) A and C, which support vessel repair and angiogenesis. Platelet α -granules also express key transmembrane proteins that become exposed on fusion with the plasma membrane and support platelet aggregate formation and leucocyte recruitment, including the major platelet integrin $\alpha_{IIb}\beta_3$, P-selectin (CD62) and CD40L. The expression of

Table 40.1 Platelet α -granule constituents.

<i>Physiological role</i>	<i>Constituent</i>
Angiogenesis	VEGF-A, VEGF-C, PDGF
Antibodies	IgG
Coagulation cascade	Factor V, fibrinogen, tissue factor pathway inhibitor
Endothelial cell activation	TGF- β
Fibrinolysis	Plasminogen, PAI-1, α_2 -antiplasmin
Growth factors	PDGF, FGF, HGF, IGF-1, EGF
Leucocyte recruitment	Chemokines: PF4, RANTES, β -thromboglobulin, ENA-78, SDF-1 α
Matrix breakdown	Hydrolytic enzymes MMP-2, MMP-9
Membrane proteins	$\alpha_{IIb}\beta_3$, P-selectin, CD40L
Bacterial killing	Microbicidal proteins
Miscellaneous	Amyloid β -protein precursor, Gas6
Proteases	Protease nexin II
Platelet aggregation	Fibrinogen, fibronectin, VWF
Irreversible aggregation	Thrombospondin (locks fibrinogen bridges between $\alpha_{IIb}\beta_3$)

Examples of platelet α -granule constituents and their physiological roles are shown. Several other molecules have also been reported to be present in α -granules and to be released on activation.

P-selectin is used to monitor platelet α -granule secretion by flow cytometry.

Platelets are enriched in signalling proteins, which facilitate the rapid switch from quiescence to activation, and have a high cytoskeletal protein content that gives rise to the dramatic changes in morphology and which enables the platelet aggregate or thrombus to withstand the very high shear forces that exist in the arteriolar system. Platelets have a network of intracellular membranes known as the dense tubular system (part of the endoplasmic reticulum) that release intracellular Ca²⁺ in response to the second messenger inositol 1,4,5-trisphosphate (IP3). Platelets have a network of invaginations of the surface membrane, known as the surface-connected canalicular system, which increase the surface area of the plasma membrane during platelet spreading and thereby provide more sites for release of intracellular granules. The surface-connected canalicular system also gives rise to membrane tethers that play a vital role in supporting adhesion. Platelets contain several mitochondria that generate energy during their short lifespan.

Animal models

Genetically modified mice and other organisms, notably zebrafish, are being increasingly used to address the *in vitro* and

in vivo function of specific genes and proteins in platelets (and thrombocytes), but with the caveat of a number of differences to human platelets with regard to rheology and protein composition. For example, the mouse genome lacks the gene for the only Fc receptor found on human platelets, FcγRIIA, and mouse platelets do not express one of the major receptors for thrombin on human platelets, PAR-1. There are also important differences in participation of protein isotypes in signalling cascades and various responses. Moreover, the relevance of many of the *in vivo* models (such as tail bleeds and vessel wall injury by ferric chloride or laser ablation) to haemostasis and thrombosis in humans is uncertain and fails to mimic the conditions that give rise to arterial thrombosis, which typically occurs on ruptured atherosclerotic plaques. Nevertheless, despite these concerns, the processes that govern platelet activation in mice and other species appear to be shared with humans, and the value of animal models in analysing platelet activation and *in vivo* haemostasis and thrombosis, and thereby establishing a foundation for ongoing and future clinical trials, is immense.

Platelet formation

Platelets are formed from megakaryocytes, one of the largest cells in the bone marrow, reaching more than 50 μm in diameter. The nucleus of the megakaryocyte undergoes a process known as endomitosis that involves nuclear replication without cellular division, giving rise to DNA ploidy values that range from $4n$ to $128n$. The reason why endomitosis occurs is not fully understood, but it may simply reflect the need to increase the DNA content to enable the cell to expand its protein synthetic capacity to generate 2000–3000 platelets per megakaryocyte. In addition, it allows cell growth and differentiation to occur without interruption by nuclear and cell divisions.

The differentiation of bone marrow progenitor cells into megakaryocytes is regulated by the cytokine thrombopoietin (TPO), which was first identified in the mid 1990s. The TPO receptor, c-Mpl, expressed on stem cells, megakaryocytes and platelets, signals via the JAK/STAT family of kinases and transcription factors, respectively. An acquired mutation in JAK2 (valine to phenylalanine residue at position 617) leads to an increase in JAK2 activity and accounts for approximately 50% of patients with essential thrombocythaemia and almost 100% of patients with polycythaemia vera, which are associated with an increase in either platelet or red blood cell counts respectively. The same mutation also underlies myelofibrosis, which often occurs as a late-stage progression of these two myeloproliferative disorders. TPO is synthesized at a constant rate in the liver and its circulating free levels are largely controlled by binding and internalization mediated through c-Mpl on the platelet surface. This provides a simple and elegant means of tightly controlling the platelet count. Thus, if the platelet count decreases, the free level of TPO rises and there is an increase in

megakaryocytopoiesis and platelet formation. Two TPO mimetics (eltrombopag and romiplostim) have recently entered clinical use for treatment of immune thrombocytopenia.

One of the outstanding questions in this field over the years has been the events underlying platelet formation. There is now a growing consensus that megakaryocyte differentiation occurs in a defined compartment of the bone marrow known as the osteoblastic niche and that megakaryocytes subsequently migrate and adhere to sinusoidal endothelial cells through a process that is regulated by the chemokine SDF-1α and its receptor CXCR4. At this vascular niche, the megakaryocytes generate long thin processes known as proplatelets, which form platelets at their terminals. The proplatelet arms protrude between bone marrow sinusoidal endothelial cells and release platelets directly into the bloodstream. This carefully orchestrated process ensures that platelets are not released into the bone marrow. Megakaryocytes also undergo chemotaxis into the bloodstream where they can also form platelets. Dynamic visualization of the events underlying thrombopoiesis within bone marrow has recently been captured *in vivo* by Junt and colleagues. To maintain a normal platelet count, approximately 1 million new platelets are released into the blood every second but this can dramatically increase by a factor of 10 in severe haemorrhage.

Thrombus formation

The events that underlie platelet adhesion and aggregation, and which eventually lead to thrombus formation, at the intermediate to high rates of shear (1000–5000/s) of the arteriolar system are discussed below and depicted in Figure 40.2.

Platelet capture and stable adhesion

The initial event that takes place on damage to the vasculature is the tethering or capture of platelets through the interaction of VWF with the GPIb-IX-V complex. VWF and GPIb do not interact unless a conformational change is induced in VWF as a consequence of its binding to collagen and/or elevated shear. The fast on-rate of association between VWF and GPIbα enables binding to take place at the intermediate to high shear forces of the arteriolar system. However, a fast off-rate of association means that this interaction alone is not sufficient to give rise to rapid stable adhesion. Thus, platelets translocate in the direction of flow on a surface of VWF or when they first come into contact with a damaged vessel wall. Application of high-resolution imaging technology has revealed that most platelets translocate in a stop-start manner through sliding rather than rolling and thus this serves to minimize the drag forces on adhesive bonds. Furthermore, the capture of platelets is facilitated by the formation of membrane tethers, thin processes of lipid bilayer that are pulled away from the platelet

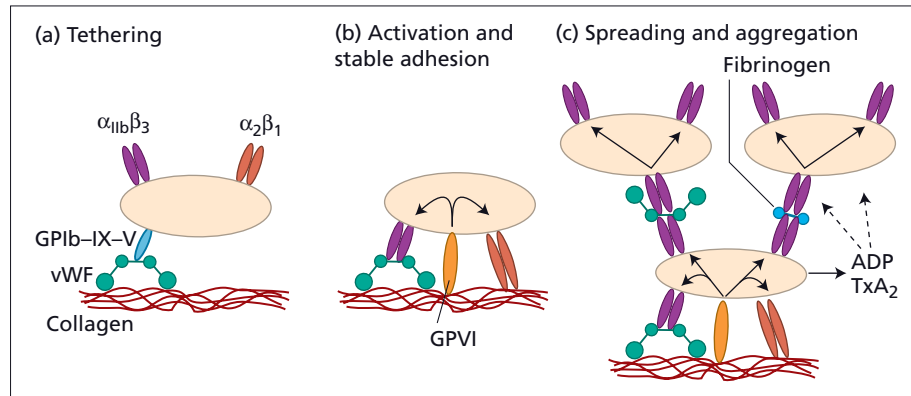

Figure 40.2 Thrombus formation at arteriolar rates of shear. Platelets are tethered by VWF bound to immobilized collagen, which then activates the low-affinity receptor GPVI leading to activation of integrins $\alpha_{11b}\beta_3$ and $\alpha_2\beta_1$, which bind to VWF/fibrinogen and collagen, respectively. This mediates stable adhesion and further activation of GPVI. The signals from GPVI

and the two platelet integrins induce spreading of platelets on the matrix and release of the feedback messengers ADP and TxA_2 . VWF and fibrinogen, in combination with ADP, TxA_2 and thrombin, mediate thrombus formation (aggregation) and stabilization (clot retraction). The formation of a procoagulant surface also supports formation of thrombin (not shown).

Figure 40.3 Platelet adhesion and aggregation at arteriolar shear. Human blood, anticoagulated with 40 $\mu\text{mol/L}$ P-PACK, was flowed over collagen or VWF at a shear rate of 1000/s for 4 min and rinsed with Tyrode buffer for 5 min. Differential interference

contrast images of adherent platelets were recorded. Where indicated, blood was pretreated with indomethacin (10 $\mu\text{mol/L}$) and apyrase (5 U/mL) to reduce the secondary mediators, TxA_2 and ADP respectively, prior to flow.

surface under the influence of haemodynamic force. These highly dynamic structures can extend as far as 30 μm in length, or ten times the size of a platelet, with much of their length being derived from the surface-connected canalicular system. The formation of membrane tethers helps to sustain adhesion within high-shear environments by minimizing the drag on captured platelets.

The conversion to stable adhesion is primarily dependent on activation of β_1 and β_3 integrins by other receptors, most

notably the collagen receptor GPVI and vessel wall-generated thrombin. This transition can be readily demonstrated *in vitro* by comparing adhesion and aggregate formation when blood flows over immobilized VWF or collagen, as illustrated by the static records shown in Figure 40.3. The majority of platelets translocate on a surface of VWF and form small stable aggregates only after several minutes, presumably as a result of weak activation of platelet integrins by GPIIb-IX-V. In comparison, platelets undergo rapid stable adhesion and form large aggre-

gates on collagen. This process is critically dependent on the binding of plasma-derived VWF to collagen through its A3 domain, unmasking the binding site for GPIb within the VWF A1 domain, and the release of the positive feedback mediators ADP and TxA₂. Dynamic imaging is required to observe this train of events in full.

The integrins that mediate stable adhesion on collagen are $\alpha_{IIb}\beta_3$ (GPIIb/IIIa) and $\alpha_2\beta_1$ (GPIa/IIa), which bind to immobilized VWF and collagen, respectively. The role of $\alpha_2\beta_1$ in this process is masked by the 50 times higher level of $\alpha_{IIb}\beta_3$, which is expressed at approximately 80 000 copies per platelet, with a further 40 000 copies on intracellular α -granules that become exposed on activation. Platelets express three other integrins that have the potential to mediate stable adhesion *in vivo*, $\alpha_5\beta_1$, $\alpha_6\beta_1$ and $\alpha_v\beta_3$, which bind to fibronectin, laminin and vitronectin, respectively. The two β_1 integrins are expressed at 1000 copies per platelet and $\alpha_v\beta_3$ at a tenfold lower level, and therefore their actions are also masked by the much greater level of $\alpha_{IIb}\beta_3$.

The capture and recruitment of circulating platelets onto a growing aggregate occurs in a similar way but in this case β_1 and β_3 integrin activation is mediated by the release of ADP and TxA₂, and the local formation of thrombin. Binding of VWF to integrin $\alpha_{IIb}\beta_3$ on the surface of activated platelets mediates tethering of non-activated platelets through GPIb–IX–V. High-resolution imaging studies have revealed that the initial stage involves discoid-shaped platelets and is reversible and independent of ADP and TxA₂. This initial phase therefore serves to recruit platelets into the growing aggregate. This is followed by an irreversible phase that is associated with a marked change in platelet morphology and platelet activation, and which is dependent on released secondary mediators and localized thrombin formation.

There are important differences in the mechanisms that give rise to adhesion and aggregation at the low and very high rates of shear found in the venous system and in stenosed arteries, respectively. At the relatively low flow that exists in venules and larger veins, which generate shear forces of less than 500/s, platelets are able to adhere directly to exposed subendothelial matrix proteins and undergo stable adhesion independent of VWF and GPIb–IX–V, although this interaction is thought to contribute to this response. Release of secondary mediators and generation of thrombin is also sufficient to enable aggregate growth to occur independent of VWF and GPIb–IX–V. At shear rates of 10 000/s and above, which are found in stenosed vessels, adhesion and aggregation are mediated entirely by the interaction of soluble and immobilized VWF with GPIb–IX–V, and are independent of platelet activation and integrin $\alpha_{IIb}\beta_3$.

Spreading

Platelets undergo a characteristic set of morphological changes on contact with a surface, known collectively as spreading, the

pattern of which is agonist dependent, as illustrated in Figure 40.4. Initial shape change or rounding is followed by the generation of finger-like projections known as filopodia, which grow from the periphery of the cell, and the subsequent formation of lamellipodia, which fill in the areas between adjacent filopodia. Actin–myosin stress fibres then serve to strengthen the spread platelets. As these events proceed, granules and organelles are squeezed into the centre of the cell, resulting in a characteristic ‘fried egg’ appearance. These dramatic changes in morphology are brought about by a powerful severing and reassembly of the actin cytoskeleton. The spreading of platelets and formation of stress fibres helps to secure the platelet and thrombus against the flow and shear forces of the vascular system.

Granule secretion and TxA₂ formation

The secretion of ADP from dense granules and the *de novo* generation of TxA₂ from arachidonic acid, liberated by the action of cytosolic phospholipase (PL)A₂, play a critical feedback role in mediating platelet activation. In nearly all cases, activation of platelets by low concentrations of agonists is potentiated by the release of the two feedback agonists, and only high concentrations of powerful stimulants such as thrombin are able to induce full aggregation (measured in a Born aggregometer) in the presence of inhibitors of the two feedback stimuli. The major physiological role of the two feedback mediators, along with thrombin, is to generate a platelet aggregate on the monolayer of cells that have adhered to subendothelial collagen (see Figure 40.3).

Secretion from platelet α -granules usually occurs concomitantly with that from dense granules, although there is evidence for subtle differences in their regulation. The α -granules contain a wide variety of protein constituents that play various roles in haemostasis, host defence and wound repair, including VWF and fibrinogen, which together with their plasma counterparts support aggregate formation. Fusion of α -granules with the platelet plasma membrane has the potential to increase the expression of $\alpha_{IIb}\beta_3$ to over 120 000 copies per platelet. This is of relevance in the use of membrane-impermeable $\alpha_{IIb}\beta_3$ blockers, as these can only reach α -granule-localized integrin following degranulation or through internalization. Fusion of α -granules also leads to expression of P-selectin on the platelet surface, which is the major ligand for P-selectin glycoprotein ligand (PSGL)-1 on circulating tissue factor-rich microparticles and leucocytes. The capture of microparticles provides a mechanism for further activation of the coagulation cascade on a growing thrombus, while binding to leucocytes contributes to inflammatory events at the vessel wall.

Aggregation

Aggregation is the specific term used for the cross-linking of activated platelets through binding of bivalent or multivalent

Figure 40.4 Distinct morphological changes in washed human platelets exposed to fibrinogen (FG), collagen-related peptide (CRP) or thrombin (THR). Representative morphology of a single platelet on each surface at specific time points (seconds)

are shown. (From Thornber K, McCarty OJ, Watson SP, Pears CJ (2006) Distinct but critical roles for integrin α IIB β 3 in platelet lamellipodia formation on fibrinogen, collagen-related peptide and thrombin. *FEBS Journal* 273: 5032–5043 with permission.)

ligands to integrin α IIB β 3. It should not be confused with agglutination, which refers to the passive cross-linking of non-activated platelets. The latter describes the response to high concentrations of the antibiotic ristocetin for example, which induces cross-linking of VWF to GPIb–IX–V. Ristocetin is used in the clinical testing laboratory to investigate possible defects or gain-of-function mutations in either plasma VWF or GPIb.

The integrin α IIB β 3 is present in a low-affinity form on non-stimulated platelets but undergoes a conformational change to a high-affinity form in response to ‘inside-out’ signals. The subsequent binding of bivalent ligands to platelets mediates platelet aggregation and adhesion. In turn, these interactions lead to clustering of α IIB β 3 on the platelet surface and the generation of ‘outside-in’ signals that regulate actin polymerization (and therefore platelet spreading) and other responses in synergy with other platelet receptors.

Fibrinogen, VWF and fibronectin have similar affinities for integrin α IIB β 3 but under low shear conditions, fibrinogen is considered to be the major ligand because of its much higher concentration in plasma. On the other hand, as discussed above, the importance of the interaction of VWF with integrin α IIB β 3 increases with shear. For many years the role of fibronectin in

supporting aggregation was considered to be minor, in part because standard Born aggregation assays are not altered in the absence of the matrix protein. However, more recent studies in fibronectin-deficient mice and in *in vitro* flow assays have emphasized an important, albeit poorly understood, role for fibronectin in the initiation, growth and stabilization of platelet aggregates. Indeed, the importance of fibronectin may be related to its ability to bind to additional proteins such as fibrinogen and thrombospondin, and in this way contributes to the stability of the platelet aggregate. Overall, however, we have a relatively poor understanding of the interplay between fibrinogen, VWF and fibronectin, and are still unable to explain why a combination of α IIB β 3 ligands is more effective in supporting aggregation and thrombus formation.

Thrombus stabilization

There is increasing recognition of the significance of so-called ‘late events’ that help to stabilize the platelet aggregate or thrombus in the high shear environment of the arterial circulation. These events involve remodelling of the actin cytoskeleton and the interaction of several platelet membrane proteins with themselves or with each other. The affinity of the latter interac-

tions is low and so these only occur when platelets are brought into close contact with each other.

The ability of blood clots to retract over a course of minutes to hours has been known for over 200 years and is termed clot retraction. The platelets are the force-generating components of this response, with integrin $\alpha_{IIb}\beta_3$ playing a fundamental role both by linking cytoplasmic actin filaments to surface-bound fibrin polymers and by generating intracellular signals that, together with those from other receptors, enable myosin to serve as a motor and drive the process. A novel actin-dependent, but fibrin-independent, mechanism of retraction has been recently described that brings newly captured platelets into the aggregate and presumably also strengthens the aggregate by reducing the shear forces at the aggregate edge.

Through the work of Brass and others, it is now recognized that the aggregate is consolidated by the binding of a number of platelet membrane proteins to themselves (homophilic interactions) or to other surface receptors on adjacent platelets (heterophilic interactions). Examples of such interactions include the binding of ephrins and Eph kinases to each other, the homophilic binding of PECAM-1, the interaction of the immunoglobulins, JAM-A, JAM-C, ESAM and CD226 with each other and possibly other ligands, and the binding of semaphorin 4D with its ligand plexin-B1. Studies using blocking antibodies and mutant mice have provided evidence that these interactions contribute to the stability of the thrombus, although in many cases it is unclear if this is through the generation of intracellular signals or by strengthening platelet–platelet interaction. There is also evidence that some of these interactions inhibit aggregate growth, such as those involving PECAM-1 and ESAM, and it is possible that these help to limit the degree of thrombus formation.

Many of the adhesion proteins that mediate platelet formation become shed during activation, including GPVI, GPIb α , GPV, P-selectin, and semaphorin 4D, and potentially this may serve to limit thrombus growth. On the other hand, in the case of CD40L, which becomes exposed on platelet activation, there is evidence that its shedding and subsequent binding to integrin $\alpha_{IIb}\beta_3$ via a KGD motif stabilizes thrombus formation.

Further research is urgently required to establish the contribution of many of these interactions and events to thrombus formation.

Procoagulant activity

The classic cascade model of blood coagulation has been replaced by a cell-based model of haemostasis in which coagulation takes place on different surfaces, in overlapping steps – initiation, amplification and propagation – such that thrombin is generated at the very sites that it is required. Activated platelets provide a negatively charged phospholipid surface for the assembly of two multiprotein complexes that form part of the intrinsic and amplification pathway of coagulation, namely

the tenase and prothrombinase complexes. A complex of FIXa and FVIIIa on the negatively charged lipid surface converts FX to FXa (tenase complex), which in turn forms a complex with FVa on the same surface to efficiently convert prothrombin to thrombin (prothrombinase complex). In this way, a large amount of thrombin is generated in the vicinity of the growing aggregate that serves to enhance platelet activation and convert fibrinogen to fibrin.

The platelet procoagulant response, which is mediated by exposure of phosphatidylserine, is elicited only by very powerful platelet agonists or combinations of agonists, and requires sustained entry of Ca^{2+} across the plasma membrane. However, the molecular basis of this response awaits identification of the ‘scramblase’ that promotes translocation of phosphatidylserine to the outer leaflet. Five patients have been described with a mild bleeding disorder linked to defective procoagulant activity, a condition known as Scott syndrome, and this provides evidence that this pathway plays an important role in thrombus formation, although the identification of further patients is required to consolidate this. Procoagulant activity can be monitored by flow cytometry in the presence of external Ca^{2+} through the binding of fluorescently labelled annexin A5, FXa and other ligands.

The activation of platelets by powerful agonists and entry of Ca^{2+} is associated with formation of microparticles and these too have been proposed as providing a massive increase in the surface area for binding of the tenase and prothrombinase complexes. However, although microparticles are a highly active area of research in the context of thrombotic disorders, it is one that is severely hampered by technical limitations due to their small size and heterogeneity, especially as microparticles are also formed by other blood cells, including leucocytes and megakaryocytes.

Stimulatory receptors and their signalling pathways

The major physiological agonists that mediate platelet activation can be divided according to whether they signal primarily through single transmembrane proteins that regulate Src and Syk family tyrosine kinases or via seven-transmembrane-spanning proteins that are coupled to heterotrimeric G proteins. The former group includes the adhesion molecules collagen, VWF and fibrinogen, and the latter the so-called ‘soluble’ agonists thrombin, ADP and TxA₂ (Figure 40.5).

The collagen receptor GPVI is the most powerful of the adhesion receptors, signalling through tyrosine phosphorylation of an immunoreceptor tyrosine-based activation motif (ITAM) in its associated FcR γ -chain, leading to formation of an LAT signalosome and activation of PLC γ 2. Integrin $\alpha_{IIb}\beta_3$ and GPIb–IX–V generate much weaker signals independent of LAT that

Figure 40.5 Schematic of the major tyrosine kinase-linked and G protein-coupled receptors regulating platelets. The major receptors regulating platelet activation and inhibition are shown. The major signalling receptors that mediate platelet activation are the tyrosine kinase-linked receptor GPVI and the G protein-coupled receptors for TxA₂, thrombin and ADP. Of this group, the P2Y₁₂ ADP receptor is unique in that it synergizes with the receptors for the other agonists to mediate powerful activation.

The GPIb–IX–V complex is critical for platelet tethering and integrins $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$ for stable adhesion and, in the case of the latter, platelet aggregation. All three of these adhesion receptors also generate weak tyrosine kinase-based intracellular signals of uncertain significance. The prostacyclin receptor (IP) elevates cAMP and, in combination with nitric oxide which elevates cGMP (not shown), mediates powerful platelet inhibition.

nevertheless mediate spreading and activation in synergy with other receptors. Signalling by GPVI and integrin $\alpha_{IIb}\beta_3$ occurs in distinct regions of the platelet membrane, with the former signalling in cholesterol-rich membrane domains known as lipid rafts (Figure 40.6). Importantly, GPVI, GPIb–IX–V and integrin $\alpha_{IIb}\beta_3$ are expressed only on platelets and their precursor cell, the megakaryocyte.

The heterotrimeric G proteins are composed of α and $\beta\gamma$ subunits, and take their name from the α subunit, although both subunits regulate effector proteins. Thrombin and TxA₂ receptors activate both G_q and G₁₃, which regulate PLC β and Rho kinase, respectively, whereas the P2Y₁ ADP receptor is coupled only to G_q. Both G proteins pathways have been shown to play important roles in mediating aggregation, although G₁₃ is only able to induce shape change in the absence of other G_q. The P2Y₁₂ ADP receptor is unique among this group of receptors in that it is coupled to the G_i family of G proteins. On its own, the P2Y₁₂ receptor induces very weak activation of platelets, but mediates powerful activation in synergy with Ca²⁺-mobilizing receptors.

Tyrosine kinase-linked receptors

GPIb–IX–V

The GPIb–IX–V is unique to platelets and consists of four subunits, GPIb α , GPIb β , GPIX and GPV, at a ratio of 2:2:2:1. It is

estimated that there are 25 000 copies of the complex on the platelet surface. The principal ligand for GPIb–IX–V is VWF, which consists of a series of multimers that vary in size from 500 to more than 20 000 kDa and which give rise to the characteristic VWF ladder when analysed by gel electrophoresis. The larger multimers of VWF are more effective in mediating platelet tethering and platelet activation. VWF is stored and released from endothelial cell Weibel–Palade bodies as an ultra-large multimer and is broken down into the smaller multimers observed in the circulation by the specific metalloproteinase ADAMTS-13. Deficiencies in ADAMTS-13 lead to the persistence of ultra-large VWF multimers in the circulation and a life-threatening thrombotic microangiopathy known as thrombotic thrombocytopenic purpura (TTP), which is characterized by VWF-rich platelet aggregates in the skin and vital organs. Multimeric VWF also interacts and stabilizes FVIII.

At high rates of shear, multimeric VWF undergoes a change from a globular to an extended form that can reach several microns in length and which has multiple platelet and collagen binding sites. VWF can also self-associate when extended to form very large filaments on the surface of endothelial cells and on collagen. In this extended form, VWF is able to tether to platelets through the GPIb–IX–V complex and thereby support adhesion and aggregation. This extended form of VWF is also induced by the bacterial antibiotic ristocetin or the snake venom toxin botrocetin, which are therefore frequently used as experi-

Figure 40.6 Schematic of GPVI and $\alpha_{IIb}\beta_3$ signalling. Activation of the collagen receptor GPVI leads to tyrosine phosphorylation of the FcR γ -chain ITAM by the two Src kinases, Fyn and Lyn. This leads to recruitment of the tandem SH2 domain-containing tyrosine kinase Syk, which mediates tyrosine phosphorylation of the adapter proteins LAT and SLP-76, and PLC γ 2. Signalling occurs in cholesterol-rich membrane domains known as lipid rafts. The integrin $\alpha_{IIb}\beta_3$ also signals through Src and Syk tyrosine

kinases leading to activation of PLC γ 2. However, there are a number of differences to the GPVI signalling cascade, including (i) Src and Syk binding directly to the β_3 cytoplasmic tail independent of an ITAM; (ii) the integrin uses Src; (iii) signalling occurs outside of lipid rafts; and (iv) is independent of LAT. These differences may account for the much weaker signal from the integrin relative to that from GPVI.

mental tools to promote binding to GPIb α in a low-shear environment.

The critical role of extended VWF in mediating platelet tethering is dependent on the fast on-rate of association of its A1 domain to GPIb α . However, as discussed above, other agonists such as collagen are required to mediate *rapid* activation of platelet integrins leading to stable adhesion and aggregation. This two-stage process may have evolved to help prevent adhesion and aggregation occurring when platelets are exposed to VWF in the absence of other stimuli, such as may occur on the surface of endothelial cells during release of the adhesive protein.

GPIb α generates weak intracellular signals through Src and Syk tyrosine kinases that mediate platelet spreading and integrin $\alpha_{IIb}\beta_3$ activation. It is speculated that this plays an important role in mediating platelet activation *in vivo* in synergy with other receptors, although studies using mice with a selective defect in signalling by GPIb α are required to test this.

GPIb-IX-V binds to several other cell surface and plasma proteins, including integrin $\alpha_M\beta_2$ (also known as Mac-1 or CR3) and P-selectin of leucocytes. The storage of platelets at 4°C has been shown to lead to clustering of GPIb-IX-V and it is believed that this leads to binding to $\alpha_M\beta_2$ and clearance of

platelets by the reticuloendothelial system, thus preventing their storage at this temperature and limiting their shelf-life. The interaction with $\alpha_M\beta_2$ and P-selectin contributes to attachment and transmigration of leucocytes through a mural thrombus. Binding to P-selectin has also been reported to support rolling of platelets on activated endothelium in low-pressure vessels.

Mutations in GPIb α , GPIb β and GPIX give rise to the bleeding disorder Bernard-Soulier syndrome, which is characterized by macrothrombocytopenia. Bernard-Soulier syndrome is a rare disorder, with only a few hundred cases described worldwide. The reduction in platelet count and increase in platelet size in this condition is due to the pivotal role of GPIb-IX-V in supporting platelet formation via the interaction of the GPIb α cytoplasmic tail and the platelet cytoskeleton.

GPVI and integrin $\alpha_2\beta_1$

Collagen is recognized as the most thrombogenic component of the subendothelial matrix. Nine forms of collagen have been described within the vessel wall, with types I and III being the predominant ones in the deeper layers of the vessel wall and type VI in more superficial layers. The major receptors for collagen on platelets are the immunoglobulin GPVI and the integrin $\alpha_2\beta_1$, which are expressed at 4000–6000 and 1500–2500

copies per platelet, respectively. There are reports of additional receptors for collagen, although these need to be confirmed and their role determined. The majority of vascular collagens activate GPVI and integrin $\alpha_2\beta_1$, with the possible exception of collagen type IV in the basement membrane which forms a lattice rather than a fibrillar structure.

Collagen is composed of three helical chains, which interact to form a superhelical structure that is interrupted by non-helical regions. The presence of glycine (G) at every third position is essential to form the helical structure. In addition, the amino acids proline (P) and hydroxyproline (O) make up approximately 10% of the helical backbone. Synthetic collagen peptides based on these three amino acids have been shown to bind selectively to GPVI or integrin $\alpha_2\beta_1$. Peptides that are specific to GPVI have a backbone of GPO residues, whereas peptides that bind to $\alpha_2\beta_1$ have a backbone of GPP residues interspersed with at least one or more GER-containing motifs, such as GFOGER. The GER sequence confers binding to the Mg^{2+} ion present in the I-domain of $\alpha_2\beta_1$. GPP is unable to bind to $\alpha_2\beta_1$ or GPVI but is required to present GER in a helical conformation that is necessary for it to bind to the integrin. Many snake toxins target GPVI, including the C-type lectin convulxin, which is a tetramer of α and β subunits and induces powerful activation through clustering.

GPVI forms a complex with the FcR γ -chain and is the major signalling receptor for collagen. The FcR γ -chain contains an ITAM, defined by the sequence YXXLX₆₋₁₂YXXL. ITAMs play a critical role in signalling by a variety of immune receptors, including T- and B-cell antigen receptors, and several Fc receptors, including the Fc ϵ RI mast cell receptor and the low-affinity immune receptor Fc γ RIIA, which is the only Fc receptor on human platelets. ITAM receptors signal through sequential activation of Src, Syk and Tec family kinases. Src family kinases, including Fyn and Lyn, mediate phosphorylation of the conserved tyrosines in the ITAM that enables binding of the tandem SH2 domain containing Syk family kinase and initiation of a downstream signalling cascade that culminates in Tec kinase-mediated phosphorylation and activation of PLC γ 2. The adapter proteins SLP-76 and LAT form an intracellular scaffold in this cascade that facilitates activation of PLC γ 2. Although the essential features of signalling by all ITAM-associated receptors are conserved, the individual proteins that make up an ITAM signalling pathway are cell specific.

Although GPVI is primarily known as a receptor for collagen, it is also activated by laminin and by globular adiponectin. Because of the low affinity for GPVI, the interaction with laminin requires prior binding to the integrin $\alpha_6\beta_1$. Laminin is a major component of the basement membrane and may therefore mediate platelet activation following minor injuries that fail to expose subendothelial collagen or tissue factor. The significance of the interaction with globular adiponectin is unclear, especially as low levels are associated with type 2 diabetes and metabolic syndrome.

The primary role of integrin $\alpha_2\beta_1$ is to support platelet adhesion to collagen at sites of damage to the vasculature and to cause a net increase in binding to GPVI in view of the modest affinity of collagen for the immunoglobulin receptor. Integrin $\alpha_2\beta_1$ also mediates weak activation of PLC γ 2, although the physiological significance of this is unclear due to the more powerful action of GPVI and the redundancy in signalling with other receptors. The physiological significance of $\alpha_2\beta_1$ in supporting thrombus formation *in vivo* is masked by the much greater level of expression of integrin $\alpha_{IIb}\beta_3$.

Several patients have been described with acquired disorders that lead to reduction or abrogation of expression or signalling by GPVI. In general, these patients exhibit mild bleeding, but the presence of additional complications means that it is unclear if this is due solely to the defect in GPVI. Only three patients have been described with an acquired deficiency of $\alpha_2\beta_1$ and they too have other vascular complications. Polymorphisms in the non-coding region of the α_2 subunit lead to a threefold to fivefold increase in expression of the integrin. A weak correlation has been found between the high-expressing polymorphic forms and thrombotic disease.

Integrin $\alpha_{IIb}\beta_3$

Integrin $\alpha_{IIb}\beta_3$ is the most abundant protein on the platelet surface and is estimated to comprise approximately 15% of surface proteins, with less than 20 nm between individual receptors. As discussed above, $\alpha_{IIb}\beta_3$ binds to several bivalent ligands in the vasculature including fibrinogen, VWF, fibronectin and vitronectin. Although all of these are capable of supporting platelet aggregation, fibrinogen is considered to be the major ligand because of its much higher concentration in plasma. In all cases, the binding of these soluble ligands requires 'inside-out' activation of integrin $\alpha_{IIb}\beta_3$ to a high-affinity conformation in the presence of divalent cations.

The clustering of $\alpha_{IIb}\beta_3$ generates weak 'outside-in' signals that have been shown to induce platelet spreading, clot retraction and secretion in combination with other platelet agonists such as ADP. The integrin signals through at least two and possibly more pathways. The most thoroughly characterized of these is the activation of Src and Syk tyrosine kinases by direct interaction with the β_3 cytosolic tail. The sequential activation of these two kinases leads to actin polymerization and activation of PLC γ 2. In addition, the β_3 cytosolic tail has been shown to bind and activate cytosolic PLA₂ independent of the former pathway. Although the work of Shattil and others has established that $\alpha_{IIb}\beta_3$ regulates Syk independent of an ITAM, there is recent evidence that the integrin signals in human platelets through the low-affinity immune receptor Fc γ RIIA, despite the fact that it is expressed at 3000–5000 copies per platelet (i.e. ~ 4% of the level of $\alpha_{IIb}\beta_3$). The challenge therefore is to establish the relative importance of all these pathways in $\alpha_{IIb}\beta_3$ signalling, although this is particularly difficult as Fc γ RIIA is not expressed in the mouse genome.

The discovery that the Arg-Gly-Asp (RGD) sequence in fibronectin mediates its interaction with integrin $\alpha_5\beta_1$ led to the unexpected discovery that small peptides or snake toxins containing this sequence could also inhibit binding of fibronectin to integrin $\alpha_{IIb}\beta_3$. This subsequently resulted in the realization that other matrix proteins use RGD to bind to integrin $\alpha_{IIb}\beta_3$, including VWF, vitronectin and CD40 ligand. Paradoxically, however, the major site of interaction of fibrinogen with the integrin is via a KQAGDV sequence at the C-termini of its two γ -chains, even though it has two pairs of RGD sequences and the binding of fibrinogen can be blocked by synthetic RGD-containing peptides.

The critical role of integrin $\alpha_{IIb}\beta_3$ in aggregation, coupled with the fact that the other antiplatelet agents available at the time (namely aspirin and ticlopidine, which has been superseded by clopidogrel) are not completely effective in preventing cardiovascular events, encouraged the groups of Collier and Phillips to develop inhibitors of integrin $\alpha_{IIb}\beta_3$ as novel antiplatelet agents. A chimeric Fab molecule, abciximab, was introduced into the clinic in 1994 and was later followed by two RGD-based peptide inhibitors, eptifibatid and tirofiban. The three inhibitors have been approved for use in patients undergoing percutaneous coronary interventions involving stenting and in patients with unstable angina. Excessive bleeding and thrombocytopenia are major side-effects for all three of these $\alpha_{IIb}\beta_3$ -blocking agents and thus limits their use to patients considered to be at high risk of thrombosis within a hospital setting. Unexpectedly, clinical trials with orally active $\alpha_{IIb}\beta_3$ antagonists were associated with increased mortality, increased bleeding and occasional severe thrombocytopenia. The reason for the lack of efficacy is partly due to induction of conformational changes in the integrin that expose neopeptides and can therefore lead to platelet activation through the low-affinity immune receptor Fc γ RIIA, as recently demonstrated by Newman's group.

G protein-coupled receptors

P2Y₁ and P2Y₁₂ ADP receptors

ADP was reported to activate platelets in the early 1960s but it has only been within the last decade that its critical role as a positive feedback agonist has finally been established. This delay in recognition arose because ADP is a weak platelet agonist, and it is only through its ability to mediate powerful platelet activation in synergy with Ca²⁺-mobilizing receptors via the P2Y₁₂ receptor that its critical role in thrombus formation is achieved. The latter is illustrated by the clinical efficacy of the P2Y₁₂ receptor antagonist, the thienopyridine clopidogrel (Plavix), in the long-term prevention of thrombosis. Clopidogrel is a prodrug that is metabolized by the liver to generate an active metabolite that covalently modifies, and therefore irreversibly inhibits, the P2Y₁₂ ADP receptor. The related thienopyridine prasugrel, which is at an advanced stage of clinical development, is metab-

olized more rapidly to the same active metabolite as clopidogrel and therefore has a faster onset of action. Two competitive P2Y₁₂ receptor antagonists that are analogues of ADP are also in clinical development, cangrelor (AR-C69931MX) and ticagrelor (AZD6140). Competitive antagonists have the advantage of a faster onset of action as well as increased safety due to their reversible nature. Ticagrelor, but not cangrelor, is available after oral administration and so has potential in the long-term treatment of patients at risk of thrombosis.

ADP stimulates sustained platelet aggregation in platelet-rich plasma through the synergy between the P2Y₁₂ receptor, which is coupled to the G_i family, and the P2Y₁ receptor, which is coupled to G_q. In contrast, each receptor stimulates only weak partial aggregation, which in the case of P2Y₁ is not sustained. There are about 150 copies of P2Y₁ per platelet and it has been proposed that its role is to support rapid platelet activation in synergy with P2Y₁₂. At later times, its action is masked by the activation of thrombin and TxA₂ receptors, which are expressed at five to ten times higher levels and which signal through G_q and G₁₃. Consistent with this, arterial but not venous thrombus formation is reduced in mice deficient in the P2Y₁ receptor or which have been pretreated with a P2Y₁ receptor antagonist. However, it is unclear whether the P2Y₁ receptor performs a similar function in humans, as patients with a bleeding disorder associated with a defect in P2Y₁ have not been described. A striking feature of the P2Y₁ receptor is its ability to undergo rapid desensitization and this, together with its low level of expression, may serve to prevent activation of platelets following exposure to ADP in the absence of other platelet stimuli. This may occur, for example, following damage of other vascular cells.

The P2Y₁₂ ADP receptor activates the G_i family of G proteins, predominantly G_{i α 2}, leading to inhibition of adenylyl cyclase and activation of phosphatidylinositol 3-kinase (PI3K). It is the latter, and possibly other pathways, that underlies its ability to synergize with Ca²⁺-mobilizing receptors, whereas inhibition of adenylyl cyclase on its own is insufficient to mediate activation. Eight gene mutations in P2Y₁₂ have been identified in patients with a mild bleeding disorder, consistent with its critical role in supporting platelet activation. This number is likely to rapidly increase as testing and sequencing procedures are refined.

TxA₂ receptor

TxA₂ signals through a single G protein-coupled receptor, the TP receptor, which is coupled to G_q and G₁₃ heterotrimeric G proteins, which activate PLC and Rho kinase, respectively. The TP receptor is alternatively spliced in its C-terminus to two isoforms, TP α and TP β , which have the same pharmacology and signal in the same way. The consensus is that platelets express only the TP α isoform and certainly the field assumes that the platelet has a single TP receptor. TxA₂ has a very short half-life and is rapidly metabolized to the inactive metabolite TxB₂, which prevents its use in functional studies, where the

stable mimetic, U46619, is preferred. TxB_2 is routinely used to monitor formation of TxA_2 by radioimmunoassay and U46619 is sometimes used in the clinical evaluation of patients with suspected thromboxane receptor defects. Arachidonic acid, which is a direct substrate for cyclooxygenase, is used to check for activity of the TxA_2 pathway.

The clinical importance of the TxA_2 pathway in platelet activation is illustrated by the antithrombotic action of aspirin, which inhibits platelet cyclooxygenase. The irreversible nature of the acetylation induced by aspirin, in combination with the inability of platelets to synthesize significant levels of new proteins, means that the effective antithrombotic concentration of aspirin is considerably lower than that required to target cyclooxygenase in other cells. Large-scale clinical trials have shown that aspirin reduces the mortality of myocardial infarction by approximately 25% and the number of major vascular events in individuals at risk by about one-third. The clinical effectiveness of low-dose aspirin is similar to that of the P2Y_{12} receptor antagonist clopidogrel. An Arg→Leu mutation in the first extracellular loop of the TP receptor has been linked to a mild bleeding syndrome in two unrelated families, although 'aspirin-like' defects are frequently seen in patients with mild platelet-based bleeding disorders, suggesting that the number of mutations in this receptor is likely to increase.

PAR-1 and PAR-4 thrombin receptors

Thrombin is among the most powerful of all platelet agonists and induces activation of human platelets through the proteolytic cleavage of PAR-1 and PAR-4, and of mouse platelets through binding to PAR-3 which facilitates cleavage and activation of PAR-4. Thrombin releases a short peptide from the N-terminal region of PAR-1 and PAR-4 to expose a sequence that functions as a tethered ligand by binding to the receptor and promoting activation. Synthetic peptides corresponding to the newly exposed receptor-specific sequences induce activation in the absence of receptor cleavage. These thrombin receptor-activating peptides can be used to selectively activate the individual PAR receptors. In humans, it is believed that PAR-1 mediates rapid activation in response to low concentrations of thrombin, whereas PAR-4 is activated by higher concentrations of the protease. PAR-1 and PAR-4 signal through G_q and G_{13} heterotrimeric G proteins, activating PLC β and Rho kinase, respectively. Patients with defects in either of the thrombin receptors have yet to be identified, possibly because defects in thrombin-mediated platelet activation are not routinely investigated in a clinical setting.

The GPIb α subunit of the GPIb-IX-V expresses a high-affinity binding site for thrombin that is believed to position the protease in the vicinity of the PAR-1 and PAR-4 receptors in order to facilitate activation, in line with increasing evidence that the various actions of thrombin are achieved through binding to proteins that localize the protease to specific sites. There is limited and controversial evidence to suggest that

binding of thrombin to GPIb α generates weak signals, but the major pathway of platelet activation is believed to be mediated through the PAR-1 and PAR-4 receptors. Several direct inhibitors of thrombin are used in the clinic as anticoagulants in patients at risk of heparin-induced thrombocytopenia. To our knowledge, there is no direct evidence indicating that their clinical efficacy is also mediated through inhibition of platelet activation.

Other platelet receptors and their ligands

Platelets express a large number and diversity of receptors for a variety of ligands, including adhesive proteins, amines, chemokines, cytokines, lipids, nucleotides, proteases and transmembrane proteins. Many of the receptors are present at such a low level, or are not ordinarily exposed to their ligand, that their physiological role in mediating or potentiating activation may be minimal, although they could potentially play a role in disease. Examples include regulation of human platelets by endothelin-1, Gas6, insulin-like growth factor, leptin, vasopressin, platelet-activating factor and PDGF. In some cases, expression of a receptor on the platelet surface appears to reflect a role in megakaryocyte development/platelet formation rather than in regulating platelet activation. Examples include the SDF-1 α receptor, CXCR4, and the TPO receptor c-Mpl. SDF-1 α plays a key role in supporting migration of megakaryocytes to the vascular niche in bone marrow and TPO is the major regulator of megakaryocyte growth and development. Both receptors also mediate weak potentiation of platelet activation, although the physiological significance of this is unclear. As discussed above, there is also increasing evidence for the role of a number of surface proteins in mediating 'late events' that serve to consolidate the growing thrombus. The function of a number of the other platelet receptors is discussed below.

5-HT_{2A} receptors

Platelets contain very high levels of 5-HT, which is taken up by an active transport mechanism and stored in dense granules. Release of 5-HT induces powerful vasoconstriction, thereby limiting blood loss. 5-HT mediates weak platelet activation through the 5-HT_{2A} receptor, which is coupled to G_q , but there is little evidence to suggest that this plays a major role in supporting thrombus formation.

α_{2A} -Adrenoceptor

Adrenaline activates the α_{2A} -adrenoceptor, which is coupled to the G_i family of proteins, predominantly G_z . As is the case for the P2Y_{12} ADP receptor, the α_{2A} -adrenoceptor is able to induce powerful platelet activation in synergy with Ca^{2+} -mobilizing receptors. Platelet dense granules contain a very low level of adrenaline and the catecholamine is also present in plasma. Recent studies in α_{2A} -adrenoceptor knockout mice have provided evidence for a minor physiological role of adrenaline in

supporting haemostasis, although it is not clear if this is also the case in humans, even though platelet function tests frequently use adrenaline as a co-agonist.

P2X₁ ATP receptor

P2X₁ is a receptor for ATP, which is released alongside ADP from dense granules. It is the only known ligand-gated ion channel on the platelet surface. Binding of ATP promotes direct entry of Ca²⁺ into the platelet, which occurs over a much more rapid time course than IP₃-mediated Ca²⁺ mobilization and subsequent entry of extracellular Ca²⁺ via store-operated Ca²⁺ entry. The P2X₁ receptor has been shown to induce platelet shape change but requires the presence of other receptors to mediate aggregation. The physiological role of P2X₁ may therefore be to facilitate rapid activation of platelets in synergy with other agonists, including ADP, in a similar way to that proposed for P2Y₁. In this context, it is intriguing that P2X₁ also undergoes extremely rapid desensitization and this too may serve to prevent 'unwanted' activation. There is evidence from studies in mutant mice that the P2X₁ receptor contributes to, but is not essential for, thrombus formation, and as yet no patients have been identified with a mild bleeding disorder attributed solely to a mutation in the ion channel.

FcγRIIA

Clustering of the low-affinity immune receptor FcγRIIA by immune complexes or via primary and secondary antibodies mediates powerful activation through an ITAM-based pathway that is believed to be similar to that used by the collagen receptor GPVI. FcγRIIA is not thought to have a physiological role in supporting thrombus formation, but it mediates activation by immune complexes and is the causative receptor in heparin-induced thrombocytopenia. It is intriguing that FcγRIIA is absent from the mouse genome and that mice platelets do not appear to express an Fc receptor.

CD36

The scavenging receptor CD36 is among the most highly expressed of platelet surface glycoproteins being present at approximately 20 000 copies per platelet. Despite the fact that it was first identified on platelets more than 30 years ago, it is only within the last 2 years through the work of Eugene Podrez and colleagues that it has been implicated as a major player in mediating the increased platelet responsiveness seen in patients with dyslipidaemia. Oxidized choline glycerophospholipids are present at sufficiently increased levels in the plasma of humans with low levels of high-density lipoprotein to potentiate activation of platelets by threshold concentrations of ADP and other agonists. Moreover, this potentiation is not seen in individuals who do not express CD36 on their platelets, suggesting that they may be protected against the dyslipidaemia-induced prothrombotic state. However, further research is required to evaluate the contribution of platelet CD36 to cardiovascular disease.

CLEC-2

The C-type lectin receptor CLEC-2 has recently been shown to mediate powerful activation of platelets in response to the snake venom toxin rhodocytin, or its endogenous ligand podoplanin. The latter is expressed on lymphatic endothelial cells, renal epithelial cells, type I lung alveolar cells and on the leading edge of tumours, where it is implicated in cancer metastasis. Mice deficient in CLEC-2 or podoplanin die shortly after birth, and embryos at mid- to late gestation from both sets of mice have blood-filled lymphatics and severe oedema due to defective separation of lymphatic vessels from the blood vasculature. CLEC-2 signals through an ITAM-like pathway similar to that used by GPVI and FcγRIIA, although intriguingly it uses a single rather than a tandem YXXL motif to activate Syk.

Second messenger pathways underlying activation

The activation of PLCγ2 and PLCβ (predominantly β2) isotypes by tyrosine kinase-linked or G protein-coupled receptors, respectively, generates IP₃ and 1,2-diacylglycerol (DG), which mobilize Ca²⁺ and activate protein kinase C (PKC), respectively. The G protein α-subunit G₁₃ regulates the GTP exchange factor (GEF), p115Rho, to form active Rho, a small G protein that regulates a number of effectors, including inhibition of myosin light chain phosphatase thereby inducing phosphorylation of myosin light chains leading to shape change and actin-stress fibre formation. G_i-coupled receptors inhibit adenylyl cyclase and activate PI3K, the latter underlying the remarkable synergy with Ca²⁺-mobilizing receptors. These second messenger pathways are discussed in further detail.

Calcium

The divalent cation Ca²⁺ plays a critical role in mediating platelet activation, usually in combination with other signalling pathways. An increase in Ca²⁺ is brought about by its release from intracellular stores by the action of IP₃ and by entry through the plasma membrane, predominantly through store-operated Ca²⁺ entry. The latter has recently been shown to occur via binding of the transmembrane protein STIM-1, which is localized to intracellular stores, to the surface membrane Ca²⁺ channel, Orai-1, with the trigger for entry being the release of Ca²⁺ from the store. The entry of Ca²⁺ through Orai-1 is critical for procoagulant activity and possibly other responses, but interestingly is not required for aggregation. The released Ca²⁺ is efficiently removed from the cytosol by Ca²⁺-ATPases in the endoplasmic reticulum (SERCA) and in the plasma membrane (PMCA).

Diacylglycerol and protein kinase C

PKC refers to a family of structurally similar lipid-regulated protein kinases that is divided into *classical* isotypes regulated

by Ca^{2+} and DG, *novel* isotypes regulated by DG, and *atypical* isotypes regulated independently of the two messengers. Human platelets express two classical isotypes, α and β , and three novel isotypes, δ , θ and η . The novel isotype PKC ϵ is also expressed in mouse platelets. PKC α is the major isoform regulating dense granule and α -granule platelet secretion in mouse platelets, with increasing evidence suggesting that the other PKCs have isotype-specific inhibitory and activatory roles.

DG, together with Ca^{2+} , regulates the Rap1 (also known as Rap1b) GTP exchange factor, CALDAG-GEF1. Rap1 plays a critical role in mediating activation of integrin $\alpha_{\text{IIb}}\beta_3$, although this role can be bypassed by high concentrations of powerful ligands. CALDAG-GEF1-deficient mice and patients with defective expression of the exchange factor (leucocyte adhesion deficiency type III) have defective Rap1 activation and a bleeding diathesis.

Phosphatidylinositol 3-kinase

PI3K generates from phosphatidylinositol 4,5-bisphosphate the 3-phosphorylated lipid second messenger phosphatidylinositol 3,4,5-trisphosphate, which is rapidly hydrolysed to phosphatidylinositol 3,4-bisphosphate, which is also believed to be a messenger. The two 5-phosphorylated lipids mediate translocation of proteins containing one or more pleckstrin homology (PH) domains to the membrane, including PLC β and PLC γ isoforms, protein kinase B (Akt) and the Tec family kinases Btk which mediates phosphorylation of PLC γ 2. Platelet express several regulatory and catalytic subunits of PI3K, although p110 β and p85 α are believed to be the major catalytic and regulatory subunits supporting activation downstream of both G protein-coupled and tyrosine kinase-linked receptors.

The molecular basis of platelet activation

The physiological end points of platelet activation are stable adhesion, aggregation, granule secretion, TxA₂ formation, spreading with stress fibre formation, clot retraction and pro-coagulant activity. These responses are regulated by a bewildering interplay between tyrosine kinase- and G protein-regulated signalling pathways, with evidence of considerable redundancy in their actions. Here we provide brief details on the major mechanisms that underlie each of these events.

Stable adhesion and aggregation

Both of these responses are mediated through activation of integrin $\alpha_{\text{IIb}}\beta_3$ by 'inside-out' signals from tyrosine kinase and G protein receptors. Activation of the integrin is brought about by the binding of talin to the β_3 cytoplasmic tail via a FERM domain in its head region. Platelet activation is associated with the recruitment of talin from the cytoplasm to the β_3 tail via a

process that remains poorly understood but which is regulated in part by binding of Rap1 to its effector protein RIAM. The interaction of talin with the β_3 tail leads to separation of a salt bridge between the α_{IIb} and β_3 subunits, and a resulting conformational change in the extracellular region of the integrin from a bent to an extended conformation. Recently, the FERM domain-containing protein kindlin-3 has also been shown to bind to the β_3 tail and to mediate activation in combination with talin, although the precise details of this interaction remain to be established. Ligand engagement of the integrin leads to clustering and generation of 'outside-in' signals that stimulate actin polymerization and PLC γ 2, which support many aspects of platelet activation including spreading and granule secretion.

Secretion

Platelet dense granule and α -granule secretion is triggered through a synergistic interaction between Ca^{2+} and PKC-regulated pathways, with both arms being critical for secretion to occur. Granule fusion is orchestrated by a superfamily of proteins termed SNAREs (soluble N-ethylmaleimide-sensitive attachment protein receptors) that form a universal membrane fusion machine. The activity of SNARE proteins is regulated by a series of chaperone proteins that facilitate membrane fusion. PKC phosphorylates several SNARE and chaperone proteins, including Munc-18, syntaxin-4 and SNAP-23, altering their affinity for their binding partners. For example, phosphorylation of Munc-18 interferes with its ability to bind to syntaxin-4 and phosphorylation of syntaxin-4 by PKC inhibits its ability to bind SNAP-23. This allows syntaxin-4 to interact with SNARE proteins on the opposing membrane, promoting fusion and granule secretion. There is evidence for differential regulation of the two sets of granules, although the molecular basis of this is not known and in general dense granule and α -granule secretion occur together.

TxA₂ formation

Cytosolic PLA₂ liberates arachidonic acid from membrane phospholipids and is regulated by Ca^{2+} and serine phosphorylation downstream of mitogen-activated protein kinases. Ca^{2+} is critical for activation whereas phosphorylation causes a relatively small increase in activity and on its own is insufficient to mediate activation. The liberated arachidonic acid is metabolized by cyclooxygenase and thromboxane synthase to PGG₂/PGH₂, which immediately convert into TxA₂, and by lipoxygenase enzymes to leukotrienes.

Actin polymerization

Activation of platelets leads to a series of dramatic changes in platelet morphology that helps to secure the thrombus at the site of injury in the high-pressure arteriolar system. In addition,

actin polymerization plays an important but poorly understood role in signalling by platelet surface glycoprotein receptors, including GPVI and integrin $\alpha_{IIb}\beta_3$. Actin is assembled into a number of morphological distinct structures, including filopodia, actin nodules, lamellipodia and stress fibres downstream of small GTP-binding proteins. For example, the small G protein Rac1 drives formation of lamellipodia in platelets through the Arp2/3 complex, while the small G protein Rho regulates formation of actin–myosin stress fibres. Mice deficient in Rac1 or treated with inhibitors of Rho kinase have unstable aggregates, emphasizing the importance of actin polymerization in generating and strengthening the thrombus. The small G protein(s) that regulates formation of filopodia and actin nodules in platelets, and the significance of these structures, is yet to be clarified.

Inhibitory agonists and their receptors

It is essential for platelets to have powerful inhibitory mechanisms that prevent activation in intact healthy vessels and which limit thrombus growth during haemostasis. The prevention of platelet activation in the intact circulation is ordinarily achieved by the antithrombotic nature of the endothelial cell surface, which has effective mechanisms for removal of platelet stimulatory agonists by endothelial cells, most notably ADP and thrombin, and by the release of NO and prostacyclin from endothelial cells. The endothelial cell surface expresses the ecto-ADPase CD39, which removes circulating ADP, and thrombomodulin, which regulates the level of thrombin. The role of CD39 in removing ADP is critical given the ability of the nucleotide to induce activation in synergy with other agonists.

The major direct mechanism of inhibition of platelet function is through elevation of the cyclic nucleotides cGMP and cAMP by NO and prostacyclin, respectively. The two cyclic nucleotides mediate their effects in platelets through regulation of cGMP-dependent protein kinase (PKG)-1 and cAMP-dependent protein kinase (PKA). In addition, cGMP regulates the three major platelet phosphodiesterases (PDEs), including inhibition of PDE3, thereby leading to an increase in the level of cAMP. There is therefore cross-talk between the two cyclic nucleotides even though many of the targets for PKG-1 and PKA are believed to be distinct. This is illustrated by the demonstration that PKG-1 but not PKA mediates inhibition of platelet activation through phosphorylation of the IP3 receptor-associated cGMP kinase substrate (IRAG), which is expressed in a macromolecular complex with PKG-1 and the IP3 receptor type 1. Phosphorylation of IRAG by PKG-1 inhibits IP3-induced Ca^{2+} release and, importantly, targeted deletion of the IP3-binding region of IRAG prevents NO-mediated inhibition of platelet activation, whereas the inhibitory effect of cAMP is retained. In contrast, elevation of cAMP has been shown to lead

to inhibition of activation of PLC. The two cyclic nucleotides induce phosphorylation of many substrates in platelets, including VASP, and it is likely that phosphorylation of several of these mediates platelet inhibition.

There is evidence that a family of platelet glycoproteins, characterized by the presence of tandem immunoreceptor tyrosine-based inhibitory motifs (ITIMs) in their cytosolic tails, mediate weak inhibition of activation by both tyrosine kinase-linked and, to a lesser extent, G protein-coupled receptors. PECAM-1 is the most characterized of this family of proteins and is expressed at a level of approximately 10 000 copies per platelet. Two further inhibitory ITIM-containing transmembrane proteins have recently been identified, G6b-B and CEACAM-1, although paradoxically a further ITIM protein that becomes exposed on activation, TREM-like transcript (TLT)-1, supports weak activation. It has been proposed that the inhibitory ITIM proteins mediate their effects through binding to the tandem SH2 domain-containing protein tyrosine phosphatases SHP-1 and SHP-2, but as yet there is no direct evidence for this. The functional significance of this relatively weak effect is unclear, and perhaps a more intriguing proposal is that ITIM receptors help to dampen down constitutive signalling by tyrosine kinases in non-stimulated platelets, thereby helping to prevent unwanted platelet activation.

The endothelial surface also plays a significant role in preventing excessive thrombus growth, again through removal of ADP and thrombin, by release of NO and prostacyclin, and by activation of the fibrinolytic pathway. Additional mechanisms also help to limit excessive growth, including shedding of platelet surface glycoprotein receptors, cleavage of intracellular proteins through calpain, and removal of intracellular messengers and reversal of phosphorylation by the action of tyrosine and serine/threonine phosphatases.

Nitric oxide

NO is the most important inhibitor of platelet function. It is constitutively released from endothelial cells and can also be inducibly upregulated. NO has a short half-life in the vasculature, of the order of 3–5 s, which results in the highest concentration of the gaseous transmitter being found in the vicinity of the endothelial cell, a key site of inhibition of platelet function. NO mediates powerful inhibition of platelet activation and promotes vasodilatation. These effects are mediated through direct activation of guanylyl cyclase, leading to the generation of cGMP and activation of protein kinase G (PKG). The substrates for PKG in platelets include PDE3, which hydrolyses cAMP as described above. Thus, NO mediates inhibition through elevation of both cAMP and cGMP. Phosphorylation of the combined PKA/PKG substrate VASP, an actin-binding protein, is often used to assess activation of inhibitory pathways and be achieved by both Western blotting and flow cytometry.

Prostacyclin

Prostacyclin (PGI₂) is the major prostaglandin released by endothelial cells. It is synthesized in stimulated endothelial cells from arachidonic acid through the sequential actions of cyclooxygenase and prostacyclin synthetase. Prostacyclin activates the seven-transmembrane-spanning IP receptor on platelets, which is coupled to G_s and thereby activates adenylyl cyclase. Prostacyclin exerts a powerful inhibitory effect on platelets and also promotes vasodilatation through elevation of cAMP. Prostacyclin also has a short half-life in the vasculature and so its primary action is believed to occur in the vicinity of the vessel wall when the growing thrombus comes into contact with the endothelium. This action is facilitated by the liberation of arachidonic acid from the platelet, which is converted to prostacyclin by the endothelial cells.

Adenosine

Platelets express the adenosine A_{2A} receptor, which is also coupled to G_s. However, the A_{2A} receptor is expressed at a low level and is not considered to be a major route of inhibition. However, increased adenosine levels induced by dipyridamole may contribute to its antithrombotic action.

Platelet-based bleeding problems

Bleeding can be due to abnormalities in platelet function/number or to extensive antiplatelet medication. Abnormalities in either platelet function and/or number are associated with an increased risk of classical bleeding symptoms and clearly demonstrate the importance of platelets in haemostasis. Patients with platelet disorders present with a typical mucocutaneous bleeding pattern of variable severity and are often prone to bleeding during surgery and trauma. However, inherited platelet defects are an uncommon cause of bleeding and are difficult to diagnose and manage, with wide variation in practices between laboratories. Before any platelet function test is requested, a full clinical and family history is taken to determine the underlying cause of the bleeding problem. This includes studying the pattern of bleeding, whether it is lifelong or recent, triggered by trauma (e.g. dentistry, surgery or accident), is present within other family members and associated with any medication the patient may be taking. As von Willebrand disease is the most commonly inherited bleeding disorder but presents with a platelet-like bleeding pattern, many patients including those with potential coagulation defects usually undergo a series of investigations for a bleeding disorder that includes platelet function and coagulation testing. Although bleeding histories are subjective and can vary within a lifetime, they remain an important screening method for diagnosing a

potential platelet defect. However, it is also important to exclude acquired defects of platelet function, including those caused by antiplatelet drugs and other clinical disorders. A complete drug history is therefore important as aspirin and non-steroidal anti-inflammatory drugs are the commonest causes of an acquired platelet defect and testing may have to be deferred and repeated. Some patients are also screened before surgery to exclude the presence of either an inherited or acquired platelet defect because of the associated increased risk of bleeding. Inherited platelet defects can be classified according to the severity of bleeding, with severe disorders such as Glanzmann thrombasthenia and Bernard–Soulier syndrome usually being detected very early in life, while more mild bleeding disorders (e.g. due to P2Y₁₂ deficiency) often not being detected for many years until the patient is exposed to surgery or trauma. Indeed, there is overlap between symptoms in milder platelet defects and the normal population, which may be partly related to varying levels of plasma VWF, making the former group difficult to diagnose. Further information on inherited platelet bleeding disorders is given in Chapter 48.

Platelet function testing

Platelet function tests are primarily used to aid in the diagnosis and management of patients presenting with bleeding problems. If a platelet defect is suspected, then there is a variety of tests available that can be used to diagnose any underlying cause of the bleeding problem. The investigation of platelet function is often affected by the collection and processing of blood samples. Platelets are prone to not only artefactual *in vitro* activation but also desensitization. Normal platelet function is highly dependent on extracellular Ca²⁺ and Mg²⁺ concentrations and so the choice of anticoagulant is important even though citrate remains the most widely used traditional anticoagulant. Most current testing is still performed on citrated blood within a few hours of sampling.

Global tests of platelet function are often initially used as screening tests during the laboratory investigation of individuals with suspected haemostatic defects. Since global tests of platelet function do not enable specific diagnosis of platelet disorders, they are normally performed as the first part of a two-step strategy that requires further testing with more specialized assays of platelet function to confirm or refute any clinical diagnosis. The most commonly proposed rationale for testing global platelet function as a first-line investigation is exclusion of a platelet function disorder so that further specialized testing can be avoided. For this reason, global platelet function tests are usually initially performed at the same time as global assays of coagulation pathway function (prothrombin time and activated partial thromboplastin time), VWF screening tests (VWF:Ag, VWF:RCo and FVIII:C) and measurement

of platelet number with a full blood counter. The most widely performed tests for initially screening platelet function disorders are currently the template bleeding time, light transmission aggregometry (LTA) and the closure time within the platelet function analyser (PFA)-100.

The bleeding time was the first *in vivo* test of platelet function and is performed by timing the arrest of bleeding from standard-sized cuts made in the skin of the forearm. Although the test has been refined, most clinicians consider the test to be poorly reproducible, invasive, insensitive (particularly to mild platelet defects) and time-consuming. Despite these drawbacks, the test is surprisingly still widely used as a first-line screening tool and can identify patients with severe platelet defects. However, given the problems faced with the *in vivo* bleeding time, a number of *in vitro* tests that attempt to accurately simulate platelet function have been developed. These include the PFA-100 and cone and plate(let) analyser (CPA) devices. These simulate high-shear platelet adhesion to foreign surfaces (e.g. collagen) and either monitor the drop in flow rate as an aperture is closed by platelet adhesion/aggregation or study the degree of platelet aggregation and surface coverage respectively. The PFA-100 instrument has been widely used for the last 10 years and provides optional replacement of the bleeding time as a limited screening test, as it is more sensitive to many platelet defects and von Willebrand disease. Although the instrument therefore has good negative predictive value for eliminating severe platelet defects and von Willebrand disease, it is very important that further diagnostic tests are still performed if clinical suspicion of a platelet defect is strong. The CPA has also been commercialized recently as the IMPACT device, which may also have potential as a screening tool, although it is still under development as a clinical test. The IMPACT-R or research version of the instrument is currently available and is not suitable for routine clinical use. However, it is highly likely that these types of instruments will be increasingly used in the future and may prove to be useful as aids in screening and diagnosing platelet defects, monitoring antiplatelet therapy and predicting bleeding and thrombosis in various patient groups.

Automated cell counting of whole blood in the modern full blood count investigation is an essential screening test in patients with abnormal bleeding. Modern blood counters can rapidly detect abnormalities in platelet number, platelet size distribution and mean platelet volume (MPV) and provide a reliable method for screening samples from patients provided good quality control procedures are followed within the laboratory. Normal results will therefore rapidly eliminate thrombocytopenia and anaemia as potential causes of bleeding and ensure that any platelet function tests that are being performed will not be affected by low platelet counts. If any abnormalities in platelet count, MPV or distribution are flagged by the instrument, then a blood smear should be examined to confirm defects in platelet number, size and granule content. Whole-blood morphology may also assist in the diagnosis of platelet

disorders by indicating abnormalities such as red cell schistocytes in TTP or neutrophil inclusions and giant platelets in MYH-9-related disorders.

Depending on the results of clinical and laboratory screening of patients, a series of diagnostic platelet function tests are usually performed. Since the 1960s, platelet aggregometry has quickly become the gold standard of platelet function testing and has revolutionized our ability to identify and diagnose a wide variety of platelet defects. Conventional Born aggregometers monitor the changes in light transmission that occur in a suspension of platelets in plasma or a physiological buffer that are stimulated with different concentrations of various agonists (e.g. ADP, collagen, adrenaline, ristocetin). Whole-blood impedance base aggregometers are now also common and measure the changes in electrical resistance between two electrodes caused by platelet adhesion and aggregation after addition of agonists. Typical parameters recorded from LTA tracings include shape change, lag phase, rate of aggregation, and maximal and final extent of aggregation. These parameters, coupled with the pattern of primary and secondary aggregation responses obtained with different dosages of different agonists, enable the experienced operator to diagnose specific signalling defects. Modern aggregometers are now multichannel, fully computerized, easy to use compact instruments and some can also simultaneously measure ATP secretion levels by luminescence (Figure 40.7). Measurement of the storage and release of the dense granular nucleotides can also be performed by a variety of alternative methods for confirming either storage and/or release defects, although recent surveys suggest that this is underused. The interpretation of aggregation traces remains challenging due to the feedback actions of ADP and TxA₂, as illustrated in Figure 40.7 for a 10- μ mol/L concentration of ADP.

The introduction of flow cytometry into haematology laboratories provided an exquisite, sensitive and powerful tool for studying and diagnosing various platelet defects. Flow cytometric analysis of platelets is performed in fresh whole blood or in platelet-rich plasma, and the technique can be used with very small fluid volumes, even in thrombocytopenia. This technique is used to determine the copy density of platelet membrane glycoproteins and receptors, and is therefore useful for confirming the absence of various glycoproteins or receptors in disease. Platelet function testing can also be performed and the ability of platelets to degranulate, express activation markers (e.g. P-selectin) and expose procoagulant phospholipids can also be diagnostically useful. A major limitation of the above tests is that they are performed at low shear conditions and therefore do not mimic accurately many of the important physiological processes of platelet adhesion, activation and aggregation that occur at higher shear rates *in vivo*. Development of new tests that attempt to accurately simulate primary haemostasis has therefore become a growth industry (e.g. PFA-100, IMPACT and Placor PRT).

Figure 40.7 The effect of pharmacological inhibitors on ADP-induced platelet aggregation and secretion. ADP ($10\ \mu\text{mol/L}$) stimulates rapid sustained aggregation and ($\alpha_{\text{IIb}}\beta_3$ -dependent) ATP secretion as measured using Born lumiaggregometry. In the presence of the cyclooxygenase inhibitor indomethacin ($10\ \mu\text{mol/L}$), ADP stimulates marked aggregation that slowly (minutes) decays, whereas secretion is abolished. Aggregation is preceded by a small increase in optical

density (shape change) that is inhibited in the presence of the P2Y_1 antagonist MRS2179 ($100\ \mu\text{mol/L}$). Aggregation and ATP secretion are partially reduced in the presence of MRS2179 ($100\ \mu\text{mol/L}$). In contrast, ADP stimulates a small transient aggregation response in the presence of the P2Y_{12} receptor antagonist AR-C67085 ($1\ \mu\text{mol/L}$), whereas secretion is abolished. (From Dawood *et al.* 2007 with permission.)

There is clearly still no gold standard for platelet testing, and indeed there may never be, and LTA remains the most widely used test. However, a variety of screening and diagnostic tests coupled with an accurate bleeding history will always be required to confirm a platelet-based bleeding disorder, simply because of the heterogeneity in the range of disorders encountered coupled with the cross-talk between receptors. Specialist test centres will therefore still be required for the identification of rare and new platelet-based defects.

Platelets and thrombosis

There is also much recent interest in the possibility of using platelet function tests to reliably detect platelet hyperreactivity in patients with arterial thrombosis (e.g. myocardial infarction, unstable and stable angina, stroke, transient ischaemic attacks and peripheral vascular disease). This could potentially allow patients to be risk stratified and their treatment adjusted accordingly to potentially improve their clinical outcomes. The increasing interest in this area and clinical discussion of aspirin or clopidogrel 'resistance' has also resulted in the development of a variety of instruments that can be useful for preclinical testing (e.g. Platelet Mapping System, VerifyNow, Plateletworks, Aspirinworks, Placor PRT). The VerifyNow test was originally developed as a whole-blood cartridge-based test to monitor $\alpha_{\text{IIb}}\beta_3$ blockade because of the narrow therapeutic window and increased bleeding risk associated with these types of drugs. The test has also been adapted to measure aspirin and P2Y_{12} block-

ade with two other cartridge formulations. Platelet responsiveness to antiplatelet drugs can now also be easily monitored by the tests mentioned as well as by LTA, whole-blood aggregometry, PFA-100 and IMPACT. Poor responders or 'resistant' individuals can therefore be identified, although it is still unclear how to manage them and whether there is a clinically relevant relationship between poor response and outcome. Emerging evidence suggests that the true incidence of so-called aspirin resistance is probably very low (when non-compliance is accounted for) and that many studies are measuring platelet hyperreactivity and not blockade of cyclooxygenase type 1. Although recent meta-analyses suggest that this could nevertheless be clinically informative, it is still unclear how to reliably identify these patients, with which test and cut-off (as different tests give different results) and then actually how to manage these patients. Testing is therefore still very much in the clinical research setting. Indeed, recent International Society for Thrombosis and Haemostasis (ISTH) Scientific and Standardization Committee guidelines suggest that aspirin resistance should still not be routinely monitored and the wider question remains whether routine testing of platelet hyperreactivity and/or drug responsiveness is actually clinically necessary. Certainly there is a spectrum of platelet responsiveness within the normal population and those individuals with a stable or even an acquired hyperreactive phenotype could theoretically be at higher risk of thrombosis.

Clopidogrel resistance is a totally different phenomenon as this is a prodrug that requires metabolism by liver cytochrome P450. This results in the generation of an active metabolite that

irreversibly inhibits the P2Y₁₂ receptor. Differences in the efficiency of metabolism between individuals (related to their P450 genotype) taking standard clopidogrel dosing results in a spectrum of responsiveness and recent meta-analysis suggests that poor responders are indeed prone to increased risk of thrombosis, especially when undergoing angioplasty. Again, there is a variety of tests available to monitor the efficacy of clopidogrel, including LTA, VASP phosphorylation and VerifyNow. One of the problems facing the investigator is not only which test to use but also the definition of a suitable cut-off defining a non-response and how to effectively manage these individuals. Although there are emerging clinical cardiology guidelines, as yet they do not include routine monitoring of clopidogrel responsiveness, but further research is required in this important area. This problem could potentially be eliminated by prasugrel (which is metabolized efficiently in clopidogrel non-responders) and the emerging direct P2Y₁₂ inhibitors cangrelor and AZD6140 (Ticagrelor), providing the risk of bleeding is within acceptable limits.

It is clear that large well-designed prospective trials are required in this area where patients with hyperreactive platelets and/or a poor response to aspirin/clopidogrel are randomized to different treatments based on a platelet function test result. Only with this type of data will personalized platelet function testing perhaps become a reality in the future.

Conclusions and future developments

Given that platelets were considered to be just pieces of circulating dust about 150 years ago, they are now one of the most important cells in pathology. Now that the megakaryocytic/platelet genome and proteomes are being defined, many new platelet proteins have been discovered and exact roles in haemostasis and thrombosis will shortly be defined. Nevertheless, with all these developments and information, the individual is left with a bewildering complexity and a feeling of 'where will it all end?' In considering this, it is important to recognize that, perhaps surprisingly, many of the proteins in platelets appear to have minor or negligible roles in regulating activation. The number of proteins and pathways that play major roles in regulating platelet activation is apparently much smaller.

The ultimate goal of most platelet research remains the development of improved antithrombotic agents that provide effective treatment without an increased risk of bleeding. Although it may never be possible to fully attain this goal, as we begin to understand more about the events that underlie thrombus formation, there will be increased opportunity for discovery of more rational forms of therapy. New medicines targeted to the very early stages of platelet activation or the amplification phase (as proven with aspirin and clopidogrel) may be more effective in preventing thrombosis without significantly disturbing normal haemostasis.

Acknowledgements

S.P.W. is a British Heart Foundation Chair. The authors gratefully acknowledge the support of the British Heart Foundation, Wellcome Trust and BBSRC, and all the past and present members of their laboratories who have significantly contributed to the ideas and thoughts that have formed the basis of this chapter. We are extremely grateful to Hans Deckmyn, Johan Heemskerk and Ban Dawood for careful reading of a near-final version and their constructive comments.

Introduction

The existence of lifelong bleeding disorders and their familial occurrence was noted in the medical literature as early as the 16th century. No doubt this was because the clinical syndrome of haemophilia is highly distinctive: early writers were impressed by the helplessness of the physician in the face of haemophilic bleeding. A full understanding of the pathophysiology and genetics of these disorders was long delayed because of the complexities of the clotting mechanism. Advances in protein chemistry and recombinant DNA technology have now produced a comprehensive account of normal coagulation, the coagulation defect in haemophilia and the underlying molecular genetics. An earlier chapter outlines the coagulation mechanism. In this chapter, the clinical features of the most common inherited bleeding disorders, haemophilia and von Willebrand disease (VWD), are described, together with a summary of the genetic lesions identified in their various deficiency states.

Advances in molecular biology have enabled more precise diagnosis and reduced the dependence on plasma-derived concentrates, at least in the economically rich countries. Direct identification of the mutation responsible for the factor deficiency in individual kindreds has provided a better understanding of structure–function relationships and the pathophysiology of the bleeding disorder. It has also superseded the use of

restriction fragment length polymorphisms (RFLPs), thus removing the uncertainty from carrier detection in the vast majority of cases.

Haemophilia A

Pathophysiology

Haemophilia A and B are caused by deficiency of factor (F)VIII and FIX respectively. FVIII and FIX are the two components of the intrinsic tenase (see Chapter 39) and so not surprisingly their absence causes virtually identical patterns of bleeding. Combined with the fact that they are both encoded on the long arm of the X chromosome (Xq28ter) they present almost indistinguishable sex-linked clinical syndromes and laboratory tests are required to determine which is present. In both cases, failure to form the intrinsic tenase complex results in failure to produce the thrombin burst characteristic of normal coagulation. As a result a loose friable fibrin mesh is produced that is mechanically easily dislodged and which has increased susceptibility to fibrinolysis. Fibrinolytic breakdown of the clot is also favoured by the failure of the weak thrombin burst to activate the thrombin-activatable fibrinolysis inhibitor (TAFI). The consequent failure to consolidate the primary haemostatic (platelet) plug results in the characteristic bleeding pattern of haemophilia, which is delayed after trauma but much prolonged. Replacement by intravenous infusion of the deficient factor can normalize the haemostatic mechanism of the haemophilic individual.

Table 41.1 Haemophilia A*: clinical severity.

<i>FVIII</i> (units/dL)	<i>Bleeding tendency</i>	<i>Relative incidence (%)</i>
< 1	Severe: frequent spontaneous [†] bleeding into joints, muscles and internal organs	50
2–5	Moderate: some 'spontaneous' bleeds, bleeding after minor trauma	30
> 5–45	Mild: bleeding only after significant trauma, surgery	20

*This table is also applicable to FIX, FX and FII deficiencies, but not to FVII, FXI, FV, FXIII or von Willebrand factor deficiencies (see text).

[†]'Spontaneous' bleeding refers to those episodes in which no obvious precipitating event preceded the bleed. No doubt, minor tissue damage consequent on everyday activities actually initiates bleeding.

Clinical features

Haemophilia A affects approximately 1 in 10 000 live births and is equally common in all ethnic groups. The vast majority of patients are male, but haemophilia can occur very rarely in females (see below). The severity and frequency of bleeding in X-linked FVIII deficiency are inversely correlated with the residual FVIII level. Table 41.1 summarizes this relationship and gives the relative frequency of the categories, based on UK national data. The main load- or strain-bearing joints (ankles, knees and elbows) are most affected but any joint can be the site of bleeding. If untreated, this intracapsular bleeding causes severe swelling, pain, stiffness and inflammation, which gradually resolves over days or weeks. It is not clear why bleeding in haemophilia shows a predilection for joints, but it has been suggested that low levels of tissue factor (TF) expression in synovial tissue may be at least part of the explanation.

Blood is highly irritating to the synovium and causes an immediate inflammatory reaction in the joint. In the longer term, blood and particularly increased iron deposition promote a chronic proliferative synovitis resulting in overgrowth of friable and highly vascular synovium that has an increased tendency to further bleeding, thus setting up a vicious circle. As a result of the vicious circle of bleeding and synovial hypertrophy, a particular joint frequently becomes the 'target joint' in an individual, whereas other joints may be relatively spared. Blood also has a rapid destructive effect on cartilage that is evident after only a single haemarthrosis. Accumulation of iron in chondrocytes may also contribute to the multifactorial degenerative arthritis, resulting in irregularity of articular contour,

Figure 41.1 Radiograph of knee joint showing advanced haemophilic arthropathy. Note the loss of cartilage, eburnation, deformity subluxation, osteophytes, subchondral cysts and irregularity of joint contours.

thinning of the cartilage, bony overgrowth and subchondral cysts, and finally ankylosis (Figure 41.1).

Muscle bleeding can be seen in any anatomical site, but it most often presents in the large load-bearing groups of the thigh, calf, posterior abdominal wall and buttocks. Local pressure effects often cause entrapment neuropathy, particularly of the femoral nerve with iliopsoas bleeding. This causes a common symptom triad of groin pain, hip flexure and cutaneous sensory loss over the femoral nerve distribution. Bleeding into the calf, forearm or perineal muscles can lead to ischaemic necrosis and contracture.

Haematuria is less common than joint or muscle bleeding in individuals with haemophilia, but severely affected patients have one or two episodes per decade. These may be painless and resolve spontaneously, but, if bleeding is heavy, it can produce clot colic. Usually, no anatomical abnormality is found to account for the haematuria on radiological investigation.

Central nervous system bleeding is uncommon but can occur after a slight head injury and remains a significant cause of death in haemophilia A. Intestinal tract bleeding usually presents as obstruction due to intramural haemorrhage, but haematemesis and melaena also occasionally occur and should be routinely investigated, as they may be due to peptic ulcer or malignancy.

Oropharyngeal bleeding, although uncommon, is clinically dangerous, as extension through the soft tissues of the floor of the mouth can lead to respiratory obstruction. Bleeding from the tongue after laceration can be very persistent and troublesome due to fibrinolytic substances in saliva and the impossibility of immobilizing the tongue.

Surgery and open trauma invariably lead to dangerous haemorrhage in the untreated individual with haemophilia. There may be persistence of haemorrhage, often after an initial short-lived period of haemostasis. Clots, if formed, are bulky and friable and break off, with renewed haemorrhage occurring intermittently over days and weeks. Today this is only seen in patients who are resistant to conventional replacement therapy due to the presence of inhibitors (see below) or when patients with mild or moderate haemophilia present after their first surgical or dental procedure.

Bruising is a feature of haemophilia A but is usually only of cosmetic significance as it remains superficial and self-limiting. Large extending ecchymoses may occasionally require treatment.

Presentation

When a woman is known to be a carrier or at high risk, the cord blood FVIII level will establish the diagnosis in the infant. However, haemophilia may be sporadic and in approximately one-third of cases there is no family history. In such cases, haemophilia may come to light in the neonatal period with cephalohaematoma or other bleeding resulting from the trauma of birth. In cultures where early circumcision is the rule, this will cause prolonged haemorrhage, as was noted in the Babylonian Talmud almost 2000 years ago. Quite often, the diagnosis is delayed until it is noticed that the infant has many large bruises from hand pressure when being picked up or from minor knocks on the cot. These sometimes cause diagnostic confusion and the erroneous label of 'non-accidental injury' may be applied, with needless psychological trauma to the parents. As soon as the infant starts to walk actively, joint bleeding begins to appear. In other children, excessive bleeding from the eruption of primary dentition, or from lacerations, leads to the performance of diagnostic tests. In patients who have some functional FVIII, even 1 or 2% (moderate haemophilia) may be sufficient to largely prevent spontaneous bleeding and delay diagnosis until bleeding occurs after trauma or surgery. Mild cases may only present in adulthood when severe trauma or surgery provokes unusual bleeding.

Investigation of coagulation defects and haemophilia

Investigation of a suspected inherited bleeding disorder usually begins with the global tests of coagulation. These tests reflect the history of coagulation investigation. Thus they force the coagulation system to function in a way that has been useful in the laboratory but which is considerably removed from normal physiology. As a result we routinely use tests such as the activated partial thromboplastin time (APTT) which, when abnormal, may indicate the presence of a severe disorder such as haemophilia or an irrelevant one such as FXII deficiency. Nonetheless, once this is understood, these tests remain extremely useful in detecting and diagnosing coagulation disorders. The principal routine tests in common use are the prothrombin time (PT) and the APTT, also known as the partial thromboplastin time with kaolin (PTTK) or the kaolin cephalin clotting time (KCCT). These tests require the activity of all the conventional procoagulant factors except FXIII; however, they do not require the presence of platelets (they are performed using platelet-poor plasma and exogenous phospholipid) and do not activate the protein C/protein S system.

Prothrombin time

In the PT, coagulation is triggered using a thromboplastin, i.e. tissue factor (TF) plus phospholipid, which may be derived from animal tissue (typically rabbit brain) or increasingly is relipidated recombinant human TF. The plasma is recalcified and the clotting time recorded. The PT will be prolonged by deficiencies of FVII, FX, FV, FII or fibrinogen.

Activated partial thromboplastin time

The APPT is triggered using a negatively charged surface (e.g. kaolin or silica) to initiate contact activation. Further progression requires the addition of phospholipid (partial thromboplastin) and calcium. It is thought that activation of coagulation rarely proceeds by this route *in vivo* and consequently deficiency of the contact factors is not associated with any increased tendency to bleeding. The APTT will be prolonged by deficiencies of FXII, FXI, FIX, FVIII, FX, FV, FII, fibrinogen, prekallikrein and high-molecular-weight kininogen. It is therefore abnormal in haemophilia A and B.

Thrombin time

The thrombin time is performed simply by adding a dilute preparation of thrombin to citrated platelet-poor plasma and recording the clotting time. Recalcification and phospholipid are not required. Prolongation of the thrombin time therefore implies that there is either an inhibitor of thrombin present (most commonly the effect of heparin) or that there is a problem with fibrin cleavage or polymerization. It is extremely sensitive to the presence of unfractionated heparin but is also prolonged by low or abnormal fibrinogen and hypoalbuminaemia.

Inhibitors

The simplest interpretation of a prolonged test of coagulation is that one or more of the factors required for its execution is deficient in the patient's plasma. A frequently encountered alternative is that an inhibitor of coagulation, usually an antibody, is present. The presence of an inhibitor is typically demonstrated by a mixing test in which normal and the test plasma (with a prolonged clotting time) are mixed in equal proportions. Correction of the prolonged clotting time by the normal plasma indicates a coagulation factor deficiency and failure to correct indicates the presence of an inhibitor.

When an inhibitor is detected, further tests are performed to determine whether it has specificity for a particular clotting factor or not. Non-specific inhibitors usually fall into the class of antiphospholipid antibodies and are paradoxically associated with thrombosis rather than bleeding (see Chapter 46). Specific inhibitors are most commonly directed against FVIII, resulting in an 'acquired' haemophilia.

Specific factor assays

When initial tests or clinical history suggests single factor deficiency, then specific factor assays are performed to determine which is affected. This is most usually done by performing a bioassay in which the ability of the test plasma to correct the defect in plasma lacking a specific factor is measured. Bioassays have the advantage of directly measuring the biological activity of the factor in question but because they also utilize other plasma components, they are susceptible to numerous interferences and confounding effects. This can be avoided in some cases by using artificial small substrates (chromogenic substrates). This aids automation and avoids interference but often does not capture all aspects of the molecule's biological activity. Finally, the physical amount of the factor present can be assessed immunologically. Immunological assays are accurate and precise, but of course do not give information about the functional activity of the molecules that have been measured.

Laboratory diagnosis of haemophilia

Initial tests show a prolonged APTT, normal PT and thrombin time (if performed) and a normal platelet count. This will usually prompt specific factor assays of FVIII, FIX and FXI and, in the case of haemophilia A, results shows FVIII clotting activity below 50 units/dL, with all other factors normal. Von Willebrand factor (VWF) antigen and activity (ristocetin cofactor) are also normal.

FVIII assays

In most laboratories the FVIII assay is a modified APTT and is often referred to as a 'one-stage assay' because the activation of FVIII and coagulation are performed in a single step. However, it is also possible to construct a 'two-stage assay' in which the FVIII is activated in a first step and then the activity is measured

in a second separate step. Chromogenic FVIII assays use a two-stage procedure. The two assays normally give similar results but the distinction is important because some defective FVIII molecules give different results in the two assays. Most commonly in these cases, the one-stage assay gives a higher result than the two-stage but the patient's bleeding phenotype is more in keeping with the latter (lower) result. Thus the assessment of the severity (and sometimes even the diagnosis) of the haemophilia can be mistaken if the two assays are not carried out and compared.

Treatment

Clotting factor concentrates

The discovery in the early 1960s that FVIII was concentrated in cryoprecipitate and the subsequent description of the production of antihaemophilic globulin in a closed bag system revolutionized treatment for haemophilia. Home treatment for the majority of patients became feasible and with the advent of lyophilized concentrates prepared from cryoprecipitate made from the plasma from many thousands of donors, the prospect of a normal life for the severely affected haemophilic individual was brought very close. However, use of such plasma-derived concentrates was associated with the transmission of hepatitis C virus (HCV), hepatitis B virus (HBV) and HIV. Although these infections were present at only low frequency in the donor population, concentrates were made from many thousands of donations and so most, if not all, batches of concentrate were infected, particularly with HCV. Since 1985 virucidal methods have been rigorously applied (such as terminal dry heat treatment, solvent/detergent treatment, nanofiltration and pasteurization) in conjunction with donor selection and plasma pool screening and quarantining. As a result of these measures, plasma-derived concentrates are now very safe such that the risk of HIV, HBV or HCV transmission is close to zero. However, there remains the problem of transmission of non-lipid-coated viruses (such as hepatitis A and parvovirus), which can survive solvent/detergent sterilization, and the possibility that new viruses will emerge. For these reasons, products are required to undergo more than one inactivation process. For FIX concentrate, the process of nanofiltration has been used, which can prevent transmission of non-lipid-coated viruses.

It has recently transpired that the prion protein responsible for variant Creutzfeldt–Jakob disease (vCJD) may be transmitted via pooled plasma concentrates, although only a single case has been reported to date. With the ongoing concern about prion transmission through blood and blood products, concentrates are no longer produced from plasma drawn from countries with notable vCJD in the donor population.

The plasma-derived clotting factor concentrates in use at present are high-purity products with a high specific activity. They are prepared chromatographically, which results in an end product of high specific activity. The advent of recombinant

clotting factor concentrates has further enhanced safety of replacement therapy.

Recombinant FVIII

The structure of the FVIII gene and the isolation of cDNA clones encoding the complete FVIII sequence were described in 1984. This has allowed the manufacture of FVIII in cell culture, which therefore eliminates the risk of disease transmission from donors. Progressive refinements have in some cases eliminated all additional animal protein from the cell culture medium and any protein added as stabilizer in the lyophilized product. Recombinant FVIII can be made either from the wild-type 'full-length' cDNA or from cDNA that has the large B domain deleted. The B domain has been shown to be completely dispensable for the procoagulant function of FVIII and its absence does not change the half-life of the molecule. It is therefore curious that one B domain-deleted product has shown a marked discrepancy between one-stage and two-stage assays. Subsequent developments suggest that the origin of the discrepancy in this concentrate may be post-translational modification rather than the absence of the B domain.

Recombinant technology may allow the development of modified bioengineered FVIII molecules with enhanced pharmacokinetics, specific activity or reduced immunogenicity. A prolonged half-life may also be achieved by coupling FVIII to other molecules such as polyethylene glycol, to liposomes or by altering glycosylation. Fusion of FVIII with Fc or albumin has also been achieved, with a markedly enhanced half-life in preclinical studies. Although there is enthusiasm for these approaches, which are all under active development, clinical trials will decide which if any are effective and safe.

Assay of recombinant clotting factors

In pharmacokinetic studies, it was found that the chromogenic assay produced considerably higher levels than one-stage assays.

The influence of phospholipids on these discrepancies was studied. It was found that when the APTT reagent was replaced by platelets in the one-stage assay, the results of the chromogenic assay and the one-stage assay were similar. Furthermore, using the principle of 'like versus like', this discrepancy between chromogenic and one-stage methods could be eliminated by using the recombinant product diluted in haemophilic plasma as a standard reference. In this case it is the standard calibration against reference plasma that is adjusted.

Treatment of haemophilia

Since the development of replacement therapy, the goal of treatment for haemophilia patients has been the prevention of haemorrhagic episodes. Based on studies from haemophilia carriers and patients with mild haemophilia, we can deduce that a level of 5–30% is adequate to arrest minor bleeds, but inadequate for major surgery or trauma. At least 60% sustained throughout the healing period is needed for normal wound healing to occur. The severity and the frequency of haemarthrosis is directly related to the degree of deficiency of the clotting factor, but the precise plasma level needed to prevent haemarthrosis is still unknown.

After trauma or at the onset of bleeding, therapeutic infusion of replacement factor should be administered as early as possible and to a haemostatic level to stop or prevent haemorrhage. The dosing of factor replacement is still based on theoretical calculations and clinical experience. Guidelines for the treatment of haemorrhagic episodes in haemophilia are given in Table 41.2, with the estimated likely effective level required for haemostasis. If sufficient FVIII is available, it is physiological to restore the FVIII level into the normal range and maintain it there by continuous infusion or frequently repeated infusion.

Formulae based on plasma volume and expected recovery give a rough guide to dosage required to achieve a given level,

Table 41.2 Indications and guidelines for factor replacement in haemophilia A and B.

Site of haemorrhage	Optimal factor level (%)	Dose (units/kg body weight)		Duration (days)
		FVIII	FIX	
Joint	30–50	20–30	30–50	1–2
Muscle	30–50	20–30	30–40	1–2
Gastrointestinal tract	40–60	30–40	40–60	7–10
Oral mucosa	30–50	20–30	30–40	Until healing
Epistaxis	30–50	20–30	40–60	Until healing
Haematuria	30–100	25–50	70–100	Until healing
Central nervous system	60–100	50	80–100	7–10
Retroperitoneal	50–100	30–50	60–100	7–10
Trauma or surgery	50–100	30–50	60–100	Until healing

Source: Escobar (2003) with permission.

but where the level is critical, as for surgery or when there is serious bleeding, it should always be checked by assay after infusion. On average, FVIII infusion produces a plasma increment of 2 units/dL per unit infused per kilogram body weight. From this, a simple formula can be derived:

$$\begin{aligned} \text{Dose to be infused (units)} \\ = [\text{weight (kg)} \times \text{increment needed (units/dL)}] / 2 \end{aligned}$$

Assessing the period of treatment required is a matter of clinical judgement of the individual episode or lesion.

Cover for surgery, other than very minor procedures, requires maintenance of normal FVIII levels for at least 1 week, followed by a period at reduced dosage during convalescence. This can be achieved either by repeated bolus injections every 8–12 hours (paying particular attention to trough levels, which should not fall below 50 units/dL) or by continuous infusion. The half-life of FVIII varies considerably and may be particularly short in children, requiring more frequent dosing. It should also be noted that the doses required during the immediate postoperative period may be considerably more than expected.

Prophylaxis

There is a long tradition of giving prophylaxis to young boys with haemophilia; prophylaxis was developed as early as 1958 in Malmö, Sweden. The rationale for the prophylactic model was the observation that chronic arthropathy was seen less frequently and less severely in individuals with a FVIII level of 1–4 units/dL.

Today prophylaxis is regarded as the standard of care for all boys with severe haemophilia. Regular prophylactic treatment is begun at 1–1.5 years before the onset of joint bleeds, so-called primary prophylaxis. Ideally, FVIII is administered every second day at a dose of 25–40 units/kg. The goal is to maintain a trough level of 1 unit/dL or more, which may require individual adjustment of size and frequency of dosing, and so to avoid all bleeds. Evidence from trials indicates that the risk of bleeding rises as the duration of FVIII levels below 1 unit/dL increases. There is good historic evidence that the Malmö model is effective in preventing haemophilic arthropathy. For the youngest cohort of boys born in 1981–90, who began prophylaxis between 1 and 2 years of age with 4000–9000 units/kg annually, both the orthopaedic and radiological scores were zero (Figure 41.2). More recently, a large randomized study comparing prophylaxis with enhanced on-demand therapy showed that after 6 years of therapy, 93% of those on primary prophylaxis had a normal joint score on magnetic resonance imaging (MRI) compared with only 55% on intensive on-demand regimens.

Use of the peripheral vein is the preferred approach when beginning prophylactic treatment. However, if this is not possible then the implantation of an indwelling venous access device (e.g. Port-a-Cath) may be necessary. Substantial experience with Port-a-Cath has been published. Although the advan-

Figure 41.2 Orthopaedic joint scores for patients intensively treated in the present. A group of 15-year-old boys compared with a less intensively treated group at different ages and with patients not receiving prophylaxis (historical control subjects). (From United Kingdom Haemophilia Centre Doctors' Organisation 2003 with permission.)

tages of such devices are recognized, septic complications remain a challenge. A number of studies have been published that show an infection rate ranging from 0.2 to 3.4 infections per 1000 catheter-days but increasing with frequency of use. Another alternative is the fashioning of a small arteriovenous fistula in the arm.

In older patients who have established joint disease or have had previous joint bleeds, prophylaxis is also effective in reducing bleeding episodes and/or slowing progression of joint disease. This 'secondary' prophylaxis may be used continuously or for a limited period to allow the synovial hypertrophy in a target joint to regress or be targeted to periods when bleeding is more likely (such as sporting activity).

Desmopressin

A non-blood-derived alternative to FVIII concentrate, desmopressin (1-deamino-8-D-arginine vasopressin) can be used to treat mild haemophilia. Desmopressin acts via the V_2 receptors on endothelial cells to stimulate exocytosis of Weibel–Palade bodies, the endothelial storage organelles that contain primarily VWF and, in some tissues, also FVIII. In practice, this effect can be used to elevate the plasma FVIII level twofold to fourfold above baseline. Desmopressin is a synthetic analogue of vasopressin and retains the antidiuretic action of the natural hormone but not its vasopressor activity. Patients are advised to restrict their fluid intake after desmopressin. This is especially

important in young children in whom unrestricted fluid intake may result in hyponatraemia and convulsions. Desmopressin is contraindicated in elderly patients and those with vascular disease, because arterial thrombosis has been reported following desmopressin in these circumstances.

Desmopressin can correct the haemostatic defect in mild haemophilia A or VWD sufficiently to cover minor surgery or treat a minor bleeding episode. A typical regimen would be to give 0.3 µg/kg body weight either by slow intravenous infusion over 20 min or by subcutaneous injection. Desmopressin also releases tissue plasminogen activator and so tranexamic acid is frequently given as well. A high-concentration nasal spray is also available that delivers 150 µg per actuation. The effect is maximal at 30 min after an intravenous dose and 1 hour following a subcutaneous or intranasal dose. The FVIII level rises threefold on average. The half-life of the endogenously released FVIII is about 8 hours but may be shorter in some cases and the fall-off should be documented. The dose can be repeated and although tachyphylaxis occurs such that the second dose may produce a rise only 30% of the first, there is often no further drop with succeeding doses. If repeated doses are given over a short interval (e.g. 48–72 hours), the FVIII response to desmopressin injection should be assayed to ensure that the reserves are not exhausted.

Complications of therapy

Inhibitors

Antibodies to FVIII (inhibitors) are most common in patients with severe rather than mild haemophilia. They are most likely to develop during childhood within the first 25 exposures to FVIII after which they are infrequent, but do rarely develop after years of treatment. Prospective studies have shown that in the past the incidence of inhibitors in patients with haemophilia has generally been underestimated. Studies to determine the true incidence are fraught with difficulty owing to bias in patient selection, frequency and sensitivity of testing and previous treatment. When studied closely, inhibitors have been detected in around 25–30% of patients with severe haemophilia at some stage in their treatment. However, many of these are low-level transient inhibitors that are not a long-term problem for treatment. The cumulative incidence of high-responding inhibitors is in the region of 10–15%. The likelihood of an individual developing an inhibitor is strongly dependent on the genetic lesion responsible for the FVIII deficiency. Patients with large deletions or stop codons in the light chain appear to be particularly prone to inhibitor development. However, some missense mutations causing mild to moderate haemophilia, particularly those in the light chain, are also associated with a high frequency of inhibitor development. Approximately 25% of patients with the common intron-22 inversion develop inhibitors. There is also evidence that when FVIII is adminis-

tered in large amounts (e.g. severe bleeds) or in association with inflammatory stimuli (e.g. surgery), this increases the likelihood of inhibitor development. As more is learned of the molecular bases for FVIII deficiency, it should be possible, perhaps in association with human leucocyte antigen typing, to define more precisely the individual risk. Because the development of inhibitors is unpredictable, it is important to test for their emergence at clinic visits and before operations.

Antibodies to FVIII frequently have a time-dependent component in their action and therefore an incubation time of 2–4 hours is required to reliably measure the full effect of the antibody. Inhibitors usually inactivate FVIII in a predictable linear manner (type 1 kinetics) but they may have complex equilibria and not inactivate all available FVIII (type 2 kinetics) and these are seen particularly in mild to moderate and acquired haemophilia. Inhibitors are most commonly measured using the Bethesda assay where 1 Bethesda unit (BU) is the amount of antibody that reduces the FVIII activity in pooled normal plasma by 50% after 2 hours incubation. Some inhibitors are 'low-responding' and remain at a low or moderate level (< 5–10 BU) after further FVIII exposure, whereas in high responders treatment with FVIII elicits a sharp anamnestic rise after 5–8 days and inhibitor levels may reach hundreds or thousands of BU. Low responders can be treated repeatedly with high doses of FVIII concentrate. However, high responders are refractory to treatment with FVIII concentrate and therefore alternative therapies are required.

Inhibitors: treatment of bleeding

Porcine FVIII functions well in human plasma but is frequently neutralized less efficiently by the anti-FVIII antibodies produced in humans with haemophilia. This has made it a useful alternative treatment in patients with inhibitors. However, it is not free of the problems associated with plasma-derived products and so recombinant porcine FVIII is in development and entering clinical trials.

At present the most common approach to achieving haemostasis in patients with inhibitors is to use a 'bypassing agent' that promotes thrombin generation without depending on the intrinsic tenase. The currently available bypassing agents are human recombinant FVIIa and a plasma-derived prothrombin complex concentrate that contains activated coagulation factors (factor eight inhibitor bypassing activity, or FEIBA). Human FVII was cloned in the mid-1980s and recombinant FVIIa was developed specifically as treatment for bleeding episodes in individuals with haemophilia complicated by inhibitory antibodies. Activated FVII is an inefficient enzyme when not complexed with TF and does not therefore produce systemic activation of coagulation when infused. Its mechanism of action in haemophilia has been the subject of much debate. It seems most likely that FVIIa binds to the surface of activated platelets at the site of injury and promotes FXa formation there. Recent

evidence suggests that platelets may be able to synthesize TF or at least acquire it from circulating microparticles. High concentrations (30–90 nmol/L) are required to generate sufficient FXa and FIIa to achieve haemostasis.

The advantages of recombinant FVIIa include viral safety, low systemic activation of coagulation, effectiveness independent of inhibitor titre and an excellent overall safety profile allowing home use and ease of administration. The main disadvantage is the short half-life and therefore the need for frequent administration. Recent studies suggest that this can be overcome by using a single very large dose for mild to moderate bleeds.

Both native and activated prothrombin complex concentrates appear to be able to bypass FVIII and have a role in the treatment of patients with FVIII antibodies. The substance(s) responsible for the FVIII bypassing activity are undefined but their efficacy appears to derive from a combination of activated clotting factors and the elevation of prothrombin concentration, which is a major determinant of thrombin generation. The activated prothrombin complex concentrates contain more of the FVIII bypassing activity and are designed specifically for use in patients with FVIII inhibitors. Activated prothrombin complex concentrates have proved efficacious in controlling bleeding in many situations. The problems with FEIBA are that it is of plasma origin and it contains some FVIII, which may cause an anamnestic rise in inhibitor titre. On the other hand, its longer dosage interval (given once or twice daily) makes it more suitable for prophylactic use. A major problem with both bypassing agents is that there is no reliable laboratory measure of their haemostatic effect.

Treatment of inhibitors: immune tolerance

Bypassing agents are considerably less effective than FVIII at achieving haemostasis and cannot yet provide reliable prophylaxis. It is therefore highly desirable to eliminate a FVIII inhibitor, a process referred to as immune tolerance induction (ITI). Basic ITI regimens involve the continued administration of FVIII, and both low-dose (25 units/kg alternate days) or high-dose (order of 100 units/kg twice daily) FVIII regimens have been used. Neither regimen has been conclusively shown to be superior and either may need to be continued for 12 months or more. Overall, the success rate is approximately 70%, after which prophylaxis must be maintained to prevent re-emergence of the antibody. The success is greatest in younger patients (< 7 years), with a historic peak titre below 200 BU, and when treatment is begun after allowing the inhibitor to fall to below 5 BU by avoiding further FVIII exposure. For resistant cases the use of a FVIII concentrate containing VWF may be more successful or the regimens may be combined with anti-CD20, or corticosteroids, alkylating agents, plasmapheresis and immunoglobulin (Malmö regimen). Success is defined as normalization of the FVIII recovery and a FVIII half-life greater than 6 hours.

Molecular genetics of haemophilia A

The FVIII gene (Figure 41.3) spans 190 kb of the X chromosome. The protein-coding regions (exons) are separated by 25 introns, some of very large size (e.g. intron 22 is over 35 kb). FVIII is synthesized in the liver, spleen and lymph nodes but also in some endothelial cells (probably in the lung), which creates the desmopressin-releasable pool. The amino acid sequence contains a triplicated region (A1, A2, A3 in Figure 41.4), whose elements are more than 30% homologous with each other. A second duplicated homology region (C1, C2) is responsible for the phospholipid-binding properties of the molecule. The third type of sequence in the protein is the heavily glycosylated B domain, which is coded entirely within exon 14, connects A2 and A3, and is removed on thrombin activation of FVIII.

The processed mRNA specifies a protein of 2351 amino acids, from which a 19-amino-acid N-terminal leader sequence is cleaved on secretion. The mature plasma protein initially consists of a single chain of 2332 amino acids, but as a result of proteolysis circulates as a series of light-chain and heavy-chain heterodimers with B domains of varying length.

The vast majority (> 90%) of FVIII circulates in complex with VWF, in the absence of which its half-life is extremely short. Studies of FVIII have identified the A3 (1648–1689), C1 and C2 domains as important for VWF binding but it is uncertain how many of these interact directly with VWF because in isolation the recombinant fragments have a much lower affinity. After thrombin activation, the cofactor consists of a heterotrimer: the N-terminal heavy chain corresponding to region A1 and the A2 domain isolated by cleavages at 372/373 and 740/741, which is held by a divalent cation-dependent linkage to the C-terminal light chain corresponding to part of A3 plus C1 and C2 (see Figure 41.4). The B domain is discarded by cleavages at 740/741 and 1689/1690. Thrombin cleavage also results in release of FVIII from VWF.

Protein C cleaves FVIIIa at 336/337 and 562/563, totally inactivating the cofactor. The crystal structure of FVIII has recently been reported and several of the interactions mapped including the FIX-binding site on the A2 and A3 domains. The C domains appear to be responsible for phospholipid binding.

Thanks to the development of polymerase chain reaction (PCR)-based rapid screening and sequencing methods, the mutations in nearly all patients with haemophilia A can be identified (Table 41.3). Consequently, a large database of mutations has accumulated and is maintained at <http://hadb.org.uk>. These include large deletions and missense mutations, as well as nonsense, frameshift, splicing (affecting mRNA processing) and insertional mutations. Surprisingly, about half of all severe haemophilia A is due to a major inversion (Figure 41.4) that occurs quite frequently during male gametogenesis (approximately 1 in 10 000 spermatozoa).

Figure 41.3 The FVIII gene and protein. Top line, scale for gene in kilobase pairs of DNA; second line, location of exons (protein-coding segments) of the FVIII gene shown as solid bars; second to third line, corresponding domains of FVIII gene and protein; fourth line, plasma FVIII is heterogeneous due to cleavage at various points within the B domain during synthesis and secretion, yielding heterodimers in which the heavy chain

(N-terminal segment) pairs from 740 to 1648 amino acids; fifth line, thrombin activation releases the a2 segment from the light chain, the B domain from the heavy chain and cleaves between the A1 and A2 domains; bottom line, inactivation of factor VIIIa by activated protein C is accompanied by cleavages at 336, releasing the a1 domain and 562 in the middle of the A2 domain.

Haemophilia A in females

True homozygous haemophilia A is rare, but well described, being due to the marriage of a carrier to an affected male, often a cousin. Severe menstrual haemorrhage occurs but responds to FVIII infusion. Haemophilia A has been described in a female with Turner syndrome. The random process of X-chromosome inactivation allows only one FVIII gene to function in each female cell. Thus carriers of haemophilia A have on average 50% of the mean normal level of the clotting factor (or its antigen FVIII:Ag). However because the process is random, skewing of the inactivation towards the X chromosome containing the abnormal or the normal FVIII gene may occur, resulting in a FVIII level that is either well within the normal range or low enough to produce a mild haemophilia phenotype. By measuring the level of VWF antigen (VWF:Ag), the autosomally coded carrier protein for FVIII, it is possible to

improve discrimination as carriers will tend to have lower levels of FVIII than VWF. Even so, there is still some overlap (about 15%) where the carriers have a normal ratio. It is therefore important to note that while a low level of FVIII strongly implies carriership, a normal FVIII level by no means excludes it.

Translocation through the FVIII locus has given rise to severe haemophilia in an affected female due to exclusive inactivation of the normal X chromosome. Due to sperm mutation in the father, especially in the prevalent inversion, a carrier can present *de novo* with no family history of haemophilia. The most usual reason for finding a low FVIII in a female if the above has been excluded is VWD. This should usually be evident from assays of VWF. Of course, VWD and haemophilia A can coexist in the same family, which makes carrier detection difficult. Type 2N VWD (see below) may also be confused with mild haemophilia A.

Table 41.3 Mutations responsible for haemophilia A.

Mutation type	No. of mutations observed	Percentage
<i>Intron 22 inversion</i>		
Distal	260	30.7
Proximal	37	4.4
Rare	5	0.6

Haemophilia B

Inheritance and diagnosis

Haemophilia B is an X-linked deficiency of FIX and the clinical manifestations are essentially the same as for haemophilia A. It is less common than haemophilia A and has an incidence of approximately 1 in 50 000 live births. FIX is responsible for the activation of FX in the presence of activated FVIII, calcium and phospholipid. FIX is synthesized in the liver and is a vitamin K-dependent protease that is similar to prothrombin, FVII, FX and protein C. The FIX gene is located on the long arm of the X chromosome and contains eight exons encoding a protein of 454 amino acids. The complete sequence of the gene has been determined and in virtually all cases of haemophilia B genetic mutations have been identified, the vast majority of mutations being missense. A haemophilia B database is also available at <http://www.kcl.ac.uk/ip/petergreen/haemBdatabase.html>.

Figure 41.4 How the tip flips: the mechanism of inversion through intron 22. The mutation is responsible for up to half of all cases of severe haemophilia A. During spermatogenesis, at meiosis the single X pairs with the Y chromosome in the homologous regions, but there is nothing to pair with most of the long arm of X. Unfortunately, the possibility of intrachromosomal pairing and crossover exists because there are three copies of a gene designated *F8A*, one lying within intron 22 and two in the opposite orientation situated 400 kb telomeric to the *FVIII* gene. Crossover with either the distal or the proximal *F8A* copy divides the *FVIII* gene in two, such that separately transcribed mRNAs are produced, neither of which encodes functional *FVIII*.

Isolated FIX deficiency is always hereditary and the clinical severity of haemophilia B generally shows the same relationship with the residual factor level as for FVIII in haemophilia A, although recent data suggest that on average the phenotype might be slightly less severe.

Treatment

The mainstay of treatment is FIX concentrate. Previously, intermediate-purity prothrombin complex concentrates containing all the vitamin K-dependent factors were used. However, these concentrates were associated with a risk of thrombosis, particularly when used repeatedly, for example in surgery. This was probably due to accumulation of high levels of FX and FII, which have longer half-lives than FIX. Subsequently, high-purity FIX concentrates have been developed produced by either monoclonal antibody or affinity chromatography methods. FIX concentrates are prepared from the same screened plasma pools as FVIII and undergo similar viral inactivation procedures. Although the FIX gene was cloned in 1982, the development of recombinant FIX was hampered by the post-translational modification that it requires. Recombinant FIX is now widely used and although it is clinically effective, the recovery is only about 80% of that observed with plasma-derived FIX.

Dosage calculation in the treatment of haemophilia B follows the same principles as set out for FVIII deficiency, except that a higher initial dosage is required because of lower recovery:

$$\text{Dose to be infused (units)} = [\text{weight (kg)} \times \text{increment needed (units/dL)}] / 0.9 \text{ (or 0.8 for recombinant FIX)}$$

Also, the longer half-life (18 hours) means that daily infusions often suffice to maintain good levels after surgery, but as with FVIII the half-life may be much shorter in children and more frequent dosing required. Severely affected patients are usually maintained on twice-weekly prophylaxis to prevent spontaneous bleeds. This is practicable because of the longer half-life of the factor.

Complications of therapy

Inhibitors

Inhibitors in haemophilia B are much less common than in haemophilia A. Only about 2–3% of patients with severe haemophilia B will develop inhibitors, but interestingly many of these inhibitors present with anaphylaxis to infusions of FIX concentrate. Unlike FVIII inhibitors, FIX inhibitors are not time dependent, but can be similarly quantitated by a modified Bethesda assay. The majority of patients who develop inhibitors have large gene deletions or nonsense mutations occurring in the first 20% of the FIX gene. Acute management of bleeding can be achieved with recombinant FVIIa (as with haemophilia A). However, immune tolerance is frequently far less successful and can be complicated by the development of nephrotic syndrome.

Gene therapy for haemophilia

Haemophilia is an excellent model for gene therapy because the clinical manifestation is the result of a deficiency of the single gene product and only a small amount of protein is required to ameliorate symptoms.

Although preliminary data from Phase I trials were encouraging, the plasma levels of FVIII or FIX attained were notably less than in the animal models and certainly insufficient to free patients from treatment with clotting factor concentrates. Also, there has been a universal short duration of transgene activity. Although no inhibitors have been documented, this remains a theoretical risk. Furthermore, the detection of small amounts of viral vector genome in the semen continues to raise the possibility of the risk of germline integration. Insertional mutagenesis has occurred in a Phase I trial of Moloney retrovirus carrying the interleukin receptor, and this has been a cause for concern but was partly the result of the selection pressures applied to the transduced cells. New vectors, particularly modified serotypes and engineered self-complementary adeno-associated virus, which rarely integrates into the host genome,

will form the next generation of gene therapeutics and are about to enter clinical trials.

The ethics of gene therapy for haemophilia are complex: it could be argued that for young patients with haemophilia, regular prophylactic factor infusions already deliver a near-normal life. Gene transfer in haemophilia has played an integral role in furthering the science of gene therapy in general but it is still likely to be a long time before it becomes routine therapy for children with haemophilia.

General organization of haemophilia care

As these are relatively uncommon disorders, with many and varied effects on patients and families at all stages of life who require care and support services across the whole field of medicine and social services, it is now accepted that this care can best be delivered comprehensively by referral centres. The staff of a major comprehensive care centre will include physicians, nurses, social workers, laboratory scientists and physiotherapists, devoting all or a substantial part of their time to haemophilia care. An orthopaedic surgeon or musculoskeletal rheumatologist prepared to see haemophilic patients regularly in a clinic set aside for their problems is a valuable addition to this team. In the UK, there is now a national service specification produced by the Haemophilia Alliance for Haemophilia and related conditions, which sets out the standards of care to be provided through the haemophilia centre network originally set up in the 1960s and early 1970s. It is recognized that not every centre can provide every facility and that there should be a fairly wide distribution according to population density, which determines numbers of patients. As defined by the national specification, the functions of a centre are to provide 24-hour emergency treatment for haemophilic patients and their families and a full range of diagnostic tests for identifying new patients and monitoring treatment. Full records should be kept of all treatments, whether given in hospital or as home therapy. Progress should be monitored through regular follow-up, with paediatric, dental and orthopaedic referrals being organized by the centre as necessary. (Many centres are indeed in paediatric departments or run by paediatricians.) Genetic counselling, including carrier detection and antenatal diagnosis, must be available for families of patients with haemophilia. Large centres providing all these facilities and treating at least 40 patients with severe haemophilia will be designated comprehensive care centres. It is envisaged that all patients will have access to a comprehensive care centre, either directly or via their smaller local centre. A part-time or full-time social worker should be part of the team, able to review the wider problems of living that affect the haemophilic patient at school, home and work. Centres provide access to specialized care for monitoring patients with HIV and HCV infection. On diagnosis, all patients are issued with a special medical card indicating

Figure 41.5 Survival in men in the UK with haemophilia who were not infected with HIV and in the general male population of the UK in 1999. Note that these data still include deaths related to hepatitis C infection. (From Darby *et al.* 2007 with permission.)

laboratory test results, inhibitor status, main centre and local centre for treatment.

Caring for haemophilic patients and their families is demanding but rewarding. Despite the setbacks in the 1980s due to virus transmission, the trend continues to be an ever-improving life expectancy and social participation, based on continuing medical progress and multiprofessional input into patient care. It is both tragic and ironic that the main foundation on which this progress rested (factor concentrate) has also been the route by which life-threatening infections have been introduced to about half of the most severely affected patients with haemophilia A. However, there are now effective therapies for both HIV and HCV infection. The younger generation of haemophiliacs is now treated with virus-safe or recombinant concentrates and has escaped both HIV and liver disease, and lead virtually normal lives (Figure 41.5).

Acquired haemophilia

This chapter is devoted primarily to the inherited form of haemophilia arising from mutations in the FVIII and FIX genes but haemophilia can also arise as a result of autoantibodies that neutralize FVIII cofactor activity. The incidence is approximately 1.5 per million per year and it tends to occur predominantly in older patients, although there is also an increased frequency after pregnancy and in association with other autoimmune disorders. The antibodies usually show time-dependent (type 2) neutralization of FVIII and a residual FVIII level is often detectable. The pattern of bleeding is distinct from that

in inherited haemophilia, with a much greater incidence of soft tissue and mucosal bleeding, often out of proportion to the FVIII level. Treatment for bleeding is the same as for inhibitors in hereditary haemophilia and suppression of the inhibitor requires immunosuppressive therapy (e.g. corticosteroids, cyclophosphamide and anti-CD20 antibody).

von Willebrand disease

Although described in 1926, our understanding of this complex and variable bleeding disorder remains far from complete. The basic defect common to all variants is a deficiency of one or more aspects of VWF functional activity. The abnormality may be quantitative and/or qualitative.

von Willebrand factor

VWF is encoded by a gene on chromosome 12, which was cloned simultaneously by several groups in 1986. The pre-pro-VWF primary translation product comprises a 22-amino-acid signal peptide, a 741-amino-acid propeptide and the 2050-amino-acid mature subunit. The pro-VWF monomer is composed of four types of domains (A–D) arranged as follows: NH₂–D1–D2–D′–D3–A1–A2–A3–D4–B1–B2–B3–C1–C2–CK–COOH. VWF is produced predominantly in vascular endothelial cells and also in megakaryocytes, although plasma VWF derives entirely from endothelial cell production. After translation the monomer enters the endoplasmic reticulum and the signal peptide is removed. The monomers then dimerize via the C-terminal cysteine knot domain before leaving the endoplasmic reticulum to the Golgi, where the dimers are joined via their N-termini to form a series of multimers with molecular masses ranging from 1000 to 20 000 kDa. During this process the molecule is extensively glycosylated with N- and O-linked glycans that form 20% of its final molecular weight. Importantly, approximately 13% of the N-linked glycans terminate in an ABO blood group antigen. In endothelial cells, multimerized VWF is then transferred into Weibel–Palade bodies, some of which pass directly to the cell surface to release their contents (constitutive pathway) while others remain in the cell for release when needed (regulated pathway). Platelet VWF does not contribute significantly to plasma VWF and is stored in the α-granules of platelets prior to release after platelet activation. During synthesis, the VWF propeptide, which is essential for multimerization, is cleaved from the mature molecule, stored with VWF in the Weibel–Palade bodies and released with it into plasma but is not known to have any further function thereafter. Some VWF is also secreted ablumenally from the base of the endothelial cell where it binds directly to collagen in the subendothelial matrix.

Rapid release of VWF from the endothelial Weibel–Palade storage granules can be induced via the regulated pathway by a

number of agonists including thrombin, adrenaline, histamine and vasopressin. This can be used to advantage by using desmopressin to treat mild forms of VWD. Elevation of plasma VWF due to increased synthesis and secretion occurs as part of the acute-phase response to injury, inflammation, infection and neoplasia, and in pregnancy and hyperthyroidism. These responses are presumed to be physiological in promoting enhanced haemostasis but could reach pathological expression in being associated with an increased risk of thrombosis. The confounding effects of stress and inflammation need to be taken into account when measuring VWF levels in attempting to diagnose VWD.

An appreciation of the complex structure–function relationship of VWF is essential in order to understand the classification of VWD. The two principal functions of VWF are (i) binding to matrix molecules, particularly collagen, at sites of vascular injury and subsequent capture of platelets to form the primary haemostatic plug and (ii) the stabilization of FVIII in the circulation. The adhesive function of FVIII requires functional binding sites for collagen and the platelet glycoproteins GPIb

and GPIIb/IIIa (also known as integrin $\alpha_{IIb}\beta_3$). The VWF released from endothelial cells into plasma is in the form of ultra-large multimers, which are subsequently cleaved into smaller forms by the action of the plasma metalloprotease ADAMTS-13. This is of critical importance because it is the high-molecular-weight multimers that have the greatest collagen- and platelet-binding activity: absent cleavage results in formation of platelet microthrombi and vascular occlusion and excessive cleavage results in increased bleeding.

Although FVIII and VWF are entirely distinct entities with separate functions (Figure 41.6), they circulate together as a complex in which VWF protects FVIII from degradation, so that a deficiency of VWF or a reduction in its ability to bind FVIII may also result in a low plasma level of FVIII. Therefore, deficiency of VWF can give rise to a dual haemostatic defect: reduced plasma levels of FVIII (due to its shorter half-life in the absence of VWF) and a defect in primary haemostasis because of the failure in assisting platelets to adhere to the cut edges of small blood vessels (see Chapters 39 and 40). Clearly, the multistep synthesis, assembly and secretion of VWF and its multiple

Figure 41.6 Assembly of FVIII–VWF complex. FVIII synthesized by hepatocytes as a single chain is partially proteolysed and (possibly) complexed with VWF prior to release. VWF is synthesized as a single-chain precursor, which dimerizes with

disulphide bond formation, then multimerizes with further disulphide exchange, with concomitant loss of a large propeptide segment. The propeptide is essential for multimer formation and probably functions as an acidic disulphide isomerase.

binding interactions provide many ways in which mutations of the VWF gene can give rise to varying types of disease. In particular, the multimeric structure is susceptible to dominant-negative effects of mutant alleles. The diagnosis of VWD is based on the recognition that for normal VWF function it must be (i) present in adequate amounts, (ii) have a normal multimeric structure, and (iii) have intact functional domains (binding sites). When any of these properties is only slightly reduced, the presence or absence of a bleeding tendency may also depend on the quality and quantity of the other components, particularly platelets and collagen, with which VWF must interact.

Clinical features

The clinical features vary according to the severity of the deficiency. The most common clinical picture is of an autosomal dominant, mild to moderately severe bleeding tendency. However, we now understand that the inheritance of VWD may be more complex than a simple autosomal dominant pattern (see below). Patients suffer from bruising, epistaxes, prolonged bleeding from minor cuts, menorrhagia and excessive, but not often life-threatening, bleeding after trauma or surgery. Patients often present for investigation in the second or third decade after prolonged bleeding from dental extraction or surgery has aroused clinical suspicion. Menorrhagia, unexplained by local or hormonal factors, can also be the presenting symptom: an estimated 20% of women with menorrhagia have VWD. The distribution of bleeding in VWD can be explained on the basis that VWF is required for platelet adhesion at high shear rate, which is the condition of flow found in the smallest blood vessels exposed to trauma in skin and mucous membranes. Haemarthroses do not occur in typical mild dominant VWD. Much less common is autosomal recessive (type 3) VWD, where VWF is completely absent and FVIII:C levels are usually around 1 or 2 units/dL. These patients have a bleeding tendency that clinically resembles severe haemophilia A, with haemarthroses, muscle bleeds and life-threatening haemorrhage after trauma, as well as proneness to small-vessel bleeding, which is not a feature of haemophilia A.

Mild bleeding symptoms of the type typical of VWD are very common in the general population and thus are not specific for the presence of a bleeding disorder. It is now recommended that a simplified bleeding score (e.g. Bowman) is used to assess the likelihood of a significant defect in haemostasis and that the result is borne in mind when interpreting the results of laboratory investigations.

Laboratory diagnosis

Preliminary diagnosis

After obtaining a suggestive personal history and a family history, the preliminary tests required are a full blood count,

coagulation screen, FVIII assay, VWF:Ag and a measure of VWF activity, usually ristocetin cofactor activity (VWF:RCo).

The laboratory diagnosis of VWD rests on assessing both the amount of VWF present (VWF:Ag) and its functional capacity. At present, it is generally possible to assess three important functions.

1 FVIII binding. Assessed first by a FVIII assay and then if this is reduced, by an assay of VWF FVIII-binding capacity using a modified ELISA-based technique.

2 Platelet-dependent function. The standard assessment of VWF adhesive functional activity remains the ristocetin cofactor assay (VWF:RCo). In this assay, dilutions of patient plasma are tested for their ability to promote platelet agglutination in the presence of the antibiotic ristocetin.

3 Collagen-binding function (VWF:CB). This recently introduced measurement is performed in an ELISA-based assay in which a well coated with collagen is used to capture VWF. Measures of VWF:RCo and VWF:CB are both sensitive to the loss of high-molecular-weight multimers, but measure different binding properties of VWF. Thus they should be seen as complementary rather than alternative assays.

In addition, a global measure of primary haemostasis is also useful. Traditionally this was provided by the template bleeding time but this has a poor sensitivity for VWD and has largely been replaced by devices such as the PFA-100. The PFA-100 has very good sensitivity for VWD, although obviously does not distinguish it from platelet disorders and will not detect collagen abnormalities. Repeatedly normal PFA-100 results make a disorder of VWF function unlikely.

Secondary tests for classification of VWD

If a deficiency suggestive of VWD is detected then further tests, in particular multimeric analysis and ristocetin-induced platelet aggregation (RIPA), are recommended to allow accurate subtyping of the VWD. The most important of these is VWF multimer size analysis, which will demonstrate the distribution of VWF multimers and the pattern of flanking bands (Figure 41.7) adjacent to the main multimer bands. Using the tests described above, VWD can be classified into a limited number of types (Tables 41.4 and 41.5). The classification of VWD has been examined many times and extensive guidelines are available, detailed in the bibliography. What follows is necessarily a limited summary of much work.

Type 1 VWD is defined as a simple quantitative deficiency of VWF and the VWF present should be functionally normal. This means that the VWF:Ag and VWF:RCo should be concordant and the VWF should have an essentially normal multimeric pattern. In practice it is acceptable that the ratio of antigen to function should be in excess of 0.7 and there should be no significant loss of high-molecular-weight multimers, although on close inspection many subtle abnormalities of multimer pattern can be discerned.

Figure 41.7 Multimer analysis of VWF from patients with VWD and normal control subjects. Note that many cases classified at present as type 2A were previously subdivided according to the details of the abnormality of triplet pattern.

The characteristic of the 2A, 2B and 2M variants is a functional deficiency of VWF activity, which is reduced to below 0.7 of the antigenic measure. In type 2A, this results from a lack of high- and intermediate-size VWF multimers, whereas in type 2M a similar loss of platelet-binding activity is seen despite the presence of normal VWF multimeric composition and is caused by mutations in the VWF GPIb-binding site. Loss of high-molecular-weight multimers in type 2A may arise from failures of intracellular processing or from accelerated proteolysis in the circulation due to mutations close to the ADAMTS-13 cleavage site. VWD due to an isolated collagen-binding defect without loss of high-molecular-weight multimers is rare, although a handful of cases have been reported. The associated bleeding disorder is mild, perhaps because VWF contains two collagen-binding sites.

In type 2B, VWF binds prematurely with platelets in the circulation and in the laboratory will agglutinate platelets at a low concentration of ristocetin (0.5 mg/mL) that has no effect with normal VWF (i.e. positive RIPA). If normal washed platelets are resuspended in the patient's plasma, the phenomenon is reproduced, demonstrating that the abnormality is in the plasma. Studies with purified type 2B VWF show that, unlike normal VWF, it binds directly to platelets without prior activation. *In vivo* this results in the loss of high-molecular-weight multimers and platelets from the circulation due to *in vivo* formation of platelet aggregates and also to increased cleavage of VWF by ADAMTS-13. Thus routine platelet aggregation studies with a range of ristocetin dosages should be performed

Table 41.4 Primary classification of von Willebrand disease.

<i>Subclassification</i>	<i>Type of VWF deficiency</i>	<i>VWF protein function</i>
Type 1	Quantitative partial deficiency	Normal
Type 2	Qualitative functional deficiency	Abnormal
Type 3	Quantitative complete deficiency	Undetectable

Table 41.5 Secondary classification of type 2 von Willebrand disease.

<i>Subtype</i>	<i>Platelet-associated function</i>	<i>FVIII-binding capacity</i>	<i>High-molecular-weight VWF multimers</i>
2A	Decreased	Normal	Absent
2B	Increased affinity for GPIb	Normal	Usually reduced/absent
2M	Decreased	Normal	Normal and occasionally ultra-large forms
2N	Normal	Markedly reduced	Normal

as part of the diagnostic work-up, as it is important to detect this variant (see below), which does not always show up in the other tests. Indeed a recent analysis showed that many patients with type 2B VWD have normal platelet counts and VWF multimer patterns.

A fourth type 2 variant, called type 2N (for Normandy), has been described. This is characterized by reduced affinity for FVIII but it is normal in other respects. Thus, laboratory investigations reveal only a reduced FVIII level (5–35%), which is easily mistaken for mild haemophilia. A clue to the correct diagnosis may come from the family history, and confirmation requires an assay of VWF FVIII-binding capacity or genetic analysis of FVIII and the VWF FVIII-binding site in the D' domain. The majority of patients are found to be type 1, which accounts for 75% of kindreds. Types 2A and 2B are fairly common, together accounting for about 15% of kindreds. Although classification has proved useful in understanding VWD and can help in planning treatment, some forms remain difficult to classify and may show features of more than one type.

Problems in diagnosis of type 1 VWD

The diagnosis of type 1 VWD implies that the patient has a significantly low level of VWF, which is responsible for an increased tendency to bleed. It is often not easy to be certain of this conclusion for the following reasons.

1 Slightly low levels of VWF are common in the population. Although the lower end of the normal range for VWF in the general population is approximately 50 units/dL, most of the 2.5% of the population who have levels below this have normal haemostasis. In particular, individuals with blood group O have VWF levels on average 30% lower than those with non-O blood groups and the lower end of a 'blood group O normal range' is approximately 35 units/dL. Thus the lower limit of the normal range is not the minimum level required for normal haemostasis (Table 41.6). Nonetheless, individuals with blood group O are over-represented in the group with type 1 VWD and there is a continuous relationship between bleeding tendency and VWF level that extends into the normal range without a clear cut-off between normal and abnormal.

2 A history of minor bleeding episodes (e.g. easy bruising, epistaxes) is very common in the population and is not a good

Table 41.6 Influence of ABO blood group on VWF:Ag values (u/dl) in volunteer blood donors.

<i>ABO type</i>	<i>N</i>	<i>VWF:Ag geometric mean</i>	<i>VWF:Ag geometric mean ± 2SD</i>
O	456	74.8	35.6–157.0
A	340	105.9	48.0–233.9
B	196	116.9	56.8–241.0
AB	109	123.3	63.8–238.2

Note the significantly lower levels in donors of blood group O compared with non-O donors.

predictor of bleeding in other circumstances such as operations. Equally, the patient may not yet have been exposed to a significant test of haemostasis.

3 As a result of the two points above, a history of, say, easy bruising and slightly low VWF levels will often be found together. However, this does not mean that the patient has VWD and caution should be exercised in drawing this conclusion as it has many consequences for the patient.

4 Intercurrent events such as stress, exercise, illness and pregnancy may all elevate the VWF level, making it difficult to be certain that a representative measure of VWF levels has been obtained. It is therefore necessary to perform carefully standardized sets of assays with concordant results on at least two occasions to be sure of the diagnosis and its severity.

5 The family history is often unhelpful, particularly in mild cases where penetrance is weak or variable. This is probably the result of the modifying effects alluded to in (1) above. It is now evident that in some families, VWD does not segregate with the VWF gene. By inference, therefore, some of the mutations responsible for the type 1 phenotype will occur at loci other than the VWF gene, although what these are remains to be determined.

6 Finally, review of many cases previously diagnosed as type 1 VWD has concluded that many are in fact better categorized as type 2M after better assessment of the VWF antigen-activity ratio.

When there is a clear bleeding history and FVIII, VWF:Ag and VWF:RCo are all clearly reduced (e.g. < 25 units/dL) and the platelet count is normal, the diagnosis is easily made (see Tables 41.4 and 41.5). However, in the absence of a clear bleeding history, individuals with VWF activity in the range 25–50 units/dL are best regarded as simply being at slightly increased risk of bleeding. When VWF levels in the range 25–50 units/dL are associated with bleeding, it is very likely that other factors such as mildly impaired platelet function play a contributory role. This is especially true of the milder cases of type 1 VWD (see below).

Treatment

Patients with mild or moderate VWD attend infrequently for treatment. The first-line treatment for minor bleeding after local measures have failed in type 1 VWD is desmopressin. This will produce a brisk rise in VWF and FVIII levels (30 min after intravenous infusion) and a shortening of the bleeding time (for details of therapy see discussion of mild haemophilia A; see p. 800). Desmopressin is much less effective in types 2A and 2M, presumably because the patient's released VWF is highly abnormal and still unable to promote platelet adhesion. Desmopressin is generally regarded as contraindicated in type 2B VWD, as the released abnormal VWF will cause circulatory platelet aggregates to form, with a further fall in the platelet count. Before relying on desmopressin for therapy, patients should be given a test dose of DDAVP in order to determine the response at 30–60 min because it varies considerably. In addition, the duration of the response is also variable and further samples at 6–8 hours should be taken: some forms of type 1 VWD (e.g. VWF Vicenza) are characterized by a much shortened survival of VWF. A therapeutic trial may also be worthwhile in type 2A as some families do respond. In type 2N, the FVIII response is of normal magnitude but is of limited efficacy due to its short duration, emphasizing the importance of making the correct diagnosis. It may still be useful for minor procedures. Desmopressin is best avoided in small children (< 2 years) as there is a risk of hyponatraemia and consequent seizures. It is also contraindicated in elderly patients or those with arterial disease as there is a risk of arterial thrombosis. Desmopressin therapy is often combined with tranexamic acid. However, tranexamic acid may be effective on its own in some circumstances such as menorrhagia or as a mouthwash for oral cavity bleeding.

In patients in whom desmopressin is ineffective or contraindicated, the next line of treatment is a concentrate containing adequate amounts of functionally active VWF with preservation of the high-molecular-weight multimers. As with all concentrates, the source of plasma and viral inactivation are also important. Recombinant VWF concentrate is not yet licensed but is in early clinical trials. Cryoprecipitate has been used in these circumstances but cannot be subjected to viral inactivation procedures and is therefore not recommended as first-line therapy. Factor concentrates will always be required for treatment of type 3 VWD. Depending on the responses obtained with desmopressin, the duration of treatment and the presence of other contraindications, they may also be required in other type 2 and type 1 variants. FVIII concentrates vary considerably in the amount of VWF they contain and in the extent to which this is degraded or remains in the form of functionally active high-molecular-weight multimers. Those that contain significant amounts of VWF that were effective in treating VWD were initially of intermediate purity, but high-purity more specifically designed VWF concentrates are now available that contain

well-preserved VWF protein. The composition and VWF/FVIII ratio varies considerably between products. It is important to remember that following infusion of some high-purity VWF with low FVIII content there is a delay of approximately 12 hours before the level of FVIII rises substantially and, if rapid correction is required, FVIII concentrate should also be given. In general, none of these replacement treatments is reliable in correcting the bleeding time, but this is not necessarily a bar to effective haemostasis. This seemingly paradoxical result may be because they do not correct the deficiency of intraplatelet VWF or because the largest high-molecular-weight multimers are not present. In situations when concentrates fail to stop bleeding, cryoprecipitate and platelet concentrates may prove effective.

Clinical course and complications

Patients with types 1 and 2 VWD lead relatively normal lives, with normal life expectancy. Menstruation is seldom a cause of severe blood loss, although menorrhagia is common. This can usually be managed satisfactorily with antifibrinolytics or by oral contraceptive estrogen/progesterone combinations. The Mirena coil is also effective. If these are not effective, then self-administration at home of desmopressin by intranasal or subcutaneous routes can be useful. In later years, some patients require hysterectomy. During pregnancy, the VWF levels rise spontaneously to the normal or low-normal range in most patients with type 1 VWD. In type 2, the response is unpredictable and should be closely monitored: because of increased production of abnormal VWF, VWF:Ag may rise to normal levels but with VWF:RCO still significantly low. Type 2B is particularly complicated in pregnancy because the rise in endogenous VWF production exacerbates the thrombocytopenia. Patients with severe type 3 disease have a clinical course resembling severe or moderately severe haemophilia A, including the development of joint damage. A small number of patients with type 3 disease develop antibodies to VWF, which inhibit its platelet adhesion-promoting property and cause rapid removal from the circulation of infused material. Unlike anti-FVIII antibodies, some anti-VWF antibodies may mediate anaphylactic shock.

Molecular genetics

The cloning of VWF cDNA and its gene has led to progress in identifying the underlying mutations responsible for the various phenotypes (Figure 41.8). As with the FVIII gene, the sheer size of the DNA region involved presents some problems of localization, but these are being overcome by powerful screening methods. A database of mutations responsible for VWD has been established at <http://www.shef.ac.uk/vwf/vwd.html>.

Type 1

In the last few years there have been extensive studies to determine the molecular basis of type 1 VWD and a number of important points have emerged. Firstly, in about 35% of cases, the disorder does not segregate with the VWF locus and is therefore presumably the result of the combination of other modifying genes, in particular the ABO locus. This phenomenon is most common in individuals diagnosed with VWD and VWF levels above 30 units/dL and involves a disproportionate number of blood group O individuals. The likelihood of the disorder segregating with the VWF gene and of a causative mutation being identified increases significantly as the VWF level falls and a mutation is found in all cases where the VWF multimer pattern is abnormal. Among those with type 1 VWD and an identified mutation, mutations are widely scattered throughout the molecule. Similarly, in the more severe cases a typical autosomal dominant pattern of inheritance with strong penetrance is seen, whereas in milder cases this is often not apparent.

Type 2

Mutations responsible for type 2 VWD affect the relevant functional site in the molecule and the corresponding portion of the gene. Mutations causing types 2M and 2B both affect the binding site for platelet GPIb on VWF and are found within the A1 domain of the molecule. They are inherited dominantly. As discussed above, type 2A may arise from increased susceptibility to proteolysis by ADAMTS-13 and this type is associated with mutations in the A2 domain. Otherwise, type 2A mutations are scattered throughout the gene but particularly in the propeptide, D'-D3 and the cysteine knot. In general, type 2A is dominant but occasional recessive forms occur. Mutations causing type 2N are found in the FVIII-binding site in the D' domain but because the binding capacity of VWF greatly exceeds the FVIII concentration, the inheritance is recessive.

Type 3

Type 3 is characterized by the complete absence of VWF and so arises from inactivating or null mutations in both VWF alleles and is inherited in an autosomal recessive manner. The rare patients who develop antibodies to VWF nearly all have large deletions of their VWF gene.

Pseudo von Willebrand disease (platelet-type)

Several families have been described with a disorder closely resembling type 2B VWD, but in whom mixing experiments show the defect to be in their platelets rather than their plasma. Patients with pseudo VWD have moderately reduced levels of VWF:Ag and platelets, with an enhanced response of their platelet-rich plasma to low levels of ristocetin (0.5 mg/mL). The addition of normal cryoprecipitate to their washed platelets

Figure 41.8 (a) Mutations found in patients diagnosed with type 1 VWD in the Canadian and European studies. Note that not all these mutations have been shown to be causal and that classification as type 1 may sometimes be contentious. (From James *et al.* 2007 with permission.)
 (b) Distribution of mutations responsible for type 2 VWD. The domain structure of the monomer is shown, as well as the regions in which the mutations cluster in relation to the functional domains of the molecule. (From Goodeve *et al.* 2007 with permission.)

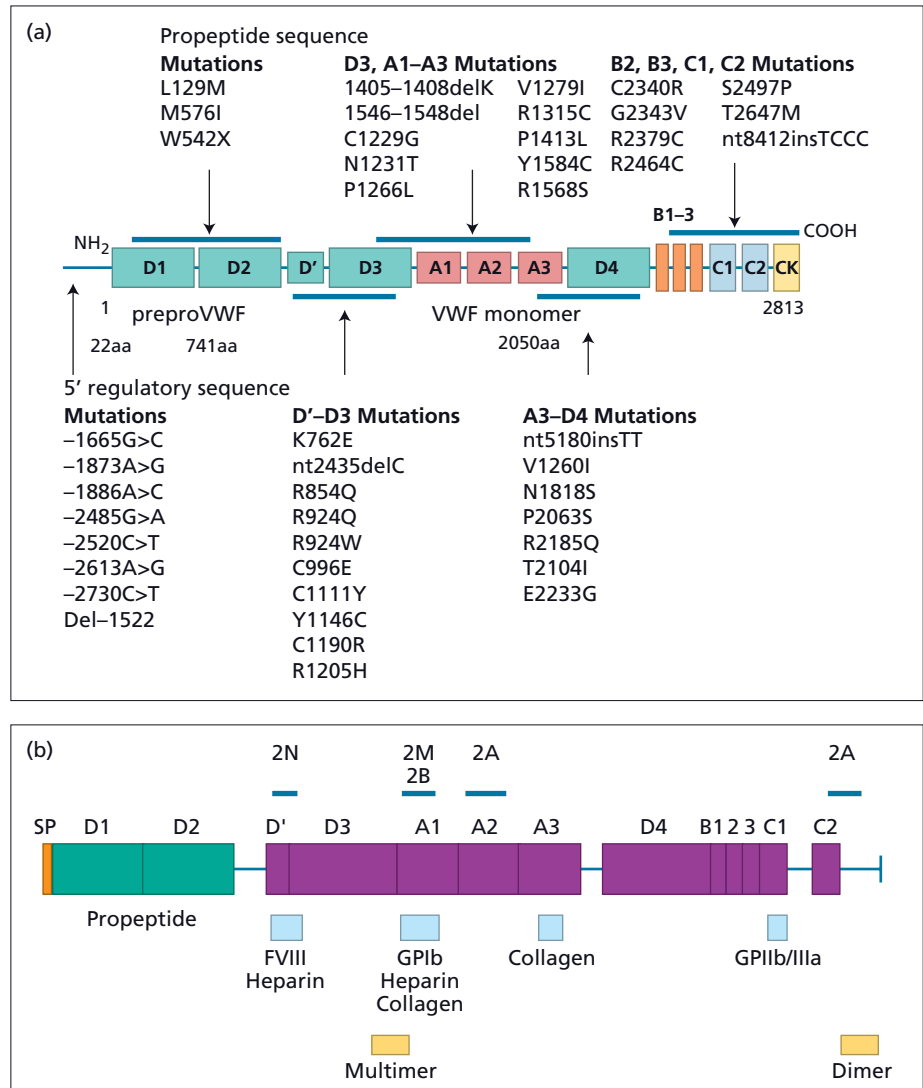

Table 41.7 Disorders associated with acquired von Willebrand syndrome and mechanism responsible.

Disorder	Mechanism	Treatment
Hypothyroidism	Reduced synthesis	Correct thyroid status
Aortic stenosis	Shear stress	Replace aortic valve
Myeloproliferative	Adherence to platelets and increased cleavage	Restore platelet count to normal
IgG paraprotein	Immune	IVIg, chemotherapy to reduce paraproteins
IgM paraprotein	Immune	Chemotherapy (IVIg ineffective)
Wilms tumour	Adsorption	Tumour removal if possible

IVIg, intravenous immunoglobulin.

causes spontaneous aggregation, whereas the reverse experiment is without effect (compare with type 2B). Missense mutations in platelet membrane GPIb, such that it spontaneously binds higher multimers of VWF, have been shown to be the underlying cause of this autosomally dominant mild bleeding syndrome. Treatment has not been extensively evaluated, but it should probably be with normal platelet concentrates, rather than desmopressin or cryoprecipitate. Thus this syndrome should be excluded by mixing tests as above or by genetic analysis before diagnosing type 2B VWD.

Acquired von Willebrand syndrome

In a number of circumstances patients may acquire a deficiency of VWF function that is not inherited. The commonest association is with a paraprotein that binds to VWF and accelerates clearance, producing a type 2A or type 3 pattern. It is also associated with myeloproliferative disease when thrombocytosis is present and in hypothyroidism (Table 41.7). Severe aortic stenosis can cause sufficient shear damage to VWF to cause an acquired von Willebrand syndrome that resolves after valve replacement. In the long term, treatment of the underlying disorder will improve the syndrome. If urgent treatment is required, then replacement therapy may be necessary (taking into account accelerated clearance) or IgG paraproteins will usually respond to intravenous immunoglobulin.

The rare bleeding disorders (RBDs), including the inherited deficiencies of such coagulation factors as fibrinogen, factor (F) II, FV, combined FV and FVIII, FVII, FX, FXI, FXIII and of multiple deficiency of vitamin K-dependent factors, are usually transmitted in an autosomal recessive manner. The prevalence of RBDs in the general population is low, and homozygous or double heterozygous deficiencies vary from 1 in 500 000 for FVII deficiency to 1 in 2 million for prothrombin and FXIII deficiencies (Table 42.1). The prevalence of RBDs is also strongly influenced by ethnicity and is significantly increased by a high rate of consanguinity in the population.

Until 1980, only sparse information on RBDs was available, but in the last decade the number of reported studies has considerably increased, particularly pertaining to the molecular aspects of RBDs. At the same time, interest in the worldwide distribution of RBDs led to the creation of large databases aimed at collecting epidemiological data and at providing information to haemophilia organizations and treatment centres involved in reducing or preventing complications of bleeding. Two recent large data collections have helped to derive the worldwide distribution of RBDs (Figure 42.1), one by the World Federation of Haemophilia (WFH, <http://www.wfh.org/>) and the other by the International Rare Bleeding Disorders Database (RBDD, www.rbdd.org). The WFH started collecting information on haemophilia care throughout the world in 1998, but collection of data on RBDs only started in 2004. The current global survey includes basic demographic information, data on care resources and treatment products, and information on the prevalence of infectious complications such as HIV and hepatitis C in individuals with haemophilia, von Willebrand disease, platelet disorders and other RBDs. The RBDD, developed in 2004, has spearheaded the development of an international network of care providers to work together to discuss prevalence, clinical manifestations, and need for coordinated and consistent data collection. The goal of this international community effort is to better identify the number of affected individuals throughout the world, to define the clinical manifestations and sequelae associated with these disorders, and to share diagnostic and treatment expertise. Comparison of the data obtained by the two surveys shows similar results, confirming that FVII and FXI deficiencies are the most prevalent RBDs (representing about 29–33% of the total number of affected patients), followed by deficiencies of fibrinogen, FV and FX (8–9%), FXIII (~ 6%) and combined FV and FVIII (~ 5%), while the rarest disorder was FII deficiency with a prevalence of 2%.

It is not possible to define a clear bleeding pattern among patients with RBDs, as symptoms are varied and heterogeneously distributed, but on the whole bleeding that endangers life, such as central nervous system (CNS) and musculoskeletal bleeding, appears to be less frequent than in haemophilia.

Table 42.1 General features of autosomal recessive deficiency of coagulation factors.

Deficiency	Estimated prevalence*	Gene (chromosome)
Fibrinogen	1 in 1 million	<i>FGA, FGB, FGG</i> (all on 4q28)
Prothrombin	1 in 2 million	<i>F2</i> (11p11–q12)
Factor V	1 in 1 million	<i>F5</i> (1q24.2)
Combined factor V and VIII	1 in 1 million	<i>LMAN1</i> (18q21.3–q22) <i>MCFD2</i> (2p21–p16.3)
Factor VII	1 in 500 000	<i>F7</i> (13q34)
Factor X	1 in 1 million	<i>F10</i> (13q34)
Factor XI	1 in 1 million	<i>F11</i> (4q35.2)
Factor XIII	1 in 2 million	<i>F13A1</i> (6p24–p25) <i>F13B</i> (1q31–q32.1)
Vitamin-K dependent coagulation factors	Reported in about 30 families	<i>GGCX</i> (2p12) <i>VKORC1</i> (16p11.2)

*Including dysfunctional proteins.

Figure 42.1 Worldwide distribution of rare bleeding disorders derived from two main large data collections (WFH and RBDD).

The laboratory diagnosis of RBDs is currently carried out by means of coagulation screening tests, such as the activated partial thromboplastin time, the prothrombin time and the thrombin time, applied to subjects reporting a clinical and family history of bleeding. Abnormal results of screening tests should be followed by specific coagulation assays in order to make the specific diagnosis of an RBD. Molecular diagnosis is based on a search for mutation in the genes encoding the corresponding coagulation factors. Exceptions are combined deficiency of FV and FVIII, caused by mutations in genes encoding proteins involved in FV and FVIII intracellular transport

(*MCFD2* and *LMAN1*), and combined deficiency of vitamin K-dependent proteins (FII, FVII, FIX and FX), caused by mutations in genes that encode enzymes involved in post-translational modification and in vitamin K metabolism (*GGCX* and *VKOR*). Genetic analysis is also important for prenatal and preimplantation genetic diagnosis, especially in those countries with a high rate of RBDs and consanguinity, particularly where genetic prevention by premature termination of pregnancy is not allowed. Since mutation detection became a relatively easy and available strategy in different laboratories worldwide, and it is not always clear whether the identified mutation could be the cause of the severe deficiency of a specific clotting factor, family history associated with allele frequency in the genetic population are important to determine if the identified mutations are common polymorphisms.

Treatment of RBDs is a difficult task, since information on the clinical management of RBDs is often scarce and replacement therapy of coagulation factors may require the prescription of unlicensed products that are not readily available. A patient's personal and family history of bleeding are important guides for management. Dosages and frequency of treatment depend on the minimal haemostatic level of the deficient factor, its plasma half-life and the type of bleeding episode. The main treatments in RBDs are represented by non-transfusional adjuvant therapies (antifibrinolytic amino acids, estrogen/progesterone) and replacement therapy of the deficient coagulation factor. Unfortunately, information on the safety and efficacy of the few available products is scarce and experience in their optimal use significantly more limited than that available for haemophilia.

Particular care should be paid to women affected by RBDs. Since the latter are inherited in an autosomal recessive manner, roughly about 50% of patients are women. This implies that the global distribution of RBDs also reflects the global distribution of affected women, posing important social and medical problems, such as excessive menstrual bleeding (or menorrhagia) and bleeding during pregnancy and childbirth. Affected women also suffer the secondary consequences of such events, such as chronic iron-deficiency anaemia and a significantly reduced quality of life, due mainly to a complicated reproductive life but also to limitations in social activities and work. Postpartum bleeding often occurs if replacement therapy is not administered after delivery. Recurrent miscarriages are also described, but only in afibrinogenaemic and FXIII-deficient women. In the end, pregnancy is not contraindicated in patients with RBDs but requires a multidisciplinary approach: the best management of pregnancy should be decided through the coordinated action of a team composed of paediatricians, haematologists and obstetricians. In addition to female healthcare, the same team should ensure investigation and management of potentially affected newborns, particularly in families already having one affected child, because severe FVII, FX and FXIII deficiency

cies present with a high risk of intracranial haemorrhage during the first week of life.

Fibrinogen deficiency

Fibrinogen deficiency is heterogeneous and two main phenotypes can be distinguished: plasma and platelet levels of the protein are not measurable or very low, leading to afibrinogenaemia and hypofibrinogenaemia. In other cases, low clottable fibrinogen contrasts with normal or moderately reduced fibrinogen antigen leading to dysfibrinogenaemia and hypodysfibrinogenaemia. Fibrinogen is produced in the hepatocyte from three homologous polypeptide chains, A α , B β and γ , which assemble to form a 340-kDa hexamer. The three genes encoding fibrinogen B β (*FGB*), A α (*FGA*) and γ (*FGG*), ordered from centromere to telomere, are clustered in a region of approximately 50 kb on chromosome 4 in humans.

Experimental disruption of the α -chain gene makes mice completely deficient in all the fibrinogen chains. There is no evidence of defective embryonic development, but the importance of fibrinogen in pregnancy is demonstrated in studies with fibrinogen knockout mice, which cannot maintain gestation to term. Both arterial and venous thromboembolic complications have been reported in afibrinogenaemic patients.

However, in the majority of patients no traditional thrombotic risk factors are present: one explanation for this predisposition is that even in the absence of fibrinogen, platelet aggregation is possible due to the action of von Willebrand factor and, in contrast to haemophiliacs, afibrinogenaemic patients are able to generate thrombin, both in the initial phase of limited production and also in the secondary burst of thrombin generation. In an *in vivo* thrombosis model, the number of embolized thrombi was sixfold higher in fibrinogen knockout mice than in wild-type mice, with large emboli very often leading to vessel occlusion (Table 42.2).

Clinical manifestations and treatment

Dysfibrinogenaemic and hypofibrinogenaemic patients are usually asymptomatic, while those with afibrinogenaemia have a bleeding tendency that usually manifests in the neonatal period, with 85% of cases presenting umbilical cord bleeding. Bleeding may also occur in the skin, gastrointestinal tract, genitourinary tract or the CNS, while persistent damage to the musculoskeletal system and resulting handicap is less frequent. A milder symptom such as epistaxis is also frequent. Women may suffer from menometrorrhagia, but some have normal menses. First-trimester abortion is common in women with afibrinogenaemia but less common in those with dysfibrinogenaemia and

Table 42.2 Knockout mouse models of coagulation factors and vitamin K dependent proteins.

Coagulation factor	Embryonic lethality	Compatible with survival to adulthood	Murine phenotype
Fibrinogen	No	Yes	Normal embryonic development, bleeding events in one-third of newborns, females with deletion of both alleles do not support pregnancy due to vaginal bleeding
FII	Partial	No	Neonatal haemorrhage, no survival beyond several days, loss of vascular integrity
FV	Partial	No	Death caused by haemorrhage in neonates, no survival beyond 2 hours, vascular defects
FVII	No	No	Normal embryonic development, death caused by haemorrhage in neonates, no survival beyond 24 days, no vascular defects
FX	Partial	No	Death caused by haemorrhage in neonates, no survival beyond 20 days, no vascular defects
FXI	No	Yes	Normal life, no tendency to spontaneous bleeding
FXIII	No	Yes	Reproduction impaired and bleeding episodes associated with reduced survival
Vitamin K dependent (<i>GGCX</i>)	Partial	No	Massive intra-abdominal haemorrhage
Vitamin K dependent (<i>VKORC1</i>)	No	No	Death caused by predominantly intracerebral haemorrhage 2–20 days after birth

has not been reported in hypofibrinogenaemia. Postpartum bleeding is relatively frequent when no prophylactic replacement therapy is given.

The conventional treatment is episodic and on-demand, in which fibrinogen is administered as soon as possible after onset of bleeding; however, effective long-term secondary prophylaxis with administration of fibrinogen every 7–14 days (particularly after CNS bleeds) has recently been described. Replacement therapy is effective in treating bleeding episodes in congenital fibrinogen disorders but, depending on the country of residence, patients receive fresh-frozen plasma (FFP), cryoprecipitate or fibrinogen concentrate. The latter is the treatment of choice because it is virally inactivated and thus safer than cryoprecipitate or FFP. In many countries fibrinogen concentrates remain inaccessible due to the cost of production.

Molecular defects

In 1999, a homozygous deletion of approximately 11 kb in the *FGA* gene was first identified as a cause of inherited afibrinogenaemia in four members of a Swiss family by Neerman-Arbez and colleagues. Since this report many other mutations, the majority in *FGA*, have been identified in patients with afibrinogenaemia (in homozygosity or compound heterozygosity) or hypofibrinogenaemia. The relatively high number of mutations located in *FGA* led to the hypothesis that mutations tend to cluster in this gene, resulting in complete lack of production of fibrinogen A α chain or of a severely truncated protein. Of particular interest are missense mutations that lead to complete fibrinogen deficiency. These are clustered in the highly conserved C-terminal globular domains of the B β and γ chains. Recent functional studies of these mutations in transfected cells have demonstrated either impaired assembly or impaired secretion of the fibrinogen hexamer, demonstrating the importance of these globular structures in quality control of fibrinogen biosynthesis. To date only two missense mutations, p.Cys64Phe and p.Met70Arg (Cys45Phe and Met51Arg, numbering without the signal peptide) located at the start of the coiled-coil in *FGA*, have been found in fibrinogen deficiency.

Among the large number of mutations identified in patients with congenital afibrinogenaemia, two common mutations were found in individuals of European origin, both in *FGA*: the Asp153SerfsX4 mutation (or c.510+1G→T according to the nomenclature guidelines of the Human Genome Variation Society, www.hgvs.org) and the *FGA* 11-kb deletion, both found on multiple haplotypes. Accordingly, the Asp153SerfsX4 should be the first mutation to be screened in all new patients of European origin. Figure 42.2 shows the mutations accounting for afibrinogenaemia and hypofibrinogenaemia identified so far. Two further residues of prime interest in screening for dysfibrinogenaemia are residue Arg16 in exon 2 on *FGA*, which is part of the thrombin cleavage site in the fibrinogen A α chain,

and residue Arg275 in exon 8 on *FGG*, which is important for fibrin polymerization.

Prothrombin deficiency

Prothrombin deficiency is perhaps the rarest inherited coagulation disorder, with a prevalence of about 1 in 2 million. Based on the measurement of prothrombin (FII) activity and antigen level, two main phenotypes can be distinguished: hypoprothrombinaemia (both levels are concomitantly low) and dysprothrombinaemia (normal or near-normal synthesis of a dysfunctional protein); hypoprothrombinaemia associated with dysprothrombinaemia was also described in compound heterozygosity. FII, a vitamin-K dependent glycoprotein synthesized by liver, is the zymogen of the serine protease α -thrombin and is encoded by a gene of approximately 21 kb located on chromosome 11. No living patient with undetectable plasma prothrombin has been reported so far, consistent with the demonstration that in mice complete prothrombin deficiency obtained by gene knockout is incompatible with life, resulting in embryonic or neonatal lethality (see Table 42.2).

Clinical manifestations and treatment

Hypoprothrombinaemia, with plasma levels below 10%, is characterized by severe bleeding manifestations such as spontaneous haematomas and haemarthroses, intracerebral bleeding and gastrointestinal haemorrhages. Clinically, dysprothrombinaemia manifests as a variable bleeding tendency that is usually less severe than true deficiency, while heterozygote subjects are usually asymptomatic although, occasionally, excessive bleeding after surgical procedures can be observed. In homozygous women menorrhagia is frequent.

Replacement therapy is needed only in homozygous patients, in case of bleeding or to ensure adequate prophylaxis before surgical procedures. Since no FII concentrate exists, FFP, prothrombin complex concentrate (PCC) or both are used for treating patients. In severe clinical settings, higher levels of prothrombin may be achieved with PCCs without the risk of potential volume overload induced by FFP. However, most PCCs contain other vitamin-K dependent coagulation factors, which could potentially induce thrombotic complications.

Molecular defects

Genetic variants have been identified all along the prothrombin gene, although frequently they involve the catalytic area, consistent with the fact that they affect the enzymatic activity of the protein. Mutations in different exons may cause similar phenotypic expression of prothrombin. Most of the natural mutants derive from missense mutations (80%), although insertion/deletions (10%), nonsense mutations (6%) and splice-site

Figure 42.2 Schematic representation of the localization of the main mutations along the human fibrinogen genes, projected onto the exons encoding the domains of the protein. Exons

(rectangles) are drawn to scale while introns (lines) are not to scale. Gross deletions are indicated by arrows.

mutations (4%) have also been described. The abnormalities may be classified according to the site of the defect, i.e. in the activation mechanism or in the protease activity of thrombin. The latter group can be subdivided into two subtypes: one in which there is defective amidolytic activity and another where there is defective interaction of thrombin with substrates because of mutations in the molecular recognition domains. Other mutations indirectly affect the catalytic activity of thrombin, as they cause perturbation of the Na⁺-binding site of the enzyme. However, while *in vitro* Na⁺ binding seems to play a major role in thrombin activity, the natural prothrombin mutants with altered Na⁺ binding described so far (Arg517Gln and Lys556Thr, in exons 13 and 14, respectively) had only a mild haemorrhagic phenotype. To date several functional studies have been performed to elucidate the structure–function relationship. However, recent biochemical characterization of natural prothrombin mutants (Des-Lys9/10 and Phe299(7)Val) has revealed an important role of the A-chain for correct function of the catalytic B-chain of thrombin. These natural mutations could affect the interaction of divalent metals with thrombin, recently localized at the interface between the A and B chains, which seem to stabilize the active conformation of thrombin. Figure 42.3 shows the mutations identified so far.

Factor V deficiency

FV has a double role in the coagulation process: it is a protein cofactor required by the prothrombinase complex for thrombin generation, but also contributes to the anticoagulant pathway by downregulating FVIII activity, so that FV deficiency may result in either haemorrhagic or thrombotic tendency. The majority of individuals with FV deficiency are characterized by concomitant deficiency of FV activity and antigen levels (type I deficiency), but approximately 25% have normal antigen levels, indicating the presence of a dysfunctional protein (type II deficiency). FV is mainly secreted by hepatocytes, but there is evidence that it can also be synthesized *in vivo* in the megakaryocyte/platelet lineage. FV is encoded by a large (80 kb) and complex (25 exons) gene located on chromosome 1. Experimental deficiency of FV in gene knockout mice leads to defective embryonic development and early haemorrhagic death. However, mice expressing minimal FV activity below the sensitivity threshold of the detection assay (< 0.1%) differ from the complete knockout mice because they do survive (see Table 42.2).

Clinical manifestations and treatment

Symptomatic patients usually present with skin and mucous membrane bleeding; epistaxis and menorrhagia are relatively frequent, even in patients with measurable FV levels. Typically, FV-deficient patients are difficult to diagnose and often come

to medical attention because of a positive family history or abnormal preoperative laboratory screen. On the whole, it appears that the clinical phenotype of patients with FV deficiency is completely different from that seen in the mouse knockout model. Haemarthroses and haematomas occur in only 25% of patients, and life-threatening bleeding episodes in the gastrointestinal tract and the CNS are rare. There are no published data on management of pregnancy in women with FV deficiency. Postoperative and oral cavity haemorrhages are common, but not fully predictable, as these symptoms also occur with plasma levels as high as 5–10%. This discrepancy is likely to be explained by the relatively poor sensitivity of FV bioassays, which do not measure those small amounts of the factor that are probably sufficient to make the deficiency compatible with life and a mild clinical phenotype. Replacement therapy with FV can be administered only through FFP, preferably virus inactivated, because no FV concentrate is available and FV is not contained in significant amount in cryoprecipitate or PCCs.

Molecular defects

Among rare coagulation disorders, FV deficiency is one of the least characterized from the molecular point of view, with only 56 genetic defects hitherto described, the majority of them identified in the last 4 years (Figure 42.4). A total of 48 mutations seem to be responsible for the type I deficiency, only one being recurrent (Tyr1702Cys, repeatedly found in Italian individuals), confirming the remarkable allelic heterogeneity of the disease. A mild type I deficiency (decrease in FV levels) has also been associated with two FV variants: the functional Met2120Thr polymorphism, demonstrated to cause about 25% reduction in FV levels, and the HR2 haplotype defined by a group of more than 10 polymorphisms; among these, the dominant contribution of the Asp2194Gly variant was demonstrated by expression experiments in eukaryotic cells. Only one genetic defect, Ala221Val, associated with type II deficiency has so far been reported. Mutations causing FV deficiency do not cover the full spectrum of possible genetic lesions, since mutations located in the promoter as well as large deletions are absent. Missense mutations are completely absent in the large exon 13, coding for the whole B domain. This can probably be explained by an increased tolerance of this domain to variations, as suggested by the fact that it is highly polymorphic and not evolutionarily conserved. Finally, no clear genotype–phenotype correlation emerges between the clinical phenotype, plasma FV levels and the corresponding associated mutations in FV deficiency. In fact, despite carriership of the same mutations, some patients often present with a more severe bleeding pattern than others. Recently, the possibility that the severe FV-deficient phenotype may be modulated by a concomitant procoagulant defect was investigated by Duckers and colleagues, who showed that congenital FV deficiency associated with reduced plasma levels of

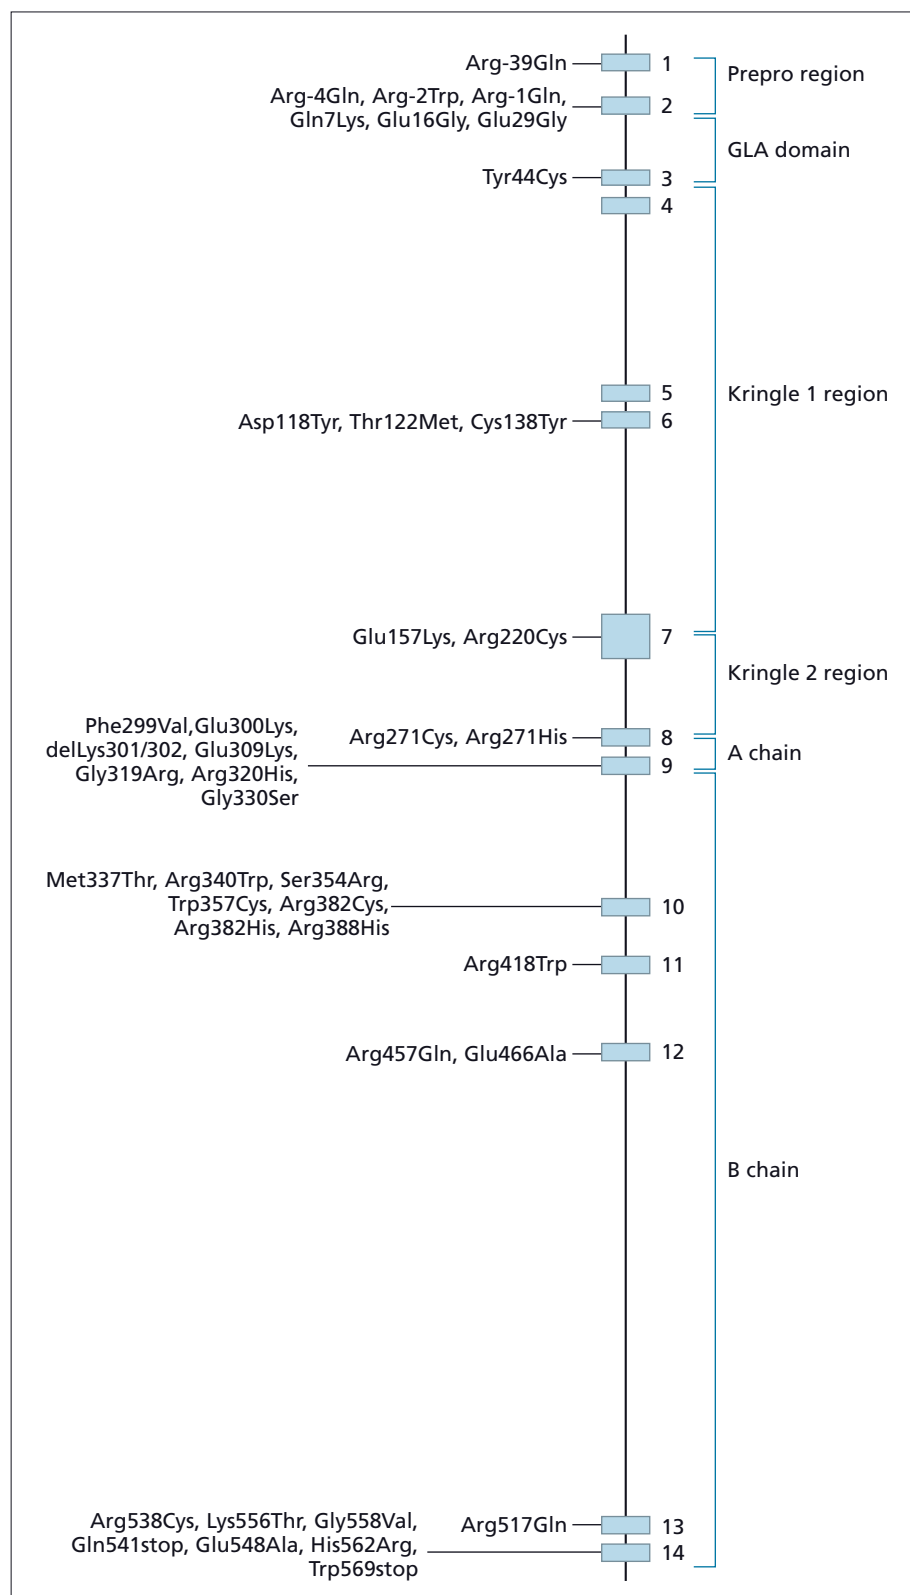

Figure 42.3 Schematic representation of the localization of the main mutations along the human prothrombin gene, projected onto the exons encoding the domains of the protein. Exons (rectangles) are drawn to scale while introns (lines) are not to scale.

tissue factor pathway inhibitor, which decreases the FV requirement for minimal thrombin generation to less than 1%, probably protects patients from severe life-threatening bleeding.

Combined deficiency of factor V and factor VIII

For many years the molecular mechanism for combined deficiency of these two factors, each transmitted with different patterns of inheritance (autosomal recessive for FV, X-linked for FVIII) and involving proteins encoded by different genes, was not understood. Finally, in 1998 combined FV and FVIII deficiency (F5F8D) was causally associated with mutations in the *LMAN1* gene, encoding lectin mannose-binding protein (previously named *ERGIC-53*), a 53-kDa type 1 transmembrane protein that acts as a chaperone in the intracellular transport of both factors. More recently, in 2003, another locus associated with the deficiency was identified in about 15% of affected families with no mutations in *LMAN1*; this was named the *MCFD2* gene, encoding multiple coagulation factor deficiency (MCFD)2 protein, which acts as a cofactor for *LMAN1*, specifically recruiting correctly folded FV and FVIII in the endoplasmic reticulum. Recent studies have failed to identify additional components of the *LMAN1*–*MCFD2* receptor complex, supporting the idea that F5F8D might be limited to *LMAN1* and *MCFD2*.

Clinical manifestations and treatment

F5F8D is characterized by concomitantly low levels (usually 5–20%) of the two coagulation factors, both as coagulant activity and as antigen. It appears that the concomitant presence of two coagulation defects does not enhance the haemorrhagic tendency observed in each defect separately (see section on FV deficiency). The phenotypes associated with mutations in *MCFD2* and *LMAN1* are indistinguishable and manifested only by deficiencies of FV and FVIII, although a selective delay in secretion of the cargo protein procathepsin C has been observed in HeLa cells overexpressing a dominant-negative form of *LMAN1*.

Symptoms are usually mild, with a predominance of easy bruising, epistaxis, and bleeding after dental extractions. Menorrhagia and postpartum bleeding have also been reported in affected women. More severe symptoms, such as haemarthroses and umbilical cord bleeding, are observed very seldom and gastrointestinal and CNS bleeding have been reported in only a few patients. Soft-tissue haematomas are unusual. Because of the mild clinical pattern, bleeding episodes are usually treated on demand and do not require regular prophylaxis. Sources of both FV and FVIII are needed and their differential plasma half-lives (FV 36 hours, FVIII 10–14 hours) have to be taken into consideration.

As there are no FV concentrates available and there is little or no FV present in cryoprecipitate or PCCs, replacement of FV can currently be achieved only through the use of FFP, preferably with virus-inactivated plasma. For FVIII replacement, a large number of products are available: the synthetic hormone desmopressin (DDAVP) can be successfully used for minor bleeding episodes to raise FVIII. However, the chemical efficacy of DDAVP needs to be tested in each patient and more than three to four consecutive treatments should be avoided. For severe bleeding, plasma-derived FVIII or recombinant FVIII concentrates are the treatments of choice and include FFP, plasma-derived concentrates and recombinant FVIII.

Molecular defects

F5F8D is caused by mutations in *LMAN1* or *MCFD2* proteins. The first is encoded by a gene of approximately 29 kb located on chromosome 18 and containing 13 exons, while the latter is encoded by a shorter gene of approximately 19 kb located on chromosome 2 and containing four exons. To date, a total of 48 mutations (Figures 42.5 and 42.6) have been described (32 in *LMAN1* and 16 in *MCFD2*; http://www.med.unc.edu/isth/mutations-databases/FVandFVIII_2006numbers.htm). All the *LMAN1* mutations reported so far are null mutations, with the exception of a Cys→Arg mutation that disrupts a disulphide bond required for oligomerization and which also destabilizes the protein. In contrast, both null and missense mutations have been identified in *MCFD2*; in particular, five of six missense mutations reported (Asp81Tyr, Asp89Ala, Asp122Val, Asp129Glu and Ile136Thr) disrupt *LMAN1* binding, indicating that *LMAN1* and *MCFD2* must function as a unit to transport FV and FVIII. Recently, Zhang and colleagues have performed a genotype–phenotype analysis to evaluate if mutations in the two different genes are associated with differences in FV and FVIII plasma levels. Mean plasma levels of FV and FVIII in patients with *MCFD2* mutations were significantly lower than those in patients with *LMAN1* mutations. These data suggest that *MCFD2* may play a primary role in the export of FV and FVIII from the endoplasmic reticulum.

Some mutations in both *LMAN1* and *MCFD2* recurred in more than one family, for example Met1Thr, 89insG and Lys302stop on *LMAN1* or IVS2+5G→A and Ile136Thr mutations on *MCFD2*. In particular, the *MCFD2* IVS2+5G→A appears to be one of the most common mutations causing F5F8D and it has now been identified in at least 13 unrelated families from different geographic regions (India, Italy, USA, Serbia and Germany).

Factor VII deficiency

FVII deficiency is the most common autosomal recessive coagulation disorder (1 in 500 000). A typical feature of this disease

Figure 42.5 Schematic representation of the localization of the main mutations along the human *LMAN1* gene, projected onto the exons encoding the domains of the protein. Exons (rectangles) are drawn to scale while introns (lines) are not to scale.

is its clinical heterogeneity, which ranges in severity from lethal to mild, or even asymptomatic forms. FVII is synthesized in the liver and is encoded by the FVII gene (*F7*) located on chromosome 13, 2.8 kb upstream of the FX gene. Plasma levels of FVII coagulant activity (FVII:C) and FVII antigen (FVII:Ag) are influenced by a number of genetic and environmental factors (sex, age, cholesterol and triglyceride levels) and it is also well known that FVII levels are modulated by *F7* polymorphisms. The majority of patients have concomitantly low levels of FVII:C and FVII:Ag, but several cases are characterized by normal or low borderline levels of FVII:Ag contrasting with lower levels of FVII:C. Most gene knockout mice made experimentally deficient in FVII develop normally, which suggests that complete lack of FVII is compatible with life (see Table 42.2).

Clinical manifestations and treatment

The severity of symptoms of FVII deficiency is variable and generally reported to be poorly correlated with plasma levels. Some patients do not bleed at all after major episodes of haemostasis. Life- or limb-endangering bleeding manifestations are relatively rare, the most frequent symptoms being epistaxis and menorrhagia. CNS bleeding was also reported to have high incidence (16%) in a series of 75 patients affected by FVII deficiency, the study concluding that the greatest risk factor for development of bleeding was trauma related to the birth process. However, these data were not confirmed by two subsequent large series of Italian and Iranian patients. Thrombotic episodes (particularly deep vein thrombosis) have also been reported in 3–4% of patients with FVII deficiency, particularly

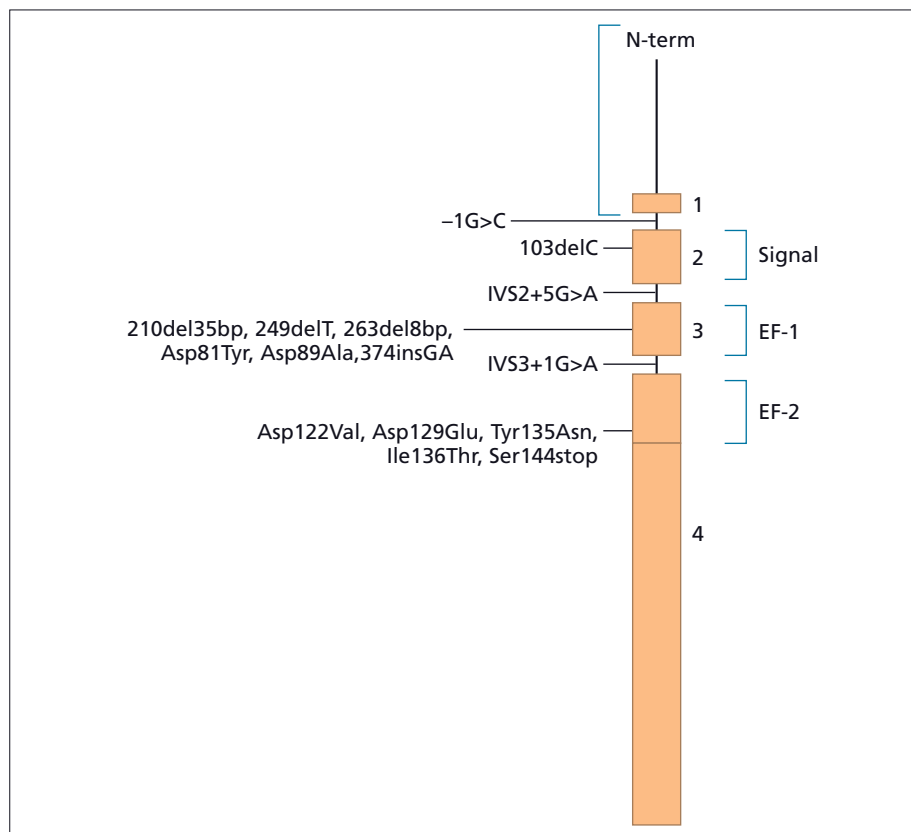

Figure 42.6 Schematic representation of the localization of the main mutations along the human *MCFD2* gene, projected onto the exons encoding the domains of the protein. Exons (rectangles) are drawn to scale while introns (lines) are not to scale.

in the presence of surgery and replacement treatment, but spontaneous thrombosis may also occur.

Lack of correlation between measured FVII:C *in vitro* and the clinical phenotype is well known and is probably due to the fact that only trace amounts of FVIIa are required to initiate coagulation *in vivo*. Empirical studies and mathematical modelling suggest that as little as 5 pmol/L (0.05% of normal FVII concentration) is sufficient to induce clot formation. None of the *in vitro* tests could differentiate between null and extremely low levels of FVII:C capable of initiating coagulation *in vivo*.

A number of therapeutic options can be offered to patients with FVII deficiency, including FFP, still used in developing countries, PCCs, plasma-derived FVII concentrates and recombinant FVIIa, which has to be considered the optimal replacement therapy because it can be used at very low dose (10–20 µg/kg). Prophylaxis has been a debated issue in FVII deficiency, especially because of the very short half-life of infused FVII in blood. *Ex vivo* studies have shown that infused recombinant FVIIa disappears quickly from the circulation but persists extravascularly bound to pericytes. These observations would support the feasibility of prophylaxis in FVII deficiency, but larger trials are needed to assess the optimal schedule.

The occurrence of frequent menorrhagic menses is almost invariably associated with iron deficiency and anaemia in

women with the severe form of FVII deficiency. Pregnancy itself does not require special precautions and uncomplicated delivery is possible without prophylaxis. However, all cases of postpartum bleeding reported so far occurred in women with low FVII coagulant activity (< 15 units/dL) not receiving prophylaxis. Therefore, delivery should occur under the coverage of a short-term replacement.

Molecular defects

The molecular bases of FVII deficiency are more extensively characterized than those of other defects, perhaps due to the relatively high frequency of this defect and small size of the gene. Mutations are very heterogeneous: missense variants are the most frequent lesions (70–80%), splice-site changes are also well represented, while nonsense mutations and small deletions are rare, particularly in the homozygous condition. Mutations are located throughout the gene, suggesting that all domains are important in maintaining the overall structure and function of FVII. The previously available online database <http://europium.csc.mrc.ac.uk/> allowed rapid access for researchers to the entire listing of *F7* mutations but is currently under revision; however, an updated overview of mutations is shown in Figure 42.7. The severe cases are all either homozygous or doubly heterozygous

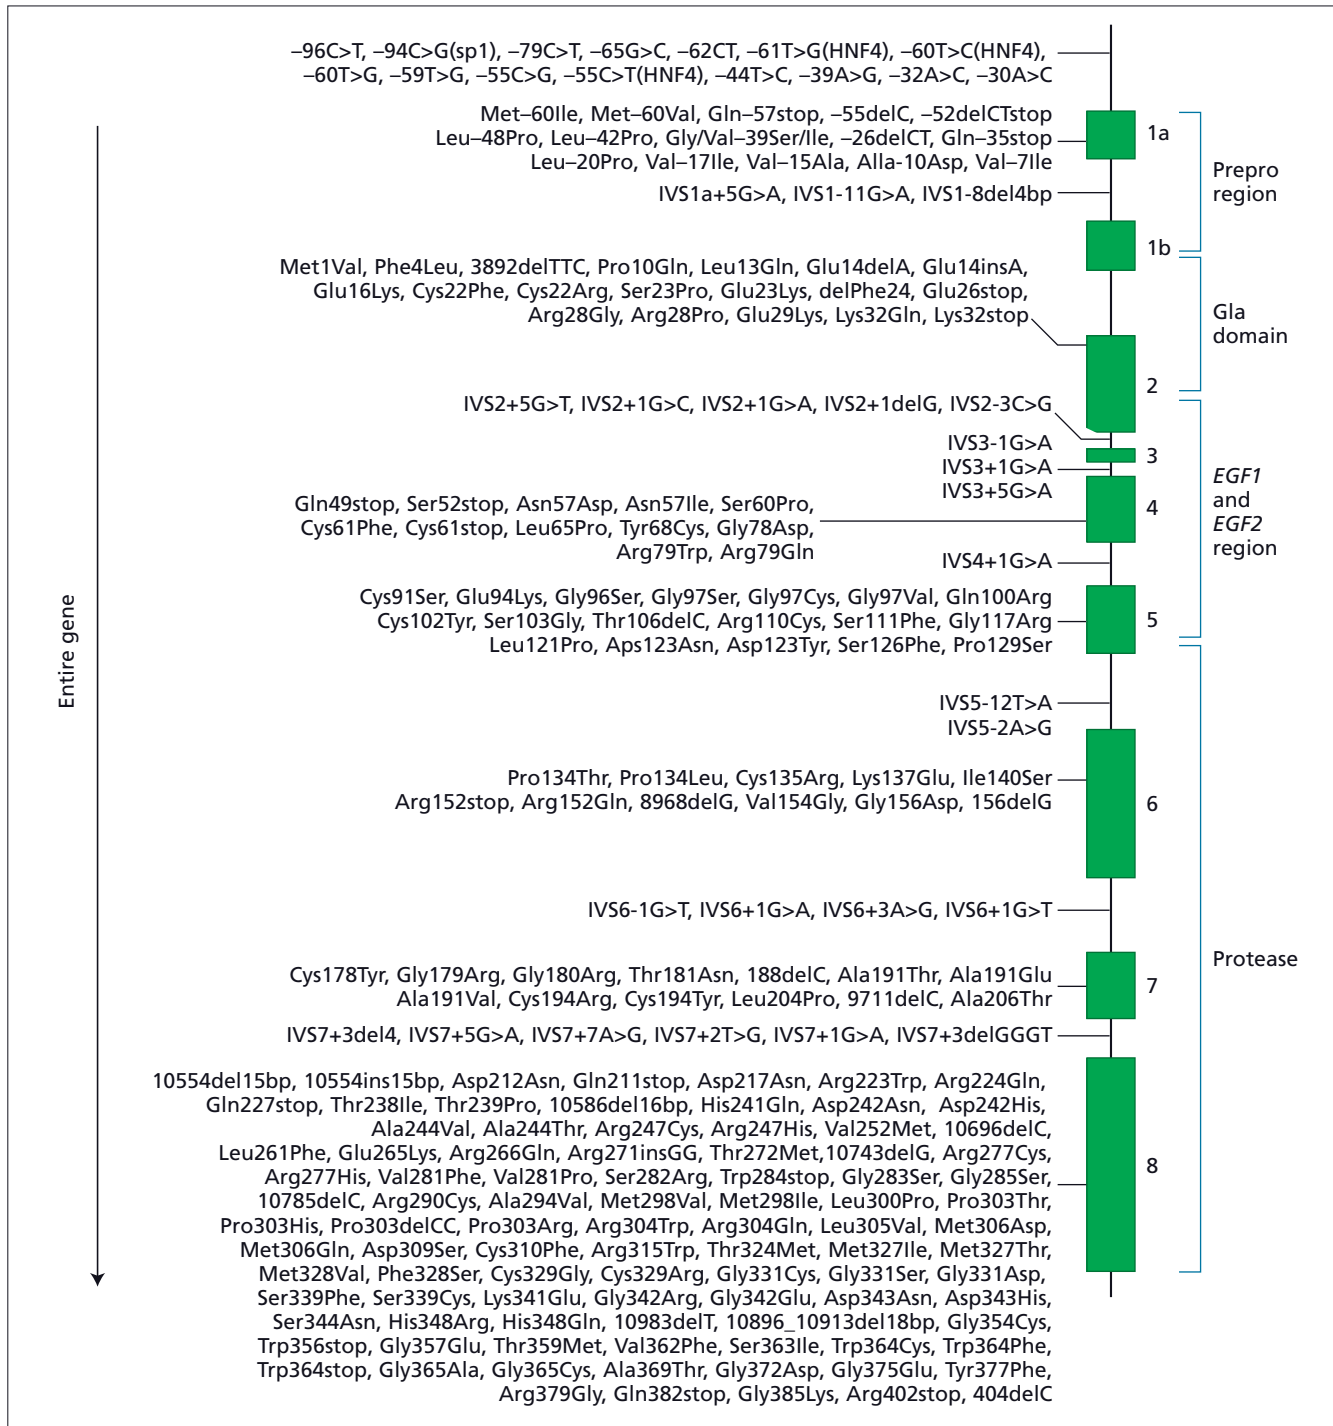

Figure 42.7 Schematic representation of the localization of the main mutations along the human FVII gene, projected onto the exons encoding the domains of the protein. Exons (rectangles)

are drawn to scale while introns (lines) are not to scale. Gross deletion is indicated by the arrow.

for mutations that disrupt expression of the protein (e.g. deletions, insertions, splice junctions and promoter mutations), resulting in FVII:C levels typically less than 2% of normal. Individuals with a mild/moderate clinical phenotype are homozygous or doubly heterozygous for missense mutations; however, some missense mutations are also associated with a severe phenotype.

Frequent mutations (Ala294Val, 11125delC, Arg304Gln, Cys310Phe) identified among hundreds of patients with FVII deficiency by different groups are associated with a range of clinical severity and neither FVII:C nor gender provide an explanation for this heterogeneity, suggesting that other modifying factors may influence the different clinical manifestations in subjects carrying the same mutation. It is known that FVII levels are modulated by *F7* polymorphisms: different genotypes demonstrated up to fivefold differences in mean FVII levels. Tightly linked polymorphisms in the 5' regulatory region regulate FVII levels and differential promoter activity *in vitro*; the p.Arg353Gln substitution in the catalytic domain, tightly associated with the decanucleotide insertion (g.-323 to -324insCCTATATCCT) and with the -401T allele in the promoter region, decreases FVII secretion, therefore reducing its plasma levels. The same effect is shown by the g.11293-11294insAA polymorphism in the 3' untranslated region of *F7* that negatively affects the steady state of mRNA levels, leading to a reduction in FVII mRNA by 40%, which subsequently reduces FVII protein levels. An additional polymorphism, located in intron 7, is characterized by the presence of a variable number of 37-bp repeats. This polymorphism is reported to be associated with variable rates of FVII transcriptional activity according to the number of repeats present in the genotype. The peculiar presence of such repeated regions, and of polymorphic variation of repeats within *F7*, requires careful design of PCR primers to detect gene rearrangements when molecular diagnosis is performed.

Factor X deficiency

FX is a glycoprotein that plays a pivotal role in the coagulation cascade, being the first enzyme in the common pathway of thrombin formation. FX is mainly synthesized by the liver and is encoded by the *FX* gene, comprising 22 kb and located on chromosome 13, a few kilobases downstream of the *F7*. The clinical phenotypes of FX deficiency are characterized by concomitantly low levels of coagulant activity and antigen, or low coagulant activity contrasting with normal or low borderline antigen values. Mice rendered experimentally deficient in FX by targeted inactivation of the *FX* gene showed frequent embryonic lethality. Those who survived bled to death intra-abdominally at birth and in the CNS within the first 3–4 weeks of life (see Table 42.2).

Clinical manifestations and treatment

In FX deficiency the bleeding tendency may appear at any age, although the more severely affected patients (FX coagulant activity < 1%) present early in life with, for instance, umbilical-stump, CNS or gastrointestinal bleeding. Patients with severe deficiencies also commonly experience haemarthroses and haematomas. The most common bleeding symptoms reported at all levels of severity are epistaxis and menorrhagia. In FX deficiency there is reasonable correlation between the severity of clinical manifestations and residual FX activity, confirming animal study results.

Data from the United Kingdom Haemophilia Centre Doctors' Organisation (UKHCDO) registry shows that the proportion of patients with this deficiency who require treatment is much higher than that of other rare coagulation deficiencies. There is no specific FX product, plasma derived or recombinant, available as yet for treatment of patients with FX deficiency; hence current treatment is based on the administration of FFP and PCCs. However, these treatments could be associated with some complications stemming from the use of large amounts of plasma, particularly in children and elderly patients with cardiac disease, or because of the high concentrations of FII, FVII and FIX in PCCs that could be associated with a risk of thromboembolic events. To overcome this problem, a freeze-dried human coagulation FIX and FX concentrate with specified amounts of FX (and FIX) has been developed recently. Therapeutic options for the control of menorrhagia include both medical (e.g. antifibrinolytics, oral contraceptives, levonorgestrel intrauterine device and clotting factor replacement) and surgical (e.g. endometrial ablation and hysterectomy). Apart from menorrhagia, women with FX deficiency, as well as women with other RBDs, are likely to develop other gynaecological problems, such as corpus luteum haemorrhage or haemoperitoneum associated with ovulation, that may warrant the adoption of prophylactic treatment. Even if pregnancy is accompanied by increased concentrations of FX, women with severe FX deficiency and a history of adverse pregnancy outcomes, such as abortion, placental abruption or premature birth, may benefit from continuous replacement therapy. Finally, heterozygotes have also been reported to have bleeding after delivery that required treatment with FFP.

Molecular defects

The gene structure and organization is homologous to that of the other vitamin-K dependent proteins, with the exception of prothrombin, suggesting evolution from a common ancestor by a process of duplication and divergence. To date, 105 mutations comprising 85 missense, 14 insertions/deletions (three gross deletions plus 11 micro insertions/deletions), six splice site, two nonsense, and one in the 5' flanking region have been reported

(Figure 42.8). Although most mutations are located in exon 8, the number of mutations located in each exon is proportional to the length of the exon itself, indicating the absence of a hotspot region on *FX* gene. Among the 105 mutations so far reported, only two were nonsense, and only one (C61X) was identified in the homozygous state in three unrelated patients.

Moreover, only a few of the entire group of missense mutations so far reported have been recurrent and found in more than one family from the same geographical area. In particular, Arg-1Thr, associated with a severe phenotype (FX coagulant activity < 1%), was identified in the homozygous state in four unrelated patients from Iran, while Gly380Arg, associated with intracranial haemorrhages, was identified in six

homozygous patients from Costa Rica; Pro343Ser (FX Friuli), associated with reduced FX coagulant activity (4–9%), was identified in more than 10 patients from northern Italy. Other mutations, such as Gly-20Arg, Gly94Arg and Gly222Asp, all associated with a severe laboratory phenotype, have been reported from different groups worldwide.

To assess whether genotypic variations could have an influence on FX plasma level, four different polymorphisms located in the promoter region (a TTGTGA insertion between position -343A and -342G, a C/T polymorphism at position -222, a C/A polymorphism at position -220 and a C/T polymorphism at position -40) have been investigated but no association was found.

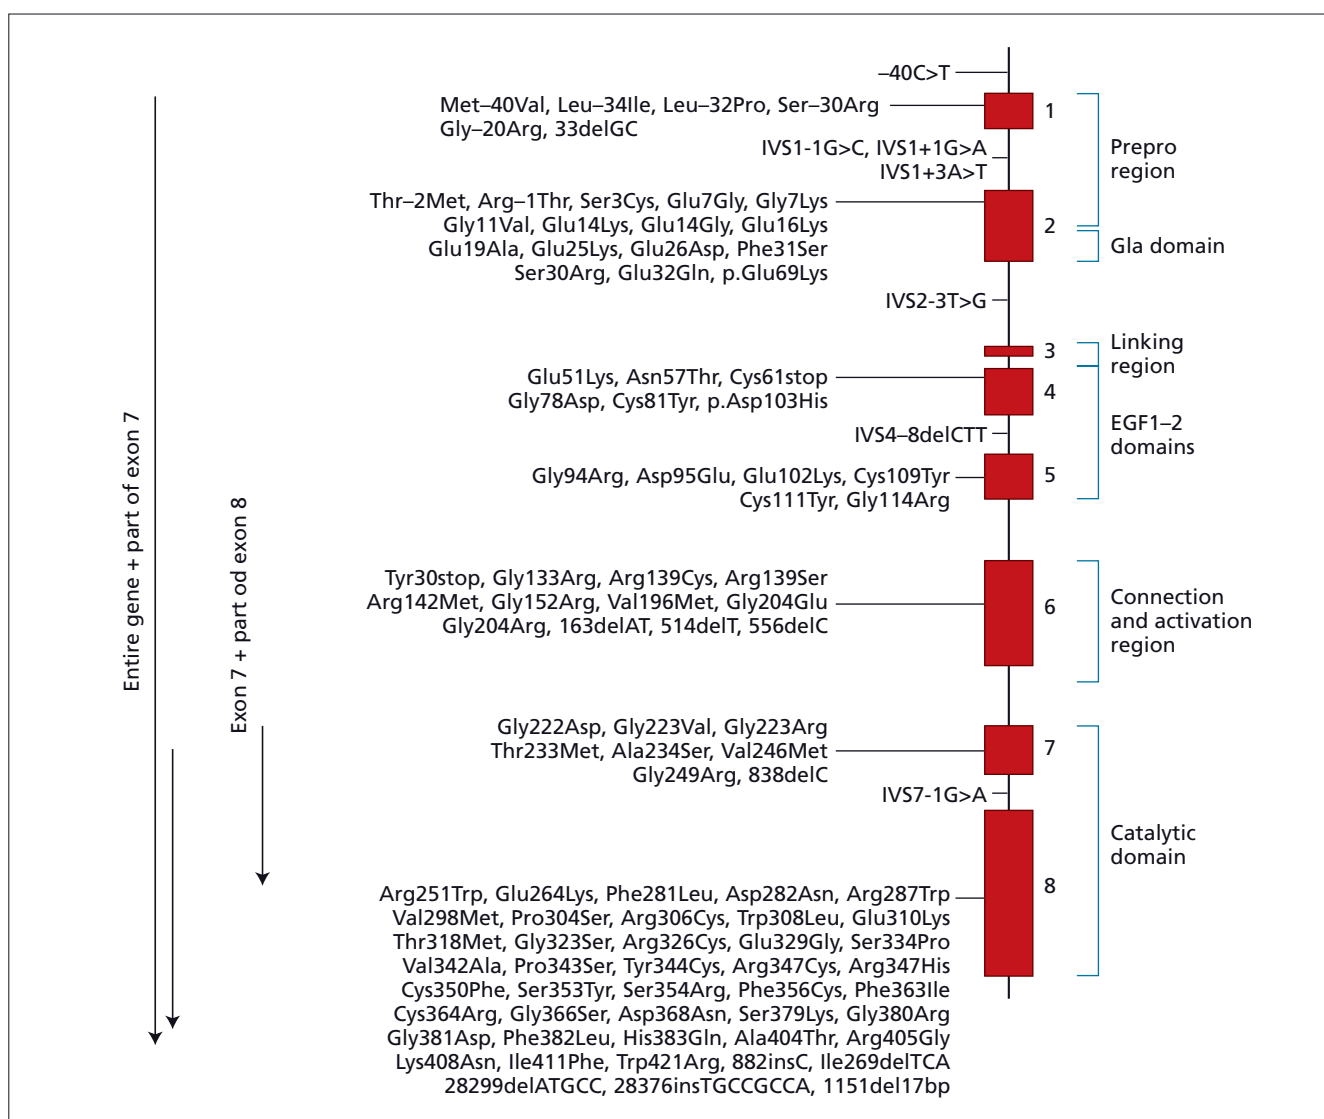

Figure 42.8 Schematic representation of the localization of the main mutations along the human FX gene, projected onto the exons encoding the domains of the protein. Exons (rectangles)

are drawn to scale while introns (lines) are not to scale. Gross deletions are indicated by the arrows.

Factor XI deficiency

FXI deficiency is characterized by a decrease in the functional activity of this plasma protein, usually accompanied by correspondingly low FXI antigen levels. More rarely, normal or borderline levels of plasma FXI antigen are associated with a dysfunctional form of the protein. The estimated prevalence of the severe deficiency in most populations is about 1 in 1 million, but is reported to be much higher in Ashkenazi Jews, heterozygosity for FXI deficiency being as high as 8%.

FXI is mainly synthesized in the liver, although tiny amounts of transcript can also be detected in megakaryocytes and platelets. The protein is encoded by the *FXI* gene, comprising 23 kb and located on chromosome 4. The existence of a platelet FXI transcript, originating from the skipping of exon 5, was hypothesized for a long time but never confirmed by subsequent work. Nonetheless, recent data support the view that FXI transcripts undergo alternative splicing, leading to the synthesis of FXI isoforms whose physiological role and importance still need to be demonstrated. In knockout mice the loss of the gene coding for this factor is compatible with life, with no tendency for spontaneous bleeding (see Table 42.2).

Clinical manifestations and treatment

The relationship between FXI levels in plasma and the bleeding tendency is not as clear-cut as for other coagulation factor deficiencies. The phenotype of bleeding is not correlated with the genotype but with the site of injury. When a site of injury with local high fibrinolytic activity is involved (e.g. urogenital tract, oral cavity after dental extraction or tonsillectomy), the risk of bleeding is increased (49–67%) in comparison to sites with less local fibrinolytic activity (1.5–40%). Usually, patients with severe FXI deficiency (1% or less) are mildly affected and most bleeding manifestations are injury-related. Surprisingly, patients with low but detectable levels of FXI are also mild bleeders, so that clinical phenotypes are not strikingly different in these two groups. This observation, already made for Jewish patients, was recently confirmed in a series of Iranian non-Jewish patients with severe or moderate deficiency (FXI coagulant activity < 1 to 5%) and in patients with mild deficiency (6–30%). All patients were mild bleeders, but those symptoms that define the severity of the bleeding tendency, such as muscle haematomas and haemarthrosis, showed a similar frequency in the two groups of factor-deficient patients (about 25%). The most frequent symptoms were oral and postoperative bleeding, which occurred in more than 50% of patients. Women with FXI deficiency are prone to excessive bleeding during menstruation, but case series of women affected by severe FXI deficiency showed that 70% of pregnancies were uneventful, despite no prophylactic treatment. Also, patients with alloantibodies that inhibit FXI do not bleed spontaneously but only during surgery or

trauma. Patients with inhibitors treated with FFP or FXI concentrates can suffer from prolonged bleeding if the presence of inhibitors is not diagnosed prior to surgery. After being exposed to plasma, 7 of 21 FXI-deficient Israeli patients homozygous for the Glu117stop mutation developed inhibitors to FXI. Recently, Zucker and colleagues showed that this also happened in an Italian woman homozygous for the same mutation after three injections of Rh immunoglobulin and without previous exposure to blood products.

Treatment is based on the use of antifibrinolytic agents, FFP, FXI concentrate and recombinant FVIIa, but care should be taken to reduce the risk of complications such as thrombotic events (especially when FXI concentrate or recombinant FVIIa is planned), volume overload, allergic reactions and development of inhibitors. Patients with partial deficiency of FXI who have no bleeding history do not require prophylactic treatment.

Molecular defects

To date, more than 180 mutations affecting *FXI* gene have been identified (Figure 42.9). These can be accessed on three different online databases:

- http://www.med.unc.edu/isth/mutations-databases/FactorXI_2007.html
- http://www.wienkav.at/kav/kar/texte_anzeigen.asp?ID=7137
- <http://www.factorxi.com>

The high allelic heterogeneity of FXI deficiency is highlighted by the distribution of genetic defects throughout the whole gene. Missense mutations represent more than 60% of all variants, only seven of them being reported to lead to the dysfunctional form of the deficiency.

Two mutations are responsible for most cases of FXI deficiency in Ashkenazi Jews, while mutations are more varied in non-Jews. The so-called type II Jewish mutation is a stop codon in exon 5, compatible with the observation that patients homozygous for this defect usually have undetectable levels of FXI. The so-called type III Jewish mutation is a missense mutation in exon 9, leading to the Phe283Leu substitution. The mutation causes defective secretion of the protein from cells, but some FXI is ultimately produced so that these patients have measurable levels of FXI (about 10%). Type II/III compound heterozygosity is the commonest cause of severe to moderate FXI deficiency in Ashkenazi Jews.

Factor XIII deficiency

FXIII is a transglutaminase, is the last enzyme to be activated in the blood coagulation pathway and functions to cross-link the α and γ fibrin chains, resulting in a stronger clot with an increased resistance to fibrinolysis. The plasma factor consists of two catalytic A subunits (FXIII-A) and two carrier B subunits

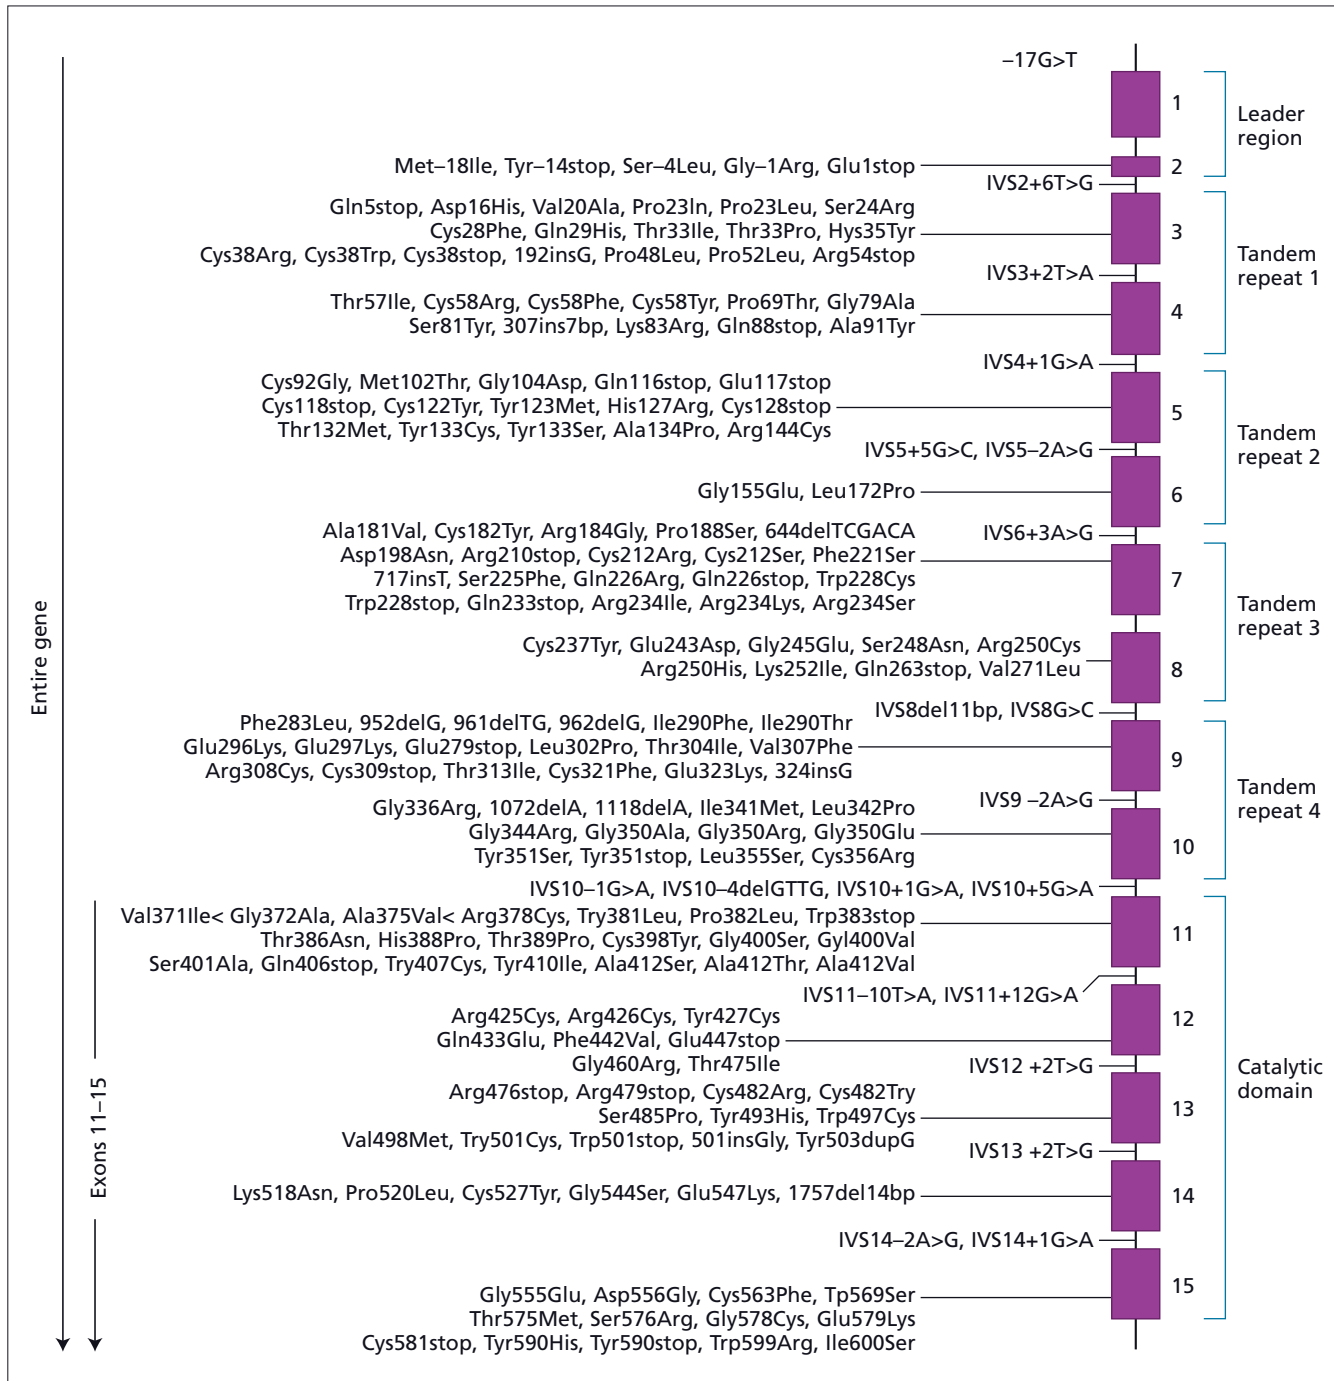

Figure 42.9 Schematic representation of the localization of the main mutations along the human FXI gene, projected onto the exons encoding the domains of the protein. Exons (rectangles)

are drawn to scale while introns (lines) are not to scale. Gross deletions are indicated by arrows.

(FXIII-B). FXIII-A is synthesized in cells of bone marrow origin, while FXIII-B is produced in the liver. The corresponding genes are located on chromosomes 6 and 1. FXIII deficiency is probably, together with prothrombin deficiency, the rarest of the

recessively transmitted coagulation factor deficiencies (1 in 2 million). In inherited FXIII deficiency, plasma levels of FXIII-A measured as functional activity or immunoreactive protein are usually extremely reduced, whereas the FXIII-B subunit is

Table 42.3 Classification of FXIII deficiency according to activity and antigen determinations of the FXIII subunits.

	<i>FXIII-A deficiency</i>		<i>FXIII-B deficiency</i>
	<i>Quantitative defect</i>	<i>Qualitative defect</i>	
Plasma activity	Reduced	Reduced	Moderately reduced
Plasma antigen A ₂ B ₂	Reduced	Normal/near normal	Reduced
Plasma antigen A	Reduced	Normal/near normal	Moderately reduced
Platelet antigen A	Reduced	Normal/near normal	Normal
Platelet antigen B	> 30%	> 30%	Reduced

reduced but always at measurable levels. Table 42.3 shows the classification of FXIII deficiency according to activity and antigen determinations of the FXIII subunits.

Studies on homozygous null mice generated by deletion of exon 7 of the FXIII gene showed that these mice were fertile, although reproduction was impaired and bleeding episodes were associated with reduced survival (see Table 42.2). A new aspect of the relationship between FXIII and wound healing has recently been reported. Following an acute myocardial infarction in an experimental model, infarct expansion, heart failure and cardiac rupture were observed in FXIII-deficient mice, probably due to inadequate healing of the myocardial tissue. Spontaneous haemorrhagic events with subsequent inflammation and fibrosis were also reported in the heart tissue of FXIII-deficient mice, suggesting that low FXIII levels may impair cardiac healing and lead to complications in patients with acute myocardial infarction.

Clinical manifestations and treatment

Patients with FXIII-A deficiency have a bleeding tendency that is usually severe, particularly because of the early onset of life-threatening symptoms such as umbilical-cord and CNS bleeding. Bleeding from the umbilical stump in the first few days of life occurs in approximately 80% of patients, and CNS bleeding in up to 30%. Ecchymoses, haematomas and prolonged bleeding following trauma are also typical. Haemarthroses and intramuscular haematomas may appear unexpectedly, although less frequently. In a recent study made on the largest group of patients with severe FXIII deficiency (93 Iranians), the most frequent mucosal tract bleeding symptom was bleeding in the oral cavity (lips, tongue, gum) followed by menorrhagia and epistaxis. Gastrointestinal bleeding is not unusual. Soft-tissue bleeding such as spontaneous haematoma and haemarthrosis occur in a large proportion of patients. In women of reproductive age, 20% had intraperitoneal bleeding that occurred at the time of ovulation, in some cases leading to hysterectomy; 50% of women had at least one miscarriage during pregnancy. The same pattern of symptoms was also recently shown by Ivaskevicius and colleagues in an international registry formed mostly of European data, where joint bleeding is reported to be more commonly periarticular than intra-articular.

On the whole, the clinical impact of FXIII deficiency can shift from that of a very severe disease to that of a mild one, depending on the adoption of prophylactic treatment. All these symptoms usually lead to an early diagnosis, so that patients who survive are often treated prophylactically, starting early in life. Monthly prophylactic infusions of FXIII concentrate are also recommended in FXIII-A-deficient women who are pregnant in order to prevent bleeding and fetal loss. In fact, it was recently reported that among these women there were seven successful pregnancies and five had received FXIII replacement. Moreover, it was found that all women with deficiency of the FXIII-A subunit miscarried, with one exception, if replacement therapy was not given during pregnancy. These data suggest that implementation of replacement therapy is crucial for pregnancy and should commence as early as possible.

This approach to treatment is rendered simple and feasible by the fact that plasma levels of FXIII of 2–5% are sufficient to prevent bleeding, and that the long *in vivo* half-life of the factor (11–14 days) makes it possible to infuse cryoprecipitate or concentrates at intervals of 1 month or longer.

Because of the risk of blood-borne diseases, FFP and cryoprecipitate are less satisfactory for treatment or prophylaxis, and FXIII concentrate is recommended whenever available. A new recombinant FXIII-A₂ concentrate (rFXIII-A₂) has recently been manufactured in *Saccharomyces cerevisiae*. The rFXIII-A₂ homodimers associate in plasma with the endogenous FXIII-B to form the stable heterotetramer FXIII-A₂B₂. In a Phase I clinical trial, rFXIII-A₂, administered to 11 patients with FXIII deficiency, seemed to have a similar half-life and pharmacokinetics to those of the native protein and appeared to be safe. Only four cases of FXIII-B deficiency have been reported to date and the bleeding symptoms appear milder than in FXIII-A-deficient patients.

Molecular defects

More than 70 mutations within *F13A* have been published (Figure 42.10) and most of them are missense/nonsense point mutations. Multiple missense/nonsense mutations have also been reported for a number of codons (77, 260, 326, 413 and 541) with codon changes AAC/AAA and AAC/AAG. In the review by Ivaskevicius and colleagues, the two most frequent

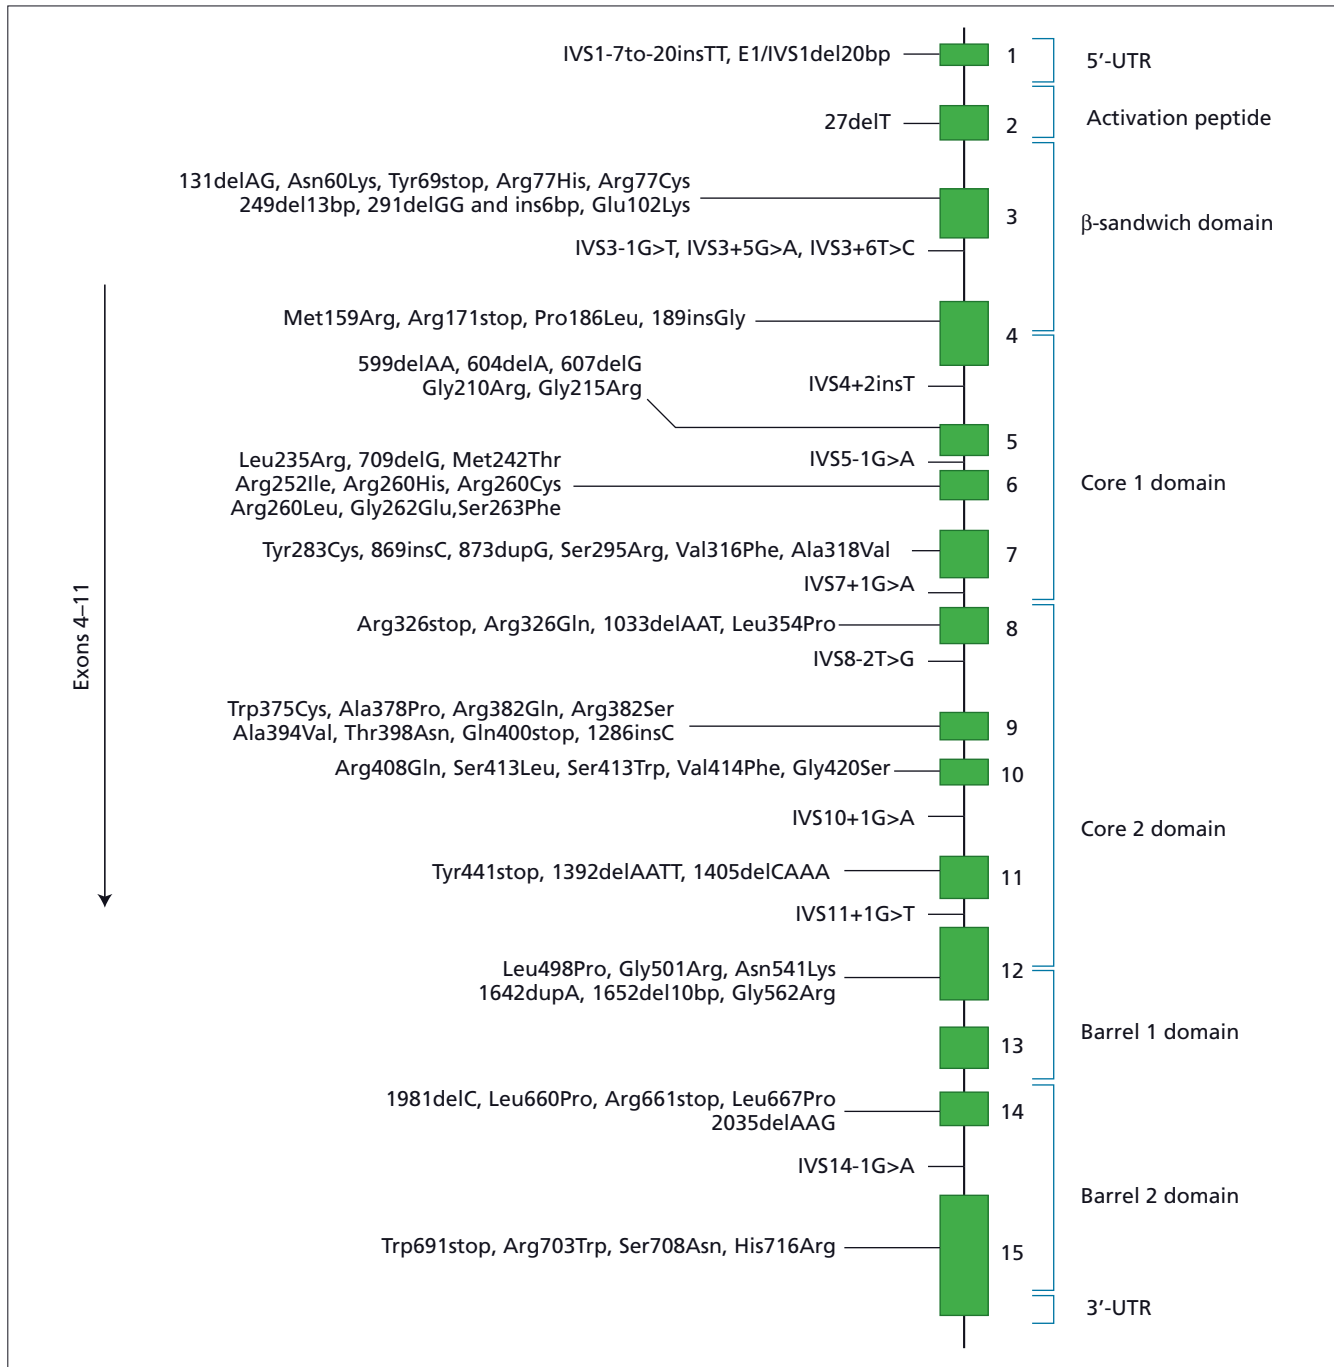

Figure 42.10 Schematic representation of the localization of the main mutations along the human FXIII-A gene, projected onto the exons encoding the domains of the protein. Exons

(rectangles) are drawn to scale while introns (lines) are not to scale. Gross deletions are indicated by arrows.

mutations affecting *F13A* were found to be the IVS5-1G→A splice-site defect and the Arg661stop mutation. Haplotype analysis in four patients with the IVS5-1G→A mutation suggested a founder effect, while the concentration

of Arg661stop mutation in Finland, Arg77Cys in Switzerland and Arg77His in Iran might also be due to founder effects, although the occurrence of these mutations at CpG dinucleotides raises the alternative possibility of independent origin.

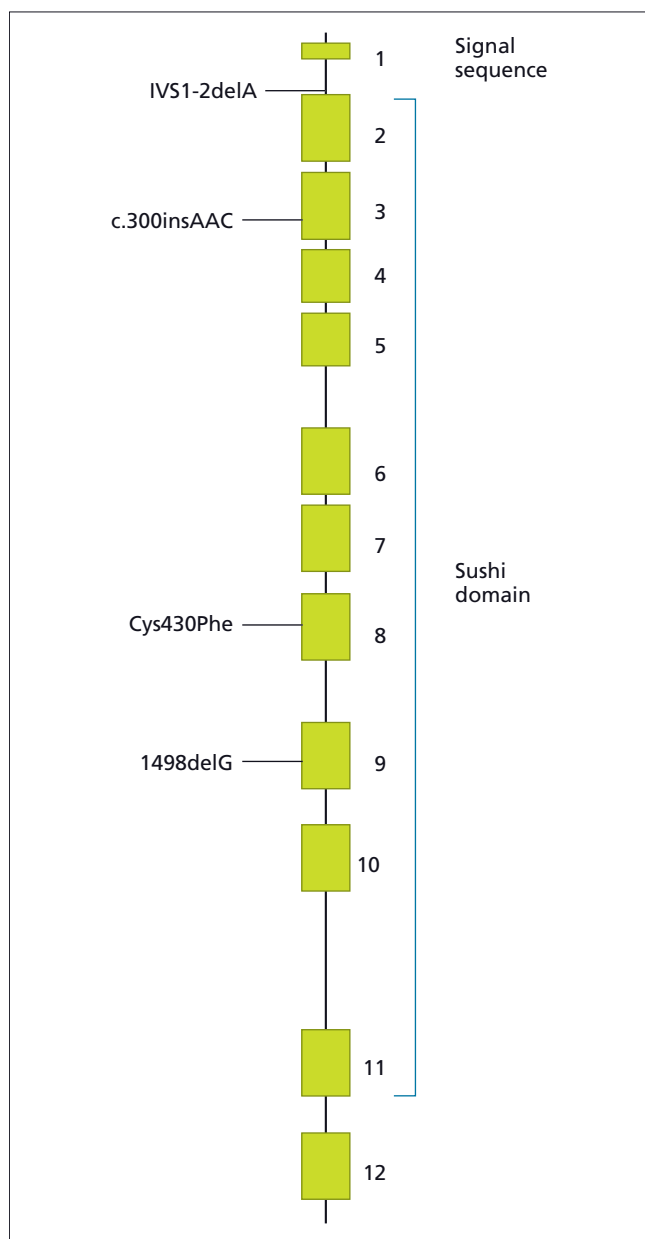

Figure 42.11 Schematic representation of the localization of the main mutations along the human FXIII-B gene, projected onto the exons encoding the domains of the protein. Exons (rectangles) are drawn to scale while introns (lines) are not to scale.

Mutations are scattered throughout the *F13A* gene and in a few studies the mutant proteins were expressed in cultured mammalian cell lines, showing that introduction of the mutation caused destabilization of protein structure and intracellular degradation.

Several polymorphisms in *F13A* have been identified. The most common are Val34Leu, Tyr204Phe, Pro564Leu, Val650Ile

and Glu651Gln. The Val34Leu variant is the most studied polymorphism, with the amino acid substitution occurring in the activation peptide sequence, three amino acids upstream from the thrombin-cleavage site. Studies have shown that the Leu34 allele variant promotes accelerated cleavage of the activation peptide once activated by thrombin and has been associated with a decreased risk of myocardial infarction. However, controversy has surrounded the role of Val34Leu in coronary artery disease, with the literature supporting both sides of the debate.

Only four mutations have been identified in *F13B* (Figure 42.11), a single-nucleotide deletion at the acceptor splice junction of intron A/exon 2 (IVS1(-2)delA), a Cys430Phe missense mutation, a G deletion in exon 9 and an AAC triplet insertion within codon Tyr80 in exon 3.

Vitamin K-dependent coagulation factors deficiency

The first case of vitamin K-dependent coagulation factors deficiency (VKCFD) was reported more than 40 years ago in a 3-month-old girl with multiple bruises and haemorrhages. The girl was studied further when she was 15 years old and was found to have immunologically measurable FII, FVII, FIX and FX that were lacking γ -carboxyglutamic acid residues. Vitamin K-dependent coagulation factors such as FII, FVII, FIX and FX require γ -carboxylation of glutamic acid residues at their Gla domains to enable binding of calcium and attachment to phospholipid membranes. The γ -carboxylation is catalysed by hepatic γ -glutamyl carboxylase (GGCX) and its cofactor reduced vitamin K (KH_2). During the reaction, KH_2 is converted to vitamin K epoxide (KO), which is recycled to KH_2 by the vitamin K epoxide reductase (VKOR) enzyme complex. Heritable dysfunction of GGCX or the VKOR complex results in the secretion of poorly carboxylated vitamin K-dependent coagulation factors, leading to combined deficiency of the vitamin K-dependent clotting factors. The γ -carboxylation of glutamic acid residues is also required for activity of the anti-coagulant factors protein C, protein S and protein Z, and although protein S and protein C levels are low in VKCFD, there are no reports of venous or arterial thrombosis. Thus, the effect of VKCFD is clearly in the bleeding area. The GGCX and VKOR proteins are encoded by two corresponding genes: *GGCX* (13 kb, 15 exons) located on chromosome 2 and the unusually small *VKORC1* (5126 bp, three exons) located on chromosome 16; the latter gene was so named because of evidence suggesting that VKOR is a multisubunit complex. Studies on heterozygous mice carrying a null mutation for *GGCX* showed normal development and normal activity of the vitamin K-dependent coagulation factors, but only half of the γ -carboxylase-deficient mice developed to term and those

delivered died due to massive intra-abdominal haemorrhages (see Table 42.2).

Clinical manifestations and treatment

VKCFD is a rare autosomal recessive bleeding disorder that often presents during infancy, although the routine administration of vitamin K may delay the diagnosis of VKCFD in neonates. Severe symptoms such as intracranial haemorrhage or umbilical stump bleeding are usually associated with factors levels below 5 units/dL. Severely affected children may also present with skeletal abnormalities such as nasal hypoplasia, distal digital hypoplasia, epiphyseal stippling and mild conductive hearing loss. Older patients can present with easy bruising and mucocutaneous or postsurgical bleeding.

Treatment with oral or parenteral vitamin K₁ should be started as soon as possible in all patients at diagnosis. However, some patients show insufficient response, and there are limited data on the effectiveness of prophylaxis with weekly administration of vitamin K₁ 10 mg. In fact, massive parenteral doses of vitamin K do not always correct FII, FVII, FIX and FX activities, and there is clear biochemical evidence that the molecules are not fully carboxylated by such treatment. In this group of patients, factor replacement by virally inactivated FFP could also be used in cases of acute bleeding episodes or before surgery. PCC is the alternative choice when a rapid increase in clotting factor levels is necessary. However, PCCs have been associated with thrombosis and disseminated intravascular coagulation, and therefore should be used with caution in some patients.

Molecular defects

The rare VKCFD autosomal disorder arises from point mutations in either the *GGCX* (type I) or *VKOR* (type II) genes, the only exception being a kindred with a 14-bp deletion in intron 1 of *GGCX*. To date, few mutations have been described for the type I disorder: Asp31Asn, Trp157Arg, Leu394Arg, His404Pro, Arg485Pro, Trp501Ser, Thr591Lys and two recently identified splice-site mutations: a G→T transversion of the first nucleotide of intron 2 (c.1358+1G→T) and an A→G transversion of the third nucleotide of intron 11 (c.10363+3A→G). With regard to the Arg485Pro mutation, Rost and colleagues identified it in two patients originating from the same region in western Germany. Since VKCFD represents a rare entity, they hypothesized a founder effect that was strongly supported by further examination of three intragenic polymorphisms of *GGCX* (c.44–140₋127dup14 and c.44–32G→A in intron 1, and c.215–385G→C in intron 2) and five microsatellite markers surrounding the *GGCX* gene (D2S417, D2S2232, D2S388, D2S237 and D2S440). The only mutation identified so far leading to type II is the homozygous Arg98Trp mutation.

Concluding remarks

Molecular defects

In general, in these patients a defect in the DNA can be identified in the genes encoding the different coagulation factors. Combined FV and FVIII deficiency, explained by defects located in genes encoding transport proteins, is a typical exception. In each coagulation defect the mutations are multiple and the majority of them are private mutations, unique for any given patient. The unique nature of the mutations complicates the approach to the control of these diseases through prenatal diagnosis in families with affected members, because it renders necessary the actual identification of the underlying mutation in each kindred. Prevention of rare coagulation disorders through prenatal diagnosis of the underlying mutations is feasible in couples who have already had affected children. Primary prevention might be achieved by discouraging consanguineous marriages. Even though the cultural, religious and economic roots of this practice are deep in Muslim communities, consanguineous marriages are becoming much less frequent in large cities and among younger generations.

The relation between genotype and phenotype is not always clear-cut. Even though in general severe mutations predicting no protein production (stop codons, deletions, insertions, splicing abnormalities) are associated with severe factor deficiencies and severe clinical phenotypes, there are a number of cases with severe deficiencies and phenotypes associated with missense mutations. Usually, missense mutations are associated with milder phenotypes despite unmeasurable factor levels, probably because some protein is produced in these cases that cannot be detected with the currently available assays.

Expression of the mutations in cultured cell lines and characterization of the recombinant proteins has been useful for understanding how well-defined molecular lesions lead to structural abnormalities and to functional defects of the protein. In some cases expression studies have documented the mechanism whereby a mutant protein is synthesized normally but is not ultimately secreted in plasma from cells. In most cases impaired folding and/or conformational changes of the mutant protein leads to both intracellular and extracellular instability, which in turn causes factor deficiency in plasma. Expression work is still in its infancy and needs to be expanded, mainly in cases of missense mutations that appear of special functional interest when projected onto the crystal structure of the coagulation factors.

Treatment

Treatment of rare coagulation disorders is with the most purified blood product available that contains the missing factor. Because of the rarity of each factor deficiency, purified factor

concentrates are not as freely available as they are for haemophilia A and B. Dosages and frequency of treatment depend on minimal haemostatic levels of the deficient factor, plasma half-life and type of bleeding episode. General recommendations for treatment on-demand, prophylaxis, pregnancy and delivery,

and for surgery of patients with rare coagulation disorders are summarized in Tables 42.4–42.6.

The avoidance of transmission of blood borne infectious agents is the primary requisite in the choice of replacement material. Solvent/detergent-treated plasma is an important

Deficient factor	Pregnancy/delivery		Surgery	
	Minimum level	Treatment	Minimum level	Treatment
Fibrinogen	> 150 mg/dL	Successful pregnancy in afibrinogenaemia is difficult without fibrinogen replacement therapy No strong data to support routine postpartum fibrinogen prophylaxis beyond the first 1–2 days	100 mg/dL	Fibrinogen concentrate (50–100 mg/kg) Antifibrinolytic agents (dental extraction)
Prothrombin	> 25%	No data	20–40%	SD-treated plasma (15–20 mL/kg) PCC (20–30 units/kg, higher doses for major surgery)
Factor V	15–25%	SD-treated plasma (15–20 mL/kg, until after delivery)	25%	SD-treated plasma (15–20 mL/kg)
Factor V and factor VIII		As for FV		As for FV
Factor VII	> 15–20%	Not required during pregnancy, unless there is a bleeding history with previous pregnancies If FVII < 20%, peripartum prophylaxis should be considered	10–15%	FVII concentrate (30–40 mL/kg) PCC (20–30 units/kg) rFVIIa (15–30 µg/kg every 4–6 hours)
Factor X	10–20%	In severe FX deficiency and history of adverse outcome, replacement therapy to cover delivery (up to 3 days) is indicated	10–20%	SD-treated plasma (10–20 mL/kg) PCC (20–30 units/kg) FX(FIX) concentrate (10–20 units/kg)

Table 42.6 Continued

Deficient factor	Pregnancy/delivery		Surgery	
	Minimum level	Treatment	Minimum level	Treatment
Factor XI	15–20%	FXI levels 15–70 units/dL, with no bleeding history: give tranexamic acid for up to 3 days (first dose during labour) FXI levels < 15 units/dL: replacement therapy should be considered at the onset of labour	15–20%	Antifibrinolytic agents (250 mg/day)
Factor XIII	10%	FXIII concentrate: 250 units per 7 days in early period, 500 units per 7 days after 23 weeks Factor replacement should be given at delivery to maintain FXIII levels > 20%	5–10%	Cryoprecipitate (2–3 bags) SD-treated plasma (3 mL/kg) FXIII concentrate (10–20 units/kg)

PCC, prothrombin complex concentrate; rFVIIa, recombinant activated FVII; SD, solvent/detergent.

source of replacement that is recommended in the majority of these disorders; virus-inactivated concentrates, when commercially available, are also safe but expensive especially for developing countries. Non-virus-inactivated plasma and cryoprecipitate should be avoided if possible. Of course the treatment of choice may change depending on the facilities of the country where the patient is resident. Cost is the next most important determinant. Virally inactivated factor concentrates are available for several deficiencies and should be preferred when virally inactivated plasma is not available or repeated infusions causing fluid overload are needed, as may occur during surgery or in cases of bleeding in the CNS. An updated registry of the available clotting factor concentrates is published by the WFH (available at <http://www.wfh.org/index.asp?lang=EN>).

Acknowledgements

We would like to thank Professor P.M. Mannucci for his great supervision and all our colleagues who have helped us recently to develop a chapter on rare bleeding disorders in *Seminars of Thrombosis and Hemostasis*. Their revision of specific types of deficiency helped us to more accurately revise our present chapter. Thanks, therefore, to Philippe de Moerloose and Marguerite Neerman-Arbez, Stefano Lancellotti and Raimondo De Cristofaro, Rosanna Asselta and Marta Spreafico, Guglielmo Mariani and Francesco Bernardi, Stefano Duga and Ophira Salomon, Mehran Karimi, Zsuzsanna Bereczky, Nader Cohan and László Muszbek, and Benjamin Brenner, Amir A. Kuperman,

Matthias Watzka and Johannes Oldenburg. We would also like to thank Isabella Garagiola and Roberta Palla for their help in writing the manuscript.

Introduction

Acquired disorders of haemostasis are a heterogeneous group of conditions with varied and often complex aetiologies. Patients may have multiple and overlapping causes for haemorrhagic symptoms and distinct conditions often have similar pathophysiology. In order to manage acquired haemostatic failure it is important to understand the mechanisms by which haemostatic disturbance occurs and how these apply in different ways to a variety of conditions.

Systemic disease may present to haematologists with symptoms of bleeding or bruising or abnormalities of coagulation tests. Alternatively, patients with known disorders may need haematological input to manage symptoms or at the time of

invasive procedures. Assessment of patients with symptoms of bleeding or bruising requires clinical review and laboratory investigation. Serial laboratory testing is often required because the haemostatic disturbance may evolve rapidly. The possibility of a congenital disorder should also be considered.

Haematologists are also often involved in the management of acutely bleeding patients who may have complex medical conditions and in whom bleeding is usually multifactorial. Critical to optimizing the management of these patients is a well-organized multidisciplinary team approach. Hospitals should have systems in place to respond rapidly to massive haemorrhage and hospital transfusion committees should establish protocols for these medical emergencies. Laboratories should be geared to producing accelerated full blood count (FBC) and coagulation results. The rapid supply of blood products and efficient transfer of these to the patient is vital to success. 'Fire drills' to test proficiency of response to emergencies are good practice in areas where massive haemorrhage often occurs, such as on labour wards and in casualty departments.

Tests of coagulation and point-of-care testing

Routine tests of haemostasis

To investigate a patient suspected of an acquired haemostatic defect, a platelet count will be required and examination of the blood film is often useful. Routine coagulation tests include the prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin time (TT) and Clauss fibrinogen level. It is important that derived fibrinogen assays are not used because results are likely to be misleading in the context of acquired haemostatic defects.

If screening tests are abnormal, correction studies help to distinguish factor deficiencies from inhibitors. Comparison of TT with the reptilase time will establish whether abnormal results are due to heparin. Measurement of fibrin breakdown products, such as D-dimers, is required for investigation of possible disseminated intravascular coagulation (DIC). Further measurement of individual coagulation factor and von Willebrand factor (VWF) levels may be required. Assessment of platelet function may be useful in some circumstances through platelet aggregation studies, platelet nucleotides or a bleeding time, although these results may be difficult to interpret in the context of an acquired haemostatic defect. The role of global platelet function analysers remains to be defined but these are available in many hospitals.

Thromboelastography

This is a point-of-care test that assesses the viscoelastic properties of whole blood samples under low-shear conditions (Figure 43.1). Its main advantage is the global assessment of the different components of clot formation including platelets and

coagulation factors. It has been used to guide blood product administration in patients undergoing liver transplantation and cardiopulmonary bypass. Other reported uses include the assessment of coagulation in liver disease, neonates, obstetrics and trauma as well as monitoring the effects of bypassing agents in haemophilia patients with inhibitors, although more studies are required to validate its role in these areas. The two main types of instruments are TEG and ROTEM, which measure the viscoelastic properties of an evolving clot in similar but distinct ways and then graphically display the changes to show all stages of the developing and dissolving clot. Different activators are available and heparinase cups can be used to investigate heparinized samples.

Thrombin generation assays

These tests measure the amount of thrombin generated over time following activation of a sample and may reflect an individual's coagulation potential. They are not available in routine practice. Assays are initiated by the addition of a trigger, usually tissue factor (TF), to recalcified plasma in the presence of phospholipids and thrombin is detected via cleavage of a chromogenic or fluorogenic substrate. When low concentrations of TF are used, contact activation must be inhibited by maize trypsin inhibitor. Several variations of these assays have been developed by varying the concentrations of TF, maize trypsin inhibitor, phospholipid and protein C-sensitizing reagents such as soluble thrombomodulin. Thrombin generation tests have been studied in the context of haemophilia, including monitoring of inhibitor bypass agent therapy. Other studies have examined thrombophilia and liver disease and monitoring of anticoagulant therapy and warfarin reversal. The clinical utility of many of these potential applications remains to be demonstrated.

Figure 43.1 Representative thromboelastographic trace.

Figure 43.2 Representative normal and biphasic waveforms. Activated partial thromboplastin time waveform patterns: (a) normal; (b) biphasic. Dashed lines denote transmittance level at 18 s (TL18) as the quantitative index: (a) TL18 = 100; (b) TL18 = 63.

APTT biphasic waveform

The Multichannel Discrete Analyser is a coagulation analyser that generates an optical profile charting changes in light transmittance over time during the process of clot formation on the routine APTT. In contrast to the sigmoidal appearance of a normal APTT waveform, a 'biphasic' appearance correlates with acquired haemostatic dysfunction (Figure 43.2). The reliability of this method has been validated in several reports and correlates with the diagnosis of overt DIC according to the International Society for Thrombosis and Haemostasis (ISTH) criteria. This biphasic response is due to calcium-dependent complex formation between C-reactive protein and very low density lipoprotein, which has been shown to increase thrombin generation.

Activated clotting time

This test is predominantly used by anaesthetists to monitor anticoagulation with heparin during cardiopulmonary bypass (CPB) surgery. It uses whole rather than citrated blood and has a linear response at the high concentrations of heparin used during CPB. The APTT cannot be used because plasma is unclottable using this method at these heparin concentrations. Measured using a specialized analyser, the activated clotting time (ACT) reference range varies according to the method and usually falls within 70–180 s. During heparinization for CPB, the goal is to exceed 400–500 s. Off-pump cardiac surgery has been described using less anticoagulation and lower ACT reference ranges of 200–300 s.

Measurement of activated coagulation factors

Many publications have reported the measurement of activated coagulation factors and inhibitors during various clinical situations. Numerous assays and markers of coagulation are

available, of which the commonest are thrombin–antithrombin complexes, prothrombin fragment 1+2 and plasmin–antiplasmin complexes. These assays are useful in a research context for understanding the pathogenesis of abnormal haemostasis but have not been shown to be useful in clinical practice.

Disseminated intravascular coagulation

DIC is characterized by the loss of localization or compensated control of intravascular activation of coagulation. Arising from diverse causes (Table 43.1), its pathology can manifest systemically and contribute to a worse prognosis for the patient. Uncoupling of the highly regulated balance between procoagulant, anticoagulant, profibrinolytic and antifibrinolytic processes can result in simultaneous bleeding and microvascular thrombosis at different vascular sites (Figure 43.3). Removal of the inciting cause is the best means of restoring haemostatic control but may not always be possible. Sepsis and malignancy account for more than half the cases of DIC.

Pathophysiology

There are several important themes in the pathophysiology of DIC (Figure 43.3): first is the central role played by the generation of thrombin; second, mechanisms that fuel and perpetuate thrombin generation become pathogenic in its dissemination; third is the parallel and concomitant activation of the inflammatory cascade; and fourth is the importance of the endothelial microvasculature in this process.

The excess bleeding in DIC is partly attributable to the depletion of coagulation factors and platelets. However, several other factors may contribute, including abnormal platelet function

Table 43.1 Clinical conditions associated with disseminated intravascular coagulation.

<i>Sepsis/severe infection</i>	Pre-eclampsia
Potentially any microorganism, including Gram-positive and Gram-negative bacteria, viruses, fungi and rickettsial infections	Intrauterine fetal demise
Malaria and other protozoal infections	<i>Vascular abnormalities</i>
<i>Trauma</i>	Giant haemangiomas (Kasabach–Merritt syndrome)
Serious tissue injury	Large vessel aneurysms (e.g. aortic)
Head injury	<i>Severe toxic or immunological reactions</i>
Fat embolism	Snake bites
Burns	Recreational drugs
<i>Malignancy</i>	Severe transfusion reactions
Solid tumours	Transplant rejection
Haematological malignancies (e.g. acute promyelocytic leukaemia)	<i>Miscellaneous</i>
<i>Obstetric complications</i>	Severe pancreatitis
Placental abruption	Heat stroke
Amniotic fluid embolism	ABO mismatch transfusion

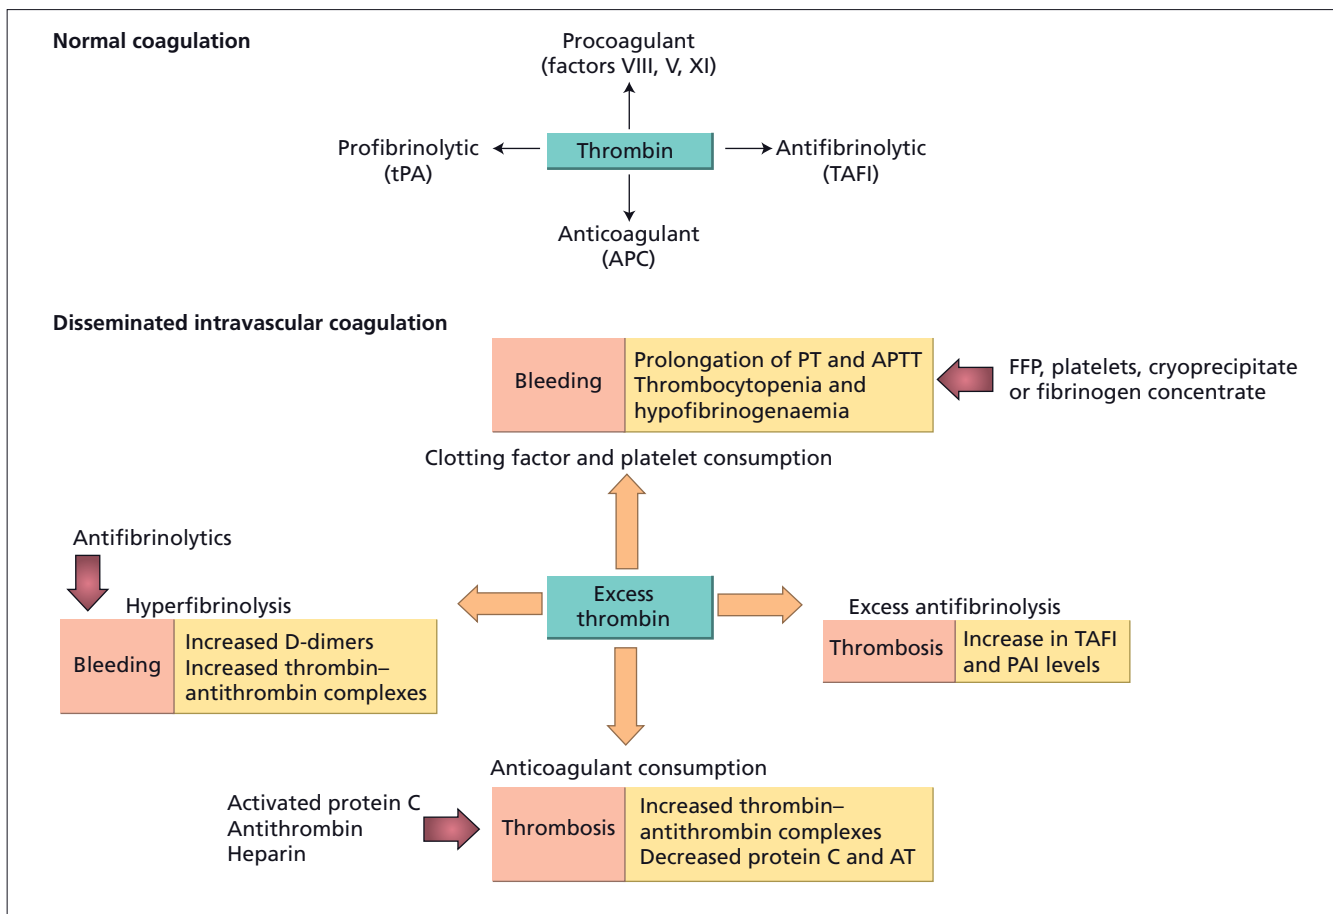

Figure 43.3 The changes in disseminated intravascular coagulation are compared with the normal coagulation. The excess thrombin generation in DIC leads to either bleeding or thrombosis (left) based on the predominant coagulation change

(right) which has occurred. The therapeutic intervention in each setting is given by the arrow towards each double box. TAFI, thrombin activatable fibrinolysis inhibitor; PAI, plasminogen activator; AT, antithrombin.

due to renal dysfunction and decreased clotting factor synthesis due to liver impairment. Conversely, microvascular thrombosis can be precipitated by reduced levels of circulating anticoagulant proteins as well as loss of receptors, such as thrombomodulin, in the microvasculature. Endothelial dysfunction can also lead to the depletion of nitric oxide and result in uninhibited platelet activation.

Thrombin generation *in vivo*

The TF pathway plays a major role in initiating thrombin generation and different aetiologies promote this in different ways. In sepsis, the infecting microorganisms induce TF expression on monocytes and other inflammatory cells, while in trauma thromboplastin-like substances can be released from injured tissues like the brain. During obstetric complications, the placenta and amniotic fluid act as rich sources of TF and phospholipid while malignant cells release products with TF-like activity. Although the TF pathway is considered more important in thrombin generation, the contact pathway through factor (F)XII activation contributes to the pathological state by activation of the kallikrein-kinin system, causing vasodilatation and hypotension and activation of fibrinolysis.

Mechanisms for disseminating and sustaining thrombin generation

When the inciting insult is persistent or severe, the amount of thrombin generated becomes continuous and excessive. This can lead to consumption and depletion of both coagulation and anticoagulant factors. Increased exposure of negatively charged phospholipid surfaces facilitates the assembly and enhances the rate of coagulation reactions. Such surfaces, mainly rich in phosphatidylserine, are provided by externalization of the inner leaflet of cell membranes upon activation and apoptosis. Cell damage also leads to the generation of microparticles from platelets, monocytes and endothelial cells that increase the circulating surface area for coagulation reactions to occur. Phospholipid surfaces are also provided by very low density lipoprotein, which can increase several fold in severe sepsis to further enhance and sustain thrombin generation. Together, these mechanisms promote a spatially and temporally expanded response that is the hallmark of DIC.

Links between inflammation and coagulation

Once activated, the inflammatory and coagulation pathways interact to amplify the response. While cytokines and proinflammatory mediators such as tumour necrosis factor (TNF), interleukin (IL)-1 and high mobility group box protein (HMGB)-1 can induce activators of coagulation, thrombin and other serine proteases interact with protease-activated receptors (PARs) on cell surfaces to promote further activation and additional inflammation. When this process becomes generalized, it escapes the well-developed local checks and balances and results in a dysregulated undirected response that fuels a vicious cycle between inflammation and coagulation. Reactive oxygen species

generated during sepsis and trauma can lead to further recruitment of neutrophils, cause lipid peroxidation and stimulate nuclear factor (NF)- κ B to initiate the transcription of cytokine genes. An important role for the complement system has also been increasingly identified. Thrombin can convert C5 to C5a and the mannan-binding lectin pathway triggers coagulation by converting prothrombin to thrombin. C4b-binding protein of the complement pathway also binds and thus depletes free protein S, the cofactor for activated protein C.

Endothelial cell activation and dysfunction

Dysfunction and failure of the endothelium beyond the host adaptive response can lead to the development of DIC. The degree to which this occurs and the dominance of thrombotic or bleeding sequelae depend on genetic and other host-related factors. Damage to and activation of the endothelium downregulates and depletes its anticoagulant receptors, such as thrombomodulin and endothelial protein C receptor, exposes subendothelial collagen that binds activated platelets, and releases plasminogen activator inhibitor (PAI)-1 that inhibits fibrinolysis and ultra-large VWF multimers to increase platelet aggregation. *In vitro* studies show a downregulation of endothelial TF expression.

Clinical features

The perturbed coagulation associated with DIC can manifest clinically at any point in the spectrum from bleeding to thrombosis. Although bleeding, ranging from oozing at venepuncture sites to major gastrointestinal or intracranial haemorrhage, is the archetypal and most obvious manifestation of DIC, organ failure due to microvascular thrombosis is much more common and often unrecognized. For example, in meningococcal septicaemia and rarely pneumococcal infection, thrombosis of the adrenal vessels can lead to adrenal insufficiency and Waterhouse-Friderichsen syndrome.

Diagnosis

DIC is a clinicopathological syndrome and, as such, there is no single laboratory test that can confirm or refute the diagnosis. In clinical practice, the diagnosis is usually made by a combination of routinely available coagulation tests in a clinical situation where DIC is suspected. DIC must be differentiated from other acquired disorders of haemostasis (Table 43.2). The typical findings are a prolonged PT and APTT, elevated products of fibrin breakdown (e.g. D-dimer), thrombocytopenia and reduced fibrinogen. However, results within the normal range for these tests do not exclude a significant consumptive coagulopathy, especially because the acute-phase response results in shortening of the APTT and increased fibrinogen. A fall in platelet number within the normal range may also be significant.

Condition	Similarities	Differences
Liver disease	Bleeding common PT, APTT abnormal Platelet count low Fibrinogen low	D-dimer usually normal* FVIII levels not affected
Microangiopathic haemolytic anaemia (e.g. HELLP, TTP)	Microthrombi common Platelet count low	Bleeding uncommon Coagulation tests normal [†]
Hyperfibrinolysis	PT, APTT abnormal Fibrinogen low	Platelet count normal
Catastrophic antiphospholipid antibody syndrome	PT, APTT abnormal Platelet count low	Fibrinogen not low D-dimer normal [‡]
Massive transfusion	PT, APTT abnormal Fibrinogen low Platelet count low	D-dimer normal

Table 43.2 Differential diagnosis of disseminated intravascular coagulation (DIC).

*Unless additional disorders which increase the D-dimer coexist.

[†]Unless coexisting DIC.

[‡]Some antibodies can affect the D-dimer results.

HELLP, haemolysis, elevated liver enzymes, low platelet count (syndrome); TTP, thrombotic thrombocytopenic purpura.

It is also important to recognize that DIC is a dynamic process and thus interpreting a series of laboratory tests over time is more relevant than looking at a single set of results. The ISTH Sub-Committee of the Scientific and Standardization Committee on DIC has recommended the use of a scoring system for overt DIC (Table 43.3). This has been prospectively validated in various studies, indicating a very high sensitivity and specificity. A strong correlation between an increasing DIC score and mortality has been demonstrated. The optical light transmittance profile of the APTT, referred to as the biphasic waveform, has also been shown to correlate well with the overt DIC score. The biphasic waveform occurs independently of prolongation in the clotting times in patients with DIC.

Markers of increased thrombin generation (thrombin-antithrombin complexes) and increased fibrinolysis (plasmin-antiplasmin complexes) as well as endothelial markers have also been investigated as laboratory markers for DIC but single determinations are neither sensitive nor specific for DIC. More importantly, their general availability is limited due to practical considerations.

Treatment

The mainstay of treatment of DIC is to remove the underlying cause. However, DIC often continues even after appropriate treatment for the underlying condition. Supportive therapy with blood products may be necessary. Although the efficacy of blood product replacement has not been proven in randomized

Table 43.3 ISTH Sub-Committee of the Scientific and Standardization Committee on DIC recommended scoring system for overt disseminated intravascular coagulation (DIC).

- Risk assessment: does the patient have an underlying disorder known to be associated with overt DIC?
If yes, proceed
If no, do not use this algorithm
- Order global coagulation tests (platelet count, PT, fibrinogen, soluble fibrin monomers or FDPs)
- Score global coagulation test results
Platelet count ($\times 10^9/L$): > 100, score 0; < 100, score 1; < 50, score 2
Elevated fibrin-related marker (e.g. soluble fibrin monomers or FDPs): no increase, score 0; moderate increase, score 2; strong increase, score 3
Prolonged PT (s): < 3, score 0; > 3 but < 6, score 1; > 6, score 2
Fibrinogen (g/L): > 1, score 0; < 1, score 1
- Calculate score
- Score ≥ 5 compatible with overt DIC. Repeat scoring daily

FDPs, fibrin degradation products; PT, prothrombin time.

controlled trials, it is a biologically rational option to replace both thrombin-promoting and thrombin-opposing proteins, particularly when there is significant depletion of these factors in a patient who is either bleeding or at risk of bleeding. In those

patients not bleeding, transfusion of platelets or plasma in patients with DIC should not be undertaken based on laboratory results. There are no clinical or experimental data to suggest that platelet or plasma transfusions worsen the thrombotic process.

In patients with DIC and bleeding or at high risk of bleeding (e.g. after invasive procedures) and a platelet count less than $50 \times 10^9/L$, transfusion of platelets should be considered, especially because platelet function may be impaired. In bleeding patients with DIC and prolonged clotting times, fresh-frozen plasma (FFP) should be administered. If fluid overload is an issue, prothrombin complex concentrates (PCCs) could be considered but these will only correct vitamin K-dependent components. Activated PCCs should not be used because these can precipitate DIC. Severe hypofibrinogenaemia ($< 1 \text{ g/L}$) requires the use of fibrinogen concentrate or cryoprecipitate to correct.

A recent large trial in patients with severe sepsis showed a non-significant benefit of low-dose heparin on mortality and suggested that this is continued in patients with DIC and abnormal coagulation parameters, in the absence of overt bleeding. Notably, these patients are at highest risk of venous thromboembolism due to immobility, recent surgery and a proinflammatory state. However, the role of heparin remains controversial and unproven.

Treatment with recombinant human activated protein C in adults with severe sepsis significantly reduced mortality at 28 days from 30.8% to 24.7% and should be considered in sepsis-related DIC. It is used as a 96-hour infusion and caution is required in patients with a platelet count less than $50 \times 10^9/L$ due to the increased incidence of intracerebral haemorrhage. Although not licensed, (unactivated) protein C concentrate has been reported as useful in meningococcal septicaemia. No evidence exists to support the use of antithrombin or tissue factor pathway inhibitor concentrates.

The use of pro-haemostatic agents may be necessary in certain instances. There are some reports of the successful use of recombinant (r)FVIIa in patients with DIC and life-threatening bleeding. Antifibrinolytic agents, such as tranexamic acid and ϵ -aminocaproic acid, are not ideal treatments for DIC except if increased fibrinolysis with bleeding is observed (e.g. some cases of prostate cancer and giant haemangiomas).

Haemostatic dysfunction in acute promyelocytic leukaemia

Acute promyelocytic leukaemia (APL), in particular the microgranular variant (AML-M3v), is associated with major coagulation disturbance including DIC in at least 80% of cases. Although the introduction of all-*trans* retinoic acid (ATRA) and arsenic trioxide as differentiation agents has markedly reduced the rate of early haemorrhagic death and almost 90% of patients are cured, the 10% mortality from bleeding complications has

not improved. Bleeding does not correlate with the clotting parameters but with a high white cell count.

The cause remains poorly understood and probably relates to enhanced proteolysis, including fibrinolysis and disruption of endothelial barrier integrity. APL blast cells express TF and can also stimulate the production of inflammatory cytokines, which can further amplify TF levels and promote thrombosis. Cancer procoagulant, a cysteine proteinase detected on APL blast cells, can activate FX independent of FVII. Both these procoagulants are noted to be progressively reduced once patients have been commenced on ATRA. ATRA has also been demonstrated to inhibit vascular endothelial growth factor (VEGF) production, which indirectly limits TF production. Annexin II expression is enhanced on the surface of the blast cells and can act as a cell surface receptor for plasminogen and its activator, tissue plasminogen activator (tPA). Elastase, cathepsin-G and proteinase-3 are present in the granules of the APL blasts and can directly degrade fibrinogen, α_1 -antitrypsin, C1 esterase inhibitor and VWF, inducing the loss of high-molecular-weight multimers.

Management of the haemostatic abnormalities revolves around supportive care, including platelet transfusions to maintain a count of at least $30 \times 10^9/L$ (or $50 \times 10^9/L$ if the patient is bleeding) and the adequate replacement of fibrinogen to at least 1.5 g/L. The use of antifibrinolytic agents is supported by some evidence but remains controversial. Although markers of coagulation activation and fibrinolysis fall rapidly and completely following the start of ATRA therapy, there appears to be a slower resolution of procoagulant markers (up to 30 days). This may partly explain the clinical observation of thromboembolic events occurring in patients on ATRA, and thus prophylactic use of low-molecular-weight heparin or other anticoagulants should be considered once bleeding manifestations have settled.

Vitamin K and related disorders

Vitamin K metabolism

Vitamin K ('K' denoting *Koagulation*) is a group of lipophilic and hydrophobic vitamins that are needed for the post-translational modification of proteins, mostly required for blood coagulation. All forms of vitamin K share a methyl-naphthoquinone ring but differ in the structures of the side-chain. Phylloquinone (vitamin K₁) is derived from plants and has a phytyl side-chain, while menaquinones (vitamin K₂), which differ in the constituent of the side-chain, are synthesized by bacteria in human and animal intestine. Menadione (vitamin K₃), a synthetic water-soluble derivative without a side-chain, has been withdrawn because its use often resulted in haemolytic anaemia and kernicterus, especially in patients with glucose 6-phosphate dehydrogenase deficiency.

Vitamin K is a cofactor for vitamin K-dependent carboxylase, an enzyme that catalyses the carboxylation of glutamic acid (Glu) residues in several proteins (Figure 43.4). A free cysteine residue in the carboxylase converts reduced vitamin K (KH₂) into a strong base that can extract hydrogen from the γ-carbon of glutamic acid. Subsequently, carbon dioxide is added to form γ-carboxyglutamic acid (or Gla). This reaction results in vitamin K 2,3-epoxide, which is recycled to reduced vitamin K by vitamin K epoxide reductase (VKOR), the enzyme inhibited by coumarin anticoagulants.

The Gla domains of the vitamin K-dependent coagulant and anticoagulant proteins (FII, FVII, FIX, FX and proteins C and S) allow calcium-dependent binding to negatively charged phospholipids of activated cell membranes. This enhances the rate of the enzymatic reactions. In the bones, carboxylation of the Gla protein osteocalcin is essential for incorporation of calcium into hydroxyapatite crystals. Retrospective studies suggest that long-term therapy with coumarin-based anticoagulants can affect vertebral bone density and fracture risk.

Vitamin K deficiency

Vitamin K deficiency can occur at any age but is more common in infants because vitamin K does not cross the pla-

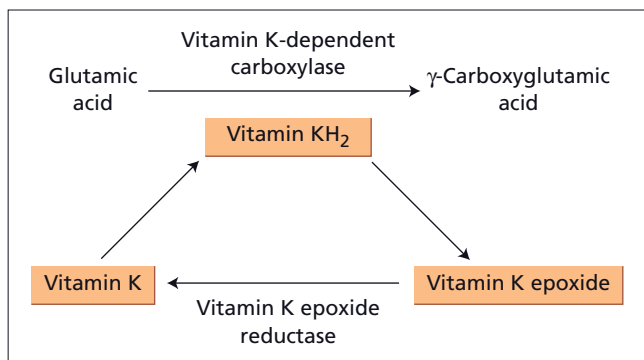

Figure 43.4 Vitamin K metabolism.

centa, breast milk has low levels and there is low colonic bacterial synthesis. The clinical presentation of vitamin K deficiency in infants is with bleeding. It was previously called ‘haemorrhagic disease of the newborn’ but is now termed vitamin K deficiency bleeding (VKDB). Supplementation of vitamin K is necessary to reduce the risk of bleeding, especially in exclusively breast-fed babies. A single intramuscular injection of vitamin K 1 mg prevents VKDB; however, if oral replacement is used, prolonged administration is required, although the exact dose is still controversial.

In adults, vitamin K deficiency is uncommon due to recycling of the vitamin and an adequate gut flora. However, a poor dietary intake in combination with antibiotic therapy can cause deficiency. Other causes of vitamin K deficiency include malabsorption, cholestatic liver disease (poor enterohepatic circulation) and drugs such as anticonvulsants and warfarin.

Vitamin K-dependent coagulation factors in healthy full-term infants are about half of normal adult values. Adult values are reached by about 6 months except for protein C, which does not reach adult levels until adolescence. Coagulation tests should be compared with age-matched reference ranges to distinguish physiological and pathological deficiencies.

VKDB in young children has been classified into early, classical and late types. The clinical features are shown in Table 43.4. The diagnostic criteria for VKDB includes a PT more than four times control in the presence of at least one of (i) a normal platelet count, normal fibrinogen level and absent fibrinogen degradation products, (ii) normalization of coagulation tests after parenteral vitamin K administration or (iii) the presence of proteins induced by vitamin K absence or antagonism (PIVKA) in plasma. The presence of PIVKA without a coagulation deficit is a marker of subclinical vitamin K deficiency.

The treatment of a non-life-threatening bleed is with vitamin K₁ (phytomenadione) given slowly intravenously. A dose of 1–2 mg is enough to fully correct the deficiency in infants aged up to 6 months, higher doses offering no advantage in efficacy or speed of reversal. There have been reports of anaphylactic reactions with the parenteral form although these are rare. The

Table 43.4 Features of vitamin K-deficiency bleeding (VKDB).

	<i>Early VKDB</i>	<i>Classical VKDB</i>	<i>Late VKDB</i>
Presentation	First 24 hours of life	Days 2–7 of life	Day 8 to 6 months of life
Cause	Infants of mothers on vitamin K-inhibiting drugs	Inadequate feeding	Cholestasis or malabsorption syndromes
Clinical presentation	Severe, with intracranial and intrathoracic bleeds	Milder, with gastrointestinal or umbilical bleeds being common	Severe, with high incidence of intracranial bleeds with ‘warning bleeds’ in up to one-third
Incidence of intracranial haemorrhage	High	Rare	Very high

PT should improve within 48 hours and if this has not occurred after three doses, continuation of vitamin K in most cases is unlikely to help. Oral replacement may be used if there is no active bleeding and absorption is normal. Patients with severe bleeding should be treated with FFP or PCC.

Poisoning with warfarin follows the accidental ingestion of large doses of warfarin or compounds with similar properties. Diagnosis is suggested by poor correction of PT or International Normalized Ratio (INR) with normal doses of vitamin K. Serum assays of warfarin concentration can be undertaken for confirmation.

Haemostatic disturbance in liver disease (Figure 43.5)

Almost all procoagulant factors, natural anticoagulants and inhibitors of coagulation are synthesized in the liver. The liver is also involved in the clearance of activated clotting factors from the circulation. The effect of liver disease on haemostasis is therefore complex and a balance between procoagulant and antithrombotic changes (Figure 43.5; Table 43.5). Routine coagulation tests such as PT and APTT are commonly pro-

Figure 43.5 Haemostatic disturbance in liver disease. The haemostatic system in liver disease (bottom) compared with normal haemostasis (top). In normal healthy adults, the procoagulant and anticoagulant systems and the profibrinolytic and antifibrinolytic systems form a balance that is not easily disturbed. In patients with liver impairment, all four components are variably reduced and additional stimuli like infections or renal failure can upset the balance very easily, leading to either bleeding or thrombosis.

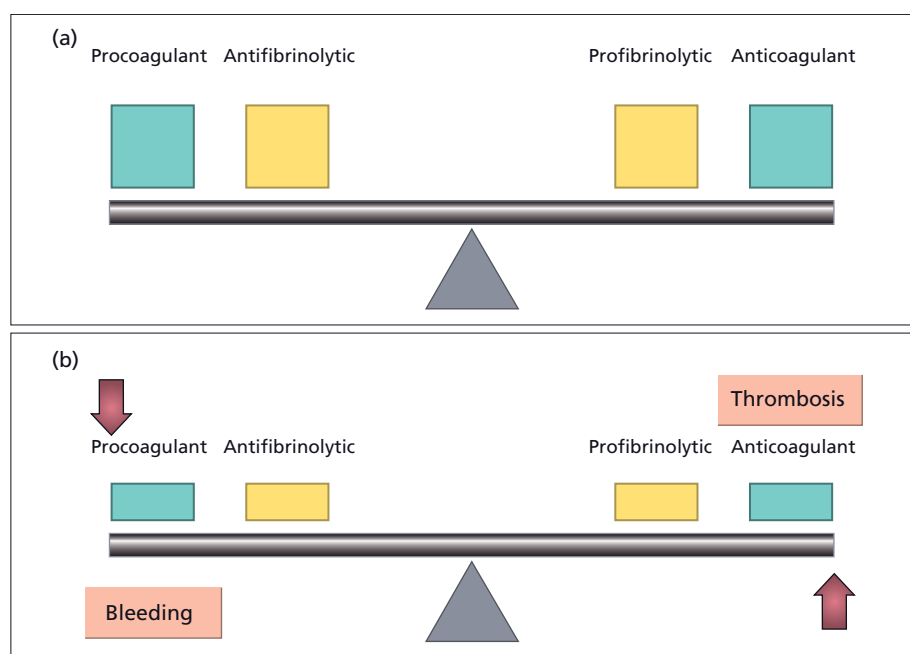

Table 43.5 Causes of increased bleeding tendency or coagulation abnormalities in liver disease.

Decreased coagulation factors	Hypofibrinogenaemia
Decreased synthesis	Impaired synthesis
Vitamin K deficiency	Loss into extravascular spaces (ascites)
Increased clearance	Increased catabolism
Abnormal coagulation factors due to hypocarboxylation	Loss due to massive haemorrhage
Decreased platelets	Dysfibrinogenaemia: abnormal sialic acid content
Sequestration in spleen or liver	Abnormal fibrinolysis
Thrombopoietin deficiency	Increased release and decreased clearance of tissue plasminogen activator
Destruction due to toxins or antiplatelet antibodies or toxins	Decreased synthesis of α_2 -antiplasmin, plasminogen and thrombin-activated fibrinolysis inhibitor
Toxic effect of alcohol on marrow	Infections
Dysfunctional platelets	Endogenous heparinoids: anti-FXa activity
Altered platelet arachidonic acid metabolism	Renal failure
Defective signal transduction	Sinusoidal endothelial cell dysfunction
Storage pool deficiency	Hypothermia
Abnormalities of the platelet glycoprotein	
Increased platelet inhibitors nitric oxide and prostacyclin	

longed in liver disease but are only sensitive to decreases in procoagulant factors and hence are liable to overestimation of the haemostatic defect. Patients with liver disease have similar thrombin generation to healthy control individuals, when tests are performed in the presence of thrombomodulin to make them sensitive to protein C deficiency.

Acute hepatitis

Patients with acute hepatitis are often thrombocytopenic (platelets $100\text{--}150 \times 10^9/\text{L}$). The mechanism for this may be immune, due to concurrent hypersplenism or DIC. Platelet function may be impaired in acute hepatitis, although this is unlikely to be of clinical significance. In acute liver disease, hepatic biosynthesis of clotting factors is impaired and this may be reflected in a prolongation of coagulation tests. The PT and FV, FVII, antithrombin and protein C levels are the most sensitive to hepatic biosynthetic dysfunction. The PT and FVII level predict survival in acute liver disease. The plasma fibrinogen may be raised in acute hepatic disturbance as part of an acute-phase response. A low fibrinogen level is associated with a poor prognosis in this context. A pattern of reduced fibrinogen and increased fibrin degradation products seen in acute liver disease may be due to hyperfibrinolysis.

Chronic liver disease

Low platelet count and abnormal platelet function are also common in liver disease and have been thought to lead to bleeding. Mild to moderate thrombocytopenia is noted in up to 30% of patients with chronic liver disease and in up to 90% of patients with terminal liver disease. In patients with cirrhosis, this is frequently related to hypersplenism, secondary to portal hypertension. In addition, dietary problems, such as folate deficiency and the direct toxic effect of ethanol on megakaryocyte function, may contribute to thrombocytopenia. A more profound thrombocytopenia in patients with hepatitis C virus (HCV) infection may be autoimmune, although the response to steroids is poor; however, approximately half of adult such patients treated with interferon alfa responded with a rise in platelet count. Recently, a Phase II study using eltrombopag, an oral thrombopoietin receptor agonist, increased platelet counts in the majority of patients with cirrhosis associated with HCV infection to more than $100 \times 10^9/\text{L}$ in a dose-dependent manner. Several platelet function abnormalities have also been demonstrated in liver disease. Despite this, recent evidence shows that VWF which binds to platelet glycoprotein is found to be increased tenfold and has been shown to support platelet adhesion despite reduced functional capacity. In addition, desmopressin did not show any efficacy in reducing blood loss in patients undergoing partial liver resection or liver transplantation.

Coagulation factor and natural anticoagulant synthesis is affected by chronic liver disease. FIX synthesis is usually reduced

less than that of FII, FVII, FX and protein C. The levels of these factors, especially FVII, have been demonstrated to fall proportionately with increasing severity of disease, with levels of FVII shown to be an independent predictor of survival (level below 34% associated with 93% mortality). Chronic liver impairment also leads to vitamin K deficiency, mainly by decreased absorption from the gut as a result of reduced bile salt secretion in cholestasis (parenteral vitamin K responsive) and decreased synthesis in parenchymal disease (parenteral vitamin K non-responsive). The PT, a test for the vitamin K-dependent factors, has been incorporated into prognostic indices of chronic liver disease, such as the Child–Pugh and Mayo End-Stage Liver Disease scores. Despite the prolongation of clotting tests such as PT and APTT, bleeding after liver biopsy or other potentially haemorrhagic procedure in patients with cirrhosis is rare, suggesting that these tests are not on their own indicative of the haemorrhagic tendency. Both these laboratory tests were developed to investigate coagulation factor deficiencies in patients with a bleeding history and as such they only measure the procoagulant factors. Overall, haemostasis is a complex interrelationship between endothelium, platelets, procoagulant proteins and inhibitors. The levels of such inhibitors (or anticoagulant proteins), antithrombin and proteins C and S are reduced in a similar manner to other clotting factors, thus potentially providing a net balance in haemostasis. Evidence for normal thrombin production in cirrhosis despite abnormal conventional coagulation tests has been recently demonstrated by thrombin generation tests, which include the other haemostatic parameters including platelets.

It is common practice to use the INR instead of the PT to access patients with liver disease. However, the INR is standardized for patients taking vitamin K antagonists and its use in patients who have liver disease requires determination of an international sensitivity index (ISI) relevant to liver disease. Recently, attempts have been made to use modifications of the INR called the $\text{INR}_{\text{liver}}$, which is free of the warfarin-based reference range.

Most patients with stable chronic liver disease have normal or increased fibrinogen, although in advanced disease fibrinogen falls. This may be due to impaired synthesis, loss into extravascular spaces (ascites), increased catabolism or massive haemorrhage. Some patients develop dysfibrinogenaemia due to increased activity of sialyltransferase expressed by immature hepatocytes generated during hepatic injury, which leads to low-molecular-weight fibrinogen with abnormal α -chains and higher sialic acid content. Dysfibrinogenaemia is reflected by a prolonged TT and/or reptilase time, with the fibrinogen antigen level reduced less than the Clauss fibrinogen. Cirrhosis can also be associated with accelerated fibrinolysis due to decreased clearance of tPA, and decreased synthesis of α_2 -antiplasmin, plasminogen and thrombin-activatable fibrinolysis inhibitor (TAFI). However, the level of TAFI deficiency in cirrhosis is not associated with increased plasma fibrinolysis when a global test

of fibrinolysis is employed. Also, the levels of plasminogen (a fibrinolytic) are reduced and those of PAI-1 (an antifibrinolytic) are high in liver disease, ultimately providing a balance for the fibrinolytic system. However, hyperfibrinolysis has been found to be a predictor of the first episode of upper gastrointestinal bleeding in cirrhotic patients with portal hypertension. This is due to delayed clotting activation because of the consumption of clotting factors and inhibition of fibrin polymerization and also secondary to reduced platelet adhesion and induction of platelet disaggregation.

Recent experiments have thrown light on non-haematological factors contributing to the bleeding diathesis in liver disease. These include bacterial infections, endogenous heparinoids, sinusoidal endothelial dysfunction and renal failure. Bacterial infections are a frequent coexisting problem in cirrhotic patients and are related to the degree of liver dysfunction. Infection is also an independent risk factor for variceal bleeding, with spontaneous bacterial peritonitis commonly preceding variceal bleeding and prophylactic antibiotic therapy shown to prevent early rebleeding. The endotoxins and inflammation due to infection can also release endogenous heparinoids from the endothelium and mast cells. These substances can have anti-FX activity that could in theory lead to bleeding. The dysfunction in sinusoidal endothelial cells makes them unable to respond to abrupt repeated increases in portal pressure (e.g. postprandial situations), which can lead to progressive dilatation of varices in cirrhosis. Life-threatening haemorrhage in patients with liver disease is often related more to portal hypertension (the localized coagulation problem is termed 'accelerated intravascular coagulation and fibrinolysis') than to net dysfunction of the clotting cascade, wherein the varices play a major part. Renal failure is also common in advanced liver disease (hepatorenal syndrome), which can impart a bleeding risk due to various reasons discussed separately. Hypothermia used as a therapeutic measure to prevent hepatic encephalopathy can reduce the enzymatic activity of plasma coagulation proteins and also has an effect on preventing the activation of platelets. Reduced hepatic clearance of activated clotting factors and lower synthesis of natural anticoagulants may predispose individuals with hepatic disease to DIC. This may occur following Gram-negative infection or in association with the insertion of a peritoneo-venous shunt. Ascitic fluid should be discarded at the time of shunt insertion to prevent this complication.

The management of a bleeding patient with hepatic dysfunction depends on the site of bleeding and the haemostatic dysfunction. Clotting function should be assessed by means of the PT, APTT, TT, and fibrinogen and D-dimer levels, although the results should be interpreted in the clinical context before transfusions are undertaken. Vitamin K should be administered intravenously (10 mg daily for 3 days) to aid biosynthesis of vitamin K-dependent factors. The widespread practice of managing the coagulopathy of liver disease with transfusions of FFP, cryoprecipitate or platelets should only be considered in the

presence of active bleeding. Large volumes of FFP may be required and this may present a management problem in patients with hepatic disease who are at risk of fluid overload. Platelet transfusion may be necessary, although platelet recovery may be reduced because of hypersplenism or immune-mediated destruction. There are no evidence-based guidelines to establish safe coagulation levels for liver biopsy and similar procedures and as such it is important to allow these only when the benefits outweighs the risks (transjugular route safer than percutaneous for liver biopsy). However, correction of the coagulopathy is particularly important before the placement of an intracranial pressure transducer in patients with hepatic encephalopathy. Spontaneous intracranial bleeding has been reported in such patients, though rarely, and this remains one of the principal concerns regarding abnormal coagulation in liver disease. In patients with evidence of increased fibrinolysis, antifibrinolytic drugs such as tranexamic acid should be considered.

Liver transplantation

The changes in the balance of haemostasis seen during liver transplantation are complex and multifactorial and can be due to surgical and non-surgical causes. Traditionally, the process of liver transplantation is split into three stages: stage I, the pre-anhepatic stage, which ends with the occlusion of the recipient's hepatic blood flow; stage II, the anhepatic phase, which ends with the reperfusion of the donor liver; and stage III, the reperfusion and neohepatic period. The risk of bleeding in the pre-anhepatic stage is related directly to the preoperative haemorrhagic risk related to the underlying liver disease. A reduction in procoagulant factors may also be seen, especially if large blood losses necessitate transfusion, leading to the dilution of clotting factors. During the second anhepatic stage, many studies have reported enhanced fibrinolytic activity. The lack of tPA clearance and the reduction in α_2 -antiplasmin may be responsible for this enhanced primary fibrinolysis. The mechanism of the increase in tPA levels is most likely due to lack of hepatic clearance. Reperfusion of the liver during the post-anhepatic phase is the crucial point of the intervention where once again fibrinolysis seems to play a pivotal role. There is a dramatic increase after reperfusion in almost three-quarters of patients who undergo liver transplantation. Usually, hyperfibrinolysis subsides within an hour, but in damaged donor liver sustained increased fibrinolytic activity may be observed. The endothelium of the donor liver is an important source of tPA; the ischaemic damage to the graft during preservation may explain the dramatic increase in plasminogen activators. Trapping of platelets in the graft may also play a role in the bleeding tendency. After reperfusion, the release of heparin-like compounds has also been shown. In the postoperative period, a reduction in platelet count is related to platelet activation and blood loss in addition to low thrombopoietin levels. The levels

of this hormone increase significantly on the first day after liver synthetic function is restored, with the platelet count normalizing in 2 weeks.

There is little evidence that one can predict the transfusion needs of a patient by examining the preoperative coagulation results. The profound coagulation abnormalities seen in fulminant hepatic failure should be corrected preoperatively. However, the correction of a mild coagulopathy in a patient with chronic liver disease prior to the operation is less likely to be of benefit. During surgery, the aim is to transfuse blood components to prevent the development of intractable coagulopathy. Whole-blood near-patient tests of haemostasis are often used in theatre to complement the tests performed in the coagulation laboratory. Many departments use algorithms based on coagulation and near-patient testing to guide FFP, red cell, cryoprecipitate and platelet transfusion during the procedure. Aprotinin can be administered to counteract the increase in fibrinolysis observed.

Hypercoagulability in liver disease

Tipping of the balance in the complex interplay between endogenous procoagulants and the anticoagulant system in liver disease can also lead to a hypercoagulable state that negates the generally believed notion of an 'autoanticoagulated state'. The hypercoagulable events may be clinically evident disease, as with portal vein thrombosis and venous thromboembolism, but in the microvasculature can be a major pathophysiological contributor to portopulmonary hypertension, liver fibrosis (termed 'parenchymal extinction' in this setting), thrombosis of extracorporeal circuits and progression of non-alcoholic steatohepatitis to cirrhosis. Hypercoagulation in liver disease may be related to poor flow, endothelial dysfunction and vasculopathy associated with a chronic inflammatory state, increased levels of FVIII and VWF, or decreased synthesis of the naturally occurring anticoagulant proteins. Hepatic fibrogenesis may be caused by tissue ischaemia and direct thrombin-mediated stellate cell activation by PAR-1 cleavage. FV Leiden mutation, protein C deficiency and increased expression of FVIII were associated with rapid progression to cirrhosis in chronic HCV. The association between hypercoagulation and increased fibrosis has led to experiments which have shown that interference with either the generation of thrombin or its downstream activity may reduce hepatic fibrosis.

Haemostatic disturbance in renal disease

Bleeding was a frequent cause of morbidity and mortality in patients with renal failure before the advent of dialysis. Common manifestations are gastrointestinal bleeding from angiodysplasia and peptic ulcers as well as prolonged bleeding from skin puncture sites. Subdural haematomas and haemorrhagic peri-

carditis are also seen but bleeding at the time of renal biopsy is rare. Bleeding is seen despite normal or elevated circulating levels of coagulation factors, suggesting that platelet abnormalities are the likely cause. This is supported by the finding of a prolonged bleeding time and reduced platelet aggregation to various agonists. Severe thrombocytopenia (platelets $< 50 \times 10^9/L$) secondary to renal failure is rare and its presence should suggest concomitant conditions such as HCV infection or vasculitis.

Platelet dysfunction with renal failure is multifactorial and can be divided into (i) intrinsic platelet defects, (ii) abnormal interaction of platelets with the endothelium, (iii) effects of uraemic toxins, (iv) effects of anaemia on platelets and (v) dialysis-related. Intrinsic platelet abnormalities reported in association with uraemia are shown in Table 43.6. The interaction between uraemic platelets and the endothelium can be markedly reduced, due partly to impaired VWF binding to platelets. As a result of excess urea, L-arginine is shunted to form guanidinosuccinic acid, which can upregulate endothelial production of nitric oxide, an inhibitor of platelet aggregation. Uraemic patients with prolonged bleeding times also have raised prostaglandin (PG)_{I₂} levels.

Anaemia-related haemostatic dysfunction is primarily a result of reduced displacement of platelets to the vessel wall by red cells. Decreased red cell number also results in reduced ADP release and decreased platelet interaction with collagen. Dialysis can improve bleeding symptoms and a likely explanation is the chronic low-level platelet activation associated with the procedure. Antifibrinolytic agents can help because fibrinogen fragments of fibrinolysis can interfere with platelet receptors. Antiplatelet drugs, antibiotics (especially those which can accumulate in renal failure) and heparin may contribute to the bleeding risk.

The bleeding time better correlates with clinical bleeding than tests of renal function, although measurement is rarely clinically useful. Adequate dialysis will improve symptoms and the bleeding time in most patients. Intravenous or intranasal

Table 43.6 Platelet abnormalities reported in uraemia.

Decreased GPIIb complexes
Reduced serotonin and ADP in the granules
Increased levels of cyclic AMP
Defective ristocetin-induced platelet aggregation
Abnormal mobilization of free cytoplasmic calcium in response to agonists
Reduced release of arachidonic acid from membrane phospholipids
Decreased conversion of arachidonic acid to thromboxane A ₂
Abnormal dense-granule and α-granule secretion
Abnormal cytoskeletal assembly
Deficient tyrosine phosphorylation

administration of desmopressin in conjunction with antifibrinolytics has also been used successfully to control uraemic bleeding. Although the response is brief (4–8 hours), the rapid onset of action is beneficial. Care is required to avoid hyponatraemia and fluid retention. Desmopressin is also thought to improve platelet function by the enhanced release of endothelial VWF multimers and also by increasing the levels of platelet glycoprotein (GP)Ib/IX.

Estrogen preparations have been used for a more prolonged effect, although the mechanism of action is not well understood. Correction of anaemia with recombinant human erythropoietin so that the haematocrit exceeds 30% improves platelet interaction with the vessel wall and has also been shown to increase the number of reticulated platelets. Other potentially beneficial effects of recombinant human erythropoietin include improved platelet intracellular calcium mobilization, increased expression of GPIb and improved platelet signal transduction. Cryoprecipitate transfusion for uraemic bleeding is going out of favour, although it may be tried if the patient is haemodynamically unstable.

Pregnancy-related haemostatic dysfunction

Normal pregnancy is associated with physiological changes in haemostasis, with increased levels of procoagulant proteins such as fibrinogen, VWF and FVIII and a fall in anticoagulants such as protein S. These changes partly contribute to the increased risk of venous thromboembolism during pregnancy.

Obstetric haemorrhage is the third most common cause of maternal death in the UK after venous thromboembolism and pre-eclampsia. The cause of bleeding is often multifactorial, with a combination of physical and acquired haemostatic defects. Consumption leads to depletion of platelets and coagulation factors, particularly fibrinogen. A particularly aggressive consumptive coagulopathy is seen with amniotic fluid embolus triggered by TF and phosphatidylserine, and is often fatal. Consumptive coagulopathy may also be triggered by placental abruption, intrauterine fetal death, pre-eclampsia and acute fatty liver of pregnancy. Once bleeding and resuscitation has started, a dilutional coagulopathy may exacerbate the haemostatic failure and contribute to the ongoing bleeding.

Treatment requires rapid recognition of bleeding and a coordinated response from obstetricians, midwives, anaesthetists and haematologists. Physical methods to control bleeding include the use of oxytocins to contract the uterus, B Lynch sutures, intrauterine balloon tamponade and uterine artery embolization. Assessment of haemostatic failure requires an urgent FBC and a coagulation screen that includes a Clauss fibrinogen because the PT and APTT may be normal despite a low fibrinogen. Blood product replacement is often required before the results of the blood test are available and empirical

replacement therapy may be necessary. In patients with severe haemostatic failure, a standard dose of FFP (15 mL/kg) is unlikely to be adequate to correct the haemostatic defect and the use of larger volumes should be anticipated. Fibrinogen should be maintained above at least 1.5 g/L and platelets above $50 \times 10^9/L$. Some centres now routinely use fibrinogen concentrate in obstetric haemorrhage to rapidly correct this clotting factor, although this product is not licensed in the UK. rFVIIa may be used if haemostasis cannot be secured by standard methods but will not be useful in the presence of low fibrinogen or thrombocytopenia.

As soon as bleeding has been controlled the patient is likely to be at high risk of venous thromboembolism; this should be assessed and appropriate prophylaxis started.

Haemostatic dysfunction associated with cardiopulmonary bypass surgery

Coronary artery bypass graft (CABG) surgery is associated with excessive bleeding in about 5% of cases. Reoperation for bleeding is required in 3–10% of cases, with a mortality of about 30%. Bleeding is more common with revision procedures. A surgically correctable source of bleeding is found in over half of cases. Bleeding due to haemostatic disturbances can be patient related or CPB related. Antiplatelet, anticoagulant or fibrinolytic drugs, particularly at the time of emergency CABG after stenting procedures, commonly contribute to perioperative bleeding. Despite its antiplatelet activity, aspirin has not been demonstrated to cause increased blood loss after CABG, and has been shown to reduce the risk of death by one-third.

Haemostatic abnormalities associated with CPB are related to the interaction of blood with the extensive non-endothelial bypass surfaces and retransfusion of pericardial blood. CPB decreases both the number and function of platelets. Platelet counts fall by 25–60% within 15 min of first passage of blood through the primed CPB circuit, in association with a prolonged bleeding time. This is due to the exposure of platelets to the high concentration of unfractionated heparin, the haemodilution caused by the oxygenator primer and the non-biological extracorporeal surface. The platelet count rarely falls below $100 \times 10^9/L$ and persistent or profound thrombocytopenia should prompt consideration of alternative causes including heparin-induced thrombocytopenia.

The observed changes in platelet function in patients undergoing CPB are due to modification of membrane components with loss of receptors, decrease in granule contents, aggregation to fibrinogen adsorbed onto the bypass circuit, mechanical trauma, exposure to hypothermia and heparin. CPB also results in increased numbers of platelet fragments and microparticles, denoting platelet activation. Following CPB, platelet function returns to normal within 1 hour, although the platelet count

may take several days to normalize. Coagulation factors fall because of haemodilution, which can be exacerbated by use of cell-salvage systems. Fibrinolysis is also enhanced by returned blood from the pericardiotomy suction.

Blood component administration in patients with excessive bleeding related to CABG is generally empirical, with replacement of FFP and platelets. Near-patient whole-blood testing has been used to assess haemostasis and fibrinolysis in the context of cardiac surgery and has been shown to help rationalize blood product usage. The time delay in obtaining routine laboratory tests often limits their use in the acute management of bleeding patients. The off-licence use of PCCs and fibrinogen concentrates has also been reported. Case reports suggest that off-licence use of rFVIIa may be considered in patients who have failed standard treatment but randomized studies have not supported a role for its use as prophylactic treatment.

Aprotinin has been used to reduce bleeding during CPB by inhibition of fibrinolysis. Double-blind studies have consistently shown its effectiveness in reducing blood loss in comparison with tranexamic acid, α -aminocaproic acid and desmopressin. However, recent reports have shown a doubling of the risk of renal failure requiring dialysis in patients undergoing complex coronary artery surgery and a 55% increase in cardiovascular and cerebrovascular events. The current use of aprotinin is contentious and under intense debate.

Haemostatic dysfunction associated with trauma

Coagulopathy associated with trauma is multifactorial and the important initiators include tissue injury, loss of procoagulant factors and platelets, physiological and therapeutic haemodilution, inflammation, hypothermia and acidosis. The localization of coagulation to the sites of injury (in contrast to DIC of sepsis) has made some experts use the term 'acute coagulopathy of trauma-shock'. Tissue damage in trauma initiates coagulation via TF, with head injury causing release of brain-specific thromboplastins into the circulation. Increased fibrinolysis due to the direct release of tPA from the endothelium is also seen, together with abnormal fibrin polymerization that increases susceptibility to cleavage by plasmin.

Massive blood loss leads to deficiencies of haemostatic factors and up to half of the fibrinogen and one-third of platelets may be lost before treatment of the injury has begun. Tissue under-perfusion contributes to the coagulopathy by enhancing anticoagulation through activated protein C and fibrinolysis through reduced TAFI. Physiological filling of the vascular space with fluid from cellular and interstitial spaces, along with the administration of intravenous fluids and plasma-poor red cells, causes haemodilution to worsen the coagulopathy. Plasma expanders are also associated with anticoagulant effects such as reduced VWF levels and their use should be limited.

The presence of an abnormal coagulation test on arrival in the emergency department correlates with the severity of injury and the mortality rate. A raised PT is the most frequent abnormality (12.4% of patients) while a low platelet count is least frequent (5.6%). An abnormal PT and APTT increased the risk of mortality by 6.3-fold and 10.7-fold, respectively.

A guide to blood product support, with transfusion triggers, that may be used in conjunction with repeated laboratory tests is given in Table 43.7. Delay in obtaining coagulation and platelet count results dictates that empirical blood product replacement is often required. Recent observations, predominantly based on experience of battlefield trauma, have prompted recommendations for aggressive and early plasma and platelet replacement. This has been termed 'damage limitation resuscitation' (ratio of 1:1:1 for red cells, plasma and platelets). This strategy has been reported in non-randomized studies to improve outcome but definitive evidence is lacking for this approach. Issues such as hypothermia and acidosis need to be addressed by using prewarmed fluids and extracorporeal warming devices and appropriate resuscitation.

Table 43.7 Guide to blood product replacement in massive blood loss.

- 1 Control bleeding using surgical and/or radiological interventions
- 2 Restore an appropriate circulating blood volume
- 3 Control exacerbating factors: hypothermia and acidosis
- 4 Blood product support as detailed below

Red cells

Use O-negative red cells first

If no record of red cell antibodies, ABO- and Rh-compatible cross-matched blood should be available within 30 min (maximum 45 min)

Replace red cells as required to maintain circulating blood volume

Use blood warmer to avoid hypothermia

Fresh-frozen plasma

Transfuse FFP early to prevent coagulopathy to maintain PT and APTT < 1.5 times normal

If PT and APTT > 1.5 times normal FFP at doses > 15 mL/kg will be required

Platelet transfusion

One to two adult doses after 1.5–2 blood volume replacement (equivalent to 8–10 bags of red cells)

Aim for platelet count > $50 \times 10^9/L$

Fibrinogen

Cryoprecipitate (dose: two donation pools)

Fibrinogen concentrates (30–50 mg/kg)

Aim for fibrinogen level > 1.5 g/L

A randomized controlled trial of rFVIIa versus placebo in 301 patients with blunt and penetrating injuries showed a reduction in 2.6 RBC units transfused for the blunt trauma subgroup and a similar though non-significant trend in the penetrating injury subgroup. The incidence of adult respiratory distress syndrome was decreased in patients with blunt injury who received rFVIIa, although there were no differences in survival or in the incidence of thromboembolic events and multiorgan failure. In view of these data, use of rFVIIa in the management of trauma has to be considered on an individual basis.

Coagulopathy in massive blood loss

Massive blood loss is usually defined as 1 blood volume (about 5 L in an adult) in 24 hours or 50% blood volume in 3 hours or more than 150 mL/hour. The associated coagulopathy is complex and multifactorial. It is partly dilutional as blood is replaced with volume expanders and red cells but DIC, hypoxia, hypothermia and acidosis contribute in some clinical situations. Haemostatic management should be to maintain a platelet count of at least $75 \times 10^9/L$, a threshold that is likely to be reached after a 2-blood-volume transfusion. A higher platelet count of about $100 \times 10^9/L$ will be needed in major trauma or central nervous system bleeding. Fibrinogen should be maintained above at least 1.5 g/L, a level that is likely to be reached after about a 1.5-blood-volume transfusion, assuming no significant additional consumptive coagulopathy.

Haemostatic therapy is to infuse platelets and FFP in volumes likely to maintain a safety margin above these critical levels. Hypofibrinogenaemia unresponsive to FFP may require cryoprecipitate or fibrinogen concentrate. It is important to predict ongoing dilution and consumption of coagulation factors and to replace these expectantly if bleeding continues. Regular measurement of FBC and coagulation screens (including Clauss fibrinogen) are important for monitoring replacement treatment, although often these are not available rapidly enough to guide initial management and empirical treatment may be required in the early phases (see Table 43.7).

Bruising

Purpura simplex (normal/easy bruising)

Distinguishing normal from pathological bruises may be difficult and individuals have variable thresholds for presenting for medical review. If bruising is not associated with other symptoms suggestive of a bleeding disorder and routine tests of coagulation (including VWF levels and platelet number) are normal, the patient can be reassured. Drugs such as non-steroidal anti-inflammatory agents or selective serotonin reuptake inhibitors are sometimes implicated.

Non-accidental bruising

Bruising is a common feature of non-accidental injury in both children and adults. Bruises that affect unusual sites, are in different stages of maturation or shaped like a hand or instrument should raise concern. In the case of children, appropriate liaison with child protection agencies should be undertaken, although the possibility of an underlying congenital or acquired bleeding disorder should also be thoroughly investigated. Self-harm may also present with bruising and should be suspected if the pattern of bruising is atypical. Deliberate ingestion of anticoagulants and long-acting vitamin K antagonists is also possible.

Senile purpura (atrophic or actinic purpura) and steroid-related purpura

Bruising is more common in elderly people due to atrophy of subcutaneous tissues and loss of collagen and elastin fibres in subcutaneous tissues. Blood vessels in the skin can be broken by minor trauma or shearing forces and typically purpura are seen on hands and forearms. If routine tests of platelet number and coagulation are normal, no further investigation is required. Long-term steroid use is also associated with bruising secondary to atrophy of collagen fibres supporting blood vessels.

Psychogenic purpura

Psychogenic purpura or Diamond–Gardner syndrome is a rare condition usually seen most commonly in women with psychological problems. It presents with painful ecchymotic lesions, mostly on the extremities and the face and rarely on less accessible parts of the body. The skin lesions can be preceded by paraesthesia or pain and are usually reported after surgery or minor trauma. The usual tests for haemostasis reveal no abnormalities. Diamond and Gardner suggested the possibility of a local reaction to the patient's own red cell stroma and gave it the name 'autoerythrocyte sensitization syndrome'.

Scurvy

Scurvy is caused by a lack of vitamin C (ascorbic acid), which is required for the hydroxylation of prolyl and lysyl residues in the formation of mature collagen. Vitamin C deficiency renders the collagen unable to self-assemble into rigid triple helices, resulting in blood vessel fragility and poor wound healing. The characteristic clinical finding is perifollicular haemorrhage but large ecchymoses can occur on the legs and trunk. Follicular hyperkeratosis and corkscrew hairs are other cutaneous features. Bleeding gums are also common. Scurvy is more common in people with poor nutrition, especially alcoholics. The diagnosis is made clinically although levels of plasma or leucocyte

vitamin C can be measured. A prompt response to vitamin C treatment is also diagnostic.

Inherited disorders of collagen and elastic fibres

Ehlers–Danlos syndrome (EDS) is a group of dominantly inherited disorders of connective tissue characterized by lax hyperelastic skin, joint laxity and poor wound healing. There are six subtypes and subtype IV is associated with severe varicosities and spontaneous rupture of major blood vessels. Bruising is seen in 90% of patients with EDS and has also been reported in people with lax joints who do not fulfil the criteria of EDS. Although mild platelet and coagulation factor dysfunction has been reported in association with EDS, it is likely that these are coincidental. Some patients have a prolonged bleeding time and this can respond to DDAVP. Other disorders such as osteogenesis imperfecta and Marfan syndrome may also be associated with bruising. Recently, a pseudoxanthoma elasticum-like disorder has been described where deficiency of the vitamin K-dependent clotting factors was noted along with the typical excessive skin folding (or cutis laxa).

Haemostatic dysfunction associated with vasculitis

The vasculitides are a heterogeneous group of disorders characterized by inflammation within blood vessel walls of different organs. It is classified by the size of the blood vessel involved and can be associated with both thrombosis, for example Behçet's disease (see Chapter 46), and haemorrhage. The classic presentation of Henoch–Schönlein purpura is palpable purpura without thrombocytopenia or coagulopathy, arthritis/arthralgia, abdominal pain and renal disease. Henoch–Schönlein purpura is more commonly associated with bleeding than thrombosis.

Arteriovenous malformations

Hereditary haemorrhagic telangiectasia

Hereditary haemorrhagic telangiectasia (HHT) is a dominantly inherited, highly penetrant, familial disease in which telangiectasia develop on the skin and mucous membranes. Associated large arteriovenous malformations may occur in solid organs. International consensus diagnostic criteria have been developed based on epistaxis, mucocutaneous telangiectasia, visceral lesions and an affected first-degree relative. A patient is diagnosed as having 'definite HHT' when three crite-

ria are present, 'suspected HHT' when two criteria are present, or 'HHT unlikely' when only one criterion is present. All the offspring of an affected individual are at risk of having the disease since HHT may not manifest until late in life.

Mutations in the *ENG* gene (encoding endoglin) and *ALK1* gene (encoding activin receptor-like kinase 1) have been described. These genes encode proteins that are involved in signalling by the transforming growth factor (TGF)- β superfamily. In healthy endothelial cells, ALK-1 and endoglin cooperate in the TGF- β /Smad pathway. In HHT types 1 and 2, either endoglin or ALK-1 fail in cooperative signalling resulting in impaired TGF- β signalling. The latter can lead to a decreased capacity to form cord-like structures typical of the angiogenic process. This leads to dysregulation in the organization of the capillary network and arteriovenous malformation. Recently, it has also been shown that TGF- β 1 has a biphasic effect on angiogenesis depending on its concentration. At high concentrations TGF- β 1 inhibits VEGF-induced endothelial cell invasion and capillary lumen formation, whereas lower TGF- β 1 concentrations potentiate VEGF activity. Increased levels of VEGF have been demonstrated in HHT (especially in patients who have frequent bleeds) and agents that inhibit VEGF, like thalidomide and bevacizumab, have been successful in treating severe HHT.

Cerebral, pulmonary and neurological involvement is described more commonly with *ENG* mutations, whereas liver involvement has been associated with *ALK1* mutations. Telangiectasia usually appears during the second and third decades of life but presentation at all ages has been described. Typical lesions are red 0.5–3 mm spots that blanch with pressure and are often noted on the skin of face and lips and mucosal surfaces of the tongue and mouth. Symptoms range from cosmetic and recurrent epistaxis and mouth bleeding to iron deficiency and intracranial haemorrhage. Epistaxis is seen in the majority of patients and is usually recurrent. Gastrointestinal bleeding from both upper and lower bowel and haematuria are also seen. Emboli, including septic emboli, may occur and antibiotic prophylaxis at the time of invasive procedures such as dental extraction is recommended. Occasionally bleeding can occur from internal organs without visible lesions.

Virtually all internal organs can be affected. The lungs develop pulmonary arteriovenous fistulae in about 30% of patients leading to haemoptysis, sometimes catastrophic, hypoxia, dyspnoea, high-output cardiac failure and clubbing. Transient ischaemic attacks, cerebral infarction and systemic emboli due to right-to-left shunting occur in about half of the patients with pulmonary arteriovenous fistulae. Pulmonary arteriovenous fistulae may worsen during pregnancy. Liver involvement is present in the majority of patients and, though often asymptomatic, can lead to cirrhosis, portal hypertension and high-output cardiac failure. Conjunctival telangiectasia may cause benign bleeds while more serious retinal bleeds can occur. Intracranial haemorrhage is associated with arterio-

enous fistulae but embolization including septic emboli also commonly cause cerebral symptoms.

Screening tests in patients with mucocutaneous telangiectasia should include FBC, ferritin, liver function tests, chest radiography, liver ultrasound and contrast echocardiography (to identify pulmonary shunts). The role of gastrointestinal endoscopy and CT angiography or MRI of lung or brain in asymptomatic patients is unclear.

Treatment options for symptomatic lesions include local options such as laser therapy of skin and mucosal telangiectasia and embolization of arteriovenous malformations in lung or nervous system. Systemic treatment with estrogens and tranexamic acid may reduce bleeding symptoms.

Kasabach–Merritt syndrome

Kasabach–Merritt syndrome is a rare condition in which a vascular tumour (Kaposiform haemangioendothelioma) is associated with thrombocytopenia, hypofibrinogenaemia and bleeding, which can be life-threatening. The thrombocytopenia in Kasabach–Merritt syndrome is presumed to be due to platelet adhesion to the abnormally proliferating endothelium. This results in the activation of platelets with secondary consumption of clotting factors, including VWF, leading to systemic haemostatic failure. Excessive flow and shear rates secondary to arteriovenous shunting also contribute. The platelet count is often less than $20 \times 10^9/L$ and platelet half-life dramatically reduced. Intralesional bleeding can cause rapid enlargement of the haemangioma and can worsen the consumptive coagulopathy. Intralesional thrombosis may rarely occur, causing spontaneous resolution of some lesions. In addition to the thrombocytopenia and abnormal coagulation, some degree of microangiopathic haemolysis may be seen, suggesting intravascular coagulopathy. Management involves supportive care and, if possible, removal of the lesion. Steroids, interferon, chemotherapy with vincristine, radiotherapy and anti-angiogenic agents have been tried.

Microthromboembolic disease

Cholesterol embolism

Cholesterol embolism is a complication of widespread atherosclerotic disease. Rupture of an atherosclerotic plaque can occur spontaneously or, more commonly, at the time of vascular surgery or invasive procedures. Anticoagulant or fibrinolytic therapy can also weaken thrombi that usually prevent the release of cholesterol crystals. The characteristic presentation is with small limb-vessel occlusion with well-preserved peripheral pulses, which may occasionally lead to gangrene. Another common skin finding is livedo reticularis, where the cutaneous

venous plexus becomes visible because of increased amounts of desaturated venous blood. Organ involvement from cholesterol emboli is dependent on the vascular supply, with renal ischaemia being the commonest. The diagnosis of this condition is often missed unless the occurrence of the clinical features is related to the triggering procedure. Fundoscopy can reveal the presence of retinal cholesterol crystals (Hollenhorst plaques) in about 25% of cases. Biopsy of the cutaneous lesion or the affected organ is required for definitive diagnosis. The prostacyclin analogue iloprost has been used successfully in painful cutaneous necrotic lesions and renal insufficiency in a single report.

Fat embolism syndrome

Fat embolization is characterized by release of fat droplets into the systemic circulation after a traumatic or iatrogenic event. Its incidence depends on the bone involved (fractures of the femoral shaft > tibia or fibula > neck of femur), isolated or multiple fractures, age (10–40 years) and gender (occurs more in males). Although more common after lower limb fractures, fat embolism syndrome can also occur after liposuction, bone marrow harvesting, total parenteral nutrition, sickle cell crisis and pancreatitis. Classically, it presents with the triad of respiratory distress, mental status changes and petechial rash 24–48 hours after pelvic or long-bone fracture. The rash is pathognomonic and is seen usually on the conjunctiva, oral mucous membranes and upper body possibly due to embolization of fat droplets accumulating in the aortic arch. The diagnosis is made clinically because laboratory and radiographic diagnosis is non-specific and inconsistent. Thrombocytopenia is common due to platelet activation and consumption into the thrombi. Management is mainly supportive with intensive care management to ensure haemodynamic stability. Aspirin and corticosteroids have also been shown to be helpful, although the use of heparin is controversial.

Warfarin-induced skin necrosis

Warfarin-induced skin necrosis is a rare condition that is due to microvascular thrombi provoked by a transient imbalance between procoagulant and anticoagulant factors. It most commonly affects the breasts, buttocks and thighs. It may occur on initiation of warfarin, especially in patients with heterozygous protein C or protein S deficiency because of the relatively shorter half-lives of the vitamin K-dependent proteins C and S compared with prothrombin. It is also seen in association with heparin-induced thrombocytopenia. It is prevented by bridging the initiation of warfarin with heparin and avoiding high loading doses. Treatment requires discontinuation of warfarin and starting therapeutic heparin. Intravenous infusions of protein C concentrate may also be used in the short term. Surgical débridement may be required in extensive cases.

Haemostatic dysfunction associated with paraproteinaemia and amyloidosis

Paraproteinaemia

Bleeding and thrombotic complications both occur in association with paraproteinaemias, although abnormalities in laboratory tests are found much more frequently than clinical effects. Bleeding is more common in Waldenström macroglobulinaemia and amyloidosis than multiple myeloma. Among myeloma patients, bleeding is most common in those with IgA paraproteinaemia. The circulating paraprotein in these conditions can (i) cause hyperviscosity and lead to arterial and retinal bleeds due to abnormal wall shear stress; (ii) inhibit or increase clearance of FVIII and VWF leading to von Willebrand disease or, less commonly, acquired haemophilia; (iii) impair platelet aggregation; (iv) inhibit fibrin polymerization; and (v) have heparin-like anticoagulant function that can be reversed by protamine. Management of these conditions is directed towards the underlying cause. Plasma exchange is of help as a temporary measure.

Amyloidosis

The pathophysiology of bleeding associated with systemic amyloidosis is multifactorial. The type of amyloidosis and the pattern of organ involvement are important determinants of the haemorrhagic tendency. AL amyloidosis, where liver and spleen involvement is frequent, is the commonest type associated with bleeding. Although FX deficiency is the most commonly found, decreased levels of all other factors, including VWF, have been reported. The coagulation factor deficiencies in these patients are thought to be due to adsorption onto amyloid fibrils. Abnormal fibrin polymerization and hyperfibrinolysis can also contribute to bleeding. Prolongation of the TT is the most common abnormality, seen in up to 90% of patients. A prolonged PT and APTT suggests FX deficiency.

Platelet dysfunction may also be seen, due to the binding of the amyloid light chains to the platelet membrane. Deposition of amyloid fibrils in the blood vessel wall and perivascular tissue may lead to impaired vasoconstriction and vessel fragility. This is exemplified by cerebral amyloid angiopathy, which can lead to intracerebral haemorrhage especially in elderly non-hypertensive individuals. The microvascular involvement also explains the 'raccoon eyes' (bilateral periorbital purpura from coughing or prolonged inverted positioning for lower gastrointestinal procedures) and the 'pinch purpura' (skin pinching leading to purpura). Several treatments have been described, including factor replacement with FFP or PCCs, platelet transfusion, DDAVP and rFVIIa. Severe FX deficiency can be difficult to manage and first-line therapy is with PCCs or FFP.

Acquired inhibitors of coagulation factors

Inhibitory autoantibodies to all coagulation factors have been described, although those against FVIII and VWF are most common.

Acquired haemophilia A

Acquired haemophilia A has an annual incidence of about 1.5 per million and usually affects older patients with a median age of about 75 years. It affects males and females equally, except in younger patients where there is a female preponderance associated with pregnancy. Acquired haemophilia A presents with a typical bleeding pattern that is distinct from that seen in congenital haemophilia. Widespread subcutaneous bleeding is common, as are muscle bleeds and gastrointestinal and genitourinary bleeding. Neurovascular compression may be limb-threatening. Haemarthroses are relatively uncommon. Fatal bleeding, such as intracranial, pulmonary, gastrointestinal and retroperitoneal, occurs in 8–22% of cases (Table 43.8). Patients remain at risk of severe bleeding until the inhibitor has been eradicated even if they present with mild bleeding. Acquired haemophilia A is associated with an underlying autoimmune (systemic lupus erythematosus or rheumatoid arthritis), malignant, lymphoproliferative or dermatological (pemphigoid) disease or pregnancy in about half of cases (Table 43.9). If acquired haemophilia A presents in association with pregnancy,

Table 43.8 Bleeding symptoms in patients with acquired haemophilia A.*

Site of bleeding	All bleeds at presentation (%)	Bleeds requiring treatment (%)
	N = 172	N = 65
Subcutaneous/skin	81	23
Muscle	45	32

it may recur in subsequent pregnancies and, if antenatal, the fetus may be affected.

Early diagnosis and urgent treatment of bleeding are key to successful management. The diagnosis is suggested by the clinical presentation and an isolated prolonged APTT. FVIII inhibitors are time and temperature dependent and in mixing studies normal plasma must be incubated for 1–2 hours otherwise the diagnosis may be missed. The diagnosis is confirmed by a low FVIII and positive Bethesda titre (Figure 43.6). In some cases diagnosis is complicated because all the intrinsic factors may be low due to inhibition of FVIII in the factor-deficient plasma used to assay other intrinsic factors. Dilution of the antibody will result in increased levels of the non-specifically reduced factors while FVIII remains low. It is important to exclude a lupus anticoagulant because this can also be associated with an apparently low FVIII and an APTT that does not correct with normal plasma. Acquired FVIII inhibitors have complex kinetics, so that not all FVIII is inhibited in a Bethesda assay. It is therefore often not possible to measure the inhibitor titre accu-

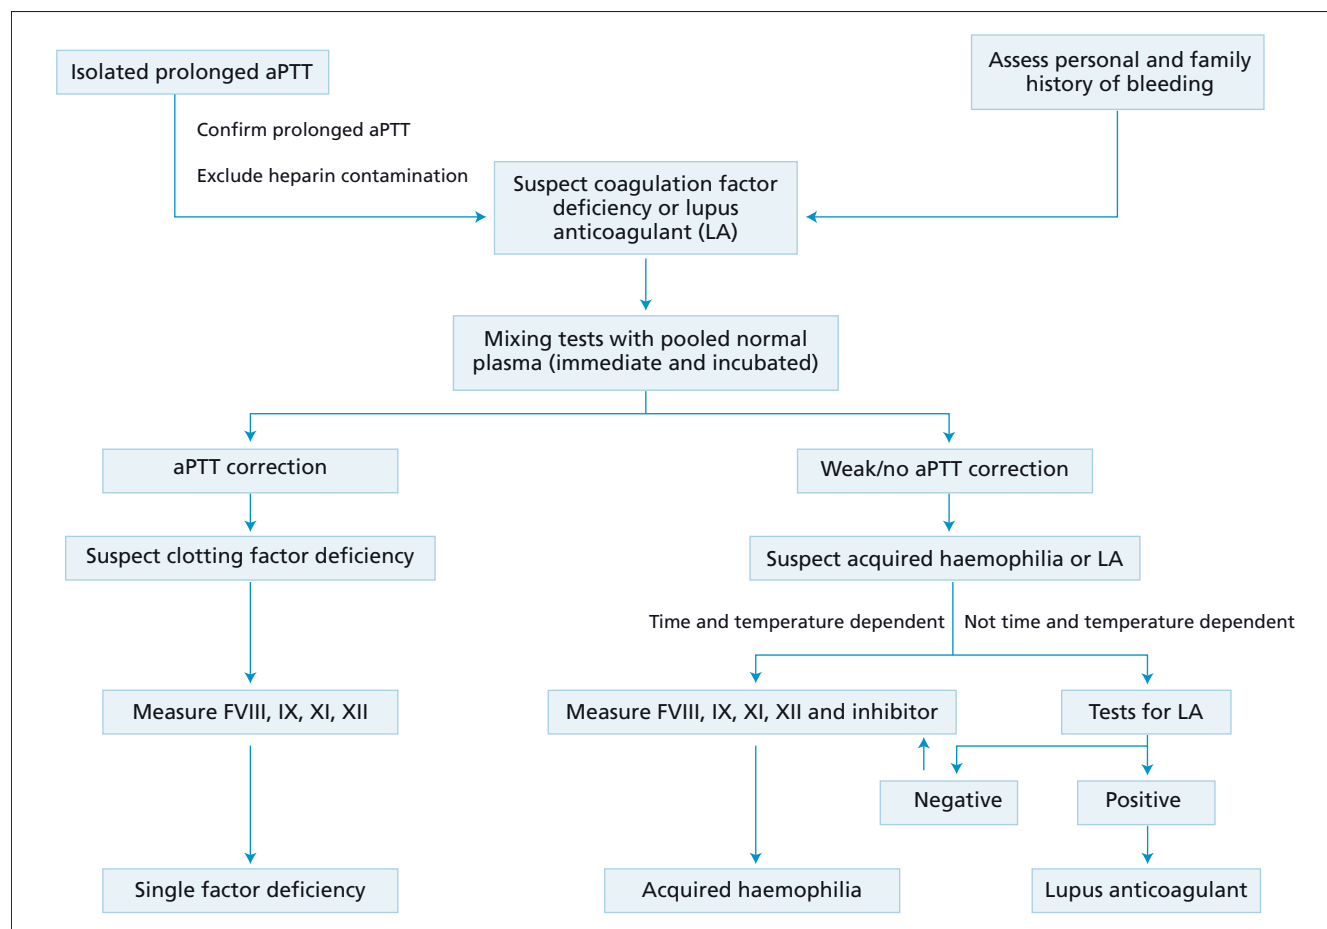

Figure 43.6 Diagnostic algorithm for an isolated prolonged APTT and possible acquired haemophilia A.

rately. The FVIII level and inhibitor titre are not predictive of the severity of the bleeding or response to treatment.

Treatment involves minimizing invasive procedures, protecting the patient from trauma, treatment of bleeds and eradication of the inhibitor. At present, the available therapies to treat bleeds are with bypassing agents, namely rFVIIa or the activated PCC FEIBA (factor eight inhibitor bypassing activity). Both agents appear to be equally efficacious. Multiple doses may be required to control bleeds and prevent recurrence. There is a risk of thrombosis associated with bypassing agents, particularly in elderly patients with risk factors for arterial thrombosis. FVIII is unlikely to be efficacious in acquired haemophilia A, although mild bleeds in patients with low-titre inhibitors and measurable FVIII may respond to desmopressin. Porcine FVIII has been used with good success in the past but is no longer available. The results of trials with a recombinant B domain-deleted porcine factor are awaited. If standard haemostatic treatment with bypassing agents fails, FVIII and immunoadsorption has been used with good effect, although this treatment modality is only available in a few specialized centres.

Immunosuppression should be started as soon as the diagnosis is made and is usually with either steroids alone or steroids plus a cytotoxic agent such as cyclophosphamide or azathioprine. A response is usually seen after 2–3 weeks but full remission takes a median of about 5 weeks. If first-line therapy fails, rituximab or combinations of cytotoxic agents may be used. Occasionally responses have been reported with ciclosporin. Intravenous immunoglobulin does not increase the response rate to other immunosuppressive agents.

Acquired von Willebrand disease

Acquired von Willebrand disease may be associated with an autoantibody, typically in the context of monoclonal gammopathy of undetermined significance, Waldenström macroglobulinaemia and other lymphoproliferative diseases, myeloproliferative disease and systemic lupus erythematosus. The antibody leads to either rapid clearance or functional inhibition of VWF. Low VWF:Ag, VWF:RCo and VWF:CB are found and measurement of the VWF propeptide may be useful in demonstrating rapid clearance. Mixing studies can be used to demonstrate the inhibitor.

Low VWF levels are also seen in hypothyroidism probably due to decreased synthesis, whereas increased VWF is associated with hyperthyroidism. Increased proteolysis of VWF in high-shear environments such as leaking cardiac valves leads to a syndrome of acquired type 2A von Willebrand disease. VWF has also been reported in association with malignancy and it is suggested that it may be adsorbed onto malignant cells. Hydroxyethyl starches used as plasma expanders have been associated with bleeding secondary to VWF deficiency. Treatment options include DDAVP, VWF concentrates and, in patients with an inhibitory antibody, high-dose intravenous immunoglobulin.

Acquired factor V deficiency

Acquired inhibitors to FV may arise spontaneously but are usually associated with exposure to topical thrombin preparations that have trace amount of bovine FV. Laboratory findings are of prolonged PT and APTT that do not correct with normal plasma. Patients may respond to FFP and, in resistant cases, platelets may be useful because surface-bound FV appears to bypass the inhibitor.

Acquired protein S deficiency

Autoantibodies to protein S have been reported in association with infection, particularly chickenpox. Patients present with skin necrosis and DIC.

Prothrombin deficiency associated with lupus anticoagulant

Although lupus anticoagulants are typically associated with thrombosis, occasionally cross-reactivity with prothrombin can lead to a bleeding disorder. Acquired deficiencies of other procoagulant and antifibrinolytic proteins have occasionally been described. Bleeding manifestations are variable and some patients with markedly abnormal laboratory tests do not bleed.

Historical introduction

A brief historical sketch is useful for delineating the progress made in understanding these complex syndromes, which are difficult to diagnose. Thrombotic thrombocytopenic purpura (TTP) was first described in 1924 by Moschowitz in a previously healthy 16-year-old girl who died after an acute illness presenting with a pentad of signs and symptoms (anaemia, thrombocytopenia, fever, hemiparesis and haematuria). Post-mortem examination showed widespread thrombi in the terminal circulation of several organs, composed mainly of platelets. Over the next three decades, other cases were described, mainly, but not exclusively, in young or adult women. Some of these cases occurred in isolation (idiopathic), others in association with diseases or conditions (Table 44.1). It was understood that anaemia was due to massive intravascular haemolysis, in turn due to fragmentation (schistocytosis) of red cells that were forced by blood flow to pass through partially occluded vessels in the terminal circulation, and that thrombocytopenia was caused by consumption of platelets due to their widespread deposition in microvascular thrombi.

Thirty-one years after Moschowitz, the paediatric nephrologist Gasser described a syndrome that was called ‘haemolytic–uraemic syndrome’ (HUS) and which, in common with TTP, exhibited microangiopathic haemolytic anaemia, consumption thrombocytopenia and microvascular thrombosis, but which

differed because it occurred in very young children, with absent or minimal neurological symptoms but severe signs of renal damage. Subsequently, when larger series of patients with HUS and TTP were examined, it became apparent that a clear distinction between the two syndromes was often difficult. Although thrombocytopenia, microangiopathic haemolytic anaemia and ischaemic symptoms due to widespread formation of thrombi in the terminal circulation of several organs were consistent features, age and the prevalence of neurological over renal symptoms could not clearly differentiate TTP from HUS and vice versa. There were, for instance, recurrent forms which, in the same individual, presented sometimes with prevalent neurological symptoms (TTP) and on other occasions with renal symptoms (HUS). The term ‘thrombotic microangiopathy’ (TMA) was then proposed, intended to emphasize the common pathology of the two syndromes, with no implication on the prevalence of neurological or renal symptoms.

In the early 1980s, a major breakthrough in understanding the pathogenesis of TMAs strengthened the idea of the unitarian terminology. Even though it had been postulated for a long time that massive thrombus formation in the terminal circulation was due to the presence of ‘toxic’ substance(s) that aggregated platelets intravascularly, the putative aggregating agent had remained elusive. In 1982, Moake and others demonstrated, first in TTP and subsequently also in HUS, that the plasma of these patients contained highly thrombogenic forms of the multimeric glycoprotein von Willebrand factor (VWF), a major adhesive protein contained in endothelial cells, platelets and plasma. Abnormal VWF multimers of particularly high molecular weight (ultra-large) bind more avidly to platelet glycoprotein (GP)Ib and aggregate platelets in conditions of high shear

stress in the terminal circulation. Accordingly, it was postulated that ultra-large VWF was the ‘toxic’ aggregating agent involved in the formation of occlusive thrombi in both TTP and HUS.

It remained to be explained why such ultra-large multimers, normally absent in the circulation, were present in patient plasma. The deficiency or dysfunction of one or more enzymes disposing of them physiologically was postulated but it was not until the late 1990s that Furlan and Tsai with their associates

independently showed that the link between ultra-large VWF multimers and TTP was a metal ion-dependent plasma metalloproteinase of 190kDa, identified in 2001 by Zheng and colleagues as a new (the 13th) member of the ADAMTS (*a disintegrin and metalloprotease with thrombospondin-1 repeats*) family of metalloproteases and therefore called ADAMTS-13 (Figure 44.1). The only known physiological function of this protease, present in plasma and in platelets, is to regulate the size of VWF by cleaving ultra-large multimers as soon as they are secreted from endothelial cells into plasma (Figure 44.2), thereby preventing their circulation in plasma and role in platelet aggregation and thrombus formation. Most importantly, both the investigators made the intriguing observation that ADAMTS-13 was deficient in patients with TTP but measurable in normal amounts in those with HUS. This observation challenged the unitarian theory of TTP and HUS as different clinical manifestations of the same pathological process, and generated the paradigm that TTP is due to low levels of the VWF-cleaving protease, which however is not involved in the pathogenesis of HUS.

As often in clinical medicine, the paradigm was not sustained by the progress of knowledge. Not all cases of TMA diagnosed

Figure 44.2 Interaction between VWF and ADAMTS-13 in plasma. VWF is secreted from endothelial cells as ultra-large multimers that anchor to endothelial cell surfaces and which are also released into the circulation. ADAMTS-13 cleaves a Tyr–Met bond in the A2 domain of VWF, severing the ultra-large multimers. Failure of cleavage leads to the persistence in plasma and on endothelial cells of ultra-large multimers, which tend to aggregate platelets, especially in conditions of high shear forces.

as TTP owing to the prevalence of neurological symptoms have low or undetectable levels of ADAMTS-13. On the other hand, even if most cases diagnosed as HUS due to the prevalence of renal symptoms have normal levels of ADAMTS-13 (particularly cases typically occurring in association with bloody diarrhoea), there are unequivocal cases of HUS, particularly the forms called atypical or diarrhoea-negative, characterized by low or undetectable protease levels. With this as historical background, we have decided to describe TTP separately from HUS in this chapter.

Thrombotic thrombocytopenic purpura

TTP is a rare disease, with an estimated incidence of 2–10 cases per million per year in all racial groups. Recently, greater awareness and perhaps improved diagnostic facilities give the impression that incidence is increasing. Even though both sexes may be affected, the syndrome is definitely more frequent in women (two-thirds of cases).

There are two different forms of TTP. Congenital TTP, caused by mutations in the ADAMTS-13 gene, is inherited as an autosomal recessive condition and is often, but not exclusively, clinically manifested at birth or during childhood. Acquired TTP can be differentiated into two types: autoimmune forms, due to autoantibodies against ADAMTS-13; and those probably secondary to massive endothelial activation with release of ultra-large VWF multimers in amounts exceeding the system's ability to degrade them, despite the presence of normal or only slightly reduced levels of ADAMTS-13 as measured with the currently available functional assay. Both these pathogenic situations are usually triggered by factors that cause massive endothelial activation. The most common physiological or pathological conditions present in the autoimmune forms are pregnancy, infections, autoimmune diseases and the use of drugs such as ticlopidine and clopidogrel. The most frequent conditions associated with the forms of TTP with normal or only slightly reduced levels of ADAMTS-13 (conventionally defined as levels above 10%) are metastatic tumours, organ transplantation (particularly allogeneic bone marrow transplantation and solid organ transplants) and the use of such drugs as ciclosporin, mitomycin and interferon alfa.

Mortality was very high (80–90%) until plasma exchange therapy was introduced, and is still unacceptably high (10–20%) despite the dramatic improvement due to the adoption of this therapeutic measure. Because of the variability of presenting symptoms and of the associated comorbid conditions (see Table 44.1), cases of TTP may be seen initially by a variety of physicians other than haematologists and pathologists, such as neurologists, nephrologists, oncologists and gynaecologists, and sometimes this hinders prompt recognition of the syndrome, an essential requisite for optimal management.

Pathology and pathogenesis

As mentioned above, the pathological basis of TTP is the widespread formation in the microcirculation of platelet thrombi, associated with relatively little endothelial cell injury and fibrin formation but with abundant intra-thrombus VWF. Microthrombi are found in several organs (mainly brain, kidney, myocardium, lung and pancreas), whereas grossly detectable thrombi, arterial or venous, are lacking. The present pathogenetic model implies that endothelial cells, activated by varied and often unidentified triggering agents, secrete large amounts of ultra-large uncleaved VWF, which aggregates platelets directly in conditions of high fluid shear stress and leads to massive intravascular platelet aggregation, ischaemic organ damage, consumptive thrombocytopenia and schistocytic anaemia. As mentioned above, two main mechanisms cause ADAMTS-13 deficiency in TTP: mutations in the gene that encodes the protease and the occurrence of autoantibodies against ADAMTS-13.

Congenital TTP

Congenital TTP is very rare (1 in 1 million) and represents 5% of all TTP cases. It usually occurs immediately after birth or during childhood, although some exceptions have been reported where the disease became manifest in adulthood or was still absent in the third decade of life. Congenital TTP is caused by homozygous or double heterozygous mutations in the *ADAMTS13* gene (located on chromosome 9q34) that affect protein secretion or function; it is inherited in autosomal recessive manner. To date, more than 80 mutations have been documented in patients with familial TTP. Analysis of the location of the mutations on the *ADAMTS13* gene reveals no evident hotspots. However, 75% of the missense mutations are found in the N-terminal part of the molecule, up to the spacer domain. Most (60%) of the identified mutations are missense; the remaining 40% (nonsense, frameshift and splicing mutations) generates truncated forms of the protein. Of those mutations analysed by *in vitro* expression studies (only 20–30% of the reported gene mutations), the majority cause severe ADAMTS-13 deficiency by decreasing its biosynthesis, intracellular trafficking and secretion and/or proteolytic activity. Also the spectrum of clinical presentation and course of congenital TTP is very wide. While some patients have neonatal disease onset and multiple recurrent episodes and develop progressive organ failure, others may only experience a single episode that develops in adulthood and which is very responsive to plasma infusion, leaving no residual organ damage. Moreover, there are cases from the same kindreds who present with very different clinical manifestations despite the same undetectable or barely detectable ADAMTS-13 activity and gene mutations: sibs with frequent and repeated episodes of TTP contrast with others who remain disease-free for prolonged periods or even lifelong.

Autoimmune TTP

Autoimmune TTP accounts for the majority of clinical cases and occurs in adults in the absence of any obvious triggering event. However, it can also arise secondary to other conditions, such as autoimmune diseases, infections, drug intake, pregnancy, sepsis, tumours and bone marrow transplantation. Autoimmune TTP is due to anti-ADAMTS-13 antibodies that inhibit the proteolytic activity of ADAMTS-13 and/or bind the protease to accelerate its clearance from plasma through opsonization and/or other yet unclear mechanisms. Anti-ADAMTS-13 antibodies are usually of IgG type, although in few cases autoantibodies of IgA and/or IgM isotype were also found. Epitope mapping of anti-ADAMTS-13 antibodies showed that autoantibodies found in the majority of patients (88%) are polyclonal (IgG4), with a primary epitope in the Cys-rich spacer. Indeed these domains have been shown to be essential for efficient VWF-cleaving activity of ADAMTS-13 and crucial in the interaction between VWF and the protease. However, subsequent studies have shown that cases of TTP are observed in patients with IgG molecules that also react with the TSP1 2–8 and CUB domains of ADAMTS-13, suggesting that autoantibodies with specificity towards more distal C-terminal domains of ADAMTS-13 may impair its function *in vivo*, probably taking part in the modulation of VWF binding. The higher incidence of autoimmune idiopathic TTP in specific ethnic groups such as Afro-Caribbeans, as well as the report of idiopathic TTP in two monozygotic twins both developing anti-ADAMTS-13 antibodies, strongly argue for a genetic predisposition even in the acquired form of the disease.

However, several observations fail to fit perfectly with this relatively straightforward mechanism of disease. Not all patients with bona fide TTP, as diagnosed by clinical criteria (thrombocytopenia and anaemia), have severe ADAMTS-13 deficiency and patients can present the characteristic features and clinical course of TTP without severe ADAMTS-13 deficiency or even with normal ADAMTS-13 activity levels. This may be explained by the inability of the functional assays available at present to reveal some types of ADAMTS-13 deficiency and/or by deficiency of VWF-cleaving proteases other than ADAMTS-13. Ultra-large VWF multimers, pivotal players in the presently accepted model of TTP, are not constantly detected in patient plasma. In some instances, there is an imbalance between their release into plasma from endothelial cells and excessive binding to platelets, so that even defective large multimers may be present in plasma. It is unclear why patients with sustained ADAMTS-13 deficiency, genetic or immunologically mediated, develop clinical symptoms and signs only sporadically. Still unknown factors that trigger excessive endothelial cell activation may be necessary for expression of the full clinical spectrum of the syndrome.

In summary, the prevailing paradigm holds that TTP is often the consequence of the defective processing of highly thrombogenic ultra-large multimers of VWF, which are secreted

in excess by endothelial cells and which are not adequately disposed of because of congenital or immune-mediated dysfunction of ADAMTS-13 (see Figure 44.2). There are data suggesting that other possible mechanisms of disease, other than VWF and its cleaving processes, may be involved in the pathogenesis of TTP.

Clinical and laboratory findings

TTP occurs frequently, unheralded, in previously healthy individuals (acute idiopathic), but also in association with physiological or pathological conditions (see Table 44.1). The presence of thrombocytopenia and haemolytic anaemia, common to all TMAs, is essential for the diagnosis of TTP. Like HUS, TTP is a clinical diagnosis and biopsies are not necessary. Platelet count is often very low in the acute phase, with values of $20 \times 10^9/L$ or less, and petechiae are frequently seen. Signs of microangiopathic haemolytic anaemia (haematocrit usually <20%) include the presence of schistocytes on peripheral blood smears, reticulocytosis, increased indirect bilirubin, low or unmeasurable haptoglobin and negative direct Coombs test. High serum lactate dehydrogenase (LDH), usually in excess of 1000 U/L, is a sensitive, albeit non-specific, sign of red cell destruction and necrosis of other tissues due to microthrombotic end-organ ischaemia and is an excellent diagnostic indicator and a parameter for monitoring evolution of the disease. Neurological symptoms (coma, stroke, seizures or focal signs such as motor deficits, diplopia and aphasia) typically fluctuate in presentation and severity as a result of the sustained formation and dissolution of thrombi in the cerebral microcirculation. Other symptoms or signs, such as headache, blurred vision, ataxia or mental status changes, are less typical. Even though only a minority of patients with TTP have elevated serum creatinine levels (>1.5 mg/dL), signs of renal involvement such as microscopic haematuria and proteinuria are frequent. High fever is not constant in TTP, despite the inclusion of this symptom in the original description. There is no or little alteration of coagulation and fibrinolysis, even though D-dimer levels are often moderately raised.

ADAMTS-13 assays

The possibility of using ADAMTS-13 data to manage TTP patients is based on the widespread availability of assays that are rapid, reliable and feasible for most clinical laboratories. Such tests include assays of ADAMTS-13 activity, ADAMTS-13 antigen and neutralizing or non-neutralizing anti-ADAMTS-13 autoantibodies. Several assays of ADAMTS-13 activity have been developed. They are based on the degradation of purified, plasma-derived or recombinant VWF multimers or of synthetic VWF peptides by patient plasma and the direct or indirect detection of VWF cleavage products by ADAMTS-13 (Figure 44.3). A number of variables may interfere with assay results.

Figure 44.3 Principles of methods for the measurement of ADAMTS-13 activity. VWF multimers picture from Siedlecki CA, Lestini BJ, Kottke-Marchant K *et al.* (1996) Shear-dependent changes in the three-dimensional structure of human von Willebrand factor. *Blood* **88**: 2939–50.

1 All the assays measure ADAMTS-13 activity in static conditions and thus do not reflect the *in vivo* physiological blood flow conditions necessary for optimal ADAMTS-13 enzymatic activity.

2 Another important variable is that denaturing agents (i.e. guanidine HCl or 1.5 mol/L urea) are required to promote the susceptibility of VWF multimers to cleavage by ADAMTS-13.

3 The use of shorter peptides, instead of full-length VWF, in enzyme immunoassay-based methods has not solved the issue of intra- and inter-laboratory variability.

Immunoenzymatic assays employing different monoclonal and polyclonal antibodies to monitor plasma antigen levels of ADAMTS-13 are available.

With regard to the detection of anti-ADAMTS-13 autoantibodies, most of them are inhibitory and they can be titrated *in vitro* by classical mixing studies, using mixtures of heat-inactivated plasma from patients and normal plasma at 1:1 dilution or several dilutions. Less frequently, autoantibodies are non-neutralizing and promote the clearance of ADAMTS-13 from blood without inhibiting its activity. These non-neutralizing antibodies can be detected by Western blotting or ELISA assays.

Clinical utility of ADAMTS-13 testing

Analysis of a large cohort of patients with congenital TTP has revealed an age-dependent clustering of cases into two relatively distinct groups. As already mentioned before, about 50% of patients present within the first 5 years of life, but a second group remains without symptoms until 20–40 years of age (Figure 44.4). Examples of siblings with the same ADAMTS-13 mutations but markedly different clinical courses have also been reported. Whereas the first studies by Tsai and Lian and by Furlan and colleagues reported that all patients with acquired TTP had severe ADAMTS-13 deficiency, subsequent studies have shown that only a proportion of patients, ranging from 13 to 70%, develop TTP concomitant with severe ADAMTS-13

Figure 44.4 Age of disease onset in patients affected by congenital TTP showing percentages of patients ($N = 78$) with different age of TTP onset. Red indicates neonatal onset, orange intermediate onset (2 months to 18 years), green adult onset (>18 years) and light blue patients who reached adulthood without developing TTP episodes.

deficiency, thus challenging the previous observations that severely deficient activity of VWF-cleaving protease is a specific diagnostic marker for discriminating TTP from other microangiopathies. The current prevailing opinion is that while undetectable or very low plasma levels of enzymatic activity (<10%) unequivocally establish a diagnosis of inherited or acquired TTP, not all patients appropriately diagnosed with TTP on the basis of clinical and laboratory signs and symptoms have severe protease deficiency *in vitro*. The cases of TTP more frequently associated with normal or moderately reduced ADAMTS-13 levels (10–40% of normal) are those secondary to other diseases or conditions, such as allogeneic bone marrow transplantation, HIV infection, chemotherapy and metastatic cancer.

An important practical problem for the clinical haematologist is whether ADAMTS-13 testing during the acute phase

of TTP helps to monitor plasma therapy and, more importantly, to predict such important short-term outcomes as clinical and laboratory remission or mortality. On the whole, the findings obtained to date fail to establish whether ADAMTS-13 and anti-ADAMTS-13 testing helps to identify patients with a higher likelihood of unfavourable outcomes. Other clinical and laboratory signs, more easily obtained than ADAMTS-13 and anti-ADAMTS-13, have been evaluated for their predictive value on the short-term outcomes of acute TTP. For instance, an index was developed based on age, haemoglobin and the presence of fever at presentation. Other authors have reported that platelet count and serum LDH are useful predictors of the response to plasma exchange during the acute episode.

After remission from an acute episode of TTP, approximately one-third of patients develop chronic recurrent disease. Hence it would be helpful to be able to predict the risk of relapse by using clinical and laboratory markers obtained at the time of the acute episode and/or during remission. Prospective and retrospective studies have shown that patients who present with undetectable ADAMTS-13 activity and detectable anti-ADAMTS-13 during the acute episode and/or during first remission are more likely to experience recurrences.

In summary, in order to diagnose TTP in the acute phase of the disease, it is not essential to assay ADAMTS-13 and to find very low or undetectable plasma levels. After having excluded other TMAs (see below), patients presenting with normal or moderately reduced ADAMTS-13 can still be appropriately diagnosed as TTP. The decision to implement plasma therapy (infusion in patients with inherited disease, exchange in acquired disease) does not warrant the availability of ADAMTS-13 values in real time. ADAMTS-13 testing appears to be more helpful as an index of relapse than as an index of diagnosis and short-term outcomes (remission and mortality rates), but larger prospective studies are warranted.

Differential diagnosis

Typical cases of HUS are distinguished from TTP by the occurrence of diarrhoeal prodromes and of more severe and persistent symptoms of renal impairment (see below). It is much more difficult to distinguish TTP from atypical HUS, except for the paradigmatic prevalence of neurological symptoms in the former and of renal failure in the latter. Other issues of differential diagnosis are concerned with conditions that present themselves as TMAs, all characterized by thrombocytopenia and microangiopathic haemolytic anaemia (Table 44.2). Therefore, accurate evaluation of the underlying conditions, symptoms and biological parameters is fundamental for determining the differential diagnosis and appropriate therapy.

Disseminated intravascular coagulation (DIC) can be distinguished by markedly increased levels of fibrin degradation products and D-dimer and, in decompensated cases, by the

Table 44.2 Clinical conditions other than TTP and HUS presenting as thrombotic microangiopathies.

Disseminated intravascular coagulation
Pre-eclampsia/HELLP syndrome
Scleroderma/systemic lupus erythematosus
Severe vasculitis
Catastrophic antiphospholipid antibody syndrome
Evans syndrome (autoimmune thrombocytopenia and haemolytic anaemia)
Heparin-induced thrombocytopenia
Disseminated malignancy

presence of hypofibrinogenaemia and prolonged prothrombin and activated partial thromboplastin times. The differential diagnosis also includes other TMAs such as pre-eclampsia and eclampsia, because pregnancy is one of the most frequent clinical associations of TTP. Malignant hypertension is less frequent, renal damage is not as severe and the degrees of anaemia and thrombocytopenia are more severe in TTP.

Tests of coagulation and fibrinolysis are usually abnormal in pre-eclampsia or eclampsia, albeit less markedly than in DIC. Abnormally high serum transaminases differentiate TTP from the so-called HELLP (haemolysis, elevated liver enzymes and low platelets) syndrome of pregnancy. Sometimes connective tissue disorders such as systemic lupus erythematosus and severe scleroderma present with widespread microvascular thrombosis, haemolytic anaemia, thrombocytopenia and fluctuating neurological symptoms. This situation may also occur in severe cases of the so-called catastrophic antiphospholipid antibody syndrome. These conditions may be distinguished from TTP because symptoms and signs are usually less severe, and laboratory tests such as antinuclear and anticardiolipin antibodies and lupus-like anticoagulant give positive results. Another element of differential diagnosis is the presence in these cases of venous and arterial thromboses in the major blood vessels.

Evans syndrome, due to the concomitant presence of anti-platelet and anti-erythrocyte antibodies, is distinguished by a positive Coombs test, lack of schistocytes and the usual absence of end-organ ischaemic symptoms. Severe ischaemic manifestations due to platelet thrombi are frequent features of heparin-induced thrombocytopenia, but TTP can be distinguished by not only lack of exposure to this drug but also the absence of haemolysis and schistocytosis. Disseminated malignancy is sometimes associated with thrombocytopenia and microangiopathic haemolytic anaemia. Until further investigations exclude or confirm the presence of metastatic cancer, it is not easy to distinguish TTP from this type of TMA.

What is the usefulness of ADAMTS-13 testing in the differential diagnosis of the aforementioned TMAs and TTP?

Table 44.3 Physiological and pathological states associated with mild to moderately severe deficiency of ADAMTS-13.

Table 44.4 Variants of TTP.

Acute sporadic (or early relapsing)
Idiopathic
Antibody mediated
Chronic recurrent
Inherited
Antibody mediated

Complete deficiency of the protease clearly directs the diagnosis towards TTP, although severe deficiency of ADAMTS-13 has also been observed in 13% of typical HUS cases and 16% of DIC. Normal or reduced but detectable plasma levels of the protease do not help in the differential diagnosis because they may be found, albeit rarely, in TTP, typical HUS, other TMAs and several other unrelated conditions (Table 44.3).

Natural history (Table 44.4)

In approximately two-thirds of cases, TTP occurs only once (acute sporadic TTP). In more than one-third of patients, the disease tends to recur after periods of remission of the acute episode. Recurrence, defined as the re-emergence of clinical and laboratory signs and symptoms of TTP after remission of the initial acute episode, has a spectrum of presentations ranging from a single relapse to several episodes developing with variable frequency. Recurrences usually present with less severe clinical manifestations, perhaps because patients become alert to the first signs and symptoms of their disease, yet their quality of life is made gloomy by the perception of an impending risk.

The chronic recurrent forms may have a genetic basis or be associated with autoantibodies, whereas the forms associated with malignancy or transplantation usually present as acute

Table 44.5 Steps in the treatment of TTP.

Clinical diagnosis (based on severe thrombocytopenia, presence of schistocytes, high serum LDH)
Plasma infusion (30 mL/kg) until plasma exchange can be started
Daily plasma exchanges (3–6 L/day) until platelets are higher than $150 \times 10^9/L$ for at least 2 days and LDH is normal
Adjuvant treatments: prednisone 1–2 mg/kg per day
Red cell transfusion as needed (avoid platelet transfusion, if possible)

episodes with a low propensity to recur (in part because of the high mortality rate).

In congenital TTP, ADAMTS-13 plasma levels are usually consistently below the limit of sensitivity of the assays available at present. It is not understood why in congenital but also in chronic recurrent TTP ADAMTS-13-deficient patients remain asymptomatic for prolonged periods of time (usually from 3 weeks to 3 months) and then thrombocytopenia and schistocytic anaemia herald the appearance of new symptoms of end-organ ischaemia.

Treatment

The modern management of TTP started with the serendipitous observations that plasma infusion improved the clinical course of TTP. Plasma exchange was subsequently found to be equally or more effective than plasma infusion. In 1991, the results of a prospective randomized clinical trial definitively confirmed the greater efficacy of plasma exchange over infusion, the clinical response rate being 78% in the former compared with 49% in the latter (mortality rates of 22% and 37%, respectively). Only recently, after the discovery of the role of VWF and its protease ADAMTS-13 in the pathogenesis of TTP, have these empirical treatments found a rationale. Plasma exchange may help by removing anti-ADAMTS-13 autoantibodies, the most frequent mechanism of acute sporadic TTP. Plasma exchange also helps to replace the deficient protease, infusion alone being probably sufficient in congenitally deficient cases with no associated autoantibody. Nevertheless, the efficacy of plasma therapies is still not fully explained, because exchange and/or infusion are definitely efficacious even in cases with normal plasma levels of ADAMTS-13 and no detectable autoantibody. A scheme summarizing the steps to be followed in the treatment of acute TTP is shown in Table 44.5.

Plasma therapy

Treatment with plasma should be initiated as soon as the clinical diagnosis is suspected (presence of schistocytic anaemia, severe thrombocytopenia and high serum LDH). There is as yet

no evidence that ADAMTS-13 and autoantibody testing are necessary before starting therapy because, as mentioned above, there are unequivocal cases of TTP with normal levels of the protease. Moreover, the available assays are time-consuming, poorly standardized and results are not always specific for TTP.

Patients critically ill with TTP are often first admitted to hospitals without facilities for plasma exchange; in such circumstances, daily infusion of large amounts of fresh-frozen plasma (FFP) (30 mL/kg) should be started promptly, taking measures to avoid volume overload (see Table 44.5). Patients are best assisted in intensive care units, where renal failure, coma, seizures and such severe side-effects of plasma exchange as congestive heart failure and catheter-related bleeding, thrombosis and infections can be optimally managed. At least 1 plasma volume should be exchanged daily until platelets rise to $150 \times 10^9/L$ or more, LDH is normal and schistocytes are no longer present on blood films. Daily treatment with plasma exchange must be continued for at least 3 days after remission has been obtained (see Table 44.5).

Treatment should be continued following this schedule for at least 10 days, whether or not early signs of clinical and laboratory improvement are observed. Daily exchanges for up to 1 month are sometimes necessary to achieve remission of TTP. It is not established whether discontinuation of plasma therapy should be abrupt or progressive. Cryoprecipitate-depleted plasma can be used instead of FFP if this fraction is available and convenient, but there is no evidence that this VWF-poor plasma is more effective than whole plasma. Plasma treated with virus-inactivation methods (e.g. solvent/detergent) should be preferred because it decreases the risk of infections associated with patient exposure to plasma from a large number of donors.

Patients with congenital TTP usually respond well to plasma infusion. A periodic plasma infusion every 2 weeks is sufficient to supply enough ADAMTS-13 to maintain low but measurable plasma levels of the protease and avoid platelet consumption, a consequence of the long plasma half-life of the enzyme. The intensity of plasma therapy cannot be tailored to each patient's case because of the lack of criteria for predicting short-term prognosis (risk of death and organ failure in the acute episode) based on the presenting features of the episode. In addition, congenital TTP often has a relapsing course, so that some patients are treated prophylactically with plasma infusions at regularly spaced intervals (every 5–7 days) in order to prevent further disease episodes. However, since relapse is not a constant finding and there are no well-established predictive factors, it is not clear which patients should undergo regular prophylaxis and what levels of ADAMTS-13 are necessary to attain remission of the acute episode and prevent recurrence. There is as yet no definite evidence that patients with congenital ADAMTS-13 deficiency develop alloantibodies, nor that an anamnestic response invariably occurs in patients with autoantibodies after they are treated with plasma.

Table 44.6 Suggested immunological treatments of refractory antibody-mediated TTP.

Prednisone: 1–2 mg/kg for at least 15 days, then tapering the drug over 45 days
Vincristine: 2 mg on day 1, then 1 mg on days 3, 6 and 9
Cyclophosphamide or azothioprine: 100–200 mg/day
Intravenous immunoglobulins
Immunoabsorption on staphylococcal protein A
Splenectomy
Anti-CD20 (rituximab)

Other therapies

Before the advent of plasma therapy, clinicians used many other treatment modalities to attempt to control the dramatic course of TTP. Their generally poor efficacy is apparent from the fact that only with the advent of plasma therapy has mortality dropped dramatically. Hence, these treatments should be generally attempted only when plasma therapy at full doses and for at least a fortnight provides no or minimal benefit (refractory TTP) (Table 44.6).

There is little or no theoretical or practical role for the use of antiplatelet agents, because these drugs (including aspirin) fail to inhibit shear/VWF-mediated platelet aggregation, the prevailing pathogenic mechanism of thrombus formation in TTP. Inhibitors of GPIIb/IIIa, by blocking binding of ultra-large VWF multimers to platelets, should perhaps be considered in the prevention or early management of chronic recurrent TTP, but in full-blown TTP they may increase the risk of thrombocytopenic bleeding. The immune pathogenesis of TTP may be tackled by using immunomodulating agents such as corticosteroids, cyclophosphamide, azathioprine, intravenous immunoglobulins and immunoabsorption on staphylococcal protein A (Table 44.6). Splenectomy has also been attempted.

In general, it is difficult to recommend a useful agent or procedure. Considering that autoantibodies are a frequent pathogenic mechanism, large doses of prednisone (1–2 mg/kg) are often prescribed in addition to plasma exchange during the acute phase of TTP, tapering this treatment when remission is obtained (see Table 44.5). The same treatment may be considered in the chronic recurrent variant of TTP due to the persistence of autoantibodies. Efficacy of corticosteroids is not unequivocally demonstrated, and the adverse effects of prolonged intake of large doses are severe. Splenectomy is an alternative option in patients with chronic recurrent forms during remission, but carries a high risk of death in severely ill patients with acute TTP.

Another recent attempt to suppress the production of anti-ADAMTS-13 autoantibodies is based on a monoclonal antibody directed against CD20 antigen (rituximab). This therapy may be considered in the chronic recurrent forms, particularly those cases of TTP not responding to treatment with plasma

exchange and refractory to other immunomodulating agents. The aim of treatment with rituximab is to block the production of anti-ADAMTS-13 antibodies by depleting B lymphocytes. Various studies have reported that this treatment plays an important role in producing prolonged remissions in chronic recurrent TTP. Published small series and case reports have described approximately 100 patients with refractory or relapsing idiopathic TTP treated with rituximab, usually at doses of 375 mg/m² every 7 days repeated for at least three or four cycles. Approximately 95% of reported patients have had a complete clinical and laboratory response within 1–3 weeks of starting treatment, including a normal ADAMTS-13 level and disappearance of anti-ADAMTS-13 antibodies. Mild acute reactions to rituximab infusion were controlled by premedication with steroids, antihistamines and analgesics. More serious complications are relatively uncommon. One patient had transient cardiogenic shock and another had symptomatic gastrointestinal infection with *Strongyloides*. Relapses appear infrequent, occurring in approximately 10% of patients after intervals of 9 months to 4 years; all but one of these patients had a second prolonged complete remission on retreatment with rituximab. It remains to be demonstrated whether the complete B-lymphocyte depletion caused by this drug is without short- or long-term consequences for patients.

A forthcoming promising approach is replacement therapy with ADAMTS-13 concentrates. A recombinant preparation has been shown to improve the defective proteolysis of VWF *in vitro*, but clinical trials with this product have not yet started. Another pharmaceutical company is considering the clinical evaluation of a DNA aptamer meant to inhibit the binding between GPIb and ultra-large VWF multimers, thereby preventing intravascular platelet aggregation in the microcirculation.

Haemolytic–uraemic syndrome

The typical form of HUS called diarrhoea-related HUS, or D(+) HUS, is acquired and occurs acutely and sporadically after gastrointestinal infections with toxin-producing bacteria, particularly in infants and young children but sometimes also in adults. There are two forms of atypical HUS. One is familial, has a sporadic or chronic recurrent course and is due to the inherited deficiency of complement factor H or other complement components. It occurs mainly in infants or young children but at least one-third of cases also occur in adults. Another atypical form of HUS occurs at all ages in association with situations commonly seen also in association with TTP (Table 44.7).

Diarrhoea-related HUS

This acute syndrome almost always occurs as a single sporadic episode, heralded 2 days to 2 weeks before by bloody diarrhoea.

Table 44.7 Variants of HUS.

Typical	Exotoxin-producing bacteria (<i>E. coli</i> 0157:H7, <i>Shigella dysenteriae</i>)
Atypical	Inherited (complement factor deficiency) Acquired (post partum, drugs, bone marrow transplantation, chemotherapy) (see also Table 44.1)

The typical symptoms are severe renal failure with oligoanuria, jaundice and haemorrhagic signs such as petechiae, haemolytic anaemia and raised levels of serum LDH, but usually less marked than in TTP. Serum creatinine and urea are definitely more abnormal than in TTP, while the presence of ultra-large VWF is much less frequent than in TTP. Signs of compensated DIC, with higher plasma levels of D-dimer, are another distinctive feature. Neurological involvement is uncommon, although coma and seizures may occur in association with uraemia and severe hypertension.

Aetiology

The most common bacterial agent that causes the prodromal gastrointestinal infection is *Escherichia coli* type 0157:H7 or, less frequently, *Shigella dysenteriae* serotype I. These and other more rarely involved infectious agents produce similar forms of exotoxins called verotoxin, shiga toxin and shiga-like toxins. These toxins, after absorption from the gastrointestinal tract into the blood, have in common the property to bind to the glycosphingolipid membrane receptor globotriaosylceramide that is particularly dense in the glomerular capillary endothelial cells of infants, young children and elderly individuals. The toxin–receptor complex is endocytosed and thereby causes cytolysis and extensive endothelial swelling and desquamation, which in turn engenders massive thrombus formation in the renal microvasculature.

Pathology and pathogenesis

The pathology of diarrhoea-related HUS is characterized by more extensive endothelial injury and less VWF and more fibrin deposition in thrombi than in TTP. The behaviour of plasma VWF is also different, because ultra-large highly thrombogenic multimers are detectable less frequently during the acute phase of the disease. This phenomenon is thought to be due to the fact that VWF multimers leaking in excess into plasma from damaged endothelial cells bind avidly to GPIb on the platelet membrane and are thereby removed from plasma, particularly the multimers of larger size. There is quasi-unanimity of views that ADAMTS-13 is normal or only mildly reduced in the plasma of patients with this variant of HUS (Table 44.8).

Table 44.8 Clinical applications of ADAMTS-13 testing in TTP and HUS.

Stage	ADAMTS-13 deficiency (<10%)	Diagnostic implications
Acute phase	Yes	TTP/atypical HUS
	No	Typical HUS/TTP cannot be excluded
Remission	Yes	Risk of relapse

ADAMTS-13 levels are usually normal or only mildly reduced in the thrombotic microangiopathies listed in Table 44.2.

Natural history

In the great majority of cases, diarrhoea-related HUS is self-limiting, with much less tendency to early or late relapses than TTP. The acute episode is often accompanied by such severe renal failure that temporary haemodialysis is frequently required. Residual renal dysfunction is common after the acute episode and renal failure requiring maintenance dialysis or kidney transplantation occurs in approximately one-third of patients.

Treatment

During the diarrhoeal prodrome antimotility agents are contraindicated, because they favour the permanence of the bacterial toxins in the gastrointestinal lumen and their passage into blood. The role of antibiotics is controversial but in practice they are often used, with a strong indication for patients with evidence or suspicion of sepsis or *S. dysenteriae* infection. In cases of significant acute renal failure, early institution of dialysis is essential in order to reduce sequelae and death. Plasma exchange is usually not recommended in patients with typical HUS, whereas it is indicated in the atypical forms (see below), emphasizing again the similarities between this variant of HUS and TTP. A possible forthcoming approach to the prevention of toxin-induced HUS is vaccination against vero/shiga toxins of children who live in endemic areas.

Familial HUS

Autosomal recessive and dominant forms of familial HUS without diarrhoeal prodromes account for about 5–10% of all cases (Table 44.7). This variant is associated with a markedly severe impairment of renal function and with a high mortality rate (approximately one-third of the cases). Approximately half of the patients who survive acute disease require maintenance haemodialysis. Approximately 50% of patients with familial atypical HUS have mutations in one of the complement regulatory proteins factor H, factor I, MCP or factor B, resulting in excessive C3 activation, membrane deposition of this complement fraction and renal cell injury. A few patients have also

been described with autoantibodies against factor H. Patients with MCP mutations have a better prognosis than those with factor H mutations or no mutation. A recessively transmitted variant of familial HUS is very rare and is associated with very low levels of factor H in plasma and with the early onset of HUS in childhood. Dominantly transmitted variants are usually due to missense mutations in the gene encoding factor H, causing the production of normal amounts of a dysfunctional protein. Dominantly transmitted HUS is usually less severe than the recessive form, and occurs in late infancy or adulthood. Low serum C3 levels may be a simple and widely available method for diagnosing affected patients and detecting family members at risk.

Treatment of familial HUS is based on the replacement of factor H with FFP, combined with transient haemodialysis to attempt to control oligoanuria and uraemia. The outcome of kidney transplantation appears to correlate with the cause of complement dysregulation. Disease has not recurred in transplanted kidneys in patients with MCP mutations, presumably because the new kidney has protective levels of endogenous MCP. In contrast, kidney transplantation alone does not correct the deficiency of plasma factors made in the liver, and the outcome is poor in patients with factor H or factor I mutations owing to disease recurrence. However, combined liver and kidney transplantation may lead to a favourable long-term outcome for recurrent HUS associated with a factor H mutation. The severity of the disease warrants gene transfer as a therapeutic approach, but lack of animal models and of suitable vectors of the transgene have hindered this approach so far.

Atypical (non-diarrhoea-related) HUS

This form can only be distinguished from TTP by the absence of neurological symptoms and the predominance of renal symptoms. There are cases of atypical HUS associated with severe deficiency of ADAMTS-13, albeit less frequently than in TTP. Atypical HUS is often associated with the postpartum period or with the intake of several drugs (see Table 44.7). Individuals who have been treated for various illnesses by bone marrow transplantation make up a relatively large subgroup. Plasma therapy, using the same protocol recommended for TTP, is the treatment of choice.

Concluding remarks

In the last few years, TTP and HUS, known for several decades to clinicians and pathologists for their dire consequences, have witnessed spectacular improvements in knowledge of the pathogenesis and development of new diagnostic criteria and seen mortality and morbidity decrease. The pivotal role of VWF

and of its major proteolytic enzyme in inducing microvascular platelet thrombi is evident, even though not all the variants of TTP, and particularly of HUS, fit this disease mechanism. Other proteins disposing of ultra-large highly thrombogenic forms of VWF may be involved. The development of laboratory methods to measure ADAMTS-13 in plasma has demonstrated that several types of TTP have very low levels of this protease. On the other hand, severe ADAMTS-13 deficiency is not found in all patients who have the appropriate clinical criteria for diagnosis of TTP (Table 44.8), questioning the significance of these criteria or the appropriateness of the currently available functional assays performed in non-physiological static conditions. The trigger(s) of full-blown TTP or HUS needs to be elucidated, because patients with constitutionally low levels of ADAMTS-13 or factor H may not manifest disease for long periods of time. It also remains to be understood which, and how many, cases respond to replacement therapy with protease concentrates, whether derived from plasma or made by recombinant DNA technologies. Meanwhile, the clinician confronted with the difficult treatment of these seriously ill patients should be cognizant that plasma therapy, mainly plasma exchange, remains the treatment of choice for all patients with clinically diagnosed TTP and the related syndrome called atypical HUS. Another important unresolved therapeutic problem is that of secondary prevention of the chronic recurrent forms. Various treatments have been tried, from chronic low-dose corticosteroids or other immunomodulatory agents (vincristine, immunoglobulins) to the more recent use of anti-CD20 monoclonal antibodies. There are anecdotal reports of the efficacy of all these agents, but their use is based on small series and reports are affected by publication bias. The prophylactic administration of plasma is plausible in the genetic forms, but much less so in the immune-mediated ones.

Diarrhoea-related HUS is now well characterized from an aetiological standpoint, so that it can be recognized and properly treated by paediatricians. A major problem remains the prevention of inherited HUS associated with factor H deficiency, because the long-term consequences of this scourge are dire. A suitable screening test is not yet available, even though there is the theoretical possibility of a DNA-based approach: most mutations are located in the exon encoding the most C-terminal short consensus repeat involved in binding factor H to complement C3b and to sialic acid molecules on host cells, thereby protecting host cells from excessive C3 activation.

There are numerous problems left to solve and, given the rarity of these conditions, clinical research on TTP and HUS must be necessarily multicentre.

In most instances heritable thrombophilia is a late-onset genetic disease with low penetrance. There is no internationally accepted definition of thrombophilia. The term is sometimes used to describe disorders of haemostasis detected in the laboratory that appear to predispose to venous thrombosis. A clinical definition of heritable thrombophilia describes an inherited tendency for venous thrombosis, i.e. deep vein thrombosis (DVT) with or without associated pulmonary embolus. The incidence of a first episode of venous thrombosis is 1.5 per 1000 person-years, with a per-person lifetime incidence of 5%. Venous thrombosis is a multicausal disease. Understanding the genetic risk factors and gene–environment interactions is necessary to understand why an individual develops thrombosis at a specific point in time. Venous thrombosis is a disease in which genetic and acquired risk factors interact dynamically. Interaction occurs when two risk factors in combination produce an effect that exceeds the sum of their separate effects. Familial thrombophilia is a multiple gene disorder and family members may have more than one identifiable defect, probably in combination with additional candidate and totally unknown defects. It is likely that

this largely explains why a dichotomous testing strategy with a limited number of factors (e.g. presence or absence of FVR506Q) has limited predictive value, resulting in little if any clinical utility for most patients (clinical utility refers to the ability of a screening or diagnostic test to improve clinical outcome).

Deficiency of the natural anticoagulant antithrombin was the first reported inherited risk factor for venous thromboembolism. Since then deficiencies of the naturally occurring anticoagulants protein C and protein S have been linked with familial thrombosis. In recent years, several other potential thrombophilic risk factors have been investigated but only the F5G1691A (FVR506Q, factor V Leiden) and the F2G20210A gene mutations have been shown to be unequivocally associated with an increased risk of thrombosis, i.e. odds ratio (OR) of 2 or greater from case–control studies. In the 1980s and 1990s thrombophilia testing became common in unselected patients and their relatives despite the fact that there was no evidence that testing had clinical utility. It is now apparent that testing for heritable thrombophilia typically does not predict likelihood of recurrence in the majority of unselected patients with symptomatic venous thrombosis (Figure 45.1). Furthermore, testing for inherited thrombophilia did not reduce recurrence of venous thrombosis in a large cohort study. There is a low risk of thrombosis in affected asymptomatic relatives of patients with thrombophilic defects followed prospectively and the results of thrombophilia tests are frequently misinterpreted. Given these considerations the clinician must consider the

Figure 45.1 Cumulative recurrence of venous thrombosis in consecutive patients with and without heritable thrombophilia followed from the end of anticoagulation after a first episode of venous thrombosis in the first (a) and second (b) Cambridge cohort studies. The hazard ratio for recurrence in patients with thrombophilia compared with those without was 1.3 (95% CI 0.8–2.0) and 1.0 (95% CI 0.5–2.1), respectively. For ease of comparison, the point of 10% cumulative recurrence at 24

months is indicated on each chart. In the second cohort, patients with postoperative thrombosis were excluded, which may account for the apparent slightly higher recurrence rate. (For related publications on these cohorts, see Baglin *et al.* 2003 and Baglin T, Palmer CR, Luddington R, Baglin C (2008) Unprovoked recurrent venous thrombosis: prediction by D-dimer and clinical risk factors. *Journal of Thrombosis and Haemostasis* 6: 577–82.)

potential clinical utility of testing for heritable thrombophilic defects in each individual patient or family affected by venous thrombosis.

Heritable thrombophilias associated with venous thrombosis

The heritable thrombophilias shown to be associated with at least a twofold increased risk of venous thrombosis are (i) deficiencies of the natural anticoagulants antithrombin, protein C and protein S, due to mutations in the corresponding genes *SERPINC1*, *PROC* and *PROS*, and (ii) two common mutations in genes encoding procoagulant factors, namely *F5G1691A* (FVR506Q, factor V Leiden) and *F2G20210A* (commonly referred to as the prothrombin gene mutation). The causal association between these heritable thrombophilias and venous thrombosis has been confirmed by comparing the prevalence of defects in patients with venous thrombosis and controls. In such studies measurement errors between cases and controls do not arise in relation to genotype and so the case–control study is the method of choice for measuring simple associations between genotype and disease. The prevalence of the heritable thrombophilias in cases and controls is shown in Table 45.1. The relative risk of venous thrombosis is estimated from the OR (the odds of the disease among those with the risk factor to the odds of the disease without the risk factor). The OR for each defect is indicated in Table 45.1. Deficiencies of antithrombin, protein C and protein S are rare and so the estimates of risks are uncertain but appear to be of the order of about a 10-fold increased risk of venous thrombosis. The FVR506Q and

Table 45.1 Prevalence of heritable thrombophilias shown to be associated with at least a twofold increased risk of venous thrombosis in patients and controls and relative risk of a first episode of venous thrombosis.

	General population	Consecutive patients with a first episode of venous thrombosis	Relative risk of venous thrombosis
Antithrombin	0.03%	1%	10–20
Protein C deficiency	0.3%	3%	10
Protein S deficiency	0.3%	3%	?–10
FVR506Q (FV Leiden)*	4%	15%	4
F2G20210A*	2%	4%	2

*The prevalence of FVR506Q and F2G20210A is determined by ethnic origin as these mutations are only prevalent in whites.

F2G20210A occur much more frequently and so the estimates of risk are more certain.

Gene–environment interaction is present when the effect of genotype on disease risk depends on the level of exposure to an environmental factor. Heritable thrombophilia is subject to a strong gene–environment interaction. For example, there is a synergistic increase in risk of venous thrombosis due to an interaction between the factor V Leiden mutation and estrogen

exposure. Another example is observed in patients with antithrombin deficiency where venous thrombosis frequently occurs when an affected patient is exposed to an environmental risk. This was evident in a study of families with type 1 antithrombin deficiency where the incidence of venous thrombosis was 20 times greater in affected family members but was strongly dependent on acquired risks. In this study the annual incidence of venous thrombosis in affected family members in any year in which they were exposed to surgery, trauma, plaster cast, hospitalization or immobilization was 20% (provoked venous thrombosis) but in any year in which there was no exposure the incidence was only 0.3% (i.e. unprovoked venous thrombosis rate). In this study the unprovoked venous thrombosis rate is only slightly, if at all, higher than the background incidence in the general population.

Antithrombin deficiency

The gene for antithrombin (*SERPINC1*) is located on the long arm of chromosome 1 and contains seven exons spanning 13.5 kb. Antithrombin (previously termed antithrombin III) is a glycoprotein (464 amino acids, 58 kDa, plasma concentration 2–3 μmol/L). Antithrombin is a serpin (*serine protease inhibitor*). Based on rates of inhibition, its primary targets are thrombin, factor (F)Xa and FIXa. Its concentration in the circulation is higher than that of prothrombin, and as only a fraction of prothrombin is converted to thrombin during coagulation, antithrombin is potentially present in vast excess over the protease, although the site will determine the local concentration of the enzyme and inhibitor. The plasma half-life of antithrombin is about 90 hours.

The serpin mechanism was confirmed by successful resolution of a crystal structure of the final serpin–protease complex by Jim Huntington in 2000. In contrast to the classical lock-and-key mechanism of protease inhibition, serpins form a stable covalent complex in which there is a dramatic conformational change in both the inhibitor and the inhibited protein that alters the properties of each, resulting in rapid clearance from the circulation. Antithrombin consists of three β-sheets and nine α-helices organized into an upper β-barrel domain and a lower helical domain. These two domains are bridged by the main structural feature of a serpin, the central A sheet (shown in red in Figure 45.2). The flexible reactive centre loop (RCL, shown in yellow) contains the scissile bond formed by the P1 arginine and P1' serine. Amino acids in the RCL are designated P1, P2 and so forth moving towards the N-terminus of the peptide sequence and P1', P2' and so forth moving towards the C-terminus of the sequence. The length and flexibility of the loop renders it highly susceptible to proteolysis. Cleavage of the RCL by thrombin, FXa or FIXa produces a conformational change during which the RCL inserts as the central strand of the expanded central A sheet (Figure 45.2c). This results in translocation of the protease to the opposite pole

of the serpin. The incorporation of the RCL as the central strand produces a hyperstable molecule such that the protease is crushed by intermolecular clashes with the hyperstable serpin. Distortion of the active site architecture disrupts the catalytic triad and results in disorganization of almost 40% of the protease architecture. The poor inhibitory activity of the circulating native form of antithrombin is conferred by intramolecular contacts that restrain the RCL and orientate the P1 arginine away from attacking proteases (Figure 45.2a). Activation causing release of the RCL is dependent on binding of glycosaminoglycans to the 'heparin-binding site' located in the region of the D-helix (cyan in Figure 45.2). An initial low-affinity interaction induces high-affinity binding (referred to as the induced fit mechanism) and this produces a conformational change in the antithrombin that releases the RCL for protease attack (Figure 45.2b). Activation increases the rate of protease inactivation 1000-fold. Successful inhibition of the protease depends on a race between complete proteolysis of the RCL with release of the regenerated protease from the cleaved loop (the substrate pathway) and incorporation of the cleaved loop into the central A-sheet with resultant capture and crushing of the tethered protease (the inhibitory pathway). The rate of inhibition relative to the substrate reaction is defined as the stoichiometry of inhibition, where a value of 1 represents a perfect inhibitor and a value of 2 would indicate that half the reactions led to cleaved antithrombin and a regenerated protease. Some mutations in the *SERPINC1* gene produce a dysfunctional antithrombin molecule in which the insertion of the RCL into the central A-sheet is retarded, turning the molecule into a substrate rather than an inhibitor. This is an example of how this highly regulated mechanism of thrombin or FXa inhibition renders antithrombin susceptible to dysfunction through genetic mutation.

Two laboratory (intermediate) phenotypes of heritable antithrombin deficiency are recognized. Type 1 is characterized by a quantitative reduction of antithrombin, with a parallel reduction in function (measured as inhibitory activity) and level of protein in the plasma (measured immunologically as the antigenic level). Type 2 deficiency is due to the production of a qualitatively abnormal antithrombin protein with dysfunction due to disturbance of the complex inhibitory mechanism of protease inhibition by a mutation in *SERPINC1* gene. The functional activity is discrepantly low compared with the antigenic level. Type 2 deficiency is subclassified according to the nature of the functional deficit.

- Type 2 reactive site (RS): mutations alter the sequence of the RCL, reducing the ability to inhibit thrombin or FXa in the presence or absence of heparin in a laboratory assay.
- Type 2 heparin-binding site (HBS): mutations affect the ability of antithrombin to bind and be activated by glycosaminoglycans and therefore result in reduced ability to inhibit thrombin or FXa only in the presence of heparin in a laboratory assay. These mutations are typically located in the

Figure 45.2 Model of thrombin destruction by antithrombin. Native antithrombin (a) circulates predominantly in an inert configuration with the reactive centre loop (RCL, shown in yellow) restrained on the C-sheet with the P1 arginine buried in a hydrophobic pocket and inaccessible to proteolytic attack. Binding of a glycosaminoglycan such as heparin sulphate to helix D (shown in cyan) induces a conformational change in the molecule that results in closure of the central A-sheet (shown in red), release of the RCL and exposure of the P1 arginine for proteolytic attack by protease (shown in green) resulting in the formation of an encounter complex (b). A heparin chain is shown bridging antithrombin and thrombin. The heparin chain binds to the D-helix of antithrombin, inducing the

conformational change and stabilizing the resultant encounter complex by binding to exosite II on thrombin. Cleavage of the RCL results in opening of the central A-sheet and incorporation of the cleaved loop as the central strand (c). This movement throws the protease to the opposite pole of the molecule where it is crushed by intermolecular clashes with antithrombin, which is now in a hyperstable conformation. Inhibition of the protease depends on incorporation of the cleaved loop into the central A-sheet with resultant capture and crushing of the tethered protease with distortion of the catalytic triad before completion of proteolysis of the RCL, which would release the protease. (Courtesy of Dr Jim Huntington, Department of Haematology, University of Cambridge.)

Figure 45.2 Continued

designated 'heparin-binding site' in the region of the D helix of the molecule.

- Type 2 pleiotropic (PE): a single mutation produces multiple effects on the structure–function relationship of the molecule, often associated with low plasma levels due to either effects on secretion or instability.

Approximately 100 point mutations (missense, nonsense or insertions or deletions causing frameshifts) and several whole or partial gene deletions have been identified as causes of type 1 deficiency. Numerous point mutations causing qualitative type 2 deficiency have been identified. Homozygous type 1 deficiency and probably homozygous type 2 RS mutations are incompatible with life. Type 2 HBS and PE mutations are associated with a lower risk of thrombosis and are compatible with life.

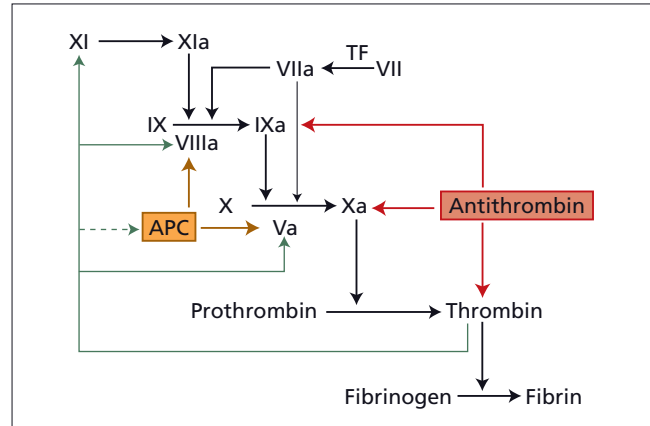

Figure 45.3 The thrombin explosion occurs in two phases: initiation and propagation. In the initiation phase, tissue factor (TF)–FVIIa generates small amounts of thrombin that enhances platelet activation (in conjunction with exposed subendothelial collagen at the site of vascular injury) and cleaves FV and FVIII to their active forms. The activation of FVa and FVIIIa amplifies thrombin generation and increasing concentrations of thrombin then lead to back-activation of FXI and the propagation phase. The activated forms of FV and FVIII are non-enzymatic cofactors that assemble and orientate the enzymes (FIXa and FXa) on the negatively charged surface of activated platelets. Antithrombin can neutralize the enzymatic coagulant factors FIXa, FXa and FIIa (thrombin). Thrombin bound to thrombomodulin cleaves protein C to its active form (APC), which proteolyzes FVa and FVIIIa and dismantles the tenase (FVIIIa–FIXa) and prothrombinase (FVa–FIIa) complexes on phospholipid surfaces, which attenuates thrombin generation. Protein S is a cofactor for the APC-mediated inactivation of FVa and FVIIIa.

Protein C deficiency

The gene for protein C (*PROC*) is located on chromosome 2 and contains nine exons spanning 11 kb. Protein C is a vitamin K-dependent glycoprotein synthesized in the liver (419 amino acids, 62 kDa, plasma concentration 65 nmol/L). Its concentration in plasma is about 100 times less than that of antithrombin. The plasma half-life of protein C is about 6 hours.

Protein C is the zymogen precursor of activated protein C (APC). Protein C is activated by thrombin bound to thrombomodulin on the endothelial surface. This is facilitated by the endothelial protein C receptor (EPCR). APC acts as a physiological anticoagulant by cleaving the cofactors FVa and FVIIIa and so thrombin generation (which is dependent on FVa and FVIIIa cofactor activity) is attenuated (Figure 45.3). Protein S is a cofactor for APC-mediated inactivation of FVa and FVIIIa.

Protein C deficiency is classified into type 1 and 2 defects on the basis of functional and antigenic assays. The relative risk of thrombosis in relation to type 1 and the various type 2 defects has not been characterized. Most heritable protein C deficiency

is due to type 1 deficiency. The majority of type 1 defects are due to point mutations. Multiple type 2 defects have been reported involving the catalytic active site, the phospholipid-binding Gla domain, the propeptide cleavage activation site and sites of interaction with substrates or cofactors.

Protein S deficiency

The gene for protein S (*PROS*) is located on chromosome 3 and contains 15 exons spanning 80 kb. A pseudogene with approximately 95% homology is located adjacent to *PROS* and this can cause difficulty with identification of mutations within the *PROS* gene.

Protein S is a vitamin K-dependent glycoprotein produced in the liver, endothelial cells and megakaryocytes (676 amino acids, 69 kDa, plasma concentration of free protein 145 nmol/L). Protein S is a non-enzymatic cofactor for APC-mediated inactivation of FVa and FVIIIa. Approximately 60% circulates bound to C4b-binding protein and is inactive. The remaining 40%, designated free protein S, is uncomplexed and is the active form. Free protein S increases the affinity of APC for negatively charged phospholipid surfaces on platelets or the endothelium and increases complex formation of APC with the activated forms of FV (FVa) and FVIII (FVIIIa). However, the degree of C4b binding has not yet been shown to be a determinant of thrombosis risk. In addition to APC cofactor activity, protein S has an independent anticoagulant effect by acting as a cofactor for TFPI (tissue factor pathway inhibitor).

Protein S defects are divided into three types. In type I deficiency both total and free protein S levels are low (and functional activity is low if measured). In type III the total protein S level is normal but the free protein S level is low. Some type III deficiency is thought to be a phenotypic variation resulting from the same genetic mutations associated with classical type I deficiency. However, it is now apparent that many patients with an apparent type III phenotype do not have heritable protein S deficiency. This may be related to the increase in C4b levels with increasing age. Type II defects are characterized by reduced activity in the presence of normal total and free levels of protein S. Type II deficiency is difficult to diagnose because functional protein S assays are imprecise.

FVR506Q (factor V Leiden)

The gene for FV is located on chromosome 1, near the *SERPINC1* gene, and contains 25 exons spanning 80 kb. FV (2196 amino acids, 330 kDa, plasma concentration of free protein 30 nmol/L) is the cofactor for activation of prothrombin by FXa in the prothrombinase complex. The plasma half-life is 15 hours. It has no cofactor activity until cleaved by thrombin or FXa at Arg709, Arg1018 and Arg1545. In 1993, Bjorn Dahlback and colleagues in Malmo described the phenomenon of resistance to APC in unrelated patients with venous thrombosis. Patient plasma was resistant to the anticoagulant effect of a fixed

amount of added exogenous APC. The effect was measured by dividing the activated partial thromboplastin time (APTT) in the presence of added APC by the APTT in the absence of added APC. APC resistance was defined as a ratio less than 2.0. Further work confirmed that increased APC resistance cosegregated with thrombosis in families with familial venous thromboembolism. The following year it was reported by a team from Leiden that the majority of patients with familial APC resistance had the same point mutation in the gene for FV, a guanine to adenine transition at nucleotide 1691 in exon 10 of the *F5* gene. This is known as the FV Leiden mutation (FVR506Q). Mutant FV Leiden has normal procoagulant activity but substitution of glutamine for arginine at position 506 results in slower inactivation by APC. FVa is a cofactor for the assembly of the prothrombinase complex, the active component of which is the activated form of FX (FXa), which converts prothrombin to thrombin (Figure 45.3). FVa is generated from FV by cleavage by thrombin, thus providing a positive feedback loop for thrombin generation. Prothrombinase activity is dependent on FVa maintaining the integrity of the enzymatic complex unit on a phospholipid surface. Thus thrombin generation is rate limited by FVa, and inactivation of FVa by APC attenuates thrombin generation. Inactivation of FVa occurs through sequential cleavage of the protein at positions Arg306, Arg506 and Arg679 by APC. Initial cleavage at R506 is necessary for subsequent cleavage at R306 and R679. Mutation of these residues (*F5G1691A*, *FVR506Q* or *FV Leiden*; *F5G1091C*, *FVA306T* or *FV Cambridge*) results in resistance to inactivation by APC. APC resistance is observed in the laboratory as an impaired plasma anticoagulant response to APC added *in vitro*, usually with an APTT-based clotting test. However, nowadays the mutation is frequently detected by direct DNA analysis rather than by a clotting assay (see section on laboratory testing). The FVR506Q mutation is present in about 4% of the white population and about 15% of unselected consecutive patients with a first venous thrombosis. The prevalence is highest in northern Europeans. The mutation is infrequent in other populations. The high prevalence and founder effect suggests positive selection and this may relate to a favourable effect on embryo implantation and hence reproduction rather than a lower risk of fatal haemorrhage in females during childbirth, as originally thought.

APC also inactivates FVIIIa by cleavage at positions Arg336 and Arg562 but mutations affecting these sites in FVIII causing an increased risk of venous thrombosis have not been reported.

APC resistance in the absence of FVR506Q occurs in about 5% of patients with a history of venous thrombosis. This is often related to high FVIII levels or low FV levels, which may be found in association with the *F5HR2* haplotype. There is evidence that APC resistance in the absence of FVR506Q is associated with venous thrombosis but defining the cause of resistance in individual patients has no clinical utility. Acquired APC resistance is explained by increased FVIII levels, pregnancy or estrogen exposure in some individuals.

F2G20210A

The gene for prothrombin is located on chromosome 2 and contains 14 exons spanning 21 kb. Prothrombin is a vitamin K-dependent protein synthesized in the liver (579 amino acids, 72 kDa, plasma concentration 2 μ mol/L). Prothrombin is the zymogen precursor of thrombin.

A single nucleotide change, guanine to adenine at position 20210 in the 3' untranslated region of the prothrombin gene (F2G20210A), is associated with elevated plasma prothrombin levels and an increased risk of venous thrombosis. This mutation was identified by the Leiden team when investigating candidate genes in the Leiden Thrombophilia Study cohort. The prevalence of the F2G20210A mutation is about 2% of whites, with a higher prevalence in southern compared with northern Europeans. The mutation increases the plasma level of prothrombin by about 30% but the mechanism has not been explained. No specific clotting test for the presence of the mutation has been described and diagnosis depends on detection of the genetic mutation by DNA analysis.

Candidate heritable thrombophilias

Peter Reitsma and Frits Rosendaal from Leiden have detailed the history of unravelling the genetic architecture of venous thrombosis risk. Initially, extended pedigrees of families with venous thrombosis were studied and plasma levels of natural anticoagulants were measured. With the advent of DNA technology, genes encoding the natural anticoagulant proteins were cloned and sequenced and hundreds of private mutations were reported, often with mutations found only in one family. Subsequently, the common public mutations (F5G1691A and F2G20210A) were found in case-control studies. Currently, common genetic markers in every gene encoding a protein involved in haemostasis are being studied in order to determine whether these markers are associated with thrombosis risk. Two types of genetic mutation cause venous thrombosis: those that reduce function (e.g. a mutation causing antithrombin deficiency) and those that increase function (e.g. FVR506Q, which renders the mutant protein resistant to inactivation, resulting in increased thrombin generation). The private mutations in *SERPINC1*, *PROC* and *PROS* and public mutations in *F5* and *F2* account for about 50% of the thrombosis risk attributable to genetic mutation. There are two approaches to identifying the remaining 50% of genetic mutations. A linkage study requires extended pedigree analysis and is limited by heterogeneity in the genetic cause of thrombosis in different families. This dilutes the apparent effect of a genetic mutation when data from different pedigrees are combined. The alternative approach is to use genetic markers of common risk alleles in association studies of unrelated individuals using genome-wide genotyping

of a large set of single-nucleotide polymorphisms (SNPs). This approach relies on the principle that common diseases are explained by common risk alleles. The weakness of this approach is that there is little evidence that this principle is true. With this approach there is also a high risk of misidentifying a risk allele (type I error) due to multiple testing and in order to offset this it is necessary to raise the significance level of testing, which then leads to decreased sensitivity (type II error). Reitsma and Rosendaal suggest that a deep resequencing project may identify genetic factors and allow powerful genetic risk profiling. This hypothesis is supported by an initial proof of principle study showing that common SNPs which in isolation confer a very small risk of venous thrombosis (hazard ratio <1.5) interact synergistically to significantly increase the risk of venous thrombosis (hazard ratio >5.0 for four SNPs).

Other natural anticoagulants

Tissue factor pathway inhibitor (TFPI) is an inhibitor of FXa and tissue factor-bound FVIIa. TFPI knockout is embryonically lethal in mice. TFPI is predominantly extravascular and so measurement in plasma samples is not representative of total TFPI availability. In a few studies plasma TFPI levels were slightly lower in patients with venous thrombosis than in normal individuals and the low levels may be a mild risk factor for venous thrombosis. Protein Z is a vitamin K-dependent protein that circulates in complex with PZI (protein Z-dependent protease inhibitor) and catalyses the inhibition of FXa. A causal relationship between PZI and/or PZ deficiency and venous thrombosis has not been demonstrated. Heparin cofactor II, a serpin with a similar structure-function relationship to antithrombin, inhibits thrombin when activated by glycosaminoglycans. Heparin cofactor II knockout mice are healthy and do not develop spontaneous thrombosis but do have a shorter time to thrombosis in an arterial injury model. A relationship between heparin cofactor II deficiency and thrombosis in humans is uncertain. A relationship between thrombosis and mutations affecting thrombomodulin or EPCR has not been established.

Other procoagulant factors

Increased FVIII levels are associated with an increased risk of both venous and arterial thrombosis but a heritable basis for this, other than through ABO blood group effects on von Willebrand factor levels, has not been established. Elevated FIX and FXI levels are also associated with venous thrombosis risk but a heritable basis for high levels associated with venous thrombosis is not established. There is equivocal evidence for a causal relationship between fibrinogen levels and venous thrombosis. Approximately 300 examples of heritable dysfibrinogenemia have been reported. The majority are asymptomatic

matic or associated with increased bleeding and very few examples are considered to be genuinely associated with an increased tendency to thrombosis, which may be arterial or venous or a combination. Dysfibrinogenaemia has been found in less than 1% of patients with a history of venous thromboembolism. It is associated with postpartum thrombosis and an increased risk of pregnancy loss. The identification and characterization of rare dysfibrinogenaemias associated with thrombosis is beyond the capability of most coagulation laboratories. Polymorphisms in the prothrombin gene have been described that may further increase the risk of venous thrombosis associated with the *F2G20210A* mutation but the effect is mild. It was previously thought that deficiency of FXII was a risk factor for venous thromboembolism but subsequent investigation strongly indicates that this is unlikely. A polymorphism in the FXIII gene (FXIIIIV341L) is significantly less common in patients with coronary heart disease than in control subjects and a protective effect for venous thromboembolism has been reported.

Fibrinolysis

A causal relationship between levels of individual specific proteins involved in regulating fibrinolysis has not been established. However, a global measure of fibrinolytic potential as measured by a plasma-clot lysis assay was associated with an approximately twofold increased risk of venous thrombosis in patients with clot lysis times above the 90th percentile of controls in the Leiden Thrombophilia Study. Analysis of the large MEGA (Multiple Environmental and Genetic Assessment) study confirmed this finding and demonstrated that hypofibrinolysis in combination with established acquired and genetic risk factors, such as *FVR506Q*, had a synergistic effect on venous thrombosis risk. A genetic basis for hypofibrinolysis in these patients was not investigated. Genetic mutation in the thrombin-activatable fibrinolytic inhibitor (TAFI) gene has not been linked to thrombosis risk, although plasma TAFI levels appeared to be weakly linked to thrombosis risk in some studies.

Homocysteine

Hyperhomocysteinaemia may be caused by genetic abnormalities but only the severe inherited abnormalities of homocysteine metabolism (homozygous cystathionine β -synthase deficiency and homozygous deficiency of methylenetetrahydrofolate reductase) result in congenital homocysteinuria associated with an increased risk of both arterial and venous thrombosis as well as premature atherosclerosis and mental retardation, epilepsy, and skeletal and eye problems. Half of patients present with venous or arterial thrombosis before the age of 30 years. The thermolabile variant of methylenetetrahydrofolate reductase

due to a common genetic mutation (*C677T*) is not a risk factor for venous thrombosis.

Treatment of patients with venous thrombosis and heritable thrombophilias

There is no evidence that heritable thrombophilia should influence the intensity of anticoagulation with heparin or warfarin. In patients with antithrombin deficiency, heparin resistance is infrequent and recurrence or extension of thrombosis while on treatment is no greater than that observed in individuals without antithrombin deficiency. Warfarin-induced skin necrosis is extremely rare, even in patients with protein C or S deficiency, such that most individuals with protein C or S deficiency do not develop skin necrosis. The intensity of maintenance therapy with warfarin should not be influenced by laboratory evidence of inherited thrombophilia. There is no evidence that recurrence on treatment is more likely in patients with heritable thrombophilia.

Long-term prospective cohort outcome studies have shown that finding a heritable thrombophilia does not predict recurrence in unselected patients after an episode of venous thrombosis. However, these studies were not powered to exclude an increased risk of recurrence specifically in relation to rare thrombophilias, such as antithrombin or protein C deficiency. Therefore, it remains uncertain if mutations in *SERPINC1*, *PROC* or *PROS* causing deficiency of the corresponding protein might predict a sufficiently high risk of thrombosis to justify long-term (lifelong) anticoagulation. Studies in thrombosis-prone families indicate a risk of recurrence that would justify long-term anticoagulation but these studies may not be representative of risk associated with the *SERPINC1*, *PROC* and *PROS* mutations per se but may be influenced by additional defects in the thrombosis-prone family members. Further studies are required to define the relative risk of recurrent events associated with the actual *SERPINC1*, *PROC* and *PROS* mutations.

Systematic reviews indicate a risk of 1.4 for recurrent venous thromboembolism in patients heterozygous for the *FVR506Q* mutation and 1.2–1.7 for the *F2G20210A* mutation. The authors concluded that the magnitude of the increase in risk was modest and by itself did not justify an extended duration of anticoagulation. An analysis of the MEGA study showed that testing for inherited thrombophilia did not reduce recurrence of venous thrombosis.

As a result of these observations, at present the following conclusions seem reasonable.

- Indiscriminate testing for heritable thrombophilias in unselected patients presenting with a first episode of venous thrombosis is not indicated.

- Decisions regarding duration of anticoagulation (lifelong or not) in unselected patients should be made with reference to whether a first episode of venous thrombosis was provoked, other risk factors, and risk of anticoagulant therapy-related bleeding, regardless of whether a heritable thrombophilia is known.
- Testing for heritable thrombophilias in selected patients, such as those with a strong family history of unprovoked recurrent thrombosis, may influence decisions regarding duration of anticoagulation. Unfortunately, in this regard identifying patients for testing is not straightforward as criteria for defining thrombosis-prone families have not been validated and the association between family history of thrombosis and detection of inherited thrombophilia is weak.

Treatment of venous thrombosis in unusual sites in patients with heritable thrombophilias

Upper limb DVT

More than 60% of episodes of upper limb DVT are associated with central venous catheters (CVC), with CVCs and cancer being the predominant risk factors. In patients without these factors heritable thrombophilias are found in one-third and there is an interaction between common thrombophilias and oral contraceptive exposure. The risk of recurrence is either not higher or marginally higher in patients with heritable thrombophilias but the absolute risk of recurrence in the presence of thrombophilia is less than 5% per year and 80% of patients are recurrence free 5 years after stopping anticoagulant therapy. Therefore thrombophilia testing is not recommended in patients with upper limb DVT.

Cerebral vein thrombosis

There is an association between thrombophilia and cerebral vein thrombosis, with an interaction between common thrombophilias, particularly *F2G20210A*, and oral contraceptive exposure. Overall the risk of recurrence of cerebral vein thrombosis is lower than previously thought, although it may be underestimated due to continuation of anticoagulant therapy in those patients thought to be at particular risk of recurrence. It has become common practice to test patients for heritable thrombophilia after cerebral vein thrombosis and some experts continue anticoagulation lifelong if there is a thrombophilic defect. In all patients acquired risks should be removed or minimized, for example combined oral contraceptive (COC) exposure and obesity. Therefore, testing for heritable thrombophilias after a first episode of cerebral vein thrombosis has unknown predictive value for recurrence and decisions regarding dura-

tion of anticoagulant therapy in relation to the results of testing are therefore not evidence based.

Retinal vein thrombosis

Vein occlusion is associated with hypertension, hypercholesterolaemia and diabetes. A relationship with heritable thrombophilia has not been established. Furthermore, it is uncertain if hypercoagulability is a contributory factor in this condition and there is no evidence that anticoagulant therapy is beneficial. Consequently, testing is not indicated in patients with retinal vein occlusion.

Intra-abdominal vein thrombosis

Myeloproliferative disorders, cirrhosis and surgery are strong risk factors for intra-abdominal venous thrombosis. The acquired *JAK2 V617F* mutation is a risk factor even in the absence of an overt myeloproliferative disorder, being found in about 15% of cases. No studies have investigated how the finding of a heritable thrombophilia should influence management. Therefore, testing for heritable thrombophilias after a first episode of intra-abdominal vein thrombosis has uncertain predictive value for recurrence and decisions regarding duration of anticoagulant therapy in relation to the results of testing are not evidence based. Many experts continue anticoagulation lifelong after intra-abdominal vein thrombosis as recurrence may be catastrophic.

Case finding

Testing for heritable thrombophilias in patients presenting with venous thrombosis allows case finding of affected asymptomatic family members. The rationale is that this permits avoidance of environmental risks (e.g. use of COCs by females) or provides an opportunity for targeted thromboprophylaxis at times of unavoidable high risk (such as surgery). However, individual risk is affected by multiple genetic and environmental factors that will be different even among first-degree relatives. Prospective cohort studies have determined the annual risk of venous thrombosis in asymptomatic family members identified after testing unselected patients presenting with venous thrombosis. The studies included more than 3500 patient-years of observation. The annual risk of venous thrombosis in asymptomatic family relatives of index patients was 0.1% for those with *F2G20210A*, 0.6% for those with *FVR506Q*, about 2% for protein C and protein S deficiency, and 4% for antithrombin deficiency. High-risk periods contribute to approximately half of all events (provoked recurrence) in patients with *FVR506Q* and thromboprophylaxis appears to reduce risk. In the EPCOT registry patients were referred to specialist centres for thrombophilia testing if they had a personal or family history of

venous thrombosis. The incidence of thrombosis on study entry was determined retrospectively in asymptomatic relatives. The risk of venous thrombosis was 16 times higher in affected relatives, with the greatest risk in relatives of patients with deficiency of a natural anticoagulant or multiple defects. The highest risk was in individuals with antithrombin deficiency (1.7% per year) or combined defects (1.6% per year). Targeted case finding of relatives with 'severe' or 'high risk' thrombophilias, such as deficiency of antithrombin, protein C or protein S, has been suggested, although the clinical utility of such methods remains uncertain and contentious among experts.

Given uncertainty, some experts argue that it is reasonable to perform testing if it is anticipated that clinical management will be influenced, for example an intensified or extended period of prophylaxis during a high-risk period. If a family history suggests a high degree of genetic penetrance, then it might be reasonable to test a symptomatic patient and then their relatives with a view to enhanced prophylaxis at times of high risk in affected members, for example thrombophylaxis in pregnancy when there is a family history of pregnancy-associated thrombosis, or intensified or extended surgical thrombophylaxis when there is a history of thrombophylaxis failure in affected members. In all cases the risks, benefits and limitations of testing should be discussed in the context of explained inheritance and disease risk. The importance of this is demonstrated by reported anxiety after testing positive and an overestimated perception of risk. Simple methods for quantifying a positive family history do not discriminate patients with and without thrombophilia and therefore the decision to test for inherited thrombophilia cannot be accurately guided by the presence or absence of a family history.

Prevention of thrombosis associated with estrogen-containing hormone preparations

In some women heritable thrombophilia has already been established, while in others it is perceived that testing would enable informed decision-making regarding use of a COC or hormone-replacement therapy (HRT). However, the absolute risk of thrombosis is low and the fact that venous thrombosis has a multiple genetic basis with incomplete penetrance makes counselling in relation to genetic testing uncertain. In many instances an alternative effective contraceptive is acceptable. Similar principles apply to HRT, although the baseline risk is higher as the population is older. Rarely is there a therapeutic indication for HRT and in most instances there is only a weak indication. If HRT is considered essential, then a non-oral formulation is associated with a significantly lower risk of venous thrombosis.

A first-degree relative with a history of venous thrombosis is a relative contraindication to an estrogen-containing hormonal preparation. The risk is dependent on the circumstances of thrombosis in the relative. For example, a history of an elderly relative who developed venous thrombosis as a complication of cancer is not a contraindication. In contrast, a relative with unprovoked venous thrombosis, or specifically a sibling developing venous thrombosis while taking a COC, should be considered a strong contraindication. In families with known heritable thrombophilias the risk of venous thrombosis can be increased in unaffected members as well as affected and so a negative thrombophilia result does not exclude an increased risk of venous thrombosis. Therefore, decisions regarding use of COCs and whether thrombophilia testing is likely to be informative should be made with reference to individual clinical risk factors and the circumstances associated with venous thrombosis in the family.

Prevention of pregnancy-associated venous thrombosis

Pregnancy is associated with a fivefold to tenfold increased risk of venous thrombosis compared with non-pregnant women of comparable age, with an absolute risk of 1–2 per 1000 deliveries. The risk of thrombosis, compared with the general age-matched female population, is increased 100-fold in pregnancy in women with a previous thrombosis. Retrospective studies in women with previous venous thrombosis for whom detailed information on the type of thrombophilia was available indicate that the rate of recurrence is similar in women with and without thrombophilia, although studies excluded women with high-risk thrombophilias (anticoagulant deficiency, multiple defects). Thrombosis rarely occurs in women whose initial event is provoked. In general, the absolute risk of pregnancy-associated venous thrombosis in women with heritable thrombophilia with no previous history is small, but women with antithrombin deficiency or those homozygous for the FVR506Q or F2G20210A mutations or who are double heterozygotes should be regarded as being at higher risk. The number of women with these defects is very small.

In women with a previous history of venous thrombosis, the major factor in determining if prophylaxis should be given is whether prior venous thrombosis was provoked or not. If the episode was unprovoked, prophylaxis should be considered and thrombophilia testing is not required if prophylaxis is given. In women with a first provoked event, the decision to test should be influenced by the strength of the provocation, for example thrombosis associated with major trauma and subsequent immobility would not be an indication for prophylaxis or testing. In women with a first-degree relative with thrombosis, the decision to test should be influenced by whether the event

in the relative was unprovoked or provoked and the strength of the provocation. If the event in the first-degree relative was associated with pregnancy or COC, then testing and finding thrombophilia should prompt consideration of prophylaxis, particularly if the symptomatic relative was known to have the same defect, especially deficiency of antithrombin or protein C. When testing in pregnancy is performed it is necessary to interpret the results with reference to the effect of pregnancy on the tests.

Pregnancy morbidity

There is evidence of an association between heritable thrombophilia and pregnancy morbidity, including early and late pregnancy loss, pre-eclampsia and intrauterine growth retardation. Randomized controlled trials with a no treatment or placebo arm in women with a history of pregnancy complications are in progress and results should be awaited before recommending that antithrombotic therapy is given to pregnant women based on testing for heritable thrombophilia.

Purpura fulminans

Purpura fulminans is a rare syndrome characterized by progressive haemorrhagic skin necrosis that occurs in neonates with congenital severe protein C deficiency at birth or in the first few days of life, and in association with infection in children and adults. The condition may occur in children without congenital anticoagulant deficiency following viral infections, with an onset within 10 days of infection. Acquired severe protein S deficiency has been reported in purpura fulminans following chickenpox infection. With bacterial infections disseminated intravascular coagulation (DIC) is often present, for example meningococcal infection. In patients with DIC or purpura fulminans due to sepsis, treatment with APC should be considered. In patients with very severe skin necrosis, testing for acquired protein C or S deficiency should be considered as plasma exchange may be beneficial. Neonates homozygous for protein C or S deficiency may be born with skin necrosis or DIC.

Oral vitamin K antagonist-induced skin necrosis

Oral vitamin K antagonist-induced skin necrosis, such as that seen with warfarin, is extremely rare, even in patients with protein C or S deficiency, such that most individuals with protein C or S deficiency do not develop skin necrosis. However, a high proportion of patients with vitamin K antagonist-induced necrosis have heritable protein C deficiency. The con-

dition has been described in patients with other heritable thrombophilias. Vitamin K antagonist-induced necrosis associated with heritable thrombophilias tends to involve a central distribution.

Thrombophilia and arterial thrombosis

The genetic risk factors for venous thrombosis and arterial atherothrombosis overlap but the material contribution of each differs between the two diseases. Hypercoagulability resulting from variation in the genetic control of blood coagulation produces a greater material contribution to venous thrombosis. However, it is becoming increasingly recognized that both genetic and acquired risk factors are common denominators for venous and arterial thrombosis. In patients presenting with venous thrombosis before the age of 40 there appears to be an increased risk of acute myocardial infarction subsequently.

Evidence of an association between heritable thrombophilia and arterial thrombosis is limited to case reports and small studies. It is possible that heritable defects that result in increased coagulability increase the likelihood of atherothrombosis. However, the material contribution of heritable thrombophilia, as compared with established cardiovascular risk factors, is not sufficient to change therapy for primary and secondary prevention. Therefore, testing young patients for heritable thrombophilia after an arterial occlusive event is unhelpful. Because there is no established causal relationship and as treatment and secondary prevention should be in relation to established cardiovascular risk factors, thrombophilia testing is not recommended. In patients with arterial thrombosis at a young age that cannot be explained by conventional cardiovascular risk factors, various causes should be considered including antiphospholipid antibody syndrome, a cardiac or large-artery source of embolus, vasculitis, aneurysm, thoracic outlet syndrome or a collagen-vascular disorder causing arterial dissection.

Neonatal stroke

Heritable thrombophilic defects are associated with perinatal brain injury. The pathogenesis is thrombosis in either cerebral arteries or cerebral veins or sinuses. Secondary brain infarction results, with subsequent cystic change. Thrombophilia is not a significant risk factor for ischaemic stroke in adults, as it does not increase the risk of arterial thrombosis (but cerebral vein thrombosis can present as stroke). In the neonate the pathophysiology of stroke is quite different and thrombophilia may increase the risk of arterial thrombosis and stroke in the neonate or fetus. There are two potential explanations for this.

- The circulation in the neonate is different. In the adult venous blood is 'filtered' by the pulmonary circulation. In the fetus and

neonate the lungs are bypassed by the ductus arteriosus and so it is possible for clots arising in the venous system to bypass the lungs and occlude a cerebral artery.

- The blood coagulation system of the neonate is different to that of the adult. It is possible that the coagulability of blood in fetal and neonatal arteries is influenced by thrombophilic defects. However, this remains to be investigated.

Testing for defects may therefore identify a material contributory factor but does not typically inform management decisions. For example, anticoagulant therapy is not usually considered in children found to have suffered a stroke in the neonatal period and there may be a significant time before a neurological deficit is recognized or the cause of stroke determined. In practice testing is sometimes performed in order to explain to parents why a stroke possibly occurred.

Laboratory methodology and testing strategy

The laboratory diagnosis of heritable thrombophilias is difficult as the tests are subject to considerable pre-analytical variables. Low levels of antithrombin, protein C and protein S occur in a variety of circumstances and test results and the clinical implications of both positive and negative results are frequently misinterpreted.

A full blood count and platelet count are useful indicators of general health and will identify myeloproliferative disorders that increase thrombotic risk. The APTT may detect some lupus anticoagulants but a sensitive assay should be used. The thrombin time will detect heparin contamination and the prothrombin time (PT) is useful for the interpretation of protein C and protein S levels. Testing is usually delayed until at least 1 month after completion of a course of anticoagulation with a vitamin K antagonist. Testing should be avoided during intercurrent illness and with use of COCs or HRT. Sometimes testing is performed during pregnancy and so interpretation of results must be made with reference to the effect of the pregnancy on results.

Functional assays should be used where accuracy and imprecision are acceptable. However, no single method will detect all defects. For example, a protein C chromogenic assay will not detect a dysfunctional protein C molecule with impaired phospholipid binding due to a mutation in the Gla domain. A clot-based protein C assay would be sensitive to this defect but imprecision of the assay would result in reduced sensitivity and specificity for other defects compared with a chromogenic assay. Similarly, the performance of antithrombin assays will be influenced by heparin, the pre-incubation time with heparin, use of FXa or thrombin as a substrate, the source of thrombin and the end-point detection method. For example, an assay utilizing a short heparin incubation time will detect heparin-

binding site defects, which may not be associated with an appreciably increased risk of venous thrombosis.

Even in families with characterized defects, a phenotypic assay may fail to accurately discriminate affected and non-affected individuals. True heritable deficiencies may not be detected and false-positive diagnoses are common.

Pre-analytical variables

Most assays are affected by clots in the sample. Antibody assays may be affected by atypical antibodies such as paraproteins, rheumatoid factor and heterophile antibodies. Chromogenic assays are subject to interference by lipaemia and haemolysis. Clot-based assays are subject to imprecision due to variation in the baseline clotting time and the levels of other factors.

Low levels of antithrombin, protein C or protein S may relate to age, sex, acquired illness or drug therapy and therefore interpretation requires knowledge of the patient's condition at the time of blood sampling. Interpretation of results in children must be with reference to the normal range for age.

Low levels of antithrombin, protein C or protein S suspected to be the result of heritable mutations should be confirmed on one or more separate samples. Demonstrating a low level in other family members supports a diagnosis of heritable deficiency and characterization of the genetic mutation can confirm the diagnosis and give some indication of thrombosis risk, particularly in the case of antithrombin deficiency.

General recommendations for laboratory tests and interpretation

- Testing at the time of acute venous thrombosis is not indicated as the utility and implications of testing need to be considered and the patient needs to be counselled before testing. As treatment of acute venous thrombosis is not influenced by test results, testing can be performed later.
- The PT should be measured to detect the effect of oral vitamin K antagonists, which will cause a reduction in protein C and S levels.
- Functional assays should be used to determine antithrombin and protein C levels.
- Chromogenic assays of protein C activity are less subject to interference than clotting assays and are preferable.
- Immunoreactive assays of free protein S antigen are preferable to functional assays. If a protein S activity assay is used in the initial screen, low results should be further investigated with an immunoreactive assay of free protein S.
- If an APC resistance assay is performed to detect FVR506Q, then the modified APC sensitivity test (predilution of the test sample in FV-deficient plasma), as opposed to the original APC sensitivity test, should be used as a phenotypic test for FV Leiden. If positive the mutation should be confirmed by a direct genetic test. An APC resistance assay is unnecessary if a direct genetic test for FV Leiden is used initially.

- Repeat testing for identification of deficiency of antithrombin, protein C and protein S is indicated and a low level should be confirmed on one or more separate samples. Deficiency should not be diagnosed on a single abnormal result.
- Rigorous internal quality assurance and participation in accredited external quality assessment schemes are mandatory.
- Thrombophilia testing must be supervised by experienced laboratory staff and the clinical significance of the results must be interpreted by an experienced clinician who is aware of all relevant factors that may influence individual test results in each individual case.

Antithrombin assays

The activity of antithrombin is measured as progressive activity towards thrombin in the absence of heparin (designated accordingly 'progressive activity') or in the presence of heparin against either thrombin or FXa (designated 'heparin cofactor activity'). Activity assays typically use a chromogenic substrate in which a small synthetic peptide is linked to *p*-nitroaniline. Cleavage of the peptide releases the *p*-nitroaniline, which turns yellow and can be measured quantitatively. Patient plasma is incubated with heparin and then an excess of thrombin or FXa is added. The heparin-activated antithrombin is complexed and neutralizes the excess thrombin or FXa. The remaining free protease quantified by cleavage of the chromogenic substrate is inversely proportional to the antithrombin level in patient plasma. Either thrombin or FXa with the appropriate chromogenic substrate can be used (Figure 45.4). The progressive assay is identical except that the patient plasma sample is not pre-incubated with heparin.

Figure 45.4 Chromogenic antithrombin heparin cofactor assay. Plasma (the source of antithrombin) is incubated with an excess of thrombin (human or bovine) in the presence of heparin. Thrombin is complexed and neutralized by heparin-activated antithrombin until all antithrombin is complexed. The residual thrombin is then detected by the chromogenic indicator. The concentration of antithrombin in the sample is inversely proportional to the residual thrombin concentration.

Interference by other proteases and inhibitors in the plasma sample is a potential problem. Interference by heparin cofactor II, another heparin-activated serpin, can be eliminated by using FXa or bovine thrombin as the target protease, as heparin cofactor II only inhibits human thrombin. The effect of other proteases in the patient plasma can be minimized by addition of a protease inhibitor such as aprotinin.

The total amount of antithrombin protein can be measured immunologically with antibodies, for example by ELISA. As antithrombin antigen levels may be normal or near normal in type II deficiency, immunological assays may fail to identify patients with these variants.

Antithrombin levels are slightly reduced in infants, during pregnancy, in women taking estrogen preparations and in some patients during heparin therapy. Levels also decrease with age and acquired low levels occur in liver disease, DIC, nephrotic syndrome, during L-asparaginase therapy, and in protein malnutrition and cachexia.

Protein C assays

Protein C defects are divided into type 1, with a reduced amount of functionally normal protein, and type 2, in which there is reduced activity due to a dysfunctional protein. In this case there is discordance between the functional and antigenic levels. The laboratory diagnosis of protein C deficiency is based on a functional assay. Most commercially available functional assays of protein C employ the specific activator Protac, a protein C activator derived from the venom of the southern copperhead snake (*Agkistrodon contortrix*). Chromogenic assays using a synthetic substrate for APC are simple to perform and can detect all type 1 defects and type 2 defects affecting the catalytic site. A chromogenic assay will not detect most other type 2 defects. Clotting assays utilizing the prolongation of either the PT or APTT after Protac activation have the capacity to detect other, but not all, type 2 defects but are subject to imprecision due to variation in the baseline clotting time and the levels of other factors, for example if there is a short APTT due to a high FVIII level, or the presence of the factor V Leiden mutation which results in a falsely low protein C activity due to APC resistance, or in the presence of a lupus anticoagulant. The diagnosis of protein C deficiency is problematic because of the wide overlap in protein C activity between heterozygous carriers and unaffected individuals. Protein C levels are not affected by pregnancy or estrogen exposure. Acquired low levels of protein C occur during anticoagulant therapy with oral vitamin K antagonists, vitamin K deficiency, DIC and liver disease.

Protein S assays

Protein S is usually quantified immunologically rather than measured functionally. Originally, free protein S was measured in plasma supernatant after precipitation of C4b-bound protein

S by polyethylene glycol (PEG). Nowadays PEG precipitation is not required as monoclonal antibodies that detect only free protein are used. Functional protein S assays are imprecise and are not used in the majority of coagulation laboratories.

Protein S levels are significantly lower in females, so much so that different normal reference ranges are required for males and females. There is a significant risk of a false-positive diagnosis of protein S deficiency in women. Protein S levels fall progressively during normal pregnancy and are reduced by estrogens. Acquired low levels of protein S occur during anticoagulant therapy with oral vitamin K antagonists, vitamin K deficiency, DIC and liver disease.

FVR506Q and APC resistance

Nowadays, the FVR506Q mutation is usually detected by direct mutation analysis. APC resistance assays typically utilize the APTT. Samples are tested with and without an added fixed concentration of APC. The clotting times are expressed as a sensitivity ratio, i.e. the APTT (seconds) of patient plasma plus APC divided by the APTT (seconds) of patient plasma without added APC; the lower the ratio, the greater the APC resistance. Platelet contamination and activation must be avoided as this will lead to APC resistance. The ratio can be normalized by dividing the patient's sensitivity ratio by the sensitivity ratio of a pooled normal plasma. If normalization is used, FVR506Q carriers should be excluded from the normal plasma pool. The APC resistance assay is abnormal not only in the presence of FVR506Q but with all other causes of heritable and acquired APC resistance and in individuals with a prolonged baseline APTT due to clotting factor deficiencies or anticoagulant therapy. It is therefore not specific for FVR506Q. Modification of the test by a 1 in 4 predilution of the test plasma in FV-deficient plasma increases the sensitivity and specificity of the assay for FVR506Q to almost 100% and this test is reliable if genetic analysis is not available.

F2G20210A

A laboratory clotting test with sensitivity and specificity for this mutation is not available and so detection is by direct mutation analysis.

Next-generation global thrombophilia tests

A test that predicts a high rate of recurrent venous thrombosis would be clinically useful. The clinical utility of such a test would be the identification of patients in whom the benefit of continued long-term anticoagulant therapy outweighed the risk. Patients with a first unprovoked venous thrombosis are at highest risk of recurrence but it is arguable if the level of risk estimated from clinical risk factors alone justifies long-term anticoagulation. A new generation of thrombophilia tests that

measure the degree of coagulability are now being investigated in clinical studies. These include biomarkers, such as D-dimer, which reflect the level of thrombin generation *in vivo*, and thrombin generation assays, which measure the capacity of a patient plasma sample to generate thrombin in response to a predefined coagulation trigger, for example low concentration tissue factor. It has now been demonstrated in several studies that the level of D-dimer or thrombin-generating potential correlates with risk of recurrent venous thrombosis. These tests appear to reflect different aspects of hypercoagulability and may be complementary in terms of clinical utility. However, it remains to be defined exactly how these tests should be used to stratify patient risk and influence clinical decisions regarding duration of anticoagulant therapy after an episode of venous thrombosis.

Counselling and genetic testing

Clinical utility refers to the ability of a screening or diagnostic test to prevent or reduce adverse health outcomes, including mortality, morbidity and disability. A test does not have inherent clinical utility; rather it is the adoption of a therapeutic or preventive intervention on the basis of the test result that influences health outcomes. Clinical utility can more broadly refer to any use of a test result to inform clinical decision-making, and this may include information considered important by individuals and families.

A large proportion of genetic counselling focuses on presenting risk information. Making sense of information can be difficult. Whenever a patient is offered an intervention there is a trade-off between benefit and risk. The benefit and risk information must be presented in ways that are relevant and understandable. In addition to the quantitative information, the qualitative aspect of risk is equally important. A relative risk does not indicate how likely it is that an outcome will occur, only how much relatively more or less likely it is. It is the absolute risk that indicates how likely an event will be. For example, the relative risk of venous thrombosis is increased twofold to sixfold in a female aged between 20 and 40 years who takes an estrogen-containing oral contraceptive (COC), depending on her age and the COC preparation. It is accepted that COC exposure increases the risk of venous thrombosis and some women presented with this information might choose not to use a COC as contraception, despite its proven efficacy and attractions. When informed that the risk would be 35-fold higher than the population baseline risk if the woman had the factor V Leiden mutation and used a COC, some women would again choose to avoid use of a COC. However, in order to make an informed decision it is necessary for the woman to know how likely it is she would suffer venous thrombosis if she did not use the COC and how much the absolute risk would change if she did use a COC. The population baseline risk of thrombo-

sis is about 1 per 10000 per year under the age of 40. If a woman used a COC it would increase about fourfold to about 4 per 10000 per year. Clearly, the risk of venous thrombosis associated with COC use is very low. For a woman with the factor V Leiden mutation, her baseline risk of thrombosis would be about 1 per 2000 per year under the age of 40, a risk that is increased about fivefold compared with a woman without this mutation. If this woman were to take a COC, her absolute risk would increase from 1 per 2000 to 1 in 300, a risk that is increased about sevenfold for her but which is 35-fold greater than the population baseline risk. For many women an annual risk of 1 in 300 is acceptable given the proven efficacy, ease of use and other obvious advantages of a COC.

Selected bibliography, 899**Introduction**

Deep vein thrombosis (DVT) is common, principally affecting the lower limbs. In many populations the annual incidence is around 1 per 1000 population. However, the disorder is highly age-dependent. For example, it is exceptional in childhood, has an incidence of the order of 1 per 10 000 population per year in young adults, and may reach 1% per annum in the very elderly. The incidence of pulmonary embolism is lower, possibly around 1 per 3000 population annually, although subclinical pulmonary embolism occurs frequently in subjects with lower limb proximal DVT. In patients who die in hospital there is evidence of pulmonary embolism in up to 20% of cases and in many it contributes to the cause of death. Clinically apparent pulmonary embolism occurs rarely when DVT is confined to calf veins, but if untreated calf vein thrombosis propagates to proximal veins in around 20% of cases, with an accompanying risk of significant pulmonary embolism. In some cases pulmonary embolism presents without identifiable DVT.

DVT is important because of the associated acute morbidity and risk of fatal pulmonary embolism, and also because of the potential long-term sequelae: a high risk of recurrent thrombosis, the development of chronic post-phlebotic symptoms, and pulmonary hypertension. The risk of recurrence after a first episode of apparently unprovoked proximal DVT of a lower limb is around 25% during the 5 years after discontinuation of

oral anticoagulant therapy and is highest during the first few months. However, the risk is considerably lower when the first event was precipitated by a transient risk factor, such as a surgical procedure. When the first episode of thrombosis affects the deep veins, the symptoms of recurrence are most commonly those of DVT also. Similarly, recurrence after a first episode of pulmonary embolism is typically with further pulmonary embolism.

Chronic post-phlebotic symptoms in the leg range from minor itching and swelling to intractable ulceration. Some degree of post-phlebotic syndrome is present in around 30% of sufferers of previous lower limb DVT 10 years after the event. It is most frequent and severe after recurrent thrombosis and uncommon after DVT confined to the calf vessels. The risk of development of pulmonary hypertension after pulmonary embolism may have been underestimated previously. Symptomatic pulmonary hypertension may be present in around 4% of subjects and is more likely if there has been recurrent pulmonary embolism.

Vessels other than the deep veins of the limbs may be affected by thrombosis, including superficial limb veins, the intracranial venous sinuses and visceral veins. The pathogenesis of superficial thrombophlebitis may differ from that of DVT. Thrombosis of retinal veins also appears to have a different pathogenesis and natural history.

As described in the preceding chapter, venous thromboembolic episodes result from the interaction of multiple risk factors. These may be gene–environment interactions or multiple environmental or acquired risk factors. In this chapter, the acquired conditions that predispose to venous thromboembolism (VTE) are considered, although in most cases it is likely

that the individual genotype influences the likelihood of thrombosis in particular circumstances. In addition to the factors listed in Table 46.1, there has been recent interest in an association between VTE and atherosclerotic disease and the metabolic syndrome.

Pregnancy and venous thromboembolism

Around 1 in 1000 pregnancies is complicated by DVT or pulmonary embolism. Massive pulmonary embolism is the leading cause of pregnancy-related death in the UK. Although the post-partum phase has been considered to be the time of highest risk, overall at least as many episodes of VTE occur antepartum, including some in the first trimester. There are notable clinical features in pregnancy-related DVT: around 90% of thromboses affect the deep veins of the left lower limb and the vast majority of cases involve the iliofemoral vein from the time of presentation; thrombosis restricted to the deep veins of the calf is uncommon in pregnancy but is more common after birth. The left-sided predominance most likely relates to the anatomical

relationship between the iliac artery and vein on that side. Many affected women develop post-phlebotic syndrome.

The pathogenesis of pregnancy-related VTE is multifactorial, as in other situations. For example, obesity may contribute. Unique factors include the raised intra-abdominal pressure and vascular compression caused by the gravid uterus, the suppressed systemic fibrinolytic capacity, the progressive increase in plasma concentrations of clotting factors from around 10 weeks' gestation, including factor (F)VIII and fibrinogen, and the fall in plasma concentration of the anticoagulant cofactor protein S. Tissue trauma from delivery contributes to the pathogenesis of post-partum VTE and operative delivery increases the risk further.

Although heritable thrombophilias contribute to the risk of pregnancy-related VTE, in around 70% of cases no hereditary thrombophilia can be identified and in 25% there is also no obvious risk factor other than otherwise normal pregnancy.

Immobility as a risk factor for venous thromboembolism

It is likely that venous stasis is a significant pathogenetic factor in VTE. For example, sitting still for 90 min reduces the flow through the popliteal vein by 50%. Immobility is a major contributor to hospital-acquired VTE, and is a factor in DVT in paralysed limbs and associated with splinting, for example in a plaster cast.

There has been considerable interest in the relationship between VTE and the physically cramped conditions encountered during travel, especially long-haul aircraft journeys. The term 'economy class syndrome' has been coined to encompass the occurrence of VTE during and after air travel. The level of risk of VTE has been exaggerated, partly due to media attention. Epidemiological data suggest a relative risk of around twofold, which persists for a few weeks after the journey. A similar level of risk applies to other modes of powered travel, including by road. Observational data indicate that the incidence of death from pulmonary embolism induced acutely by air travel is less than one in a million journeys. The duration of the flight is a factor, with some evidence that VTE risks begin to increase progressively with flight time of greater than 4 or 5 hours. As in other situations, the pathogenesis is multifactorial, for example the elderly and less mobile are more at risk. The contribution of the particular environmental conditions within a pressurized cabin, particularly hypobaric hypoxia, to hypercoagulability is disputed. At present it is reasonable to assume that any form of long-distance powered travel carries a low but increased risk of VTE and to recommend simple precautionary measures such as maintenance of hydration and calf exercises and ambulation in order to maintain venous flow in the lower limbs.

Iatrogenic venous thromboembolism

VTE is common in hospitalized subjects, despite the widespread adoption of physical and pharmacological methods of thromboprophylaxis. As indicated above, immobility is probably a significant contributory factor. In postoperative patients and acutely ill medical patients, features of the acute-phase response, such as increased fibrinogen and FVIII concentrations in plasma, and reactive thrombocytosis also play a part. The highest prevalence of VTE occurs after major orthopaedic surgery to the lower limb. In hip replacement and knee replacement surgery subclinical DVT is frequently detectable by imaging, although there is evidence that clinically significant VTE may be becoming less common due to improvements in surgical techniques and materials, as well as wider use of thromboprophylaxis.

Indwelling venous devices

Indwelling venous devices, such as Hickman catheters, are a significant cause of DVT, which may progress to complete occlusion of the superior vena cava. Up to 60% of patients with central venous catheters (CVCs) will develop a complication secondary to the device, thrombosis being one of the most common. Thrombosis associated with CVC may involve the catheter tip, the length of the catheter, the catheterized vessel in the upper limb, the central vasculature of the neck/mediastinum, or a combination of these. A higher incidence of thrombosis is seen in catheters with larger external diameters and those with a tip positioned distal to the superior vena cava. Other factors that predispose to a higher rate of catheter-related thrombosis include catheter infection, infusion of sclerosing chemotherapeutic agents, extrinsic vessel compression and a previous history of VTE.

Patients with CVC-related thrombosis may present with swelling and/or pain of the arm, neck or face. Some may present with symptoms suggestive of a pulmonary embolism or with catheter malfunction. Many of the symptoms are non-specific and for this reason imaging is required to confirm or exclude thrombosis. Contrast venography remains the reference standard for diagnosis of CVC-related thrombosis but this is invasive and may be painful. Ultrasonography is the most accurate non-invasive test, with a sensitivity and specificity of 93% and 95% respectively.

Treatment of CVC-related thrombosis remains poorly studied. There are several treatment options available: anticoagulation alone, systemic thrombolysis, low-dose local thrombolysis and catheter removal, or any combination of the above. Systemic thrombolysis may cause bleeding and should be avoided. Warfarin has been used to prevent catheter thrombosis in patients with cancer but appears to be ineffective and may result in increased bleeding. Almost all episodes of VTE in neonates are provoked by indwelling vascular devices.

Pharmaceuticals

Combined oral contraceptive

Iatrogenic VTE associated with use of the combined oral contraceptive is of particular importance because it affects healthy women in a young age group. The overall risk of VTE in a pill user is around fourfold to fivefold higher than in a non-pill user, although this is influenced greatly by the presence of some heritable thrombophilias, as described in the previous chapter. The risk is also increased by obesity and older age. Fortunately, the absolute risk remains acceptable because of the low background prevalence of thrombosis in women of childbearing age. Estrogen-containing preparations induce a state of reduced sensitivity to activated protein C, and this appears to be more marked with the third-generation contraceptives than second-generation preparations. (Most preparations in current use contain an equivalent dose of estrogen, usually 30–35 µg of ethinylestradiol. However, the progestagen content varies. In so-called second-generation oral contraceptives this is levonorgestrel, whereas in third-generation products it is desogestrel, gestodene or norgestimate.) There is convincing epidemiological evidence that the third-generation pills also carry a greater risk of clinical VTE. Progestagen-only oral contraceptives appear to carry a lower risk of VTE such that their use can be considered in women in whom the combined oral contraceptive is deemed to be contraindicated, for example due to previous VTE or presence of thrombophilia.

Hormone-replacement therapy

Hormone-replacement therapy (HRT) is also associated with VTE. In this case the absolute risk is higher due to the greater background prevalence of VTE in older women. Observational data indicate a very high rate of VTE in women with a previous history of venous thrombosis who embark upon HRT subsequently. Such is the level of risk that HRT is generally contraindicated in such women. If there are overwhelming indications for HRT (usually disabling menopausal symptoms) some clinicians consider warfarin thromboprophylaxis alongside HRT in high-risk situations. Also, the procoagulant changes induced by transdermal preparations appear to be less marked, suggesting that they may be less likely to provoke VTE than oral formulations and may be considered in those thought to be at increased risk of VTE.

Chemotherapeutic agents

Use of chemotherapeutic agents and adjunctive therapies in malignancy has been linked to VTE. Notable examples are asparaginase in acute lymphoblastic leukaemia, thalidomide in myeloma and tamoxifen in breast cancer. Tamoxifen blocks estrogen receptors but has weak estrogenic activity and this may underly the association with VTE. Asparaginase inhibits protein synthesis, and markedly reduced plasma concentrations of anti-

thrombin may be one mechanism of the prothrombotic state associated with its use. The pathogenesis of thrombosis associated with thalidomide has not been fully elucidated but it is noteworthy that some data suggest that aspirin may reduce the incidence of the complication. This potentially implicates platelets in the pathogenesis. It appears to be associated particularly with use of the agent in myeloma, rather than other indications.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is an important diagnosis because failure to recognize the syndrome carries a high risk of death from associated venous or arterial thrombosis. It is due to development of antibodies to a complex of heparin and platelet factor 4 that induces intravascular platelet activation and consumption. Typically, the platelet count begins to fall between 5 and 10 days after first exposure to heparin. In subjects with previous recent exposure it may occur earlier and very occasionally the thrombocytopenia develops after heparin has been discontinued. The condition may complicate heparin administered at any dose, including as perioperative thrombophylaxis and even when very low doses are used to maintain the patency of intravascular cannulae. Indeed, there are very occasional reports of a clinically identical syndrome developing in the absence of exposure to administered heparin. HIT is around 10-fold less common with low-molecular-weight preparations than with unfractionated heparin. The synthetic pentasaccharide fondaparinux appears unlikely to cross-react with HIT antibodies or to cause HIT. In contrast to other drug-related immune thrombocytopenias, the degree of thrombocytopenia is rarely severe and bleeding is not a feature. There may be systemic symptoms including fever and a local reaction at the heparin injection site, such as erythema or even skin necrosis after subcutaneous administration. Because of platelet activation there is often new thrombosis, and this may manifest before the platelet count reaches thrombocytopenic levels. When heparin has been administered to treat arterial disease the new thrombosis is most commonly arterial, and in treatment of DVT there is usually extension of the presenting thrombus, often with pulmonary embolism. Thrombotic stroke, myocardial infarction, visceral ischaemia and disseminated intravascular coagulation have all been reported.

Confirmatory laboratory tests are not entirely satisfactory. Immunoassays for heparin/platelet factor 4 are sensitive but lack specificity because a significant proportion of subjects treated with heparin have positive antibody tests but neither thrombocytopenia nor thrombosis. In contrast, bioassays which rely on activation of normal platelets in the presence of test plasma and a low concentration of heparin are specific but high sensitivity is difficult to achieve. Sensitivity is improved by use of platelet serotonin secretion as an end point and employment of donor platelets of proven sensitivity. Specificity

is achieved by the demonstration of a positive result with a low heparin concentration, which is absent in the presence of a high concentration. Because of the limitations of these confirmatory tests, monitoring of the platelet count and a high index of clinical suspicion are essential whenever heparin is administered.

The most practical approach to diagnosis outside the intensive care unit, where thrombocytopenia is common due to the other causes that may coexist with HIT, is the employment of a scoring algorithm based on the timing of onset of thrombocytopenia, presence or absence of new thrombosis, presence or absence of other potential cause of thrombocytopenia, and the degree of thrombocytopenia (the four T's algorithm). If the probability score is high, heparin should be stopped. When a high score is combined with an immunoassay, this results in improved sensitivity and specificity for HIT. Consideration of the antibody titre provides additional evidence, low-titre antibodies being less specific. A British Committee for Standards in Haematology guideline gives advice on the diagnosis and management of HIT using this approach.

When there is a noteworthy fall in the platelet count that cannot be accounted for in any other way, heparin, in all forms, must be discontinued. An alternative anticoagulant must be administered immediately as the risk of thrombosis persists for several days after heparin withdrawal. Warfarin given alone is contraindicated as massive thrombosis has been described in this situation, most likely due to the rapid fall in protein C caused by warfarin against a background severe prothrombotic state. Aspirin is insufficient. The antibody may cross-react with low-molecular-weight heparins and they should be avoided. Danaparoid is a mix of anticoagulant glycosaminoglycans, predominantly heparan sulphate and dextran sulphate, and has been used in HIT. There is a significant risk of cross-reactivity with the HIT antibody *in vivo*, which may not be predicted by *in vitro* testing. Lepirudin is used frequently in HIT. It carries no risk of cross-reactivity but there should be caution if used in the presence of renal impairment. Warfarin can be introduced once an adequate anticoagulant effect with the thrombin inhibitor has been established. Fondaparinux has been used, but experience is less than that with lepirudin and danaparoid.

The pathogenetic antibodies tend to become unmeasurable in the ensuing few months but further exposure to heparin should be avoided for at least 6 months.

Haemostatic treatments

Haemostatic treatments may induce thrombosis, most notably prothrombin complex concentrates. They should not be used to reverse the coagulopathy in severe liver impairment as major thrombosis has been reported, with disseminated intravascular coagulation and death in some cases. This is probably due to impaired clearance of activated clotting factors in liver failure.

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is an important thrombophilic condition because it is of high prevalence and is associated with considerable morbidity and mortality. The essential features are arterial or venous thrombosis or recurrent pregnancy loss or placental dysfunction occurring in a subject in whom laboratory tests for antiphospholipid antibody are positive. Diagnostic criteria have been established in order to standardize diagnosis for the purposes of clinical studies (Table 46.2).

Limb DVT, pulmonary embolism and ischaemic stroke are the principal thrombotic manifestations, but any vessel may be involved. A characteristic of APS in an individual patient is the tendency to cause recurrent problems in the same vascular bed. The full range of clinical features is not necessarily present. For example, women can have severe thrombotic events without pregnancy complications and those with pregnancy complications most commonly have no other manifestation. In addition to thrombosis and pregnancy failure, additional clinical and

Table 46.2 Diagnostic criteria in APS.

Clinical criteria*

Thrombosis: arterial, venous or microvascular thrombosis in any tissue or organ

Laboratory criteria*

Antiphospholipid antibody

IgG or IgM anticardiolipin antibodies at moderate or high concentration[†]; IgG or IgM anti- β_2 -GPI >99th percentile and/or

Lupus anticoagulant

Pregnancy complications

Unexplained death of morphologically normal fetus at or beyond 10 weeks of gestation

Three or more unexplained consecutive miscarriages before 10 weeks

One or more premature births of a morphologically normal fetus before 34 weeks of gestation due to pre-eclampsia, eclampsia or severe placental insufficiency

*There must be at least one clinical and at least one laboratory criterion present. The laboratory test must be consistently positive on at least two occasions 12 weeks apart as transient antibodies may occur, for example in infection. Such antibodies are not usually associated with clinical events.

[†]Evidence on the definition of moderate/high concentration. In general, values of IgG anticardiolipin > 40 GPLU are considered to be moderate-titre antibodies; >99th percentile has been employed also. The significance of low-titre antibodies is less clear.

laboratory features are variably present in APS. These include mild thrombocytopenia and an unusual dermatological feature, livedo reticularis. Cardiac valvular abnormalities occur in up to 30% of patients, but are usually subclinical. Most commonly the mitral or aortic valve is affected, often with valve thickening or incompetence. However, haemodynamic changes as a consequence of valvular damage are rare. Exceptionally, the syndrome may manifest as widespread microvascular occlusion, with multiorgan failure, so-called catastrophic APS.

APS may occur with another chronic systemic autoimmune disease, usually systemic lupus erythematosus (SLE), when the term 'secondary antiphospholipid syndrome' is used. In primary APS there is no evidence for another relevant underlying condition.

Antiphospholipid antibodies

Antiphospholipid antibodies are a family of antibodies reactive with proteins that have the property of binding to negatively charged phospholipids. The most important is β_2 -glycoprotein I (β_2 -GPI), as pathogenic antibodies (i.e. those most strongly associated with clinical events) are most frequently reactive with this protein. β_2 -GPI is a member of the complement control protein family. It has five domains. It is now known that antiphospholipid antibodies reactive with each of these five domains may occur but it is only those which recognize a specific epitope on domain I that are pathogenic. Antibodies to other proteins which have affinity for negatively charged phospholipid have been implicated in the syndrome, including protein C, protein S and annexin V.

The lupus anticoagulant (LA) is an *in vitro* phenomenon in which the antiphospholipid antibody slows clot formation, thereby lengthening the clotting time. This is probably due to impairment of the assembly of the components of prothrombinase on phospholipid due to interference by the antibody (Figure 46.1). LA is due to antibodies reactive to β_2 -GPI/

Figure 46.1 Antiphospholipid antibody binding: explanation for the lupus anticoagulant phenomenon.

phospholipid or to prothrombin/phospholipid. The β_2 -GPI-dependent antibodies also bind in anticardiolipin assays, as the glycoprotein is present in test serum and often in assay reagents. LA due to prothrombin-reactive antibodies may be negative in anticardiolipin assays. Therefore some subjects with APS have LA and anticardiolipin and some LA only. Others have anticardiolipin without LA, due to the presence of non- β_2 -GPI and non-prothrombin-dependent antibody or possibly to relative insensitivity of the coagulation assays for LA. Because antiphospholipid antibodies are so heterogeneous, a comprehensive laboratory approach is essential for their reliable detection. In most laboratories, ELISAs employing cardiolipin and coagulation-based assays for LA remain the principal diagnostic tools. ELISA for β_2 -GPI may offer improved specificity. The pathogenicity of IgA anticardiolipin antibodies is disputed and their detection is not utilized routinely in diagnosis.

Pathogenic mechanisms in APS

The pathogenesis of pregnancy failure and thrombosis in APS is not fully understood. Animal experiments support a pathogenic role for antibodies to β_2 -GPI. Important candidate mechanisms for thrombosis are antibody-induced concentration of prothrombin on phospholipid surfaces *in vivo* resulting in enhanced thrombin generation, interference with the activated protein C anticoagulant pathway, increased von Willebrand factor activity, and increased monocyte and endothelial tissue factor expression. Increased platelet activation and inhibition of fibrinolysis by antiphospholipid antibodies have also been proposed. In relation to pregnancy failure, again numerous pathogenic mechanisms have been proposed. It is noteworthy that early miscarriage is a common feature and occurs before full placentation. This raises doubts whether a thrombotic mechanism is causal. Therefore, it is of considerable interest that a body of evidence is accumulating for a role of complement activation in pregnancy loss in APS. Of particular note in this context, heparin is effective in preventing embryo loss in a murine model of APS and it does so through inhibition of complement rather than via an anticoagulant mechanism. This raises the possibility that similar mechanisms may be relevant to early pregnancy loss in women with APS. Placental dysfunction is the hallmark of second- and third-trimester complications of intrauterine fetal death, intrauterine growth restriction, pre-eclampsia and placental abruption. The aetiology of the placental dysfunction has been related to placental infarction and an acute atherosclerosis in the maternal spiral arteries, although these are not universal features. One interesting hypothesis for the cause of placental insufficiency is displacement of annexin V from trophoblast by antiphospholipid antibodies, with resultant acceleration of thrombin generation on the exposed negatively charged phospholipid.

Laboratory diagnosis of antiphospholipid antibodies

In diagnosing APS it is essential to consider that antiphospholipid antibodies are not specific to the syndrome. In addition to transient antibodies, which may for example be triggered by intercurrent infection, some chronic infections are associated with antiphospholipid antibodies, such as syphilis and hepatitis C. Antiphospholipid antibodies may also be detected incidentally in healthy subjects and they occur in relation to use of some drugs, particularly chlorpromazine. These drug-induced and infection-related antibodies do not usually appear to be associated with the clinical thrombotic manifestations of APS. In some cases they appear to be neither β_2 -GPI nor prothrombin dependent.

The diagnosis of APS relies on the demonstration of the persistent presence of either LA by coagulation tests or of antiphospholipid antibodies by solid-phase immunoassays for anticardiolipin and/or β_2 -GPI. Reliance on just one type of assay may lead to false-negative assessment of antiphospholipid antibodies. Overall, among the commonly applied assays, it appears that those for LA associate most strongly with clinical events. In relation to solid-phase assays, high-titre antibodies and IgG antibodies associate more strongly with clinical manifestations than do IgM and lower-titre antibodies.

Coagulation assays (lupus anticoagulant tests)

The LA assay is a double misnomer for it is neither a test for SLE nor for an *in vivo* anticoagulant. LA tests are indirect assays that rely on slowing of the clotting time of plasma through interference by antiphospholipid antibodies. The tests most frequently employed are the activated partial thromboplastin time (APTT), the dilute Russell's viper venom time (DRVVT) and, less frequently now, the kaolin clotting time (KCT).

Platelet activation causes exposure of negatively charged phospholipid at the cell surface and therefore contamination of test plasma with platelets must be minimized, as these will limit the sensitivity of tests particularly when plasma must be stored frozen prior to testing. Platelet depletion may be achieved in various ways, most commonly by careful double centrifugation.

None of the above coagulation assays is specific for LA. Specificity and sensitivity are also reagent dependent. For example, some partial thromboplastin reagents are insensitive to LA. If the same reagent is employed for LA tests as in routine laboratory screening for coagulopathy, sensitivity to LA must be assured. Factors that lengthen or shorten clotting times (other than antiphospholipid antibodies) potentially interfere in LA tests. Examples are anticoagulant drugs and clotting factor deficiencies and inhibitors, which lengthen clotting times, and increased clotting factor levels, especially FVIII, which shortens the time to clotting in the APTT for example, potentially masking the presence of LA.

In order to reduce the risks of false interpretation, in addition to prolongation of clotting time in a phospholipid-dependent coagulation test, the criteria for LA positivity also include (i) evidence of an inhibitor demonstrated by mixing studies and (ii) confirmation of the phospholipid-dependent nature of the inhibitor. In principle, laboratory tests should employ a detection or screening stage (prolongation of the clotting time) and a confirmation stage showing (i) failure of correction of the prolongation when normal plasma is added in order to exclude factor deficiency as the cause of the prolongation and (ii) that the prolongation is phospholipid dependent, for example by showing that addition of excess phospholipid corrects the clotting time. To achieve this, and because no LA test consistently shows 100% specificity and sensitivity, more than one test system should be used for detection of LA. The prothrombin time and thrombin time should also be performed as they are not usually affected by the presence of LA and the results assist in the interpretation of LA tests, for example when there is undisclosed anticoagulant therapy.

The APTT is commonly employed as the initial screening test for LA. Its specificity for inhibitor detection is improved by inclusion of a mixing study with platelet-free normal pooled plasma. When prolongation of the APTT is due to coagulation factor deficiency, the clotting time corrects when the test is repeated on an equal mixture of patient and normal plasma, whereas the prolongation above normal may persist with LA, consistent with its inhibitory activity. However, correction in a mixing study does not exclude LA, as a weak antibody is obviously diluted out by addition of normal plasma and this may be sufficient to abolish its effect. Very occasionally LA causes enhancement of the prolongation of the APTT when normal plasma is added. This phenomenon has been called the lupus cofactor effect but is the exception rather than the rule. Inhibitors to clotting factors, usually FVIII, are associated with bleeding rather than thrombosis but also cause prolongation of the clotting times which may not be corrected by addition of normal plasma. Typically, FVIII inhibitors are time-dependent, unlike LA. Diagnostic confusion may arise due to LA that prolongs the APTT, causing erroneously low results in coagulation factor assays based on the APTT. A normal APTT is insufficient to exclude LA and additional tests must be performed.

The DRVVT does not involve the clotting factors of the extrinsic system, unlike the APTT, nor FVII, unlike the prothrombin time. Any inhibition of coagulant-active phospholipid in the test by LA results in a prolonged DRVVT. However, as is the case with all LA tests, it is not specific. Deficiencies of clotting factors, for example FII and FX due to warfarin therapy, will also prolong the DRVVT. The specificity of the test is improved by repeating it in the presence of a high concentration of phospholipid, which should result in partial or complete correction of the prolonged clotting time if it is due to LA. This phospholipid is conveniently provided as platelet membranes in which negatively charged phospholipid is exposed by freezing

and thawing. In the presence of LA, the ratio of test to normal plasma clotting time is often in excess of 1.2, and corrects to less than 1.2, or at least partially, in the platelet neutralization procedure. As with all coagulation tests, because of variations in reagents and techniques it is essential that laboratories derive local normal ranges using a large number of plasma samples from healthy volunteers.

In the KCT no additional phospholipid is employed. The test therefore resembles the APTT in that it involves the extrinsic and common pathways of coagulation but the sensitivity to LA is enhanced because the small amount of phospholipid present is only that derived from residual platelets in the test sample and plasma lipids. The test is affected by clotting factor deficiencies and anticoagulants, but specificity can be improved by use of normal plasma mixing at more than one ratio to test plasma. LA is identified when the KCT fails to correct even after relatively large proportions of normal plasma are added, whereas in factor deficiency the KCT is corrected with small amounts of normal plasma.

Alternative tests for LA may be employed but are not in general use. They include the tissue thromboplastin inhibition test and clotting tests that use venoms other than Russell's viper venom. Examples are Taipan and Textarin venoms. Many laboratories rely on commercial assay kits for LA testing. It is essential that steps are taken to ensure internal and external quality assurance.

Solid-phase assays (for anticardiolipin and anti- β_2 -GPI antibodies)

Solid-phase assays for antiphospholipid antibodies, such as the anticardiolipin ELISA, allow rapid processing of numerous serum samples and the results are not affected by factor deficiency or the use of anticoagulants. The introduction of international standards allows the calculation of anticardiolipin results in IgG or IgM antiphospholipid units (GPLU and MPLU, respectively) related to a given concentration of affinity-purified anticardiolipin immunoglobulin. Despite this, there remains a lack of precision, and comparability between laboratories using different assays is not ensured. Clinicians should be aware of the performance of the assay in use.

The detection of anticardiolipin allows the diagnosis of APS in a subject with an appropriate clinical history, even when LA is absent. However, the anticardiolipin assay is not a substitute for the LA test, nor does it confirm that LA is present due to the antibody heterogeneity referred to above. Furthermore, the clinical significance of low-titre anticardiolipin is doubtful. Thus, in cases where the anticardiolipin titre is less than 30GPLU and tests for LA are negative, a diagnosis of APS may not be conclusive. Under these circumstances it is particularly important to consider other causes of thrombosis or miscarriage.

Specific assays for anti- β_2 -GPI antibodies have been developed, and several commercial kits are available. Anti- β_2 -GPI

antibody assays may show higher precision and better correlation with the thromboembolic complications in APS and SLE than assays for anticardiolipin, and are less likely to show transient positive results in association with infection. Antiprothrombin antibodies generally exhibit poor specificity for venous thrombosis and recurrent fetal loss, and may be found in patients with infection, and are not included in the consensus criteria for diagnosis of APS.

The prevalence of antiphospholipid antibodies in subjects with thrombosis varies with selection criteria for testing. Because the risk of recurrent thrombosis appears to be great, antiphospholipid antibodies should be sought in subjects with arterial, venous or microvascular thrombosis where no other cause is apparent. Examples are younger subjects with ischaemic stroke in the absence of cardiovascular disease and subjects with unprovoked VTE.

The prevalence of persistent antiphospholipid antibodies among women with recurrent first-trimester miscarriage is around 15%, although a proportion of these are low-titre antibodies. In women with recurrent miscarriage due to APS the prospective fetal loss rate may be as high as 90%. In contrast, the prevalence of positive tests for antiphospholipid antibodies in unselected women of childbearing age is around 3% and they are not sensitive predictors of poor pregnancy outcome in women with no history of pregnancy complications. Because miscarriage is a common phenomenon, screening for antiphospholipid antibodies is not indicated after a single event. Maternal antiphospholipid antibodies may be downregulated during pregnancy, so tests are best performed preconceptionally when possible. A small proportion of women with antiphospholipid antibodies also have anti-Ro antibodies. Their detection is important as anti-Ro is associated with a 2% risk of complete heart block in the fetus and a 10% chance of neonatal lupus.

Management of APS

Thrombosis

There is wide variability in severity of prothrombotic states between individuals with APS. The management of patients with antiphospholipid antibodies and previous thrombosis remains contentious. Retrospective observational studies suggested that these patients should remain on indefinite oral anticoagulation, maintaining an International Normalized Ratio (INR) of 3–4. However, subsequent prospective randomized studies indicate that a lower target INR of 2–3 is effective in preventing recurrent thrombosis in the majority of patients with previous venous thrombosis. There is less certainty in arterial thrombosis; for example, clinical observation suggests that there is a significant subpopulation of APS with small-vessel thrombosis, some evident as lacunar infarcts on magnetic resonance imaging, who appear to require a target INR of 3–4 to prevent recurrent cerebral thrombosis.

Immunosuppressive therapy is not generally indicated in primary APS other than in the very rare case where thrombosis recurs despite intensive anticoagulant therapy. Corticosteroids and other immunomodulatory therapies have been administered. An exception may be catastrophic APS when combination treatment with antithrombotics, corticosteroids and other immunomodulatory therapies such as rituximab are administered as potentially life-saving emergency measures.

Pregnancy

The management of recurrent fetal loss is based on the use of anticoagulation with empirical doses of heparin, usually low-molecular-weight heparin in the UK, often in combination with low-dose aspirin. Initial studies indicated that this approach increases the chance of a successful outcome of a healthy live birth from 30 to 70–80%, although the total number of cases in randomized studies is limited and trials have given conflicting results. Nevertheless, low-molecular-weight heparin prophylaxis has become standard, although some clinicians believe that combination antithrombotic therapy as a first line should be reserved for women with a previous history of fetal death while those with recurrent miscarriage should be given supporting care as first line, with aspirin or aspirin/heparin reserved for those with further pregnancy failure. Corticosteroids are ineffective and their use is associated with frequent maternal morbidity from hypertension, glucose intolerance and premature labour.

Thrombophylaxis for those with APS and a previous history of thrombosis is based again on use of low-molecular-weight heparin, although there is neither consensus on dosing nor the need to monitor therapy.

Venous thromboembolism and cancer

Cancer is a major risk factor for VTE. VTE is the major cause of morbidity and mortality after the cancer itself in patients with malignancy. It is estimated that almost 15% of cancer patients will have a thromboembolic event. Post-mortem studies have shown that thromboembolism is common in patients who die of cancer. Of all oncology patients, palliative-care inpatients have the highest risk of VTE with a DVT prevalence that may be as high as 50%, including bilateral deep vein thromboses. Chemotherapy may also increase that risk: thalidomide is a prominent example. The risk of thrombosis varies with type of cancer, ovarian, brain and pancreatic cancers having the highest rates. Lymphomas and leukaemias account for a significant proportion of thromboses as do colonic and lung cancers.

In Trousseau syndrome, the cancer-related phlebitis is recurrent and migratory and affects both the superficial and deep veins, in contrast to the more common association of lower limb DVT in cancer. Unusual sites such as arms and neck, as

well as superficial veins of the thorax and abdomen may be involved. Typically, such a patient has an occult tumour, usually adenocarcinoma, although it is also a feature of acute leukaemia. In Trousseau syndrome, conventional anticoagulation often fails to prevent recurrent thromboses.

Prothrombotic changes associated with malignancies

In Table 46.3 the components of Virchow's triad are used to illustrate the features that lead to oncology patients having such a high risk of thrombosis. There are specific abnormalities unique to cancer patients, the so-called tumour procoagulants. Tumour procoagulants are surface molecules on cancer cells that activate coagulation. The two principal tumour cell procoagulants are tissue factor and cancer procoagulant. The latter directly activates FX without involvement of FVII. The increasing number of tumour procoagulants that have been described are listed on the International Society for Thrombosis and Haemostasis registry. APS has also been reported in malignancy, particularly in association with paraproteins.

Difficulties in management

Cancer patients with thrombosis are at particularly high risk of recurrent thrombotic events. Cohort and population-based studies have shown that the risk of recurrence after stopping anticoagulation in cancer patients is approximately double that in non-cancer patients. Treatment with anticoagulation in cancer patients is often unsuccessful, due to the high risk of recurrent VTE and major bleeding. Unfortunately, these risks are associated with oral anticoagulation intensities within the usual therapeutic range. The risks are greatest during the first

few weeks of anticoagulation treatment and increase with cancer extent. Several studies have demonstrated significant increases in rates of bleeding, as high as 20% among cancer patients receiving oral anticoagulation. Within the palliative care setting, where patients have far more advanced disease, the bleeding incidence was higher, even with strict monitoring of anticoagulation. Oral anticoagulation in cancer patients is complicated further due to anorexia, vomiting, liver impairment and drug interactions. Moreover there may be frequent interruption to treatment due to thrombocytopenia and the need for invasive procedures, and venous access is often difficult in these patients especially if they have had previous chemotherapy through peripheral veins.

The decision to use oral anticoagulation in this group of patients should not be taken lightly and safe treatment requires intensive monitoring of INR and the burden of repeated blood tests. Disillusionment with the use of oral anticoagulation in cancer patients has led to trials assessing low-molecular-weight heparins in cancer. The CLOT trial randomized over 650 cancer patients with symptomatic proximal DVT and/or pulmonary embolism to treatment with dalteparin for 5–7 days and then randomization to either oral anticoagulation maintaining a target INR of 2.5 or dalteparin. In the dalteparin arm a full treatment dose was given for 1 month and then reduced to 75–80% of this dose. After 6 months there was a significantly reduced rate of recurrent VTE in the dalteparin group of 8.8% compared with 17.4% in the group with oral anticoagulation. Bleeding was also significantly reduced. A similar reduction in VTE was found in patients with cancer who entered the LITE study where treatment dose tinzaparin was compared with oral anticoagulation after VTE. These data support the use of low-molecular-weight heparin rather than warfarin in patients with cancer and VTE.

Thrombotic risk in polycythaemia rubra vera and essential (primary) thrombocythaemia

If left untreated, patients with polycythaemia vera (PV) have a median survival of 18 months, with the majority dying of vascular occlusion. The occlusive lesions may involve the larger vessels or the microvasculature. In PV, large-vessel events involve arteries and veins equally whereas in essential thrombocythaemia (ET) arteries are more commonly involved. A high proportion of thromboses occur in the cerebral circulation, although thrombosis widely distributed in the arterial and venous systems, including the splanchnic vessels, has been well documented. Hepatic vein and portal vein thromboses are more commonly associated with PV than ET. Indeed it has been reported that some patients with apparently idiopathic hepatic or portal vein thrombosis have subclinical myeloproliferative disease based on the finding of erythropoietin-independent erythroid colony growth in marrow culture or presence of JAK2 mutation. In PV there is good evidence that the incidence of

Increased platelet activation

vascular occlusion is positively related to the packed cell volume, with the lowest incidence in patients with good control of haematocrit. The role of thrombocytosis in risk of thrombosis in PV is disputed. The risk of thrombosis in PV also increases with advancing age and a past history of thrombosis.

ET is often diagnosed in the subclinical phase but a number of studies suggest that overall survival is determined principally by occurrence of thrombosis. In one study the rate of thrombosis ranged from around 2% per patient-year in those aged less than 40 to 15% in those aged greater than 60. In around 50% of cases of ET, the JAK2 V617F mutation is detectable. Whether subjects with the mutation are more likely to develop thrombosis is a subject of current investigation.

The pathogenesis of thrombosis in ET is poorly understood. Elevated platelet counts are implicated, with platelet counts greater than $600 \times 10^9/L$ being associated with increased incidence of vascular occlusion. Although treatment to reduce abnormal counts will reduce the frequency of events, a proportion of patients will still experience thrombosis. In addition, some patients with ET will remain thrombosis-free with no treatment to reduce their platelet count.

The microvascular events and vasomotor manifestations of both PV and ET almost certainly relate to quantitative and qualitative changes in platelets, for they are not seen in other forms of polycythaemia or thrombocytosis. It is possible that similar small-vessel occlusive and vasomotor changes seen in the feet and hands may also occur in other parts of the body. Erythromelalgia, a syndrome consisting of painful burning red extremities with normal peripheral pulses, is the characteristic vasomotor disturbance. Physical findings may be absent or there may be warmth, duskiness and mottled erythema of the involved areas. Livedo reticularis is occasionally found. In the digital vessels, usually of the toes but occasionally the fingers, the development of thrombosis can lead to digital ischaemia and gangrene. In relation to the cerebral circulation, a range of symptoms and signs including transient cerebral ischaemia, transient monocular blindness, migraine, headaches and seizures are seen. Both the cerebrovascular complications and erythromelalgia of myeloproliferative disease may respond promptly to low-dose aspirin and/or platelet cytoreduction.

Conventional risk factors for cardiovascular disease are implicated in the pathogenesis of thrombosis in ET, including hypertension, smoking, hypercholesterolaemia and diabetes, and should be considered in deciding whether cytoreductive therapy is indicated.

Acute promyelocytic leukaemia

In comparison with the severe haemorrhagic presentation in the majority of cases of acute promyelocytic leukaemia (APL), acute arterial thrombosis is a rare presenting feature. Thrombosis is associated with the microgranular variant of APL, which accounts for 25% of all cases, characterized by a paucity of

myeloid granules and a lobulated monocytoic nucleus. The cells stain positive with Sudan black and myeloperoxidase and there is a high incidence of CD34 positivity. Vascular occlusion is more common when a high white cell count ($> 150 \times 10^9/L$) predisposes to leucostasis. It is thought that the leukaemic cells release procoagulants. It is important to recognize this variant of APL because the use of all-*trans* retinoic acid may increase the risk of thrombosis due to a further increase in peripheral white cell count exacerbating leucostasis.

Inflammation and thrombosis

Systemic inflammation is a potent prothrombotic stimulus (Table 46.4). Inflammation upregulates procoagulant factors, downregulates physiological anticoagulants, inhibits fibrinolytic activity and increases the platelet count. Inflammatory mediators promote coagulation by causing endothelial cell activation and increasing the expression of tissue factor. Endotoxin, tumour necrosis factor (TNF) and interferon- 1α induce tissue factor expression primarily on monocytes/macrophages and probably in atherosclerotic plaques as well. Thrombin, a key enzyme in coagulation, also has cytokine-like activities for it augments leucocyte adhesion and can activate endothelium, leucocytes and platelets. Thrombin-mediated signalling through protease-activated receptor (PAR)-1 on vascular cells has recently been shown to mediate production of chemokines such as MCP-1, leading to recruitment of inflammatory cells including monocytes. Activation of these cells by thrombin increases the expression of negatively charged phospholipids such as phosphatidylserine on the surface of the cells, promoting surface procoagulant activity.

Interleukin (IL)-6 and its family of molecules mediate the acute-phase response. This increases liver synthesis of plasma proteins including fibrinogen and other coagulation proteins,

thus priming the blood coagulation system for action. IL-6 also increases platelet reactivity. Plasma levels of the recently discovered vitamin K-dependent anticoagulant protein Z, which acts by inhibiting FXa, fall during inflammation; thus protein Z appears to be a negative acute-phase protein.

Of all the physiological anticoagulant pathways, the protein C pathway appears to be the most influenced by inflammation. Thrombomodulin and endothelial cell protein C receptor are both downregulated by inflammatory cytokines such as TNF- α . There is inhibition of the promoter of the thrombomodulin gene as well as active pinocytosis to remove existing surface molecules, while neutrophil elastase readily cleaves thrombomodulin from the endothelial cell surface. Moreover, thrombomodulin is very sensitive to oxidation of an exposed methionine by oxidants produced by leucocytes. These observations have led to studies demonstrating apparent therapeutic value of activated protein C in subjects with multiorgan failure due to severe sepsis.

Endothelial cell activation occurs in inflammation. This causes downregulation of fibrinolytic activation by increased production of plasminogen activator inhibitor (PAI)-1. There may also be cleavage of glycosaminoglycans from the surface of the endothelium, so that there is loss of heparan sulphate and other molecules that activate antithrombin.

As a consequence of these changes, conditions that provoke an inflammatory response are associated with increased risk of venous thrombosis. These include inflammatory bowel disease, Behçet disease, systemic tuberculosis, SLE and diabetes. Atherosclerosis can be considered a chronic inflammatory state and has recently been associated with an increased incidence of venous thrombosis and, more recently, the metabolic syndrome has been implicated. Furthermore, epidemiological studies indicate an excess of minor illness, including infections, in the weeks preceding episodes of VTE. The association between inflammation and thrombosis emphasizes the need for thromboprophylaxis in patients hospitalized on medical wards. Implementation of pharmacological thromboprophylaxis has been inadequate in such patients.

Haematological prothrombotic states due to non-malignant diseases of the blood and bone marrow

Paroxysmal nocturnal haemoglobinuria (see Chapter 11)

Venous thrombosis occurs in up to 40% of patients with paroxysmal nocturnal haemoglobinuria (PNH) and represents a significant cause of morbidity and mortality. Frequently it is the presenting feature. Thrombosis most commonly occurs in the hepatic veins, portal veins and sagittal sinus. Hepatic vein thrombosis leading to Budd–Chiari syndrome is the common-

est site and affects 15–25% of patients with PNH. Presentation is with pain in the right upper quadrant, jaundice and abdominal distension due to hepatomegaly and ascites. Thrombosis in splanchnic veins results in persistent abdominal pain, and symptoms and signs of intestinal obstruction may occur if infarction of the bowel ensues. Thrombosis of the splenic vein leads to splenomegaly and occasionally splenic rupture can occur. Portal vein thrombosis produces ascites and the later development of oesophageal varices. Sagittal sinus thrombosis is the most frequent neurological complication. Symptoms include severe headache. There may be evidence of raised intracranial pressure, impaired conscious level and focal neurological signs. Occasionally, painful discoloured skin lesions occur when the dermal veins are affected. These lesions rarely ulcerate. Occasionally, skin lesions can resemble purpura fulminans; these can affect large areas of skin with necrosis and demarcation. Pregnancy in PNH is associated with an increased risk of fetal loss (40%) as a result of thrombosis and haemorrhage.

The pathogenesis of thrombosis in PNH remains uncertain. Platelets are capable of compensating for the decreased expression of decay accelerating factor (CD55) due to the presence of factor H, a similar protein, that is present within α -granules. In PNH there is also a deficiency of membrane inhibitor of reactive lysis (MIRL, CD59), a glycosylphosphatidylinositol (GPI) anchor-dependent protein. In the absence of CD59, platelet lysis is minimized by the release from the cell surface of excess membrane attack complex by exovesiculation. The externalized phosphatidyl serine on the microvesicles released into the circulation acts as the binding site for prothrombinase complex. It is likely that the release of procoagulant microvesicles contributes to the increased risk of venous thrombosis. Increased platelet activation and an increased sensitivity to aggregation by thrombin have also been described. Fibrinolysis is also affected in PNH. Urokinase-type plasminogen activator receptor is also a GPI-bound protein that is absent from PNH cells. It binds urokinase to the cell surface and converts plasminogen to plasmin.

Thrombotic thrombocytopenic purpura

See Chapter 44.

Sickle cell disease

In sickle cell disease the pathophysiology involves microvascular and macrovascular occlusion with sickled cells. There is also considerable clinical and post-mortem evidence of cerebral, pulmonary and placental thrombosis, suggesting a prothrombotic tendency in these patients. Additional evidence for a prothrombotic state is enhanced thrombin generation, as shown by increased levels of prothrombin fragment 1+2 and thrombin–antithrombin, in patients with sickle cell disease in their steady

state when compared with age-matched controls. There is also evidence that sickled erythrocytes adhere more readily to vascular endothelium and strongly accelerate coagulation due to abnormal exteriorization of procoagulant anionic membrane phospholipids. Comparison of the coagulation and fibrinolytic pathways in sickle cell patients with ethnically matched controls has shown increased levels of von Willebrand factor during sickling, although it is not clear whether this is specific or part of the acute-phase reaction. Low levels of protein C, protein S and heparin cofactor II are well described. The aetiology of the reduction of these physiological anticoagulants is unclear. It may relate to impaired liver function from repeated hepatic sickling, whereas increased consumption has also been proposed as a cause. Low heparin cofactor II levels are also found in other chronic haemolytic anaemias such as thalassaemia intermedia, suggesting that chronic haemolysis may also lead to increased consumption of this protein. Nephrotic syndrome, sometimes associated with sickle nephropathy, leads to low antithrombin levels and a prothrombotic state.

Introduction and epidemiology

Venous thromboembolism (VTE), which comprises deep vein thrombosis (DVT) and pulmonary embolism (PE), is responsible for an estimated 60 000 deaths annually in the UK based on epidemiological modelling. The clinical incidence of VTE is about 1 per 1000 per annum in adults, with a slight preponderance in men. Two-thirds present as DVT and one-third as PE. The major outcomes are death, recurrent VTE, post-thrombotic syndrome, pulmonary hypertension and major bleeding due to anticoagulation. Within 1 month of diagnosis, about 6% of patients with DVT and 10% of those with PE die. The mortality rate for PE has been estimated to be as high as 30% in some patient groups due to the high failure rate of recognizing PE before death, with mortality rates being highest in those with cancer.

Despite the incidence of VTE increasing with age (1 per 10 000 per annum under 30 years of age and 5–6 per 1000 per annum by the age of 80), deaths also occur in the younger age group due to failure to consider the diagnosis. The increased numbers of VTE with ageing may relate to the increasing presence of other illnesses and also an inherent increased coagulability with ageing.

Approximately 60% of cases of fatal PE are hospital acquired, i.e. 32 000 per annum in the UK with 25 000 being preventable with appropriate thromboprophylaxis. Interestingly, more VTE is diagnosed in the 3 months following hospitalization than during admission. As a rule of thumb, in the natural history of post-orthopaedic surgery, the median time for DVT to present is 7 days after the event, with PE presenting 21 days postoperatively. Thus both cases and fatalities usually occur after hospital discharge, which is why 'hospital-acquired VTE' rather than 'hospital VTE' is considered appropriate. However, within hospital PE accounts for 10% of deaths.

Mechanisms

Virchow's triad described in 1859 remains the best model of venous thrombogenesis. Changes in blood flow, vessel wall or blood coagulability comprise the triad, and usually a combination of these are present. The multi-hit hypothesis of thrombosis recognizes that more than one factor is usually operating to cause VTE, although the number of factors required to cause thrombosis decreases with ageing. The major risk factors are given in Table 47.1. Immobility is the key factor in those who do not have major thrombophilias or vessel wall abnormalities, and increases the risk of VTE 10-fold. Just sitting still for 90 min reduces blood flow in the popliteal vein by 40%. The term 'seated immobility syndrome' (also known as SIT syndrome) has been coined to encompass VTE precipitated by prolonged

sitting, the term thus encompassing traveller's thrombosis and 'e-thrombosis' (caused by sitting at a computer workstation).

Diagnosis of venous thromboembolism

Diagnosis relies on the use of objective diagnostic methods. Over 80% of DVT episodes are clinically silent and often confined to the calf veins. The concern is that such asymptomatic DVT can become symptomatic and/or embolize. There is no way of predicting which patients will develop symptomatic VTE, and it is well recognized that significant numbers of massive fatal PE occur without warning and as a result of asymptomatic DVT. Thus the clinical approach to VTE is to maintain a high index of suspicion and to treat until the diagnosis is refuted or confirmed by objective testing.

Clinical presentation of PE depends on the size, location and number of emboli and the patient's underlying cardiorespiratory reserve. The classic triad of chest pain, haemoptysis and dyspnoea is present in less than 20% of patients, while 97% of patients with PE have at least one of the following: pleuritic chest pain, dyspnoea, respiratory rate above 20/min. Tachycardia and tachypnoea are the most frequent signs. A right-sided S3

Table 47.2 Clinical scores used for predicting the probability of DVT prior to further testing.

<i>Risk factors, symptoms or signs</i>	<i>Points</i>
Active cancer (treatment ongoing or terminated within 6 months or palliative care)	1
Paralysis, paresis, recent plaster cast on the leg	1
Recent confinement to bed of more than 3 days or major surgery within 12 weeks	1
Localized tenderness along the deep venous system	1
Swelling of the entire leg	1
Calf circumference > 3 cm larger than the asymptomatic leg (measured 10 cm below the tibial tubercle)	1
Pitting oedema (more on the symptomatic side)	1
Collateral flow in superficial veins (not varicose veins)	1
Previous DVT	1
Alternative diagnosis as or more likely than DVT	-2

In the case of symptoms from both legs, the leg with the most pronounced symptoms is used.

sound, widely split second sound, the murmur of tricuspid regurgitation and an accentuated S2 closure sound may be found. Fever is present in 14%. Massive PE has a mortality of 18–33% and may present with shock, dyspnoea and confusion.

Chest radiography may show either nothing specific or the Westermark sign (dilatation of the pulmonary artery proximal to the emboli with sharp cut-off), while ECG may not show the classic signs of right ventricular strain such as P pulmonale and S1Q3T3. Arterial blood gases and transthoracic echocardiography have too low sensitivity. The main role of these tests is to exclude other conditions, such as acute myocardial infarction. However, risk factors for VTE and clinical symptoms and signs with the highest predictive value can be assigned points that are added to obtain a clinical 'score' (Tables 47.2 and 47.3) that can be used as the first step in a diagnostic strategy to reduce costs and the requirement for invasive diagnostic procedures.

The next step is the measurement of fibrin D-dimers, which are split products of fibrin degraded by plasmin, where the D-fragments of two fibrin molecules still are covalently bound and often also in complex with the E-fragment. Several methods can be used, such as enzyme-linked immunosorbent assay (ELISA), whole-blood agglutination of erythrocytes, latex agglutination or immunofiltration. ELISA methods have the best sensitivity but are not practical for near-patient testing, whereas the others are semi-quantitative or qualitative methods. There are also quantitative automated latex methods. The

manual latex methods have lower sensitivity and negative predictive value for exclusion of DVT or PE. Each hospital should provide information on the sensitivity and specificity of the test chosen for D-dimers. In general, a D-dimer assay is used for its negative predictive value (i.e. to exclude VTE) when the clinical score indicates low clinical probability. A positive result cannot be used for confirmation of the diagnosis owing to low specificity. For this reason, D-dimer is not a useful test in pregnancy or after surgery or in acute illness or the elderly.

Whenever the clinical probability is high and/or the D-dimer test is positive, confirmation using diagnostic imaging techniques is necessary, aiming to use the most non-invasive method. In patients with massive PE and hemodynamic instability, rapid risk assessment is necessary and so bedside echocardiography has become the most popular tool. Spiral multislice chest computed tomography (CT) is also useful for identifying patients who may benefit from thrombolysis or embolectomy. Cardiac biomarkers, including troponin and the natriuretic peptides, are sensitive markers of right ventricular function. Low levels of troponin, B-type natriuretic peptide (BNP) and NT-terminal proBNP are highly sensitive for identifying patients with an uneventful clinical course. Multislice chest CT is useful not only for diagnosing or excluding PE but also for risk assessment. A right-to-left ventricular dimension ratio above 0.9 on the reconstructed CT four-chamber view identifies patients at increased risk of early death.

Objective diagnosis with imaging techniques

Venography was the gold standard for diagnosing DVT, but the diagnostic accuracy is dependent on a high-quality examination. The veins and possible thrombi have to be well visualized and interpreted by an experienced radiologist, as artefacts may be difficult to differentiate from thrombi. A non-ionic contrast medium with low osmolarity should be used to minimize side-

effects and the risk of a post-venographic DVT. Caution is still needed with regard to renal failure.

Ultrasonography of the leg veins is non-invasive and has no contraindications and thus has largely replaced venography as the method of choice. Diagnostically, it depends on the skill of the operator and has lower sensitivity than venography, especially for the veins of the calf. The simplest variant is compression ultrasonography, where a cross-section of the vein is compressed with the transducer. A non-compressible vein is diagnostic for DVT. The pelvic veins are not accessible with this method and recurrent thrombosis is difficult to discern. The most sophisticated variant of the technique is colour Doppler, which can determinate flow in several venous segments simultaneously, although generally the sensitivity is higher for proximal than for distal DVT. Low clinical probability in combination with a negative ultrasonographic examination, including the common and superficial femoral veins, the popliteal vein and the trifurcation in the proximal part of the calf, is considered sufficient to exclude DVT. However, with medium clinical probability, a negative ultrasonographic examination should be repeated within 1 week and, if still negative at that point, DVT is satisfactorily excluded. Presentation with high clinical probability and negative ultrasonography requires further investigation with venography. Suspected recurrent DVT is better served by venography as a first-line investigation, for ultrasound has low sensitivity in this setting.

Objective verification of suspected PE has typically been obtained with ventilation–perfusion (V/Q) lung scanning, following a normal chest radiograph. Perfusion scanning with technetium-99m (^{99m}Tc) albumin macroaggregates is a sensitive but not very specific method. The specificity is improved by adding ventilation scanning, usually with xenon-133 (¹³³Xe) aerosol or ^{99m}Tc-labelled carbon particles (Technegas), considering a V/Q mismatch (negative ventilation and positive perfusion scan) indicative of PE. However, an embolus may cause bronchospasm and thereby a ventilation defect and, more importantly, a V/Q mismatch may occur with several other conditions, including tumours, pneumonia, atelectasis, chronic obstructive pulmonary disease and others, and it does not differ between old and new emboli. The interpretation of lung scans is difficult, especially with patients with low or intermediate probability for PE, and thus other methods should be preferred for concurrent cardiopulmonary disease. Treatment can safely be withheld if the perfusion scan is negative or with a low-probability scan in combination with low clinical probability. A high-probability lung scan, which should require perfusion defects corresponding to at least two segments, together with high clinical probability has a positive predictive value of more than 90%.

Spiral CT of the lungs has good interobserver agreement and the number of inconclusive examinations is definitely lower than with V/Q scanning. With multislice techniques and a slice thickness of 2 mm, adequate assessment of 93% of the

segmental arteries and of 62% of the subsegmental arteries is achieved. Although the diagnostic accuracy for subsegmental PE is low with spiral CT, follow-up studies have shown that it was safe to withhold treatment on presentation of a negative examination.

If there is a high clinical probability for PE and a negative perfusion scan or negative spiral CT, one possibility is to investigate for thrombi in the legs with bilateral ultrasonography or otherwise to proceed with pulmonary angiography. With contrast medium of low osmolarity, pulmonary angiography was not associated with mortality and only 0.4% of serious complications in four studies with more than 3000 patients. Although pulmonary angiography is considered the gold standard for diagnosis of PE, there are both false-positive and false-negative results, and the interobserver variability is poor when the PE is located in subsegmental arteries. Nevertheless, the method appears to exclude with great certainty those PE that require therapy.

A novel possibility with high specificity and sensitivity for DVT and potential for PE is magnetic resonance imaging (MRI) direct thrombus imaging, which requires no contrast but relies on the formation of methaemoglobin in hypoxic trapped red cells within venous thrombi. This acts as an endogenous contrast agent when imaged using a T1-weighted magnetic resonance sequence – appearing as high signal.

Investigation for concomitant cancer

The prevalence of cancer is approximately 20% in many cohort studies of patients with VTE. In a minority the malignancy is occult at the time of VTE. However, there is no evidence that screening for malignancies in those with VTE decreases the mortality and morbidity in those who are detected to have cancer. Instead, directed examinations should be performed when suspicion is raised by clinical signs or symptoms. Underlying cancer should be considered in patients with bilateral DVT, concomitant deep and superficial vein thrombosis at separate locations or recurrent VTE despite anticoagulation.

Therapeutic agents

All agents discussed below have in common the obvious side-effect of bleeding.

Thrombolytic therapy

Streptokinase and recombinant tissue plasminogen activator are widely available fibrinolytic agents. Streptokinase, a glycoprotein purified from the supernatant of β -haemolytic streptococci, in complex with plasminogen, cleaves other plasminogen molecules to plasmin. This indirect action results in complex pharmacokinetic characteristics. Furthermore, streptokinase is immunogenic, which may cause allergic reactions as well as a

reduced or absent response on repeated use or after a recent infection with streptococci. Recombinant tissue plasminogen activator is an autologous glycoprotein, produced commercially with recombinant DNA technology, and it has a direct enzymatic effect on plasminogen that is strongly enhanced by the presence of fibrin.

Anticoagulant therapy

For over 50 years, therapeutic anticoagulation was limited to the use of unfractionated heparin (UFH) and oral vitamin K antagonists. Although both are highly effective, both have major drawbacks, most notably their unpredictable pharmacokinetics, so that their use has become synonymous with monitoring. The arrival of new oral anticoagulants with predictable pharmacokinetics has led to great excitement.

Heparin

Heparin was first isolated between 1916 and 1922 by the medical students Jay McLean and Emmett Holt at Johns Hopkins University. As the source of the preparation was canine liver, it was named after the Greek word for liver, $\eta\pi\alpha\rho$ or *hepar*. In the 1930s it was used as an anticoagulant in human trials and its use became widespread after the Second World War.

UFH is a naturally occurring glycosaminoglycan produced by mast cells and basophils. The pharmaceutical product is derived from tissues rich in mast cells such as porcine intestine or bovine lung. UFH is a polymer of repeating disaccharide units, primarily comprising sulphated glucosamine and uronic acid with a heterogeneous mixture of differing chain lengths; most preparations have a mean molecular mass of 13–15 kDa.

A specific pentasaccharide sequence of the heparin molecule binds to antithrombin, inducing a conformational change and a 1000-fold increase in antithrombin activity. In turn, antithrombin inhibits thrombin and factor (F)Xa. Only the pentasaccharide sequence is required to generate anti-FXa activity, whereas a longer sequence of 18 saccharides, including the pentasaccharide, is necessary to bind thrombin to cause thrombin inhibition.

Heparins are only active when administered parenterally. UFH can be given intravenously or subcutaneously; intramuscular administration should be avoided as it can result in large haematomas. At typical therapeutic doses, the half-life of intravenous UFH is 45–60 min, demanding continuous intravenous infusion. Given subcutaneously UFH has a lower bioavailability than intravenous heparin; activity starts at 2 hours and lasts approximately 10 hours, necessitating twice-daily dosing.

A slight fall in platelet count (< 30% compared with baseline) occurs in up to one-third of patients within the first 4 days of starting heparin. This reversible dose-dependent phenomenon is not associated with bleeding or thrombotic complications and does not require cessation of heparin. More marked falls in platelet count (> 50% compared with baseline) should raise the possibility of heparin-induced thrombocytopenia (HIT). HIT

is a life-threatening complication of heparin treatment and occurs in 0.3–6.5% of those receiving UFH. The onset is typically between 5 and 10 days after starting UFH unless heparin has previously been administered, in which case it may begin earlier. The cause is development of an IgG antibody to a complex of heparin and platelet factor 4, which is capable of activating and depleting platelets. Because the thrombocytopenia is due to platelet activation, patients with HIT are paradoxically at high risk of both venous and arterial thrombosis. Other features may include necrotizing skin changes at heparin injection sites or a history of anaphylactoid reactions to heparin injection. A clinical scoring system for suspected HIT is useful in determining the need for further investigation. The diagnosis of HIT may be confirmed by specific ELISA or by functional platelet studies. The treatment is immediate cessation of all types of heparins (including line flushes) and initiation of an alternative anticoagulant such as danaparoid, hirudin or fondaparinux at therapeutic doses. Platelet transfusion is contraindicated, and warfarin should not be started until the platelet count has recovered, as it may cause microvascular necrosis.

Prolonged use of UFH can lead to osteoporosis by increasing osteoclast activity and reducing osteoblast numbers; 2% of patients receiving treatment-dose UFH for more than 9 months developed vertebral fractures. The risk of osteoporosis is considerably lower for low-molecular-weight heparin than for UFH.

Low-molecular-weight heparin (LMWH) is produced by enzymatic or chemical depolymerization of UFH. Since its introduction in the late 1970s, LMWH has largely superseded UFH by virtue of its more predictable pharmacokinetic profiles, less frequent dosing and lower incidence of adverse effects. LMWH consists of a mixture of glycosaminoglycan chains of molecular mass 3000–5000 Da. LMWH has the same principal mode of action as UFH, but the inhibition of thrombin is reduced compared with the inhibition of FXa, as the former effect requires longer polysaccharide chains for binding to thrombin. The bioavailability after subcutaneous injection is better than for UFH and the effect is more predictable, due to less binding to plasma proteins. The half-life is also longer (3–5 hours), so that a once-daily subcutaneous injection is sufficient. Intravenous administration of LMWH is rarely used.

Treatment with UFH requires monitoring with the activated partial thromboplastin time (APTT), whereas with LMWH monitoring is rarely needed, with the main exception being renal failure when inhibition of activated FX (anti-FXa) is measured. Side-effects such as HIT and osteoporosis are less common with LMWH. Although there are differences in molecular range, sulphation, ratio of FXa to thrombin inhibition, and pharmacokinetic characteristics between different LMWH preparations, there is no evidence for clinically important differences between them.

Fondaparinux is a synthetic drug consisting of the antithrombin-binding pentasaccharide sequence found in the

heparin molecule. The pentasaccharide binds the antithrombin molecule, causing a conformational change that enhances its activity against FXa. Because there are no additional saccharides to provide the necessary bridging function for thrombin binding, fondaparinux has no activity against thrombin. Fondaparinux is given as a subcutaneous injection and has a half-life of 17 hours, making it suitable for once-daily dosing. Clearance is exclusively renal, so dose adjustment in renal failure is required and it is not recommended in those with a creatinine clearance below 30 mL/min. Fondaparinux does not bind to platelet factor 4, so has no capacity to cause HIT.

Danaparoid is a heparinoid that consists of the glycosaminoglycans heparan sulphate, dermatan sulphate and chondroitin sulphate but without any heparin. Accordingly, it has low cross-reactivity with antibodies induced by heparin and it is therefore mainly used in patients with HIT. It is administered intravenously or subcutaneously and has an effect that is similar to UFH in the prevention and treatment of VTE.

Vitamin K antagonists

The vitamin K antagonists or coumarins were first isolated by Karl Paul Link at the University of Wisconsin in the 1930s. The observation that cows bled to death after eating mouldy clover had led Link's team to isolate the anticoagulant factor from the contaminated clover. Link later developed a synthetic coumarin derivative. This was patented by the Wisconsin Alumni Research Foundation who named it warfarin as a contraction of the organization's acronym, WARF, and the word coumarin. The use of coumarins became widespread in the 1940s.

There are two groups of vitamin K antagonists, the more commonly used coumarin derivatives and the indanediones, and their availability varies between countries. They exert their effect via inhibition of the enzymes vitamin K epoxide reductase and vitamin K reductase, which are required for the regeneration of KH₂ from vitamin K epoxide. The latter is generated when the vitamin K-dependent coagulation factors (FII, FVII, FIX and FX, as well as the physiological inhibitors protein C and protein S) undergo post-translational modification with γ -carboxylation of approximately 10 glutamic acid residues in the N-terminal Gla domain.

During treatment with vitamin K antagonists, typically three of these residues remain in the non-carboxylated state, which reduces the ability of these coagulation factors to bind calcium and to localize the coagulation process to phospholipid surfaces. The vitamin K antagonists are bound to plasma proteins, mainly albumin (98–99%), and are metabolized by the hepatic cytochrome P450 enzymatic system. Interactions with other drugs or food may occur at many levels (Table 47.4) and constitute a major disadvantage. There are a number of common genetic polymorphisms of the CYP2C9 enzyme primarily responsible for warfarin metabolism. The most common polymorphisms, CYP2C9*2 and CYP2C9*3, are each seen in around

Table 47.4 Mechanisms for drug interactions with vitamin K antagonists with typical examples of such drugs.

Enhancement of vitamin K pathway: vitamin K, lipid emulsions
Reduced endogenous synthesis of vitamin K: induced by antibiotics
Accelerated catabolism of coagulation factors: thyroid hormone, androgens
Decreased synthesis of coagulation factors: clofibrate
Decreased warfarin absorption due to binding: colestyramine
Increased absorption of warfarin: acarbose
Inhibition of cyclic interconversion of vitamin K: second-/third-generation cephalosporins
Inhibition of cytochrome P450 (CYP3A4): clarithromycin
Inhibition of cytochrome P450C9, S-enantiomer: sulfapyrazone
Stereoselective inhibition of hydroxylation, R-enantiomer: cimetidine
Non-stereoselective clearance: amiodarone
Induction of hepatic enzymes: barbiturates, rifampicin
Displacement of protein binding: etoposide
Potentialiation of the warfarin receptor effect: clofibrate
Antiplatelet effect: acetylsalicylic acid

10% of whites, and are associated with a reduced warfarin requirement.

A small proportion of individuals (< 1%) have a hereditary resistance to all coumarins mediated by reduced affinity of the coumarin receptor and require very large doses of coumarins (> 30 mg warfarin daily) to achieve an anticoagulant effect. Because of coumarin's unpredictable pharmacokinetics, treatment requires regular monitoring. This was initially with the prothrombin time (PT). With the widely adopted use of a standardized calibration system, the International Normalized Ratio (INR), the reliability of comparisons of treatment intensities at different laboratories has been improved. The INR from an individual sample is calculated using the formula $INR = (PT_{\text{patient}}/PT_{\text{control}})^{ISI}$.

Rare side-effects of vitamin K antagonists are skin necrosis, purple toe syndrome, rash and toxic hepatitis, whereas the adverse effect of warfarin on bone mineral density is debated. Skin necrosis can occur in approximately 1 in 5000 patients in early initiation of treatment, and is due to an imbalance between mildly depressed vitamin K-dependent coagulation factors and a more pronounced initial reduction of protein C and protein S, resulting in a hypercoagulable state with thrombus formation in small veins and venules in the dermis and subcutaneous fat. The purple toe syndrome is a very painful, burning, dark-blue discoloration of the toes and sides of the feet, probably due to cholesterol embolization from atherosclerotic plaques that have become friable owing to reduced fibrin deposition or haemorrhage into the plaques several weeks after initiation of anticoagulation. Skin rashes may be papular, vesicular or urticarial

and often very itchy. Vitamin K antagonists also have a teratogenic effect, with skeletal malformations, optic atrophy and mental impairment, occurring in a small percentage of babies of exposed mothers.

Direct thrombin inhibitors

All are only active parenterally and are administered mainly by intravenous infusion. Hirudin is a 65-amino-acid polypeptide, originally discovered in the saliva of the medicinal leech *Hirudo medicinalis*. Two recombinant derivatives are available, lepirudin and desirudin. Hirudin is an irreversible direct thrombin inhibitor, binding to both the active and substrate-recognition sites of the thrombin molecule. As the clearance of hirudin is exclusively renal, the half-life is highly dependent on renal function. With normal renal function, hirudin has a half-life of 60 min after intravenous administration, but in those with end-stage renal failure the half-life can be as long as 300 hours. Hirudin is licensed for the treatment of thrombosis associated with HIT. Unfortunately, 40–70% of patients develop hirudin antibodies after a week of treatment; although they are rarely inhibitory, they may bind to hirudin and reduce renal clearance, resulting in a prolonged half-life.

Bivalirudin is a recombinant 20-amino-acid polypeptide analogue of hirudin. It binds to the substrate-binding site of thrombin, but unlike hirudin can be cleaved by thrombin itself, making bivalirudin a reversible thrombin inhibitor. Bivalirudin has a half-life of 25 min following intravenous injection. Because only a proportion of excretion is renal, clearance is less dependent on renal function than for hirudin. Argatroban is a small-molecule reversible thrombin inhibitor derived from the amino acid arginine with a half life of around 40 min; clearance is primarily hepatic. Because of their short half-lives, argatroban and bivalirudin have been used principally in the management of HIT and during percutaneous coronary procedures in patients at risk of HIT.

All these parenteral direct thrombin inhibitors require therapeutic monitoring, usually by APTT, with a typical target ratio of 2.0–2.5. The ecarin clotting time is a better alternative, but is less widely available. There is no specific reversal agent for these direct thrombin inhibitors. Options in bleeding patients include blood product support, activated prothrombin complex concentrates or recombinant activated FVII. Hirudin is not cleared by haemodialysis.

Oral direct thrombin inhibitors

Dabigatran

Dabigatran is a novel synthetic small-molecule direct thrombin inhibitor that binds reversibly to both fibrin-bound and free thrombin and has predictable pharmacokinetics and so does not require monitoring. It has a plasma half-life of 14–17 hours, permitting once-daily dosing. Clearance is predominantly renal, and dose adjustment in renal failure may be necessary.

Dabigatran causes prolongation of APTT, but not in a linear dose-dependent fashion; more accurate monitoring can be achieved using the ecarin clotting time. Dabigatran is licensed for thrombophylaxis after orthopaedic hip and knee replacement, and in clinical trials it has been shown to be non-inferior to warfarin in the management of VTE; patients randomized to dabigatran had fewer minor bleeds but more dyspepsia and more drug discontinuation. A Phase III study, RE-LY, evaluated the efficacy and safety of two different doses of dabigatran relative to warfarin in over 18000 patients with atrial fibrillation. Dabigatran 110 mg was non-inferior to warfarin for the primary efficacy end point of stroke or systemic embolization, whereas dabigatran 150 mg was significantly more effective than warfarin or dabigatran 110 mg. Major bleeding occurred significantly less often with dabigatran 110 mg than warfarin; dabigatran 150 mg had similar bleeding to warfarin.

Oral direct factor Xa antagonists

Several oral direct FXa antagonists (i.e. they do not require antithrombin to exert their activity) are undergoing clinical trials; indeed rivaroxaban is now licensed for thrombophylaxis after orthopaedic joint replacement.

Rivaroxaban

Rivaroxaban has an oral bioavailability of 60–80% and has a rapid onset of action, reaching peak concentration at 3 hours and a half-life of 5–9 hours. Excretion is predominantly renal. In clinical trials where it was used as thrombophylaxis after orthopaedic hip and knee surgery, it was found to have superior efficacy to enoxaparin. Results from trials in other areas are awaited.

Novel anticoagulant drugs

There are a number of other novel oral anticoagulants in the pipeline, thus ensuring that the days of dependence on warfarin and heparin are numbered. Apixaban is an orally bioavailable small-molecule direct FXa inhibitor undergoing Phase III trials whose excretion is predominantly biliary and so it may be useful in renal failure. Others of interest include tecarfarin, a warfarin variant that is not metabolized by cytochrome P450 and thus has the potential to give more time in range.

Initial treatment of venous thromboembolism

Before treatment is started, blood samples for haemoglobin, platelet count, APTT and PT should be obtained for baseline assessment of the risk of bleeding. In addition, with anticipated treatment with LMWH, serum creatinine, and with thrombolytic therapy plasma fibrinogen and blood group and save, should also be performed. Thrombophilia screening is of no utility at this stage for the results do not usually affect immediate patient management. Moreover, false-positive results may

be obtained because levels of physiological anticoagulants are usually reduced at the time of an acute thrombus due to consumption.

Thrombolytic therapy

The most serious consequence of VTE is fatal PE. Many patients die before a diagnosis of PE has been made. Massive PE with unstable haemodynamics has a high mortality, but the prognosis improves dramatically with rapid lysis of the emboli. The benefit-to-risk ratio of thrombolysis in proximal DVT is as yet uncertain but it is recommended for unstable patients with PE, although these patients represent less than 5% of all patients hospitalized for PE. The streptokinase/urokinase PE thrombolysis trials showed that thrombolytic therapy successfully decreases pulmonary artery pressures acutely, with improvements in the lung scan and arteriogram at 12 and 24 hours, although there was no overall decrease in mortality in those receiving thrombolysis compared with those receiving heparin therapy. The use of thrombolytic treatment in patients with sub-massive PE is controversial.

Contraindications to thrombolysis include active internal bleeding, a stroke within 2 months, and an intracranial process such as neoplasm or abscess (Table 47.5). Relative contraindications include surgery within 10 days, uncontrolled hypertension

Table 47.5 Contraindications to thrombolytic therapy.

Absolute contraindications

Active internal bleeding
Known haemostatic disorder
Cerebrovascular accident, craniocerebral trauma or neurosurgery within 6 months
Active intracranial process

Relative contraindications

Major surgery, biopsy, puncture of non-compressible vessels, vaginal delivery, external heart massage or major trauma within 7 days
Vascular or eye surgery within 3 weeks
Gastrointestinal bleeding, acute pancreatitis or pericarditis within 3 months
Uncontrolled hypertension (diastolic \geq 110 mmHg)
Age > 80 years
Diabetic retinopathy

In addition, caution should be observed during the first trimester of pregnancy, the first 20 hours of menstruation, bacterial endocarditis and where there are abnormal screening tests for haemostasis. Patients with previous treatment with streptokinase within 3–4 months are unlikely to respond to repeated treatment due to antibody formation. Adherence to these precautions and contraindications should be more strict for the treatment of DVT than of massive PE.

and pregnancy. Haemorrhagic complications are higher in patients with a recent invasive procedure such as pulmonary angiogram or placement of an inferior vena cava (IVC) filter. There is a reported incidence of intracranial haemorrhage of approximately 2%, with higher rates in the elderly and those with poorly controlled hypertension. The major haemorrhage rate ranges from 11 to 20%.

Heparin is discontinued 30 min before thrombolytic therapy and restarted 2–4 hours after its discontinuation. Regional or local infusion of fibrinolytic agents has not proved to be more effective, for bleeding complications are still prevalent. Antipyretics such as paracetamol may be given for febrile reactions and steroids for more pronounced allergic reactions, but prophylaxis with the latter does not provide any additional benefit.

With major haemorrhage, the infusion should be stopped and blood losses replaced. For patients undergoing streptokinase therapy, the situation is more complex. Because of the indirect pharmacokinetics, a paradoxical effect may occur if the infusion of streptokinase is slowed or stopped. More plasminogen will then become available for transformation to plasmin by already circulating streptokinase–plasminogen complexes. It is therefore vital to reduce the proteolytic potential, which can be done with aprotinin, an antiplasmin agent. Conventional inhibitors of fibrinolysis, such as tranexamic acid, are not effective as they only counteract plasminogen conversion to plasmin but do not inhibit already formed plasmin. With very low levels of fibrinogen and major haemorrhage, infusion of fibrinogen (concentrate or cryoprecipitate) is also indicated.

Plasma fibrinogen level should be monitored every 12–24 hours. If the level is not reduced whatsoever, it is unlikely that a thrombolytic effect is achieved. The target is approximately 0.2–1.0 g/L, but levels higher than 0.2 g/L do not exclude the risk of haemorrhage, and therapeutic levels do not provide a guarantee for removal of the thrombus.

Venous thrombectomy

There are insufficient data to evaluate the long-term benefit of surgical removal of the thrombus. The procedure is often combined with formation of an arteriovenous fistula to improve the flow, but there is not enough evidence to show that this increases the patency rate of the vein. Bleeding is common, often requiring transfusion, and a fatal outcome has been reported in up to 14%. The benefit of the treatment is that relief of symptoms is immediate, and it may be considered in the rare cases when loss of the limb is imminent.

Inferior vena cava filters

A temporary or permanent filter provides a tool to prevent further PE by reducing the risk during the first 12 days from 4.8% to 1.1%. However, PE can still occur in patients with IVC filters, and there is also a small risk of thrombosis at the site of

filter insertion. The primary indication for an IVC filter is the prevention of PE in patients with established VTE who have a contraindication to anticoagulation. Once the filter is in place, there is a tendency for clinicians to delay anticoagulation. However, anticoagulation should be considered in all patients with an IVC filter once a temporary contraindication to anticoagulation has passed. A large randomized trial showed no reduction in mortality or long-term risk of PE after 2 years of permanent indwelling catheters; indeed there was an increased risk of recurrent thrombosis.

Anticoagulant therapy

The objective of anticoagulant therapy in the acute phase is to prevent further progression of the thrombus as well as (further) PE. It is not sufficient to start treatment with vitamin K antagonists alone, because of the delay of about 5 days until they provide full anticoagulation. A once-daily treatment dose of subcutaneous LMWH can be given and will have immediate effect and so patients with DVT are usually managed as outpatients, unless they have renal failure where intravenous UFH is required. With UFH an initial intravenous bolus should be given and treatment is continued with intravenous infusion until anticoagulation with a coumarin, usually started simultaneously, has become effective. Treatment with UFH is targeted at an APTT of 2–2.5 times the upper limit of normal, which is measured 4 hours after starting the infusion and then at least once daily. With APTT below the target range, another bolus dose is given and the infusion rate is increased. Conversely, with APTT above the treatment range, the infusion may be halted for 30 min and should be restarted at a reduced rate.

Failure to reach the therapeutic APTT range is associated with a poor antithrombotic effect, whereas a possible association between long APTT results and bleeding complications is less evident. Occasionally, there may be difficulties in reaching a therapeutic APTT with inherited and acquired deficiencies of antithrombin. If the APTT is not prolonged despite increased doses of UFH, and especially if there is clinical deterioration, the antithrombin level should be measured and, if there is a deficiency, the addition of antithrombin, either by using fresh frozen plasma or antithrombin concentrates, should be considered. More often, a therapeutic APTT is not achieved despite normal antithrombin levels, but there is no evidence of clinical progression. This condition is believed to be caused by high levels of acute-phase proteins, such as FVIII or histidine-rich glycoprotein, which counteract the prolongation of APTT but apparently not the antithrombotic effect of heparin. Measurement of anti-FXa in these patients often demonstrates therapeutic levels and should be taken into account so that undue increment of the dose of heparin is avoided.

If the baseline APTT is prolonged, the reason may be presence of a lupus anticoagulant (mildly to moderately prolonged APTT) or congenital deficiency of FXII (severely prolonged

APTT for homozygous patients), and monitoring of treatment with UFH is often difficult. The alternatives are monitoring with anti-FXa or treatment with LMWH, which does not require monitoring.

Patients with suspected PE can be managed in the same way with LMWH subcutaneously and vitamin K antagonists orally. It is thus possible to give this treatment on an outpatient basis, but patient safety has so far not been demonstrated for outpatient management of PE in a randomized trial. Treatment for DVT with LMWH can be undertaken safely without hospitalization. Randomized trials have demonstrated equal effect and safety with LMWH injected once or twice daily. For hospitalized patients, LMWH is associated with a lower incidence of haemorrhage than treatment with UFH. In the case of very ill patients or with a high risk of bleeding, it still may be preferable to treat with UFH, infused intravenously, in view of the shorter half-life if the treatment has to be discontinued abruptly and protamine sulphate used to neutralize residual UFH. Interestingly, initial treatment with LMWH instead of UFH is associated with a reduced mortality during 3 months of follow-up due to an increased survival in the subgroup of patients with concomitant cancer.

Although the dose of LMWH is adjusted according to body weight, there are conflicting data regarding whether the dose should be increased linearly or 'capped' in obese patients. Patients with mild to moderate renal failure (serum creatinine 200–400 µmol/L) should have anti-FXa levels after 2–3 days at the time of peak concentration and, if above 1 unit/mL, the dose should be reduced. For patients with severe renal failure UFH is preferred.

Patients with VTE should be mobilized early, preferably within 1 day, unless thrombolytic therapy is given. Mobilization does not increase the risk of new PE, and pain and swelling of the leg diminish more rapidly than if the patients are immobilized for 1 week. Patients should wear compression stockings as soon as they are out of bed.

Primary prophylaxis (thrombophylaxis)

A systematic review by the US Agency for Healthcare Quality and Research ranked PE as the most common preventable cause of hospital death, and thrombophylaxis as the number one strategy to improve patient safety in hospitals. Despite good clinical evidence of the efficacy and cost-effectiveness of thrombophylaxis, there has been failure of its implementation internationally.

Most inpatients have several risk factors for VTE. The baseline risk is estimated to be 5–15% for those adults who are acutely unwell in medical beds, with risks of about 50–60% in hip replacement surgery and severe stroke and nearly 100% in spinal cord injury/polytrauma cases. The arguments for using thrombophylaxis in all those at risk include the following.

- Despite the recognition of specific risk factors, it is impossible to predict exactly which individuals within a group at risk will have VTE.
- Screening with ultrasound has low sensitivity for DVT and is not cost-effective.
- Over 80% of DVT are clinically silent and often confined to the calf vein. The concern is that such asymptomatic DVT can become symptomatic and/or embolize. There is no way of predicting which patients will develop symptomatic VTE without warning and as a result of asymptomatic DVT. Therefore in view of our inability to predict the exact individuals in a high-risk group who will develop VTE, the standard approach is to administer thrombophylaxis to all those at risk.

Efficacy and safety of thrombophylaxis

Many randomized clinical trials over the past 35 years have demonstrated the efficacy and safety of thrombophylaxis, summarized elegantly and regularly by the American College of Chest Physicians. The National Institute for Health and Clinical Excellence (NICE) have produced guidelines for the UK. Thrombophylaxis can be separated into mechanical and pharmacological methods.

Mechanical methods

Mechanical approaches include antiembolic stockings, intermittent pneumatic compression devices, mechanical foot pumps and IVC filters. All except IVC filters reduce the risk of DVT. IVC filters reduce the risk of embolism from an established DVT and can therefore be considered secondary prophylaxis. Antiembolic stockings apply graded circumferential pressure on the legs, greatest distally, which increase the velocity and volume of blood flow in the deep veins. They have a lower grade of compression compared with graduated compression stockings used in patients with post-thrombotic syndrome, and need to be fitted correctly to work effectively. Intermittent pneumatic compression causes sequential compression of the legs in a wave-like milking effect. Foot pumps squeeze the plexus of veins known as the venae comitantes of the lateral plantar artery and thus reduce venous stasis.

The poor quality, low number and poor end points of the studies of mechanical thrombophylaxis have been widely criticized. A recent well-conducted study showed that thigh-length stockings do not alter the risk of DVT after stroke but did have a 5% risk of skin breaks, ulcers, blisters and skin necrosis. Mechanical methods are contraindicated in patients with critical limb ischaemia, limb fractures and severe neuropathy, while ill-fitted stockings may cause oedema, arterial ischaemia and superficial thrombosis.

The key end point of the efficacy of thrombophylaxis is reduction in death rate due to PE, and to ascertain this requires thousands of patients in one or several trials, which would need

to include post-mortem studies. Such studies have not been performed for mechanical thromboprophylaxis. However, the main advantage of mechanical methods is that they do not produce an increased bleeding risk. Stockings and intermittent pneumatic compression act in a synergistic manner when combined with pharmacological agents in surgical patients. However, there is no evidence to suggest that there is any benefit when IVC filters are added to appropriate thromboprophylaxis. Insertion is common in trauma patients who have a very high risk of VTE, but this has never been shown to be protective in a trial.

Pharmacological

UFH and LMWHs have been clearly shown to reduce the risk of death due to PE. The modern trials of pharmacological thromboprophylaxis use a composite primary outcome measure of symptomatic and asymptomatic VTE. A meta-analysis of 46 trials of UFH thromboprophylaxis in surgery showed that UFH, when compared with placebo, reduced the all-cause mortality from 4.2% to 3.2%. Fatal PE were reduced from 0.8% to 0.3%, symptomatic PE from 2.0% to 1.3% and DVT from 22% to 9%. However, bleeding events were significantly increased from 3.8 to 5.9%.

A problem with UFH is the need for frequent dosing. Thrice-daily dosing of UFH 5000 units was more effective in reducing the rate of VTE and especially PE, but the risk for major bleeding is significantly increased compared with twice-daily dosing. UFH has been largely superseded by LMWHs whose longer half-lives allow once-daily administration, although UFH remains the first choice in renal dysfunction, in which LMWH accumulates, causing increased bleeding, due to its long half-life and renal excretion. LMWH has been shown to reduce the risk of VTE by a similar amount as UFH (60–70%), with a similar bleeding risk compared with placebo.

Hospital-acquired VTE is more common in medical than surgical patients because medical patients are the commonest admissions. Indeed 70–80% of hospital-acquired fatal PE occurs in medical patients. Apart from being an older cohort, 40% of medical patients have more than one risk factor for VTE, including previous VTE, cancer, stroke, heart failure, chronic obstructive airways disease, sepsis and bed rest. Approximately 5000 acutely ill medical patients have been entered into randomized controlled trials comparing LMWH with placebo and studies comparing LMWH with UFH. For example, the MEDENOX study showed that enoxaparin 40 mg was superior to both enoxaparin 20 mg and placebo given for a median of 6 days to acutely ill medical patients. There was a significant reduction in DVT between 6 and 14 days in those patients who received enoxaparin 40 mg to 5.5%, compared with 15% who received placebo ($P < 0.001$). There were no significant differences in bleeding between the groups. Fondaparinux is also licensed for thromboprophylaxis. Postoperative adjusted-dose oral vitamin K antagonists are unfashionable in Europe due to the

unpredictable pharmacokinetics of warfarin leading to a significant risk of both over- and under-anticoagulation.

The evidence for using antiplatelet drugs in thromboprophylaxis is based on methodologically flawed studies and has been shown to be inferior to LMWH. For example, in a trial of joint replacement randomized to aspirin or LMWH, the relative reduction in VTE risk of LMWH was 63% over aspirin. Moreover, aspirin is associated with an increased risk of bleeding, especially when combined with other methods. Its use in thromboprophylaxis is not recommended in all the major guidelines.

For how long should thromboprophylaxis be given?

The acute-phase response that produces a prothrombotic state persists for weeks after surgery. Although the risk of postoperative DVT is highest within the first few weeks after surgery, VTE complications may occur later. Extended prophylaxis for up to 35 days has been shown to reduce VTE in those with ongoing significant risk factors for VTE, and so LMWHs are licensed for extended use for 28–35 days in major hip, abdominal or cancer surgery, reducing the risk of VTE by a further 60% from 2.7% to 1.1%.

Secondary prophylaxis

After a VTE, if initial treatment with UFH or LMWH is not followed by a period of secondary prophylaxis, the risk of recurrence over 90 days is 29%. Secondary prophylaxis is usually given with vitamin K antagonists, commonly with warfarin. In some European countries, phenprocoumon or acenocoumarol is prescribed predominantly. Phenprocoumon has a half-life of 160 hours compared with 20–55 hours for warfarin, which may cause difficulties when the drug has to be eliminated quickly in case of overdose or haemorrhage. Acenocoumarol has a half-life of only 11 hours, and this does not result in a requirement for twice-daily dosing. Comparative studies with warfarin and acenocoumarol have demonstrated a similar effect and safety profile.

Treatment with a vitamin K antagonist should be started concomitantly with the initial anticoagulant therapy, or once the diagnosis of PE or DVT is established. The optimal intensity is an INR of 2.0–3.0, at least during the first 6 months after an episode of VTE. It may take 3–10 days to reach this target range and the maintenance dose varies from 1 to 20 mg daily. The time to reach the therapeutic range and to find the individual maintenance dose is shortened with higher initial dosing (warfarin 15 mg daily versus lower doses, or warfarin 10 mg vs. warfarin 5 mg) and by using a nomogram or computer software for the dose adjustments. The higher induction dose of 15 mg should be avoided in patients with a high risk of bleeding and is contraindicated in patients with deficiency of protein C or

S because of the increased risk of warfarin-induced skin necrosis.

The initial treatment with UFH or LMWH may be discontinued when the vitamin K antagonist has been given for at least 5 days and an INR of at least 2.0 has been achieved for two consecutive days. The secondary prophylaxis with vitamin K antagonists is then continued for a period that sometimes can be decided very shortly after the diagnosis of VTE, but which often requires reassessment due to the results of evaluation for thrombophilia or other investigations that may favour a longer treatment period. Conversely, bleeding complications or poor compliance may prompt a shortening of the planned treatment period. In order to improve the quality of anticoagulant therapy, it is crucial that the patient is followed properly as an outpatient.

Treatment is monitored by measuring the INR. Dose adjustments become more precise, with less INR results outside the therapeutic range, if decision support aids, such as nomograms, algorithms or computer software, are used. Staff in charge of dose adjustments should be trained and follow a large number of patients regularly. Well-motivated patients should be encouraged to perform self-testing with capillary blood sampling using a 'point-of-care' instrument and to be in charge of dose adjustments, with advantages in terms of less clinical complications. This requires some training and visits to an anticoagulant clinic a few times per year for comparison of the results with those obtained at the laboratory.

All patients who receive vitamin K antagonists should be informed about the following (printed information should also be provided).

- The risk of bleeding.
- Whom to contact whenever such symptoms occur.
- The risk of using acetylsalicylic acid and non-steroidal anti-inflammatory drugs, which impair platelet function, and about the alternatives that can be used. Although paracetamol interacts with warfarin, this is not clinically significant.
- Vast numbers of drugs interact with vitamin K antagonists so that the possibility of an interaction should be questioned for each new drug prescribed. Several herbal medicines, including St John's wort, ginseng and garlic, reduce the concentration of warfarin in blood.
- The effect of large amounts of dark green vegetables, which contain considerable amounts of vitamin K and may therefore neutralize the anticoagulant effect, but stressing that a regular intake of moderate amounts of vegetables is recommended.

Duration of secondary prophylaxis with oral vitamin K antagonists

The optimal duration of secondary prophylaxis is dependent on a risk-benefit analysis between avoidance of haemorrhagic complications and recurrent VTE. Meta-analyses have shown that a longer duration reduces the risk of recurrence, but treat-

Table 47.6 Factors associated with a higher risk of recurrence of venous thromboembolism.

Higher risk
Triggering risk factor not identified
Proximal DVT and/or PE
Presence of cancer
<i>Thrombophilic defects</i>
Deficiency of antithrombin, protein C or protein S
Homozygosity for FV Leiden or prothrombin G20210A
Antiphospholipid antibodies
<i>Follow-up of the thrombotic disease</i>
Persistently increased D-dimers
Remaining thrombus on ultrasound examination
Lower risk
Triggering risk factor removable or permanent
Distal DVT
<i>Thrombophilic defects</i>
Heterozygosity for FV Leiden
Heterozygosity for prothrombin G20210A
<i>Follow-up of the thrombotic disease</i>
Normalized level of D-dimers
Normalized ultrasound

ment for more than 6–12 months is associated with an increased risk of bleeding. Factors associated with a higher risk of recurrence are shown in Table 47.6. For the majority of patients, treatment of at least 6 months is recommended. Shorter treatment is indicated for a distal DVT and temporary risk factor, such as trauma, surgery or oral contraceptives (6 weeks), or for patients with a high risk of bleeding (3 months).

In randomized trials on the duration of secondary prophylaxis, there has typically been an annual incidence of 2–4% of major haemorrhage. One option to reduce this risk is to reduce the intensity of anticoagulant therapy, and studies on coumarins targeted at an INR of less than 2.0 have shown a favourable risk-benefit profile. Large randomized trials on low-intensity warfarin therapy in the extension of secondary prophylaxis after at least 3–6 months of treatment, targeted at the usual INR of 2.0–3.0, have shown that a prophylactic antithrombotic effect is obtained but perhaps less than with full intensity, although the annual incidence of major haemorrhage was only 0.9–1.0% and may be an option in some low-risk patients. However, secondary prophylaxis targeted at an INR of 1.5–2.0 was not tested in patients with active cancer, for whom even standard vitamin K antagonist therapy is often insufficient (see below).

A decision in favour of prolonged anticoagulation should be weighed against the cost and burden for the patient of monitor-

Table 47.7 Suggested duration of secondary prophylaxis in relation to presence of risk factors.

<i>Condition</i>	<i>Duration</i>
<i>Thrombophilic defects not identified or unknown</i>	
First event, distal DVT, provoked by temporary risk factor	6 weeks
First event, distal DVT with idiopathic or permanent risk factor, or any proximal DVT or PE	6 months or longer
As above with increased risk of bleeding	3 months
Single life-threatening event	12 months or longer
First event, active cancer	Until cancer resolved
Second event, contralateral DVT	As after the first event
Second event, ipsilateral or PE	12 months or longer
More than two events	Indefinitely
<i>Thrombophilic defects identified*</i>	
Deficiency of antithrombin	Indefinitely
Deficiency of protein C or protein S	12 months or longer
Homozygous form of thrombophilic defect	Indefinitely [†]
Double heterozygous for thrombophilic defects	Indefinitely
Antiphospholipid syndrome	Indefinitely
Hyperhomocysteinaemia	As without [‡]
Elevated FVIII activity	6 months or longer
FV Leiden mutation, heterozygous	As without the defect
Prothrombin polymorphism, heterozygous	As without the defect
Life-threatening event and any defect	Indefinitely

*Independent of the event being provoked by a temporary or permanent risk factor, whenever the thrombophilic defect is permanent.

[†]Possibly excluding the homozygous form of prothrombin G20210A.

[‡]Consider the use of B vitamins thereafter.

ing the treatment, effects on the quality of life in view of restrictions regarding diet and other concomitant medications and, finally, the fact that about 1% of patients annually will have a major haemorrhage. Suggestions for the duration of secondary prophylaxis are given in Table 47.7. However, a significant minority of patients may wish to stop coumarins and instead take thrombophylaxis at times of haemostatic stress, for example prophylactic doses of LMWH at times of surgery or during long-haul air travel.

Although it is not clear that the risk of recurrence is higher after the second episode of VTE than after the first, recurrent

DVT in the ipsilateral leg causes additional damage to the venous valves and increases the risk of post-thrombotic syndrome significantly. Patients with PE have a higher risk of recurrent symptomatic PE than do patients with initial DVT, and extension of secondary prophylaxis may thus be justified after recurrent PE. Patients with antiphospholipid syndrome have a high risk of recurrence without anticoagulation and therefore anticoagulation should be extended.

Cessation of vitamin K antagonists is often associated with an increment in prothrombin fragment 1+2 and D-dimers, independent of whether they were stopped abruptly or gradually, and so there seems to be no clinical benefit in stopping gradually.

Management in the case of bleeding or surgery

Excessive anticoagulation may be identified as an isolated prolonged INR above 4 or in combination with bleeding. Although elimination of one dose of the vitamin K antagonist, possibly followed by a reduction of the maintenance dose, may suffice in most cases, the addition of oral vitamin K₁ 1 mg reduces the risk of bleeding. The reason for excessive anticoagulation should be investigated and may reveal an interaction with other drugs or irregular dosing.

In the case of major or life-threatening bleeding, reversal with vitamin K₁ is too slow, as only a weak effect is noticed after 2 hours and the full effect occurs after 6 hours. Replacement of the deficient vitamin K-dependent coagulation factors is necessary, but the volumes of fresh plasma required are so large (typically 2–3 L to reduce the INR from 4.0 to 1.5 in a patient with body weight of 80 kg) that there is a substantial risk of volume overload. Prothrombin complex concentrate is the agent of choice: it carries no risk of volume overload and has undergone viral inactivation to eliminate the risk of transmission of HIV or hepatitis B or C. A few cases with thromboembolic complications in association with the use of prothrombin complex concentrate have been reported, but the risk appears small as no complications were observed in prospective cohorts.

In patients with bleeding at INR levels within or below the therapeutic range, cancer should be suspected and investigations of the source are indicated.

For minor surgery, such as tooth extractions or dermatological surgery, anticoagulant therapy can be maintained within the therapeutic range. Randomized trials have shown an excellent prophylactic effect against bleeding complications after dental extractions if the patients were prescribed mouth rinses with the fibrinolytic inhibitor tranexamic acid every 6 hours.

For major surgery, the INR has to be reduced to below 1.5, either by complete interruption or by reduction in the vitamin K antagonist. Substitution with LMWH or UFH is given peri-operatively until therapeutic INR has been regained.

Secondary prophylaxis with LMWH

Secondary prophylaxis with UFH twice daily subcutaneously, adjusted to prolong the APTT 1.5 times the normal value at 6 hours after injection, has been shown to be as effective as vitamin K antagonists. However, this never gained any popularity due to the requirement for two doses and adjustments. A meta-analysis of studies on secondary prophylaxis, comparing LMWHs with vitamin K antagonists, has shown that they are equally effective and safe. LMWH injected once daily subcutaneously may be the drug of choice for patients with a short treatment duration (6 weeks or less), with pronounced difficulties in achieving stable INR values, or when monitoring of the vitamin K antagonist is problematic. The dose of LMWH should be approximately 50% of the initial treatment dose and monitoring with anti-FXa is not required unless there is impairment of renal function or the patient is obese. The risk of osteoporosis with long-term LMWH is minimal and HIT is very rare.

Treatment of patients with cancer

In cohorts of unselected patients with VTE, the prevalence of cancer is about 20%. Even occult cancer increases the risk of thrombosis for several years until it becomes clinically manifest. The diagnosis and treatment of patients with VTE and known cancer differs somewhat from what has been described above. The diagnosis of DVT with ultrasonography or phlebography may become false positive due to obstruction of the iliac vein by a pelvic tumour mass or metastases, and CT may therefore be the diagnostic method of choice. Compression of a pulmonary artery by a tumour mass or tumour emboli may simulate perfusion defects by PE, both on lung scanning and on pulmonary angiography. Measurement of D-dimers may not be of any value in these patients, who typically have elevated levels even in the absence of VTE.

Initial treatment should preferably be given with LMWH in view of the survival benefit in patients with cancer over the following 3 months in comparison with those treated with UFH. Although patients with cancer have massive VTE more frequently than those without cancer, thrombolytic therapy is very hazardous, as the risk of bleeding is aggravated by necrosis in highly vascularized tumour tissue, erosion of normal tissues and thrombocytopenia due to bone marrow invasion by tumour or aplasia after chemotherapy. In some of these patients, the risk of bleeding is so pronounced that in the case of PE or massive DVT there is an indication for an IVC filter.

Long-term anticoagulation with coumarins in patients with cancer is unsatisfactory, because there is an increase in the annual risk of recurrence of 14–18% compared with patients without cancer and, paradoxically, an increase in major bleeding of 7–11%. For secondary prophylaxis, LMWH at a dose of

75% of the initial treatment dose may be a better alternative than vitamin K antagonists. Long-term LMWH may prolong survival in patients with cancer and VTE, and perhaps also in those without VTE. This does probably not apply to terminally ill patients but rather to those with an expected survival of at least 1 year. However, many questions remain to be answered: the mechanism for this effect, whether the effect is confined to certain types of cancer, the minimum treatment period required and the optimal dose of LMWH. Secondary prophylaxis should continue as long as active cancer is present, unless the severity of bleeding complications precludes treatment.

Venous thromboembolism in pregnancy

The incidence of VTE in association with pregnancy is 0.5–1.0 per 1000 with one to two fatal cases of PE in 100 000 pregnancies. DVT occurs commonly in the left iliofemoral vein. This may generate a clinical picture that is different from the one generally seen in DVT. The only symptoms may be abdominal cramps, sciatic back pain or fever. Objective diagnosis is even more important in the pregnant patient, as failure to treat an undiagnosed VTE as well as treatment of a false-positive diagnosis may cause harm.

Pressure from the uterus on the pelvic veins may simulate the effect of thrombosis on ultrasonography, particularly in the third trimester. These examinations are more accurate if the mother is resting on her side. The radiation dose from phlebography, ventilation–perfusion lung scanning, spiral CT or pulmonary angiography is so small that the possible risk for the child of future malignancy caused by radiation or hypothyroidism due to free iodine is substantially less than the risk of missing the diagnosis. These examinations should therefore be performed if they are considered to be important for the diagnosis, but obviously with all available precautions. MRI or direct thrombosis imaging is not known to cause any harm to the fetus and, if available, may be a useful diagnostic tool. D-dimers are not helpful in these patients, who often have increased levels, especially during twin pregnancies or pre-eclampsia.

Thrombolytic therapy may be considered for massive DVT or PE, but the risk of bleeding is particularly high if this is used shortly before or during the delivery or the puerperium. Thrombectomy for iliac or iliofemoral DVT can be performed safely, but there are no studies to show that this gives any better results than anticoagulant therapy.

Despite the lack of clinical trials of LMWHs during pregnancy, they are widely used because of their ease of administration and good safety profile. There is debate as to whether twice-daily administration is better than once daily, for the half-life of LMWH is shorter in pregnancy due to improved renal clearance. It is not clear whether anti-FXa levels need to be monitored in pregnancy; there have been no clinical trials to

assess the level of anti-FXa activity required in pregnancy, so target levels are extrapolated from non-pregnant studies. After VTE some physicians continue with the treatment dose until the end of pregnancy, but usually secondary prophylaxis is carried on with a reduced dose of LMWH. Vitamin K antagonists should be avoided if possible because of an increased risk of fetal haemorrhage and because of teratogenic effects. Unlike coumarins, UFH and LMWH do not cross the placenta.

At the time of delivery, blood samples are taken on admission for platelet count, APTT and PT to evaluate the risk of bleeding, and LMWH administration ceased. According to current guidelines, based on expert opinion, regional anaesthesia cannot be commenced or terminated within 24 hours of a treatment dose of LMWH or 12 hours after the previous prophylactic dose of LMWH. After acute VTE in pregnancy, after birth the prophylaxis is continued for at least 6 weeks and with a total duration that is at least as long as would have been chosen for a non-pregnant patient with the same risk factors. Alternatively, coumarins can be given after delivery, and LMWH is then stopped when the INR is within 2.0–3.0 for at least 2 days and after a minimum of 5 days. Neither LMWH nor vitamin K antagonists are secreted in breast milk in any amounts that can have an effect on the baby, although it seems sensible to ensure that the neonate receives intramuscular vitamin K to prevent haemorrhagic disease of the newborn.

Women with inherited antithrombin deficiency require higher doses of heparin and regular anti-FXa activity monitoring. Administration of antithrombin concentrate should be considered in association with delivery to allow for safe cessation of LMWH.

The post-thrombotic syndrome

Thrombi that do not undergo thrombolysis or which are not removed rapidly will destroy venous valves in the healing process, where they are transformed into fibrous tissue. Venous return of blood becomes impaired, accompanied by increased venous pressure. Permeation of fluid to the extravascular space causes oedema and creates a perivascular barrier to plasma proteins, which reduces the transport of nutrients to the tissues and results in skin atrophy and, in the most severe cases, venous ulcers. This process takes between 1 and 5 years, sometimes even longer, and is seen in 30% of patients 2 years after an event. The tools available to reduce the risk of developing the post-thrombotic syndrome include the following.

- Thrombolytic therapy, which has limited use due to the risk of haemorrhage.
- Ensure that more than 50% of the time on coumarins is in the target range.
- Graduated compression stockings for 2 years after an episode of DVT reduce the incidence of post-thrombotic syndrome by half. It is not known if shorter or longer treatment would have

similar or more pronounced effects. Knee-high stockings are sufficient for the vast majority of patients; they should be of compression class II (20–30 mmHg), fitted individually and should be worn whenever the patient is not recumbent.

Chronic thromboembolic pulmonary hypertension

A prospective long-term follow-up study of patients after PE showed that 3.8% of patients at 2 years had evidence of chronic thromboembolic pulmonary hypertension, suggesting that it is a relatively common complication of PE. The diagnosis should be considered in those with dyspnoea after PE. Pulmonary endarterectomy is the first treatment of choice in patients with severe pulmonary hypertension, and it reduces pulmonary vascular resistance dramatically, although the perioperative mortality is 5–9%. Five-year survival of over 80% has been described.

Introduction

In haemostasis, a sequence of local events culminates in spontaneous arrest of bleeding from a traumatized blood vessel. The normal haemostatic mechanisms are sufficient to seal any vascular discontinuity. Three closely linked biological systems are involved: platelets, blood vessels and coagulation proteins. Platelets, anucleate cells that are derived from the cytoplasm of bone marrow megakaryocytes, circulate in the bloodstream for about 7–10 days. In the resting state platelets do not normally interact with endothelial cells or other blood cells but do so when the vessel wall is disrupted. Adhesion to exposed sub-endothelial components allows platelet activation and release of active substances (e.g. ADP) from intracellular organelles that amplify and propagate activation and, finally, platelet aggregation that plugs the ruptured blood vessel. At this primary stage of haemostasis platelets stop bleeding from damaged blood vessels transiently and provide the surface which promotes blood coagulation that strengthens the platelet plug (the secondary phase of haemostasis). Clinically, abnormalities of platelet adhesion and aggregation exhibit a history of spontaneous and/or easy bruising and a prolonged skin bleeding time. The characteristic clinical features of abnormal bleeding due to platelet deficiencies are distinct from those seen in disorders of plasma coagulation factors (Table 48.1). The occurrence of superficial bleeding in patients with platelet disorders as opposed to the deeper bleeding in patients with clotting factor disorders is a useful clinical pointer, but it must be remembered

that the activities of platelets and coagulation factors are closely related.

Bleeding associated with platelet abnormalities manifests as haemorrhages from small vessels. Petechiae usually develop on the skin and the visible mucous membranes, but they may be distributed throughout the body including internal organs. Characteristically, bleeding resulting from platelet diseases is immediate and transient, tends to stop promptly with local pressure and does not recur when the pressure is removed. When this pattern of bleeding occurs in the neonatal period, infancy and childhood, a congenital platelet disorder should be suspected. However, the disease may be clinically silent and the patient may enter adult life before bleeding occurs.

The family history may be of great importance, providing a characteristic pattern of inheritance, but it should be remembered that a negative family history does not exclude an inherited platelet abnormality, i.e. the family history is usually negative in autosomal recessive traits. A comprehensive medical history and a careful clinical examination of the patient presenting with a haemorrhagic disorder is crucial for the correct diagnosis. Subsequent laboratory tests chosen on the basis of the clinical information obtained will lead to a precise definition, where possible, of the platelet abnormality.

Congenital defects of platelets may give rise to bleeding syndromes of varying severity and are difficult to classify because of the rarity of many forms, the extreme heterogeneity, and also because of incomplete knowledge about a variety of diseases. Table 48.2 classifies congenital platelet disorders into two main groups: thrombocytopenias and thrombocytopathies. Each group is further divided according to specific criteria based on functional and biochemical defects. Such a classification, as others, should be viewed as tentative, because some disorders may be characterized by multiple pathogenetic factors whereas others are grouped together for convenience of classification rather than on their known pathophysiology.

Table 48.1 Main specific clinical differences between diseases of coagulation factors and platelet disorders.

<i>Findings</i>	<i>Disorders of coagulation</i>	<i>Platelets/vessels</i>
Onset of bleeding	Delayed after trauma	Spontaneous or immediately after trauma
Mucosal bleeding	Rare	Common
Petechiae	Rare	Characteristic
Deep haematomas	Characteristic	Rare
Ecchymoses	Large and solitary	Small and multiple
Haemarthrosis	Characteristic	Rare
Bleeding from superficial cuts and scratches	Minimal	Persistent; often profuse
Sex of patient	80–90% male	Equal

Table 48.2 Classification of congenital platelet disorders.

Thrombocytopenia

Non-inherited thrombocytopenia

- Drugs and chemical agents
- Isoimmune thrombocytopenia
- Infiltration of bone marrow
- Infections
- Other causes

Inherited thrombocytopenias

- Thrombocytopenias with reduced platelet size
- Thrombocytopenias with normal platelet size
- Thrombocytopenias with increased platelet size

Thrombocytopathies

- Disorders of platelet adhesion
- Disorders of platelet signalling transduction
- Disorders of platelet aggregation

Thrombocytopenias

Thrombocytopenia defines a subnormal number of platelets in the circulating blood, usually below $100 \times 10^9/L$. Acute thrombocytopenia is the most frequent cause of severe bleeding and the risk of haemorrhage is inversely proportional to the platelet count, with spontaneous bleeding occurring frequently at a platelet count below $20 \times 10^9/L$. When automated methods are used, ‘artefactual thrombocytopenia’ or pseudothrombocytopenia can be observed. Different mechanisms can cause a falsely low platelet reading. This may happen in patients with a wide variety of clinical disorders. Non-technical factors inducing

pseudothrombocytopenia include paraproteinaemias, cold agglutinins, giant platelets, previous contact of platelets with foreign surfaces (i.e. dialysis membrane), lipaemia and EDTA-induced platelet clumping. The possibility of a pseudothrombocytopenia must be ruled out through manual counting and/or examination of an adequately stained blood film before concluding that a patient has true thrombocytopenia.

Congenital non-inherited thrombocytopenia

Congenital thrombocytopenia not ascribed to inherited causes may be the result of a series of pathogenetic mechanisms, most likely attributable to deficient marrow platelet production or enhanced platelet destruction.

Drugs and chemical agents

The maternal use of drugs and chemical agents may cause thrombocytopenia by suppressing platelet production, by damaging platelets directly or by inducing the formation of platelet antibodies. Maternal ingestion of ethanol, thiazides, chlorpropamide, tolbutamide, estrogens, steroids and other drugs may selectively suppress thrombopoiesis. Alkylating agents, antimetabolites or chemotherapeutic drugs capable of crossing the placenta may lead to severe thrombocytopenia in newborns as the result of a predictable suppression of the bone marrow. The maternal ingestion of quinine, quinidine, hydralazine or selected antibiotics known to induce immune-mediated thrombocytopenia may induce congenital immune-mediated thrombocytopenia. In these newborns, thrombocytopenia usually improves rapidly and very rarely gives rise to severe or fatal haemorrhages.

Alloimmune thrombocytopenia

Immune thrombocytopenia may also result from the placental transfer of platelet antibodies formed as the result of active immunization of the mother by fetal platelet isoantigens, if the fetus has inherited a paternal platelet-specific antigen that induces antibody formation. Transplacental passage of the maternal antibody, usually of the IgG isotype, may induce severe thrombocytopenia in the fetus. This usually occurs when the mother has PLAI-negative platelets and the fetus carries PLAI-positive platelets. Newborns may show petechiae and purpura, or more severe bleeding at the time of birth, or may appear normal at delivery and then manifest severe bleeding within the first week after birth. In this case, thrombocytopenia usually improves within 1 month but severe and fatal intracranial haemorrhages may occur.

Bone marrow infiltration

Congenital thrombocytopenia caused by bone marrow infiltration is extremely rare, being limited to cases of disseminated reticuloendotheliosis and congenital leukaemia. Thrombocytopenia with or without associated myeloid and

erythroid depression occurs in children with numerous infiltrative disorders, including solid tumours, myelofibrosis, Gaucher disease, Niemann–Pick disease and the mucopolysaccharidoses.

Infections

Thrombocytopenia, usually mild but sometimes very severe, is commonly seen in infected newborns and several mechanisms are probably responsible. In fact, impaired platelet production as a result of invasion of megakaryocytes, the destruction of circulating platelets and the formation of antigen–antibody complexes may explain many instances of thrombocytopenia associated with viral infections. Maternal infection with toxoplasma, cytomegalovirus, rubella, herpesviruses or hepatitis varicella, as well as recent maternal vaccinations (rubella), may induce congenital thrombocytopenia.

Other causes

Occasionally, children born to women with chronic idiopathic thrombocytopenic purpura manifest congenital thrombocytopenia. It is conceivable that autoantibodies causing the disease in the mother cross the placenta and bind fetal platelets. Other causes of congenital thrombocytopenia due to increased platelet consumption or destruction include common maternal disorders such as pre-eclampsia, systemic lupus erythematosus or other autoimmune diseases, especially if the woman has antiphospholipid antibodies. A moderate to severe thrombocytopenia has been observed in association with giant cavernous haemangioma, first described by Kasabath and Merritt, in which the consumption of platelets occurs primarily within the tumour. Thrombocytopenia is often found associated with coagulation abnormalities typical of disseminated intravascular coagulation and the severity tends to parallel the size of the vascular tumour.

Inherited thrombocytopenias

Several inherited diseases may present with thrombocytopenia as an accompanying feature of generalized bone marrow failure (e.g. Fanconi anaemia) or metabolic diseases causing marrow infiltration (e.g. Gaucher disease). These and other complex clinical syndromes (e.g. Noonan syndrome) are not discussed in this chapter. Inherited thrombocytopenias are very rare. In some of these diseases thrombocytopathy may coexist with thrombocytopenia (e.g. Bernard–Soulier syndrome, Wiskott–Aldrich syndrome). These diseases are discussed in the appropriate section according to the most prominent defect. As proposed by the Italian Working Group, both platelet size and the presence (syndromic) or absence (non-syndromic) of other clinical features, different from those deriving from platelet abnormalities, are helpful criteria for classifying inherited thrombocytopenias.

Inherited thrombocytopenias with reduced platelet size

Wiskott–Aldrich syndrome (WAS) is a rare (1 in 250 000) X-linked recessive disorder characterized by eczema, susceptibility to infections associated with defects in cellular and humoral immunity, and thrombocytopenia with reduced platelet size. The gene responsible for WAS maps to Xp11.4 and codes for a protein, WASp, expressed only in haemopoietic-derived cells and which is involved in the transduction of signals from the receptor to the actin cytoskeleton. Intermittent bleeding, recurrent bacterial and viral infections, and progressive eczema occur during the first months of life. Death at an early age commonly results from intracranial haemorrhage, infection or lymphoreticular malignancy. A number of kindreds have been reported in whom *X-linked thrombocytopenia* (XLT) occurred alone or in association with partial manifestations of WAS. XLT is caused by a mutation within the WAS gene. Patients with XLT mainly suffer from an isolated bleeding tendency.

Inherited thrombocytopenias with normal platelet size

Congenital deficiency of megakaryocytes is a rare form of thrombocytopenic purpura in the newborn and may occur with skeletal, renal or cardiac malformations. Isolated *congenital amegakaryocytic thrombocytopenia* is an autosomal recessive syndrome leading to bone marrow aplasia later in childhood. This disorder is associated with abnormalities in the expression or function of the thrombopoietin receptor c-Mpl, and a series of mutations in the c-Mpl gene (*THPO*) have been identified. Most commonly, associated skeletal anomalies are present. Bilateral agenesis of the radius is the most commonly associated abnormality, so-called *thrombocytopenia with absent radius* (TAR) syndrome. The TAR syndrome is an autosomal recessive disease characterized by severe, even fatal, haemorrhagic manifestations. Although abnormalities in the thrombopoietin/c-Mpl signalling pathway have been suggested, no mutations have been found in genes coding for these proteins. In some infants, the ulna and humerus may also be absent and other skeletal abnormalities may occur. In addition, proximal radio-ulnar synostosis, syndactyly and other skeletal abnormalities are reported in association with an autosomal dominant congenital amegakaryocytic thrombocytopenia in patients carrying heterozygous mutations of the *HOXA11* gene. Less commonly, patients manifest cardiac and other minor defects. *Schulman–Upshaw syndrome*, which is caused by mutations in the *ADAMTS13* gene, is characterized by thrombotic thrombocytopenic purpura with neonatal onset (congenital microangiopathic haemolytic anaemia), thrombocytopenia and frequent relapses, and response to fresh plasma infusion.

Inherited thrombocytopenias with increased platelet size

Thrombocytopenias with increased platelet size are characterized by the presence of an increased platelet volume with a reduced number of platelets (megathrombocytopenia) and are the commonest inherited forms of thrombocytopenias. Among them, a series of diseases have been characterized at the molecular level, whereas other clinical entities still await clear identification of the molecular defect. Giant platelets and moderate thrombocytopenia are most frequently found in certain populations of Mediterranean extraction and may also be associated with other inherited or congenital syndromes, such as May–Hegglin anomaly, Bernard–Soulier syndrome and stomatocytosis. *May–Hegglin anomaly* is a rare autosomal dominant disease characterized by giant platelets and basophilic inclusions (Döhle bodies) within granulocytes. Large Döhle bodies are seen in peripheral blood and in bone marrow granulocytes, and most patients show mild neutropenia but no significant susceptibility to infection. About 50% of patients have significant thrombocytopenia deriving from ineffective thrombopoiesis, but the occurrence of life-threatening haemorrhage is rare. In patients suffering from May–Hegglin anomaly the platelets show not only a greatly increased (twice normal) volume but most of them also display bizarre morphology and hypergranularity. Closely related to the May–Hegglin anomaly is a group of other autosomal dominant diseases known as Sebastian, Fetchner and Epstein syndromes. Their main characteristic is the presence in almost all patients of giant platelets with thrombocytopenia. In addition, patients may develop sensorineural hearing loss, cataract and glomerulonephritis, and most of them display Döhle bodies. The exact classification of patients according to the presence or absence of the above-mentioned clinical signs is shown in Table 48.3. The molecular basis of these syndromes has been elucidated. All these clinical entities are caused by mutations that occur within a gene (*MYH9*) located on the long arm of chromosome 22 (22q13.1). This gene codes for the heavy chain of non-muscle myosin IIA (NMMHC-IIA), a protein involved in the contractile activity of the cytoskeleton.

Grey platelet syndrome (GPS) is a rare disorder inherited as an autosomal dominant trait, although recessive transmission has been shown. It is characterized by large platelets with a

selective deficiency in the number and content of α -granules. As a result of this, platelets are either markedly hypogranular or agranular and display deficiency of α -granule proteins, such as fibrinogen, von Willebrand factor, thrombospondin, β -thromboglobulin and platelet factor 4. Recently, a missense mutation has been identified at position 759 in the *GATA1* gene that induces an amino acid change (Arg216Gln) which segregates in an X-linked fashion, suggesting that the *GATA1* gene is required for regulation of platelet α -granules. Thrombocytopenia is usually pronounced and severe bleeding may occur. *Mediterranean macrothrombocytopenia* is an asymptomatic disorder with moderate isolated thrombocytopenia and large platelets inherited as an autosomal dominant trait. The condition is characterized by mild or no clinical manifestations and normal bone marrow megakaryocytosis, platelet survival and *in vitro* platelet functions. Platelets from some patients suffering from Mediterranean macrothrombocytopenia show reduced expression of the GPIb/IX platelet receptor and heterozygous mutations within the GPIb α (*GP1BA*) or GPIb β (*GP1BB*) genes have been described. Therefore, in these patients Mediterranean macrothrombocytopenia may be classified as a heterozygous form of Bernard–Soulier syndrome (see below). The remaining patients with Mediterranean macrothrombocytopenia do not show a reduction in the content of the GPIb/IX platelet receptor and the pathogenesis of this form remains to be clarified.

A thrombocytopenia resulting from enhanced platelet destruction may be present in *type 2B von Willebrand disease*. Patients suffering from this syndrome show a qualitative abnormality of plasma von Willebrand factor (VWF) such that VWF binds inappropriately to circulating platelets. The molecular bases are mutations within the VWF gene, usually in exon 28, that give rise to increased reactivity of VWF with the platelet receptor GPIb/IX. Clearance of the resulting VWF–platelet complexes leads to thrombocytopenia and the selective loss of the largest VWF multimers from plasma. In general, the degree of thrombocytopenia is moderate and bleeding is of variable severity. A mutation in the VWF gene has been identified in a kindred previously labelled *Montreal platelet syndrome*, a very rare platelet disorder characterized by giant platelets, reduced platelet count and spontaneous *in vitro* platelet aggregation; this

Table 48.3 Main clinical differences among syndromes due to mutations within the *MYH9* gene.

Disease	Macrothrombocytopenia	Renal disease	Hearing loss	Cataract	Leucocyte inclusion*

kindred has now been reclassified as having type 2B von Willebrand disease. Type 2B von Willebrand disease should be distinguished from the rare pseudo von Willebrand disease (or *platelet-type von Willebrand disease*). The defect in this autosomal dominant condition results from mutations in the gene encoding the GPIIb α subunit of the platelet receptor GPIIb/IX. The few mutations identified give rise to a gain of function of the platelet receptor and increase the affinity for VWF, resulting in spontaneous binding of platelets to VWF and leading to shortened platelet survival and thrombocytopenia. The reasons why most patients suffering from platelet-type von Willebrand disease show variable enlarged platelets remain unclear.

Other very uncommon causes of macrothrombocytopenia are *Jacobsen syndrome* and *Paris–Trousseau syndrome*. Both are syndromic diseases inherited as autosomal dominant traits and characterized by chromosomal deletion encompassing the same region of chromosome 11 (11q23.3–q24.2). A heterozygous deletion of the *FLII* gene has been identified in unrelated children with deletions of 11q23 and Paris–Trousseau thrombocytopenia. Interestingly, in patients suffering from Jacobsen syndrome without thrombocytopenia, the chromosomal deletion did not include the *FLII* gene, suggesting that deletion of this gene is responsible for the thrombocytopenia that occurs in most patients with Jacobsen and Paris–Trousseau syndromes.

Thrombocytopathies

Platelets have a complex ultrastructure comprising a multitude of molecules and the malfunctioning of any of these may give rise to a specific disease (Figure 48.1). Platelets participate in haemostasis by adhering to exposed elements of the subendothelial matrix. They then spread onto the subendothelial

surface, become activated, release the contents of their storage organelles, and aggregate to each other. Abnormalities in any of these stages – adhesion, activation, secretion and aggregation – may give rise to congenital disorders of platelets. Patients suffering from any of these diseases usually show a bleeding diathesis with a prolonged bleeding time and a normal platelet count.

Disorders of platelet adhesion

The interaction of platelet receptors with elements of the subendothelium, collagen, fibronectin and blood components allows platelet adhesion to the subendothelium, but it also occurs through the bridging effect of VWF (Figure 48.2). A series of receptors have been identified on the platelet surface and they interact with one or more of these elements. The most important receptors are GPIIb/IX and $\alpha_2\beta_1$ (previously known as GPIa/IIa). The $\alpha_2\beta_1$ receptor is one of the receptors on the platelet surface that binds collagen and is a member of the integrin β_1 subfamily. Other receptors for collagen are GPIV and GPVI. Binding of molecules to these receptors leads to the subsequent binding to other receptors, which serves to reinforce adhesion and to generate intracellular signals, such as calcium mobilization and protein phosphorylation.

Bernard–Soulier syndrome

Bernard–Soulier syndrome (BSS) is a bleeding disorder characterized by giant platelets on the blood smear, mild or moderate thrombocytopenia, and prolongation of the skin bleeding time disproportionate to the thrombocytopenia. BSS is a recessively inherited autosomal disorder and consanguinity is common in reported kindreds. Based on reported data, the frequency of BSS has been estimated to be approximately 1 in 1 million population. Bleeding may be severe and fatal haemorrhages may occur.

Figure 48.1 Schematic representation of the complex structure of platelets. Abnormalities of any platelet complex can lead to an alteration in a specific function.

Figure 48.2 Platelets circulate in the bloodstream and do not interact with endothelial cells (a) unless the vessel wall is damaged (b). Adhesion of platelets to injured blood vessel wall (c) and spreading on it (d) are possible through the interaction of platelet receptors with their ligands and VWF–collagen.

Cutaneous haemorrhages and muscle and visceral bleeding are common. Epistaxis and menorrhagia may be difficult to control. Haemarthrosis has also been reported. Platelet counts range from as low as $20 \times 10^9/L$ to near normal and, on the peripheral blood film, over 80% of platelets are usually larger than $2.5 \mu m$, often up to $8.0 \mu m$ in diameter. The number of bone marrow megakaryocytes is usually normal.

Patients presenting with BSS show absent platelet agglutination in response to ristocetin (in the presence of human VWF) and normal aggregation, ATP secretion and thromboxane (Tx) B_2 formation in response to a variety of aggregating agents, and delayed response to thrombin. Biochemical and cellular factors contributing to these abnormalities have been clarified. Because of the defective binding with VWF, platelets in BSS do not agglutinate in response to ristocetin and have substantial reduction in their ability to adhere to sites of vascular injury where subendothelial VWF becomes exposed. As a consequence, plug formation, the primary haemostatic response, is impaired in BSS and increased and prolonged bleeding occurs. Variable levels of the GPIb–IX–V complex have been detected on the platelet surface of patients with BSS, some patients with BSS exhibiting nearly normal amounts (variant type of BSS). Despite the difference in glycoprotein content, the clinical bleeding problems and platelet functional and morphological abnormalities of these patients were indistinguishable from the classical BSS phenotype.

The GPIb–IX–V receptor complex provides the principal site mediating the interaction of platelets with the adhesive VWF. The entire cDNA sequences encoding the protein chains comprising this receptor have been deduced, allowing studies on the molecular basis of the syndrome. This complex consists of four proteins: the disulphide-linked α -chain (135 kDa) and β -chain

(25 kDa) of GPIb and the non-covalently associated subunits GPIX (22 kDa) and GPV (82 kDa). They all share structural and functional features suggesting a common evolutionary origin. Different transcripts encode the four polypeptide chains and, with the exception of that of GPIb β , genes show continuous (intron-depleted) open reading frames. In addition, each element contains one or more homologous 24-amino-acid leucine-rich glycoprotein repeats. The genetic heterogeneity in the glycoprotein content of BSS patients shows that multiple molecular abnormalities may lead to a similar clinical disorder, and implies that BSS may be the result of defects within the subunits that hamper the coordinate expression of the complex on the platelet membrane. In this respect, BSS would resemble abnormalities of other multi-subunit complexes, in which a defect in a single subunit prevents the assembly and surface expression of the complex.

In addition to quantitative and qualitative abnormalities of the GPIb α gene, the recognized BSS phenotype has also been documented in patients with detrimental mutations within platelet GPIX and GPIb β genes. Very few patients with a defect in one of the platelet receptors for collagen have been described. These patients show mild bleeding disorders and a selective impairment, at a variable extent, in collagen response, adhesion to subendothelial surfaces and collagen-induced platelet aggregation. Platelets have two major receptors for collagen, the $\alpha_2\beta_1$ integrin, with a major role in adhesion of platelets to subendothelial surfaces, and GPVI, mainly involved in platelet activation. Thus, it is conceivable that collagen binding to platelets occurs through a multistep mechanism involving first the attachment of platelets to exposed collagen of the subendothelium in flowing blood by means of the $\alpha_2\beta_1$ receptor and then platelet activation through a second receptor, GPVI.

Disorders of platelet signalling transduction

Platelets that adhere to the subendothelial surface become activated and begin the production or release of several intracellular messengers, which modulate a series of platelet responses such as calcium mobilization, protein phosphorylation and production of arachidonic acid. Activated platelets also release substances stored in their granules, some of which act in the recruitment of additional platelets and lead to the formation of the primary haemostatic plug (Figure 48.3). Several signalling mechanisms are involved in events that govern platelet responses, starting with platelet adhesion to injured blood vessel and leading to secretion and aggregation. Available evidence suggests that specific abnormalities in platelet signalling mechanisms may be the basis of platelet dysfunction, and the term 'platelet signalling disorders' defines a group of heterogeneous abnormalities in platelet secretion and signal transduction. Congenital defects of platelet signalling mechanisms are grouped together for convenience of classification rather than by the pathophysiology of specific diseases. Patients suffering from these defects represent the vast majority of subjects presenting with inherited thrombocytopathies.

Many platelet receptors are coupled to G proteins: P2Y₁ and TxA₂ receptors and thrombin act via G_{αq}; prostaglandin recep-

tors activate whereas P2Y₁₂ receptors inhibit adenylate cyclase through G_s and G_{i2} respectively. Platelet activation by means of binding to receptors gives rise to hydrolysis of phosphoinositide by phospholipase (PL)C, leading to the formation of inositol trisphosphate, which in turn functions as a messenger to release calcium from intracellular stores. In addition, hydrolysis of phosphoinositide leads to the formation of diacylglycerol that activates protein kinase C. The activation of protein kinase C is thought to play a major role in platelet secretion and in the activation of the α_{IIb}β₃ complex. Although defects in PLC activation, calcium mobilization and protein phosphorylation have been suggested in several patients, unique patients have been reported with deficiency in platelet G_{αq}, G_s hyperfunction and reduced expression of PLCβ₂.

Following stimulation, platelet PLA₂ mobilizes arachidonic acid from the phospholipid pool. The arachidonic acid is then metabolized by cyclooxygenase and thromboxane synthase to form TxA₂, a strong platelet-aggregating agent that is necessary for the secretion response. A defect in arachidonic acid mobilization and TxA₂ production has been identified in some patients. Few patients with impaired liberation of arachidonic acid have been described. Platelets in individuals with this defect show abnormal aggregation and secretion in response to a series of stimulating factors but normal production of TxA₂ in response to arachidonic acid. Several patients have been reported with deficiency of cyclooxygenase and show a slightly prolonged bleeding time and impaired platelet aggregation. In addition, a few patients show a defect in TxA₂ formation and present with a variable bleeding diathesis.

Disorders of platelet aggregation

Platelet aggregation may be defined as the interaction of activated platelets with one another and occurs after adhesion of platelets to the wall of the injured blood vessel. A series of factors are capable of inducing platelet aggregation and may be classified as primary and secondary platelet-aggregating agents. Primary aggregating agents are those factors, such as ADP, adrenaline and thrombin, able to directly induce platelet aggregation independently of their ability to release intraplatelet ADP or to induce the production of prostaglandins. Secondary aggregating agents are factors that induce aggregation of platelets through their ability to provoke the release reaction of ADP or the synthesis of prostaglandins. Accordingly, disorders due to impairment of platelet aggregation may be classified into defects of primary aggregation (Glanzmann thrombasthenia), selective impairment of platelet receptors (ADP, adrenaline) and defects of secondary aggregation (storage pool disease, selective impairment of platelet receptors such as thromboxane and collagen). *In vitro*, a series of substances are employed to challenge platelets and the manner in which they respond to these stimuli may be helpful for identifying specific thrombocytopathies (Table 48.4).

Figure 48.3 Platelets, after adhering to the subendothelial surface (a), become activated, release intracellular messengers (b) and aggregate each other leading to the formation of the primary haemostatic plug (c).

Table 48.4 Platelet response to aggregating agents in different thrombocytopathies.

<i>Disorder</i>	<i>ADP</i>	<i>Adrenaline</i>	<i>Collagen</i>	<i>Arachidonic acid</i>	<i>Ristocetin</i>

Defect of signal transduction	Variable impairment	Variable impairment	Variable impairment	Variable impairment	Present
Glanzmann thrombasthenia	Absent	Absent	Absent	Absent	Present
δ -Storage pool disorder	Impaired	Impaired	Impaired	Variable	Present
Thromboxane receptor defect	Impaired	Impaired	Impaired	Impaired	Present

Defects of primary aggregation:**Glanzmann thrombasthenia**

Glanzmann thrombasthenia (GT) is a bleeding diathesis marked by prolonged bleeding time, normal platelet count, and absence of platelet aggregation in response to platelet agonists such as ADP, collagen, arachidonic acid and thrombin. Platelet agglutination induced by ristocetin and VWF is normal. This congenital bleeding disorder is associated with impaired or absent clot retraction. GT is one of the less common of the congenital bleeding disorders (prevalence 1 in 1 million) and is transmitted as an autosomal recessive trait; consanguinity has been reported in affected kindreds. The clinical features are those expected with platelet dysfunction: easy and spontaneous bruising, mucosal membrane bleeding, subcutaneous haematomas, and petechiae. Rarely, patients suffer from intra-articular bleeding with resultant haemarthroses. Fatal haemorrhages have been reported.

Quantitative or qualitative (variant GT forms) abnormalities of the platelet $\alpha_{IIb}\beta_3$ integrin (also known as GPIIb/IIIa complex) have been shown to be responsible for this disorder. Mutations within the genes that code for $\alpha_{IIb}\beta_3$ subunits have been described in GT patients. As with other integrins, α_{IIb} and β_3 subunits are prominent integral components of the platelet membrane that form heterodimers containing specific sites for platelet–platelet cohesion. The $\alpha_{IIb}\beta_3$ integrin serves as a platelet receptor for fibrinogen, fibronectin, vitronectin and VWF. In addition, the $\alpha_{IIb}\beta_3$ integrin modulates, to some extent, calcium influx, cytoplasmic alkalinization, tyrosine kinase phosphorylation and clot retraction.

The clinical heterogeneity of GT has been stressed on the basis of platelet function testing or using crossed immunoelectrophoresis, Western blot, flow cytometry and fibrinogen binding. Type I GT is characterized by the lack of surface-detectable $\alpha_{IIb}\beta_3$ complex and a profound defect in platelet aggregation and clot retraction. At variance with type I, platelets of patients suffering from type II GT have detectable, but mark-

edly reduced, amounts of the $\alpha_{IIb}\beta_3$ receptor on their surface, usually 10–20% of normal values. Platelets manifest sufficient amounts of receptors to allow microaggregate formation, although there is still a profound defect in the ability to form large aggregates. Clot retraction is only moderately impaired. In addition, a series of patients with a variant form have been described who present near-normal levels of the $\alpha_{IIb}\beta_3$ complex, which is dysfunctional in that platelets, when activated, can neither aggregate nor bind fibrinogen. Extreme variability in the clinical symptoms is present, even among patients with similar degrees of platelet abnormality and prolongation of the bleeding time. In general, no aggregation abnormalities are detected in heterozygotes, but a decreased amount of the $\alpha_{IIb}\beta_3$ integrin has been reported, platelet content being approximately half of normal.

Selective impairment of platelet receptors

Defects of platelet ADP receptors have been characterized in a few patients and all suffered from a bleeding diathesis. On the platelet surface, different types of ADP receptors have been identified, including two G protein-coupled receptors, P2Y₁ and P2Y₁₂. The P2Y₁ receptor is responsible for the shape change of platelets and transient platelet aggregation, giving rise to centralization of platelet granules and formation of filopodia, while the P2Y₁₂ receptor is involved in amplification of the response and in the stabilization of platelet aggregates through full activation of the $\alpha_{IIb}\beta_3$ integrin. The P2Y₁₂ receptor defect is inherited as an autosomal recessive trait and most patients so far identified were born from consanguineous parents. In these patients, blunted platelet aggregation in response to ADP, with a retained shape change, has been reported. Only one patient has been briefly reported with a defect of the P2Y₁ receptor. This patient showed impaired platelet aggregation in response to ADP and other agonists.

The selective impairment of adrenaline (α_2 -adrenergic) receptors has been associated with bleeding. A number of indi-

viduals with an impaired aggregation response to adrenaline and a congenital defect of platelet α_2 -adrenergic receptors have been described and some of them presented a history of easy bruising.

Defects of secondary aggregation

Secondary aggregation disorders are more frequent than primary aggregation disorders and the most common in this category are the storage pool deficiency (SPD) syndromes. SPD syndromes may be classified in a system that takes into account the content of both dense and α granules (Figure 48.4). Thus δ -SPD identifies patients who show low platelet content of dense granules only. Patients with deficiency of both types of granules are designated $\alpha\delta$ -SPD. Finally, patients presenting with reduced or absent platelet content of α -granules but normal levels of dense granules (α -SPD) are categorized as patients with GPS. The disorder is heterogeneous and the term SPD includes a group of disorders having as their common feature a diminution in secretable substances stored in platelet granules.

A storage pool disease is found as an associated defect in most of the patients carrying other rare syndromes, such as WAS and the TAR syndrome. However, the majority of patients presenting with an SPD have no associated diseases and are otherwise normal. The clinical features of this type of secondary aggregation disorder are those expected with a platelet function defect and consist of easy and spontaneous bruising, mucocutaneous haemorrhages, haematuria and epistaxis. Patients with δ -SPD or $\alpha\delta$ -SPD usually have absent ADP- and adrenaline-induced secondary aggregation waves, although the primary waves are present. Patients with δ -SPD may present a severe or partial

Figure 48.4 In platelets, granules are the storage site for substances that are important in the haemostatic process. The α -granules contain proteins involved in adhesion (fibronectin, VWF), cell-cell interaction (P-selectin) and in promoting coagulation (FV, platelet factor 4), whereas the content of dense granules is important in recruiting additional platelets (ADP, serotonin).

granule deficiency. Collagen-induced aggregation is absent or markedly reduced, whereas ristocetin-induced agglutination is normal. In several kindreds, the disorder appeared to be inherited as an autosomal dominant trait. However, in other families the type of inheritance could be not determined. In the absence of other congenital abnormalities or an associated α -granule deficiency, SPD is inherited as an autosomal dominant trait.

The other forms of δ -SPD coincident with other congenital abnormalities, such as TAR, are usually inherited as autosomal recessive traits, or as X-linked traits as in the case of WAS. An SPD is usually present in Hermansky-Pudlak syndrome and in Chédiak-Higashi syndrome. *Hermansky-Pudlak syndrome* (HPS) is a rare autosomal recessive inherited disorder characterized by the presence of oculocutaneous albinism, absence of platelet dense granules, and infiltration of ceroid-pigmented reticuloendothelial cells in the lung and the colon, leading to pulmonary fibrosis and inflammatory bowel disease. HPS results from the abnormal formation of intracellular vesicles. The impaired function of specific organelles indicates that the causative genes encode proteins operative in the formation of lysosomes and vesicles. HPS displays genetic heterogeneity and, so far, mutations in eight orthologous genes have been found in patients with this disease: *HPS1*, *HPS2* (*AP3B1*), *HPS3*, *HPS4*, *HPS5*, *HPS6*, *HPS7* (*DTNBP1*) and *HPS8* (*BLOC1S3*).

In *Chédiak-Higashi syndrome* (CHS) a variable degree of oculocutaneous albinism and a poor resistance to respiratory and cutaneous infections are usually found. The infections are generally fatal during infancy or in early childhood but patients may also die of a chronic lymphohistiocytic infiltration known as the accelerated phase during the second or third decades of life. CHS is extremely rare and is inherited as an autosomal recessive trait. Unlike HPS, CHS does not seem to display locus heterogeneity and the only gene proved to cause CHS, *LYST*, is located on chromosome 1q42.1-42.2. HPS and CHS both present findings typical of an SPD: bleeding of mucosae, epistaxis and spontaneous soft-tissue bruising. On the other hand, in *Quebec platelet disorder*, a rare autosomal dominant bleeding disease associated with abnormal proteolysis of α -granule proteins, platelets show increased stores of urokinase plasminogen activator and genetic studies implicate a major role for a mutation in an uncharacterized *cis* element near the urokinase plasminogen activator gene. Intraplatelet generation of plasmin is thought to trigger degradation of stored α -granule proteins, increasing risks for a number of bleeding symptoms, including delayed-onset bleeding after haemostatic challenges that responds only to fibrinolytic inhibitor therapy. Recently, Paterson *et al.* clarified the pathogenesis of the Quebec platelet disorder: a duplication of the *PLAU* gene.

Several patients have been described with selective impairment of the TxA_2 receptor, a mild lifelong disorder, exhibiting mucosal bleeding and easy bruising and defective platelet aggregation in response to several agents but not thrombin. Autosomal dominant inheritance has been suggested in some cases.

Therapy

As a rule, there is no specific treatment for the vast majority of congenital platelet disorders. In congenital thrombocytopenias due to maternal use of drugs or chemical agents, thrombocytopenia recovers after a few days to a few weeks, as in the case of thiazide drugs. In surviving thrombocytopenic newborns infected with rubella or cytomegalovirus, platelets levels may return to normal after several months. In newborns with alloimmune congenital thrombocytopenia, platelets return to normal values in 14–21 days. Only severe cases need to be treated with washed platelets, corticosteroids or exchange transfusions. In general, the main treatments in patients with congenital platelet diseases are general measures aimed at avoiding bleeding and the use of supportive therapeutic approaches for controlling haemorrhage. However, since types and severity of bleeding vary in different patients, therapeutic approaches have to be individualized.

General measures

Education of patients is of great importance. Patients and their parents have to be instructed to avoid trauma. Regular dental care may be helpful in preventing gingival bleeding. Drugs that impair platelet functions, such as acetylsalicylic acid-containing medications, should be avoided. In women, oral contraceptives can be used to prevent menorrhagia. Local measures, such as the application of firm pressure in the case of epistaxis, will usually suffice in the event of mild bleeding.

Drugs

Antifibrinolytic agents are useful as an adjunctive measure to prevent and control mild or moderate bleeding and may stop menorrhagia and other mild bleeding manifestations from mucous membranes, such as epistaxis. In the case of more serious bleeding, antifibrinolytic drugs such as tranexamic acid may be used, either 15–25 mg/kg orally three times daily or 10 mg/kg i.v. three times daily.

Desmopressin (1-desamino-8-D-arginine vasopressin or DDAVP) is the mainstay of therapy of patients with congenital platelet defects. Depending on the platelet defect, administration of DDAVP may shorten the bleeding time. Intravenous, subcutaneous or intranasal administration of DDAVP increases factor VIII and VWF transiently by releasing them from storage sites and its use has been suggested to be of value in some patients presenting with congenital platelet defects, such as those with BSS, May–Hegglin anomaly, GPS, SPD and GT. The drug is usually administered at a dose of 0.3 µg/kg in 50 mL of saline by slow intravenous infusion (over 30 min) in order to avoid possible hypotensive effects. In general, since the response to DDAVP varies among patients but is constant in each patient, a test dose may be of value in identifying those patients who

will benefit from this treatment in order to prevent or control future bleedings.

The use of recombinant activated factor VII (rFVIIa) has been proved to be helpful in the treatment of bleeding in haemophilic patients with inhibitors. Recently, administration of rFVIIa has been employed to stop bleeding in patients with congenital platelet disorders, such as BSS, SPD and GT. In addition, in thrombasthenics this drug has been employed to avoid bleeding during surgical procedures. However, adverse reactions have been described, such as venous thromboembolism and arterial ischaemia. Based on the evidence from the literature, rFVIIa is currently approved in Europe for prophylaxis and treatment of bleeding in patients with GT with antibodies to GPIIb/IIIa and/or HLA, and past or present refractoriness to platelet transfusion. The recommended dose is a bolus injection of 90 µg/kg at 2-hour intervals for a minimum of three doses.

A second generation of synthetic thrombopoietin agonists, including AMG 531 and eltrombopag, have shown great potential in the treatment of forms of thrombocytopenia, including immune thrombocytopenic purpura and chemotherapy-induced thrombocytopenia. It is conceivable that thrombopoietin agonists would be helpful in congenital thrombocytopenia with reduced plasma levels of endogenous thrombopoietin.

Platelet transfusions

Platelet transfusions, using platelets from HLA-matched donors when available, are employed to control severe haemorrhage in thrombocytopenic patients or in individuals with thrombocytopathies. Since the risk of post-traumatic as well as of spontaneous bleeding increases as the platelet count falls, spontaneous haemorrhage becomes common as platelet count drops below $20 \times 10^9/L$ and is extremely likely at counts below $5 \times 10^9/L$. Extensive clinical experience has shown that control of bleeding is possible on achievement of an adequate elevation in the circulating platelet count. However, the coexistence of platelet dysfunction has to be taken into account in order to correctly calculate the dosage of platelets required. Platelet transfusions are effective in controlling bleeding but may be responsible for transmission of infectious diseases, febrile reactions or development of alloimmunization. In patients carrying thrombocytopathies, platelet transfusions should be employed only for the treatment of severe bleeding because of the risk of alloimmunization. The occurrence of platelet alloimmunization is more frequent in patients lacking a membrane glycoprotein, such as in BSS and GT. Alloantibodies develop because the deficient proteins are recognized as foreign and, in turn, induce refractoriness to platelet transfusion.

Other measures

Splenectomy has generally no effect in congenital thrombocytopathies and in thrombocytopenias but has proven effective in

patients with WAS. Allogeneic bone marrow transplantation may provide, in theory, an effective cure for inherited disorders involving platelet count or function, restoring normal megakaryocytopoiesis. Transplants have been successfully performed with complete correction in patients with WAS and severe GT. However, the risks of such a drastic procedure still outweigh those related to bleeding tendency and it is therefore rarely required in patients suffering from congenital platelet disorders.

Conclusions

Over the last few years, a series of improvements to better understand the pathogenesis of congenital platelet disorders have been achieved. In several congenital platelet diseases, the

gene responsible has been identified and several patients have been characterized at molecular level (Table 48.5). This information has allowed more accurate comprehension of congenital thrombocytopenias and thrombocytopathies. Careful collection of personal and family clinical data, physical examination and appropriate laboratory testing are of value for the evaluation of a patient presenting with bleeding due to congenital platelet disorders (Figure 48.5). Using this approach, in many instances it is possible to correctly identify the platelet defect. However, despite recent advances in knowledge, in most patients with a congenital bleeding disorder and impairment of platelet function, the underlying molecular mechanisms are still unknown. In the near future, one of the challenges will be to ameliorate our understanding of congenital platelet disorders in order to obtain powerful tools for prevention, diagnosis and therapy of bleeding. On the other hand, gene therapy may offer

Introduction

Primary immune thrombocytopenia (ITP), previously called idiopathic thrombocytopenic purpura, is an autoimmune bleeding disorder that affects both children and adults. Until fairly recently, it was considered an autoantibody disorder in which platelets, opsonized with antiplatelet antibody, were removed prematurely by the reticuloendothelial system. More recently, studies have shown that in many patients there is a relative platelet underproduction that contributes to the thrombocytopenia seen in this disease.

Many patients have no clinical problems but bleeding may occur. ITP is unpredictable in its clinical course. To date, treatment has aimed at reducing the platelet destruction, mainly through immunosuppression. However, new thrombopoietin receptor agonists have been developed that enhance bone marrow platelet production. These newer targeted treatments are likely to be associated with less toxicity due to immunosuppression than traditional therapies.

Clinical features

The two principal forms of ITP, paediatric and adult, are quite distinct in their underlying cause and presentation. In

children, ITP may follow a viral illness or immunization. The profound thrombocytopenia may be associated with extensive petechiae, purpura and bruises. There may also be bleeding from mucous membranes such as the nose or mouth. Despite the severity of the clinical features, most children need little treatment, and undergo spontaneous remission in the majority of cases. Around 15% will develop a more chronic form of the disease.

ITP in adults is much more insidious. There is generally no prodromal illness and the patient may be aware of petechiae or excessive bruising, and seek medical attention. ITP is often diagnosed by chance, for example during hospital admission for surgery or full blood count (FBC) is checked for other reasons. This is particularly true if the platelet count is not very low and there are no skin manifestations of thrombocytopenia.

ITP, particularly in adults, is heterogeneous. Many patients suffer few clinical problems related to their thrombocytopenia while others have major bleeding from the outset. The platelet count alone appears to be an unreliable predictor of outcome, and the clinical symptoms and signs of ITP are influenced by patient age, general health, comorbidities, medication and many other factors that have not been identified. In addition, there may be an acquired platelet dysfunction caused by antibody binding to an important region of the glycoprotein molecules on the platelet surface. Autoantibodies reacting with glycoprotein (GP)IIb/IIIa may affect platelet aggregation, and anti-GPIIb/IX autoantibodies can impair platelet adhesion to the subendothelial matrix, causing unexpectedly severe bleeding for the level of platelet count. Other autoantibodies such as antiphospholipid antibodies occur in up to 30% of patients with

Table 49.1 New Consensus Terminology definitions.

Immune thrombocytopenia	Primary (old term 'idiopathic') Secondary (SLE, etc.)
Diagnosis	Requires platelet count $< 100 \times 10^9/L$
'Acute' and 'chronic' replaced by	'Newly diagnosed', 'persistent' and 'chronic' (see Figure 49.1)
Severe ITP	Where there is clinically relevant bleeding irrespective of platelet count
Refractory	Failed splenectomy or relapse <i>and</i> severe ITP or risk of bleeding

ITP, and these may affect platelet and vascular function. However, in general, unlike the thrombocytopenia that accompanies bone marrow failure, serious bleeding is not common in patients with ITP. The reason for this is not completely understood, but is believed to be partly due to the large proportion of young (metabolically active) platelets present in ITP compared with other causes of thrombocytopenia. The other factor which is often overlooked is that the large platelets in ITP are not counted accurately by automated counters. The true platelet count in patients with ITP is therefore higher than the reading given when using an automated analyser.

Reaching a consensus on terminology

Until recently, comparing data from clinical studies in ITP has been made extremely difficult due to the inconsistent way in which terminology has been used. For example, the term 'refractory' has been interpreted in different ways. For some it implies the post-splenectomy patient who has failed to respond or who has relapsed. Others interpret the term to mean those who do not respond well to treatment irrespective of splenectomy status. Similarly, deciding what constitutes a 'complete response' to therapy differs from study to study, making comparisons of drug treatments fraught with problems.

In order to address this, a group of experts held a consensus meeting and agreed on the terminology that should be used in ITP. These have been published and will be used in all drug trials, and in the clinic, from now on. The key terminologies are listed in Table 49.1.

Chronic ITP implies disease that has been present for 12 months or more from diagnosis. Previously, the term 'chronic' applied to individuals who had ITP for 6 months or longer. However, because patients may remit between 6 and 12 months, the term 'chronic' has now been redefined to refer to those individuals whose ITP has been present for 12 months or greater (Figure 49.1).

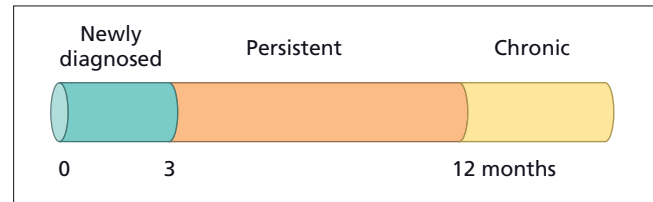

Figure 49.1 Stages of ITP using the new Consensus Terminology. After diagnosis until 3 months the patient is described as having newly diagnosed ITP. If the ITP persists beyond 3 months, it is termed persistent ITP and once the 12-month milestone has been reached the disease is described as chronic ITP.

Pathophysiology

ITP in adults is a typical organ-specific autoimmune disease and, in common with other autoimmune diseases, there is a skewing of the Th1/Th2 response towards Th1 (proinflammatory). These are disorders in which there are antibodies or cells (B cells, T cells, antigen-presenting cells, or others) that react against self antigens. These may cause disease if the target tissue is damaged. The binding of antibodies to target cells results in clearance of the antigen from the body. The normal adaptive response, such as that seen in microbial infection, results in complete removal of the non-self antigen. In autoimmune disease, however, there is continual production and incomplete clearance of the antigen, leading to perpetuation of the immune attack. In ITP the antigen is platelet glycoprotein, found on megakaryocytes and platelets.

Autoimmune disorders occur in around 5% of the population, although not all are symptomatic. In all, there are more than 80 distinct disorders, most of which are uncommon, apart from rheumatoid disease and autoimmune thyroiditis. Autoimmune diseases are clinical syndromes in which there is loss of tolerance to self, mediated by activation of T or B lymphocytes or other cells.

ITP is multifactorial

From studies of other autoimmune diseases, it is quite clear that ITP has a multifactorial basis, and that loss of tolerance to a self antigen alone is not sufficient to generate the autoimmune disorder. Patients probably require (i) a specific set of genetic determinants, such as polymorphisms within major histocompatibility complex (MHC), CTLA4, or other genes; (ii) dysregulation of the immune response (involving dendritic cells, T or B cells, or all three); and (iii) an environmental 'trigger'. The trigger may be infectious, for example a viral infection. Autoimmune disease arises only when all these determinants are present in an individual at the same time. This is further reinforced by the observation that self-reactive lymphocytes are

commonly found in normal individuals. For example, siblings of patients who have autoimmune disorders are more likely to have autoantibodies themselves, with no overt evidence of autoimmune disease. This may be because they have not been exposed to the environmental trigger required to tip the balance towards autoimmune disease.

Antiplatelet antibodies and their targets

The autoantibodies involved in ITP are generally IgG, but IgA and IgM autoantibodies have been reported. Opsonized platelets are removed prematurely by the reticuloendothelial system via an Fc-dependent mechanism. In addition, the autoantibodies may impair megakaryocyte growth and development, platelet release and may also induce apoptosis of megakaryocytes. The overall result of this is failure of platelet production.

There are various assays for measuring antiplatelet antibodies. Looking for the presence of platelet-associated IgG is of no value since this is found in non-immune as well as immune thrombocytopenia. More sophisticated assays, such as the monoclonal antibody-specific immobilization of platelet antigens (MAIPA) assay, has greater specificity (90%) albeit with low sensitivity (50–65%). Using MAIPA, platelet-associated IgG and antigen capture assays, several platelet antigens have been characterized. These include GPIIb/IIIa ($\alpha_{IIb}\beta_3$, the fibrinogen receptor) and GPIb/IX (the von Willebrand receptor), which appear to be the most frequently involved. Less commonly, GPIa/IIa, GPIV and GPV are involved. Recent reports suggest that around 40% of autoantibodies are reactive to both GPIIb/IIIa and GPIb/IX. In terms of disease chronicity, GP-specific autoantibodies may be important in the pathogenesis of chronic ITP; from available data GPIIb/IIIa appears to play a major role in the development of chronic ITP in 30–40% of cases.

Which platelet epitopes are involved?

Research has shown that the 33-kDa chymotryptic core fragment of GPIIIa is a frequent target of the autoantibodies. Fujisawa and colleagues, using synthetic peptides corresponding to GPIIIa sequences, showed that in 5 of 13 sera from patients with chronic ITP, binding was to residues 721–744 or 742–762, corresponding to the carboxy-terminal of GPIIIa. Recently, Nieswandt and colleagues have examined the pathogenic effects of IgG monoclonal antibodies of different IgG subclasses against murine GPIIb/IIIa, GPIb α , GPIb/IX, GPV and CD31. Their findings suggest that, at least in mice, the antigenic specificity of the antiplatelet antibodies determines the pathogenic effects rather than the IgG subclass. They also demonstrated that antibodies against GPIb/IX caused thrombocytopenia through an Fc-independent mechanism, while that from autoantibodies against GPIIb/IIIa involved the Fc system.

So far we have focused our attention on the B cells in ITP. However, at the T-cell level, it has been demonstrated that T cells from patients with chronic ITP will proliferate *in vitro* to disulphide-reduced GPIIb/IIIa or the molecule's tryptic peptides. This suggested that autoreactive CD4⁺ Th cells in chronic ITP need to recognize a modified GPIIb/IIIa molecule, implying that antigen-processing mechanisms within recipient antigen-presenting cells may be required to present GPIIb/IIIa autoantigens in the context of self HLA-DR molecules. Subsequently, mapping studies using six large (200 amino acids) recombinant fragments encoding different portions of the GPIIb α and GPIIIa chains showed that the T cells from patients with ITP recognized primarily the amino-terminal portion of the two GP chains (GPIIb α 18–259 and GPIIIa 22–262) and that these molecules also stimulated the production of antiplatelet autoantibodies. Ultimately, the GPIIIa molecule has been mapped for CD4⁺ T-cell specificities by using 15-mer peptides of the GPIIIa chain and this has revealed several immunodominant peptides spanning the entire breadth of the molecule.

The role of *Helicobacter pylori* in the development of ITP

This Gram-negative microaerophilic bacterium is the main cause of gastritis and peptic ulcer disease. It has also been implicated in the development of gastric adenocarcinoma and mucosa-associated lymphoid tumours, and in some autoimmune disorders. A number of studies have shown improvement in platelet counts in ITP patients positive for *H. pylori* following eradication of the bacterium. However, the data from different studies are conflicting, with some centres showing a very high rate of response to eradication while others have a low rate. Further support for the involvement of *H. pylori* in ITP comes from studies which have shown that there is a reduction in the level of antiplatelet antibodies in plasma following eradication of the bacterium.

How *H. pylori* may initiate or perpetuate ITP is not known. Possibilities include molecular mimicry, where there is cross-reactivity between the antibody, bacterium and platelet antigens. The bacterial protein Cag-A may be the target antigen and research has shown that there is molecular mimicry between Cag-A and platelet-associated antibodies. Further evidence of involvement of bacterial antigens and ITP comes from the work of Semple and colleagues who showed that, in the presence of platelet autoantibodies, the lipopolysaccharide of Gram-negative bacteria can enhance platelet phagocytosis. Although the role of *H. pylori* is not fully elucidated, it is worth screening patients with ITP for the presence of the bacterium and eradicating with standard triple therapy to see whether the patient's platelet count responds.

In paediatric ITP, the underlying cause of thrombocytopenia is most likely molecular mimicry or immune complex deposi-

tion. In a typical case of molecular mimicry, the child generally suffers a trivial viral illness or receives an immunization. The antibody against the virus, by chance, recognizes an epitope on the platelet. This results in platelet opsonization followed by platelet destruction. An alternative mechanism involving immune complex formation occurs when immune complexes between antibody and viral antigen are adsorbed onto the platelet surface leading to the premature removal of the platelet. Immune complexes are transient phenomena and as far as we are aware do not cause ongoing platelet destruction.

T cells may also be involved

The role of T cells in the development of ITP is becoming clearer. That T cells are involved has been known for some time, since the autoantibodies in ITP are predominantly of the IgG subclass, and isotype switching from IgM to IgG requires T-cell help. However, some 40% of patients with chronic ITP have no detectable autoantibodies yet are thrombocytopenic and appear to have true ITP. CD8⁺ T cells have been linked to the pathogenesis of many autoimmune diseases such as type 1 diabetes,

Figure 49.2 Model of cell-mediated cytotoxicity in chronic ITP. In the case of chronic ITP in the active phase, cytotoxic lymphocytes release toxic contents, such as granzyme B and perforin, and platelet lysis occurs.

and recently it was shown that ITP patients have a direct CD8⁺ T cell-mediated cytotoxicity that induces platelet destruction. At present, however, it is unknown whether cell-mediated platelet destruction contributes to the severity of disease or to the difficulty of treatment in some patients with ITP. However, recent studies by Wadenvik's group in Sweden suggests that in some patients with ITP, T cells may interact directly with platelets inducing platelet lysis (Figure 49.2).

Thrombopoietin levels in ITP

Since thrombopoietin (TPO) is the principal growth factor involved in platelet production, it might be expected that TPO levels would be raised in patients with ITP. Plasma TPO levels are undoubtedly elevated in patients with aplastic anaemia, chemotherapy-induced thrombocytopenia and other marrow failure syndromes. However, in ITP, levels of TPO are normal or only modestly elevated (Figure 49.3). The reason for this has been poorly understood until fairly recently.

The liver produces TPO at a constant rate and this binds to TPO receptors on platelets and megakaryocytes. The free (unbound) TPO is able to stimulate the bone marrow to generate sufficient platelets to counterbalance the natural daily platelet losses through platelet senescence. The key here appears to be the free TPO component. The greater this level, the more the bone marrow is driven to produce increased numbers of platelets. If the megakaryocyte mass and platelet numbers are increased, such as in ITP, TPO is bound to the receptors on these cells, leaving little free TPO to stimulate the bone marrow

Figure 49.3 In normal individuals serum thrombopoietin (TPO) levels are low. In aplastic states, due to the absence of megakaryocytes and platelets (which bind TPO), TPO levels are high. In patients with ITP, the platelet count is low and TPO levels are normal or modestly elevated. This is believed to be due to absorption of free TPO by the increased megakaryocyte and platelet mass which is found in ITP. (From Nichol 1998 with permission.)

Table 49.2 Potential causes of thrombocytopenia in ITP.

Autoantibody opsonization of platelets leading to destruction by the reticuloendothelial system
Autoantibody opsonization of megakaryocytes, with inhibition of megakaryocyte growth, differentiation and platelet release
Autoantibody-induced megakaryocyte apoptosis
Relative thrombopoietin deficiency
Molecular mimicry and immune complex formation
T-cell direct lysis of platelets

in patients with ITP. There is therefore a relative lack of TPO in patients with ITP, which compounds the platelet losses that occur through increased destruction of platelets by the reticuloendothelial system.

In summary, ITP is much more complex than originally believed, with several mechanisms leading to thrombocytopenia (Table 49.2).

Natural history of ITP

This has not been systematically studied. It is not clear which patients require treatment, whether treatment has any major beneficial effect on the patient, whether patients live longer, or whether treatment alters the natural history of the disease. For the majority of patients, ITP is a fairly minor disorder. Serious bleeding is not common and clinical sequelae of the disease are generally absent in patients with platelet counts above $30 \times 10^9/L$. There have been a few studies published looking at clinically relevant bleeding and platelet count. In normal individuals, there is a correlation between the platelet count and bleeding. The lower the platelet count, the more likely is bleeding. In ITP this is not the case, and most patients with ITP show little bleeding until the platelet count drops below $20 \times 10^9/L$. One study showed that no grade 4 bleeding occurred in patients with platelets greater than $10 \times 10^9/L$.

Diagnosis

Despite significant advances in our understanding of ITP, the diagnosis remains one of exclusion in both paediatric and adult ITP. A thorough history should be obtained, looking for diseases that might cause thrombocytopenia. The patient should be asked about bleeding during previous surgery or dentistry. The sites of bleeding should be determined. In children, the possibility of child abuse should be considered, although abused children will not generally have petechial haemorrhages or purpura, though they may have bruising.

Antithyroid antibody and thyroid function
Pregnancy test
Antinuclear antibodies
Viral PCR for parvovirus and cytomegalovirus
<i>Tests of unproven or uncertain benefit</i>
Glycoprotein-specific antibody
Thrombopoietin assay
Reticulated platelet count
Indirect platelet-associated IgG
Bleeding time
Platelet survival study
Serum complement levels

*The need for bone marrow remains contentious and the indications for performing this test are discussed in Table 49.4.

A full physical examination should be normal apart from the expected clinical signs associated with thrombocytopenia. In addition to the 'dry purpura' of ITP, there should be an examination of the mucous membranes, including the mouth, and optic fundi looking for the presence of retinal haemorrhage. Enlargement of the liver, spleen or lymph nodes suggests an alternative diagnosis.

The laboratory investigation of ITP is straightforward. The FBC should confirm the isolated thrombocytopenia. There may be a degree of iron deficiency anaemia but this should be in proportion to the clinical history. There should be no abnormal white blood cells or red cell fragments in ITP. If the latter are found, the underlying diagnosis may be thrombotic thrombocytopenic purpura, a disorder that is far more serious than ITP and which requires urgent treatment. Table 49.3 outlines the

most useful tests in the diagnosis of ITP, along with other tests that are either of limited value or no value.

Bone marrow examination

Previously, one of the mainstays of diagnosis was assessment of the bone marrow. The rationale behind this was the possibility of a patient having a marrow disorder such as leukaemia, lymphoma or infiltration. It was believed that detection of these by performing a bone marrow aspirate and trephine biopsy would aid diagnosis and management. However, studies to date have shown quite clearly that in patients with isolated thrombocytopenia, and with no atypical symptoms or signs, no cases of bone marrow pathology were detected. For this reason, recent guidelines do not recommend performing a bone marrow examination in such individuals. If patients fail to respond to, or relapse following, first-line treatment, then a bone marrow examination should be carried out. Similarly, if there is any hepatomegaly, splenomegaly, lymphadenopathy or any clinical or laboratory feature suggesting the presence of a disease other than ITP, a bone marrow examination should be performed. Bone marrow examination should also be performed if the patient is above the age of 60 years, since myelodysplasia becomes more likely, and myelodysplastic syndrome may resemble ITP. Finally, a bone marrow examination should possibly be carried out if splenectomy is being contemplated (Table 49.4), but in patients who have previously responded well to first-line therapies this test is probably unnecessary.

Cytologically, the bone marrow in ITP generally shows normal development and maturation of all cell lines. Megakaryocyte numbers are typically normal or increased. Increased numbers of small megakaryocytes may be a feature, suggesting increased proliferation of megakaryocytes required to compensate for the peripheral blood thrombocytopenia. What has not been appreciated until very recently is that the megakaryocytes may not be producing platelets at a sufficient rate, possibly through inhibition of platelet formation or release caused by the autoantibodies. In addition, MacMillan and others have shown that the binding of the glycoprotein autoantibodies may have other profound effects on thrombopoiesis, including the induction of apoptosis of megakaryocytes. The thrombocytopenia in ITP may therefore be due to peripheral destruction of platelets and a failure of production.

Table 49.4 Indications for bone marrow examination in ITP.

Before splenectomy (but see text)

Management

Major haemorrhage is the most feared event in patients with ITP. Over the years, attempting to prevent this by treating all patients with a platelet count below $30 \times 10^9/L$ has led to over-treatment. However, catastrophic bleeding is not commonly seen and the main aim of treatment today has shifted away from trying to normalize the platelet count towards finding a strategy that will allow the patient to achieve a 'safe' platelet count. What constitutes a safe platelet count will vary from patient to patient, and also each patient with ITP will have differing requirements throughout their disease history. For example, a young patient with platelet count of $20 \times 10^9/L$ should be safe to work and carry out normal day-to-day activities but would not be deemed safe if he or she wished to ski or undergo surgery. The safe platelet count would therefore be higher during these haemostatic challenges. So the one-size-fits-all approach has failed to work over the years and has caused increased morbidity and mortality in patients due to the adverse effects associated with many of the treatments in current use. When considering ITP treatments, we need to separate these into two major approaches: short-term and long-term treatments. These are discussed later.

There are many current treatments for ITP, although most have not been approved (licensed) for this indication. Those that do have a licence for ITP include corticosteroids, intravenous immunoglobulin (IVIg) and intravenous anti-D. All the others, of which there are many, have been used for many years but they have never undergone formal study and are not specifically approved for ITP. Even those that are licensed have variable licences, where the drugs are available in some European countries but not others. TPO receptor agonists are available in the USA and Australia but have not been fully approved in many other countries including the European Union.

All current treatments are of relatively low efficacy when used alone (around 30%), and all treatments address solely platelet destruction. They do this through a variety of different mechanisms but the net result is immunosuppression. The original rationale behind this was that in order to reduce the degree of autoantibody production, platelet opsonization and destruction by the reticuloendothelial system, the entire immune response should be suppressed. To some extent this works, although the treatments are purely palliative and once the treatment stops the platelet count drops to baseline levels once again. The disadvantage of immunosuppression is that, as well as reducing the level of antiplatelet antibody or diminishing the effectiveness of the reticuloendothelial system, normal immunity is suppressed. This can lead to infections and other complications. One study from 2001 showed quite clearly that, of the patients with ITP who died, at least half succumbed to infection caused by the immunosuppressive agents.

Traditionally, treatments have been grouped into first line, second line, third line, and so on depending on the disease stage in which they are used. These terms are not particularly useful clinically but do provide a guide as to which treatments to use initially and which should be used later.

First-line therapies comprise corticosteroids, IVIg and anti-D. These three treatments work fairly quickly (within 24–48 hours) and their efficacy rates are high at around 70–80%. The disadvantage of these and most of the other treatments is that the platelet count generally drops once the treatment is stopped. These treatments are seldom curative, and must be considered palliative therapies. In addition, IVIg and anti-D are pooled blood products.

If patients fail to respond to first-line treatment they may then be given a second-line drug, such as azathioprine or mycophenolate mofetil. These agents are much slower-acting and the efficacy rates are much lower than with first-line therapies (Table 49.5). As with first-line drugs, second- and third-line treatments are palliative.

Splenectomy is a surgical second-line option for patients who have relapsed after treatment with a first-line drug, although many clinicians prefer to defer splenectomy until later in the disease course. The rationale behind splenectomy is that the spleen is generally the main site of platelet destruction (and probably autoantibody production), so that removing the spleen prolongs the lifespan of the platelets and the platelet count rises. Although considered ‘curative’, splenectomy does not in fact cure ITP. Usually the autoantibodies remain and continue to opsonize the platelets. However, the main organ of platelet destruction has been removed and hence this is a form of phenotypic ‘cure’.

Table 49.5 Treatment options after first-line therapy.

Non-approved second-line treatments

- Azathioprine
- Dexamethasone
- Methylprednisolone
- Ciclosporin
- Mycophenolate mofetil
- Cyclophosphamide
- Danazol
- Dapsone
- Vincristine
- Rituximab

Surgical second-line treatment

- Splenectomy

Approved second-line treatments

- Romiplostim
- Eltrombopag

Short-term treatment

This refers to treatments lasting 2 weeks or more, which can be used when patients have a sudden drop in their platelet count leading to an unacceptably low platelet count, or when patients face haemostatic challenges such as planned surgery or dentistry or other high-risk activity, where the main risk is excessive bleeding. Patients are generally started on treatment 1 or 2 weeks prior to the event, with regular monitoring of platelet counts. Providing the counts reach a satisfactory level, the surgery or other procedure is carried out and the treatment is stopped shortly afterwards. By about 2 weeks the platelet count will have drifted back to baseline levels. Table 49.6 shows the target platelet counts for the most common procedures.

Long-term treatment

This is required when patients have an unsupported platelet count that is too low for normal day-to-day activities. Generally, these patients will have failed other therapies or, if they responded to corticosteroids, they require unacceptably high doses to maintain a safe count. In this setting the aim is not to achieve a specific count but rather to move the platelet count into a ‘safe’ zone. This will vary from patient to patient. In general, once platelets exceed $15\text{--}20 \times 10^9/\text{L}$ the risk of bleeding is low. Older individuals, or those with comorbidities or previous bleeding, will generally require a higher platelet count.

As we have already seen, most of the existing treatments used for long-term platelet control have known toxicities. The aim with long-term treatment is to use a treatment that has acceptable levels of toxicity but which achieves the desired platelet count.

Role of splenectomy for long-term control of the platelet count

Splenectomy has been used as a treatment for ITP for many years. The procedure increases the lifespan of antibody-coated platelets and may reduce antibody production. Responses are seen in about two-thirds of patients who achieve a normal platelet count, and the response is often sustained with no additional therapy for at least 5 years. Even patients who do not have a complete response may still expect a partial or transient

Table 49.6 Target platelet counts for procedures.

<i>Procedure</i>	<i>Target platelet count</i>
Dentistry (non-invasive)	Splenectomy
Dentistry (fillings, local anaesthesia)	$\geq 30 \times 10^9/\text{L}$
Minor surgery	$\geq 50 \times 10^9/\text{L}$
Major surgery	$\geq 80 \times 10^9/\text{L}$

increase in platelet count. Around 14% of patients do not respond and approximately 20% of responders will relapse months or years later.

Postoperative complications of splenectomy

In a recent systematic analysis, the complication rates of splenectomy were 12.9% with laparotomy and 9.6% with laparoscopic splenectomy. The mortality rate is 1.0% with the open laparotomy procedure and 0.2% with laparoscopy.

Venous thromboembolism (VTE) may occur following splenectomy, particularly if the platelet count rises to $1000 \times 10^9/L$ or more. ITP itself carries a small increased risk of VTE, although the exact level of risk is not known, but there may be an additive VTE effect in patients with ITP who undergo splenectomy. ITP patients should be evaluated for this risk and appropriate thromboprophylaxis should be provided.

Predicting the response to splenectomy

Clinicians have long sought possible predictors of response to splenectomy. Potential predictors have included response to oral corticosteroids, IVIg and others. Indium-labelled autologous platelet scanning appears to be the most sensitive predictor of response to splenectomy. However, indium scanning is not available in every hospital but is limited to only a few centres worldwide.

Prevention of infection after splenectomy

Splenectomized patients are at long-term risk for opportunistic post-splenectomy infection (OPSI) with encapsulated bacteria. OPSI is often rapidly progressive and has a poor outcome. The main organisms responsible for sepsis in splenectomized patients are pneumococci (50%), meningococci and *Haemophilus influenzae*.

In order to prevent OPSI, patients should be given prophylactic polyvalent pneumococcal vaccine at least 4 weeks prior to, or 2 weeks after, splenectomy with revaccination according to local guidelines. *H. influenzae* b and meningococcal C conjugate vaccinations should also be administered prior to splenectomy. Revaccination in susceptible individuals for *H. influenzae* should be administered according to local guidelines. Vaccination status should be recorded in the case notes. In patients who have received rituximab in the past 6 months, vaccinations may not be effective due to B-cell depletion.

In the UK the Chief Medical Officer advises the long-term use of oral antibiotics in the form of phenoxymethylpenicillin 250–500 mg twice daily, or equivalent, or erythromycin 500 mg twice daily if the patient is allergic to penicillin. However, the need for lifelong antibiotic prophylaxis remains unproven.

Patients with refractory ITP

The term 'refractory' has caused confusion over the years due to a lack of agreement about whether the term should be used

only for patients who have failed splenectomy. The new Terminology Consensus document published in 2009 defines refractory ITP as that where the patient has undergone splenectomy which has failed or relapsed, and who has 'severe' ITP (clinically relevant bleeding) or a risk of bleeding. Some 20% or more of adult patients fall into this category. Clinically, patients with refractory ITP pose a major challenge since, by definition, they are resistant to many of the treatments in current use. They often have low platelet counts, in addition to bleeding that is difficult to control since the disease is unresponsive to conventional therapies.

Is drug treatment needed?

Many adults with chronic refractory ITP are able to tolerate severe thrombocytopenia (platelet count as low as $10 \times 10^9/L$) relatively well, with near-normal quality of life. For patients who fail to respond to standard therapies and who require treatment, a limited number of options are available. The risks of continuing therapy should be discussed and evaluated with the patient and compared with the benefits that treatment may provide. Patients should be assessed for other possible causes of their thrombocytopenia, including drug-induced, infection, inherited thrombocytopenia and myelodysplastic syndromes. Instead of receiving further ineffective treatments, many patients choose to live with lower platelet counts and, providing they remain free of bleeding, a watching brief can be kept. If any bleeding does occur, the patient can be treated with rescue therapy such as IVIg in combination with intravenous corticosteroids or cyclophosphamide, aimed at raising the platelet count rapidly.

Rituximab

This chimeric monoclonal antibody targets the CD20 antigen on B cells and is licensed for B-cell non-Hodgkin lymphoma. There have been several studies of its use in ITP and other autoimmune haematological disorders. However, there are no randomized controlled studies and the drug has not been approved for use in ITP. Nonetheless, rituximab does appear to be effective in ITP, even when patients have failed multiple therapies. The largest review of rituximab in ITP was conducted by Arnold and colleagues, whose data suggest that around 60% of patients will respond to rituximab and approximately 40% of all patients will achieve a complete response. The responses are bimodal, with an early phase within 1–2 weeks and a second peak at about 6–8 weeks. Response duration varies from 2 months in partial responders to 5 years or more in about 15–20% of initially treated patients.

There are safety concerns with rituximab. For example, it should be used with caution in any patient who has positive hepatitis B core antibody status since hepatitis B may be reactivated. Adverse events associated with rituximab are usually

mild or moderate, with a low incidence of infections. However, B- and T-cell repertoires do not return to normal even when B-cell numbers have normalized. Severe infectious complications, including *Mycoplasma pneumoniae* and *Aspergillus niger*, echovirus, papovavirus and cytomegalovirus, have been reported. There are also reports of over 50 cases of progressive multifocal leucoencephalopathy (PML) associated with rituximab treatment in patients with lymphoma and connective tissue disorders. The use of cyclophosphamide, a potent immunosuppressant, appears to increase the risk of PML.

In terms of dosing, instead of using standard lymphoma doses (375 mg/m² weekly for 4 weeks), lower doses of rituximab (100 mg i.v. weekly for 4 weeks) have been shown to be equally effective. Finally, rituximab in combination with high-dose dexamethasone has recently been explored as a first-line treatment option, and appears to be highly effective in treatment-naïve patients.

Combination chemotherapy

This form of treatment may be effective for some patients with chronic refractory ITP. Recently, Tao and colleagues investigated a combination comprising intravenous cyclophosphamide on days 1–5 or 7 and prednisone on days 1–7, combined with vincristine on day 1, and one of the following: azathioprine on days 1 to 5 or 7 or etoposide on days 1–7. The overall response rate in the 31 patients treated was 67.9%, including a complete response in 41.9%; the therapy was well tolerated. Other combinations, such as CHOP and COP, have been used. However, the toxicities and side-effects of these therapies make them unpopular with both clinicians and patients.

Other treatments that have been used with variable success include alemtuzumab, stem cell transplantation and interferon alfa. These modalities of treatment have low efficacy and high toxicities and are best avoided, unless they are used within a trial setting.

New treatments: TPO receptor agonists

Because of the relative lack of TPO seen in ITP, as discussed earlier, there is the potential to use exogenous TPO in order to stimulate the bone marrow to generate more platelets. Early experience with recombinant human TPO (rhTPO) and recombinant human megakaryocyte growth and development factor (rhMGDF) yielded mixed results. The drugs appeared to be effective in raising the platelet count, but cross-reacting antibodies to the drugs neutralized endogenous TPO, making patients more thrombocytopenic than before the drug was given. For this reason development of rhTPO and rhMGDF ceased. More recently, rather than develop TPO receptor agonist drugs based on endogenous TPO, where there would be significant sequence homology and the potential for neutraliz-

ing antibodies to develop, pharmaceutical companies decided to create drugs with no sequence homology to the native TPO protein. Two TPO receptor agonists are now approved in the USA: one is a peptibody called romiplostim, and the other, eltrombopag, is a small non-peptide molecule. Both have been studied in patients with ITP both before and after splenectomy. The efficacy rates are encouraging in all patients, and since they do not involve immunosuppression and are not corticosteroid-based, they appear to offer many advantages over the drugs in current use. These drugs are likely to be used in place of the non-approved and relatively ineffective standard ITP therapies for non-pregnant adults, since the drugs have not been licensed for ITP in pregnancy or childhood. Studies in the latter have recently been approved in a number of countries in the European Union.

ITP in children

Children with ITP are treated based on clinical bleeding, quality of life and not just platelet count. Severe bleeding is uncommon in children with ITP, even when the platelet count is very low ($< 10 \times 10^9/L$). The incidence of intracranial haemorrhage (ICH) in children with ITP is around 0.1–0.5%. As with adult ITP, there is no method to predict which children will develop ICH, and this complication has been reported even in children receiving treatment for ITP. In general, however, ICH is commoner in patients with refractory or resistant disease than at initial presentation. Investigation of childhood ITP is similar to that in adults, although the incidence of *H. pylori* infection is much lower and there is no need to screen for this.

‘Watch and wait’ policy

Around 70% of children with acute ITP do not have significant bleeding symptoms and can be managed without drug therapy. Admission to hospital should be reserved for children with clinically significant bleeding, such as severe epistaxis or gastrointestinal or other bleeding. Most children with minor, mild or moderate symptoms can be safely managed in the outpatient setting. The emphasis is towards treating symptoms rather than platelet counts, since the platelet count is a surrogate marker and does not accurately predict clinical outcome.

General measures for persistent and chronic ITP in children

The management of children with persistent/refractory ITP is much the same as for newly diagnosed ITP. Many children stabilize with an adequate platelet count ($> 20\text{--}30 \times 10^9/L$) and have no symptoms unless injured. In children who are less than 10 years of age at diagnosis, spontaneous remission is likely to occur, and expectant management can continue depending on the risk of bleeding and the degree of activity restriction of the

child. The onset of menstruation may be problematic and can be managed with antifibrinolytic agents and the combined contraceptive pill.

The optimal management of chronic ITP in childhood is not known. Treatment should be tailored to each individual child and situation, and therapy should be effective and it should not carry more risk than the untreated condition.

Treatment options in childhood ITP

Children with severe bleeding symptoms should be treated. Treatment should also be considered in children with moderate bleeding or those at increased risk of bleeding.

First-line treatment in children

The majority of children require no medical treatment, and can be managed using a 'watch-and-wait' policy. If treatment is deemed to be required, options include IVIg, anti-D and corticosteroids. The other drugs used in adult ITP are not suitable for childhood disease due to their toxicities and long-term sequelae.

IVIg raises the platelet count in more than 80% of children and does so more rapidly than steroids or no therapy. Transient side-effects are seen in 75% of children. Intravenous anti-D immunoglobulin can be given to Rh(D)-positive children as a short infusion and is useful in the outpatient setting. Mild extravascular haemolysis is common, with a mean drop in haemoglobin of 1 g/dL. Like IVIg, anti-D is a pooled blood product but it is derived from a smaller donor pool. The safety profile of anti-D is good with no reported transmission of infection to date. However, there have been reports of severe intravascular haemolysis leading to disseminated intravascular coagulation, most of which have been fatal. Prednisolone at a dose of 1–2 mg/kg daily for a maximum of 14 days is effective in around 75% of children (platelet count $> 50 \times 10^9/L$) within 72 hours. More prolonged high-dose corticosteroid regimens are associated with increased toxicity. There are data to suggest that higher doses of prednisolone (4 mg/kg) for shorter courses may be more effective and associated with fewer side-effects.

ITP in pregnancy

Thrombocytopenia occurs in 5% of pregnancies, but most of these cases are gestational rather than immune-mediated. The diagnosis of ITP involves the exclusion of other causes of thrombocytopenia during pregnancy. Patient history, physical examination, blood count and blood film examination are used as in non-pregnant patients. The work-up of a pregnant patient with ITP is essentially the same as that of a non-pregnant patient. There are some conditions specific to pregnancy and these should be considered when investigating a pregnant patient with thrombocytopenia (Table 49.7).

Table 49.7 Causes of maternal thrombocytopenia in pregnancy.

Gestational thrombocytopenia
Pre-eclampsia, HELLP syndrome, disseminated intravascular coagulation
Folate deficiency
Massive obstetric haemorrhage

SLE serology
Review of the peripheral blood film
Reticulocyte count
Bone marrow examination: not required to make the diagnosis of ITP in pregnancy

Laboratory investigation of ITP in pregnancy

ITP in pregnancy, as with other types of ITP, is a diagnosis of exclusion. All investigations carried out in pregnancy are aimed at excluding conditions that may result in thrombocytopenia. Some disorders such as thrombotic thrombocytopenic purpura and HELLP syndromes require urgent diagnosis and treatment since the mortality rates are high (Table 49.8).

Management of ITP in pregnancy

There should be close collaboration between the obstetrician, haematologist, obstetric anaesthetist and neonatologist. Treatment is largely based on the risk of maternal haemorrhage. Throughout the first two trimesters, treatment is initiated when the patient is symptomatic and/or when platelet counts fall below $20 \times 10^9/L$, or when it is necessary to produce an increase in platelet count to a level considered safe for procedures such as obstetric delivery or epidural anaesthesia. Patients with platelet counts of $20\text{--}30 \times 10^9/L$ or more do not require routine treatment.

Delivery

A platelet count above $50 \times 10^9/L$ is generally acceptable for standard vaginal or Caesarean delivery. For epidural anaesthesia

a platelet count of $75 \times 10^9/L$ is required, although this is not evidence-based.

Treatment options in pregnancy

The primary treatment options for maternal ITP are similar to those of other adult ITP patients, namely corticosteroids and IVIg. There is limited evidence for the use of intravenous anti-D, splenectomy and azathioprine. Other agents, such as vinca alkaloids, rituximab, danazol and most immunosuppressive drugs (apart from azathioprine), should not be used in pregnancy because of possible teratogenicity.

Corticosteroids

These are the most cost-effective option. Prednisolone is initially given at a dose of 10–20 mg/day and may then be adjusted to the minimum dose that produces a haemostatically effective platelet count. At least 90% of the administered dose of prednisone is metabolized in the placenta by 11β -hydroxylase, but high doses may have an effect on the fetus.

Intravenous immunoglobulin

If prolonged high-dose steroid therapy is required or significant side-effects occur, or a rapid platelet increase is required, IVIg should be considered. The conventional doses of IVIg and likely response rates are similar to those seen in non-pregnant patients.

Options for maternal ITP refractory to first-line treatment

As with non-pregnant adults, combining first-line treatments in the refractory patient may be appropriate in the weeks prior to delivery. High-dose methylprednisolone (1000 mg), possibly in combination with IVIg or azathioprine, has been suggested as a treatment for pregnant patients refractory to oral corticosteroids or IVIg. Azathioprine has been used for many years in the post-transplant setting and this drug appears to be safe in pregnancy though the response is generally slow. Splenectomy in pregnancy is rarely required but if essential is best carried out in the second trimester.

Management of the neonate (of mothers with ITP)

ITP in the neonate (from mothers with ITP) accounts for 3% of all cases of thrombocytopenia at delivery. The fetal or neonatal platelet count cannot be reliably predicted from the maternal platelet count. After delivery, a cord blood platelet count should be determined in all cases. Intramuscular injections (such as vitamin K) in the fetus should be avoided until the platelet count is known. Those infants with subnormal counts should be observed clinically and haematologically as the platelet count tends to fall further to a nadir between days 2 and 5 after birth.

Anaemia of chronic disease

The anaemia of chronic disease (ACD) is a common normochromic or mildly hypochromic anaemia that occurs in patients with a systemic disease (Table 50.1). It is characterized by a reduced serum iron and iron-binding capacity, and normal or raised serum ferritin with adequate iron stores (Table 50.2). It is not due to marrow replacement by tumour, bleeding, haemolysis or haematinic deficiency, although these often complicate it.

Pathogenesis

The key factor in the pathogenesis of chronic anaemia in the setting of inflammation, infection and malignancy is an increased level of hepcidin. Hepcidin binds to ferroportin and the complex serves to prevent transmembrane iron transport. The body utilizes this mechanism to reduce the supply of iron

to microorganisms, but it also results in the reduction of iron absorption from the intestine and the sequestration of iron within macrophages, reducing supply of iron to developing erythrocytes. Additional mechanisms result from increased levels of inflammatory cytokines, including interleukin (IL)-1, IL-6, tumour necrosis factor (TNF) and transforming growth factor (TGF)- β . These interact with accessory marrow stromal cells and with the erythroid progenitors themselves to reduce their sensitivity to erythropoietin. In this way, the marrow is attempting to aid the recruitment of pluripotent stem cells to produce white blood cells in order to combat infection/inflammation and possibly malignancy. These inflammatory cytokines have also been shown to reduce the circulating level of erythropoietin. However, the deficiency in erythropoietin is relative: although the plasma erythropoietin level in ACD remains inversely correlated with the haemoglobin, compared with patients with other types of anaemia and normal renal function it is inappropriately low. The plasma levels of TNF- α , IL-1 (IL-1 α and IL-1 β) and IL-6 are raised. TNF and IL-1 have been shown in experimental systems to reduce erythropoietin production by cultured hepatoma cells. In addition, IL-1 α inhibits erythropoietin production by isolated serum-free perfused kidneys. A mild decrease in red cell lifespan occurs in

Table 50.1 Conditions associated with anaemia of chronic disorders.*Chronic infections*

Especially osteomyelitis, bacterial endocarditis, tuberculosis, abscesses, bronchiectasis, chronic urinary tract infections

Other chronic inflammatory disorders

Rheumatoid arthritis, juvenile rheumatoid arthritis, polymyalgia rheumatica, systemic lupus erythematosus, scleroderma, inflammatory bowel diseases, thrombophlebitis

Malignant diseases

Carcinoma (especially metastatic or associated with infection), lymphoma, myeloma

Others

Congestive heart failure, ischaemic heart disease, AIDS

Table 50.2 Haematological features of anaemia of chronic disease.

Haemoglobin	Not less than 9 g/dL
Mean corpuscular volume	Normal or mildly reduced (usually 77–82 fL)
Mean corpuscular haemoglobin	Usually normal; occasionally reduced
Serum iron	Reduced
Total iron-binding capacity (transferrin)	Reduced
Transferrin saturation	Mildly reduced
Serum ferritin	Normal or increased
Serum and urine hepcidin	Raised
C-reactive protein	Usually raised
Erythrocyte sedimentation rate	Usually raised

ACD but is at a level that could be compensated by a normal marrow. TNF has been shown to increase apoptosis in erythroid cells.

Inhibition of erythropoiesis

Both TNF and IL-1 inhibit erythropoiesis *in vitro* and it is likely that TNF increases apoptosis of bone marrow erythroid cells. Anaemia is observed in humans treated with TNF and in animals receiving either cytokine. The effect of IL-1 is probably mediated by interferon (IFN)- γ secreted by T lymphocytes, whereas TNF action is probably mediated by IFN- γ produced by marrow stromal cells. IL-6 and TGF- β may also have roles as mediators of ACD through inhibition of erythropoiesis.

Iron metabolism

A characteristic in ACD is the presence of a low serum iron with adequate reticuloendothelial iron stores, but with a reduction of iron granules in marrow erythroblasts. A fall in serum transferrin and a rise in serum ferritin occur as part of the acute-phase response. The fall in serum iron can occur as early as 24 hours after the onset of a systemic illness, and will persist during the course of a prolonged illness. The fall in serum iron results from an impaired flow of iron from cells (including intestinal mucosal cells, hepatocytes and macrophages) to plasma. This is due to increased secretion of hepcidin by hepatocytes in response to inflammation. Hepcidin inhibits release of iron from macrophages and iron absorption. Inflammation can cause a 100-fold increase in urinary hepcidin excretion. Microbial products may act on Kupffer cells to secrete IL-6, which then stimulates hepcidin secretion from hepatocytes. Low serum iron inhibits proliferation of microorganisms. Hepcidin secretion is also increased in iron overload. This seems unlikely to be due to a direct effect on hepatocytes. It is possible that iron in Kupffer cells or sinusoidal cells, like infection, stimulates production of cytokines, which act on hepatocytes.

In clinical specimens, there is a significant positive correlation between serum and urinary hepcidin and serum ferritin levels. The cytokines TNF, IL-1 and IFN- γ have all been shown to cause reduced serum iron and increased serum ferritin concentrations. The fall in serum iron is probably mainly, if not entirely, due to hepcidin. Anaemia usually reduces hepcidin secretion. In ACD, this effect is clearly abrogated by the effect of inflammation or malignancy increasing its secretion. Increased lactoferrin, occurring in response to inflammation and mediated by cytokines, competes with transferrin for iron and forms a complex that is taken up by macrophages in the liver and spleen. Increased intracellular apoferritin synthesis occurs in response to inflammation and malignancy and this too will bind iron. Both of these mechanisms reduce the amount of iron available for binding to serum transferrin.

Treatment

The severity of the anaemia correlates with the activity and severity of the underlying chronic disease. Successful therapy of this leads to a reduction in the levels of the mediator cytokines, increased erythropoietin production and reduced inhibition of erythropoiesis. Correction of the anaemia may take weeks or months. Pharmacological doses of recombinant erythropoietin have been used successfully to improve anaemia in patients with rheumatoid arthritis, cancer and myeloma. This observation suggests that inadequate erythropoietin production and its reduced action are more important than disturbed iron metabolism in the pathogenesis of ACD. It further suggests that the suppressive action of various cytokines can be overcome by use

of pharmacological doses of erythropoietin. Iron therapy should be reserved for patients who have genuine iron deficiency.

Malignancy

Anaemia

Anaemia is the most frequent haematological abnormality in cancer patients and may be due to many causes (Table 50.3). ACD (see above) will affect almost all cancer patients at some stage of their illness. The degree of anaemia reflects the extent of the malignancy and may be worsened by the myelotoxic effects of chemotherapy. Plasma erythropoietin levels tend to be inappropriately low and therapy with recombinant erythropoietin can reduce transfusion requirements by improving the haemoglobin level in cancer patients undergoing chemotherapy.

Haemolysis

Warm antibody autoimmune haemolytic anaemia (AIHA) is most frequently found in association with the following malignant diseases: chronic lymphocytic leukaemia, Hodgkin disease and non-Hodgkin lymphoma. However, it has also been reported in association with solid tumours (e.g. carcinoma of the ovary). Cold-antibody AIHA is less common, but occurs in association with monoclonal cold agglutinins in chronic cold agglutinin disease, Waldenström macroglobulinaemia and myeloma.

Table 50.3 Causes of anaemia in cancer patients.

Type of anaemia	Associations
Anaemia of chronic disease	All neoplasms
Blood loss	Gastrointestinal neoplasms, gynaecological neoplasms
Haemolysis	
Immune	Ovarian carcinoma, lymphoma, others
Non-immune	Mucin-secreting adenocarcinomas
fragmentation syndrome	
Haemolysis: secondary to drugs	Mitomycin, ciclosporin, cisplatin
Pure red cell aplasia	Thymoma
Megaloblastic	Chemotherapy, folate deficiency, cobalamin deficiency (gastric carcinoma)
Leucoerythroblastic	Metastatic disease in bone marrow
Marrow hypoplasia	Chemotherapy/radiotherapy
Myelodysplasia	Chemotherapy/radiotherapy

Microangiopathic haemolytic anaemia (MAHA) with intravascular haemolysis may occur in association with disseminated carcinoma. An abrupt onset of anaemia and thrombocytopenia often occurs, with a leucoerythroblastic blood picture, reticulocytosis and red cell fragmentation. Renal failure may occur as a complication. Mucin-secreting adenocarcinomas (especially gastric), breast cancer and lung cancer are the most common underlying malignancies; in about one-third of patients with MAHA, it is the presenting feature of the tumour. Abnormal blood vessels may be within the tumour itself (or within metastatic tumour thrombi, especially in the lungs) or fibrin deposition may occur at other sites because of disseminated intravascular coagulation (DIC). Widely disseminated disease with bone marrow infiltration is almost always present and the outlook is poor. A syndrome resembling MAHA and idiopathic haemolytic-uraemic syndrome (HUS) has been reported with a number of chemotherapeutic agents and following allogeneic bone marrow transplantation. Principal among these is mitomycin, although cisplatin, carboplatin, bleomycin and ciclosporin have also been reported to be responsible. Immune complex deposition has been implicated in the pathogenesis.

Red cell aplasia

Acquired pure red cell aplasia is associated with a thymoma in approximately 50% of patients, although it complicates only approximately 5% of thymomas. Antibodies to erythroid precursors have been demonstrated in some patients, and removal of the thymoma (which is usually benign) leads to resolution of the anaemia in about half of those affected. Immunosuppressive therapy with cyclophosphamide, ciclosporin, steroids or plasma exchange may be helpful in patients who relapse. Red cell aplasia may also occur in a minority of patients with chronic lymphocytic leukaemia (CLL) or non-Hodgkin lymphoma and with large granular lymphocytic (LGL) leukaemia and as part of general marrow aplasia due to chemotherapy or radiotherapy.

Leucoerythroblastic anaemia

The blood film (Figure 50.1) shows the presence of erythroblasts and granulocyte precursors (e.g. myelocytes and myeloblasts). It is seen in primary myelofibrosis but is also frequent when there is marrow infiltration by tumour. This disturbs the marrow microvasculature and allows early release of the precursors. Marrow infiltration is most commonly observed in breast (Figure 50.2), prostate and haematological malignancies, but also in tumours of lung, thyroid, kidney and gastrointestinal tract and melanoma. It can also occur as a reflection of active bone marrow response to peripheral consumption (acute haemolysis, DIC, septicaemia, hypersplenism) or of extramedullary haemopoiesis (e.g. myelofibrosis or megaloblastic anaemia).

Figure 50.1 Nucleated red cells and an immature myeloid precursor in the peripheral blood film of a patient with a leucoerythroblastic anaemia.

Figure 50.2 Bone marrow aspirate showing infiltration by metastatic breast carcinoma.

Other causes

Megaloblastic and dyserythropoietic anaemias are most commonly due to chemotherapy-induced disturbance of DNA synthesis within the bone marrow. Folate deficiency may also occur in patients with a poor diet and widespread disease. Cobalamin (vitamin B₁₂) deficiency due to underlying pernicious anaemia may complicate cancer of the stomach. Both chemotherapy and non-ionizing radiotherapy may lead to the development of myelodysplastic syndrome (MDS), which may progress to acute myeloid leukaemia (AML). Alkylating agents, especially melphalan and chlorambucil, nitrosoureas and epipodophyllotoxins in particular have been implicated, and there is evidence of a synergistic effect of these agents with small chronic doses of radiotherapy. The principal categories of patients affected are those who have received therapy for a haematological malignancy, but patients treated for non-haematological malignan-

cies (especially ovarian and gastrointestinal carcinoma) are also susceptible. The median latency prior to onset of MDS is 2–3 years and AML usually supervenes 6 months to 2 years later.

Treatment

Erythropoietin is effective in reversing anaemia in a proportion of patients with malignant disease, for example myeloma, lymphoproliferative disorders, MDS and carcinomas. It is recommended if the haemoglobin is less than 10 g/dL or in symptomatic patients with haemoglobin of 10–12 g/dL. Recombinant erythropoietin is not justified if the haemoglobin is above 12 g/dL as its use has been associated with an increased risk of thrombosis. The expression of both erythropoietin and its receptor is reported in a range of human tumours, including breast, prostate, colon, ovary, uterine and head and neck squamous tumours. Caution is therefore advised in the use of recombinant erythropoietin to treat cancer-related and cancer treatment-related anaemia, and further studies are required. Dosage is 10 000 IU three times per week or 30 000 IU as a single weekly dose. The dose could be increased if there is no response (< 1 g/dL rise in 4 weeks).

Patients most likely to respond are those who have low pre-treatment erythropoietin levels (< 100 mU/mL), well-preserved marrow function and normal/low levels of serum ferritin (< 400 ng/mL). A number of studies have demonstrated that erythropoietin therapy can lead to a reduced need for blood transfusion, better quality of life for patients and possibly improved overall outcome of anticancer therapy.

Polycythaemia

This is a rare complication of non-haematological malignancy. It usually arises through elaboration by tumour cells of erythropoietin and erythropoietin-like peptides. The tumours most commonly associated are renal cell carcinoma and hepatoma; others include uterine myoma, androgen-secreting ovarian tumours, pheochromocytoma and cerebellar haemangioblastoma. Non-malignant conditions affecting these organs (e.g. renal cysts, viral hepatitis) may also rarely be associated.

White cells (Table 50.4)

Granulocytosis

Granulocytosis is a frequent manifestation of non-haematological malignancies. In part, the response is due to inflammation induced by the tumour. Interaction of tumour cells with host T lymphocytes and mononuclear phagocytic cells leads to the production of a range of cytokines, which induce white cell proliferation and differentiation. Tumour cells may also secrete specific agents that directly stimulate reactive proliferation. Cancer patients frequently have opportunistic infections, may bleed and are typically on a range of medications, all of which may influence the level of the white cell count.

Table 50.4 White cell changes in malignancy.

Neutrophils increased	Most, especially renal Hodgkin disease
Neutrophils decreased	Bone marrow infiltration Hypersplenism Treatment induced Chemotherapy/radiotherapy Large granular lymphocytic leukaemia
Basophils increased	Myeloproliferative disorders
Eosinophils increased	Hodgkin disease T-cell lymphomas Metastatic adenocarcinoma Other tumours (e.g. lung) Drug allergy Opportunistic infection
Monocytes increased	Carcinoma Hodgkin disease
Monocytes decreased	Treatment induced
Lymphocytes increased	Lymphoid malignancies Post splenectomy Opportunistic infection
Lymphocytes decreased	Treatment induced Radiotherapy/chemotherapy Lymphoma Opportunistic infection

Granulocytopenia

This is most frequently due to chemotherapy or radiotherapy but may also occur with widespread marrow infiltration, for example by lymphoma or due to LGL leukaemia.

Platelets

Thrombocytopenia (Table 50.5)

This may arise through decreased production or accelerated peripheral destruction and/or hypersplenism. The former may result from extensive marrow infiltration or be secondary to chemotherapy or radiotherapy. Hypersplenism is usually due to splenic infiltration by a haematological malignancy (e.g. lymphoma, CLL) but is rarely due to obstruction of the splenic or portal vein by hepatic and pancreatic malignancies. Increased destruction occurs with DIC. Immune thrombocytopenia may occur in association with haematological malignancy (CLL, lymphoma, MDS) and rarely may complicate solid tumours (e.g. breast, lung, ovary).

Table 50.5 Thrombocytopenia in patients with malignant disease.

<i>Decreased production</i>
Chemotherapy/radiotherapy
Marrow infiltration
<i>Accelerated destruction</i>
Hypersplenism
Disseminated intravascular coagulation
Drug-induced haemolytic–uraemic syndrome
Autoimmune thrombocytopenia

Thrombocytosis

A raised platelet count is frequently seen as a reactive phenomenon in patients with malignancy but is usually less than $1000 \times 10^9/L$ and is rarely of clinical significance.

Platelet function abnormalities

Impaired platelet function leading to excessive bleeding is primarily seen in myeloproliferative disorders (e.g. essential thrombocythaemia) and MDS. Paraproteins, especially IgM in Waldenström macroglobulinaemia and IgG in myeloma, are frequent causes of impaired platelet aggregation and adhesion. Increased platelet aggregation occurs in cancer patients when tumour cells release adenosine diphosphate (ADP), prostaglandins or thrombin. Increased platelet adhesiveness has also been reported, but is probably secondary to other coagulation changes.

Coagulation (Table 50.6)

A wide range of coagulation changes can occur in patients with malignant disease and can predispose to either haemorrhage or thrombosis. The distinction between activation of the coagulation part of the haemostatic pathway (i.e. DIC), which leads physiologically to activation of fibrinolysis (secondary fibrinolysis), and primary or direct activation of fibrinolysis may be difficult, and in some ways academic, in view of the intimate and dynamic relationship that exists between the coagulation and fibrinolytic pathways. These patients may also have other general medical problems, including infection; they may have undergone surgery, chemotherapy or radiotherapy and will typically be on a range of medications. All these factors may contribute to coagulation changes.

Disseminated intravascular coagulation

Chronic or compensated DIC is probably underdiagnosed in cancer patients. It occurs particularly in those with gastrointestinal, lung, pancreatic and breast neoplasms. Thrombosis, including migratory thrombophlebitis (Trousseau syndrome)

Table 50.6 Coagulation changes in malignancy.*Bleeding tendency*

Disseminated intravascular coagulation, acute or chronic

Primary fibrinolysis

Acquired platelet function defect

Thrombocytopenia

Circulating anticoagulants/inhibitors

Treatment-related bleeding disorders

Thrombotic tendency

Venous stasis: bed rest, venous compression/invasion by tumours

Increased coagulation factors: FI, FV, FVII, FVIII, FIX, FXI

Decreased inhibitors of coagulation: low antithrombin, proteins C and S

Direct activation of coagulation by tumour cells: FVII, FX

Indirect activation: via trypsin release, mucin secretion, monocytes or endothelial damage

Increased platelet aggregability and adhesiveness

Thrombocytosis

and non-bacterial thrombotic endocarditis, is a more frequent manifestation of DIC than haemorrhage. In contrast, acute or uncompensated DIC is uncommon with solid tumours but occurs frequently with acute promyelocytic leukaemia (APL, FAB M3) and is associated with excessive bleeding. The triggering event in APL is likely to be release from the malignant promyelocytes of procoagulants and proteases, which may directly activate both coagulation and fibrinolysis. Tumour cells may activate coagulation by release of tissue factor (TF), which activates factor (F)VII. Direct activation of FX through the action of a cancer procoagulant has been reported in lung, kidney, colon and breast cancer. The sialic acid moiety of secreted mucin can directly activate FX, whereas the systemic release of trypsin in pancreatic tumours can also activate coagulation. Tumour cells may also activate the monocyte/macrophage system to produce procoagulant materials including TF and FX activators.

Primary fibrinolysis

This is less common as a cause of increased bleeding than DIC, but can occur, for example, in patients with prostatic cancer who undergo surgery. The release of proteases from leukaemic cells in both APL and monocytic leukaemia has been reported to induce fibrinolysis. Platelet counts tend to be higher than those seen in DIC, and fibrinogen levels are low, with raised fibrin degradation products (FDPs).

Acquired circulating anticoagulants (Table 50.7)

The most frequent is an acquired von Willebrand syndrome (both type 1 and type 2 disease) in patients with a paraprotein

Table 50.7 Circulating anticoagulants in malignancy.*Factor inhibitors*

Factor V

Factor VII

Factor VIII

von Willebrand factor inhibitors

Paraproteinaemic disorders

Lymphoma

Myeloproliferative disorders

Chronic lymphocytic leukaemia

Others

Heparin-like anticoagulants: dysproteinaemias

or a B-lymphoid malignancy. A number of different mechanisms may operate. The paraprotein may be directed against an epitope within the FVIII–von Willebrand factor (VWF) molecule and inactivate it, or reduce its plasma half-life. Alternatively, immune complexes may form which bind non-specifically to FVIII–VWF and accelerate its clearance, or the malignant lymphoid cells may actually adsorb FVIII–VWF onto their surface. Paraproteins may also interfere with cross-linking of fibrin.

Treatment-induced bleeding disorders

Thrombocytopenia and MAHA may occur as a result of therapy (see below). Cancer patients with poor nutrition or who are on long-term antibiotics may develop vitamin K deficiency. L-Asparaginase induces defective hepatic protein synthesis and can lead not only to impaired production of coagulation factors but also to low levels of antithrombin, plasminogen and proteins S and C, and so give rise to thrombosis, most seriously of the cerebral veins. Mithramycin, which is used in the treatment of malignant hypercalcaemia, causes thrombocytopenia as well as platelet function defects, coagulation factor deficiencies and increased fibrinolytic activity.

Connective tissue disorders (Table 50.8)**Anaemia**

ACD (see above) is the most common haematological abnormality seen in patients with rheumatoid arthritis (RA). Iron deficiency may coexist, particularly in patients taking non-steroidal anti-inflammatory agents. Folate deficiency may occur with severe disease and poor dietary intake. Warm-type AIHA with IgG and complement on the red cell surface is most frequently seen in systemic lupus erythematosus (SLE), although it can occur in the other connective tissue disorders, notably RA

Table 50.8 Haematological changes in connective tissue disorders.*Anaemia*

Anaemia of chronic disease

Myelofibrosis
 Drug-related changes (e.g. aplastic anaemia due to gold, phenylbutazone; PRCA due to penicillamine)
 Cryoglobulinaemia
 Amyloidosis

and mixed connective tissue disorders. Sideroblastic anaemia has been reported in both SLE and RA, but MDS must be excluded. Pure red cell aplasia and dyserythropoietic anaemia with ineffective erythropoiesis are rare complications of SLE. Haemolysis can also occur as part of thrombotic thrombocytopenic purpura (TTP), complicating SLE.

White cells

The inflammatory process in connective tissue disorders can lead to a neutrophilia. Neutropenia is a feature of Felty syndrome, which is associated with splenomegaly in patients with RA. The pathogenesis is multifactorial and involves increased margination of neutrophils, sequestration of neutrophils within the enlarged spleen, and immune complex-mediated and humoral inhibition of granulopoiesis in the marrow. Antibodies

to mature neutrophils have also been reported in SLE. Lymphopenia occurs in both SLE and RA, and may be a measure of disease activity. Eosinophilia may be seen in SLE, RA, polyarteritis nodosa and Churg–Strauss syndrome. The pathogenesis is unknown, but presumably involves release of cytokines by T lymphocytes. Functional defects in polymorph and lymphocyte function have been reported in SLE and RA.

Platelets

Immune thrombocytopenia is a common manifestation of SLE and also occurs in mixed connective tissue disorders, scleroderma, RA and dermatomyositis. Autoantibodies to platelets may also impair platelet function. TTP is an association of SLE. Thrombocytosis is a non-specific reaction to inflammation and tissue damage in connective tissue disorders.

Coagulation

A wide diversity of coagulation changes may occur in patients with connective tissue disorders. In part, this may be due to liver and renal disease or to drug therapy. DIC has been reported in SLE patients who have high levels of circulating immune complexes and resulting angiopathy. The lupus anticoagulant (see Chapter 47) occurs as a complication in about 10% of patients with SLE and is associated with a thrombotic tendency, thrombocytopenia, recurrent miscarriages and pulmonary hypertension. Specific coagulation factor inhibitors encountered in patients with connective tissue disorders (especially SLE) include antibodies to VWF and to FVIII, FVII and fibrinogen.

Other changes

RA is one of the commonest causes of amyloidosis. An increased incidence of haematological malignancies (principally Hodgkin and non-Hodgkin lymphomas and B-lymphoproliferative disorders, including paraproteinaemias) has been noted in SLE, RA and, particularly, Sjögren syndrome. A wide range of haematological abnormalities also results from immunosuppressive therapy in these patients.

Renal disease (Table 50.9)**Anaemia**

In acute renal failure, anaemia is commonly due to the drug or condition causing the renal failure, for example haemolysis due to sepsis or TTP. In chronic renal failure, anaemia is the most important haematological abnormality and its management has been revolutionized by the availability of recombinant human erythropoietin. Patients with acute or chronic renal failure

↓ Fibrinolysis	

develop a normochromic normocytic anaemia, with the presence of ecchinocytes (burr cells) in the blood film. The reticulocyte count is normal or slightly low, and the bone marrow shows normoblastic erythropoiesis without the erythroid hyperplasia expected at that level of anaemia. Patients who have undergone nephrectomy tend to be more severely anaemic than patients with polycystic disease. Reduced erythropoietin levels occur in renal failure and this is the dominant cause of anaemia.

An increase in serum creatinine above 133 µmol/L is associated with the loss of the normal inverse linear relation between plasma erythropoietin and haemoglobin concentration, but there is no direct correlation between reduction in glomerular filtration rate and impairment of renal erythropoietin production. Circulating inhibitors of erythropoiesis have also been

demonstrated. Chronic ambulatory peritoneal dialysis is more effective than haemodialysis in removing these inhibitors but, as recombinant erythropoietin can overcome these inhibitors, they are not of great clinical significance. Red cell survival is diminished in renal failure, but this is also a minor factor. Iron deficiency can arise through blood loss (exacerbated by haemodialysis). Folate deficiency arises in dialysed patients but is now prevented by prophylactic folic acid therapy. Renal failure is associated with elevated levels of 2,3-diphosphoglycerate and a right shift of the haemoglobin–oxygen dissociation curve.

Recombinant erythropoietin therapy can fully correct anaemia in renal failure. It can be administered intravenously, subcutaneously or intraperitoneally. The subcutaneous route is effective at lower doses, and it is usual to commence at 5–75 units/kg per week, given in two or three divided doses. Anaemia is corrected up to a level of 10–12 g/dL at a rate of 1 g/dL per month. Subclinical iron deficiency and impaired mobilization of storage iron are often present, so concomitant iron therapy is usually required. This can often be easily accomplished by the administration of intravenous iron, for example as iron dextran. An impaired response to recombinant erythropoietin should prompt a suspicion of iron, cobalamin or folate deficiency, haemolysis, infection, occult malignancy, aluminium toxicity or hyperparathyroidism. Hypertension occurs in about one-third of patients treated with recombinant erythropoietin and is dose dependent; the risk of thrombosis of an arteriovenous fistula is also increased.

The optimum dose of erythropoietin is one that restores the haemoglobin level to the normal or near-normal range and improves symptoms without increasing the risk of thrombosis; for most patients, this is approximately 12–12.5 g/dL and should not exceed 14 g/dL.

Polycythaemia

Secondary and inappropriate polycythaemia may result from either ectopic erythropoietin production by renal tumours or regional renal hypoxia (in benign disease and following renal transplantation), which disturbs physiological erythropoietin homeostasis. Up to 5% of patients with renal cell carcinoma have paraneoplastic polycythaemia.

Haemostatic abnormalities

Abnormal platelet function is probably due to the accumulation of toxic metabolites (e.g. guanidinosuccinic and phenolic acids). DDAVP (1-deamino-8-D-arginine vasopressin) therapy, which leads to the appearance of large multimers of VWF, can shorten the bleeding time in anaemic patients. Dysfibrinogenemia has been reported rarely, whereas FDPs are often elevated and may prolong the thrombin time. Hypercoagulopathy with a predisposition to thrombosis can also occur, especially after recombinant erythropoietin therapy.

Haemodialysis with heparin anticoagulation can cause platelet activation. Fibrinolytic activity, antithrombin and protein C are all reduced in renal failure, and FV, FVII, FVIII:C and FX are increased. Thrombosis (particularly of the renal vein) is a particular feature of the nephrotic syndrome. Platelet hyperaggregability with increased plasma β -thromboglobulin is described and hypoalbuminaemia may enhance the synthesis of prostaglandins involved in platelet activation.

Endocrine disease (Table 50.10)

Both hyperthyroidism and hypothyroidism are associated with mild anaemia, which is usually normochromic and normocytic, but may be macrocytic in hypothyroidism. A raised mean corpuscular volume (MCV) can occur without anaemia in hypothyroidism, and low MCV has been described in thyro-

Table 50.10 Haematological changes in endocrine disease.

Estrogen therapy: \uparrow FVIII, \uparrow VWF

Cushing syndrome: \uparrow FII, FIV, FIX, FXI, FXII

toxicosis. Thyroid hormones stimulate erythropoiesis, and tissue oxygen demands are increased in hyperthyroidism, whereas in hypothyroidism oxygen utilization is reduced. However, plasma volume is also increased and part of the anaemia in hypothyroidism is dilutional and/or due to defective iron utilization. Coexistent deficiencies of iron (due to menorrhagia or achlorhydria), folate and cobalamin must be excluded.

There is an increased incidence of pernicious anaemia in patients with hypothyroidism, hypoadrenalism and hypoparathyroidism. Antithyroid drugs (carbimazole, methimazole and propylthiouracil) can cause aplastic anaemia or agranulocytosis. Anaemia in patients with diabetes mellitus is usually due to complications of diabetes, although hyperglycaemia itself may lead to shortened red cell lifespan and decreased erythrocyte deformability. Polycythaemia (usually pseudo) can also occur with endocrine diseases. In anterior pituitary disease, androgen deficiency and adrenal insufficiency, a normochromic normocytic anaemia is common. Changes in leucocyte number and function are rarely of clinical significance, although many have been reported. Chemotaxis, phagocytosis and intracellular killing may all be disturbed in diabetes mellitus. Coagulation changes may contribute to a mild bleeding diathesis in hypothyroidism and to the thrombotic predisposition in diabetes mellitus.

Liver disease (Table 50.11)

Liver disease causes a greater range of haematological change than does disease in any other organ, with the exception of the bone marrow. The liver is an important source of erythropoietin in the fetus, and serves as a haemopoietic organ *in utero*; extramedullary haemopoiesis occurs within the adult liver only in pathological states (e.g. myelofibrosis, severe haemolysis or megaloblastic anaemia).

Anaemia

Anaemia occurs in up to 75% of patients with chronic liver disease. Portal hypertension often results in splenomegaly, which may cause haemodilution and pooling of red cells. Haemorrhage is a frequent complication, often due to oesophageal varices, and the red cell lifespan is shortened even in uncomplicated liver disease. Ferrokinetic studies suggest that the bone marrow response to anaemia is suboptimal, and many of the mechanisms that operate in ACD (see above) may be relevant. Macrocytosis occurs in approximately two-thirds of patients and erythropoiesis is macronormoblastic, indicating abnormal marrow function. Macrocytosis is particularly frequent in alcoholics, in whom reversible sideroblastic change may also occur. Target cells occur as the surface area of the cell increases, due to increased membrane lipid content without an increase in volume. Echinocytosis is fairly common because of

- Benign monoclonal gammopathy (biliary + other cirrhosis)
- Cryoglobulinaemia (hepatitis B, hepatitis C, alcohol)

binding of the red cell membrane by abnormal high-density lipoproteins. In contrast, true acanthocytes are uncommon in uncomplicated liver disease, although they are a characteristic finding in 'spur-cell anaemia' (non-immune haemolytic anaemia in patients with alcoholic cirrhosis). Zieve syndrome, comprising haemolytic anaemia with hypertriglyceridaemia in patients with alcoholic liver disease, is also rare. Haemolysis due to the direct toxicity of copper ions on red cells is characteristically an early presentation of Wilson disease. Intracorporeal changes are rare in liver disease. However, abnormal pyruvate kinase activity has been demonstrated in Zieve syndrome, and reduction of hepatocyte glucose-6-phosphate dehydrogenase (G6PD) levels in G6PD-deficient individuals, and in neonates, may exacerbate and prolong hyperbilirubinaemia with haemolysis. Viral hepatitis, including hepatitis A, B and C but most frequently hepatitis viruses yet to be fully characterized, may lead to a transient and mild pancytopenia or to severe aplastic anaemia.

Platelets and haemostasis

These are discussed in Chapter 39.

Liver transplantation

Orthotopic liver transplantation (OLT) is increasingly used for end-stage liver disease. Thrombocytopenia is frequently present prior to transplantation. The count tends to fall postoperatively despite platelet transfusions and this may be due to platelet sequestration in the transplanted liver. Immune thrombocytopenia has also been reported after OLT. Antibody-mediated haemolysis occurs in recipients of ABO-incompatible grafts, but the engrafted liver can also produce mild haemolysis due to anti-recipient ABO antibody. This is a form of humoral graft-versus-host disease (GVHD), but T cell-mediated GVHD has also been reported after OLT. Although aplastic anaemia is a rare complication of viral hepatitis, there are reports that it may occur in as many as 30% of patients transplanted for fulminant non-A, non-B viral hepatitis.

Infections (Tables 50.12 and 50.13)

Infection may produce a tremendous variety of haematological changes. Many of these are covered in other sections of this book.

Viruses**Anaemia**

Haemolytic anaemia due to red cell autoantibody production, usually of the warm type, may occur, although cold-antibody syndromes have been reported in measles, influenza, infectious

Table 50.12 Haematological changes in viral infection.

Red cells	Neutropenia
<i>Anaemia</i>	Aplasia (see above)
Autoimmune	Complicating myalgic encephalitis (?Enteroviruses, EBV)

Human immunodeficiency virus (HIV)	
Others including herpesviruses, varicella, influenza	
Non-immune	Platelets
Microangiopathic haemolytic anaemia	Thrombocytosis (e.g. Kawasaki)
Reduced red cell production	Thrombocytopenia
Marrow hypoplasia	Often history of viral prodrome in childhood immune thrombocytopenic purpura
EBV (especially in X-linked lymphoproliferative syndrome)	Autoimmune: EBV, hepatitis, rubella, CMV, HIV
Hepatitis viruses	↓ Production: aplasia (see above), measles, dengue, CMV, others
HIV	↑ Consumption: disseminated intravascular coagulation (DIC)/haemolytic–uraemic syndrome (see below)
CMV (especially after renal or bone marrow transplantation)	
Others (rare) include togaviruses epidemic haemorrhagic fevers, dengue	
Red cell aplasia	Coagulation changes
Parvovirus B19, especially with haemolytic anaemia	DIC, especially varicella, vaccinia, rubella, arbovirus with/without microangiopathy, epidemic haemorrhagic fevers
White cells	Haemolytic–uraemic syndrome: coxsackievirus, mumps, echoviruses
Neutrophilia	Haemophagocytosis
Especially HIV, influenza, hepatitis, rubella, adenoviruses, measles, mumps, CMV and EBV as part of nearly all viral infections	Herpesviruses, adenoviruses, CMV

mononucleosis and mumps. Paroxysmal cold haemoglobinuria is rare and occurs in children due to Donath–Landsteiner IgG anti-P antibodies. Non-immune MAHA may be associated with TTP or DIC, which may be the result of viral infections.

Anaemia due to transient red cell aplasia is seen with parvovirus B19 infection in patients with haemolytic anaemias ('aplastic crisis'). This virus may also cause erythema infectiosum, or fifth disease, in children. It invades and destroys red cell progenitors and the aplasia is terminated when neutralizing IgM and IgG antibodies develop. If the virus attacks pregnant women, it may cross the placenta and cause spontaneous abortion or hydrops fetalis. Intravenous immunoglobulin therapy has been used for severe cases (e.g. in pregnancy, HIV infection and after bone marrow transplantation). Bone marrow aspirate shows characteristic giant erythroblasts.

Anaemia occurs with pancytopenia in virus-associated bone marrow aplasia, for example with hepatitis viruses. The presence of viruses, either within lymphocytes or on their cell surface, may lead to production of a range of cytokines (including TNF, IFN- α and IFN- γ), which inhibit haemopoietic cell proliferation *in vitro* and *in vivo*. This may cause a substantial reduction in erythropoiesis and is presumably the mechanism

underlying neutropenia and lymphopenia in viral infections. In infectious mononucleosis and other viral infections such as viral hepatitis, the virus infects B lymphocytes and the characteristic activated lymphocytes seen on the blood film are a reactive population of T cells.

Platelets

Thrombocytopenia may occur due to multiple mechanisms. Children with idiopathic thrombocytopenic purpura frequently give a history of a preceding viral illness, and autoantibody production is well described in infectious mononucleosis, rubella and cytomegalovirus infections. Reduction of bone marrow thrombopoiesis is frequently subclinical, but it is particularly important in virus-associated aplasia and dengue fever. Thrombocytosis can also occur in response to viral infections.

Bacterial, fungal and protozoal infections

Anaemia

ACD can occur in acute infections, overwhelming septicaemia and chronic or suppurative infection. Haemolytic anaemia is less common, but can occur through both immune (e.g. cold

Peripheral destruction (e.g. DIC)

PCH, paroxysmal cold haemoglobinuria.

antibodies with anti-I specificity in *Mycoplasma* infection) and non-immune mechanisms. Direct red cell invasion frequently results in severe haemolysis in infections caused by *Bartonella bacilliformis*, with elements of intravascular haemolysis (due to increased red cell fragility) and extravascular haemolysis. *Clostridium perfringens* produces an α -toxin (a lecithinase) and a θ -toxin, and *Staphylococcus aureus* an α -toxin, which act as

haemolysins to cause severe intravascular haemolysis. DIC and MAHA can occur in any severe bacterial, fungal or protozoal infection. HUS has been associated with a range of bacterial infections, including *Salmonella*, *Shigella* and *Campylobacter* spp., but most frequently with verotoxin-producing strains of *Escherichia coli*.

White cells

Neutrophilia is the most common manifestation. Circulating neutrophils constitute less than 5% of the total body pool, and the neutrophil response shows great individual variation, with no clear relationship to the severity of the infection. The term *leukaemoid reaction* is used to describe marked leucocytosis ($> 50 \times 10^9/L$), with circulating immature forms occurring in patients with non-leukaemic conditions, typically severe infection or haemolysis or with generalized malignancy. Such reactions are more common in children. Features that distinguish such a reactive leucocytosis from CML include the presence of toxic granulation, elevated leucocyte alkaline phosphatase, Döhle bodies, and the lack of twin peaks of neutrophils and myelocytes in the differential count. Neutropenia can also occur with virtually any bacterial infection, although it has been most frequently noted with *Salmonella*, *Rickettsia* and *Brucella*. Defects of neutrophil function may also occur.

Platelets

Thrombocytosis is frequent in patients with chronic infections, and during the convalescent phase of acute infections. Thrombocytopenia also occurs during severe bacterial or fungal infection, particularly where there is bloodstream invasion or in intensive care patients. Certain rickettsial infections (e.g. Rocky Mountain spotted fever) are almost always associated with thrombocytopenia. Accelerated platelet destruction is the most frequent mechanism and can arise through DIC or microangiopathy with platelet attachment to damaged endothelium. Immune destruction can also occur and circulating immune complexes may lead to thrombocytopenia. Decreased platelet production is a less common mechanism, but may occur (e.g. in disseminated tuberculosis). The inflammatory and procoagulant responses to infections are clearly related. TNF- α , IL-1 α and IL-6 may activate coagulation and inhibit fibrinolysis, whereas thrombin may stimulate inflammatory pathways. In severe infection, the end result may be endovascular injury, DIC, multiorgan failure and death.

Haemostasis

DIC occurs frequently and may dominate the clinical picture in certain infections (e.g. bacterial meningitis). The acute-phase response that accompanies severe infection can lead to a rise in a range of coagulation factors, which may contribute to thrombotic manifestations. Suppurative thrombophlebitis, particularly in association with indwelling catheters, can occur in relation to both Gram-positive and Gram-negative infections.

In patients with systemic inflammation and organ failure due to acute infection, plasma protein C levels are reduced, and recombinant human activated protein C given as an intravenous infusion over 96 hours reduces the death rate but may be associated with increased risk of bleeding. Activated protein C promotes fibrinolysis and inhibits thrombosis and inflammation and reduces circulating levels of D-dimers and IL-6.

Malaria

Anaemia is the most prominent haematological manifestation of malarial infection. It is most marked with *Plasmodium falciparum*, which invades erythrocytes of all ages (*P. vivax* and *P. ovale* invade only reticulocytes, *P. malariae* only mature cells) and can give parasitaemia levels as high as 50%. Cellular disruption and haemoglobin digestion lead directly to haemolysis. Parasitized cells have an increased osmotic facility and lose deformability; they thereby become sequestered and destroyed within the spleen, which often becomes massively enlarged. Non-parasitized cells may then become sequestered within the spleen and a raised plasma volume contributes to the anaemia. In addition, malarial antigens may attach to non-parasitized red cells to give rise to a positive direct antiglobulin test and haemolysis via a complement-mediated immune response. Acute intravascular haemolysis with haemoglobinuria, often leading to renal failure ('blackwater fever'), occurs rarely in *P. falciparum* infection.

An inadequate bone marrow response to anaemia is seen with relative reticulocytopenia at times of active infection, with some recovery after effective therapy. TNF levels are typically elevated and ACD occurs. Leucocyte numbers may be slightly increased or normal, but leucopenia as a result of splenomegaly and impaired marrow function is characteristic. Eosinophilia is variable. Thrombocytopenia is seen in nearly 70% of *P. falciparum* infections and has multifactorial aetiology. Autoimmune mechanisms may operate as for red cells, splenic sequestration is a contributory factor, DIC (either acute as in blackwater fever, or low grade and chronic) is common, and ADP release from damaged red cells may lead to platelet activation and consumption.

Haemophagocytic lymphohistiocytosis (or haemophagocytic syndrome) (Table 50.14) (see also Chapters 10 and 17)

This may occur in association with a wide range of systemic illness including malignancies (e.g. lymphoma), infections (particularly viral, e.g. Epstein–Barr virus, HIV) and autoimmune diseases. It typically manifests as fever, splenomegaly and jaundice with cytopenias. It is particularly common in patients

who are immunosuppressed or who are acutely ill (e.g. septicaemic). A familial form is recognized (familial haemophagocytic lymphohistiocytosis; see Chapter 17) Macrophage activation syndrome is a variant form of haemophagocytic lymphohistiocytosis that occurs in children with juvenile RA. Pancytopenia is usual, although cytopenias affecting an individual cell lineage also occur, and coagulopathy due to associated DIC is frequently present. Abnormal liver function commonly coexists. The serum ferritin is usually markedly elevated. The bone marrow (Figure 50.3) shows the presence of increased numbers of histiocytes displaying haemophagocytosis. Myelofibrosis and/or marrow hypocellularity are present in a minority of cases. The underlying mechanisms are poorly understood. Excessive production of cytokines (e.g. IFN- γ and TNF- α) by dysregulated T cells has been demonstrated. In macrophage activation syndrome, increased levels of IL-6, IL-8, IL-12, IL-18 and macrophage inflammatory protein (MIP)-1 α

have also been reported. Treatment should be directed at the underlying disease process. Possible precipitating or complicating infection must be treated after appropriate cultures have been taken. Tuberculosis should be excluded. Immunosuppressive therapy (e.g. methylprednisolone) is appropriate if the condition occurs in the setting of an autoimmune condition. Anti-TNF antibody therapy has been successfully used in selected cases. Epstein–Barr virus-associated haemophagocytic lymphohistiocytosis may be indistinguishable from T-cell lymphoma and responds to chemotherapy, such as etoposide-containing regimens. The condition is usually of brief duration until recovery or, sometimes, death occurs.

Haematological aspects of pregnancy (Table 50.15)

Pregnancy poses a major physiological challenge to the human body and a number of haematological changes accompany it.

Table 50.15 Haematological changes during pregnancy.

<i>Anaemia</i>
Dilutional
Iron deficiency
Folic acid deficiency
Aplastic anaemia
<i>White cells</i>
Neutrophil leucocytosis
<i>Platelets</i>
Thrombocytopenia
Immune thrombocytopenic purpura
Eclampsia
Haemolytic–uraemic syndrome
Thrombotic thrombocytopenic purpura
HELLP syndrome (haemolysis, elevated liver enzymes, low platelet count)
Disseminated intravascular coagulation (DIC)
Drug induced
<i>Coagulation</i>
Coagulation factors: vitamin K-dependent factors FII, FVII, FIX, FXI, FX increased, FVIII increased, von Willebrand factor increased, fibrinogen increased
Coagulation inhibitors: protein C increased or no change, protein S decreased, antithrombin decreased or no change
Fibrinolytic activity decreased
DIC due to: abruptio placentae, intrauterine fetal death, amniotic fluid embolism, obstetric sepsis, eclampsia

Anaemia

Maternal plasma volume increases by approximately 50% during the first and second trimesters of pregnancy, whereas the corresponding increase in red cell mass is only 20–30%. A dilutional anaemia results, so that the lower limit of normal haemoglobin concentration is approximately 10.5 g/dL between 16 and 40 weeks of pregnancy. The increase in maternal red cell mass, transfer of iron to the fetus (which takes place largely in the third trimester) and blood loss during labour together impose a requirement of about 800 mg of iron, so that iron deficiency frequently arises in mothers with normal or reduced iron stores. Folic acid requirements are also raised during pregnancy (increased folate breakdown due to increased nucleic acid synthesis in mother and fetus) and routine supplementation is advised even during early pregnancy to prevent megaloblastic anaemia and neural tube defects in the fetus. A physiological rise in MCV of 5–10 fL occurs during normal pregnancy with pre-existing aplasia. AIHA occurring during pregnancy is typically severe and refractory to therapy.

White cells

A mild neutrophil leucocytosis with a left shift and occasional Döhle bodies occur during normal pregnancy.

Platelets

The normal range for the platelet count ($140\text{--}400 \times 10^9/\text{L}$) does not alter during pregnancy; thrombocytopenia occurring during pregnancy requires evaluation. Gestational thrombocytopenia complicates 8–10% of pregnancies and is characterized by mild thrombocytopenia occurring for the first time during pregnancy (platelets $80\text{--}150 \times 10^9/\text{L}$) and is usually not associated with neonatal thrombocytopenia or significant bleeding in the mother. Maternal immune thrombocytopenic purpura may antedate or present during pregnancy: it is often associated with increased levels of platelet-associated IgG, although this is a non-specific finding and the presence of serum platelet autoantibodies to platelet glycoproteins (GP)IIb/IIIa or GPIb/IX is more specific. The management of immune thrombocytopenic purpura is discussed in Chapter 49. Thrombocytopenia is regularly seen in pre-eclampsia. The mechanism is unknown, but increased aggregation is suggested, as low-dose aspirin therapy may reduce platelet consumption. TTP may occur at any time during pregnancy but typically it is before 24 weeks; the use of fresh-frozen plasma and plasma exchange has been shown to improve fetal outcome. HUS typically occurs within 48 hours of delivery in an otherwise normal pregnancy.

The potentially fatal syndrome of haemolysis, elevated liver enzymes and low platelets (HELLP) occurs in up to 10% of pregnancies complicated by eclampsia. The existence of coagulation abnormalities with red cell fragmentation suggests that

microangiopathy, DIC and endothelial damage all have a role in its pathogenesis. Fetal and maternal outcomes are characteristically poor.

Basophilic stippling, crenated red cells and large platelets are characteristic peripheral blood findings in acute fatty liver of pregnancy.

Coagulation changes

Normal pregnancy is associated with a range of alterations to haemostatic components (see Table 50.15), which combine to give an increased risk of haemorrhage, thrombosis and DIC, occurring in up to 40% of patients with abruptio placentae, leading to haemorrhage and shock. Amniotic fluid embolism typically occurs during the course of a difficult delivery in a multiparous woman and rapidly leads to a picture of chronic low-grade DIC, with onset over a period of 1–2 weeks. Venous stasis resulting from the gravid uterus combines with the coagulation changes to make pregnancy a hypercoagulable state; operative delivery imposes an additional risk.

Haematological aspects of HIV infection (Table 50.16)

HIV infection and its treatment cause a range of haematological effects. The newer generation of treatments with highly active antiretroviral therapy (HAART) is changing the natural history of AIDS and increasingly turning it into a chronic disease. HAART is also less toxic, particularly to the marrow, than the treatments it has replaced in the developed world and the treatments that continue to be used to treat AIDS in the developing world.

Pathophysiology

The major mechanism by which HIV infection suppresses haemopoiesis is through the action of cytokines (e.g. IFN- γ , TNF- α). These are elaborated by activated lymphocytes in response to infection and have been shown to induce progenitor cell apoptosis and reduced growth of short-term marrow cultures. Direct infection of CD34 cells by HIV also occurs and cross-culture experiments have demonstrated that HIV infection impairs proliferation of CD34 cells from AIDS patients more than its effect on bone marrow stromal cells. Morphological evidence of ineffective myelopoiesis is seen in the marrow, with evidence of myelodysplasia in all three lineages. An increased number of plasma cells is also frequently observed.

Anaemia

This is the commonest abnormality, occurring in up to 80% of patients; it may be due to a range of factors (see Table 50.16).

Table 50.16 Haematological complications of HIV.

Acute myeloid leukaemia

HUS, haemolytic–uraemic syndrome; MDS, myelodysplastic syndrome; TTP, thrombotic thrombocytopenic purpura.

HIV infection itself is a prominent cause of ACD. There is a reduction in erythropoiesis as a result of the mechanisms described above. Infiltration of the marrow by tumour, such as Hodgkin lymphoma, is much commoner among HIV-positive subjects than among the normal population. There is also a relative reduction in erythropoietin levels. Treatment of HIV infection by HAART will lead to an improvement in anaemia.

Other common causes include bleeding and infection. Certain infections, such as *Mycobacterium avium* and parvovirus B19, may directly involve the marrow and lead to decreased red cell production. Nutritional anaemia frequently arises from a defective diet and gastrointestinal disease (e.g. due to infection or drug toxicity) is common. Vitamin B₁₂ deficiency is seen in up to one-third of HIV-positive subjects and iron and folate deficiency are also common. Although treatment-induced anaemia is less common in the HAART era, treatment is a contributory factor in more than 50% of cases.

White cells

Leucopenia is frequently seen and predominantly due to lymphopenia. Neutropenia also occurs and is multifactorial. Granulocyte and monocyte production are reduced in HIV

infection; drug-induced changes are common and autoimmune neutropenia also occurs. Granulocyte colony-stimulating factor has been successfully used to improve the neutrophil count in infected HIV-positive subjects. Defects in neutrophil and monocyte function have also been demonstrated.

Platelets

Thrombocytopenia is seen in up to 50% of HIV-infected patients. Reduced platelet production can occur for the reasons described above; however, it is usually due to increased platelet destruction. This is often antibody mediated (immune thrombocytopenia; see Chapter 49). HIV-specific antibodies have been shown to share a common epitope with antibodies against platelet GPIIb/IIIa. Non-specific absorption of immune complexes onto platelets also occurs and predisposes to immune thrombocytopenia. Reduced platelet production is common in HIV-positive subjects and direct infection of megakaryocytes by HIV has been described. Morphologically abnormal megakaryocytes are seen in the marrow. Other causes of thrombocytopenia include infection and microangiopathy. Both HUS and TTP are well described in the setting of HIV infection, particularly in the era before HAART. Treatment of thrombocytopenia depends on the cause. Treatment of HIV infection using HAART frequently leads to improvement in the platelet count. Immune thrombocytopenia in HIV-infected subjects is treated in the same way as in the non-HIV population. However, immunosuppression carries particular risks and steroids should be used with extreme caution. Splenectomy is often effective, and anti-CD20 monoclonal antibody therapy may also be used.

Coagulation

Coagulation abnormalities can occur in the setting of infection and acute illness. Circulating coagulation inhibitors have also been described. Protein S deficiency is well described and predisposes to an increased risk of thrombosis. DIC is common in the setting of infection and HIV infection.

Other changes

Lymphoma is the commonest tumour in HIV-positive subjects (Chapter 35). Other haematological malignancies are also

reported to occur with increased frequency, for example myeloma and AML. HIV-positive subjects who develop these malignancies often display a prolonged premalignant phase, with smouldering myeloma and myelodysplasia frequently reported.

Introduction

For the purposes of this chapter, 'tropical diseases' refers to infectious diseases occurring predominantly in tropical areas. The chapter has been divided into two sections, covering tropical diseases in which organisms can be visualized in the blood or bone marrow and those that cause secondary haematological abnormalities.

Around the world, 1 in 35 people (i.e. 2.9% of the population) are migrants, moving mostly from poorer to richer countries. In the UK, net international migration contributed to 68% of the population growth in 2005 and travelling migrants are responsible for a major component of imported tropical infections. Rapid increases in worldwide travel mean that haematologists need to know about the tropical diseases that can cause haematological abnormalities and be able to take relevant travel histories from patients. They also need to be aware of ethnic variations in reference ranges to avoid wasting resources on unnecessary investigations and to avoid causing undue anxiety for the patient.

Ethnic variations in reference ranges

The white blood cell count and relative and absolute neutrophil counts are lower in black people, Yemenite Jews, Palestinians

and Saudi Arabians than in white people. After the age of 1 year, Africans have lower counts than West Indians or black Americans (Table 51.1). This is due to the non-white populations having a greater number of neutrophils in the storage pool. Stimulation of a neutrophil response in these ethnic groups leads to rises in the neutrophil count to the same level as white populations irrespective of the baseline level. Indian, Chinese and Southeast Asian populations have the same white blood cell and neutrophil counts as white northern Europeans. The platelet counts in healthy West Indians and Africans may be 10–20% lower than in Europeans living in the same environment. It is not clear whether there are true ethnic variations in eosinophil counts but counts of up to $2 \times 10^9/L$ have been described in healthy blood donors in Africa. Interpretation of variations in blood counts should therefore take account of the individual's ethnic background.

Tropical diseases with organisms in peripheral blood or bone marrow

Malaria

Epidemiology and biology

Four species of plasmodia cause malaria in humans: *Plasmodium falciparum*, *P. vivax*, *P. ovale* and *P. malariae*. *Plasmodium falciparum* is by far the most dangerous and causes the greatest mortality and morbidity. Over 80% of *P. falciparum* infections in the UK are acquired in sub-Saharan Africa, while 85% of *P. vivax* infections are acquired in South Asia, especially India and Pakistan. In 2007, 1548 cases of malaria were reported in the

Table 51.1 Automated white cell (WBC) and neutrophil counts in adults of different ethnic origins (95% ranges).

	Male		Female	
	WBC ($\times 10^9/L$)	Neutrophil count ($\times 10^9/L$)	WBC ($\times 10^9/L$)	Neutrophil count ($\times 10^9/L$)
White	3.7–9.5	1.7–6.1	3.9–11.1	1.7–7.5
Afro-Caribbean	3.1–9.4	1.2–5.6	3.2–10.6	1.3–7.1
African	2.8–7.2	0.9–4.2	3.0–7.4	1.3–3.7

Figure 51.1 Life cycle of the malarial parasite.

UK, of which 1139 (73%) were due to *P. falciparum* and 256 (16%) to *P. vivax*; there were five deaths. Malaria rates were highest in immigrants returning from visits to their countries of origin and accounted for one-third of all reports. The majority of travellers (81%) had not taken malaria prevention tablets.

Malaria is transmitted by the bite of an infected female *Anopheles* mosquito. The infecting agent is the sporozoite and thousands of these spindle-shaped cells may be injected by a single bite. Infrequently, transmission may also occur through blood transfusion, bone marrow transplantation and transplacentally (0.5% of all UK cases). There have also been reports of

malaria transmission in aircraft or near airports in temperate zones due to infected mosquitoes being brought to non-malarious areas.

Within a few hours of an infected bite, the sporozoites enter the hepatocytes, where they divide (Figure 51.1). Rupture of the hepatocyte releases the parasites into the blood where they attach to red cell membranes using specific receptors. The parasites feed on the red cell stroma, and the digestion products form the characteristic brown pigment (haemozoin) that accumulates in phagocytic cells. In the red cells asexual replication of the trophozoites (ring forms) occurs, giving rise to erythro-

cyte schizonts. The schizonts mature into merozoites and are released into the circulation to reinfect other red cells. The periodicity of this release varies with the species and is responsible for the classical cyclical nature of malaria fevers. Relapses, which can occur months or years after the primary illness, are characteristic of infection with *P. vivax* and *P. ovale*, and are due to maturation of persistent hypnozoites in the liver.

A few of the trophozoites develop into male and female banana-shaped gametocytes and are taken up by the mosquito at a blood meal. Inside the midgut of the mosquito, they undergo sexual reproduction and sporozoites migrate to the salivary glands, ready to infect another host when the mosquito bites.

Unlike the schizonts of *P. vivax*, *P. ovale* and *P. malariae*, those of *P. falciparum* are not commonly seen in the peripheral blood of the human host. This is because *P. falciparum*-infected cells have surface cytoadherence molecules that enable them to be sequestered in the deep tissues. Therefore *P. falciparum* schizonts only appear in the blood in very severe infections or in splenectomized patients. Sequestration is responsible for some of the severe clinical consequences of *P. falciparum* malaria, such as cerebral malaria.

Clinical features

The time between the infected bite and the appearance of clinical symptoms and parasites in the peripheral blood varies between species. It is 7–30 days (mean 10 days) in *P. falciparum* but can be months, or even years, with other species, particularly *P. vivax* and *P. ovale*, because of their hypnozoite stage. The dormancy time of hypnozoites varies with the different strains.

Maximal immunity to malaria takes around 10 years to develop and is lost over the course of 1–5 years if the individual leaves a malarious area and is no longer exposed to infections. This is often not appreciated by students or immigrants from malaria-endemic countries, who are more prone to severe attacks of malaria when they return home after a prolonged period in a non-malarious area.

All four *Plasmodium* species produce factors that cause release of tissue cytokines, especially from leucocytes. These cytokines produce fever and contribute to anaemia through marrow suppression. Splenomegaly is a common feature of

acute malaria and mild jaundice may also occur secondary to haemolysis. Other clinical features vary with different species.

Plasmodium falciparum

Plasmodium falciparum is the only species associated with complicated and severe disease. Death may occur after a single exposure to malaria, particularly in those with no immunity such as non-immune travellers or young children in endemic countries. Despite this, the majority of infections cause a self-limiting febrile illness. Recurrent fevers and other symptoms of malaria may be due to either recrudescence of blood forms that persist between attacks or to reinfection with a new strain or species. Recurrent attacks with different strains lead to the development of clinical immunity but not necessarily to complete clearance of parasites. Parasites may therefore be detected in a high proportion of adults in endemic areas who are clinically asymptomatic.

In addition to fever with rigors, nausea and hot and cold phases, *P. falciparum* infection can also present with diarrhoea and cough (Table 51.2). Serious complications include severe anaemia, cerebral involvement and failure of major organs such as kidneys and liver.

During pregnancy, immunity to malaria is reduced and parasite density increases. Even if parasites cannot be visualized in the peripheral blood, they may be sequestered in the placenta and compromise fetal development. *Plasmodium falciparum* is therefore an important cause of low birth weight in neonates and anaemia in pregnant women. Both of these factors have a detrimental effect on the later development of the infant.

Plasmodium malariae

The incubation period of *P. malariae* may be several weeks. It is associated with recurrent fever, anaemia and enlargement of the liver and spleen. Without treatment, recrudescences may occur with decreasing severity over many years. Clinical symptoms of malaria have been reported up to 30 years after the initial infection.

Plasmodium vivax and Plasmodium ovale

These species cause a similar clinical picture with bouts of fever occurring periodically up to 5 years after the initial infection. These are relapses, due to reinvasion of red cells by hypnozoites,

Table 51.2 Clinical features of *P. falciparum* malaria infection.

Target organ	Clinical features	Potential common misdiagnosis
Gastrointestinal	Diarrhoea, vomiting	Traveller’s diarrhoea
Respiratory	Cough, pulmonary oedema	Pneumonia, cardiac failure
Neurological	Delirium, coma, convulsions, focal neurological signs	Encephalitis, meningoencephalitis
Renal	Oliguria, haemoglobinuria	Nephritis
Hepatic	Jaundice, hypoglycaemia	Hepatitis
Haematological	Anaemia, splenomegaly	Viral infection, lymphoma

rather than recrudescences, which are due to incomplete treatment of the primary infection. The trigger for hypnozoites to reactivate after dormancy is unknown.

Haematological abnormalities

Normochromic normocytic anaemia is common, particularly in children, but the degree and rapidity of onset are very variable. The haemoglobin may fall by up to 2 g/dL each day. In malaria-endemic regions, chronic anaemia due to nutritional deficiencies, intestinal helminths, HIV and haemoglobinopathies may be compounded by the effects of malaria. In chronically anaemic patients, the oxygen dissociation curve is shifted to the right so they are better able to tolerate further falls in haemoglobin. The clinical effects of anaemia in malaria are therefore due to a combination of the degree and rate of fall of haemoglobin.

The anaemia associated with malaria has multiple aetiologies. Red cells containing parasites are removed from the circulation by the reticuloendothelial system. There is also accelerated destruction of non-parasitized cells and dyserythropoiesis in the bone marrow. Both parasitized and non-parasitized red cells lose deformability and the high shear rates in the spleen enhance their removal by that organ. In acute malaria reticulocyte response is suppressed. Erythropoietin levels are usually elevated, although occasionally they are less than anticipated for the degree of anaemia.

Uncommon complications of malaria that can exacerbate the anaemia are hyperreactive malarial splenomegaly and 'blackwater fever'. Hyperreactive malarial splenomegaly is characterized by massive splenomegaly with hypersplenism (see later) and occurs as a result of a disordered immune response to malaria. Blackwater fever is associated with severe intravascular haemolysis with haemoglobinuria, and can lead to acute renal failure. It has been associated with antimalarial drugs, particularly quinine, and may be more common in individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

The high prevalence of severe anaemia in areas with intense malaria transmission has generally been ascribed to malaria, but recent studies in Malawian children have suggested that the anaemia is multifactorial, with bacteraemia, malaria, hookworm, HIV and deficiencies of G6PD, vitamin A and vitamin B₁₂, but not iron and folate deficiency, being important.

Case fatality rates of children with severe anaemia in Africa are 9–18% and mortality rises steeply at haemoglobin concentrations of less than 4 g/dL. Severe decompensated malarial anaemia can be accompanied by hypovolaemia and acidosis and therefore requires urgent intravenous rehydration and blood transfusion. The high risk of transfusion-transmissible infections in poorer countries makes it especially important to prevent and adequately treat the milder forms of anaemia so that transfusions can be avoided. Antimalarial prophylaxis, presumptive malarial treatment and insecticide-treated bednets are valuable in reducing malaria infections and anaemia in specific

groups, such as pregnant women and young children, in endemic countries.

The white cell count in malaria is usually normal but may be raised in severe disease. Other white cell changes that have been described in malaria include a leucoerythroblastic response, monocytosis, eosinopenia and a reactive eosinophilia during the recovery phase. Neutrophil activation, indicated by raised leucocyte elastase levels, may be apparent in severe malaria. Mild thrombocytopenia with counts around $100 \times 10^9/L$ is common. It is due to increased splenic clearance and is associated with increased platelet turnover and raised thrombopoietin levels. Pancytopenia without massive splenomegaly has also been described.

The bone marrow of patients with acute malaria due to any of the four species shows prominent dyserythropoiesis. This may persist for weeks after the acute infection and is caused by intramedullary cytokines produced by the infection. Erythrophagocytosis and macrophages containing malaria pigment are frequently seen in marrow samples from malaria patients.

Although malaria is associated with thrombocytopenia and activation of the coagulation cascade and fibrinolytic system, bleeding and haemorrhage are uncommon even though the prothrombin and partial thromboplastin times may be prolonged. The trigger for this activation is unknown but there is evidence that it may be a combination of procoagulant cytokines and parasitized erythrocytes, which can directly activate coagulation pathways. Disseminated intravascular coagulation (DIC) is not important in the pathogenesis of severe malaria. Fibrinogen levels are often increased and there is rapid fibrinogen turnover with consumption of antithrombin and factor (F)XIII, and increased fibrin degradation products (FDPs). Microparticle formation from platelets, red cells and macrophages also causes widespread activation of blood coagulation. Malaria has recently been found to result in increased levels of circulating active von Willebrand factor (VWF).

Haematological indicators of a poor prognosis in severe malaria include:

- leucocytosis $> 12 \times 10^9/L$;
- severe anaemia (packed cell volume $< 15\%$);
- thrombocytopenia $< 50 \times 10^9/L$;
- prolonged prothrombin time (> 16 s);
- prolonged partial thromboplastin time (> 40 s);
- reduced fibrinogen (< 2 g/L);
- hyperparasitaemia $> 100\,000/\mu L$ (high mortality $> 500\,000/\mu L$);
- $> 20\%$ of parasites are pigment-containing trophozoites and schizonts;
- $> 5\%$ of neutrophils contain visible malaria pigment.

Genetic haematological protection mechanisms

Plasmodium vivax needs Duffy blood group antigen as a receptor to enter red cells. This antigen is absent in at least two-thirds of black races who consequently have a natural resistance to infec-

tion with *P. vivax*. The protective effect of HbAS against the life-threatening complications of malaria is well recognized. Similar but less marked protection is associated with other red cell genetic abnormalities such as G6PD deficiency, α thalassaemia trait and HbC trait.

Diagnosis

Microscopy

Direct visualization of parasites by light microscopy using a combination of thick and thin blood films is the gold-standard diagnostic technique for malaria (Table 51.3 and Figure 51.2). A Romanowsky stain (e.g. Field, Giemsa, Leishman) pH 7.2 is used so that the parasite cytoplasm stains blue and the nuclear chromatin red. A thick blood film should be used as the first screening tool as it allows larger volumes of blood to be examined than the thin film. However, the parasites appear distorted due to the process of lysing the red cells so this method cannot be used for parasite morphology and speciation. A thin blood film allows visualization of undistorted parasites and of the size and shape of the red cells but has low sensitivity because of the small amount of blood that can be examined.

The disadvantages of basing a diagnosis of malaria on blood film examination include the following.

- A negative film does not exclude malaria: at least three films taken during episodes of fever should be examined and even if these are negative it does not entirely exclude the diagnosis especially in the presence of antimalarial drugs.

- A positive film does not prove that symptoms are due to malaria: asymptomatic parasitaemia is common in adults from endemic areas.
- Parasites, particularly *P. falciparum* gametocytes, may be washed off the slide during staining; bulk staining of slides may result in transfer of parasites between slides.
- Parasite density does not necessarily correlate with disease severity, although heavy parasitaemia (> 5% of red cells infected) indicates a poor prognosis.

Malaria pigment may persist in phagocytic cells for several weeks after an acute attack and may be helpful in retrospective diagnosis of malaria. Automated haematology analysers may produce an abnormal pattern on the white cell differential count histogram. Debris below the white cell threshold may be due to malaria parasites and manual examination of blood films is indicated if this pattern is flagged up by the analyser.

Antigen detection

Rapid diagnostic tests for malaria are based on detection of the malaria antigen histidine-rich protein (HRP)2 or parasite lactate dehydrogenase (pLDH). They have been incorporated into immunochromatographic antigen-capture kits for rapid diagnosis. The sensitivity of these dipstick strip tests approaches that of thick film microscopy (i.e. 0.002% parasitaemia equivalent to 100–200 parasites/ μ L of blood). HRP2 protein may remain positive for 14 days after successful treatment and false positives due to rheumatoid factor have been reported. pLDH

Table 51.3 Differentiating features of human *Plasmodium/Babesia* species in stained thin blood films.

	<i>P. falciparum</i>	<i>P. malariae</i>	<i>P. vivax</i>	<i>P. ovale</i>	<i>Babesia sp.</i>
Appearance of infected red blood cells (size and shape)	Both normal	Normal shape; size normal or smaller	1.5–2 times larger than normal; shape normal or oval	As for <i>P. vivax</i> , but some have irregular edges	Both normal
Red cells with multiple parasites/cell	Common	Rare	Occasional	As for <i>P. vivax</i>	Common
Stages present in peripheral blood	Rings and gametocytes; occasionally schizonts	All stages	All stages	As for <i>P. vivax</i>	Only rings and rare pear-shaped forms ('Maltese cross'); no gametocytes
Ring form (young trophozoite)	Delicate small ring; scanty cytoplasm; sometimes at the edge of red cell ('accolé form')	Ring one-third of the diameter of cell; heavy chromatin dot; vacuole sometimes 'filled in'	Ring one-third to half of the diameter of cell; heavy chromatin dot	As for <i>P. vivax</i>	Resembles ring of <i>P. falciparum</i> ; look for pear-shaped structure
Gametocyte	'Crescent' or 'sausage' shape is characteristic	Round or oval; dark coarse pigment	Round or oval	Round or oval (smaller than <i>P. vivax</i>)	No gametocyte

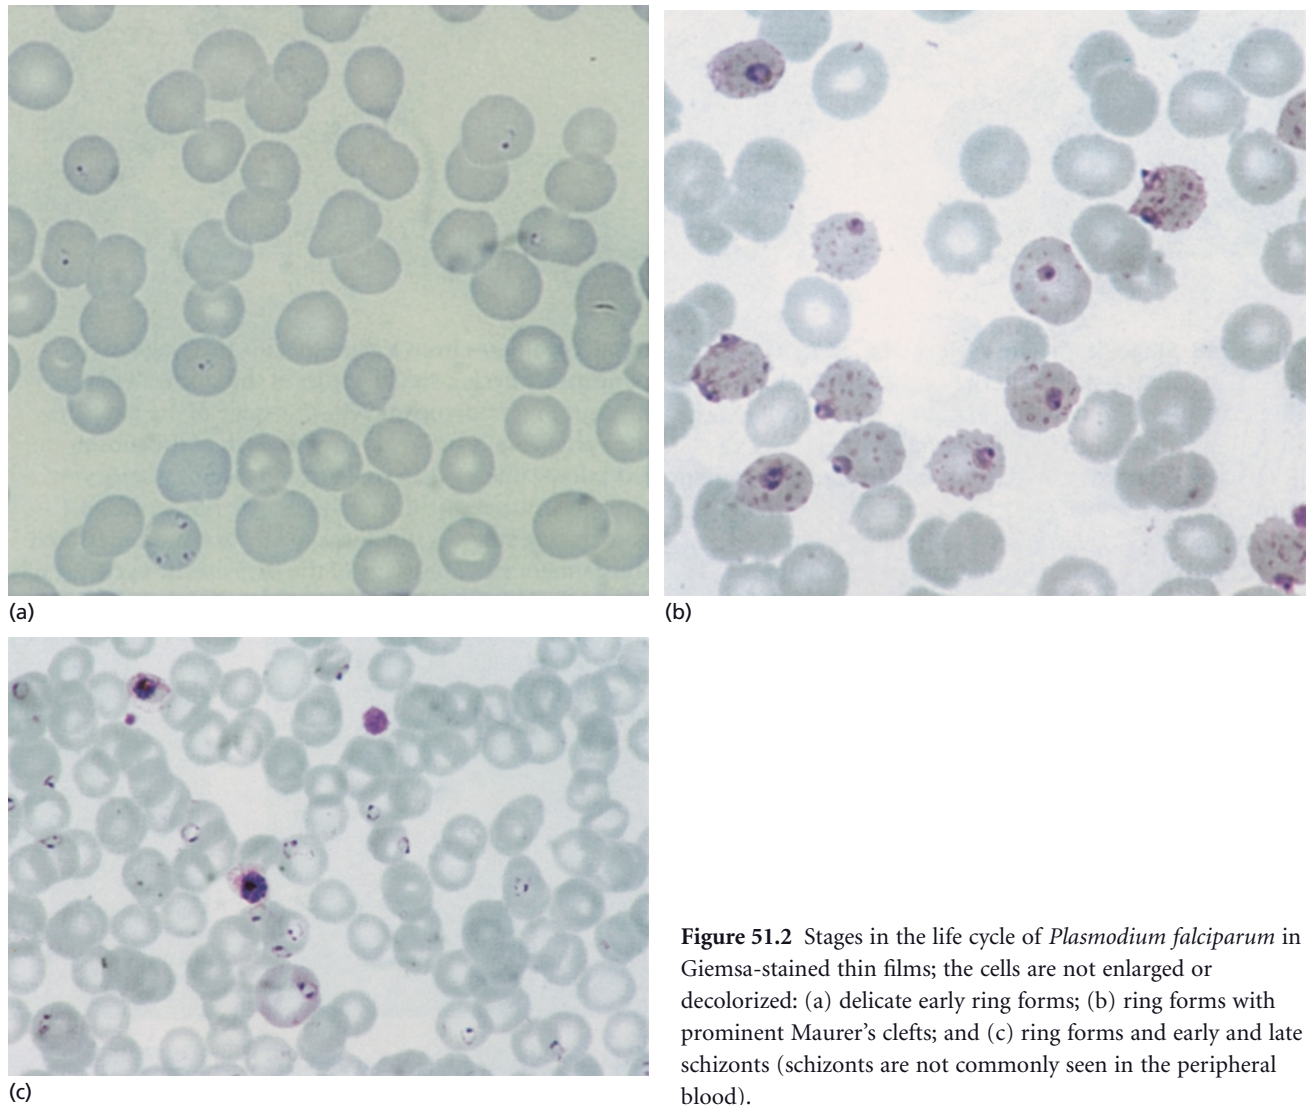

Figure 51.2 Stages in the life cycle of *Plasmodium falciparum* in Giemsa-stained thin films; the cells are not enlarged or decolorized: (a) delicate early ring forms; (b) ring forms with prominent Maurer's clefts; and (c) ring forms and early and late schizonts (schizonts are not commonly seen in the peripheral blood).

is only produced by viable parasites so it becomes negative 2–3 days after successful treatment. None of these kits are able to provide quantitative information about parasitaemia but some are able to distinguish between *P. falciparum* and other species.

Potential uses of malaria antigen detection tests include:

- confirmation of malaria diagnosis on a blood film;
- detection of *P. falciparum* when the microscopist is inexperienced (e.g. on-call or emergency situations);
- determination of species when there is a possibility of mixed infection;
- monitoring response to treatment (not HRP2-based tests).

Antibody detection

Malarial antibodies can remain in the blood after the eradication of parasites, so their detection is not useful for diagnosis in the acute attack. The main uses of malarial antibody detection are for excluding malaria as a cause of recurrent fever, for

population surveys and as a screening test for blood transfusion purposes.

DNA-based methods

DNA probes have been developed for malaria diagnosis but their use is generally restricted to research and epidemiological surveys.

Haematological implications of treatment for falciparum malaria

Chloroquine was the first-line treatment for malaria in many countries for decades and was generally well tolerated. However, widespread parasite resistance has now seriously restricted its use and it is therefore being superseded by newer drugs, often in combination, to reduce the development of resistance. Some antimalarial drugs have significant haematological side-effects, as described below.

Pyrimethamine is used in combination with a long-acting sulphonamide, such as sulfadoxine (as in Fansidar). It is a dihydrofolate reductase inhibitor and may therefore induce megaloblastic anaemia and other cytopenias. The sulphur component of these combinations may rarely cause cytopenias and methaemoglobinaemia.

Dapsone acts by inhibiting the synthesis of dihydrofolic acid and is used as part of a fixed combination with proguanil or chlorproguanil. It may be associated with haemolytic anaemia, methaemoglobinaemia and eosinophilia.

Primaquine, an inhibitor of protein synthesis, is active against the hypnozoites of *P. vivax* and the gametocytes of *P. falciparum*. It causes oxidant haemolysis in patients with G6PD deficiency and, rarely, methaemoglobinaemia.

Quinine is usually reserved for life-threatening infections especially in endemic countries. It acts by disrupting the food vacuole of the parasite. Rarely, it is associated with immune thrombocytopenia and severe intravascular haemolysis.

Mefloquine, halofantrine and artemisinin-related compounds do not commonly cause significant haematological side-effects. A combination of artemether and lumefantrine (Coartem or Riamet) is commonly used as first-line treatment in endemic areas. It has no major haematological side-effects.

Some antibacterial drugs, such as doxycycline, clindamycin, trimethoprim and sulphonamides, have also been used for their antimalarial effect and may be associated with haematological side-effects.

For malaria due to *P. vivax*, *P. ovale* and *P. malariae*, chloroquine is still widely used for treatment as resistance is generally low; primaquine is added to prevent relapses in vivax and ovale malaria.

Babesiosis

Epidemiology and biology

Babesiosis is not a tropical disease but is briefly described here as it can be confused with malaria. Babesiosis is endemic in the northeastern and upper midwestern regions of the USA and is found sporadically in other parts of the USA, Europe, Asia, Africa and South America. It is primarily a disease of animals and rarely infects humans. It is due to a protozoan parasite transmitted by the bite of the ixodid tick. Following the bite, the organisms penetrate red cells, where they take on an oval, round or pear shape and multiply by budding. The erythrocytic ring forms of *Babesia microti* and *B. divergens* may be confused with malaria *P. falciparum* rings, but they do not produce pigment or cause alterations in red cell morphology. A minority of organisms take on a folded shape and are thought to be gametocytes.

Babesia bovis, *B. microti* and *B. divergens* are responsible for the majority of human infections, which range from asymptomatic to severe and occasionally are fatal. Most of the cases reported from Europe have been due to *B. divergens* and

occurred in patients without a functioning spleen. In North America almost all the cases have been due to *B. microti*, which usually produces a subclinical infection. Specific laboratory diagnosis of babesial infection is made by morphological examination of Giemsa-stained blood smears, serology and amplification of babesial DNA using polymerase chain reaction (PCR).

Clinical features

The incubation period varies from 1 to 4 weeks, and the severity and progression of the clinical features vary with the infecting species. Most patients have no recollection of a tick bite. The disease presents with fever, prostration, mild hepatosplenomegaly and haemolytic anaemia with jaundice and haemoglobinuria. Severe complications, including acute tubular necrosis, respiratory distress and DIC, and a fulminant fatal course has been described in patients who are splenectomized, immunosuppressed, infected with HIV or elderly.

Haematological abnormalities

The anaemia may be mild to moderately severe and is due to parasite-induced abnormalities in the red cell membrane. Haemolytic anaemia, which may last for several weeks, is a prominent feature of babesiosis, particularly in splenectomized individuals. Although the haemolysis is due to complement or antibody coating of the red cells, the direct antiglobulin test (DAT) is usually negative. Haptoglobin levels are reduced and the reticulocyte count is increased. The presence of parasitaemia needs to be interpreted with caution as parasites may persist for months after the resolution of symptoms and the level of parasitaemia does not parallel the severity of disease (see Table 51.3). Babesia parasites may be confused with Pappenheimer bodies in splenectomized patients with active haemolysis. Thrombocytopenia may occur in severe cases. Total white cell counts are usually normal or low.

Haematological implications of treatment for babesiosis

The combination of atovaquone and azithromycin is the treatment of choice for mild or moderate babesiosis, whereas clindamycin and quinine and exchange transfusion are indicated for severe disease. Atovaquone has been associated with anaemia and neutropenia; azithromycin and clindamycin have been associated with neutropenia and thrombocytopenia.

Filariasis

Epidemiology and biology

There are two groups of human filariasis: those that occur in the blood (lymphatic filariasis) and those that occur in the skin (onchocerciasis). Only lymphatic filariasis is considered in this chapter, as it is associated with detectable organisms in the peripheral blood.

Two species of filarial worms cause lymphatic filariasis in humans and are relevant for haematologists, *Wuchereria ban-*

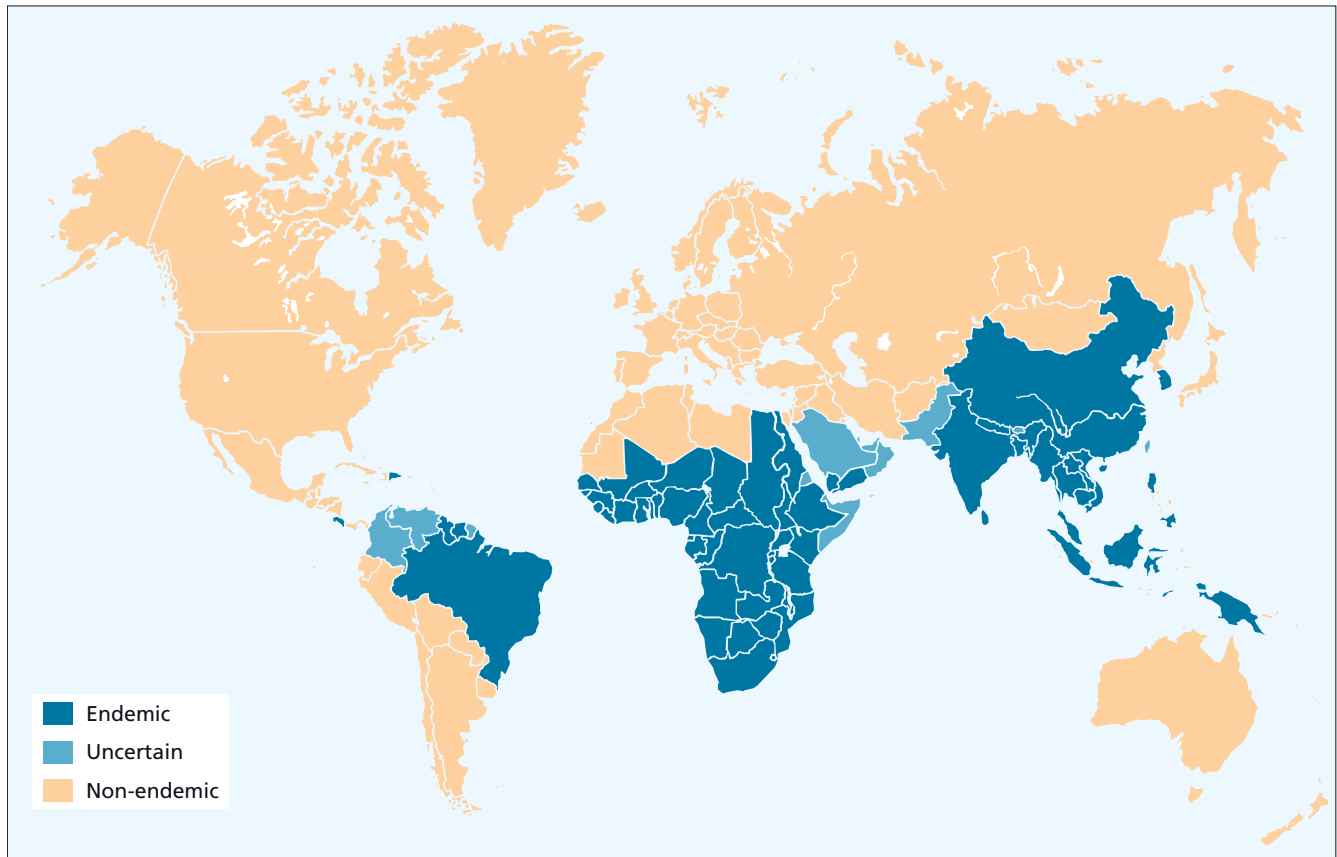

Figure 51.3 Global distribution of lymphatic filariasis.

crofti and *Brugia malayi*. They have different geographical distributions, with *W. bancrofti* being the most widespread. More than 90% of infections due to *W. bancrofti* are found in Asia, although it also occurs in Africa, America and the Pacific Islands. Filariasis due to *B. malayi* occurs in China, Indo-China, Thailand, Malaysia, Indonesia, the Philippines and south-west India (Figure 51.3).

The worms are 4 cm (male) to 10 cm (female) in length and can live for over 10 years in the lymphatics. Microfilariae, which are 250–300 µm long, are produced by the female worm and released into the blood after 3–8 months, where they may live for up to 1 year. Microfilariae densities can reach 10 000/mL but are usually much lower. They exhibit daily periodicity in the blood and this timing is designed to match the biting habits of their mosquito vectors, culicine and anopheline mosquitoes. The microfilariae develop in the mosquito and pass into the proboscis, ready to be injected into another human.

Clinical presentation

There is wide variation in the presenting features of lymphatic filariasis, which may occur 6 months or more after the infective bite. The symptoms and signs are due to lymphangitis. There

are recurrent bouts of fever with heat, redness and pain over lymphatic vessels. In fair-skinned people, the lymphangitis can be seen to spread distally (i.e. the opposite direction to septic lymphangitis). In *W. bancrofti* infection, these repeated episodes of inflammation eventually result in the typical chronic picture of filariasis, including hydrocele, lymphoedema and elephantiasis, chyluria and tropical pulmonary eosinophilia. The clinical picture in *B. malayi* infection is similar but it does not cause hydrocele or chylous urine.

Other filariae with blood-inhabiting larvae

Loa loa

This occurs in the rain-forest belt of Africa, especially West Africa. The adult worms migrate through the subcutaneous tissues, including the conjunctiva, and occasionally can be seen passing across the eye.

Mansonella perstans

This is a non-pathogenic and common infection of people in Africa. These organisms may therefore coexist in the blood with *W. bancrofti* but can be distinguished by their smaller size and absence of a sheath.

Mansonella ozzardi

This is also probably non-pathogenic and occurs in the West Indies and South America.

Haematological abnormalities

Eosinophilia is the major and most frequent haematological abnormality produced by lymphatic filariasis. Tropical pulmonary eosinophilia is an unusual complication of filariasis and is due to an immunological hyperresponsiveness to microfilariae in the lungs. It is more common in men than women. Although microfilariae are absent from the blood in this syndrome, they may be seen in lung biopsies and adult worms can be visualized in lymphatics on ultrasound. There is an extreme eosinophilia, with eosinophil counts of greater than $10 \times 10^9/L$; the level of eosinophilia is not related to the severity of symptoms. In tropical pulmonary eosinophilia, diethylcarbamazine treatment reduces the eosinophil count and produces resolution of symptoms. This rapid response to treatment distinguishes filariasis from other causes of marked eosinophilia, such as helminths that affect the lungs (*Ascaris*, *Strongyloides*, *Schistosoma* subsp. *trichinosis* and *Toxocara*).

Diagnosis of filariasis

The adult worms residing in the lymphatics are inaccessible, so diagnosis is based on finding microfilariae in the peripheral blood. The level of filaraemia is inversely related to the clinical signs because much of the damage is due to immunological responses to the microfilariae rather than to the organisms themselves. Furthermore, the presence of microfilariae does not necessarily mean that they are causing clinical problems and, conversely, a lack of microfilariae in the blood does not exclude a diagnosis of filariasis. The peripheral blood findings must therefore be assessed in the context of the clinical picture.

To optimize the chances of finding scanty microfilariae in the blood, the sample should be taken at the appropriate time for the expected peak concentration of microfilariae (i.e. around midnight or midday for nocturnally and diurnally periodic forms respectively). There are many techniques for demonstrating microfilariae in the laboratory. The simplest method is a wet preparation of fresh blood. Microfilariae will survive in venous blood collected into EDTA for 2 days at room temperature. Motile microfilariae can be seen on a slide under low power and can be counted in a counting chamber. Numbers of microfilariae may be low, requiring concentration techniques such as blood filtering.

For species identification, thick and thin blood films should be stained with Giemsa or haematoxylin and the microfilariae differentiated according to the pattern of their sheaths, nuclei distribution and size (Figure 51.4). The edges of the film should be examined carefully as microfilariae tend to be concentrated at the periphery and are easily missed if the microscopist immediately uses high power in the centre of the film.

Detection of circulating antigen by enzyme-linked immunosorbent assay (ELISA) or immunochromatography (ICT) has replaced microscopy for the diagnosis of bancroftian, but not brugian, filariasis. An antigen ICT card test is available for the detection of *W. bancrofti*, which does not react with other filariae and is highly sensitive (100%) and specific (92%). Filarial DNA can be detected by PCR, and ultrasound scans can help identify adult worms within the lymphatic system. Serological tests are not very helpful as most individuals from endemic areas have antibodies to crude filarial antigens and there is cross-reactivity with other filariae and nematodes.

Haematological implications of treatment for filariasis

Oral diethylcarbamazine is the drug of choice in all forms of lymphatic filariasis, including subclinical infection. Alternative

(a)

(b)

Figure 51.4 Microfilariae of *W. bancrofti* in thick film: (a) microfilaria showing the negative impression of the sheath ($\times 365$); (b) tail of the microfilaria showing that the nuclei do not extend into the tail ($\times 912$).

treatments include combinations of albendazole and ivermectin. None of these drugs has common, serious haematological side-effects. It has recently been discovered that depletion of *Wolbachia* endobacteria, a symbiont of *Onchocerca*, by tetracycline antibiotics leads to long-lasting sterility of adult female worms.

African trypanosomiasis (sleeping sickness)

Epidemiology and biology

African sleeping sickness is caused by the haemoflagellate protozoa *Trypanosoma brucei gambiense* in West and Central Africa, and *T. brucei rhodesiense* in eastern Africa (Figure 51.5). These parasites are fusiform in shape, 12–35 µm long and morphologically indistinguishable from each other. The disease is transmitted by the bite of the tsetse fly, which is only found in Africa. The trypanosomes multiply by fission in the vicinity of the infected bite and are then disseminated by the bloodstream. Congenital transmission has also been described.

The distribution of African sleeping sickness is determined by the ecological limits of the tsetse fly vector and lies in the region between Senegal and Somalia in the north and the Kalahari and Namibian deserts in the south. Sleeping sickness is an important public health problem in Central African

Republic, Chad, Democratic Republic of Congo, Côte d'Ivoire, Guinea, Malawi, Uganda and United Republic of Tanzania. During recent epidemic periods the prevalence reached 50% in several villages in the Democratic Republic of Congo, Angola and southern Sudan. Improved surveillance has reduced the number of new cases over the last decade.

Clinical features

The bite of a tsetse fly is very painful and causes a small indurated lesion that may persist for some days. The local multiplication of the trypanosomes may cause a marked inflammatory reaction (a chancre) that regresses after 2–3 weeks. Entry of the trypanosomes into the bloodstream is associated with fever, which tends to be less marked in West African trypanosomiasis than in the East African variety. East African trypanosomiasis is primarily a disease of cattle and only enters human hosts by accident. It is therefore less well tolerated than West African sleeping sickness, having a more aggressive course and intense symptoms.

The early stages of sleeping sickness can be associated with prominent lymphadenopathy, particularly of the posterior cervical nodes, and mild splenomegaly. These features may be suggestive of infectious mononucleosis, tuberculous lymphadenitis or a lymphoproliferative disorder. Severe anaemia, haemorrhages and petechiae may occur at this stage.

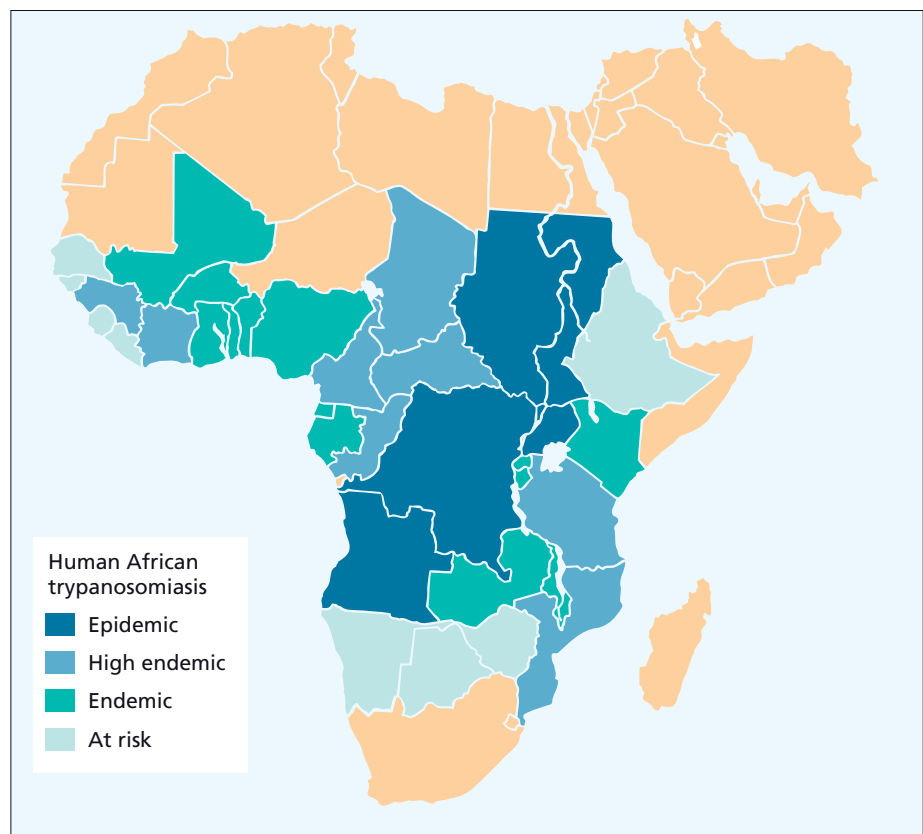

Figure 51.5 Global distribution of African trypanosomiasis.

Both types of African sleeping sickness cause a protracted febrile illness which, despite the name, is not always associated with drowsiness. Death is inevitable if the disease is left untreated. As the disease progresses parasitaemia decreases, trypanosomes invade the central nervous system (CNS) and neurological disturbances due to inflammatory chronic meningoencephalitis supervene. In West African trypanosomiasis, the disease runs its course over several years but in East African trypanosomiasis infection CNS involvement may occur within weeks.

Haematological abnormalities

The aetiology of the anaemia in sleeping sickness is multifactorial but primarily due to phagocytic removal of immune complex-coated red cells from the circulation. Trypanosomes liberate haemolytic factors that contribute to this process, and increases in plasma volume cause a dilutional anaemia. There is a failure to incorporate iron into red cell precursors and the resulting dyserythropoiesis means that the bone marrow is unable to compensate for the fall in haemoglobin. There may be a moderate leucocytosis with increased monocytes, lymphocytes and plasma cells. Mott morular cells have also been described in sleeping sickness. The bone marrow is hypercellular, with areas of gelatinous degeneration.

As the disease advances, a bleeding tendency may develop due to thrombocytopenia, vascular injury and coagulopathy. Platelet dysfunction has also been described and is manifest as clumping and abnormal aggregation responses. DIC with raised FDPs may occur in the later stages. Although some of these haematological changes can be linked to the non-specific polyclonal activation of B cells, overall the mechanisms underlying these are not well understood.

Diagnosis of sleeping sickness

Trypanosomes can be seen on stained thin blood films but the number of trypanosomes in the circulation can vary considerably and is often low, so concentration techniques are usually required. Quantitative buffy coat method is the technique of choice for diagnosis of African sleeping sickness. This involves concentrating the trypanosomes at the plasma–platelet interface in a special microhaematocrit tube using differential centrifugation. Parasites are identified by labelling with the fluorescent marker acridine orange.

Wet preparations of fluid aspirated from the lymph nodes, bone marrow or cerebrospinal fluid (CSF) may also reveal live motile organisms. This technique is more likely to be productive in the case of infection with *T. brucei rhodesiense* than *T. brucei gambiense*. The organisms are fragile so care must be taken not to damage them when making the smears.

The highly specific and sensitive serological card agglutination test for trypanosomiasis (CATT) may be used in conjunction with a direct visualization method. If these tests are positive,

then CSF examination is mandatory to determine the stage of the illness.

Haematological implications of treatment for African sleeping sickness

Pentamidine and suramin are the drugs of choice for the early stages of West and East African trypanosomiasis respectively. They have a cure rate of around 90% but are only able to achieve modest CSF concentrations so they cannot be used for later stages of the disease. The most common haematological side-effects of pentamidine are leucopenia, thrombocytopenia and anaemia. Suramin has serious side-effects, including haemolytic anaemia and bone marrow toxicity.

Melarsoprol, an arsenic-based compound, has been the drug of choice for late-stage sleeping sickness but is highly toxic, with a mortality of 4–12%. Its main adverse effect is a fatal encephalopathic syndrome; haematological toxicity is not a particular problem.

Eflornithine is expensive but is of benefit in late-stage sleeping sickness, particularly West African disease; 25–50% of patients treated with this drug exhibit bone marrow toxicity with pancytopenia.

American trypanosomiasis (Chagas disease)

Epidemiology and biology

Chagas disease is caused by a haemoflagellate protozoa, *T. cruzi*, which is transmitted by triatomine bugs that infest poor-quality housing. It can also be transmitted through blood transfusions and congenitally. It is restricted to a region in the Americas between Argentina and the southern states of the USA.

Clinical features

The incubation period is usually a couple of weeks but may be up to several months if transmission was through blood transfusion. In the acute phase, swelling at the site of entry of the organism, a chagoma, may be accompanied by fever, mild hepatosplenomegaly and local or generalized lymphadenopathy. The trypanosomes multiply intracellularly in muscle tissue, particularly the heart, colon and oesophagus. Once infection has occurred, the organisms will be present for life unless treatment is given. The chronic phase of the disease is associated with heart disease in 30% of infected individuals, which is manifest as arrhythmias and cardiomegaly. A small proportion of individuals also have clinical involvement of the gastrointestinal tract and other hollow organs resulting in loss of peristalsis, organomegaly and organ failure. Asymptomatic infection is common and poses a problem for blood transfusion services in endemic areas, so some countries routinely screen blood for American trypanosomiasis.

Diagnosis of Chagas disease

Although similar methods to those used for African trypanosomiasis can be helpful for diagnosis, serological tests are more commonly used as the primary diagnostic tool. They are based on enzyme immunoassay or immunofluorescent antibody test and have good sensitivity. PCR may also be useful but is not in routine use.

Haematological implications of treatment for American trypanosomiasis

There are only two effective drugs for the treatment of *T. cruzi* infection, nifurtimox and benznidazole. Major haematological side-effects are not common with either drug, although agranulocytosis has been reported with benznidazole.

Leishmaniasis

Epidemiology and biology

Visceral and cutaneous leishmaniasis are caused by protozoan flagellates that are transmitted through the infective bite of a phlebotomine sandfly. Following an infected bite, parasites spread from the inoculation site to the mononuclear phagocytic system. Only the visceral form (kala-azar) is associated with organisms in haemopoietic tissues and thus is considered here. Visceral leishmaniasis is due to the species *Leishmania donovani* and *L. infantum* and is found in 47 countries throughout the world, with extension limits from 45° N to 32° S; 90% of cases are in Bangladesh, India, Nepal, Sudan and Brazil (Figure 51.6). The number of cases of visceral leishmaniasis, particularly around the Mediterranean basin in southern Europe, has increased in association with HIV-related immunosuppression.

Clinical features

The clinical expression of leishmaniasis depends on both the genotypic potential of the parasite and the immunological response of the patient. Incubation period varies from days to years but is generally 2–6 months. Onset can be sudden with high fever, or gradual with intermittent fever. Diarrhoea, joint pains, weight loss and bleeding gums occur in the acute phase. This is followed by progressive muscle wasting, protuberant abdomen, fever, weight loss, anaemia and hepatosplenomegaly. The splenomegaly appears early and the spleen increases in size in relation to the duration of the disease, so that eventually it may reach into the left hypochondrium. In immunocompromised patients, such as transplant recipients and those with advanced HIV disease, kala-azar behaves like an opportunistic infection.

Haematological abnormalities

Normochromic normocytic anaemia is a frequent and clinically significant feature of visceral leishmaniasis and haemoglobin levels of 7–10 g/dL are common. The massive splenic enlargement results in hypersplenism with consequent pancytopenia. Liver dysfunction with jaundice, ascites and deranged coagulation may occur in the late stages and has a poor prognosis. The bleeding tendency may be exacerbated by thrombocytopenia. In all patients with unexplained splenomegaly, pancytopenia or fever, a high index of suspicion of leishmaniasis needs to be maintained to prevent fatalities.

Diagnosis of leishmaniasis

Definitive diagnosis is based on detection of the parasites, or their DNA, in smears of bone marrow, splenic aspirate or fluid aspirated from enlarged lymph nodes.

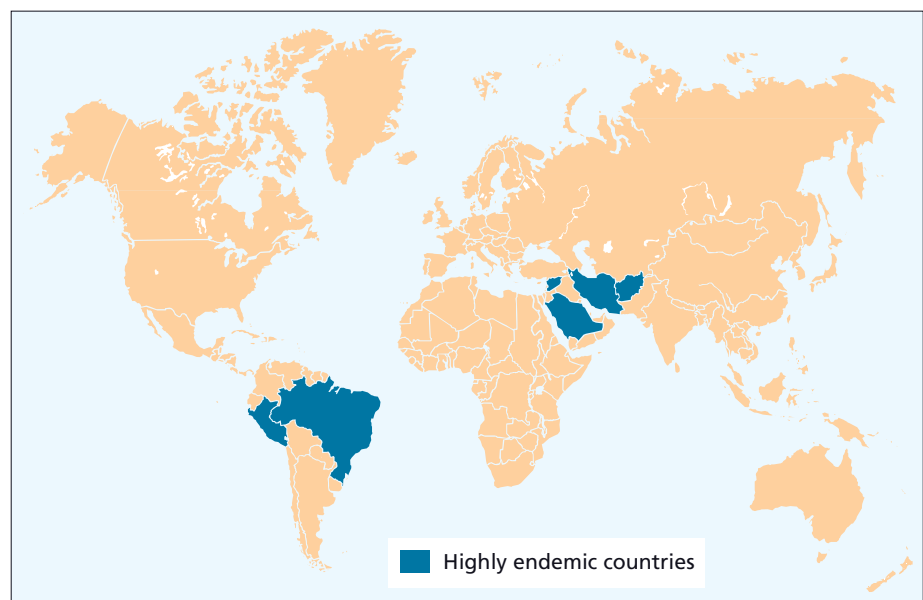

Figure 51.6 Global distribution of visceral leishmaniasis.

Figure 51.7 Bone marrow aspirate of leishmaniasis infection showing a macrophage containing numerous organisms. The presence of both a nucleus and a small paranuclear kinetoplast gives the organisms their characteristic 'double-dot' appearance (MCG $\times 940$).

On microscopy *Leishmania* are usually seen as intracellular amastigotes in mononuclear cells but can also be seen extracellularly (Figure 51.7). They are 2–6 μm in diameter and contain a nucleus lying close to the rod-shaped kinetoplast, and an internal flagellum. Using a Romanowsky stain, the nucleus and kinetoplast stain purple and can be clearly distinguished. Amastigotes can be seen in both bone marrow aspirates and in trephine-impression smears. They are rarely seen in peripheral blood and then only in buffy coat preparations.

Direct microscopic visualization is less sensitive than molecular diagnosis, particularly when there is co-infection with HIV. PCR can be performed on lesion aspirate, marrow, blood and biopsy material. The indirect fluorescent antibody tests ELISA and DAT are useful for detecting antibodies to visceral leishmaniasis, but results may be inconclusive in immunosuppressed patients.

Haematological implications of treatment for leishmaniasis

For the last 80 years, the treatment of leishmaniasis has been based on pentavalent antimonials, although their mode of action is still unclear. Sodium stibogluconate is the most commonly used antimonial. It can be associated with worsening anaemia and thrombocytopenia, although its most serious detrimental effects are on cardiac function. Resistance levels to antimonials are high in some countries including India, Bangladesh, Brazil and Sudan, so other options such as amphotericin, paromomycin and miltefosine need to be considered. HIV co-infected patients do not respond well to antimonials so for these individuals amphotericin is the drug of choice. Amphotericin can produce haematological side-effects, commonly normocytic normochromic anaemia, but its most serious

Figure 51.8 Patient with massive splenomegaly due to hyperreactive malarial splenomegaly.

toxicity is related to renal, cardiac, neurological and hepatic dysfunction. Side-effects can be reduced by using the liposomal preparation. Immunocompromised patients may require prophylaxis to prevent relapses.

Non-specific haematological abnormalities associated with tropical diseases

Hypersplenism

Hypersplenism is a syndrome characterized by splenomegaly and cytopenias. Tropical infections associated with massive splenomegaly include hyperreactive malarial splenomegaly, visceral leishmaniasis, schistosomiasis and trypanosomiasis (Figure 51.8). The cytopenias in hypersplenism are due to a combination of sequestration and haemodilution. The degree of expansion of plasma volume is proportional to the size of the spleen, and can be improved by splenectomy. The thrombocytopenia and neutropenia are rarely severe enough to cause clinical problems. Most of the thrombocytopenia is due to pooling in the spleen which, when massively enlarged, can hold up to 90% of the platelet mass. Neutropenia is the result of increased marginalization of granulocytes. Treatment of the underlying disorder generally leads to regression of the splenomegaly with resolution of the haematological abnormalities.

Tropical diseases associated with changes in the full blood count

Anaemia

Anaemia of chronic disease is a common and non-specific finding in many types of tropical infections. Some infections are responsible for specific types of anaemia. For example, hook-

worm infection contributes to iron deficiency anaemia, and megaloblastic anaemia secondary to parasite consumption of vitamin B₁₂ is a feature of infection with the tapeworm *Diphyllobothrium latum*. Intraerythrocytic parasites, such as those that cause malaria and babesiosis, may be associated with significant intravascular haemolysis.

White cell abnormalities

Severe infections particularly due to bacteria may cause a neutrophilia and a leukaemoid reaction with circulating myeloid precursors and neutrophils with toxic granulation, vacuolation and Döhle body formation. Lymphocytosis with neutropenia, splenomegaly, nose bleeds, rash and neurological complications is a feature of rickettsial diseases (e.g. typhus, Q fever, trench fever). Some, such as trench fever, may persist for many years and are transmissible in blood transfusions. The absence of neutrophilia in the presence of marked fever is a particular feature of typhoid. Lymphocytosis or monocytosis may also be present in typhoid; other clinical features include hepatosplenomegaly and, in severe disease, haemorrhage from ileal ulcers exacerbated by DIC. Helminths and other predominantly tropical organisms that invade tissues may be associated with a significant eosinophilia ($> 0.5 \times 10^9/L$). Such diseases include loiasis, lymphatic filariasis, schistosomiasis, trichinosis, toxocariasis, strongyloidiasis, hydatid disease, oriental liver flukes and guinea worm.

Tropical infections with fever and haemorrhage

Relapsing fever

Relapsing fevers are borne by either lice or ticks. Louse-borne relapsing fever is endemic in the horn of Africa and Rwanda. Tick-borne relapsing fever has a wider distribution through Africa, the Mediterranean basin and the Middle East. They have a relapsing course and severe disease is characterized by fever with jaundice, neutrophilia, thrombocytopenia and DIC. There is a marked bleeding tendency, with petechial haemorrhage and epistaxis. Spiral organisms (*Borrelia* spp.) can be seen in the blood. Relapsing fevers respond well to tetracycline but this must be given with care as it can generate a severe life-threatening Jarisch–Herxheimer reaction.

Viral haemorrhagic fevers

These are caused by arenaviruses, filoviruses, bunyaviruses and flaviviruses and are classified according to their reservoir hosts and their primary means of transmission. They are divided into:

- rodent-associated viruses (e.g. Lassa fever, hantaviruses);
- arthropod-borne viruses (e.g. dengue, yellow fever and Chikungunya viruses);
- unknown vectors or hosts (e.g. Marburg, Ebola).

They often occur in epidemics, have human-to-human transmission and may only be suspected if a relevant travel history

is elicited from the patient. Dengue and yellow fever are becoming increasingly important imported infections.

Dengue

The four types of dengue virus belong to a group of flaviviruses and are transmitted by *Aedes* mosquitoes. Dengue is endemic in tropical areas of Asia, Africa, South America and the Caribbean and is particularly virulent in Southeast Asia, including Thailand and Vietnam. There has been a resurgence of the disease as a result of urbanization, poverty, the demise of *Aedes* eradication programmes and increasing travel.

Primary infection occurs in young children and is usually asymptomatic. Older children and adults develop acute fever, headache and myalgia ('breakbone fever'). Leucopenia may accompany this stage of the illness. Severe complications may arise in those who have had previous dengue infection. These include hypotensive shock, marked thrombocytopenia with spontaneous bleeding, neutropenia, bone marrow hypoplasia and abnormal megakaryocytopoiesis.

Lassa fever, Ebola virus and Marburg virus

These are endemic in equatorial Africa and are important because they cause potentially fatal infections and have the ability to spread from person to person. Only about 10% of infected individuals become ill. Of these 1–2% develop fatal disease. The clinical features of these three haemorrhagic fevers are similar and are characterized by headache, fever and oesophagitis. Spontaneous bleeding occurs in 25% of hospitalized patients and is thought to be due to abnormal platelet function. Case reports suggest that treatment with ribavirin may be helpful.

Yellow fever

Yellow fever virus is transmitted by *Aedes* mosquitoes and exists throughout equatorial Africa, and northern and central southern America. It invades hepatocytes, causing hepatocellular dysfunction and jaundice. Fever, myalgia and back pain may be followed by jaundice, bleeding and, in the most severe cases, renal failure.

Selected bibliography, 983**Developmental haemopoiesis**

Haemopoiesis begins in the yolk sac in the third week of gestation and moves sequentially to the aorta–gonad–mesonephros (AGM) by 5 weeks' gestation, the liver by 6–8 weeks and the bone marrow around the 11th week of gestation. The AGM involutes early in the first trimester and the liver is the principal site of haemopoiesis until the end of the third trimester. The predominant lineage during fetal life is erythropoiesis but platelets and all types of leucocyte found in adult blood are also seen from as early as 4–5 weeks' gestation.

There are a number of differences between erythropoiesis in neonates and adults: red cell morphology is distinctive with large numbers of crenated red cells, particularly in preterm neonates (Figure 52.1); red cell lifespan is reduced (35–50 days in preterm infants, 60–70 days in term infants); susceptibility to oxidant-induced injury is increased because of differences in the glycolytic and pentose phosphate pathways; the erythropoietin response to anaemia is blunted; and specific embryonic and fetal globin chains are synthesized (Table 52.1). The first globin chain produced is ϵ -globin, followed by α - and γ -globin chains. Haemoglobin F (HbF, $\alpha_2\gamma_2$) is produced from 4–5 weeks' gestation and is the predominant haemoglobin until after birth. Adult haemoglobin (HbA, $\alpha_2\beta_2$) is produced from 6–8 weeks' gestation, but remains at low levels until after birth. In term babies, the average HbF at birth is 70–80%, the HbA is 25–30%,

there are small amounts of HbA₂ and sometimes a trace of Hb Barts (γ_4).

Immediately after birth, rates of haemoglobin synthesis and red cell production fall in response to the sudden increase in tissue oxygenation at birth. In term babies, the haemoglobin reaches a mean of 13–14 g/dL at 4 weeks and 9.5–11 g/dL at 7–9 weeks of age. Studies of well preterm infants show a steeper fall in haemoglobin, reaching a mean of 6.5–9 g/dL at 4–8 weeks of age. The reticulocyte count falls after birth as erythropoiesis is suppressed and increases to normal values at 6–8 weeks of age. The blood volume at birth varies with gestational age and the timing of clamping of the cord. In term infants, the average blood volume is 80 mL/kg and in preterm infants 106 mL/kg (range 85–143 mL/kg). Term and preterm babies have adequate stores of iron, folic acid and vitamin B₁₂ at birth. However, stores of both iron and folic acid are lower in preterm infants and are depleted more quickly, leading to deficiency after 2–4 months if the recommended daily intakes are not maintained.

Neonatal anaemia**Definition and pathophysiology**

Any neonate with a haemoglobin of less than 13 g/dL at birth should be considered anaemic and may require investigation (Figure 52.2). However, it is important to be aware that the haemoglobin concentration is affected by the site of sampling (it is up to 4 g/dL lower in venous than in heel-prick samples in

Figure 52.1 Typical erythrocyte morphology in a preterm neonate. Crenated red cells are a normal feature of the blood film of preterm neonates during the first few weeks of life. This film is from a neonate born at 26 weeks’ gestation and shows the number of crenated cells present in neonates under 28 weeks’ gestation. The numbers of these cells is inversely proportional to gestational age at birth.

Table 52.1 Composition of haemoglobins in the human embryo, fetus and neonate.

Haemoglobin	Globin chains		Gestation
	α -Globin gene cluster*	β -Globin gene cluster*	
<i>Embryonic</i>			
Hb Gower 1	ζ_2	ϵ_2	From 3–4 weeks
Hb Gower 2	α_2	ϵ_2	
Hb Portland	ζ_2	γ_2	From 4 weeks
<i>Fetal</i>			
HbF	α_2	γ_2	From 4 weeks
<i>Adult</i>			
HbA	α_2	β_2	From 6–8 weeks
HbA ₂	α_2	δ_2	From 30 weeks

*The α -globin gene cluster is situated on chromosome 16 and the β -globin gene cluster on chromosome 11. Note that fetuses and neonates with α -thalassaemia major, who are unable to synthesize α -globin chains, will have Hb Portland as well as Hb Barts (β_4), detectable by haemoglobin electrophoresis or HPLC.

the first few days of life) and the timing of the clamping of the cord (around 3 g/dL higher after late clamping). The clinical significance of neonatal anaemia depends on whether the baby is able to maintain adequate tissue oxygenation. This in turn depends on the position of the haemoglobin–oxygen dissociation

Table 52.2 Common causes of neonatal anaemia.

<i>Reduced red cell production</i>
Diamond–Blackfan anaemia
Congenital viral infections, e.g. parvovirus, cytomegalovirus
Congenital dyserythropoietic anaemia
Pearson syndrome
<i>Increased red cell destruction (haemolysis)</i>
Alloimmune: haemolytic disease of the newborn (Rh, ABO, Kell, other)
Red cell membrane disorders, e.g. hereditary spherocytosis
Red cell enzyme deficiencies, e.g. pyruvate kinase deficiency
Some haemoglobinopathies, e.g. α -thalassaemia major, HbH disease
<i>Blood loss</i>
Occult haemorrhage before or around birth, e.g. twin–twin, fetomaternal
Internal haemorrhage, e.g. intracranial, cephalhaematoma
Iatrogenic, due to frequent blood sampling
<i>Anaemia of prematurity</i>
Impaired red cell production plus reduced red cell lifespan

tion curve, which is principally determined by the concentrations of HbF and 2,3-diphosphoglycerate (2,3-DPG); a high HbF and low 2,3-DPG both shift the curve to the left, i.e. the affinity of haemoglobin for oxygen is increased and less oxygen is released to the tissues. This is the situation just after birth and may be more of a problem for very preterm babies as their HbF levels are greater than 90%. Over the first few months of life, 2,3-DPG levels rise and HbF levels fall so that the haemoglobin–oxygen dissociation curve gradually shifts to the right, the oxygen affinity of haemoglobin falls and oxygen delivery to the tissues increases, ameliorating the effects of the falling haemoglobin.

Causes of neonatal anaemia

Anaemia may be caused by reduced red cell production, increased red cell destruction (haemolysis) or blood loss (Table 52.2).

Neonatal anaemia due to reduced red cell production

The main diagnostic clues to reduced red cell production are the combination of a low reticulocyte count ($< 20 \times 10^9/L$) with a negative direct antiglobulin test (Coombs test). The most common causes are congenital parvovirus infection and genetic red cell aplasias, particularly Diamond–Blackfan anaemia (DBA).

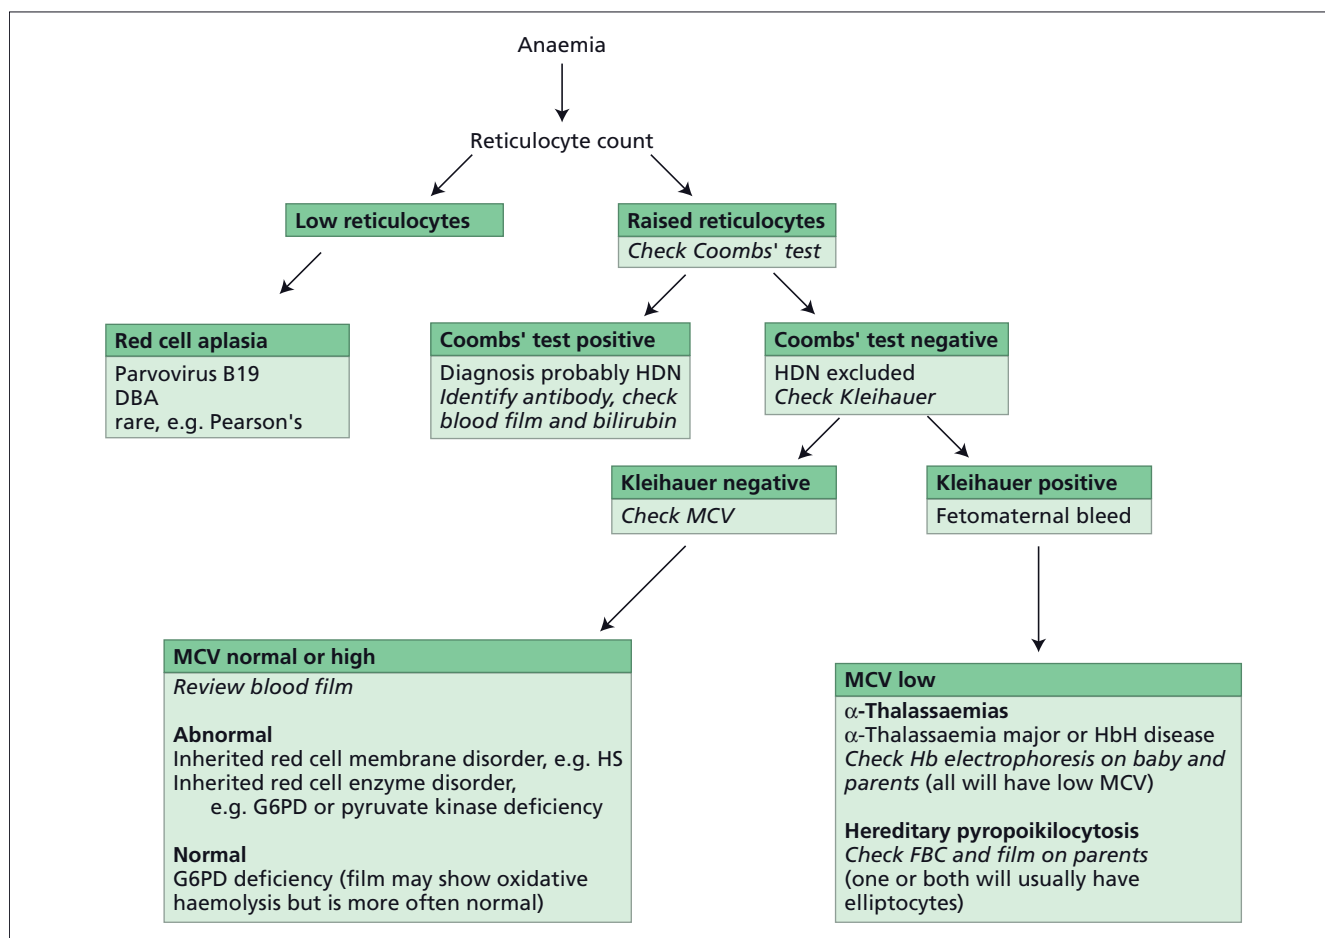

Figure 52.2 A diagnostic algorithm for neonatal anaemia. The most useful screening tests for investigating unexplained neonatal anaemia are the reticulocyte count, the Coombs test and the mean corpuscular volume (MCV) of the red cells. DBA,

Diamond–Blackfan anaemia; G6PD, glucose-6-phosphate dehydrogenase; HDN, haemolytic disease of the newborn; HS, hereditary spherocytosis.

Parvovirus B19 and fetal/neonatal anaemia

Maternal infection with parvovirus B19 can cause severe fetal anaemia and in 9% of cases leads to intrauterine death. The baby has marked reticulocytopenia (often $< 10 \times 10^9/L$) and thrombocytopenia may also occur. The diagnosis is made by maternal serology and demonstration of B19 DNA in the fetus or neonate by dot-blot hybridization or polymerase chain reaction (PCR) of peripheral blood (bone marrow aspiration for morphology and parvovirus B19 PCR may be necessary in difficult cases). Severe cases require intrauterine transfusion but have a good long-term outcome if they survive to delivery.

Genetic red cell aplasia

Apart from DBA, the genetic causes of congenital red cell aplasia are extremely rare. They include congenital dyserythropoietic anaemia (CDA) and Pearson syndrome; the other inherited bone marrow failure syndromes, such as Fanconi anaemia, are

almost never present at birth. DBA, which occurs in five to seven babies per million live births, has a clear family history in 20% of cases (autosomal dominant or recessive) and appears to be sporadic in the remaining 80%. It usually presents as increasing anaemia over the first few weeks or months of life but more severe cases manifest as second-trimester anaemia or hydrops fetalis. Around 40% of infants have associated congenital anomalies, particularly craniofacial dysmorphism, neck anomalies and thumb malformations similar to those seen in Fanconi anaemia. The blood film shows normochromic red cells with an absence of polychromasia and nucleated red cells despite severe anaemia (Figure 52.3). Reticulocytopenia is usually severe but automated reticulocyte counts of $20\text{--}30 \times 10^9/L$ are sometimes seen. Erythroid precursors are absent in the bone marrow aspirate. These features are diagnostic of DBA if parvovirus infection is excluded. Raised red cell levels of adenosine deaminase (ADA) in the patient and/or parents may be useful

Figure 52.3 Blood film from a neonate with Diamond–Blackfan anaemia. This baby presented with fetal anaemia at 20 weeks' gestation and received intrauterine transfusion. At birth, the baby had normochromic anaemia and the blood film showed a complete absence of polychromasia and nucleated red cells, despite a haemoglobin of 7 g/dL.

for confirming the diagnosis, although normal red cell ADA levels do not exclude DBA. Recent studies indicate that DBA is due to defects in structural ribosomal proteins (RP). At present mutations in six genes (*RPS19*, *RPS24*, *RPS17*, *RPL5*, *RPL11* and *RPL35a*) have been identified and account for about 50% of DBA cases, *RPS19* mutations being the commonest (25% of all DBA). In the neonatal period, the only treatment of DBA is red cell transfusion, although steroids are used in older infants and children.

The other genetic causes of congenital red cell aplasia, CDA and Pearson syndrome, can be distinguished from DBA by marrow morphology. In Pearson syndrome, which is caused by mutations in mitochondrial DNA and presents with normochromic anaemia, neutropenia, thrombocytopenia and failure to thrive in the first few weeks of life, there is highly characteristic vacuolation of early erythroid cells on the marrow aspirate (Figure 52.4). Unfortunately, the prognosis for children with Pearson syndrome is very poor, with few surviving beyond the second year of life. Mutations in *codanin-1* and *SEC23B* have recently been shown to be responsible for many, but not all, cases of type I and II CDA respectively.

Neonatal anaemia due to increased red cell destruction (haemolysis)

The main diagnostic clues suggesting a haemolytic anaemia are increased numbers of reticulocytes and/or circulating nucleated red cells (Figure 52.5), unconjugated hyperbilirubinaemia, a positive Coombs test (if immune) and characteristic changes in

Figure 52.4 Pearson syndrome. Bone marrow aspirate from a neonate with Pearson syndrome showing typical vacuolation of erythroblasts and a dysplastic megakaryocyte.

the morphology of the red cells on a blood film (e.g. hereditary spherocytosis; Figure 52.5). The main cause of immune haemolytic anaemia is haemolytic disease of the newborn. The main causes of non-immune neonatal haemolysis are red cell membrane disorders, red cell enzymopathies and, occasionally, haemoglobinopathies (Table 52.2).

Immune haemolysis, including haemolytic disease of the newborn

The principal alloantibodies causing haemolytic disease of the newborn are those against rhesus antigens (anti-D, anti-c and anti-E), anti-Kell, anti-Kidd (J^k), anti-Duffy (F^y) and antibodies of the MNS blood group system, including anti-U. Anti-D is the most frequent alloantibody causing significant haemolytic anaemia, affecting 1 in 1200 pregnancies. Anti-Kell antibodies are less common but can cause severe fetal and neonatal anaemia as they inhibit erythropoiesis as well as causing haemolysis. Most babies with haemolytic disease of the newborn present with jaundice and/or anaemia; in severe cases there is hepatosplenomegaly and/or skin deposits due to extramedullary haemopoiesis. ABO haemolytic disease occurs only in offspring of women of blood group O and is confined to the 1% of such women who have high-titre IgG antibodies. Haemolysis due to anti-A is more common (1 in 150 births) than that due to anti-B. In contrast with anti-rhesus antibodies, both anti-A and anti-B usually cause hyperbilirubinaemia without significant anaemia; however, hydrops has occasionally been described. The blood film in ABO haemolytic disease characteristically shows very large numbers of spherocytes with little or no increase in nucleated red cells (see Figure 52.5a); this contrasts with rhesus haemolytic disease of the newborn, in which there are few spherocytes and large numbers of circulating nucleated red cells (see Figure 52.5b).

Figure 52.5 Haemolytic disease of the newborn. (a) Blood film from a baby with rhesus haemolytic disease of the newborn due to anti-D showing polychromasia and large numbers of nucleated red cells but relatively few spherocytes. (b) Blood film from a neonate with ABO haemolytic disease of the newborn due to anti-A showing very large numbers of spherocytes, polychromasia and no nucleated red cells.

Management of haemolytic disease of the newborn

All neonates at risk should have cord blood taken for measurement of haemoglobin, bilirubin and a Coombs test and should remain in hospital until hyperbilirubinaemia and/or anaemia have been properly managed. Rhesus-alloimmunized infants with haemolysis should receive phototherapy from birth, as the bilirubin can rise steeply; this prevents the need for exchange transfusion in some infants. In haemolytic disease due to anti-Kell, anaemia is usually more prominent than jaundice and minimal phototherapy may be necessary despite severe anaemia. ABO haemolytic disease of the newborn usually just requires phototherapy as anaemia is uncommon. The indications for exchange transfusion in haemolytic disease of the newborn are:

- severe anaemia (haemoglobin < 10 g/dL at birth); and/or
- severe or rapidly increasing hyperbilirubinaemia.

The British Committee for Standards in Haematology (BCSH) have published useful guidelines for neonatal exchange transfusion. Intravenous immunoglobulin has been used to reduce the need for exchange transfusion but the value of this approach remains to be proven in clinical trials. Neonates with haemolytic disease due to anti-rhesus antibodies may develop 'late' anaemia at a few weeks of age, requiring 'top-up' transfusion; irradiated blood must be used for infants previously receiving intrauterine transfusion to prevent the risk of transfusion-associated graft-versus-host disease. Recombinant erythropoietin sometimes prevents the need for top-up transfusion for late anaemia but is not effective when haemolysis is brisk. Folic acid (500 µg/kg daily) should be given to all babies with haemolysis until they reach 3 months of age.

Neonatal haemolytic anaemia due to red cell membrane disorders

In neonates, these disorders present with jaundice and moderate anaemia (usually due to hereditary spherocytosis), as an incidental finding on routine blood films in the absence of

jaundice or anaemia (usually hereditary elliptocytosis) or, occasionally, as severe transfusion-dependent haemolytic anaemia with a characteristic low mean corpuscular volume (MCV) of 50–60 fL (usually due to hereditary pyropoikilocytosis). The main clues are a family history and an abnormal blood film, as red cell membrane disorders can nearly always be recognized by the characteristic shape of the red cells (Figure 52.6a). Identification of the exact type of membrane abnormality may require specialized investigations. The osmotic fragility test is of limited value in neonates and recent data indicate that the dye binding test is more useful. If the clinical phenotype is severe and family history or family studies are unhelpful, red cell membrane electrophoresis is indicated to clarify the diagnosis (on pretransfusion blood samples to minimize diagnostic confusion due to transfused cells).

Hereditary spherocytosis occurs in 1 in 5000 live births to parents of northern European extraction. It is caused by mutations in the genes for spectrin, ankyrin, protein 4.1 or protein 3 and is usually inherited in an autosomal dominant fashion. The blood film shows spherocytes and is identical to that of ABO haemolytic disease (Figure 52.6b). Neonatal anaemia due to hereditary spherocytosis is usually moderate (haemoglobin 7–10 g/dL); it is not uncommon for affected neonates to require one or two transfusions during the neonatal period before a transfusion-free plateau haemoglobin of 8–10 g/dL is achieved after a few months. *Hereditary elliptocytosis*, which is caused by different mutations in the genes for spectrin, ankyrin or protein 4.1, usually has no clinical manifestations in the neonate apart from elliptocytes on the blood film. However, neonates who are homozygous or compound heterozygous for hereditary elliptocytosis mutations have severe haemolytic anaemia. The most common form is *hereditary pyropoikilocytosis*, which causes severe transfusion-dependent haemolytic anaemia. The diagnosis is easily made from the low MCV and blood films of the baby (which show bizarre fragmented red cells and microspherocytes; see Figure 52.6a), and both parents (one or both of whom

Figure 52.6 Red cell membrane disorders. (a) Blood film from a baby with hereditary pyropoikilocytosis showing microspherocytes, red cell fragments and polychromasia. (b) Blood film from a neonate with hereditary spherocytosis showing large numbers of spherocytes and polychromasia.

usually has elliptocytosis). Red cell transfusion is necessary until the child is old enough to undergo splenectomy, to which there is an excellent response.

Neonatal haemolysis due to red cell enzymopathies

The commonest inherited red cell enzymopathies presenting in the neonatal period are glucose-6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase deficiency. *G6PD deficiency* has a high prevalence in individuals from Central Africa (20%) and the Mediterranean (10%). In neonates, G6PD deficiency nearly always presents with jaundice within the first few days of life; the vast majority of affected neonates are boys, as the *G6PD* gene is on the X chromosome. The jaundice is often severe, whereas anaemia is uncommon. The blood film is usually completely normal but in the small number of neonates with anaemia due to G6PD deficiency the blood film shows typical changes of oxidative haemolysis. The diagnosis is made by assaying G6PD on a peripheral blood sample. The pathogenesis of the jaundice is unclear as most babies with G6PD deficiency have no evidence of haemolysis. Management of neonatal G6PD deficiency requires close monitoring of the bilirubin to prevent kernicterus, particularly when interactions with other risk factors for neonatal hyperbilirubinaemia are present, such as Gilbert syndrome or hereditary spherocytosis, and also the counselling of the babies' parents regarding which medicines, chemicals and foods may precipitate haemolysis. For the vast majority of patients there is no chronic haemolysis and no anaemia and therefore folic acid supplements are not indicated.

Pyruvate kinase deficiency is the second most common inherited red cell enzymopathy in neonates and is transmitted in an autosomal recessive fashion. It is clinically heterogeneous, varying from anaemia severe enough to cause hydrops fetalis to a mild unconjugated hyperbilirubinaemia. In severe cases, the jaundice has a rapid onset within 24 hours of birth and exchange transfusion may be required. The diagnosis is made by measur-

ing pretransfusion red cell pyruvate kinase activity; in mild cases enzyme activity may be relatively modestly reduced making the diagnosis difficult and it is often useful to assay levels in the parents for confirmation. The blood film is sometimes distinctive but more often shows non-specific changes of non-spherocytic haemolysis. Management in the neonatal period depends on the severity of the jaundice and anaemia; some, but not all, children are transfusion dependent and folic acid supplements should be given to prevent deficiency due to chronic haemolysis.

The other red cell enzymopathies are rare. The most important in the neonatal period is *triosephosphate isomerase deficiency*, as one-third of patients present with neonatal haemolytic anaemia, often many months before the devastating neurological features of this disorder become apparent. Another cause of acute haemolysis confined to the neonatal period is *infantile pyknocytosis*. This poorly understood condition, which is probably due to transient glutathione peroxidase deficiency, usually presents at 1–6 weeks of age, produces moderately severe anaemia requiring one to two red cell transfusions, shows changes of oxidative haemolysis on the blood film (Figure 52.7) and resolves by 6–12 weeks of age. Measurement of glutathione peroxidase levels in affected neonates may be useful (parental levels are normal) but the diagnosis is usually easily made from the blood film.

Neonatal haemolysis due to haemoglobinopathies

The only haemoglobinopathy that presents typically in the neonatal period is α -thalassaemia major, as all four α -globin genes are deleted. Occasional non-thalassaemic structural α - and γ -globin gene mutations, which are clinically completely silent in adults and children, cause transient neonatal haemolytic anaemia in the neonate because they are unstable (e.g. Hb Hasharon, Hb Poole), whereas the major β -globin haemoglobinopathies (sickle cell disease and β -thalassaemia major) rarely manifest clinically in neonates.

Figure 52.7 Infantile pyknocytosis. Blood film from a neonate with infantile pyknocytosis and a low level of erythrocyte glutathione peroxidase showing pyknocytes, fragmented red cells, polychromasia and occasional spherocytes.

α -Thalassaemia major predominantly affects families of Southeast Asian, Mediterranean or Middle Eastern origin, and presents with second-trimester fetal anaemia or hydrops fetalis, which is fatal within hours of delivery. The only long-term survivors of α -thalassaemia major are those who have received intrauterine transfusions followed by regular postnatal transfusions and/or a bone marrow transplant. There is also a high incidence of hypospadias and limb defects in survivors and others have severe neurological problems. If intrauterine transfusions are delayed until anaemia is severe, neonatal pulmonary hypoplasia is a cause of early mortality. The diagnosis of α -thalassaemia major should be suspected in any case of severe fetal anaemia that presents in the second trimester, and any case of hydrops fetalis with severe anaemia in which the parents come from high-prevalence areas, particularly Southeast Asia. Checking the blood counts of the parents will immediately identify whether they are at risk of having a child with α -thalassaemia major: both parents will have hypochromic microcytic red cell indices, with MCV usually below 74 fL and mean corpuscular haemoglobin (MCH) usually less than 24 pg. The diagnosis of α -thalassaemia major is confirmed by haemoglobin electrophoresis or HPLC (which shows Hb Barts, Hb Portland and sometimes HbH; HbF and HbA are absent); the blood film shows hypochromic microcytic red cells with vast numbers of circulating nucleated red cells (Figure 52.8).

Neonatal anaemia due to blood loss

Blood loss as a cause of neonatal anaemia may be very obvious (e.g. a cephalhaematoma or rupture of the cord) or be concealed and easy to miss unless specifically sought (e.g. fetomaternal bleeds). Usually, the most serious blood loss occurs prior to delivery and important causes of this are twin–twin transfusion and fetomaternal blood loss. *Twin–twin transfusion* occurs

Figure 52.8 α -Thalassaemia major. Blood film from a neonate with α -thalassaemia major, born at 28 weeks' gestation, showing severe hypochromia, microcytosis, target cells, polychromasia and nucleated red cells.

in monochorionic twins with monochorial placentas. If the bleeding is chronic, there may be a marked difference in birth weight between twins: the donor twin is smaller, pale, lethargic and may have overt cardiac failure; the recipient twin may be plethoric, with hyperviscosity and hyperbilirubinaemia and polycythaemia.

Fetomaternal haemorrhage occurs spontaneously or secondary to trauma usually in the third trimester. Most episodes involve very small quantities of blood (0.5 mL or less) but acute loss of more than 20% of the blood volume may cause intrauterine death, circulatory shock or hydrops. Diagnostic clues are anaemia at birth in an otherwise well baby with no or minimal jaundice. The most useful diagnostic tests are a Coombs test to exclude immune haemolysis, a reticulocyte count to exclude red cell aplasia, a Kleihauer test on maternal blood to quantify the number of HbF-containing fetal red cells in the maternal circulation and a blood film (Figure 52.9). Blood loss around the time of delivery is usually due to obstetric complications (e.g. placenta praevia, placental abruption); in these circumstances, the babies are often extremely ill, with circulatory shock, anaemia worsening rapidly after birth, large numbers of circulating nucleated red cells and disseminated intravascular coagulation (DIC).

Anaemia of prematurity

The normal fall in haemoglobin in preterm neonates has been termed 'physiological anaemia of prematurity', as it does not appear to be associated with any abnormalities in the baby. The pathogenesis is not fully elucidated but contributory factors include the reduced lifespan of fetal erythrocytes, the relatively low erythropoietin concentration, the rapid growth rate and iatrogenic blood loss. Routine supplementation of preterm

Figure 52.9 Fetomaternal haemorrhage. (a) Blood film from a neonate with a haemoglobin of 5 g/dL at birth due to a large fetomaternal haemorrhage; the main features are the marked polychromasia, large numbers of nucleated red cells and normal red cell morphology. (b) Kleihauer test showing HbA-containing maternal 'ghost' cells and pink-staining HbF-containing fetal cells.

neonates with folic acid and iron means that nutritional deficiency rarely plays a role. The diagnosis is usually straightforward: a well preterm baby with a slowly falling haemoglobin, unremarkable blood film showing normochromic/normocytic red cells, slightly low reticulocytes ($20 \times 10^9/L$) and no nucleated red cells.

Management of anaemia of prematurity and the role of erythropoietin

The severity of anaemia of prematurity and thereby the need for red cell transfusion can be reduced by (i) limiting iatrogenic blood loss by appropriate use of blood tests; (ii) administering iron and folate supplements to all preterm infants (iron 3 mg/kg daily from 4–6 weeks of age or iron-fortified formula with 0.5–0.9 mg/dL of iron and folic acid 50 µg daily or 500 µg once weekly); and (iii) judicious use of erythropoietin. The many controlled trials of recombinant erythropoietin for prevention of neonatal anaemia have been reviewed extensively. Erythropoietin reduces the number of transfusions in relatively well infants with low transfusion requirements, but not in sick preterm infants who have a need for frequent phlebotomy and multiple transfusions. The main roles for recombinant erythropoietin in neonates are in ameliorating the anaemia in infants who have received intrauterine transfusions for alloantibody-mediated anaemia and in preterm babies of Jehovah's Witnesses. The usual dose is 300 µg/kg of epoetin beta by subcutaneous injection three times per week, starting in the first week of life, together with oral iron supplements.

Indications for red cell transfusion in neonatal anaemia

The BCSH recently revised their guidelines for transfusion of fetuses, neonates and older children; the guidelines contain recommendations about the products and indications for red cell transfusion in neonates. These are consensus guidelines and need to be adapted for use in each individual neonatal intensive

Table 52.3 Causes of neonatal polycythaemia.

Intrauterine growth restriction
Maternal hypertension
Maternal diabetes
Chromosomal disorders: trisomy 21, 18 or 13
Twin–twin transfusion
Delayed clamping of the cord
Endocrine disorders: thyrotoxicosis, congenital adrenal hyperplasia

care unit, depending on the case mix of babies, as adherence to strict neonatal transfusion guidelines reduces both the number of transfusions and donor exposure.

A simple diagnostic approach to neonatal anaemia

Red cell disorders associated with neonatal or fetal anaemia present in three main ways: with a low haemoglobin, with jaundice due to haemolysis or with hydrops. A diagnostic algorithm to help identify which of these causes is most likely, which can be excluded and what further investigations are most appropriate is shown in Figure 52.2.

Neonatal polycythaemia

For both term and preterm infants, polycythaemia can be defined as a central venous haematocrit of greater than 0.65, as there is an exponential rise in blood viscosity above this level. However, even at haematocrits greater than 0.70, only a minority of neonates have clinical signs of hyperviscosity, such as lethargy, hypotonia, hyperbilirubinaemia and hypoglycaemia. Causes of polycythaemia are shown in Table 52.3. Treatment is

controversial and is not necessary in infants with very minor symptoms (e.g. borderline hypoglycaemia or poor peripheral perfusion). Infants with neurological signs and a haematocrit greater than 0.65 should have a partial exchange transfusion (using a crystalloid solution such as normal saline) to reduce the haematocrit to 0.55.

White cell disorders

Normal values

In the neonate, normal values for leucocytes, particularly neutrophils, are affected by a number of factors including gestational age, postnatal age, antenatal history, perinatal history and ethnic origin. Neutrophil counts in healthy babies increase for the first 12 hours then fall to a nadir at 4 days of age. The neutrophil count is higher in capillary samples and after vigorous crying; it is lower in neonates of African origin. Healthy preterm babies often have circulating myeloblasts and lymphoblasts, although these usually form less than 5% of the white cell differential count.

Neutropenia

A pragmatic approach is to consider a neutrophil count at birth of less than $2 \times 10^9/L$ as abnormal and worth monitoring, and a neutrophil count during the first month of life of less than $0.7 \times 10^9/L$ as significant enough to merit further investigation.

Causes of neutropenia

The commonest cause of neutropenia at birth in preterm neonates is reduced neutrophil production, secondary to intrauterine growth restriction or maternal hypertension. Most affected neonates also have thrombocytopenia and increased erythropoiesis (polycythaemia and/or increased circulating nucleated red cells), secondary to fetal tissue hypoxia. The neutropenia resolves spontaneously usually within a few days of birth. The commonest cause of neutropenia in term infants is bacterial or viral infection. Other important causes of neutropenia are alloimmune neutropenia and severe congenital neutropenia (SCN) due to failure of neutrophil production (e.g. Kostmann syndrome), both of which predispose to severe neonatal infection.

Alloimmune neutropenia is the neutrophil equivalent of haemolytic disease of the newborn and alloimmune thrombocytopenia, and may affect 3% of all deliveries. It occurs when fetal neutrophils express paternally derived neutrophil-specific antigens absent on maternal neutrophils and against which the mother produces IgG neutrophil alloantibodies. The causative antibodies are usually anti-NA1 or -NA2. It presents in the first few days of life with fever and infections of the respiratory tract,

urinary tract and skin, particularly due to *Staphylococcus aureus*, and the mainstay of treatment is antibiotics. The diagnosis is made by demonstrating antineutrophil antibodies in the mother and baby, which react against paternal, but not maternal, neutrophil antigens. The neutropenia is self-limiting, usually resolving within 1–2 months.

Congenital and inherited neonatal neutropenias should be sought when the neutropenia is prolonged, if there is a relevant family history or consanguinity or if the baby has typical dysmorphic features (e.g. thumb/radial abnormalities in Fanconi anaemia). SCN is the most likely cause in the neonatal period. Infants usually present with severe infections and a marked neutropenia ($< 0.2 \times 10^9/L$), often with a compensatory monocytosis. The diagnosis is made by the severity of the neutropenia, the bone marrow appearance (arrest of differentiation at the myelocyte/promyelocyte stage) and the absence of antineutrophil antibodies. The inheritance of SCN can be autosomal recessive or dominant or X-linked. Mutations in *ELA2* (neutrophil elastase) are the most common cause of SCN, but other causes include mutations in *GFI1* (growth factor-independent protein 1) and *WAS* (Wiskott–Aldrich syndrome protein, WASp). Recently, homozygous mutations in the *HAX1* gene were found to explain the SCN in the original Kostmann family but this appears to be a rare cause of the disease.

Congenital leukaemias

The most common forms of congenital leukaemia are acute monoblastic leukaemia and acute megakaryoblastic leukaemia; acute megakaryoblastic leukaemia is particularly common in babies with Down syndrome. The babies present with signs of anaemia, thrombocytopenia and/or skin lesions caused by leukaemic infiltration. The blood film and bone marrow aspirate show large numbers of primitive blast cells. The prognosis is extremely poor; few are cured by chemotherapy and bone marrow transplantation may be the best option. Around 5–10% of neonates with Down syndrome have a transient megakaryoblastic leukaemia also known as transient abnormal myelopoiesis or transient myeloproliferative disorder (TMD), characterized by leucocytosis and circulating blast cells (Figure 52.10). TMD develops in fetal life and nearly always presents in the first week of life. Most cases spontaneously resolve within 2–3 months and no treatment is indicated, but 20–30% subsequently develop acute megakaryoblastic leukaemia within the first 5 years of life. Mutations in the *GATA1* gene are found in virtually all cases of TMD and acute megakaryoblastic leukaemia associated with Down syndrome.

Haemostasis and thrombosis in the newborn

Bleeding and thrombotic problems are relatively common in neonates, particularly in those who are preterm and/or sick, and

Figure 52.10 Transient leukaemia in a neonate with Down syndrome. Leucoerythroblastic blood film showing increased numbers of blast cells, which spontaneously returned to normal by 2 months of age.

the number of genetic and acquired causes of thrombophilia that can be identified in neonates and their families is rising.

Developmental haemostasis

Coagulation proteins are present at measurable levels from the 10th week of gestation and gradually rise during fetal life. They do not cross the placenta, or do so in very small amounts, and therefore need to be independently synthesized by the fetus. 'Normal values' in the neonate vary not only with gestational but also with postnatal age. Data for babies at less than 30 weeks' gestation derive from fetoscopy samples: levels of the vitamin K-dependent factors (FII, FVII, FIX and FX) and of FXI and FXII are all low (< 40% of adult values) and remain so during the first month of life. In contrast, even in preterm babies (> 30 weeks), levels of FV, FXIII and fibrinogen are normal at birth and levels of FVIII and von Willebrand factor (VWF) are normal or increased. Platelet counts at birth in term and preterm neonates are within the normal adult range. Many studies have found impaired function of neonatal platelets *in vitro* in term and preterm infants; the most consistent abnormalities are reduced aggregation in response to adrenaline, ADP and thrombin. Their significance in clinical practice is unclear as the bleeding time is normal in term and preterm infants (≤ 135 s).

Screening tests for bleeding disorders

Nearly all significant bleeding disorders in neonates can be identified using simple screening tests; exceptions are FXIII deficiency and platelet function disorders. It is often helpful to test both parents for coagulation abnormalities to help identify

inherited disorders as there is considerable overlap between the deficiency states and the lower limit of normal. The most useful screening tests in neonates are the prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin time (TT), fibrinogen and platelet count. Bleeding times are generally unhelpful in neonates and investigation of platelet function abnormalities is often deferred until a few months of age when platelet aggregometry and PFA-100 become practical.

Inherited coagulation disorders

The commonest inherited disorders presenting in the neonatal period are FVIII deficiency (haemophilia A), which has a frequency of 1 in 5000 male births, and FIX deficiency (haemophilia B), which occurs in 1 in 30000 male births.

Factor VIII deficiency

Almost 40% of patients with inherited FVIII deficiency present in the neonatal period. The clinical signs include intracranial haemorrhage, cephalohaematomas and bleeding after circumcision or from venous or arterial puncture sites. As in adults, the diagnosis is made by finding an isolated prolonged APTT and reduced FVIII clotting activity. Acute management of the bleeding neonate with haemophilia requires intravenous administration of recombinant FVIII (50–100 units/kg twice daily) to achieve FVIII levels of 1.0 unit/mL. As the half-life of FVIII is shorter than in adults, more frequent dosing or a continuous FVIII infusion may be required. For neonates with intracranial bleeding treatment with FVIII should continue for at least 2 weeks. Fibrin glue may be useful in circumcision-associated bleeds. For patients diagnosed prenatally, vaginal delivery is safe provided that no difficulties are anticipated and vacuum extraction is avoided. The role of prophylactic FVIII administration to haemophilic newborns following difficult delivery to reduce the risk of intracranial bleeding (1–4%) is controversial but is increasingly used. Prophylactic FVIII should also be used for a newborn haemophilic when a previous sibling has had a major intracranial bleed.

Factor IX deficiency

Deficiency of FIX is clinically indistinguishable from FVIII deficiency. As FIX levels are also low in liver disease and vitamin K deficiency, it is important to recheck FIX levels at 6 weeks and 6 months of age if the diagnosis is in doubt. Neonates with bleeding are treated with recombinant FIX concentrate (100 units/kg i.v. once daily, monitored to achieve a FIX level of 1.0 IU/mL).

von Willebrand disease in neonates

The two forms of von Willebrand disease (vWD) that can present in neonates are type 2B vWD, which presents with thrombocytopenia and bleeding is uncommon, and type 3 vWD, which has a clinical phenotype similar to haemophilia

as levels of both VWF and FVIII are low. The inheritance in type 3vWD is autosomal recessive. The diagnosis is made by measuring VWF, FVIII and the pattern of VWF multimers. At present, type 3vWD is treated with intermediate purity FVIII (Haemate-P is the most commonly used product).

Factor XIII deficiency

This rare autosomal recessive disorder usually presents with delayed bleeding from the umbilical cord during the first 3 weeks of life. The diagnosis is made by measuring clot solubility in 5 mol/L urea solution as a screening test followed by a specific FXIII assay; molecular tests for the common mutations are also available. The routine diagnostic coagulation screen is normal. Bleeding is treated with FXIII concentrate; cryoprecipitate (10 mL/kg) can also be used.

Acquired disorders of coagulation

Causes of acquired coagulopathy in neonates include vitamin K deficiency, DIC, liver disease, metabolic disorders, extracorporeal membrane oxygenation and giant haemangiomas (Kasabach–Merritt syndrome).

Vitamin K deficiency

Levels of vitamin K-dependent procoagulant factors (FII, FVII, FIX and FX), protein C and protein S are low at birth because of poor placental transfer of vitamin K, low vitamin K stores at birth, low vitamin K in breast milk and the lack of bacterial vitamin K synthesis in the sterile neonatal gut. Vitamin K deficiency can lead to haemorrhagic disease of the newborn, also known as vitamin K deficiency bleeding (VKDB). Early VKDB presents in the first 24 hours of life with severe gastrointestinal and intracranial haemorrhage. It is usually due to maternal medication that interferes with vitamin K, for example anticonvulsants (phenobarbital, phenytoin), antituberculous therapy and oral anticoagulants. Classical VKDB presents at 2–7 days in 0.25–1.7% of babies who have not received prophylactic vitamin K at birth, especially if breast-fed or with poor oral intake. Late VKDB occurs between 2 and 8 weeks after birth and presents with sudden intracranial haemorrhage in an otherwise well breast-fed term baby or in babies with liver disease.

The diagnosis of VKDB is usually made by an isolated prolonged PT, which corrects following vitamin K administration. If doubt remains, assays of the inactive form of FII (decarboxyprothrombin; PIVKA II) can be used to confirm the diagnosis. Treatment of VKDB is vitamin K 1 mg intravenously or subcutaneously with fresh-frozen plasma only in severe haemorrhage. Classic and late VKDB can be prevented by a single intramuscular dose of vitamin K or, slightly less effectively, by weekly 1-mg oral doses of vitamin K over the first 12 weeks of life (in exclusively breast-fed infants neither single oral dose vitamin K nor daily very low dose vitamin K 25 µg are effective in preventing classic VKDB). Some studies, but not others, suggest a link

between intramuscular vitamin K at birth and later childhood malignancies. In healthy babies, the choice of which route of administration is increasingly being left to parents. However, infants of mothers taking drugs that inhibit vitamin K (e.g. warfarin) are at risk of early VKDB and these babies should receive intramuscular vitamin K 1 mg as soon as possible after birth.

Disseminated intravascular coagulation

The main triggers of DIC in neonates are severe hypoxia and/or acidosis and sepsis. It occurs in sick neonates and presents with generalized bleeding, including pulmonary haemorrhage and oozing from venepuncture sites. The usual pattern of coagulation abnormalities in neonatal DIC is prolongation of the PT, APTT and TT, together with low platelets and fibrinogen. D-dimers are increased but are not specific and can be found in healthy neonates with no evidence of coagulopathy. The most important aspect of management of DIC is treatment of the underlying cause. Blood product replacement is indicated for clinical bleeding, aiming to maintain the platelet count above $30 \times 10^9/L$ and fibrinogen greater than 1 g/L.

Neonatal thrombocytopenia

Thrombocytopenia occurs in 1–5% of all neonates and up to 50% of neonates who are preterm and sick. It usually presents in one of two clinical patterns: early thrombocytopenia (within 72 hours of birth) and late thrombocytopenia (after 72 hours of life) (Table 52.4). The most frequent causes of early thrombocytopenia in preterm infants are intrauterine growth restriction and maternal hypertension or diabetes; the most frequent causes in term infants are neonatal alloimmune thrombocytopenia (NAITP) and thrombocytopenia secondary to maternal immune thrombocytopenic purpura (ITP). The most common causes of late thrombocytopenia are sepsis and necrotizing enterocolitis.

Neonatal alloimmune thrombocytopenia

This is the platelet equivalent of haemolytic disease of the newborn and affects around 1 in 1000 pregnancies. It is frequently severe (platelet count $< 30 \times 10^9/L$) and occurs in the first pregnancy in almost 50% of cases. Thrombocytopenia results from transplacental passage of maternal platelet-specific antibodies to human platelet antigens (HPA), which the mother lacks but which the fetus inherits from the father. In 80% of cases, these are anti-HPA-1a antibodies and in 10–15% anti-HPA-5b; occasional cases are due to anti-HPA-3a. HLA-DRB3*0101-positive women are 140 times more likely to make anti-HPA-1a than HLA-DRB3*0101-negative women. Intracranial haemorrhage occurs in 10% of cases, with long-term neurodevelopmental sequelae in 20% of survivors.

The diagnosis is made by demonstrating platelet antigen incompatibility between mother and baby and anti-HPA anti-

Table 52.4 Causes of neonatal thrombocytopenia.*Early (< 72 hours)*

Placental insufficiency (PET, IUGR, diabetes)
 Neonatal alloimmune thrombocytopenia
 Birth asphyxia
 Perinatal infection (group B *Streptococcus*, *Escherichia coli*,
Listeria)
 Congenital infection (CMV, toxoplasmosis, rubella)
 Maternal autoimmune (ITP, SLE)
 Severe rhesus HDN
 Thrombosis (renal vein, aortic)
 Aneuploidy (trisomy 21, 18, 13)
 Congenital/inherited (TAR, Wiskott–Aldrich)

Late (> 72 hours)

Late-onset sepsis and necrotizing enterocolitis
 Congenital infection (CMV, toxoplasmosis, rubella)
 Maternal autoimmune (ITP, SLE)
 Congenital/inherited (TAR, Wiskott–Aldrich)

CMV, cytomegalovirus; HDN, haemolytic disease of the newborn; ITP, idiopathic thrombocytopenic purpura; IUGR, intrauterine growth restriction; PET, pre-eclampsia; SLE, systemic lupus erythematosus; TAR, thrombocytopenia with absent radii.

bodies in the mother. Transfusion with HPA-compatible platelets is recommended for neonates with platelet counts below $30 \times 10^9/L$ and/or those with bleeding. Intravenous IgG (total dose 2 g/kg, over 2–5 days) may be useful if thrombocytopenia is prolonged. Prenatal management of NAITP is controversial. Most centres have abandoned the invasive approach, except in very high risk cases, as this relies on fetal blood sampling plus fetal transfusion with HPA-compatible platelets, which carries a risk of preterm delivery and fetal death. Instead, most centres now use a non-invasive approach relying on maternal intravenous IgG therapy during the second half of pregnancy.

Neonatal autoimmune thrombocytopenia

This is secondary to transplacental passage of maternal platelet autoantibodies in maternal ITP and systemic lupus erythematosus (SLE), which affects 1–5 in 10 000 pregnancies. Around 10% of infants develop thrombocytopenia, which is severe in less than 1%. In babies with severe thrombocytopenia, intravenous IgG is usually effective. In some cases neonatal thrombocytopenia is prolonged and may last 6–8 weeks before spontaneously resolving.

Indications for platelet transfusion

A number of countries have published consensus guidelines to help decide the indications for platelet transfusion in term and

preterm neonates. In general, platelet transfusion is not considered necessary in well babies if the platelet count is above $20\text{--}30 \times 10^9/L$. Most groups agree that the threshold for transfusing sick babies, particularly preterm babies in the first few weeks of life, should be higher ($30\text{--}50 \times 10^9/L$).

Neonatal thrombosis: physiology and developmental aspects

Neonates have an increased risk of thrombosis (2.4 per 1000 hospital admissions) compared with older infants and children. This is largely due to the physiologically low levels of many of the inhibitors of coagulation and the frequent use of indwelling vascular catheters. Concentrations of antithrombin, heparin cofactor II and protein C are decreased at birth; protein S levels are also low but overall protein S activity is normal as it exists mainly in its free active form due to the virtual absence of its binding protein (C4b-BP) in neonates. Levels of plasminogen at birth are only 50% of adult values so neonates have a reduced ability to generate plasmin in response to fibrinolytic agents.

Screening tests for thrombophilia in neonates

The only inherited deficiencies for which there is a proven role in neonatal thrombosis are deficiencies in proteins C and S, which cause purpura fulminans. FV Leiden and the prothrombin 20210A promoter mutation (prothrombin^{20210A}) have not yet been reported to cause neonatal thrombotic problems in isolation. Recent guidelines from the Haemostasis and Thrombosis Task Force of the BCSH state that congenital thrombophilia should be considered and screened for in any child with:

- clinically significant thrombosis, including spontaneous thrombotic events, unanticipated or extensive venous thrombosis, ischaemic skin lesions or purpura fulminans; and
- a positive family history of neonatal purpura fulminans.

The screening tests that should be performed in all suspected cases of thrombophilia include protein C activity, protein S, antithrombin, FV Leiden and prothrombin^{20210A}. In addition, babies with thrombosis born to mothers with SLE and/or antiphospholipid syndrome should be tested for lupus anticoagulant, as antiphospholipid antibodies may cross the placenta and are a rare cause of neonatal thrombosis in such babies. The relevance of serum lipoprotein a and the MTHFR genotype to neonatal management is unclear at present.

Inherited thrombotic disorders in neonates**Proteins C and S deficiency**

Protein C deficiency occurs in 1 in 160 000–360 000 births. Affected babies usually present within hours or days of birth

with purpura fulminans, in which there is DIC and rapidly progressive life-threatening haemorrhagic necrosis due to dermal vessel thrombosis or cerebral, renal vein or ophthalmic thrombosis. The diagnosis of protein C deficiency is made by the clinical picture and undetectable levels of protein C (< 0.01 units/mL) in the patient, together with heterozygote levels in the parents. Protein C-deficient heterozygotes rarely present as neonates and have low protein C levels, which may overlap with the lower limit of normal in the first few months of life, delaying diagnosis until 6 months or later. Treatment is with protein C concentrate (40 units/kg, aiming to maintain a plasma level > 0.25 units/mL). Protein S deficiency presents with identical features; levels of protein S are undetectable (< 0.01 units/mL) and treatment is with fresh-frozen plasma (10–20 mL/kg) to maintain a plasma protein S in excess of 0.25 units/mL.

Antithrombin deficiency

Homozygous antithrombin deficiency usually presents later in childhood but neonatal deep venous thrombosis and inferior vena cava thrombosis have been reported. Heterozygous antithrombin deficiency is more common (1 in 2000–5000 births); it usually presents in the second decade of life but neonatal presentation with aortic thrombosis, myocardial infarction and cerebral dural sinus thrombosis may occur.

Acquired thrombotic problems in neonates

The most common risk factors for neonatal thrombosis are an intravascular catheter and shock, secondary to sepsis, hypoxaemia or hypovolaemia. Thrombosis particularly affects the renal veins, the aorta, aortic arch or cerebral vessels. Catheter-related thrombosis causes more than 80% of venous thromboses and more than 90% of arterial thromboses. The diagnosis is made by Doppler ultrasound or contrast angiography. Treatment of catheter-related thrombosis depends on the severity and extent of thrombosis. The first step is prompt removal where possible. If signs progress despite catheter removal, unfractionated heparin or low-molecular-weight heparin should be started using a dosing regimen adapted for neonates. Thrombolytic therapy with urokinase or tissue plasminogen activator has been used successfully for catheter-related thrombosis in neonates, but experience in preterm neonates is very limited. It is important to maintain fibrinogen at levels less than 1 g/L and the platelet count greater than $50 \times 10^9/L$ in neonates receiving thrombolytic therapy, and heparin (starting dose 28 units/kg per hour) is often given to maintain vessel patency after thrombolytic therapy, although there is no evidence that this is beneficial. Excellent guidelines for antithrombotic therapy in neonates are regularly updated by the American College of Chest Physicians.

MCH, mean corpuscular haemoglobin; MCHC, mean corpuscular haemoglobin concentration; MCV, mean corpuscular volume; PCV, packed cell volume.

World Health Organization classification of tumours of the haematopoietic and lymphoid tissues

Myeloproliferative neoplasms

Chronic myelogenous leukaemia, *BCR-ABL1* positive
 Chronic neutrophilic leukaemia
 Polycythemia vera
 Primary myelofibrosis
 Essential thrombocythaemia
 Chronic eosinophilic leukaemia, not otherwise specified
 Mastocytosis
 Cutaneous mastocytosis
 Systemic mastocytosis
 Mast cell leukaemia
 Mast cell sarcoma
 Extracutaneous mastocytoma
 Myeloproliferative neoplasms, unclassifiable
 Myeloid and lymphoid neoplasms associated with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB* or *FGFR1*
 Myeloid and lymphoid neoplasms associated with *PDGFRA* rearrangement
 Myeloid neoplasms associated with *PDGFRB* rearrangement
 Myeloid and lymphoid neoplasms with *FGFR1* abnormalities

Myelodysplastic/myeloproliferative neoplasms

Chronic myelomonocytic leukaemia
 Atypical chronic myeloid leukaemia, *BCR-ABL1* negative
 Juvenile myelomonocytic leukaemia
 Myelodysplastic/myeloproliferative neoplasms, unclassifiable
 Refractory anaemia with ringed sideroblasts (RARS) associated with marked thrombocytosis*

Myelodysplastic syndromes

Refractory cytopenia with unilineage dysplasia
 Refractory anaemia
 Refractory neutropenia
 Refractory thrombocytopenia
 Refractory anaemia with ring sideroblasts
 Refractory cytopenia with multilineage dysplasia
 Refractory anaemia with excess blasts
 Myelodysplastic syndromes associated with isolated del(5q)
 Myelodysplastic syndromes, unclassifiable
 Myelodysplastic syndromes in children

Acute myeloid leukaemia

Acute myeloid leukaemia (AML) with recurrent genetic abnormalities
 AML with t(8;21)(q22;q22), *RUNX1-RUNX1T1*
 AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22), *CBFB-MYH11*
 Acute promyelocytic leukaemia with t(15;17)(q22;q11-12), *PML-RARA*
 AML with t(9;11)(p22;q23), *MLLT3-MLL*
 AML with t(6;9)(p23;q34), *DEK-NUP214*
 AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2), *RPN1-EVI1*
 AML (megakaryoblastic) with t(1;22)(p13;q13), *RBM15-MKLI*
 AML with mutated *NPM1**
 AML with mutated *CEBPA**
 Acute myeloid leukaemia with myelodysplasia-related changes
 Therapy-related myeloid neoplasms
 Acute myeloid leukaemia, not otherwise categorized
 AML with minimal differentiation
 AML without maturation
 AML with maturation
 Acute myelomonocytic leukaemia
 Acute monoblastic and monocytic leukaemia

Postgraduate Haematology: 6th edition. Edited by A. Victor Hoffbrand, Daniel Catovsky, Edward G.D. Tuddenham, Anthony R. Green
 © 2011 Blackwell Publishing.

Acute erythroid leukaemia
 Acute erythroid leukaemia, erythroid/myeloid
 Acute pure erythroid leukaemia
 Acute megakaryoblastic leukaemia
 Acute basophilic leukaemia
 Acute panmyelosis with myelofibrosis
 Myeloid sarcoma
 Myeloid proliferations related to Down syndrome
 Transient abnormal myelopoiesis
 Acute myeloid leukaemia associated with Down syndrome
 Blastic plasmacytoid dendritic cell neoplasm
 Acute leukaemias of ambiguous lineage
 Acute undifferentiated leukaemia
 Acute biphenotypic leukaemia

Precursor lymphoid neoplasms

B lymphoblastic leukaemia/lymphoma
 B lymphoblastic leukaemia/lymphoma, not otherwise specified
 B lymphoblastic leukaemia/lymphoma with recurrent cytogenetic/molecular genetic abnormalities
 B lymphoblastic leukaemia/lymphoma with t(9;22)(q34;q11.2), *BCR-ABL1*
 B lymphoblastic leukaemia/lymphoma with t(11q23), *MLL* rearranged
 B lymphoblastic leukaemia/lymphoma with t(12;21)(p13;q22), *TEL-AML1 (ETV6-RUNX1)*
 B lymphoblastic leukaemia/lymphoma with hyperdiploidy
 B lymphoblastic leukaemia/lymphoma with hypodiploidy (hypodiploid ALL)
 B lymphoblastic leukaemia/lymphoma with t(5;14)(q31;q32), *IL3-IGH*
 B lymphoblastic leukaemia/lymphoma with t(1;19)(q23;p13.3), *E2A-PBX1 (TCF3-PBX1)*
 T-lymphoblastic leukaemia/lymphoma

Mature B-cell neoplasms

Chronic lymphocytic leukaemia/small lymphocytic lymphoma
 B-cell prolymphocytic leukaemia
 Splenic marginal zone lymphoma
 Hairy cell leukaemia
 Splenic lymphoma/leukaemia, unclassifiable
 Splenic diffuse red pulp small B-cell lymphoma*
 Hairy cell leukaemia variant*
 Lymphoplasmacytic lymphoma
 Waldenström macroglobulinaemia
 Heavy chain diseases
 Alpha heavy chain disease
 Gamma heavy chain disease
 Mu heavy chain disease
 Plasma cell myeloma

Solitary plasmacytoma of bone
 Extraosseous plasmacytoma
 Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
 Nodal marginal zone B-cell lymphoma
 Paediatric type nodal marginal zone lymphoma
 Follicular lymphoma
 Paediatric type follicular lymphoma
 Primary cutaneous follicle centre lymphoma
 Mantle cell lymphoma
 Diffuse large B-cell lymphoma (DLBCL), not otherwise specified
 T-cell/histiocyte-rich large B-cell lymphoma
 DLBCL associated with chronic inflammation
 EBV-positive DLBCL of the elderly
 Lymphomatoid granulomatosis
 Primary mediastinal (thymic) large B-cell lymphoma
 Intravascular large B-cell lymphoma
 Primary cutaneous DLBCL, leg type
 ALK-positive large B-cell lymphoma
 Plasmablastic lymphoma
 Primary effusion lymphoma
 Large B-cell lymphoma arising in HHV8-associated multicentric Castlemann disease
 Burkitt lymphoma
 B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma
 B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma

Mature T-cell and NK-cell neoplasms

T-cell prolymphocytic leukaemia
 T-cell large granular lymphocytic leukaemia
 Aggressive NK-cell leukaemia
 Systemic EBV-positive T-cell lymphoproliferative disease of childhood (associated with chronic active EBV infection)
 Hydroa vacciniforme-like lymphoma
 Adult T-cell leukaemia/lymphoma
 Extranodal NK/T-cell lymphoma, nasal type
 Enteropathy-associated T-cell lymphoma
 Hepatosplenic T-cell lymphoma
 Subcutaneous panniculitis-like T-cell lymphoma
 Mycosis fungoides
 Sézary syndrome
 Primary cutaneous anaplastic large-cell lymphoma
 Primary cutaneous aggressive epidermotropic CD8-positive cytotoxic T-cell lymphoma*
 Primary cutaneous $\gamma\delta$ T-cell lymphoma
 Primary cutaneous small/medium CD4-positive T-cell lymphoma*
 Peripheral T-cell lymphoma, not otherwise specified
 Angioimmunoblastic T-cell lymphoma

Anaplastic large-cell lymphoma, ALK positive
Anaplastic large-cell lymphoma, ALK negative*

Hodgkin lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma
Classical Hodgkin lymphoma
 Nodular sclerosis classical Hodgkin lymphoma
 Lymphocyte-rich classical Hodgkin lymphoma
 Mixed cellularity classical Hodgkin lymphoma
 Lymphocyte depleted classical Hodgkin lymphoma

Histiocytic and dendritic cell neoplasms

Histiocytic sarcoma
Langerhans cell histiocytosis
Langerhans cell sarcoma
Interdigitating dendritic cell sarcoma
Follicular dendritic cell sarcoma
Dendritic cell tumour, not otherwise specified
Indeterminate dendritic cell tumour
Fibroblastic reticular cell tumour

Post-transplant lymphoproliferative disorders

Early lesions

 Reactive plasmacytic hyperplasia
 Infectious mononucleosis-like

Polymorphic post-transplant lymphoproliferative disorder

Monomorphic post-transplant lymphoproliferative disorder
 (B- and T/NK-cell types)*

Classical Hodgkin lymphoma-type post-transplant lymphoproliferative disorder

*These represent provisional entities or provisional subtypes of other neoplasms. They are provisional because there are insufficient data to support their being a definite entity, significant controversies about their defining features and/or uncertainty about whether they are unique or closely related to other definite entities. Further classify according to the lymphoma they resemble.
