Chromosome deletions and disorders of chromosome number (aneuploidy) are among the most frequent karyotypic abnormalities seen in haematological malignancies, and result in an increase or decrease in the copy number of many genes. Increases in chromosome number are seen frequently in haematological malignancy. Hyperdiploidy is the most frequent cytogenetic abnormality of childhood ALL, and any chromosome can be duplicated. Trisomy 8 is the most common numeric abnormality of clonal myeloid disorders and can be seen in AML, myelodysplasia and myeloproliferative disorders. Presumably, quantitative chromosomal changes of this sort give rise to altered expression levels of oncogenes or tumour-suppressor genes that contribute to tumorigenesis. However, within an individual tumour that exhibits a complex karyotype, many of the changes may not be directly pathogenic in themselves, but merely serve as markers of genomic instability (see also Chapters 30 and 33).

Chromosomal deletions are large, frequently spanning several megabases and encompassing numerous genes. Identifying the key molecular consequences of a deletion is therefore a difficult task. Studies of retinoblastoma demonstrated that deletions may act to remove the remaining normal copy of a tumour-suppressor gene (*RB*), the other allele of which has been inactivated by mutation. This model seems to apply to mantle cell lymphoma, in which 11q deletions remove one copy of the *ATM* gene in up to 50% of cases. Careful screening of the remaining allele in tumour samples of patients with an 11q deletion revealed inactivating mutations in virtually all cases, suggesting the importance of inactivating both copies of the *ATM* gene in this disease.

However, this 'two-hit' model may well not hold for many of the deletions associated with haematological malignancies. Several deletions have been studied in considerable detail, including the 5q and 20q deletions associated with myeloid malignancies. The usual strategy has been to define a common deleted region that is lost in all cases and then to search for mutations in the remaining allele of genes within the common deleted region. This approach has so far failed to identify target genes, and it is likely that the pathogenetic mechanisms are more complex than originally envisaged for at least two reasons. First, loss of one copy of a gene can be sufficient to affect cellular behaviour – a situation termed haploinsufficiency. As the remaining allele of such genes would be structurally intact and unmutated, their identification presents considerable challenges. Second, it may be necessary for a deletion to remove more than one critical target gene in order to exert a tumorigenic effect. Indeed, different combinations of critical genes may be removed by deletions of varying sizes that affect a given region.

Small-scale mutations

Most of our understanding of the molecular pathogenesis of haematological malignancies has come from studies of chromosomal abnormalities, particularly because chromosome translocations identify the site of key target genes. However, smaller mutations, undetectable at the cytogenetic level, also play a critical role in promoting malignancy. There are many ways in which small-scale mutations can enhance or disrupt protein function, ranging from amino acid substitution, through internal tandem duplication to premature protein truncation. The discovery of these mutations requires careful screening of candidate genes in patient samples, and it is likely that many examples are yet to be identified.

Several activating mutations have been identified. For example, the importance of stem cell factor (SCF) and its receptor, KIT, for the normal growth and survival of mast cells led to a search for mutations in these genes in systemic mastocytosis. It is now clear that up to 40% of cases, particularly those with bone marrow involvement, have an activating point mutation in the *KIT* gene, most frequently Asp816Val. This mutation substitutes

a hydrophobic residue into the activation loop of the kinase domain of c-KIT, probably increasing the ease with which it switches to an active configuration and stabilizing it in this conformation. FLT3, another receptor tyrosine kinase, is activated by internal tandem duplications, which are seen in 20% of cases of AML. Although the amount of DNA duplicated varies, it is always transcribed in frame and leads to constitutively active tyrosine kinase activity, conferring a growth advantage on the cells and a poor prognosis for the patient. In a further 7% of AMLs, constitutive activation of FLT3 occurs through a single amino acid substitution of a hydrophobic residue for Asp835, analogous to the c-*KIT* mutations in systemic mastocytosis.

One of the most common family of genes to be mutated in tumours of all cell types is the RAS family. Up to 20% of all cancers have mutations in a RAS family member, most commonly KRAS and NRAS. The RAS family members are critical components of multiple signal transduction networks, especially those that transmit extracellular growth signals to the nucleus. The mutations found in cancers all compromise the GTPase activity of the RAS protein, promoting accumulation of the active GTP-bound isoform, thus leading to a permanent 'switched on' state.

Inactivating point mutations are commonly seen also. Screening of patients with lymphomas suggests that important cell cycle regulators such as the p53 and retinoblastoma genes are frequently mutated and non-functional. These are often secondary events, occurring during clinical evolution, and their presence usually correlates with poor prognosis, transformation to higher grade disease and/or drug resistance. Such tumour-suppressor genes generally require both alleles to be mutated or deleted to promote tumorigenesis. However, heterozygous inactivating point mutations of the gene encoding the transcription factor C/EBPα are found in 20% of cases of M2 AML. Within the haemopoietic system, this gene is expressed exclusively in and is critical to the differentiation of myelomonocytic cells. The mutation leads to premature truncation of the full-length protein, but leaves intact the translation of a smaller protein initiated downstream of the mutation. The smaller protein then acts in a 'dominant negative' manner to block the function of the wild-type protein translated from the intact allele, leading to a differentiation block in myelomonocytic cells. Hence, although heterozygous, mutations of this sort can be functionally equivalent to homozygous loss-of-function mutations.

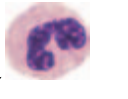
Epigenetic effects

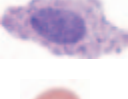
There is a mounting body of evidence that, in addition to genetic changes, tumorigenesis also involves epigenetic alterations that affect gene function without altering the nucleotide sequence. In a normal cell, epigenetic mechanisms control several important functions, including transcription, DNA replication, imprinting and X-inactivation.

DNA methylation is generally associated with transcriptional silencing of the neighbouring gene. Disordered patterns of DNA

methylation have been found in a wide variety of haematological malignancies. There is global genomic hypomethylation evident in CLL lymphocytes and AML blasts compared with normal haemopoietic cells. In addition, certain candidate genes implicated in neoplasia can be either hyper- or hypomethylated compared with normal cells. DNA hypomethylation has been identified at a number of loci implicated in haematological malignancies, including *BCL2* (in CLL), *TNF-β* (in CML and AML), *H-RAS* (in CLL) and *FMS* (in AML). Given that hypomethylation generally promotes transcriptional activity, it is certainly plausible that such epigenetic changes could cause over-expression of these oncogenes. Conversely, DNA hypermethylation of several tumour-suppressor genes, such as *p16(INK4A)*, E-cadherin and *HIC1*, has also been described in CLL and AML.

Histone modification has also emerged as a key epigenetic mechanism that regulates transcription, and disorders of histone acetylation are well described in leukaemia. Histone acetylation is controlled by two opposing families of enzymes, histone acetyltransferases, which promote a relaxation of chromatin structure, and histone deacetylases (HDACs), which generate a closed chromatin configuration together with transcriptional repression. Several transcription factor fusion proteins are thought to act by recruiting HDACs and other repressor molecules that silence target genes that are important for normal differentiation, thus resulting in maturation arrest.

It is clear that epigenetic modifications are widespread in haematological malignancies. Most are thought unlikely to represent initiating lesions, but probably reflect downstream consequences of the primary genetic changes. Nonetheless, if various different initiating events act through a shared epigenetic mechanism, the latter may represent a fertile source of targets for novel therapies with broad applicability. This concept underlies the interest at present in developing therapeutic inhibitors of HDACs and DNA methyltransferases.




Consequences of acquired genetic abnormalities

This section illustrates the mechanisms by which acquired genetic changes may result in malignant transformation. Five specific examples have been chosen to illustrate how distinct cellular processes may be corrupted: tyrosine kinase signalling (the myeloproliferative disorders); intracellular signal transduction (juvenile myelomonocytic leukaemia); regulation of gene transcription (AML); cell cycle control (mantle cell lymphoma); and apoptosis (follicular lymphoma).

Tyrosine kinases and myeloproliferative disorders

Tyrosine kinases are critical for the response of haemopoietic progenitor cells to external growth stimuli. The binding of a ligand to the extracellular surface of a receptor tyrosine kinase (RTK) promotes receptor dimerization, which, in turn, stimulates autophosphorylation of specific tyrosine residues within the intracellular aspect of the protein. The dimerization and increased kinase activity result in recruitment of effector molecules

Figure 28.5 Tyrosine kinase genes are frequent targets for mutation or rearrangement in a number of myeloproliferative disorders. However, the molecular mechanisms underlying polycythaemia vera, essential thrombocythaemia and myelofibrosis remain obscure.

Disease	Tyrosine kinase
CML	BCR-ABL
CMML	TEL-PDGFRB
Hypereosinophilic syndrome	FIP1L1-PDGFRA
Mastocytosis	c-KIT
Polycythaemia vera	?
Essential thrombocythaemia	?

and activation of the downstream signalling pathway. Cytoplasmic tyrosine kinases are also thought to be activated by phosphorylation and dimerization.

Myeloproliferative disorders are associated with activation of several tyrosine kinases (Figure 28.5). In some of these diseases, activation of the tyrosine kinase stems from formation of a fusion protein, which undergoes spontaneous dimerization (Figure 28.6a). However, kinase activity can also be increased by more subtle mutations (e.g. c-KIT in mastocytosis). As a consequence of these changes, the corresponding signalling pathway is activated and this provides the transformed cell with a proliferative or survival advantage.

In CML, the *BCR* gene becomes fused in frame with the *ABL* tyrosine kinase gene as a consequence of the Ph translocation (Figure 28.6b). This usually results in the formation of a fusion protein with molecular weight of 210 kDa (hence p210$^{BCR–ABL}$). The fusion protein affects multiple different cellular processes, including intracellular signalling, apoptosis, transcriptional regulation and cellular adhesion. Transgenic mouse models have demonstrated that BCR–ABL is capable of inducing dramatic expansion of myeloid precursors *in vivo*, and can produce a phenotype that resembles the human form of the disease.

Several critical domains in the fusion protein have been mapped, and have provided important insights into its biological activity (Figure 28.6b). The coiled-coil domain in the first exon of *BCR* provides a dimerization motif that results in spontaneous dimerization and constitutive kinase activity. Other domains implicated in oncogenicity are the SH2 domain and the C-terminal actin-binding domain, both in the ABL portion; these domains appear to be important for interaction with regulatory molecules and subcellular localization of the fusion protein.

Numerous downstream pathways are affected by the presence of the BCR–ABL protein, including the RAS, PI3K, STAT and MAP kinase signalling cascades. The breadth of the pathways perturbed explains the protean effects of the fusion protein. For example, activation of the RAS pathway is thought to contribute to the increased cell division and proliferation seen in CML cells; altered interaction with the actin cytoskeleton and adhesion complexes may underlie the diminished adhesion to inhibitory bone marrow stromal cells; and STAT5-dependent upregulation of BCLXL is implicated in the reduced apoptosis of CML progenitors.

As shown in Figure 28.6b, a smaller protein, p190$^{BCR–ABL}$, is found in Ph-positive ALL, in which the breakpoint occurs in an earlier intron of the *BCR* gene than that usually seen in CML. The p190$^{BCR–ABL}$ has a higher level of constitutive tyrosine kinase activity than the p210$^{BCR–ABL}$ protein, and it is thought that this may contribute to the more aggressive behaviour of the ALL. A p230$^{BCR–ABL}$ isoform is also found rarely patients with CML. In some cases, it is associated with a morphological picture resembling chronic neutrophilic leukaemia and less frequent

transformation to blast crisis. These variants illustrate how even seemingly small structural differences in a fusion protein can cause substantial differences in disease phenotype.

PDGFRβ is a fusion partner for several translocations seen in a clinical syndrome of atypical (BCR–ABL negative) CML or myelomonocytic leukaemia with eosinophilia. Patients often exhibit a degree of myelofibrosis, with splenomegaly being found in about one-half of the reported cases, and there is a striking male preponderance. The first of these translocations to be described was the t(5;12), which results in a TEL–PDGFRβ fusion protein, but a number of other fusion partners have been identified, all of which contribute a dimerization domain (Figure 28.6c). In the TEL–PDGFR-β fusion, the first 154 amino acids of the TEL transcription factor are fused in frame with the carboxy-terminus of PDGFR-β. The TEL portion contains the helix–loop–helix protein interaction domain, which permits spontaneous dimerization of the fusion protein, even in the absence of ligand binding, and there is evidence that the fusion protein has constitutive tyrosine kinase activity. Downstream signalling in cells expressing the *TEL–PDGFRβ* fusion gene is also qualitatively abnormal. The TEL–PDGFR-β protein phosphorylates and activates STAT1 and STAT5 proteins, pathways that wild-type PDGFR-β does not use.

RAS family signalling and juvenile myelomonocytic leukaemia

Juvenile myelomonocytic leukaemia (JMML) is a rare disorder of childhood characterized by a marked expansion of both myeloid and monocytic lineages, with varying degrees of dysplasia and exquisite sensitivity to granulocyte–macrophage colony-stimulating factor (GM-CSF) in colony assays. These features reflect the fact that components of the GM-CSF receptor signalling pathway are frequently mutated in JMML (Figure 28.7).

Mutations in the N-*RAS* gene are seen in many haematological malignancies, including AML, myelodysplastic syndrome (MDS) and chronic myelomonocytic leukaemia (CMML), especially in the subtypes of these diseases, which have a monocytic component. Analyses of samples from patients with JMML have shown point mutations in N-*RAS* in about 40% of cases. The point mutations cause single amino acid substitutions, which result in constitutively active forms of the protein and thus dramatically enhance signalling from the GM-CSF receptor.

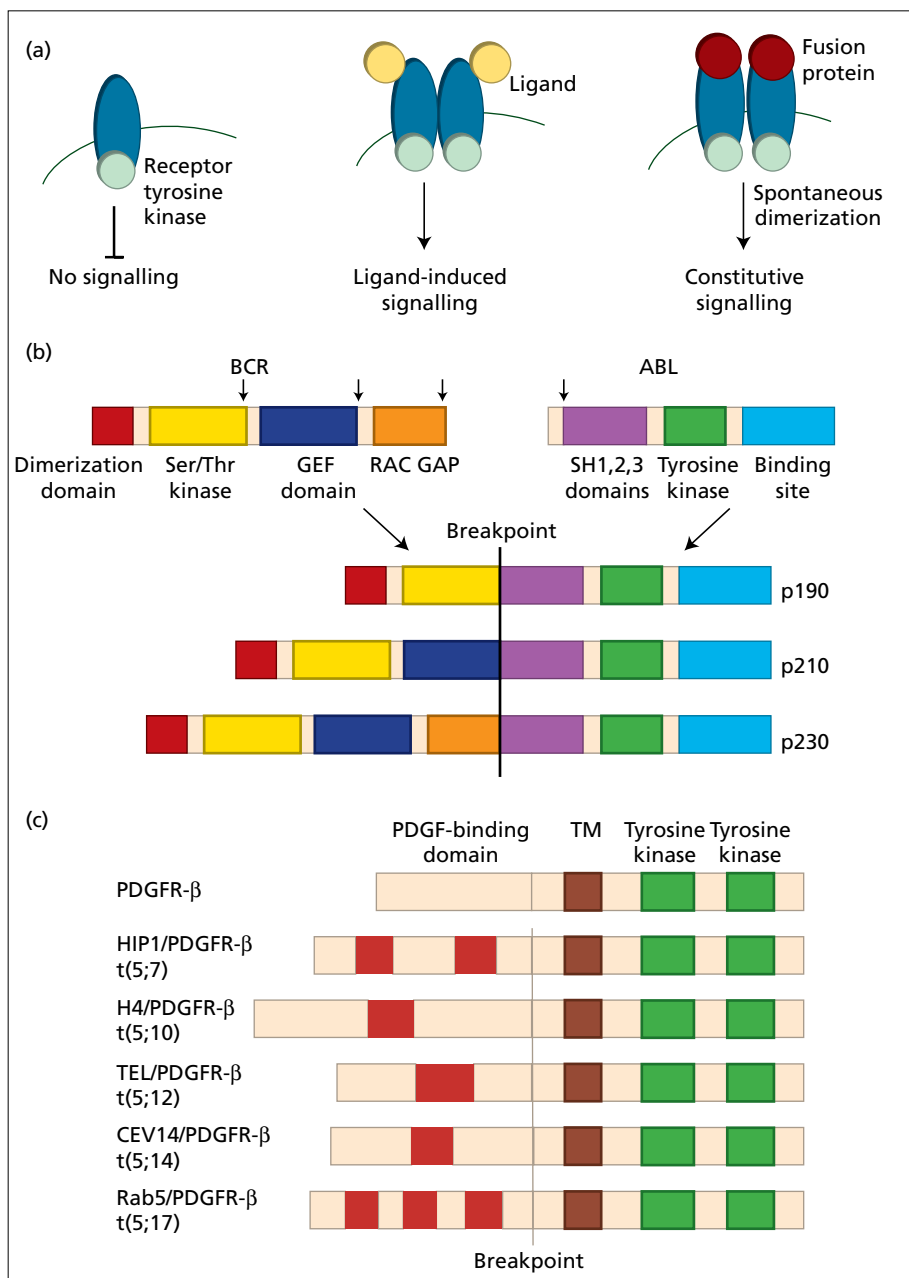
The neurofibromin (*NF1*) gene is also a target for mutations in JMML, but in this case the result is loss of NF1 activity. The incidence of JMML is increased in neurofibromatosis type 1, an autosomal dominant disorder caused by inactivating mutations in the *NF1* gene. This gene encodes a protein that directly interacts with and inhibits the activity of RAS proteins. Patients who have both neurofibromatosis type 1 and JMML have a high frequency (60%) of inactivating mutations of the second *NF1* allele in the leukaemic cells. Furthermore, inactivating *NF1* mutations are found in sporadic cases of JMML without the


Figure 28.6 Tyrosine kinase fusion proteins are constitutively active as a consequence of spontaneous dimerization. (a) Diagram indicating how tyrosine–kinase fusion proteins mimic ligand-induced activation. (b) CML is caused by fusion of the *BCR* gene on chromosome 22 to the *ABL* gene on chromosome 9. The tyrosine kinase domain of the *ABL* gene (green) is retained in all the different fusion transcripts, and becomes constitutively activated in the fusion protein. Different breakpoints within the *BCR* gene (arrows) lead to different-sized fusion proteins, which have different phenotypic effects, but all of which retain the dimerization motif (red). (c) Five different fusion partners for *PDGFR*β have been identified in translocations causing a myeloproliferative syndrome. The *PDGFR*β gene contributes a tyrosine kinase domain (green), whereas all the fusion partners contribute a dimerization motif (red).

clinical syndrome of neurofibromatosis. It appears, therefore, that *NF1* acts as a tumour-suppressor gene, and that inactivation of both alleles allows unchecked signalling through the RAS pathway.

A similar story has been discovered for a gene, *PTPN11*, which encodes a tyrosine phosphatase, SHP2. Germline mutation of this gene can cause a developmental disorder, Noonan's syndrome, which is associated with an increased incidence of JMML. Up to 34% of non-syndromic patients with JMML have somatic mutations of *PTPN11* in the leukaemic cells. The muta-

tions all cause amino acid substitutions clustering in the N-terminal SH2 domain of the protein, which are thought to result in enhanced phosphatase activity. Like RAS, SHP2 signals through the MAP kinase pathway, and cell lines expressing the mutant proteins show a growth advantage over untransformed cell lines.

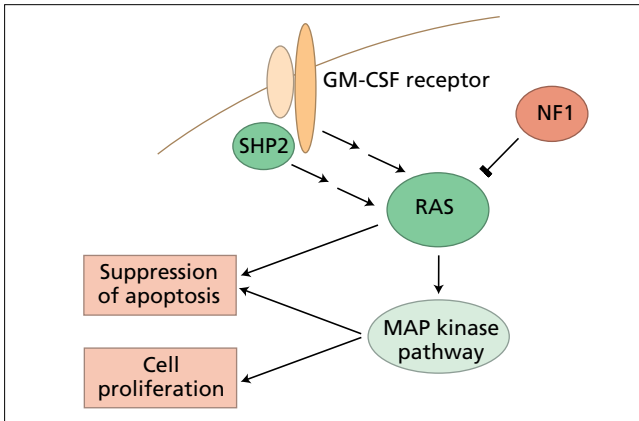
Thus within the GM-CSF receptor signalling pathway, activation of a positive component (such as RAS) has the same pathological consequences as inactivation of an inhibitory component (NF1). Moreover, the mutations in N-*RAS*, *NF1*


Figure 28.7 Distinct components of the GM-CSF signalling pathway may be mutated in JMML. Acquired activating mutations (green) are frequently found in the *RAS* gene and in the SHP2 phosphatase encoded by the *PTPN11* gene, leading to increased activity of the MAP kinase pathway. Inactivating mutations (red) of the inhibitory *NF1* gene are also associated with JMML. The three types of mutation are mutually exclusive, suggesting that each alone is sufficient to dysregulate GM-CSF receptor signalling.

and *PTPN11* are mutually exclusive. In other words, individual patients carry mutations in only one of these genes, suggesting that mutation of just one component is sufficient to activate the signalling pathway.

The core binding factor complex and acute myeloid leukaemia

Genes encoding transcription factors are common targets for rearrangements or mutation in acute leukaemia. Many of these translocations have been found to play important roles in regulating the behaviour of normal haemopoietic stem or progenitor cells, implying that perturbation of normal transcription programmes can be particularly leukaemogenic. Individual transcription factors usually function as part of a multiprotein complex, and it has become clear that different components of a given complex may be involved in distinct forms of acute leukaemia.

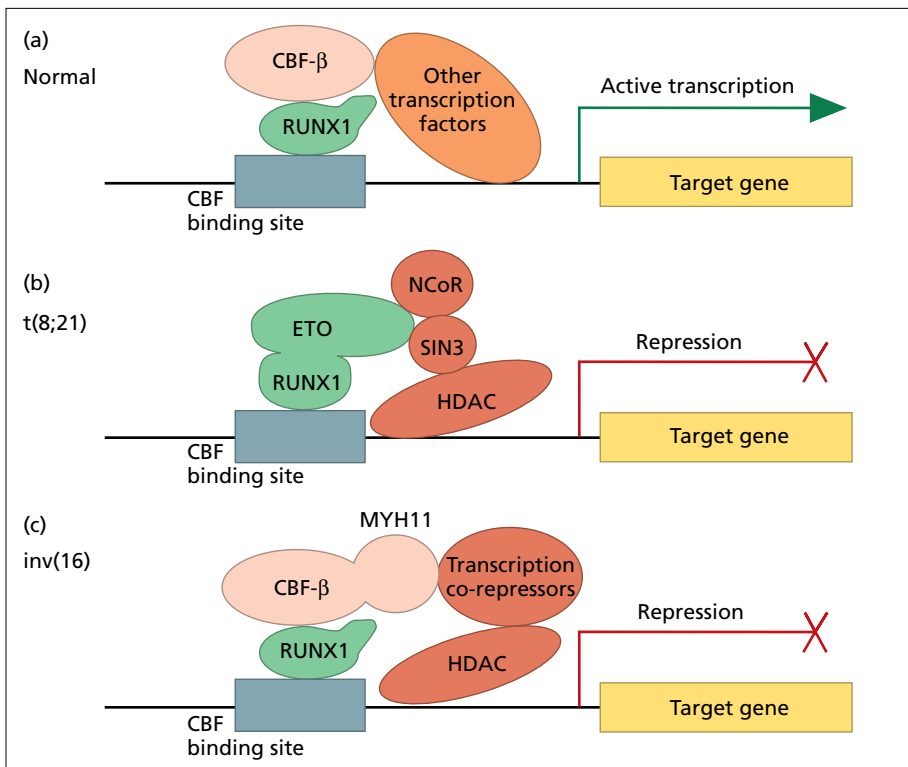
These principles are exemplified by the core binding factor (CBF) complex, made up of RUNX1 (also known as AML1 and CBF-α) and CBF. The normal CBF dimer recognizes and binds specific DNA sequences through the RUNX1 subunit and regulates many genes important for the differentiation of haemopoietic cells, such as interleukin 3 (IL-3), GM-CSF and the enhancer for immunoglobulin heavy chain (Figure 28.8a). Adjacent binding sequences in the DNA are important for other transcription factors, and it seems that the CBF dimer acts as a transcriptional organizer by recruiting other transcription factors into a large multimeric complex that regulates expression of target genes. Mice lacking RUNX1 fail to develop definitive haemopoiesis, confirming the vital importance of the CBF dimer for normal haemopoietic differentiation.


Figure 28.8 The genes encoding components of the CBF transcription factor complex are frequent targets in AML. (a) RUNX1 binds a specific DNA sequence motif, and recruits CBF-β to form a heterodimeric complex. This then acts as a transcriptional organizer, attracting other specific transcription factors and promoting target gene transcription. (b) The t(8;21) translocation results in fusion of RUNX1 to the ETO protein, which recruits a series of transcriptional repressors, including histone deacetylases, leading to target gene inactivation. (c) In cells carrying the inv(16) rearrangement, the CBF-β–MYH11 fusion protein binds to RUNX1 and then recruits transcriptional repressors.

The genes for the two CBF subunits represent the most commonly involved genes in acute leukaemia translocations, with the t(12;21) (*TEL–RUNX1*) found in 25% of childhood ALL, the t(8;21) (*RUNX1–ETO*) in 15% of AML (Figure 28.8b) and the inv(16) (*SMMHC–CBFβ*) found in 10% of AML (Figure 28.8c). How do the translocations involving *RUNX1* and *CBFβ* mediate their leukaemogenic effects? Dominant negative inhibition appears to be central to the process. *In vitro* experiments confirm that binding of wild-type *RUNX1* to gene enhancers is inhibited in the presence of *RUNX1–ETO*. Moreover, mice carrying the *RUNX1–ETO* fusion gene together with a wild-type *RUNX1* allele have exactly the same embryonic lethality phenotype as mice completely lacking *RUNX1*.

The mechanisms by which the fusion genes exert their dominant inhibitory effects are beginning to be understood. The fusion partners of the *CBF* genes appear to recruit nuclear co-repressor complexes, leading to transcriptional inhibition of target genes. In fact, in the *RUNX1–ETO* translocation, the *ETO* moiety recruits a complex comprising three proteins, N-CoR, SIN3 and a histone deacetylase, resulting in histone deacetylation, a change in chromatin structure and target gene repression (Figure 28.8b). Similarly, the CBF-β–MYH11 fusion protein of inv(16) complexes with the normal RUNX1 subunit through the CBFβ moiety, and recruits several transcription repressors via the MYH11 component (Figure 28.8c). The end result is similar for both situations – transcriptional silencing of genes required for normal differentiation and a consequent maturation arrest.

However, rearrangement of an individual transcription factor gene is not sufficient to give rise to acute leukaemia, an observation consistent with the multistep theory of tumorigenesis discussed above. Instead, there is mounting evidence for a model in which development of AML requires both a block to differentiation, frequently provided by subversion of a transcription factor gene, together with a proliferative signal, frequently provided by an altered tyrosine kinase. Consistent with this idea, the FLT3 receptor tyrosine kinase is activated in 25% of AML, and has been shown to cooperate with PML–RAR in a mouse model of acute promyelocytic leukaemia.

Cell cycle control, apoptosis and lymphoma

There is an intimate relationship between the cell cycle and apoptosis. Each phase of the cell cycle is tightly controlled by specific molecular 'checkpoints', which monitor for DNA damage and mitotic spindle formation before permitting cell cycle progression. If a checkpoint recognizes damage to the DNA or mitotic apparatus, this triggers programmed cell death (apoptosis). The enzymes involved in cell cycle control and apoptosis are among the commonest targets of mutation in all cancers, including haematological malignancies.

Figure 28.9a summarizes some of the ways in which cell cycle control may be corrupted in mantle cell lymphoma (MCL). The characteristic chromosomal abnormality associated with this disease is a t(11;14) translocation, leading to juxtaposition of cyclin D1 gene (also known as *BCL1*) with an *IGHJ* segment. Cyclin D1 functions late in G_1 phase, immediately before entry to S-phase, and binds and activates two kinases, CDK4 and CDK6. The cyclin–CDK complex then phosphorylates and inactivates the retinoblastoma (Rb) protein, which is then unable to repress transcription of genes important for the transition to S-phase. Experimental evidence confirms that forced overexpression of cyclin D1 similar to that seen in mantle cell lymphoma leads to a shortened G_1 phase, but overexpression in itself is not sufficient to induce lymphoma in transgenic mice.

Cooperating mutations and epigenetic changes have been found in other genes in the cyclin D1–CDK4-Rb pathway in patients with mantle cell lymphoma. In one study, deletions of *p16*(*INK4A*), which codes for an inhibitor of the cyclin D1–CDK4 complex, were seen in 40% of mantle cell lymphomas, and deletions of Rb were present in a further 40% of cases. These additional mutations in genes of the cyclin D1 pathway correlated with markers of active cell proliferation and more aggressive clinical behaviour. Furthermore, epigenetic modifications have been found, such as hypermethylation of *p16(INK4A)*, which may also reflect gene inactivation. This pattern of several co-existing and synergistic mutations in the same pathway contrasts with the situation in JMML, in which mutations in different components of the RAS–MAP kinase pathway tend to be mutually exclusive.

Up to one-half of all mantle cell lymphomas also exhibit deletions of 11q and the deleted region includes the locus of the *ATM* gene. The *ATM* gene is essential for checkpoint controls at the G_2–M transition in particular, and is activated by double-stranded breaks in DNA (Figure 28.9b). The remaining *ATM* allele in patients with 11q deletions is almost invariably affected by inactivating mutations, resulting in aberrant splicing, truncation or abnormal structure of the protein. Similarly, in the absence of 11q deletions, biallelic point mutations in *ATM* have been found in mantle cell lymphoma, and patients with a germline mutation in the *ATM* gene (heterozygote carriers for ataxia telangiectasia) have a marked increase in incidence of malignant lymphomas. Taken together, these observations support the hypothesis that *ATM* functions as a tumour-suppressor gene in mantle cell lymphoma.

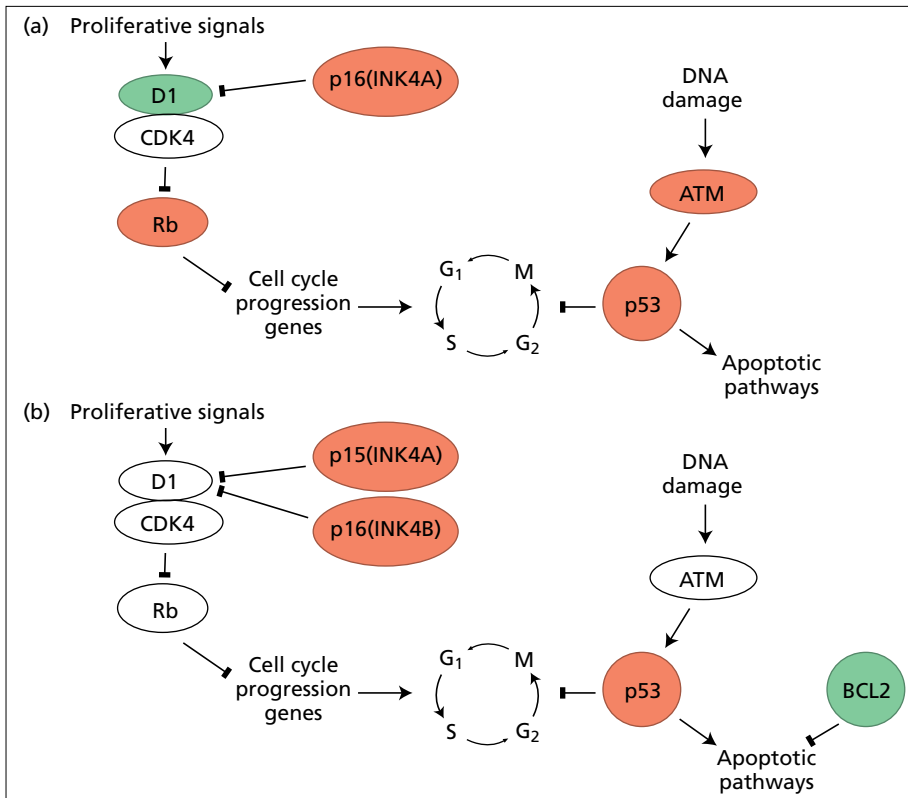
Follicular lymphoma is characterized by overexpression of the anti-apoptotic protein BCL2 (Figure 28.9b), as a result of a translocation t(14;18) in which the *BCL2* gene is placed under control of an *IGH* enhancer. Increased levels of BCL2 protect the lymphoma cells from a range of apoptotic signals, suggesting a model whereby cells do not have a proliferative advantage as such, but accumulate through lack of cell death. BCL2 overexpression will also reduce the ability of chemotherapeutic agents to induce apoptosis, and this may explain why it is notoriously difficult to cure patients with follicular lymphoma. Transgenic mice in which *BCL2* is placed under control of an *IGH* enhancer


Figure 28.9 Pathways controlling the cell cycle and apoptosis are corrupted in mantle cell and follicular lymphomas. (a) In mantle cell lymphoma, cyclin D1 is frequently upregulated (green) by the t(11;14) translocation, leading to enhanced progression through the G_1–S transition. Inactivating mutations (red) in the inhibitory proteins p16(INK4A), Rb, p53 and ATM may cooperate to exaggerate this effect and dysregulate other cell cycle checkpoints and apoptotic pathways. (b) Follicular lymphoma is characterized by overexpression of the anti-apoptotic factor BCL2. Transformation to high-grade lymphoma is associated with inactivating mutations or deletions affecting *p53*, *p15*(*INK4B*) and *p16*(*INK4A*).

show an accumulation of mature B cells, propensity to autoimmune diseases and follicular hyperplasia. Malignant lymphomas only develop in the mice after a long latency, and tend to be associated with disruption of other key genes, such as the cell cycle regulator *MYC*.

In human disease, follicular lymphoma may terminate in an aggressive, chemotherapy-resistant large cell transformation. Numerous second hits have been associated with this transformation, and these mutations preferentially involve cell cycle regulators such as those involved in mantle cell and other lymphomas. In particular, deletions involving *p15*(*INK4B*) and *p16*(*INK4A*) are found in 70% and *p53* mutations in up to 30% of transformed follicular lymphomas. Presumably these additional mutations confer a proliferation advantage on the cells, resulting in the more aggressive growth.

Summary

The cellular and molecular basis for many haematological malignancies is beginning to be understood, and these studies have already established numerous fundamental principles of broad relevance to cancer biology. This understanding of molecular pathogenesis is transforming the modern practice of clinical haematology. The diagnosis and classification of lymphomas and leukaemias has been revolutionized by the discovery of causative cytogenetic and molecular abnormalities that allow more accurate definition of clinical subtypes with distinct prognosis and treatment response rates. Moreover, drugs such as imatinib for CML and ATRA for acute promyelocytic leukaemia are the first examples of molecularly targeted therapies, and are likely to herald a new era in the treatment of haematological and other malignancies.

Diagnosis and classification of acute leukaemia

29

Barbara J Bain

Introduction

The diagnosis of acute leukaemia usually follows the presentation of a patient with clinical features suggestive of this disease, with relevant laboratory evaluation therefore being performed. Less often, the diagnosis is an incidental one when a blood count is requested because of an unrelated condition. In some patients, an unequivocal diagnosis of acute leukaemia can be made from a blood count and blood film but in other patients bone marrow aspiration is required for diagnosis. When a bone marrow aspirate is not essential for diagnosis, it is nevertheless necessary for further classification and to provide optimal material for cytogenetic analysis. In a small minority of patients, in whom a hypocellular or fibrotic bone marrow leads to a poor aspirate being obtained, only a trephine biopsy permits a definitive diagnosis of acute leukaemia. In other patients, this procedure is not essential. Immunophenotyping is a necessary part of the initial evaluation unless the leukaemia is obviously myeloid. With the increasing use of immunophenotyping, cytochemical stains are now less used, but they continue to have a role in the confirmation of a diagnosis of acute myeloid leukaemia; they have no role in the diagnosis of acute lymphoblastic leukaemia unless immunophenotypic analysis is not available. Cytogenetic analysis should be performed in all patients with acute leukaemia, since knowledge of the karyotype is essential for determining the prognosis and for choice of optimal treatment. Molecular genetic analysis is not yet a routine part of diagnosis but is likely to become so. The place of different modes of investigation in the diagnosis and classification of acute leukaemia is summarized in Table 29.1.

Table 29.1 The role of different laboratory procedures in the diagnosis and classification of acute leukaemia.

Investigation	Role
Full blood count and blood film	Essential in all patients
Bone marrow aspirate	Essential in all patients
Bone marrow trephine biopsy	Selective, necessary in patients with a hypocellular or fibrotic marrow
Cytochemical stains	Selective, useful if a leukaemia is not obviously myeloid
Immunophenotyping	Indicated in all patients in whom the leukaemia is not obviously myeloid; can provide means of monitoring for minimal residual disease
Cytogenetic analysis	Essential in all patients, best performed on a bone marrow aspirate
Molecular genetic analysis including fluorescence *in situ* hybridization (FISH)	Selective; is likely to become more important if monitoring for minimal residual disease is found to be necessary for optimizing treatment
Storage of bone marrow films wrapped in aluminium foil at −20°C	Useful if cytochemistry or molecular genetic analysis is retrospectively found to be necessary
Storage of DNA	Appropriate in a research setting

Table 29.2 A summary of the FAB classification of acute leukaemia.

Categories of AML	Categories of ALL
M0, AML with minimal evidence of myeloid differentiation	L1, ALL with fairly small uniform lymphoblasts
M1, AML without differentiation	L2, ALL with more pleomorphic lymphoblasts
M2, AML with differentiation	L3, ALL with basophilic vacuolated lymphoblasts*
M3 and M3 variant, acute promyelocytic leukaemia and its hypogranular/microgranular variant	
M4, acute myelomonocytic leukaemia	
M5, acute monoblastic (M5a) or monocytic (M5b) leukaemia	
M6, acute leukaemia with at least 50% erythroblasts in the bone marrow	
M7, acute megakaryoblastic leukaemia	

*In the WHO classification, cases with L3 morphology, with a mature B-cell immunophenotype and with Burkitt's lymphoma-related translocations would not be categorized as ALL.

It is insufficient to merely make a diagnosis of acute leukaemia, or even of acute myeloid leukaemia (AML) or acute lymphoblastic leukaemia (ALL). Further classification is essential in order to determine the prognosis and select the most appropriate treatment. Further classification is also essential in order to advance our knowledge, for the ultimate benefit of patients as well as for the advancement of scientific knowledge of both normal and abnormal haemopoiesis.

When facilities are limited, acute leukaemia can be classified on the basis of cytology and cytochemistry, as initially proposed by the French–American–British (FAB) group. This will mean that some cases of AML with minimal evidence of myeloid differentiation could be misclassified as ALL, but the diagnosis will be correct in the great majority of cases. If cytology and cytochemistry are supplemented by selective immunophenotyping in all cases that are not obviously myeloid, the diagnosis will be further refined. Cases of acute megakaryoblastic leukaemia and of acute myeloid leukaemia without cytological or cytochemical evidence of differentiation will be recognized and a positive, rather than default, diagnosis of ALL will be made. Cases of acute biphenotypic leukaemia will remain unrecognized without more extensive use of immunophenotyping. This approach leads to assignment to eight FAB categories of AML and three FAB categories of ALL, as summarized in Table 29.2 (Figures 29.1–29.23). It is also possible to classify acute leukaemia purely on the basis of the immunophenotype, as proposed by the European Group for the Immunological Characterization of Leukaemias (EGIL). This approach is not recommended as it ignores important
Figure 29.1 Acute myeloid leukaemia, FAB M0 type. Blast cells with no evident features of differentiation and with negative reactions for Sudan black B and myeloperoxidase. On immunophenotypic analysis, all B and T markers were negative but there was expression of CD13 and CD33. Without immunophenotyping such cases cannot be distinguished from L2 acute lymphoblastic leukaemia. Bone marrow film, MGG.
Figure 29.2 Acute myeloid leukaemia, FAB M0 type. Blast cells express CD13. Cytospin preparation, alkaline phosphatase–anti-alkaline phosphatase (APAAP) technique.
Figure 29.3 Acute myeloid leukaemia, FAB M1 type. Blast cells are small to medium in size with a high nucleocytoplasmic ratio and one of them contains an Auer rod. Sudan black B and peroxidase reactions were positive. Peripheral blood film, MGG.
Figure 29.5 Acute myeloid leukaemia, FAB M2 type. There is differentiation to promyelocytes and in one of the two patients there is one neutrophil and a blast cell containing an Auer rod. Bone marrow, MGG.
Figure 29.4 Acute myeloid leukaemia, FAB M1 type. Blast cells containing Auer rods. Peripheral blood film, myeloperoxidase reaction.
Figure 29.6 Acute myeloid leukaemia, FAB M2 type. In this patient there is basophil differentiation and characteristic granules are seen in the blast cells. Peripheral blood film, MGG.

information and leads to patients with the same type of disease being assigned to different categories. For example, patients with FAB M2 AML associated with t(8;21)(q22;q22) could be assigned to the EGIL category of 'AML of myelomonocytic lineage' or if, as not infrequently occurs, there were aberrant expression of CD19, to the EGIL category of 'AML with lymphoid antigen expression'. The optimal approach to the classification of acute leukaemia is one that seeks to identify real biological entities, using all the information available. Approaches based on morphology, immunophenotyping and cytogenetic analysis (MIC classification), or with the addition of molecular genetic analysis (MIC-M classification) have been proposed and this approach has been adopted in part by the World Health Organization (WHO) classification.

The roles of specific techniques in diagnosis and classification

Morphology and cytochemistry

A blood film, bone marrow aspirate film and manual differential counts of blood and bone marrow films should be performed in all patients. The WHO expert group advises a 200-cell differential count on a peripheral blood film and a 500-cell differential count on a bone marrow film. Performing a 500-cell differential count on the bone marrow is particularly important if the percentage of blasts cells is at a level that is critical for diagnosis (around 20%) since the precision of the count is otherwise poor. The erythroid, granulocytic/monocytic and megakaryocyte
Figure 29.7 Acute myeloid leukaemia, FAB M2, same patient as in Figure 29.6 demonstrating that the cytoplasmic granules show the characteristic stippled pattern of basophil granules. Ultrastructural examination, lead and uranyl acetate stain.
Figure 29.8 Acute hypergranular promyelocytic leukaemia, FAB M3 category of acute myeloid leukaemia. Blast cells are in a minority, the dominant cell being a hypergranular promyelocytes, some with bundles of Auer rods. Bone marrow film, MGG.

Figure 29.9 Acute hypogranular or microgranular promyelocytic leukaemia, FAB M3 variant category of acute myeloid leukaemia. The leukaemic cells are either blast cells or highly abnormal promyelocytes with a characteristic lobed nucleus in which a broad isthmus joins two distinct lobes. The abnormal promyelocytes, particularly those in the circulating blood, show few if any granules on light microscopy. Bone marrow film, MGG.
Figure 29.10 Acute myeloid leukaemia, FAB M4 category. There are some blasts showing granulocytic differentiation and others showing monocytic differentiation. Granulocytic differentiation is more obvious in the bone marrow (left) and monocytic in the peripheral blood (right). In this case the granulocytic differentiation is neutrophilic but sometimes it is eosinophilic (Figure 29.12) or, rarely, basophilic. Bone marrow and peripheral blood films, MGG.

lineages should be assessed for dysplastic features and the presence of Auer rods should be noted. The eosinophil count should be noted, as should the presence of eosinophil precursors with atypical large pro-eosinophilic granules with basophilic staining characteristics [suggestive of a the presence of inv(16)(p13q22) or t(16;16)(p13;q22)] (Figure 29.12). The features of hypergranular promyelocytes (cytoplasm packed with brightly staining granules, bundles of Auer rods, giant granules) should be sought (Figure 29.8) and, equally importantly, the characteristic cytological features of hypogranular or microgranular promye-

locytes (bilobed nuclei with a broad isthmus joining the two lobes and sometimes fine dust-like granules) (Figure 29.9) should be identified.

If cytochemistry is to be performed, the most useful reactions are (i) a myeloperoxidase reaction or Sudan black B or
Figure 29.11 Acute myeloid leukaemia, FAB M4 category. Both Sudan black B (left) and alpha naphthyl acetate esterase (right) reactions are positive.

Figure 29.14 Acute myeloid leukaemia, FAB M5a category. The monoblasts in this patient show no nuclear lobulation. One cell contains a ribosomal–lamellar complex, the nature of which was confirmed on ultrastructural examination. Cytospin preparation, MGG.

Figure 29.12 Acute myeloid leukaemia, FAB M4 category, with eosinophilic differentiation. This category of AML is often referred to as M4Eo AML, although this is not a FAB category. There are mature eosinophils and eosinophil precursors. The latter have large pro-eosinophilic granules, which have basophilic staining characteristics. Bone marrow film, MGG.
Figure 29.15 Acute myeloid leukaemia, FAB M5b category. Monocytic differentiation is apparent. Bone marrow film, MGG.

Figure 29.13 Acute myeloid leukaemia, FAB M5a category. The blasts are large with abundant cytoplasm. They show little signs of differentiation, but one cell has an indented nucleus. Nucleoli are large and prominent. Sometimes there are fine azurophilic granules. Bone marrow film, MGG.
Figure 29.16 Acute myeloid leukaemia, FAB M5a category. Strong non-specific esterase activity. Cytospin preparation, alpha-naphthyl-acetate esterase reaction.
Figure 29.17 Acute myeloid leukaemia, FAB M6 showing erythropoiesis that is dysplastic and grossly megaloblastic; there is an excess of proerythroblasts but also of immature granulocytes, including blast cells. Bone marrow film, MGG.
Figure 29.18 AML with an immature erythroid phenotype. The 'blast cells' do not show any cytological features of differentiation but were shown by reactivity with anti-glycophorin A antibodies to be primitive erythroid cells. This type of AML was not included in the FAB classification but could be designated 'M6 variant'. Cytospin preparation, MGG.

(ii) an alpha-naphthyl acetate esterase reaction (either alone or in combination with naphthol AS-D chloroacetate esterase, to facilitate the recognition of FAB M4 AML). A periodic acid–Schiff (PAS) stain can contribute to the recognition of FAB M3 and M3 variant AML because of the blush-like positivity that fills the cytoplasm and it can also highlight the presence of dysplastic erythroblasts and megakaryocytes. In ALL, particularly B-lineage ALL, a characteristic pattern of 'block positivity' is often seen (Figure 29.24); however, a PAS stain is no longer indicated in suspected ALL, unless there is no access to immunophenotyping. Similarly, an acid phosphatase stain for the recognition of Golgi zone staining in T-lineage ALL (Figure 29.25) is redundant if immunophenotyping is available.
Figure 29.19 Acute myeloid leukaemia, FAB M7 category. Bone marrow trephine biopsy shows blast cells (left) and increased reticulin deposition (right).
Figure 29.20 Childhood acute lymphoblastic leukaemia, FAB L1 type. The blast cells have a high nucleocytoplasmic ratio, lack visible nucleoli and are relatively small. This patient's leukaemic cells were of B-lineage and expressed CD10. Bone marrow film, MGG.

Immunophenotyping

Immunophenotyping is now usually performed largely by flow cytometry using anticoagulated whole blood or bone marrow samples in which red cells have been selectively lysed. Antibodies that are directly labelled with fluorochromes are generally used since this permits two-colour or three-colour analysis, by which
Figure 29.21 Childhood acute lymphoblastic leukaemia, FAB L2 type. The blast cells are mainly large and have one or two prominent nucleoli, which range in size from small to large. Bone marrow film, MGG.
Figure 29.22 'Acute lymphoblastic leukaemia' of Burkitt type, FAB L3 type. The blast cells have prominent cytoplasmic basophilia and are heavily vacuolated. The immunophenotype was that of a mature B cell with expression of surface membrane immunoglobulin and the case would therefore be classified as non-Hodgkin's lymphoma rather than ALL in the WHO classification. Bone marrow film, MGG.

Figure 29.23 Acute hypogranular promyelocytic leukaemia, FAB M3 variant category of acute myeloid leukaemia (left) contrasted with acute monocytic leukaemia, FAB M5b type (right). The cells of monocyte lineage have more abundant cytoplasm and the nucleus is often kidney shaped rather than there being two distinct lobes. The cells of M3 AML are strongly peroxidase-positive whereas those of M5b AML have weaker peroxidase activity but are strongly positive for non-specific esterases, such as alpha naphthyl acetate esterase.
Figure 29.24 Acute lymphoblastic leukaemia, periodic acid–Schiff (PAS) stain showing a single block of PAS-positive material in each blast cell; this is therefore referred to as 'block positivity'. Cytospin preparation of cerebrospinal fluid, PAS stain.

co-expression of antigens can be evaluated. Forward light scatter (proportional to cell size) and sideways light scatter (determined by cell structure, including granularity) can be analysed and related to antigen expression. Techniques for detection of cytoplasmic and nuclear antigen expression are essential, the former for detecting the earliest expression of lineage-related antigens, such as CD3, CD13 and CD22 and for the detection of cytoplasmic antigens (myeloperoxidase) or cytoplasmic epitopes (CD79a), and the latter for detection of the nuclear expression of terminal deoxynucleotidyl transferase (TdT). Although expression of a specific antigen is often reported as a percent-

age, with an arbitrary cut-off point (such as 20%) for a marker to be considered positive, visual analysis of clusters is also important. For example, making a distinction between leukaemic B-lineage lymphoblasts and normal immature B-lineage cells (haematogones) is facilitated by observing (i) the stronger expression of TdT and the weaker expression of CD10 and CD19 by haematogones; (ii) the heterogeneous expression of different antigens in comparison with the more homogeneous expression by leukaemic lymphoblasts; and (iii) lack of aberrant myeloid
Figure 29.25 T-lineage acute lymphoblastic leukaemia showing acid phosphatase activity restricted to the Golgi zone. Cytospin preparation, acid phosphatase reaction.

antigen expression, which is seen in some leukaemic lymphoblasts, and in appropriate synchronous expression of lymphoid antigens in comparison with the asynchronous expression that can occur in leukaemia. Some of these subtle differences are obscured if only the percentage of positive cells is considered.

Analysis may be performed on 'gated' cells, with gating, for example, on cells characterized by CD45 expression and sideways light scatter. However, it is important that all data are initially collected ungated so that no information is lost; if subsequent analysis employs gating, the final report must make clear what gating procedure was followed and what percentage of cells fell within the gate. It should be noted that some monoblasts and the hypergranular promyelocytes of M3 AML often do not fall within the 'blast window' and that some B-lineage lymphoblasts do not express CD45, so gating must be done with care.

Various panels of antibodies have been proposed for the diagnosis and further classification of acute leukaemia, for example by the USA–Canadian Consensus Group and by the British Committee for Standards in Haematology (BCSH) (Table 29.3). In addition, the WHO expert group has modified the EGIL proposals for diagnosis of acute biphenotypic leukaemia (Table 29.4) and, if immunophenotyping is done for this purpose, then it is recommended that all these antibodies are included so that classification is uniform between different countries and centres. If there is a possibility of a monoclonal antibody being used in therapy (e.g. Myelotarg, anti-CD33, in AML) then it should be included in the diagnostic panel.

Table 29.3 Panels of monoclonal (or polyclonal) antibodies recommended by the British Committee for Standards in Haematology (BCSH) and by the US–Canadian Consensus Group for the Diagnosis and Classification of Acute Leukaemia.

		BCSH	*Consensus group*
Primary panel	B lymphoid	CD19, cCD22, cCD79a, CD10	CD10, CD19, anti-kappa, anti-lambda
	T lymphoid	cCD3, CD2	CD2, CD5, CD7
	Myeloid	CD13, CD117, anti-cMPO	CD13, CD14, CD33
	Not lineage specific	Nuclear TdT	CD34, HLA-DR
Secondary panel	B lymphoid	μ, SmIg (anti-kappa and anti-lambda), CD138	CD20, Sm/cCD22
	T lymphoid	CD7	CD1a, Sm/cCD3, CD4, CD8
	Myeloid	CD33, CD41, CD42, CD61, anti-glycophorin A	CD15, CD16, CD41, CD42b, CD61, CD64, CD71, CD117, anti-cMPO, anti-glycophorin A
	Not lineage specific	CD45	CD38, nuclear TdT
	Non-haemopoietic	MAb for the detection of small round cell tumours of childhood	
Optional	B lymphoid	CD15 (a myeloid marker often expressed on *MLL*-rearranged B lymphoblasts) and 7.1/NG2 (also for *MLL*-rearranged ALL)	
	T lymphoid	Anti-TCRαβ, anti-TCRγδ	
	Myeloid	Anti-lysozyme, CD14, CD36, anti-PML (MAb PLl-M3), HLA-DR (for negativity in M3 AML)	

c, cytoplasmic; CD, cluster of differentiation; MAb, monoclonal antibody; MPO, myeloperoxidase; Sm, surface membrane; TCR, T-cell receptor; TdT, terminal deoxynucleotidyl transferase.

Table 29.4 WHO criteria for the diagnosis of biphenotypic leukaemia.

Score*	B lineage	T lineage	Myeloid
2	cCD79a, cIgM cCD22	CD3 (c or Sm anti-TCR (αβ or γδ)	MPO
1	CD19 CD10 CD20	CD2 CD5 CD8 CD10	CD117 CD13 CD33 CD65
0.5	TdT CD24	TdT CD7 CD1a	CD14 CD15 CD64

*If > 2 points is scored for both myeloid and one of the lymphoid lineages the case is classified as biphenotypic; in the original EGIL recommendations CD117 scored 0.5 rather than 1.
c, cytoplasmic; CD, cluster of differentiation; Ig, immunoglobulin; MPO, myeloperoxidase; Sm, surface membrane; TCR, T-cell receptor; TdT, terminal deoxynucleotidyl transferase.

A secondary role for immunophenotyping is that of defining a leukaemia-related phenotype in an individual patient that can subsequently be used for monitoring minimal residual disease (MRD) (Figure 29.26). For this purpose, an extended antibody panel permits the defining of a leukaemia-associated immunophenotype in a larger proportion of patients. Table 29.5 shows the types of leukaemia-related phenotype that can be used for MRD monitoring.

The use of immunophenotyping to indicate prognosis or as a surrogate marker for a cytogenetic/molecular genetic subset of acute leukaemia is not generally of any great importance. An exception to this may be the rapid recognition of an immunophenotype typical of M3 AML (Figure 29.27) but, even in this instance, if molecular techniques are available they are generally preferred.

Cytogenetic analysis

Cytogenetic analysis will be discussed in detail in Chapter 30, but its role in the classification of acute leukaemia will be dealt with in this chapter. When resources permit, it should be carried out in all patients for the following reasons: (i) patients with AML can be assigned to three broad prognostic groups and their
Figure 29.26 Scatterplot of flow cytometry immunophenotyping in acute myeloid leukaemia; there is expression of CD7, CD33, CD34, CD117 and HLA-DR. The co-expression of myeloid markers and CD7 could be used in this patient for the identification of minimal residual disease (with thanks to Mr Ricardo Morilla).

Table 29.5 Leukaemia-associated immunophenotypes that can be identified at diagnosis of acute leukaemia and can subsequently be used to monitor minimal residual disease.

Type of abnormality	Example
Aberrant expression of an antigen more appropriate to another lineage	Lymphoid-associated antigens, such as CD2, CD4, CD5, CD7, CD19 or CD20, on myeloid cells
	Myeloid-associated antigens, such as CD13, CD15, CD33, CD65 or CD66c, on lymphoid cells
	Natural killer or T-lineage-associated antigens, such as CD56, expressed on B lymphoblasts
Asynchronous expression of antigens or failure to express expected antigens synchronously	Co-expression of terminal deoxynucleotidyl transferase, CD10 and strong CD34 with cytoplasmic μ chain or strong CD19, CD20, CD21 or CD22
	Co-expression of CD34 or terminal deoxynucleotidyl transferase with CD11b, CD14, CD15, strong CD33 or CD65
	Failure to express CD13 and CD33 synchronously
Abnormally weak or abnormally strong antigen expression	Increased expression of CD10
	Increased expression of CD33
Expression of antigens that are not usually expressed in the tissue being examined	Presence in the bone marrow of cells (i) expressing CD1a or (ii) expressing both cytoplasmic CD3 and either terminal deoxynucleotidyl transferase or CD34 or (iii) co-expressing CD4 and CD8
Figure 29.27 Scatterplot of flow cytometry immunophenotyping in acute promyelocytic leukaemia (FAB category M3); there is expression of CD33, CD34 and CD117 but CD13 and HLA-DR are not expressed. CD33 is more consistently expressed than CD13 in M3 AML and lack of expression of HLA-DR is characteristic (with thanks to Mr Ricardo Morilla).

treatment can be modified accordingly; (ii) specific categories of AML requiring very specific therapeutic strategies can be identified (particularly M3 and M3 variant); and (iii) it facilitates the recognition of therapy-related acute leukaemia and the distinction between alkylating agent-related and topoisomerase-II-interactive drug-related leukaemia. Cytogenetic analysis is essential if the WHO classification of AML is to be used.

Table 29.6 The role of detection of molecular genetic abnormalities in acute leukaemia.

Abnormality detected	Relevance of detection
PML–RARA fusion in AML	Use of all-trans-retinoic acid and possibly arsenic trioxide; good prognosis so overtreatment should be avoided
AML1–ETO fusion in AML	Good prognosis, overtreatment should be avoided
CBFB–MYH11 in AML	Good prognosis, overtreatment should be avoided
High hyperdiploidy in ALL	Good prognosis, overtreatment should be avoided
ETV6–AML1 fusion in ALL	Relatively good prognosis, overtreatment should be avoided; particularly sensitive to asparaginase
BCR–ABL fusion in AML, ALL or acute biphenotypic leukaemia	Poor prognosis in AML and ALL, intensive treatment may be justified and the therapeutic use of tyrosine kinase inhibitors could be considered
MLL–AF4 fusion in infant acute leukaemia	Poor prognosis, intensive treatment with drugs directed at both lymphoblasts and myeloblasts is justified
FLT-3 internal tandem duplication in AML	Use of tyrosine kinase inhibitors may prove relevant
Any abnormal fusion gene, a rearranged immunoglobulin or T-cell receptor gene or WT1 overexpression	Potential for monitoring of minimal residual disease

Molecular genetic analysis

Molecular genetic analysis has been discussed in Chapter 28, but its role in the classification of acute leukaemia will be dealt with in this chapter. It has the following advantages over conventional cytogenetic analysis: (i) it can yield results when cytogenetic analysis has failed or when only normal metaphases are seen; (ii) it can confirm the presence of a specific fusion gene in patients with a variant rather than a classical translocation; (iii) it will detect some relevant abnormalities that cannot usually be detected by cytogenetic analysis, e.g. ETV6–AML1 (TEL–AML1) fusion in B-lineage ALL associated with a usually cryptic t(12;21)(p12;q22) translocation; (iv) it will detect other molecular abnormalities that do not have any cytogenetic correlate because they are always submicroscopic events, e.g. GATA1 mutation in transient abnormal myelopoiesis or acute megakaryocytic leukaemia in Down's syndrome, or internal tandem duplication of FLT-3, seen in multiple morphological subtypes of AML; and (v) it can give rapid results so that clinical decisions can be based on the analysis. However, it should be noted that molecular genetic analysis will only permit the detection of abnormalities that are specifically sought whereas in conventional cytogenetic analysis all chromosomes are assessed. At present, molecular genetic analysis is applied selectively, to supplement cytogenetic analysis in the recognition of specific categories of good-prognosis and poor-prognosis AML and ALL. The most useful techniques include fluorescence in situ hybridization (FISH) (both for the detection of specific fusion genes and for the detection of high hyperdiploidy), the reverse transcriptase polymerase chain reaction (RT-PCR) and immunofluorescence to demonstrate the abnormal microparticulate distribution of PML protein in M3 and M3 variant AML. The last technique is important since it can be done more speedily than conventional cytogen-

etic analysis and can thus permit the early application of optimal specific treatment. This and other molecular abnormalities that are often sought in acute leukaemia are shown in Table 29.6.

A potential future use for molecular genetic analysis is the monitoring of minimal residual disease, if this is shown to give clinically useful information. Suitable techniques include the monitoring of the transcript of a fusion gene or the identification of a patient-specific T-cell receptor (TCR) or immunoglobulin gene rearrangement. A further potential use for molecular genetics is for the identification of abnormal gene expression, e.g. FLT-3 expression, that may indicate that leukaemic cells will be susceptible to tyrosine kinase inhibitors or other specific drugs.

The classification of acute leukaemia

The WHO criteria for the diagnosis and classification of acute myeloid leukaemia

The WHO criteria for the diagnosis of AML are shown in Table 29.7. The most important differences from the FAB criteria are (i) the lowering of the threshold for the percentage of blast cells to 20% in the blood or bone marrow; and (ii) the recognition of cases of acute leukaemia with an even lower blast count if specific acute leukaemia-associated cytogenetic or molecular genetic abnormalities are present.

The WHO classification of AML is hierarchical. Therapy-related cases are first recognized and assigned to subcategories related to alkylating agents/radiotherapy, topoisomerase II-interactive drugs or 'other'. Cases associated with certain specified cytogenetic or molecular genetic rearrangements (those shown in Table 29.7) are then assigned to a category of 'AML

Table 29.7 WHO criteria for the diagnosis of acute myeloid leukaemia.

Blast cells are 20% or more in either peripheral blood or bone marrow

Presence of
t(8;21)(q22;q22) or *AML1–ETO* fusion gene
inv(16)(p13q22) or t(16;16)(p13;q22) or *CBFB–MYH11* fusion gene
t(15;17)(q22;q12) and variants or *PML–RARA* fusion gene or variants
Translocation with an 11q23 breakpoint and *MLL* gene rearrangement
Figure 29.28 Acute myeloid leukaemia associated with t(8;21)(q22;q22) showing FAB M2 morphology with dysplastic maturing granulocytes. The basophilic cytoplasm of the blast cells and the prominent Golgi zone is characteristic of this type of acute leukaemia. This translocation leads to formation of an *AML1(RUNX1)–ETO* fusion gene. These cases are assigned to the WHO category of AML with recurrent cytogenetic abnormality. Bone marrow film, MGG.
Figure 29.29 Acute myeloid leukaemia associated with inv(16)(p13q22) showing FAB M4 morphology plus abnormal eosinophil maturation, often referred to as M4Eo. There is an eosinophil myelocyte with prominent pro-eosinophilic granules, which have basophilic staining characteristics. This chromosomal inversion leads to formation of a *CBFB–MYH11* fusion gene. These cases are assigned to the WHO category of AML with recurrent cytogenetic abnormality. Bone marrow film, MGG.

with recurrent genetic abnormalities' (Figures 29.28–29.34). Remaining cases are next assessed for bilineage or trilineage dysplasia, and if this is found they are assigned to the category of 'AML with multilineage dysplasia'. The criteria for significant dysplasia are that at least 50% of cells of at least two lineages must be dysplastic. Cases with multilineage dysplasia are further categorized as (i) with an antecedent myelodysplastic syndrome or myelodysplastic/myeloproliferative disorder and (ii) without any such antecedent disease. After cases have been assigned to the category of 'AML with multilineage dysplasia' any remaining cases, including those with other recurrent cytogenetic or molecular genetic abnormalities, are assigned to 'AML, not otherwise specified' and are subcategorized on morphological grounds in a manner similar to that used in the FAB classification but with three extra categories. These extra categories are: (i) acute basophilic leukaemia (Figure 29.35); (ii) acute panmyelosis with myelofibrosis; (iii) myeloid sarcoma. An algorithm showing how the WHO classification is applied is shown in Figure 29.36.
Figure 29.30 Acute myeloid leukaemia associated with t(16;16) (p13;q22). There are three blast cells and one eosinophil myelocyte with prominent pro-eosinophilic granules; the same fusion gene is found as in patients with inv(16)(p13q22), and the same cytological features. These cases are assigned to the WHO category of AML with recurrent cytogenetic abnormality. Bone marrow film, MGG.

(a)

(b)
Figure 29.31 Peripheral blood films from two patients with acute promyelocytic leukaemia associated with t(15;17)(q22;q21): (a) acute hypergranular promyelocytic leukaemia showing two hypergranular promyelocytes; (b) acute hypogranular promyelocytic leukaemia showing characteristic bilobed nuclei. This translocation leads to formation of a *PML–RARA* fusion gene. These cases are assigned to the WHO category of AML with recurrent cytogenetic abnormality. MGG.

Other integrated approaches to the classification of AML

The WHO classification specifies four cytogenetic/molecular genetic categories but does not include other less common but nevertheless clearly defined categories. Of the four categories included, two are discrete entities with an overall good prognosis. These are, first, cases with an *AML1–ETO* fusion gene, whether or not t(8;21)(q22;q22) is present or detected, and, second, cases with a *CPFB–MYH11* fusion gene, whether or not inv(16) (p13q22) or t(16;16)(p13;q22) is present or detected. The WHO classification includes 'acute promyelocytic leukaemia, AML with t(15;17)(q22;q12) (*PML–RARA*) and variants'. This approach tends to blur the very real differences between acute
Figure 29.32 Acute myeloid leukaemia associated with t(11;17)(q23;q21); cytological features are closer to FAB M2 category although two hypergranular promyelocytes are apparent. M3-like or M2/M3 are convenient morphological designations for this type of AML. These cases are assigned to the WHO category of AML with recurrent cytogenetic abnormality but it should be noted that this type of leukaemia, which is associated with formation of a *PLZF–RARA* fusion gene, differs in several respects from acute promyelocytic leukaemia (whether classical or hypogranular) associated with t(15;17)(q22;q21) and a *PML-RARA* fusion gene. Bone marrow film, MGG.
Figure 29.33 Acute myeloid leukaemia associated with t(9;11)(p21–22;q23) showing FAB M5a morphological features. This translocation leads to formation of a *MLL–AF9* fusion gene. These cases are assigned to the WHO category of AML with recurrent cytogenetic abnormality. Peripheral blood, MGG.

promyelocytic leukaemia (either classical or variant) with a *PML–RARA* fusion gene and other cases with variant translocations involving *RARA* but not *PML*. Since AML with t(11;17) (q23;q21) and a *PLZF–RARA* fusion gene (Figure 29.32) responds neither to all-*trans*-retinoic acid (ATRA) nor to arsenic trioxide,
Figure 29.34 Acute myeloid leukaemia associated with t(11;19)(q23;p13.1) showing FAB M2 morphological features. This translocation leads to formation of a *MLL–ELL* fusion gene. These cases are assigned to the WHO category of AML with recurrent cytogenetic abnormality. Bone marrow film, MGG.

it seems important that it is *not* regarded as the same disease as acute promyelocytic leukaemia with a *PML–RARA* fusion gene. Defining optimal therapy for these and other even less common leukaemias with *RARA* rearrangement necessitates each of them being recognized as a discrete entity. The WHO classification also groups together all cases with an 11q23 breakpoint and rearrangement of the *MLL* gene, despite the very clear differences between different subtypes of leukaemia with *MLL* rearrangement. The European 11q23 Workshop (see Bain 2001) found that different *MLL* fusion genes were associated with different age ranges, different proportions of AML and ALL, different proportions of M4, M5a and M5b AML and different proportions of *de novo* and therapy-related cases. Although this does not yet have any therapeutic implications, these are clearly all different diseases and they would probably be better not aggregated into a single category.

In addition to the cytogenetic/molecular genetic entities recognized by the WHO classification there are other similar subtypes of AML with characteristic disease features which could be recognized. Some of these are summarized in Table 29.8 (Figures 29.37 and 29.38). The existence of categories of AML with a specific molecular genetic abnormality but without any specific associated cytogenetic abnormality should also be acknowledged. Important among these is AML, often FAB type M1, associated with mutation of the *CEBPA* gene; this is found in as many as 10% of cases of AML and appears to be associated with a good prognosis, particularly if there is no coexisting *FLT-3* abnormality. Recognition of this category of AML could be important in order to avoid overtreatment of good-prognosis patients.

The WHO classification of acute lymphoblastic leukaemia

The most important alterations to the FAB classification made by the WHO group is that there is a clear separation of precursor-B and precursor-T lymphoblastic leukaemia/lymphoma
Figure 29.36 Flow chart showing how the WHO hierarchical classification is applied.

Figure 29.37 Acute myeloid leukaemia associated with inv(3)(q21q26) showing a binucleate micromegakaryocyte. Bone marrow film, MGG.

from cases with the immunophenotype of a mature lymphoid cell, whereas cases with a leukaemic presentation and those with a lymphomatous presentation are grouped together. The practical implication is that most cases categorized in the FAB classification as L3 ALL are reassigned to the category of Burkitt's lymphoma since they express surface membrane immunoglo-

bulin, do not usually express TdT, and have the same translocations that are found in Burkitt's lymphoma with a lymphomatous presentation. This reassignment is of some clinical relevance since it has been recognized for some time that these patients do much better with alternative intensive chemotherapeutic regimens rather than with chemotherapy that would be appropriate for ALL. There remain a small number of cases of L3 ALL that have a precursor-B cell immunophenotype, e.g. cases with

Table 29.8 Cytogenetic/molecular genetic entities not included in the WHO classification of AML.

Cytogenetic abnormality	Molecular genetic abnormality	Disease characteristics
t(9;22)(q34;q11)	BCR–ABL fusion gene	Mainly de novo but may follow topoisomerase II-interactive drugs, most often FAB M0 or M1, poor prognosis
t(6;9)(p23;q34.3)	DEK–CAN fusion gene (also known as DEK–NUP214)	Therapy related (either alkylating agent or topoisomerase II-interactive drugs) or de novo, most often FAB M2, may have Auer rods, dysplastic features and basophilic differentiation, poor prognosis
inv(3)(q21q26) or t(3;3)(q21;q26)	Dysregulation of EVI1	Therapy related or de novo, association with diabetes insipidus, multiple FAB categories, megakaryocyte numbers preserved, trilineage dysplasia with prominent megakaryocyte dysplasia, poor prognosis
t(8;16)(p11;p13)	MOZ–CBP fusion gene	Mainly de novo but may follow topoisomerase-II-interactive drugs, often FAB M5 with phagocytic blast cells and abnormal coagulation, poor prognosis
t(1;22)(p13;q13)	RBM15–MKL1 fusion gene (also known as OTT–MAL)	Acute megakaryoblastic leukaemia in infants, may originate in intrauterine life, often low percentage of bone marrow blast cells, intermediate prognosis
t(16;21)(p11;q22)	FUS–ERG fusion gene (also known as TLS–ERG)	Mainly FAB M1 and M2 AML, poor prognosis

t(1;19)(q23;p13), which should continue to be categorized as ALL.

Conclusion

The diagnosis and further classification of acute leukaemia requires a full assessment of the medical history, family history and physical findings, and careful assessment of cytological features in blood and bone marrow. The use of cytochemistry is selective. Application of immunophenotyping can be selective but is tending to become universal when facilities are readily available. Ideally, cytogenetic analysis should be universally applied, with molecular analysis being used selectively. Careful and detailed evaluation is important for the care of individual patients and for the advancement of knowledge.

Cytogenetics of leukaemia and lymphoma

30

Christine J Harrison

Introduction

Cytogenetics has contributed significantly to the understanding of the genetics of leukaemia and lymphoma over the last 40 years. Chromosomal rearrangements result in the movement of a gene to a new chromosomal location, thus bringing it under the influence of another gene, which may control its expression. This occurs in one of two ways: (i) deregulation of expression, causing abnormal expression of a gene; or (ii) by the generation of a new fusion gene product with aberrant activity. These observations have confirmed the importance of cytogenetic rearrangements in leukaemogenesis and recognized the concept of malignancy as an acquired genetic disorder. The purpose of a cytogenetic investigation in a haematological disorder is to determine whether the karyotype (chromosomal make-up) of the affected cells is abnormal (i.e. different from the constitutional karyotype). Chromosomal findings are important for the classification and diagnosis of the disorder. In acute leukaemia, the karyotype is an independent prognostic factor, now with an impact on therapy. Cytogenetic investigation during the course of an indolent leukaemia may be used to predict transformation to a more aggressive phase. The outcome of bone marrow transplantation can be determined by cytogenetics if the donor and recipient are of opposite sex or if a chromosomal abnormality was found at diagnosis. Successful engraftment can then be distinguished from regeneration of host cells and impending relapse. In this chapter, cytogenetic nomenclature and techniques for studying chromosomes in haematological malignancies are presented first. Then follows a description of the main cytogenetic abnormalities under the headings of the different haematological disorders with which they are associated. Where known, the genes involved will be named, together with a description of the genetic consequences of the chromosomal rearrangement. The diagnostic and prognostic importance of the abnormalities will be discussed.

Techniques

Chromosome preparation: band staining

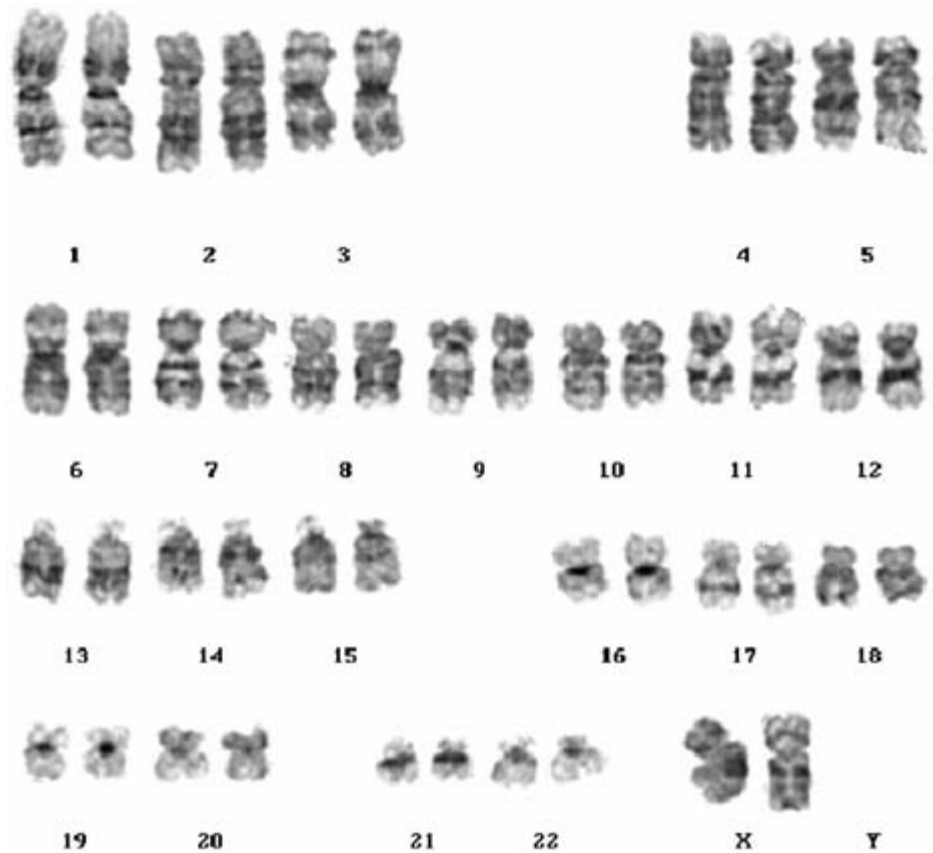
In the haematological disorders, bone marrow and peripheral blood, or cells from lymph node biopsies of lymphomas, are investigated for the presence of dividing malignant cells. Chromosomes are visible only in the condensed form that they adopt in metaphase of cell division (mitosis). They are arrested in metaphase by the spindle poison colcemid and are stained by so-called banding techniques, the standard one being trypsin–Giemsa (or G) banding. This produces a specific banding pattern, clearly visible with bright-field microscopy, in which darkly staining regions of chromatin alternate with lighter staining regions. The banding pattern of each chromosome pair is unique, allowing positive identification of every chromosome (Figure 30.1). At mid-metaphase, a total of 240–330 bands can be seen over the whole karyotype. This increases to 850 or more in prometaphase. Chromosomal analysis has led to the description of many cytogenetic changes acquired in haematological malignancies. It also provides important information on the heterogeneity of cell populations and can detect several abnormalities simultaneously in a single cell. However, it is limited to cells which are mitotically active and must be representative of the malignant clone.


Figure 30.1 Karyogram of a G-banded metaphase from a normal female, 46,XX. Note the 22 pairs of autosomes, 1–22, and the two X chromosomes.

Molecular techniques

Chromosomal abnormalities that cannot be resolved by G banding may be discovered by molecular cytogenetic techniques, otherwise known as FISH (fluorescence *in situ* hybridization). The increasing number of FISH techniques have become an integral part of cytogenetic analysis and must be regarded as complementary, not replacement, tools. FISH analysis requires some pre-knowledge of the abnormality in order to select the appropriate probes, now available to an infinite number of genes and DNA sequences as a result of the Human Genome Mapping Project. Probes are available to each chromosome pair, known as chromosome paints, which can confirm suspected rearrangements and facilitate the analysis of complex chromosomal rearrangements. One of the most appealing aspects of FISH has become the ability to detect a number of targets in several colours at the same time in the same cell. Ultimately, 24-colour FISH (multiplex-FISH or SKY, differing only in the imaging system used to discriminate the fluorochromes) extends the painting technique for the simultaneous analysis of all chromosomes (Figure 30.2). Multiple-colour chromosome band-specific probes now exist (Figure 30.3).

Centromeric, subtelomeric or locus-specific probes can be used to detect aneuploidy, loss or amplification at a particular locus, or subtle/cryptic translocations. The advantage of FISH over cytogenetics is that it can be used to investigate chromosomes and genes in the non-dividing interphase cells as well as metaphases. For interphase FISH assays, it is possible to score large numbers of cells, which is helpful in cases where the mitotic cells are not representative of the malignant clone. Dual-colour translocation probes are now in routine use for interphase FISH detection of important translocations. They consist of probes specific for each of the genes disrupted in the translocation, labelled with different fluorochromes, usually red and green. Single fusion (S-FISH) dual-colour probe sets contain sequences for part of the genes involved in a translocation, and give one red, one green and one red/green (yellow) signal in cells carrying the translocation (Figure 30.4). One limitation of S-FISH for the detection of a fusion gene is the false-positive rate (the frequency with which the signals randomly collocalize in normal cells). Two improvements have increased the sensitivity of FISH and significantly reduced the false-positive rate. One has been the introduction of a third probe labelled with an alternative fluorochrome, giving an extra signal in a third colour, and another the use of two probes which span the breakpoints of both genes, giving a dual fusion in the positive cells. Since the chance occurrence of this signal pattern is virtually zero, this is the most sensitive approach to use.

of fusion transcripts arising from translocations. PCR may be performed on genomic DNA when the breakpoints are tightly clustered, or on RNA transcripts using reverse transcriptase PCR (RT-PCR) when breakpoints are more variable. Gene expression may be quantified using real-time PCR. This technique can be used to track the abnormal clone throughout the course of the disease and thus will quantitatively detect minimal residual disease in patients who have achieved complete remission. There is currently intense interest in the use of DNA microarrays to determine global gene expression patterns, which may be of both diagnostic and prognostic value.

Terminology

Normal human somatic cells contain a diploid set of 46 chromosomes in 23 pairs: 22 pairs of autosomes, numbered 1–22, and a pair of sex chromosomes, XX (female) and XY (male), as shown in the karyogram (Figure 30.1). Each chromosome has a long (q) and a short (p) arm, separated by a primary constriction, the centromere. The chromosome arms are divided into regions and subregions based on the bands, and are numbered from the centromere outwards towards the ends (telomeres). This enables abnormalities to be described in terms of the affected region of the chromosome. Thus, 11q23.2 refers to the long arm of chromosome 11, region 2, subregion 3, subsubregion 2 (Figure 30.5).

Chromosomal abnormalities may be random or clonal. For the purposes of chromosomal classification, only clonal abnormalities are considered. These may be numerical or structural. Numerical changes result in gain or loss of one or more chromosomes. Gain of any single individual chromosome results in trisomy for that chromosome (indicated by the prefix +). The loss of a chromosome results in monosomy for that chromosome (indicated by the prefix −). Cells with numerical changes

Figure 30.2 Normal metaphase painted in 24 colours by multiplex-FISH. Each chromosome pair is seen as a different colour, discriminated by sophisticated computer software.

In addition to FISH, other molecular techniques can be exploited to look for genetic abnormalities in malignant tissue. DNA can be investigated by Southern blotting to discover the presence of a deletion or a translocation in which a particular gene is deleted or disrupted in the creation of an aberrant fusion product. The polymerase chain reaction (PCR) with appropriate primers has now superseded Southern analysis for the detection

Figure 30.3 Karyogram of a normal male painted in seven colours in such a way as to produce coloured bands along the chromosome arms (Rx-FISH) allowing identification of the individual chromosome pairs.
Figure 30.4 Four interphase nuclei showing individual signals specific for the ABL (red) and BCR (green) genes on the normal chromosomes 9 and 22 respectively and the BCR/ABL fusion (red/green collocalized signals appearing yellow) indicating the presence of the Philadelphia chromosome.

show a change of ploidy from the normal diploid complement and are classified by the number of chromosomes as less than (hypo) or greater than (hyper) the nearest ploidy number as follows: near-haploid, 23–29 chromosomes; low hypodiploid, 30–39 chromosomes; high hypodiploid, 40–45 chromosomes; diploid, normal 46 chromosomes; pseudo-diploid, 46 chromosomes with an abnormal chromosome complement; low hyperdiploid, 47–50 chromosomes; high hyperdiploid, 51–65 chromosomes; hypo- or hypertriploid, 69 ±, range 66–80 chromosomes; near-tetraploid, 92 ±, range 81–103 chromosomes.

Structural abnormalities result from chromosomal breakage. They include deletions (del) when part of a chromosome arm is missing [e.g. del(11)(q23) is loss of chromosomal material distal to the breakpoint 11q23] or translocations (t) when chromosomal material is exchanged with another chromosome [e.g. t(4;11)(q21;q23) indicates that material distal to the breakpoint on chromosome 4 at 4q21 is exchanged with material distal to the 11q23 breakpoint]. Translocations may be balanced, which assumes a reciprocal exchange with no loss of chromosomal material, or unbalanced, in which one of the derived chromosomes (der) is missing. A reciprocal translocation may be simple, involving two chromosomes, or complex, between three or more chromosomes. Inversion (inv) describes the inversion of the segment of a chromosome lying between two bands. The description of the chromosomal make-up of the cell is called the karyotype and is written strictly according to an International System for Human Cytogenetic Nomenclature. By convention, this lists the number of chromosomes in the cell,
Figure 30.5 Schematic representation (ideogram) of the G-banding pattern of chromosome 11.

followed by the sex chromosomes, followed by a description of the abnormal chromosomes in numerical order. The number of cells with that karyotype then follows in square brackets. Thus,50,XY,–7,+8,t(9;22)(q34;q11),+13,+19,+der(22)t(9;22)

(q34;q11)[18]/46,XY[2] describes a bimodal cell population in which 18 cells belong to an abnormal clone and two are chromosomally normal. Each cell in the abnormal clone has 50 chromosomes with loss of chromosome 7, gains of chromosomes 8, 13 and 19, a balanced translocation between chromosomes 9 and 22 with breaks at 9q34 and 22q11 and an additional copy of the derived chromosome 22 from this translocation.

Cytogenetic and molecular genetic events

Oncogene activation by chromosomal translocation

Many human oncogenes are located at breakpoints consistently found in chromosomal changes in leukaemia and lymphoma. The gene situated at the other breakpoint of a translocation is likely to be a gene of functional importance. As a result of the translocation, genes that are normally separated are brought together. In this new location, they will be subject to control by their new rather than their normal neighbouring genes, leading to deregulation and abnormal expression. Alternatively, a new fusion gene with aberrant activity will be generated.

Recessive genes, translocations and leukaemogenesis

Leukaemias associated with total or partial chromosome loss suggest that malignancy can result from the unmasking of a recessive malignant gene by the loss of its normal allele. It has been generally assumed that deletions mark the site of tumour-suppressor genes, which behave according to Knudson's two-hit hypothesis of tumour-suppressor gene inactivation. In this model, one allele of the gene could be inactivated by a microdeletion or point mutation or transcriptionally silenced by methylation of the promoter, with the second allele subsequently deleted. A haploinsufficiency model of tumour-suppressor gene inactivation is also possible, in which inactivation of one copy of a target gene, for example by deletion, could be sufficient to contribute to the pathogenesis of a haematological malignancy. Partial or total trisomies would also be expected to perturb gene dosage. An increase in the number of copies of a given proto-oncogene per cell might result in malignant transformation. At present, this is largely speculative, but amplification of proto-oncogenes has been demonstrated in association with homogeneously staining regions (HSRs) and double minutes (DMs). Amplification of the genes *MLL* and *AML1* has been reported in acute myeloid leukaemia (AML) and acute lymphoblastic leukaemia (ALL) respectively. In AML, amplification of c-*MYC* has been described in association with the increased expression of this oncogene.

The main chromosomal abnormalities found in chronic myeloid leukaemia (CML), AML, T- and B- lineage ALL, mature B-cell leukaemias, lymphomas and plasma cell dyscrasias will be discussed, together with their molecular, biological and clinical importance, in the following sections.

Chronic myeloid leukaemia (see also Chapter 37)

The most consistent chromosomal abnormality associated with a haematological malignancy is the Philadelphia chromosome (Ph), described in 1960 as the first cytogenetic abnormality to be associated with human malignancy. The Ph is the derived chromosome 22 from the translocation t(9;22)(q34;q11) (Figure 30.6). In CML, this translocation is found in 92% of patients. Of these patients, approximately 5% have a variant translocation, with the reciprocal chromosome apparently being other than chromosome 9, and 4% have a complex translocation, clearly involving chromosomes 9 and 22 with one or more additional chromosomes. The t(9;22) joins 3′ sequences of the *ABL* gene at 9q34 to the 5′ sequences of the *BCR* gene at 22q11, giving rise to the *BCR–ABL* fusion gene. Breakpoints within *BCR* occur within a 5.8-kb region, termed the major breakpoint cluster region (M-BCR), either between exons 13 and 14 (b2a2) or between exons 14 and 15 (b3a2) This transcribes an aberrant 8.5-kb mRNA, encoding a chimeric p210 protein with enhanced tyrosine kinase activity. Up to 8% of CML patients are Ph negative, without apparent rearrangement of chromosomes 9 or 22, in which the BCR–ABL fusion transcript is detectable by molecular analysis. In some cases, the *BCR–ABL* fusion is present on a cytogenetically normal chromosome 22 as a result of a cryptic insertion of *ABL* into *BCR*. In others, *BCR* is inserted into *ABL* on chromosome 9 (Figure 30.7). Several molecular methods have been utilized to detect the *BCR–ABL* rearrangement. FISH detects the juxtaposition or disruption of *BCR* and *ABL* genes in
t(9;22)

Figure 30.6 Partial karyogram of chromosomes 9 and 22 from a patient with CML, showing t(9;22). The normal chromosome of each pair is on the left and the abnormal (translocated) chromosomes are on the right (arrowed).
Figure 30.7 The same metaphase from a patient with CML examined by FISH (left) and G banded chromosomal analysis (right). Although the chromosomes 9 and 22 are apparently normal by G-banding, the BCR–ABL fusion is formed by the cryptic insertion of BCR into ABL on chromosome 9 (red/green–yellow signal) (arrowed). ABL (red) and BCR (green) signals are also visible on the normal chromosomes 9 and 22 respectively.

metaphase and interphase cells (Figure 30.4); Southern blotting determines whether the *BCR* gene is rearranged from analysis of genomic DNA; RT-PCR determines the presence of BCR–ABL mRNA; and Western blotting analyses cell lysates to determine the presence of BCR–ABL protein. These approaches are particularly useful in patients whose karyotype is normal or ambiguous.

As BCR–ABL is consistently transcribed, whereas ABL–BCR is not, the BCR–ABL transcript was identified to play the aetiological role in the development of CML. It is now known from RT-PCR and FISH studies that extensive deletions of *ABL*- and *BCR*-derived sequences are seen around the translocation breakpoint on the derivative chromosome 9 in up to 30% of patients at diagnosis, which may account for the lack of expression of the reciprocal transcript. Such deletions have been associated with a poorer outcome. Since patients with complex/variant translocations have a higher incidence of deletion, it may be the deletion itself rather than the type of translocation that is linked to the poorer prognosis in these patients.

The progression of CML from chronic phase to blastic transformation is accompanied by additional abnormalities in 80% patients. These changes include duplication of the Ph, isochromosome 17 [i(17)(q10)], +8 and +19, either as a single change or in any combination. In the chronic phase, 5–10% of Ph-positive patients have additional chromosomal changes. The significance of additional changes at diagnosis of CML is not clear and may be an indication of genetic instability rather than a sign of early progression. However, any additional change detected after diagnosis during serial chromosomal analyses is generally predictive of impending transformation.

Patients have been successfully treated with interferon-α, with approximately 80% achieving a haematological response measured by a reduction in the number of Ph-positive cells in the bone marrow. The demonstration that BCR–ABL encodes a receptor tyrosine kinase led to the discovery of new therapeutic strategies in which an inhibitor of the tyrosine kinase domain of the BCR–ABL chimeric protein, imatinib mesylate (STI571 or Gleevec/Glivec), was found to be effective in treatment. The cytogenetic response with this drug is highly successful, although the results from long-term follow-up are not yet available.

Acute myeloid leukaemia (see also Chapter 31)

The majority of cases of AML (70%) are characterized by one of a variety of chromosomal abnormalities, many of which have now been molecularly characterized. These abnormalities correlate closely with morphological and clinical features and are a key determinant in outcome. They identify distinct biological subsets of disease, to which therapeutic approaches can be

Table 30.1 Significant chromosomal abnormalities in AML.

+22			M4Eo		

specifically tailored. This is particularly relevant to patients with good-risk cytogenetic features. The French–American–British (FAB) classification of AML consists of eight main groups (M0–M7) with two subtypes M3V (variant) and M4Eo (with increased or abnormal eosinophils). Those chromosomal abnormalities most commonly associated with AML, where known, the genes involved, their FAB types and associated clinical features are given in Table 30.1.

Good-risk cytogenetic groups

t(8;21)(q22;q22)

This translocation (Figure 30.8a) occurs predominantly in FAB type M2 (acute myeloid leukaemia with granulocytic maturation at or beyond promyelocyte stage) and a number of cases of M4 (myelomonocytic leukaemia). It fuses the core binding factor alpha gene (CBFα, AML1 or RUN1) on chromosome 21 with ETO on chromosome 8 to produce a novel chimeric gene, which is frequently accompanied by the loss of a sex chromosome (−Y in males and −X in females). In up to 8% of cases, the translocation is cryptic, requiring alternative molecular detection methods as described above. The translocation is found in all

age groups, but is most common under the age of 40 years. It is associated with a good outcome and, in current treatment trials, is considered as good risk and treated accordingly.

inv(16)(p13q22), t(16;16)(p13;q22)

These abnormalities of chromosome 16 are found in AML M4 and are notable for their association with abnormal eosinophilia (M4Eo) and a good prognosis. The inv(16)(p13q22) (Figure 30.8b) involves an in-frame fusion of the smooth muscle myosin heavy-chain gene, MYH11, normally on 16p13 and another core binding factor gene, CBFβ, normally on 16q22. This subtle chromosomal change has frequently been overlooked by cytogenetic analysis of poor-quality preparations, therefore FISH and RT-PCR have become routine detection methods.

t(15;17)(q22;q21)

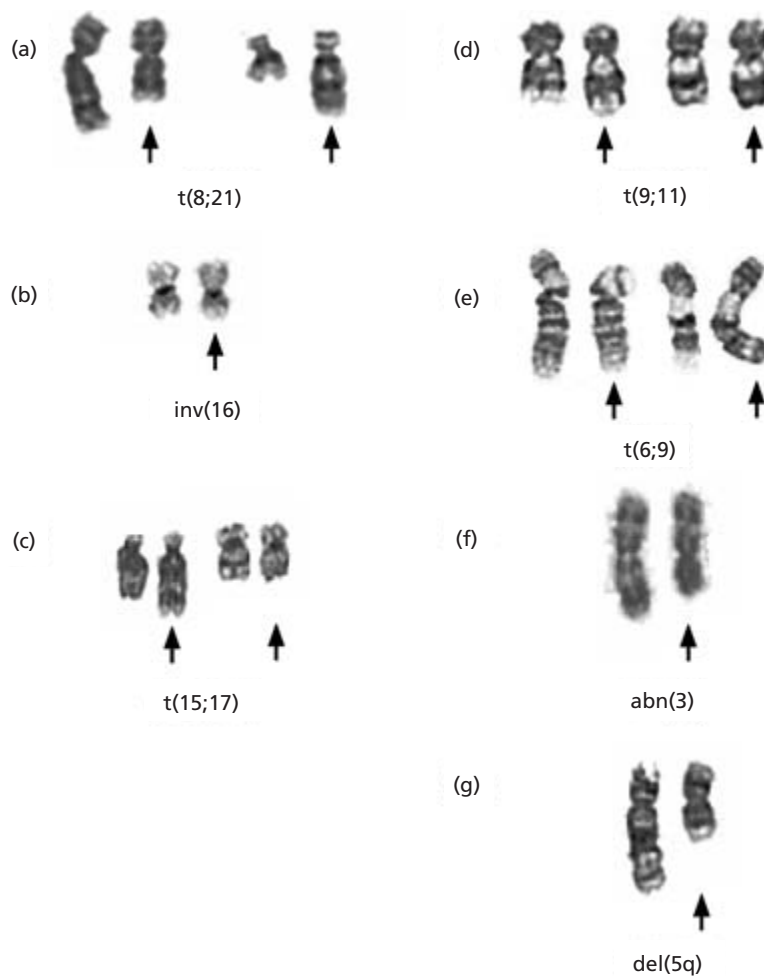
The translocation t(15;17)(q22;q21) (Figure 30.8c) is specific for AML M3 and M3v (acute promyelocytic leukaemia) and is most often found in patients < 35 years old. It results in the rearrangement of the retinoic acid receptor alpha (RARα) gene, located at 17q21, which is fused to the PML gene on chromosome 15, a gene which is transcribed in normal haemopoietic cells. Thus,


Figure 30.8 Partial karyograms from marrow cells of patients with acute myeloid leukaemia, each showing a chromosomal rearrangement. The normal chromosomes are on the left and the abnormal ones are on the right (arrowed).

the chimeric gene appears to play a role in the differentiation block that occurs in AML M3. The prognosis in these patients is good and of particular interest is their response to treatment with all-*trans*-retinoic acid (ATRA). This acts by converting the PML–RAR-α fusion protein from a transcriptional repressor to a transcriptional activator, thus inducing terminal differentiation of the leukaemic clone. This has conferred significant improvements in survival in combination with standard therapy. ATRA has now been adopted as a component of first-line therapy for this disease, highlighting the importance of accurate identification of this chromosomal abnormality. FISH and RT-PCR have become important tools in the detection of *PML–RARα*, as described for *BCR–ABL*. In AML M3, patients have been identified with atypical karyotypic features. These include the rare alternative translocation t(11;17)(q23;q21), whereby *RARα* is fused to the *PLZF* gene. The identification of these variants is important as, unlike the classic t(15;17) cases, they are resistant to ATRA.

Among these three groups of patients with favourable primary cytogenetic abnormalities t(8;21), inv(16) and t(15;17), the significance of additional chromosomal abnormalities has been a subject of some controversy; however, the majority of studies suggest that they do not have a major impact on prognosis.

Other chromosomal abnormalities

Abnormalities of 11q23 (see also Chapter 33)

Chromosomal rearrangements of 11q23 involving the *MLL* gene have been described most frequently in infants presenting at < 1 year of age. Numerous partner genes have been identified, but in AML, particularly M5 (monocytic leukaemia), the translocation t(9;11)(p21;q23), involving *AF9,* is the most common (Figure 30.8d). Although this translocation provides the best outcome compared to other *MLL* translocations in AML, survival is relatively short.

t(6;9)(p23;q34)

Bone marrow basophilia has been reported in a number of patients with the translocation, t(6;9)(p23;q34) (Figure 30.8e). Patients are often < 30 years of age and outcome is generally

poor. The breakpoint at 9q34 is different from the Ph and interrupts a gene known as *CAN*. As a result of the translocation, *CAN* fuses with the gene *DEK* on 6p23 and encodes a DEK/CAN protein.

inv(3)(q21q26), t(3;3)(q21;q26)

Abnormalities involving chromosome bands 3q21 and 3q26 are found in all FAB types and are associated with an extremely poor prognosis (Figure 30.8f). Trilineage myelodysplasia, abnormalities of the megakaryocyte series and abnormal thrombopoiesis are common in this patient group. Three genes have been mapped to 3q26; *EVI1*, *EAP* and *MDS1/EVI1*. Aberrant expression of *EVI1* has been demonstrated in patients with 3q26 abnormalities.

Other chromosomal abnormalities specific to childhood AML include t(1;22)(p13;q13). This translocation occurs in less than 1% of childhood cases of AML and yet has been found in almost 100% of infants with M7 (megakaryoblastic leukaemia), usually as the sole cytogenetic change. This translocation fuses the *MAL* and *OTT* genes on chromosomes 22 and 1 respectively. The resulting OTT–MAL fusion protein regulates *HOX* gene expression. The cryptic translocation t(5;11)(q35;p15.5) is associated with a deletion of the long arm of chromosome 5. It involves *NUP98* at 11p15 with *NSD1*. The rare but recurrent translocation t(7;12)(q36;p13) is restricted to infants with AML, is cryptic and involves *ETV6* (*TEL*) at 12p13 and *HLXB9* at 7q36.

There are a number of chromosomal changes which occur in all FAB types. These include deletions of chromosome 5 [del(5q)] (Figure 30.8g), in which a variable portion of the long arm is missing. The proximal breakpoints vary but the distal breakpoint usually involves 5q31–q33, including the commonly deleted segment, which has been mapped to 5q31 in AML and MDS, the proposed site of a tumour-suppressor gene. The location of myeloid growth factor genes on 5q and the acquired hemizygosity of these genes in clones with monosomy 5 or del(5q) are subject to numerous investigations into the mechanisms of leukaemogenesis associated with this chromosomal change. Nevertheless, the relationship between these genetic events and neoplastic change remains elusive.

Monosomy 7 or del(7q) also frequently occur. Although the extent of the deletion of 7q is variable, two commonly deleted regions have been mapped by molecular methods to 7q22 and 7q32–q33.

Acquired hemizygosity of 17p in clones with i(17)(q10) or del(17p) has been shown to be associated with mutations of the *p53* gene, a tumour-suppressor gene, located on 17p. The oncogeneic potential of the mutated form of this gene suggests that these chromosomal abnormalities are of prime importance for malignant transformation.

Trisomy 8 is a common abnormality in AML. It often accompanies other chromosomal changes as a secondary abnormality. Thus, it has been difficult to evaluate this change in terms of risk.

The detection of trisomy 8 is amenable to FISH-based techniques using centromeric probes and chromosome painting, particularly when metaphases are of poor quality. Interphase-FISH using centromeric probes has demonstrated that trisomy 8 may be present in a greater proportion of patients than originally thought.

Abnormalities of chromosomes 5 and 7 (monosomy or partial long-arm deletion) and abnormalities of 3q, particularly in association with a complex karyotype (usually described as four or more structural and/or numerical changes in the same clone), predict an adverse prognosis. They are found most frequently in adults over the age of 55 years and are invariably associated with a particularly poor treatment response.

Secondary leukaemia

Chromosomal abnormalities have been described in up to 90% of cases of AML following cytotoxic treatment and arising as a secondary malignancy (s-AML). A similar incidence of abnormalities is found in patients with AML who have been exposed to environmental genotoxic agents. The chromosomes most frequently involved are 5 and 7. The clones tend to have highly complex karyotypes and these patients have a poor response to treatment. A t(3;21)(q26;q22) has been described in a number of s-AML cases, which fuses *MDS1–EVI1* with *AML1*. Other abnormalities involving the *AML1* gene and rearrangements of 11q23, including the translocation t(4;11)(q21;q23), are found in s-AML following treatment with topoisomerase II inhibitors, such as epipodophyllotoxins. Cytogenetic analysis was important in establishing the existence of leukaemia induced by these drugs and distinguishing them from cases induced by other alkylating agents.

Myelodysplastic syndromes
(see also Chapter 40)

The myelodysplastic syndromes (MDS) are a collection of five clinicopathological entities occurring most frequently in the elderly, with a wide spectrum of clinical behaviour and survival outcome. Between 40% and 70% of patients with primary MDS have chromosomal abnormalities. In secondary (therapy related) MDS, the incidence is much higher. The detection of a clonal cytogenetic change is useful in difficult cases to establish the definitive diagnosis of MDS. Cytogenetic findings are an independent prognostic variable and have been instrumental in predicting the likelihood of progression from MDS to AML. In classification systems, such as that of the World Health Organization, cytogenetics is now mandatory to the prognostic scoring of a newly diagnosed patient. Many of the karyotypic changes are similar to those found in AML and the myeloproliferative disorders. In general, they are unbalanced, with chromosome

loss, deletion and unbalanced translocations. The most common single abnormalities are del(5q), monosomy 7, trisomy 8 and del(20q). However, multiple chromosomal changes are common. A complex karyotype, which may include the abnormalities listed above, carries a higher incidence of progression to acute leukaemia and signifies a particularly grave prognosis. An abrupt change from a simple to highly complex karyotype heralds leukaemic transformation in patients who previously had a stable clinical course over many years, thereby advocating serial monitoring of patients with stable disease.

The 5q minus syndrome

Deletion of a portion of the long arm of chromosome 5 is found in a wide spectrum of haematological disorders, including AML, secondary leukaemia and myeloproliferative disorders. However, the term '5q minus syndrome' refers specifically to a condition first described by Van den Berghe and colleagues in 1974 in which a clone with del(5q) is the sole chromosomal abnormality. A commonly deleted segment of 5q has been identified at 5q33, which is different from that defined for AML and MDS and is likely to harbour a different tumour-suppressor gene. Most affected patients are elderly females with severe refractory anaemia, without an excess of blasts, with no underlying haematological disorder and no significant history of exposure to drugs or toxins. Generally they have a favourable outcome and relatively long survival, with only ~10% of patients progressing to AML. Additional abnormalities which may be present and influence survival adversely include del(7q), −7, +8, +11, −17 and +21.

Myeloproliferative disorders
(see also Chapter 46)

The myeloproliferative disorders (MPDs) are a group of disorders defined by proliferation of one or more lineages of the myeloiderythroid series. This includes polycythaemia rubra vera, idiopathic myelofibrosis, undifferentiated MPD and essential thrombocythaemia (ET). Chromosomal abnormalities are seen in 30–40% of patients, although rarely in ET. There is no pathognomonic chromosomal abnormality associated with these disorders, but cytogenetic investigation is important to rule out Ph-positive CML. Some consistent chromosomal abnormalities have been described, including del(20)(q11), +8, +9, del(13)(q13−q31) and partial trisomy 1q, which seem to be associated with a poor prognosis. Frequently, the detection of a chromosomal abnormality in these cases is the only way to distinguish a malignant clone from a non-malignant hyperplasia.

Translocations in atypical MPD involving the chromosome band 8p11, most frequently t(8;13)(p11;12) and t(8;9)(p11;q34), define a rare group of patients described as 8p11 myeloproliferative syndrome. These translocations disrupt the fibroblast growth factor receptor-1 gene (FGFR1), a receptor protein tyrosine kinase that maps to 8p11. Patients with rearrangements of FGFR1 have distinctive clinical features, notably prominent eosinophilia. In a similar manner, translocations involving 5q33 disrupts the platelet-derived growth factor beta receptor (PDGF-β), another receptor tyrosine kinase which maps to 5q33. The first such translocation to be reported was t(5;12)(q33;p13), in which PDGFβ fuses with the ETV6 gene at 12p13. In these translocations, it seems that deregulation of PDGFβ as FGFR1 leads to a consistent clinical phenotype that might be better classified as a distinct subtype of chronic MPD. In a similar manner to that described for CML, these patients respond to treatment with imatinib mesylate.

Acute lymphoblastic leukaemia
(see also Chapters 32 and 33)

Clonal chromosomal abnormalities are found in up to 80% of patients with ALL. They are closely related to the biology of the disease and indicate the genes involved in leukaemogenesis. Cytogenetic classification is based on the number of chromosomes and structural changes, which are important in both childhood and adult ALL to distinguish good- from high-risk patients. Significant chromosomal abnormalities and the genes involved are listed in Table 30.2. Cytogenetic studies in ALL are particularly difficult owing to the frequent low mitotic index of the abnormal blasts and the notoriously poor chromosome morphology. This can be largely overcome by using FISH or RT-PCR to screen for the significant chromosomal abnormalities.

B-precursor ALL

t(9;22)(q34;q11)
Of significance is the Ph chromosome, which is associated with a particularly poor outcome in ALL. This abnormality occurs more frequently in adults (in whom it accounts for up to 20% cases, increasing exponentially with age) than in children (among whom it is found in 2–3% cases). The Ph translocation, t(9;22)(q34;q11), in ALL is cytogenetically indistinguishable from that found in CML (Figure 30.6). In the majority of cases of ALL, the breakpoint in BCR occurs between exons 1 and 2 (e1 and e2) in the minor breakpoint cluster region (m-BCR) and exons 1 and 2 of ABL (e1a2). This generates a 7-kb mRNA giving rise to a p190 protein product. In some cases, the breakpoint is in M-BCR, resulting in the production of the p210 protein product as found in CML. Both result in raised tyrosine kinase activity, which induces the increased growth of the clone. As described for CML, FISH provides an accurate method of detection of this abnormality in poor-quality metaphases. The use of RT-PCR for the detection of mRNA in Ph-positive cases can be used to monitor the clone in remission with much greater sensitivity than that achieved by cytogenetic analysis. The two

Table 30.2 Significant chromosomal abnormalities in ALL.

Immunophenotype	Chromosomal rearrangement	Genes	Genes	Associated features	Prognosis
c-/pre-B ALL	HeH				Good
	near-haploidy				Very poor
	t(1;19)(q23;p13)	PBX1	E2A		Medium
	t(4;11)(q21;q23)	AF4	MLL	High WBC, infants	Very poor
	t(9;22)(q34;q11)	ABL	BCR-M or m	Higher incidence in adults	Very poor
	t(12;21)(p13;q22)	ETV6	AML1	Children	Good
	t(17;19)(q22;p13)	HLF	E2A	Variant t(1;19)	
T ALL	t(1;14)(p32;q11)	TAL1	TCRδ		
	t(5;14)(q35;q32)		HOX11L2		
	t(7;9)(q35;q32)	TCRβ	TAL2		
	t(7;9)(q35;q34)	TCRβ	TAN1		
	t(7;11)(q35;p13)	TCRβ	RBTN2		
	t(7;14)(p15;q11)	TCRγ	TCRδ		
	t(8;14)(q24;q11)	c-MYC	TCRα		
	del(9p)	p16			Poor
	t(10;14)(q24;q11)	HOX11	TCRα		
	t(11;14)(p13;q11)	RBTN2	TCRδ		
	t(11;14)(p15;q11)	RBTN1	TCRδ		
	inv(14)(q11;q32)	TCRα	IgH		
Mature B ALL	t(2;8)(p12;q24)	Igκ	c-MYC	L3

	t(8;22)(q24;q11)	c-MYC	Igλ	L3	

molecular variants of Ph-positive ALL do not apparently correlate with either different clinical features or with prognosis.

t(1;19)(q23;p13)

The translocation t(1;19)(q23;p13) fuses the *E2A* gene at 19p13 with the *PBX1* gene at 1q23 to form the *E2A/PBX1* fusion gene. The translocation is strongly associated with a pre-B immunophenotype and it occurs in two forms, a balanced translocation, t(1;19), and an unbalanced form, der(19)t(1;19) (in which the reciprocal product, der(1)t(1;19), is lost and the normal chromosome 1 is duplicated) (Figure 30.9a). Clinically, patients with the two forms appear identical, but the unbalanced form is associated with a significantly better prognosis than the balanced form. FISH probes directed to *E2A* reliably detect balanced and unbalanced forms of t(1;19) and the other rare abnormalities involving *E2A*.

t(17;19)(q21;p13)

The translocation t(17;19)(q21;p13) is a variant of t(1;19) resulting in the fusion of *E2A* with the hepatic leukaemia factor (*HLF*) gene on chromosome 17. Although limited numbers of patients have been reported, the prognosis is poor.

MLL rearrangements

The translocation t(4;11)(q21;q23) (Figure 30.9b) is the most frequently occurring *MLL* rearrangement in ALL, in which *MLL* fuses with AF4 located to chromosome band 4q21. This translocation identifies a particularly well-defined subgroup with a number of associated high-risk features, including white blood cell count $> 50 \times 10^9$/L (frequently $> 100 \times 10^9$/L) and a pre-B immunophenotype with some expression of myeloid features. It is most common in infants with ALL and in adults it is found more frequently in patients over the age of 40 years. The translocation occurs rarely between the ages of 2 and 10 years. A poor prognosis is associated with infants and adults. *MLL* is involved in a large number of translocations with a range of partner genes, many of which have been molecularly identified. A dual-colour FISH probe is available which reliably detects all *MLL* rearrangements. The identification of the subtle translocation t(11;19)(q23;p13) is shown in Figure 30.10.

t(12;21)(p13;q22)

This translocation occurs in up to 25% of children and 3% of adults with B-lineage ALL. In spite of this high incidence, it was discovered much later than the other ALL associated abnormal-

(a)

der(19)t(1;19)

(b)
t(4;11)

Figure 30.9 Partial karyograms of translocations seen in ALL, der(19)t(1;19) (a) and t(4;11) (b). Abnormal chromosomes 19 and 4 are on the right and abnormal 11 is on the left. Note that the two copies of chromosome 1 accompanying t(1;19) are normal.

Figure 30.10 Metaphase from a patient with ALL showing the t(11;19) by FISH The probe set comprises two probes, 5′ and 3′ of *MLL* bcr, labelled with red (5′ distal) and green (3′ proximal). The red/green–yellow fusion signal is seen on the normal chromosome 11. As a result of the translocation the two probes become separated, the 5′ probe remains on the abnormal chromosome 11 (green signal) and the 3′ probe is relocated to chromosome 19 (red signal).

ities. The reason was that it is invisible by G-banded chromosomal analysis and was brought to light by chance chromosome painting in 1994. The translocation results in the fusion of the *ETV6* gene on chromosome 12 with *AML1* on chromosome 21. The *ETV6–AML1* fusion can be reliably detected by dual-colour FISH using specific probes (Figure 30.11) and by RT-PCR. Initial reports associated this translocation with a good prognosis. This has been reviewed as a number of patients have been shown to experience a late relapse. Deletions of the homologous *ETV6* allele have been reported in the majority of cases, which is believed to be a significant initiating event in the development of leukaemia in patients with t(12;21).

Ploidy

Ploidy classification embraces a heterogeneous group of numerical chromosomal changes, with an important role in prognosis. In particular, the high hyperdiploid group (which includes patients with 51–65 chromosomes) has been consistently shown to have the best outcome compared with any other chromosomal group in ALL. Chromosomal gains are non-random, with chromosomes 4, 6, 10, 14, 18, 17, 21 and X most frequently gained (Figure 30.12). The good prognosis has been linked to the gains of chromosomes 4, 10, 17 and 18. Interphase FISH using chromosome-specific centromere probes can be success-

fully used to look for high hyperdiploid clones in bone marrow samples which fail to achieve a cytogenetic result (Figure 30.13). Structural chromosomal changes accompany chromosomal gain in more than 50% of high hyperdiploid cases. It appears that structural change does not compromise the excellent prognosis of this group. It is of particular interest that high hyperdiploidy is the most frequent abnormal finding in children and a rare finding in adults. It is important to exclude the presence of one of the poor-risk translocations in a high hyperdiploid clone before designating the patient as good risk. In contrast to high hyperdiploidy, near-haploidy (23–29 chromosomes) and low hypodiploidy (30–39 chromosomes), both rare findings in ALL, are associated with an extremely poor prognosis. The chromosomes gained to the haploid chromosome set reflect the same additional chromosomes as seen in the high hyperdiploid patients. These abnormal clones often have an accompanying cell population with an exact doubling of their chromosome number. Although this resembles a classic good-risk high hyperdiploid karyotype, it confers no change to the dismal prognosis of these patients. Near-triploidy and near-tetraploidy are rare in childhood ALL, but in adults they account for approximately 5% of patients, in whom they are associated with a poor outcome.
Figure 30.11 Metaphase from an ALL patient with t(12;21) showing the *ETV6–AML1* fusion on the abnormal chromosome 21 (red/green-yellow fusion signal). A small red signal from part of AML1 identifies the abnormal chromosome 12 (right hand red signal; arrowed), while the other red signal (left hand) indicates the normal chromosome 21. There is no complementary green signal seen on the homologous chromosome 12 indicating that an *ETV6* deletion accompanies the translocation in this patient.

Mature B-cell ALL

More than 80% of mature B-cell ALL (ALL L3) have one or other of three translocations consistently found in Burkitt's lymphoma: t(8;14)(q24;q32) (approximately 80%), t(2;8)(p12;q24) (6%) or t(8;22)(q24;q11) (14%) (Figure 30.14a–c). Chromosomes 14, 2 and 22 code for the immunoglobulin heavy-chain (*IgH*), and light-chain kappa (*Igκ*) and lambda (*Igλ*) genes respectively. The oncogene c-*MYC* is located at chromosome band 8q24. As a result of each translocation, the coding regions for *c-MYC* are brought into close proximity with one of the *Ig* genes. The recombination of *Ig* genes with c-*MYC* upregulates *c*-MYC expression, resulting in uncontrolled expansion of a malignant B-cell clone.

Although the translocation appears identical in African Burkitt's lymphoma (which occurs endemically in equatorial Africa and is associated with the presence of the Epstein–Barr virus (EBV) in more than 90% cases) and in sporadic cases (found in Europe and North America, in the absence of viral infection), a difference is seen at the molecular level. In sporadic cases, breakpoints occur either within or 5′ of *c-MYC* and in the switch region of *IgH,* c-*MYC* is structurally altered as a result of this translocation. Most endemic African Burkitt's lymphomas involve the *IgH* J_H region, c-*MYC* is not rearranged and break-

points are scattered widely over a 300-kb region upstream of the gene.

T-lineage ALL

The overall incidence of cases T-ALL classified by immunophenotyping is approximately 10% in childhood and 18% in adult ALL. The main chromosomal changes are shown in Table 30.2. The chromosomal abnormality detection rate by cytogenetic analysis is extremely low. It has been reported that ~20% of cases have translocations mapping to the chromosomal regions encoding one of the four T-cell receptor (*TCR*) genes, alpha/delta (*TCRα/δ*), beta (*TCRβ*) and gamma (*TCRγ*) at 14q11, 7q32 or 7p15 respectively. These translocations juxtapose a *TCR* promoter/enhancer element to one of many transcription factors located at or near the breakpoints of the partner chromosomes. Molecular studies have indicated that the incidence of these rearrangements is much higher than reported by cytogenetics alone. Similarly, molecular techniques have demonstrated hemi- and homozygous loss of genes located at 9p21-p22 in up to 80% of childhood cases of T-ALL, many without cytogenetic evidence of deletion of 9p. The genes of interest are two related tumour-suppressor genes, *MTS1* and *MTS2* otherwise known as *p16(INK4a)* and *p15(INK4b)*. These genes encode proteins that act as inhibitors of cyclin D-dependent serine-threonine kinases, which are necessary for the transition from G1 to S phase of the cell cycle. Further, it has been demonstrated that deletions of *TAL1* and the cryptic translocation t(5;14)(q35;q32), involving transcriptional activation of *HOX11L2*, occur in 45% of T-ALL. Also found, but not exclusive to T-ALL, are abnormalities of the long arm of chromosome 6 (6q), in approximately 12% patients.

Chronic lymphoproliferative disorders
(see also Chapter 38)

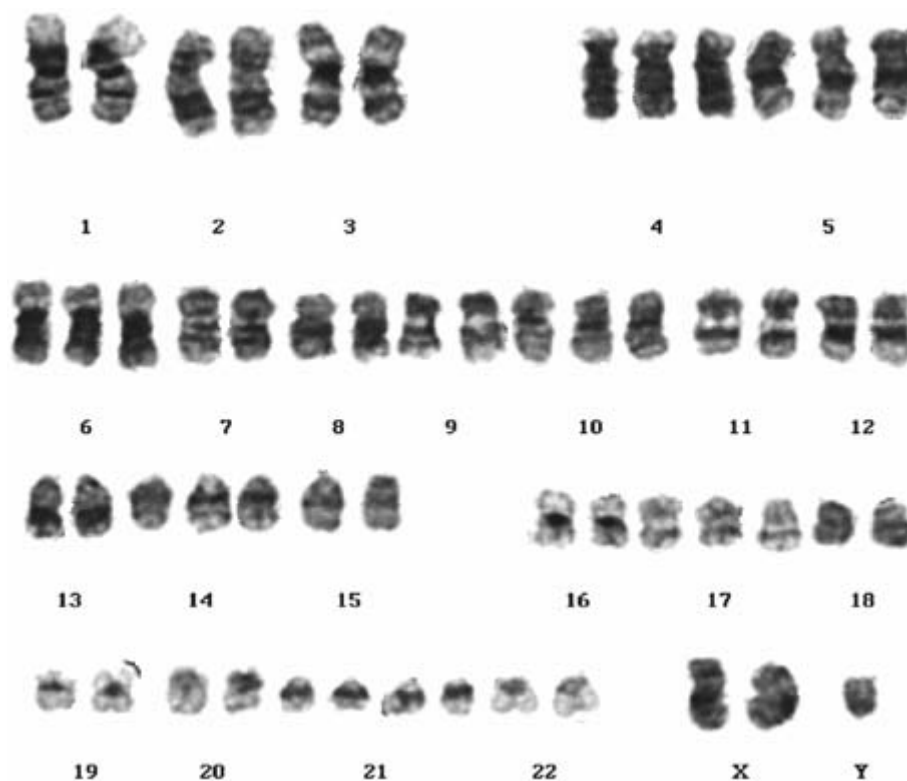
These disorders are characterized by the malignant proliferation of mature lymphocytic cells in the bone marrow and peripheral blood. Chronic lymphocytic leukaemia (CLL) and prolymphocytic leukaemia (PLL) are predominantly B-cell disorders. T-cell disorders account for only 5% of cases. Both mature B and T cells are particularly inert in culture and have to be stimulated into mitosis for cytogenetic analysis with mitogens, which even then may fail to stimulate the abnormal cells. Thus, it has been difficult to estimate the frequency of chromosomal abnormalities. The use of FISH, directed to the common changes, has increased the abnormality detection rate to approximately 80%. The major cytogenetic changes are listed in Table 30.3. In B-cell CLL these include trisomy 12, del(13q), del(11)(q22–q23), which includes the *ATM* gene (mutated or deleted in ataxia telangiectasia), and deletions or translocations of 17p13, usually resulting in loss of the p53 gene. In contrast to other low-grade B cell disorders, abnormalities


Figure 30.12 Karyogram of a hyperdiploid cell (55 chromosomes) from a male patient with ALL. Note the three copies of chromosomes 4, 6, 10, 14 and 17, the four copies of chromosome 21 and the additional X chromosome. This karyotype is associated with good prognosis in children.
Figure 30.13 Two interphase nuclei from the bone marrow of an ALL patient with hyperdiploidy. The application of specific centromere probes has shown additional copies of chromosomes 10 and 17 indicated by the three red and green signals respectively.

Table 30.3 Significant chromosomal abnormalities in CLL.

Chromosomal abnormality	Genes	Genes	Incidence (%)
t(2;14)(p13;q32)	Bcl-11A	IgH	< 1
del(6q)			6
del(11q)			18
trisomy 12			16
del(13q)	RB1		55
t(14;18)(q32;q22)	IgH	Bcl-2	< 1
del(17p)	p53		7
t(14;19)(q32;q13)	IgH	Bcl-3	< 1

affecting the *IgH* locus at 14q32 are rare in B CLL. The translocation t(14;19)(q32;q13) has been reported in a number of cases. In view of the association with small lymphocytic lymphoma this is listed in the malignant lymphoma section. T-cell cases (large granular lymphocytic leukaemia) may rarely have an inversion of chromosome 14, inv(14)(q11q32), and/or translocations involving 14q11, often accompanied by trisomy 7 and del(6q). Specifically in T-PLL, deletions or mutations of the *ATM* gene occur in association with abnormalities of 14q11.

Recent studies have shown that the mutational status of the *IgH* variable region (V_H) is an important prognostic factor in CLL. By comparison, trisomy 12 and del(13q) do not have independent prognostic significance. Abnormalities of 11q and 17p usually occur in patients with non mutated V_H genes and are associated with a shorter median treatment free interval and

overall survival compared to patients with non mutated V_H genes who lack these genomic deletions.

Malignant lymphomas

Non-Hodgkin's lymphomas

Chromosomal analysis of lymph nodes in the non-Hodgkin's lymphomas (NHL) reveals 80–90% with karyotypic abnormalities. In patients with bone marrow involvement, the abnormal clone can frequently be found in bone marrow and peripheral blood cells. The prognosis of individual patients is highly dependent on clinical parameters including age, performance status and tumour burden. However, certain chromosomal abnormalities, while not disease specific, can provide additional prognostic information.

Burkitt's lymphoma

The cytogenetics of Burkitt's lymphoma are described above with mature B-cell ALL.

Non-Hodgkin's, non-Burkitt's lymphomas

The most consistent cytogenetic abnormalities in NHL are listed in Table 30.4. Follicular lymphoma, the most common B-cell malignancy, is associated with the translocation t(14;18)(q32;q21), which is found in ~90% cases (Figure 30.14d). The breakpoint on chromosome 14 occurs in the *IgH* locus within or directly

adjacent to a J_H segment. The breakpoints on chromosome 18 cluster within a 5.4-kb region flanking a transcriptionally active locus termed *Bcl-2*, also named *CCND2*, a putative oncogene which inhibits apoptosis (programmed cell death). The t(14;18) causes dysregulation and increased expression of *Bcl-2*, both by transcriptional activation and by abnormal post-transcriptional regulation of Bcl-2 mRNA, inhibiting apoptosis. Transformation of follicular lymphoma into a high-grade lymphoma is often accompanied by karyotypic evolution.

Mantle cell lymphoma is typically characterized by the proliferation of small lymphocyes with irregular nuclei, derived from the normal follicular mantle zone. The translocation t(11;14)(q13;q32) is the characteristic chromosomal abnormality seen in approximately 70% of cases (Figure 30.14e), sometimes in association with other abnormalities. The breakpoint on chromosome 14 is found within the J_H segment of the *IgH* gene, the breakpoints on chromosome 11 are clustered to within eight nucleotides of an oncogene termed *Bcl-1*, or *CCND1*, a cell cycle control element. The gene product, cyclin D1, is overexpressed. Dual fusion, dual-colour FISH with *IgH* and *Bcl-1* probes, has become the most sensitive method for detection of this translocation.

Small lymphocytic lymphoma or atypical CLL is associated with a t(14;19)(q32;q13). This involves the fusion of *IgH* with *Bcl-3*, a transcription factor normally located at 19q13.

Diffuse large-cell B-cell lymphomas (DLCL) are the most heterogeneous of lymphoma subtypes and can develop at different stages of B cell maturation. Up to 90% have clonal

chromosomal abnormalities, of which ~50% are translocations involving *IgH*, whose most common partners are *Bcl-2* (20%), *c-MYC* (10%) and *Bcl-6* at 3q27 (7%) (Figure 30.14f). In contrast to *Bcl-2* and *c-MYC* rearrangements, which invariably involve the *Ig* loci, *Bcl-6* is frequently juxtaposed to non-*Ig* genes as a result of translocations with a variety of different partner chromosomes, occurring in up to 40% of DLCL. *Bcl-6* codes for a novel zinc finger protein sharing homologies with several known transcription factors. A further 5% of DLCL *Ig* translocations involve either the *Bcl-8* gene at 15q11, the *NFKB2* gene at 10q24 or a series of clustered genes at 1q21 which include *MUC1*. Chromosomal gains in DLCL include trisomies of chromosomes 3, 7, 11, 12 and 18. Chromosomal segments shown to be commonly amplified include the genes *Bcl-2*, *c-MYC*, *REL* (2p) *GLI*, *CDK4* and *MDM2* (12q), while commonly deleted regions include 1p, 1q, 3p, 3q, 6q and 7q. Although the presence of *Bcl-2* gene translocations has no prognostic significance, overexpression of Bcl-2 protein, which may occur in the absence of *Bcl-2* rearrangements, correlates with both short disease free and overall survival. Similarly, p53 mutations, overexpression of p27 and cyclin D3 with concurrent disruption of *p16(INK4a)*, p14 and *ARF* genes on 9p, correlate with aggressive disease and short survival.

Lymphoplasmacytoid lymphoma is associated with the t(9;14)(p13;q32), which juxtaposes the *PAX5* gene on chromosome 9 to the *IgH* gene, resulting in *PAX5* overexpression.

Anaplastic large-cell lymphoma is a specific morphological entity of T or null cell immunophenotype, with expression of CD30 and epithelial membrane antigen, occurring more frequently in childhood lymphoma. The translocation t(2;5)(p23;q35) is specific for this lymphoma type, and results in the fusion of the nucleophosmin (*NPM*) gene at 5q35 to the anaplastic lymphoma kinase gene (*ALK*) at 2p23, producing the NPM–ALK fusion protein. Rare variants have been described which involve *ALK* but not *NPM*.

Plasma cell dyscrasias (see also Chapter 41)

Multiple myeloma is a relatively common haematological malignancy in which the outlook for patients is poor. Detailed cytogenetic investigations of myeloma have increased in importance following the demonstration that they have prognostic significance. Chromosomal analysis is difficult owing to the small numbers and the low mitotic index of plasma cells in the bone marrow of these patients. With careful attention to culture times and conditions, successful cytogenetic results have been achieved, revealing highly complex karyotypes from which recurring chromosomal abnormalities have emerged. These include specific numerical changes giving rise to characteristic patterns of hyperdiploidy, with gains of chromosomes 3, 5, 7, 9, 11, 15, 18, 19 and 21, the loss of chromosome 13 and hypodiploidy. Hyperdiploidy is often accompanied by abnormalities of chromosome 1, specifically the unbalanced translocation, der(1;16)(q10;p10). The application of FISH techniques has substantially improved the interpretation of complex karyotypes and has shown that cytogenetic analysis alone underestimates the incidence of chromosomal abnormalities in myeloma.

The most significant structural chromosomal changes in myeloma, as shown in Table 30.5, are rearrangements involving the switch regions of the *IgH* gene with other partners at a high incidence of 75%. Four of these appear to be significant primary rearrangements. These are *CCND1* (*Bcl-1*) in the translocation t(11;14)(q13;q32); two genes *FGFR3* and *MMSET*, which are simultaneously involved in t(4;14)(p16;q32); to a lesser extent *c-MYC* in t(8;14)(q24;q32), *IRF4* in t(6;14)(p25;q32) and *MAF* in the t(14;16)(q32;q23).

Monosomy 13 and deletions of the long arm, specifically involving the chromosomal band 13q14, also frequently occur in myeloma. They are associated with a poor prognosis, particularly in association with raised serum β_2-microglobulin levels,

Table 30.5 Significant chromosomal abnormalities in myeloma.

Chromosomal abnormality	Genes	Genes	Incidence (%)
t(4;14)(p16;q32)	FGFR3/MMSET	IgH	15
t(6;14)(p25;q32)	IRF4	IgH	15
t(8;14)(q24;q32)	c-MYC	IgH	5
t(11;14)(q13;q32)	CCND1	IgH	16
t(14;16)(q32;q23)	IgH	MAF	5
del(13q)			40–80

and the progression of monoclonal gammopathy of undetermined significance (MGUS) to myeloma. As a result of these significant findings, interphase FISH has now become the method of choice for the detection of *IgH* rearrangements and deletions involving 13q14. The same chromosomal changes have been identified from cytogenetic and FISH analysis of MGUS, plasma-cell leukaemia and systemic monoclonal immunoglobulin light chain amyloidosis.

Summary

Cytogenetic analysis of the malignant cells of patients with haematological malignancies has contributed to advances in diagnosis, prognosis and patient management. The results have impinged on treatment, leading to an improved outlook for a significant number of patients. The development of molecular cytogenetic techniques has overcome some of the limitations of G-banded cytogenetic analysis and has offered opportunities to uncover abnormalities not identified by conventional methods. Chromosomal and genetic probes have added a new dimension to chromosome analysis, enabling the detection of subtle chromosomal changes in DNA and RNA from malignant tissues and extending chromosome analysis to interphase cells. These advances have led to a considerable expansion in the scientific knowledge of haematological malignancies. From the discovery of many leukaemia-specific cytogenetic changes, subsequent sequencing and cloning of the genes involved has uncovered a variety of biochemical pathways involved in leukaemogenesis, to which specific therapy is beginning to be targeted. Continued interaction of cytogenetics and molecular biology promises to lead to the detection of many more leukaemia-specific genes and continue the contribution to a better understanding of leukaemogenesis.

Acute myeloid leukaemia

31

Alan K Burnett

Epidemiology of disease

Acute myeloid leukaemia (AML) has an incidence of 2–3 per 100 000 per annum in children, rising to 15 per 100 000 in older adults. It can occur at all ages but has its peak incidence in the seventh decade (Figure 31.1). The incidence does not appear to be increasing beyond that expected in an ageing population. The fact that most cases occur in older patients has important implications for treatment strategies, in that biological variation associated with chemoresistance and comorbidity, which limits treatment options, increases with age.

Pathophysiology

The more carefully AML is studied, the clearer it becomes that there is considerable heterogeneity between cases with respect to morphology, immunological phenotype, associated cytogenetic

and molecular abnormalities and, more recently, patterns of gene expression. This is reflected in the substantially different responses to treatment. Some entities are becoming so distinct that they are regarded as different diseases with specific approaches to treatment.

Acute myeloid leukaemia is a malignant clonal disorder of immature cells in the haemopoietic hierarchical system. Leukaemic transformation is assumed to occur in many cases at, or near, the level of the haemopoietic stem cell before it has embarked on any lineage commitment. Some cases may originate at a slightly later stage in cells that are committed to lineage differentiation. These cells have abnormal function characterized by a failure to progress through the expected differentiation programme and/ or to die by the process of apoptosis. Associated with this may be the retention of the stem cell characteristic of self-renewal. This leads to the accumulation of a clone of cells, which dominates bone marrow activity and leads to marrow failure. The potential for arrest of haemopoiesis at different time points partially
Figure 31.1 Age distribution of AML in the population of Wales: a population study.

explains why there can be such a variation in the leukaemic or 'blast' population characterizing the individual case. Adenopathy or organomegaly can occur but are not usual features. Extramedullary disease can occur, including cerebrospinal infiltration, but this is not usual, unlike in lymphoblastic leukaemias. Similarly, most patients present with low peripheral blood counts. While in the majority of cases no direct cause is found, there is an association with irradiation, smoking, some rare congenital abnormalities and chemical exposure. Perhaps the most frequently identified cause is progression from other myeloproliferative disorders, e.g. myelodysplasia, or as a consequence of prior chemotherapy for another malignancy.

Non-random chromosome abnormalities are found in the majority of cases. These may be structural (gain or loss of material) or reciprocal balanced translocations. The significance of these changes is developing at a steady pace and will be discussed below as far as the clinical implications are concerned.

Several molecular changes have also been discovered, either by association with the known cytogenetic abnormalities or somewhat by chance (Table 31.1). There is a variable level of proof at this stage as to whether the recognized molecular abnormalities are sufficient in themselves to cause leukaemia. The most common molecular mutation associated with AML has been found in the FLT receptor.

FMS-like tyrosine-3 (FLT-3) is a member of the platelet-derived growth factor receptor (PDGF-R) subfamily or receptor kinases and is most similar to FMS, KIT and the PDGF receptors. The receptor is expressed in haemopoietic cells restricted to the CD34-positive fraction and a CD34-negative subfraction of dendritic cell precursors. It is also expressed on neural tissues. Normal FLT-3 receptor is expressed on AML blasts in most cases and can be overexpressed or asynchronously expressed in that it can be expressed not strictly in association with CD34 expression. Most mutations are present in the juxtamembrane domain of the receptor and comprise internal tandem repeats of variable size that are always in frame and therefore expressed. Such mutations are found in approximately 25% of AML cases. Additional point mutations have been found on the activation loop of the interrupted kinase domain, usually at aspartate-835. The consequence of these mutations are activation of the receptor by phosphorylation, which promotes proliferation and resistance to apoptosis. Not only is the mutation the commonest mutation in AML, but a large clinical experience confirms that it is strongly predictive of relapse. Mutations are associated with high white cell counts and blast percentage at diagnosis. They are not uniformly distributed across the FAB or cytogenetic subgroups, being rare in FAB M0, M6 and M7 and most common in M3. The incidence is highest in patients with t(15;17), trisomy 8 and normal karyotype and uncommon in other favourable groups and in virtually all poor-risk cytogenetic groups.

There is an increasing belief that most tumours are a result of multiple 'hits' or molecular changes and that a single change may be insufficient to cause the full leukaemic phenotype. In AML, the phenotype is a consequence of both a proliferative lesion and a failure of differentiation, and it seems probable that molecular abnormalities which affect both functions are required. This understanding is already leading to the concept of therapeutic agents which inhibit the molecular consequences of these abnormalities.

Disease classification

The disease is confirmed by an excess of primitive 'blast' cells in the bone marrow, originally in the FAB classification required to be at least 30%. The French–American–British (FAB) morphological classification has been useful in developing a common vocabulary, but has little predictive value with the widespread use of genetic markers. The new system now recognizes 11 subtypes (see Chapter 29). Quality cytochemistry can provide valuable additional diagnostic information. Further precision can be added by immunophenotyping. Although widely used, in many cases where high-quality morphology and cytochemistry is available it is not strictly required to confirm the diagnosis as AML. As will be discussed later, the leukaemic blasts may demonstrate an 'aberrant' immunophenotype which can have potential use in monitoring response to treatment.

Cytogenetics (see also Chapter 30)

The recognition of non-random chromosome abnormalities associated with the various types of AML has had a major impact on the understanding of disease and has opened the way to unravel the molecular genetic defects and aids in the appropriate choice of treatment. A typical range of the more common abnormalities is shown in Figure 31.2. Some of the consequential molecular changes have been carefully investigated and, in the case of some of the reciprocal translocations, the molecular breakpoints have been cloned. Some of these are illustrated in Table 31.1.

The morphological, cytogenetic, immunological and molecular abnormalities are frequently associated as illustrated in Table 31.2. This, together with clinical response data, has led to a recognition that a predominantly morphological classification is no longer adequate to define some subsets which are better recognized as distinct clinically relevant entities based on cytogenetics. This has resulted in a new classification devised on behalf of the World Health Organization (WHO) (Chapter 29). Another key change in the revision is that the lower threshold blast percentage in the bone marrow is now set at 20%. From a therapeutic point of view, this transfers the proportion of patients with myelodysplastic syndrome [subgroup – refractory anaemia with excess blasts in transformation (RAEBt)] to acute leukaemia. It is still to be convincingly shown that these patients will benefit from a 'leukaemia approach' to their management.

Treatment

Aspirations for treatment

Given the age distribution of patients who will present with the disease, it must first be decided what the goals of treatment are in an individual patient. In young people, there is little doubt that there is the prospect of significant benefit to be gained from an intensive approach. With increasing age, which is often associated with comorbidity and less responsive disease, the balance of benefit changes to a more palliative approach. Much of what is known about the prospects of successful treatment is derived from large clinical trials. In young patients, these results are usually representative of what can be expected for any age-matched patients. However, only a selected minority of older patients

(aged > 60 years) will enter trials, so trial-derived information may be less transferable to the whole population in this age group. A substantial majority of older patients are not considered fit for the usual intensive approach and the priority for such patients is palliative care, optimization of quality of life and minimal hospitalization. Examination of survival in population studies illustrates the dominant effect of age (Figure 31.3).

Treatment strategy

The initial clinical priority is to apply chemotherapy to improve marrow function by inducing complete remission (CR). Conceptually, this means an approximate two log reduction in tumour burden. This becomes compatible with a bone marrow which appears normal morphologically and is functionally able to produce normal numbers of circulating cells. The traditional
Figure 31.3 Survival of AML in relation to patient age. Data from a Welsh population database.

consensus definition of CR is based on these premises, i.e. < 5% blast cells in a cellular marrow durable for at least 28 days with a peripheral neutrophil count of 1.5×10^9/L and platelet count of > 100×10^9/L, and absence of extramedullary disease. In some cases, these criteria may be met but the morphology is dysplastic. It is not clear whether this is associated with a greater risk of relapse. Similarly, some patients meet the marrow criteria but do not achieve full peripheral regeneration. In some circumstances, these features may represent a pre-existing dysplastic state; in others it may represent the effects of overtreatment of that particular individual. In the former case, this may have adverse connotations while in the latter it represents optimum treatment. As more sophisticated molecular techniques have become available, it is clear that it is still possible to detect residual disease when all morphological and functional criteria are met. Such techniques (RT-PCR) are capable of detection at a level of 1 in 10^4 or 1 in 10^5 residual cells, but such markers are available for only a minority of cases in which the molecular lesion has been characterized (see also Chapter 34). When it is possible (i.e. in an individual who is heterogeneous for an X-linked marker) to use molecular markers of clonality, it has been noted that in some cases marrow remissions are clonal when they would be expected to represent both alleles of the clonal marker. Sometimes the molecular signature is that of the same clone as the leukaemic cells, suggesting that what the remission represents is a precursor or differentiated state of the malignant clone. It has also been noted that clonal remissions may be derived from the uninvolved allele.

Clinical experience has demonstrated that further intensive post-remission treatment is required to 'consolidate' CR. This is delivered at the same intensity as induction, to achieve further cytoreduction. Under these circumstances, it is possible to achieve disease levels that are beyond the level of molecular detection. It is not clear how many intensive consolidation courses are required, but two or three are generally used in younger patients, and a stem cell transplant may be included. Where intensive induction and consolidation can be given, e.g. in younger patients, maintenance chemotherapy is not required. A pictorial description of treatment is shown in Figure 31.4.

Treatment details

Induction of remission

The backbone of treatment for 30 years has been the combination of daunorubicin and cytosine arabinoside (Ara-C). Usually daunorubicin is given for 3 days in a dose of 45–50 mg/m^2. Ara-C is given for 7–10 days as a continuous infusion or by bolus doses of 100–200 mg/m^2/day. Many clinical trials have been conducted which have tested variations of this standard of care. Alternatives to daunorubicin (adriamycin, mitoxantrone, idarubicin, aclarubicin) or different doses have not yet been shown to be superior overall, although current studies are exploring higher anthracycline doses. Idarubicin may achieve a better quality of remission, as reflected in a reduced relapse risk in younger patients, but it is more myelosuppressive and limits the intensity of consolidation treatment. In general, on a dose-equivalent basis, daunorubicin remains the anthracycline of choice. Higher doses (3 g/m^2) of Ara-C in induction have been tested in recent years, with mixed results and no convincing evidence of overall benefit. Intermediate doses (400 mg/m^2/day versus 200 mg/m^2/day) have recently been tested in younger patients without demonstrating a difference.

Comparison of induction treatment is not simply measured by the rate of remission. By achieving a greater degree of cytoreduction, without necessarily getting more patients into CR, one treatment may be superior because it results in less subsequent relapses (Figure 31.4). The beneficial effect of the addition of a third drug to the induction combination has some evidence to support it. This will usually be etoposide or thioguanine. A large comparative study did not show any difference between these
Figure 31.4 Diagnostic presentation of treatment strategy.

two drugs when used at the third drug in combination with daunorubicin and Ara-C. The majority of patients who are going to enter remission will do so after one course of treatment. If an incomplete response is obtained then a second course of the same combination is indicated. A further group will enter remission, but these patients have thus shown themselves to have less sensitive disease, and this is reflected in a modestly increased risk of relapse later. If patients fail to achieve a substantial reduction in marrow blasts in the first course or fail to enter complete remission with a second course, they should be considered refractory to the drugs used up to that point and transferred to an alternative treatment schedule.

Supportive care (see also Chapter 36)

It is unusual for induction chemotherapy not to clear most of the leukaemic blasts; however, this is at a cost of 3–4 weeks of severe pancytopenia. Several components of supportive care have to be in place during this period. Careful monitoring of biochemical parameters of renal and hepatic function and coagulation is required. Central venous access is now considered essential, together with high-quality and readily available blood product support.

A priority is the prevention and management of infection. Most patients will receive prophylactic oral antibiotics and antifungals to minimize the risk of infection during the neutropenic period, although the routine use of the latter can still be debated. Since hospital-acquired infections are becoming an increasing problem, it can be safer for the patient to be at home provided that close monitoring can be undertaken in the day hospital and that rapid readmission to specialist care is available.

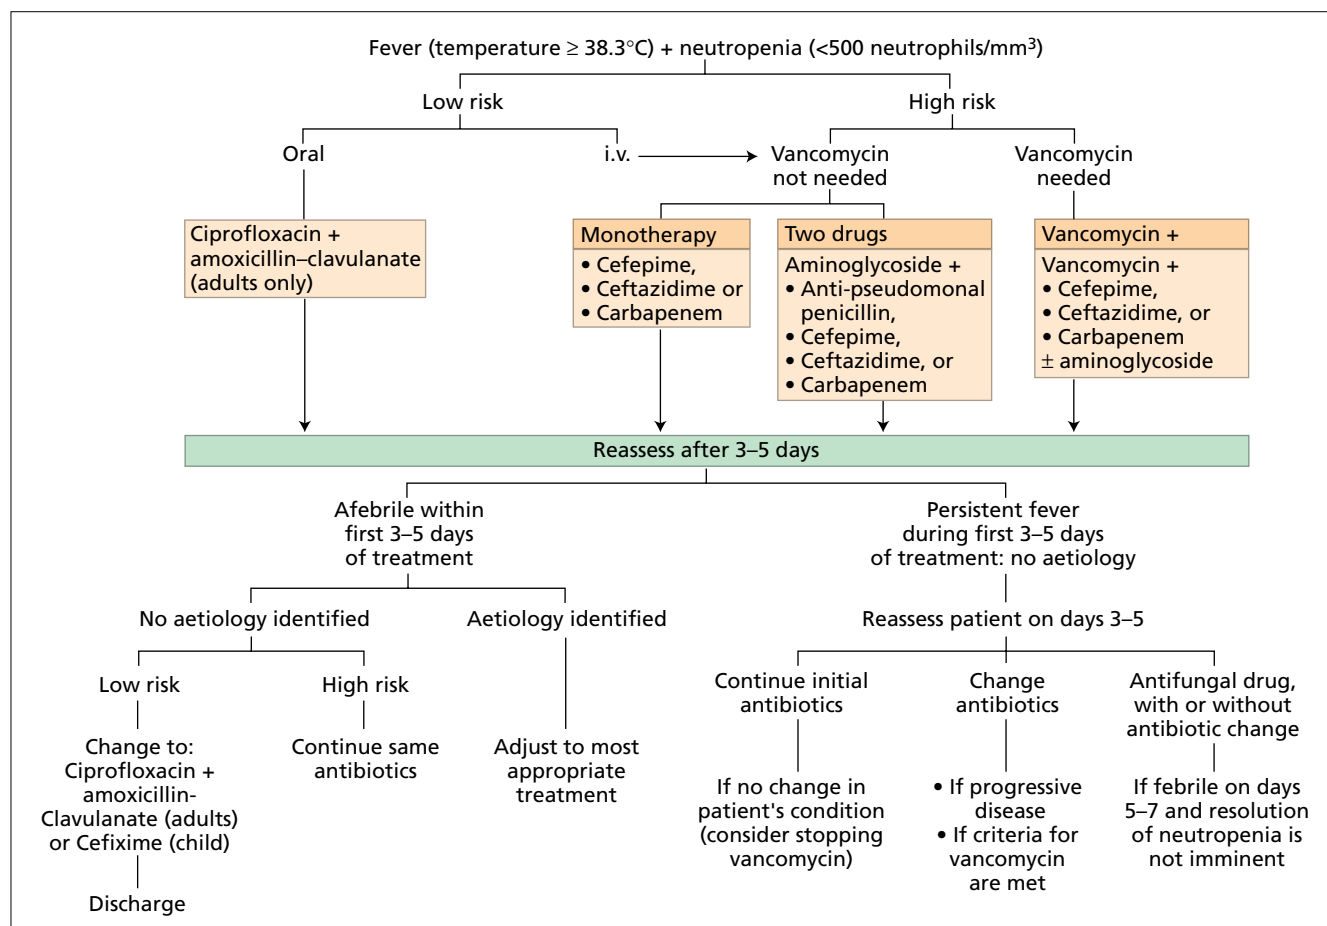
In spite of prophylactic measures, most patients will become febrile during neutropenia. This must be considered as an indication of a serious, and potentially fatal, infection. The common pathogens are staphylococcal, caused by the use of central catheters, and, increasingly, fungal infections – *Candida* and *Aspergillus*, which are related to the duration of severe neutropenia which results from the more intensive chemotherapy now used. Particular patterns of infection will be determined within individual institutions, which will dictate the particular approach to empirical antimicrobial intervention. Fungal infections are a particular problem, not only related to more intensive treatment, but because of continuous building works which are a usual feature of hospital environments. Guidance on intervention should not only be literature evidence based but should incorporate local microbiological issues, as exemplified in Figure 31.5. Nursing expertise is an essential component. It seems probable that improvements in remission rates in recent years can largely be attributed to better supportive care and nursing skills which have enabled more intensive treatment to be given safely.


Figure 31.5 Management of febrile neutropenia (adapted from Hughes *et al.* 2002).

Recombinant growth factors (G-CSF or GM-CSF) have a potential use in two respects. If they can curtail the duration of neutropenia there will be less risk of death during the aplastic phase following induction chemotherapy. This may increase the rate of remission. Second, as many leukaemia cells exhibit receptors for these growth factors, it may be possible to pretreat the patient with growth factor to bring the leukaemic cells into the cell cycle and thereby make them more susceptible to chemotherapy. Extensive studies using G-CSF or GM-CSF to curtail neutropenia have been carried out. Some general conclusions can be made. The duration of neutropenia can be reduced by a few days, but it is less easy to demonstrate a reduction in episodes of febrile neutropenia. There is generally no improvement in remission rate. Growth factor use has not increased leukaemic growth or involved relapse.

The reasons for incorporating growth factors or not into routine practice are primarily economic. Their use may enable patients to leave hospital earlier. If the local policy is to hospitalize patients during neutropenia, this may save resources. Fewer studies have been carried out to see whether growth factor

'priming' of the leukaemic population would be advantageous. They have generally been unsuccessful but a recent positive study may rekindle interest in this approach.

Results of induction treatment

With this approach to treatment, 50–85% of patients will achieve remission. Of those who do, about 70% will require one course. A number of factors influence the prospects of achieving remission. Age is a dominant and independent risk factor and a continuous variable. Eighty per cent of patients < 60 years will achieve CR, but this prospect diminishes with age (Table 31.3). Clinical performance score at diagnosis is also highly predictive. In younger patients, fewer patients tend to present with poorer performance scores so this prognostic factor does not move the overall remission rate to any great extent. A larger proportion of older patients will have a poorer risk score and therefore the score has more predictive impact. The distribution of cytogenetic subtypes is related to age, with more responsive subtypes more frequently seen in younger patients and less responsive patients, aggregating in older patients. Tumour burden at

Age	< 35	35–55	55–60	61–65	66–70	71–75	75+
Complete remission (%)	88	82	77	62	63	48	59

Table 31.3 Relationship of complete remission rate to patient age. Patients were all given intensive chemotherapy (data derived from the UK Medical Research Council AML Trial database).

diagnosis, as represented by white blood count, serum albumin or lactate dehydrogenase (LDH) levels, will adversely impact on response to induction treatment. It is now possible to measure a number of proteins in the leukaemic blasts which are involved in drug efflux. These 'resistance' proteins, for example P-gp, tend to be more frequent in older patients, and to correlate with a lower remission rate. If patients have had an antecedent haematological disorder, e.g. myelodysplasia, the remission rate will be about 20% lower than in age-matched groups. About 10–25% of patients embarking on intensive induction chemotherapy will die during the aplastic phase from non-leukaemic causes, which is essentially a failure of supportive care. Induction deaths tend to be associated with the adverse features already mentioned.

Consolidation treatment

Having achieved remission, the priority is to prevent relapse. Optimization of induction treatment is still required as it will influence the quality of remission and thereby the subsequent rate of relapse. Three options are available for younger patients once remission has been achieved – further chemotherapy at induction level of intensity; chemotherapy with autologous stem

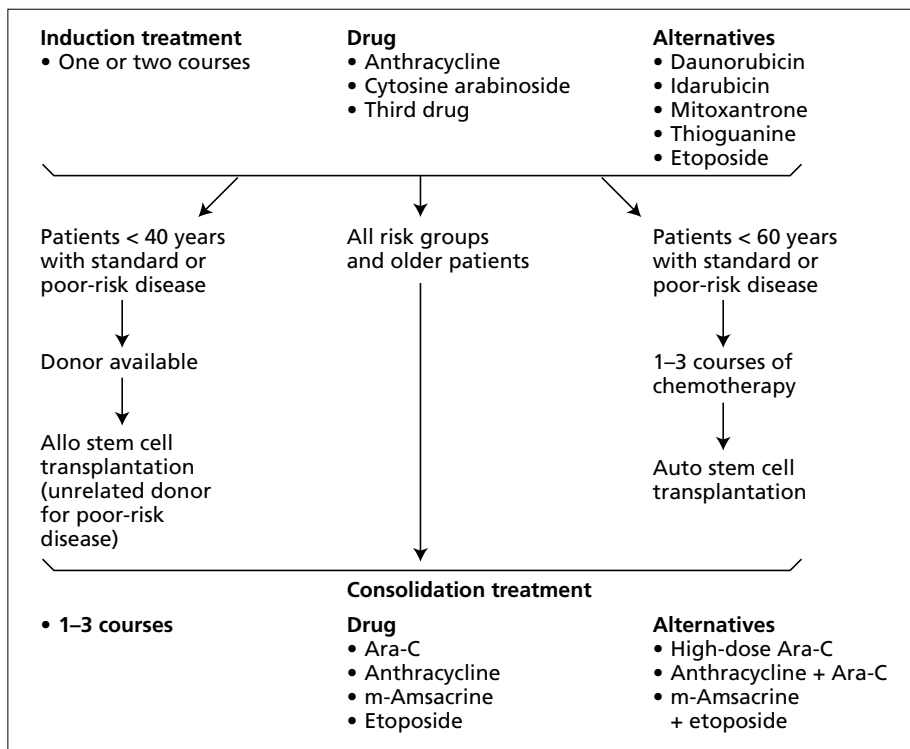
cell transplantation; or allogeneic stem cell transplant with or without prior chemotherapy. Chemotherapy will usually involve a further two or three chemotherapy courses. At this point in the treatment, there is a theoretical logic in using different drugs to minimize the risk of selecting chemoresistant leukaemic clones. Combinations, using Ara-C at increased dosage, amsacrine, etoposide and alternative anthracyclines, are often used (Figure 31.6). Few studies have made direct comparisons between specific combinations, but rather they try to work out how many consolidation courses are needed. Two or three courses that are intensive enough to induce 3–4 weeks' neutropenia appears to be achievable but is reaching the limit of tolerability and compliance. High-dose Ara-C (3 g/m^2 on alternate days over 5 days) has been shown to be superior to lower doses (400 mg/m^2 or 100 mg/m^2), but no studies have so far studied intermediate Ara-C doses, which may be just as effective with less toxicity. It has been suggested that high-dose Ara-C is more effective in the most responsive subtypes of disease i.e. those with lower risk disease, based on cytogenetic prognostic markers. Overall, 50–55% of younger patients who enter remission will relapse – usually within the first 2 years. In older patients, the risk is much higher, at 80%.


Figure 31.6 Treatment options in AML.

Allogeneic stem cell transplantation

There is little doubt that the most effective way to prevent leuk-aemic relapse in younger patients is allogeneic transplantation from an HLA-compatible sibling donor. Most of the extensive data available are derived from patients in whom the graft was of bone marrow. In these circumstances, the relapse risk will be reduced from 45% to about 20%. As there are non-leukaemic causes of death, the overall expectation of cure for recipients of allo-BMT is around 60%. Some of these survivors will have morbidities that survivors of chemotherapy will avoid, and this needs to be taken into account when advising patients. As the risk of transplant complications, graft-versus-host disease (GvHD) and infections, in particular, increases with age, this approach is normally limited to patients under 45 years, although the precise age cut-off remains controversial and will be a matter of the relative risk of the transplant, and of disease recurrence.

Some transplant-related factors may predict for a more favourable outcome, such as a male donor, a cytomegalovirus (CMV)-negative donor when the host is CMV negative and a higher cell count in the graft, and so influence the decision to undergo the treatment. The extent to which the high-dose preparative regimen that is necessary to ensure engraftment or the immunological reactivity of the donor marrow via donor T cells eliminates residual leukaemia has been debated extensively. At least some contribution from the immunological effect of 'graft-versus-leukaemia' is assumed. Experience with donors who are mismatched at more than one HLA locus has not been encouraging, but using fully matched unrelated donors has become more reliable, particularly with the development of molecular methods of tissue typing. In expert hands, in carefully selected young patients, this approach may be equivalent to having a sibling donor.

Once remission has been achieved there is probably no definite requirement to administer more than one course of consolidation chemotherapy before the allograft. But this usu-ally happens because of the time required to identify a donor and make the necessary arrangements for the transplant. It does not appear that variations in transplantation protocols have a major effect on overall survival, e.g. choice of myeloablative schedule, GvHD prophylaxis or whether bone marrow or peripheral blood is the source of stem cells.

Because the applicability of transplant is limited, by treatment-related complications, to younger patients, and yet has a very powerful anti-leukaemic effect, there is recent interest as to whether a non-ablative allogeneic transplant will have a role for older patients. This approach does not require the traditional intensive treatment to ablate the host marrow but provides enough immunosuppression to enable the donor stem cells to engraft. Over a period of weeks, the host haemopoiesis becomes donor, i.e. changes from host to mixed to donor chimerism. Other clinical indications have demonstrated that full chimeric engraftment in older patients can be achieved with treatment modalities that are not ablative to the bone marrow. The hope is that this provides sufficient graft-versus-leukaemia (GvL) effect. In AML, in a conventional allogeneic transplant, it is not clear how important the GvL effect is, so it remains to be seen whether non-ablative transplants have a role in consolidation of AML in older patients.

Autologous stem cell transplantation

(see also Chapter 25)

For younger patients who lack donors, harvesting stem cells from the bone marrow or peripheral blood during remission and using them after a period of cryopreservation for haemato-logical rescue after myeloablative chemo-radiotherapy has been widely used. This approach has also been shown to be a more effective way of preserving remission compared with chemo-therapy. The treatment-related mortality is lower (5–10%) than with allogeneic transplant, but it lacks a GvL mechanism so the relapse risk is higher (around 35–40%). This results in an overall survival of 50–55% of those who receive this approach. Because the complications are not particularly age related, patients up to their mid-50s can safely undergo this procedure, but the results of autologous transplant in older patients (over 60 years) is not encouraging.

Patients who receive the autograft early in remission (e.g. within 3 months) do less well than those treated at 3–6 months because of a higher relapse rate. This may reflect patient selection, but it has also been interpreted to mean that, for an autograft to be successful, consolidation chemotherapy before-hand has an important role in cytoreduction of leukaemia cells before the marrow is harvested, so-called 'in vivo' purging of disease. Initially there was concern that returning stem cells to patients would be illogical unless efforts were made to eliminate contaminating leukaemia cells first – so called 'ex-vivo' purging. Various chemical, cellular and immunologically based tech-niques were used without clear evidence of benefit. Most clinical experience was gained using 'unpurged' bone marrow sup-porting myeloablative chemoradiotherapy, which was usually cyclophosphamide with total body irradiation or busulphan with cyclophosphamide.

One of the problems with the use of autologous bone marrow has been delayed peripheral blood count recovery, particularly of platelets. This seems to be a feature of AML and is less obvious in other disease indications. Recent attention has turned to using peripheral blood or combining peripheral blood and marrow stem cells to ameliorate this problem. This has improved haemo-poietic recovery but may be associated with an increased risk of relapse, thus giving no overall survival advantage.

Comparison of consolidation options

For patients under 55 or 60 years, all three treatment options are available, so the dilemma is which treatment approach to take. About 45% of patients entering remission will survive with chemotherapy alone. Of those who receive an allogeneic or autologous stem cell transplant, 55–60% and 50%, respectively,

will survive. Patients who receive a transplant are not equivalent to patients receiving chemotherapy alone. They have survived long enough to receive the transplant, whereas those who could not have the transplant may not have done so because they relapsed. Some studies demonstrate that 40% of patients with a donor do not receive an allograft.

Another less frequently considered option is to delay the transplant until there is disease recurrence. Primary treatment of relapse with transplantation is associated with a high rate of failure, so it is necessary to establish a second remission first. It is possible, however, to salvage overall about 15% of patients who relapse from chemotherapy. Based on risk factors, it is possible to define those patients who, if they relapse, are likely to enter a second remission. In this subgroup the transplant can therefore be delayed because, if first-line treatment does fail, a second CR can be reliably obtained and a transplant delivered. If there is a low chance of second remission, there is a stronger case for transplant as part of first-line treatment.

Several prospective randomized trials have compared chemotherapy with autologous transplantation and allograft with chemotherapy. In the latter case, these comparisons are not truly randomized comparisons but rather comparing patients who are found to have donors – and assumed to be intended to receive an allograft – with those for whom no donor is found. This 'donor versus no-donor' comparison is a substitute for the randomization. Although the conclusions are not universal, and in spite of the superior ability of autograft to reduce the risk of relapse, there have been no differences in survival between these approaches. When those with donors are then compared overall there is only a modest survival benefit in favour of allotransplant. When the cytogenetic risk of relapse is taken into account, as will be discussed below, it would appear that transplantation is not required for good-risk patients, and in the absence of an emerging improvement for poor-risk patients allogeneic transplant including from unrelated donors is the chosen approach. There is a prospect that chemotherapy may continue to improve so the question of whether allograft will continue to be the best option for standard-risk patients remains open.

Factors influencing the risk of relapse

As treatment of disease in younger patients has improved, so the heterogeneity of disease has also become apparent with respect to differences in relapse risk. On multivariate analysis a number of factors have emerged that can predict the risk of relapse irrespective of treatment schedules used, including stem cell transplantation.

Cytogenetics (see also Chapter 30)

Patients with t(8;21) and inv(16) have a high remission rate, a lower risk of relapse and a higher rate of second remission, and have a 5-year survival of 65–75%. These patients tend to have lower expression of the 'resistance proteins' and a low frequency of FLT-3 receptor mutations (to be described below). Acute promyelocytic leukaemia (APL) is now regarded as a separate entity which is uniquely responsive to retinoic acid. In most cases, the disease is characterized by t(15;17), which predicts sensitivity for a differentiation and apoptotic response to retinoic acid. These abnormalities are frequently associated with additional abnormalities such as –X or Y or 9q– in the case of t(8;21), and trisomy 8 in the case of t(15;17). These additional changes do not adversely affect the favourable prognosis. Similarly, the FLT-3 mutation is expressed in about 35% of APL cases but does not affect prognosis in this group of patients. Together, these good-risk patients make up about 25% of patients under 60 years (Figure 31.2), with a tendency to accumulate in the younger age groups. When good-risk patients occur in the older group, they continue to represent a more favourable group, with a survival of 35% compared with an overall survival of 15–20% in that age group in those treated with intensive chemotherapy.

About 15% of younger patients have cytogenetic abnormalities which are associated with a lower remission rate and a relapse risk on conventional chemotherapy of 85%. These can be identified as –5, del(5q), –7, abnormal 3q, t(9;22), and complex (more than three unrelated changes). Such patients need to be identified early because, even if a remission is achieved, it will be short-lived. Currently, transplantation represents the only viable treatment, but even that is associated with a high relapse risk.

Patients who do not fall into the categories described are regarded as standard risk. They have a 5-year survival of 40–45% (Figure 31.7). The impact of this risk stratification is apparent irrespective of chemotherapy used or whether patients receive an allograft or autograft. There are some minor discrepancies between published series, e.g. trisomy 8 and 11q23 are regarded as poor risk in some series. In larger series, it emerges that 11q23 cases with a t(10;11) rearrangement are poor risk (17% survival), whereas other series show in excess of 50% survival in younger patients.

In older patients, the overall survival of chemotherapy is around 15–20% at 5 years; it is therefore less easy to delineate cytogenetic risk subgroups. Adverse groups are more frequent, and favourable subgroups are less common. This in part accounts for the poorer prognosis of AML in older patients. It is still possible to derive a hierarchical risk stratification in the older patients based on similar criteria already described for younger patients. Some extremely poor subgroups can be identified (Figure 31.7b).

Age

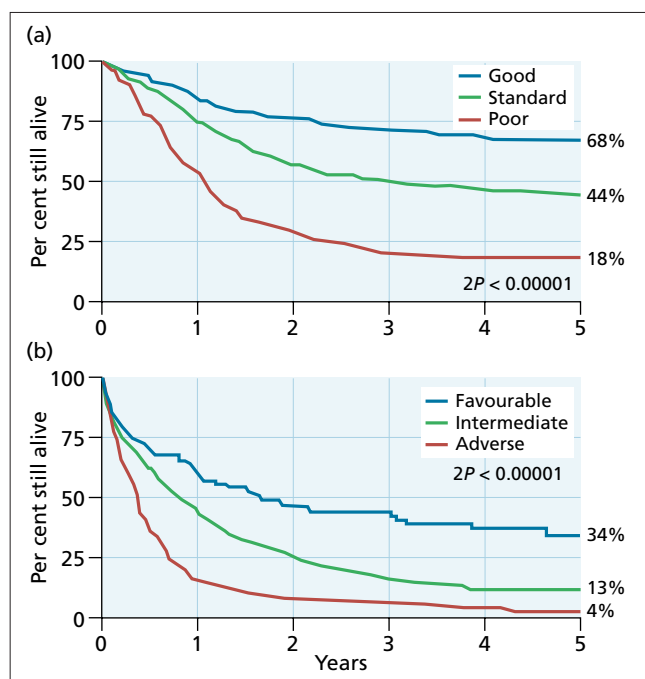
Increasing age from children to the elderly who are given intensive chemotherapy is associated not only with a poorer chance of achieving remission but also with an increasing risk of relapse, even allowing for obvious differences in comorbidities and distribution of cytogenetic risk groups. Leukaemias in the elderly


Figure 31.7 The impact of cytogenetic risk groups on treatment outcome. (a) The survival of patients aged < 60 years with good-risk abnormalities, t(8;21); inv (16); t(15;17), with or without other abnormalities. Poor risk is associated with changes involving chromosome 5 or 7, del 3q or complex abnormalities (more than three abnormalities). The standard-risk group comprises patients who do not have the abnormalities included in the good- or poor-risk categories. (b) The outcome for patients > 60 years old with these abnormalities who were treated with intensive chemotherapy. The relative proportion of those abnormalities in each age group is shown in Figure 31.2.

more frequently express the drug transport proteins associated with chemoresistance, as will be discussed below.

Response to induction chemotherapy

Patients who enter remission with the first course will have a lower relapse risk than those who require a further course. This has been recognized in various ways. For example, the presence of residual blasts in the bone marrow on day 14 can be used as a reason to give additional treatment. The blast percentage in the bone marrow assessed on recovery from the first treatment course has been shown to be highly predictive, i.e. patients who have more than 20% blasts, even though remission is subsequently achieved, will have a high relapse risk. Both cytogenetics and age are related to this response. When the morphological appearances are related to cytogenetic risk group, it is clear that, for good-risk patients, failure to clear the marrow with the first course is not an adverse feature, whereas in poor-risk patients even those who clear blasts in the first course will have a poor

Table 31.4 Relationship between blast status and cytogenetic group after course 1.

Cytogenetic group	CR (%)	PR (%)	RD (%)
Favourable	77	68	76
Standard	49	41	16
Poor	26	24	4

CR, complete remission; PR, partial remission; RD, resistant disease.
Figure 31.8 The impact of the presence of a *FLT-3* mutation on relapse risk in each of the risk groups as shown in Figure 31.7a. The presence of a mutation in good-risk patients is predominantly in the t(15;17) group but does not significantly change the relapse risk in good-risk patients.

prognosis. In standard cytogenetic risk patients, it is those who fail to clear the marrow that have an adverse risk. From such data, a risk definition incorporating cytogenetics and marrow response can be obtained which identifies the standard cytogenetic risk group that fails to clear the marrow in the poor-risk group (Table 31.4). This can be further related to age (Table 31.3), which suggests that the impact of older age is clearest in the standard risk patients who clear marrow blasts.

FLT-3 mutations

Not only has this mutation emerged as the most frequent in AML but several large series conclude that it is also a major prognostic factor, particularly for predicting relapse. It provides additional refinement to cytogenetic predictive groups (Figure 31.8). At the moment, there are insufficient data to suggest that patients with a mutation will benefit from a transplant.

Performance score

In older patients, standard assessments of performance vary considerably. These scores are highly predictive for induction treatment success, and also will inevitably relate to which patients are considered candidates for an intensive approach to treatment.

White blood count

High tumour load is an adverse feature for both induction and relapse risk. The threshold for risk is not definitive. A count of 50×10^9/L is often quoted. In subgroups a prognostic influence is apparent at much lower counts, e.g. in APL a white count at diagnosis of greater than 10×10^9/L is usually agreed as predictive of a higher relapse risk. The impact of a high white count is less than that of cytogenetics but may have isolated value when cytogenetics is not available.

Resistance proteins

One of the important biological differences between disease in the older patient and that in younger ones is the increased frequency in older patients of the expression of proteins involved in drug transport. These are associated with chemoresistance to some of the drugs used in AML, such as anthracyclines and etoposide. Expression also tends to be associated with a stem cell phenotype and adverse cytogenetics. The most widely studied is P glycoprotein (P-gp), which is an energy-dependent transporter protein product of the *MDR1* gene on chromosome 7 and which belongs to the ATP-binding cassette (ABC) transporter family. AML in older patients frequently overexpresses this protein, which has been shown to be predictive for inferior rates of remission and remission durations. The expression levels reported may vary in different series because of differences in techniques of measurement. Quantitative flow cytometry has brought a degree of consistency to measurement, but a functional assessment (of dye efflux) and blockage with P-gp inhibitor is also recommended. *In vitro* preclinical studies have demonstrated that available agents such as cyclosporin or its analogue PSC-833 can block P-gp function; however, only one trial to date has so far shown that using such agents has a clinical benefit. This may be because P-gp is not the only mechanism of chemoresistance.

MRP1 (multidrug resistance protein 1) is another ABC transporter family gene and is located on chromosome 16. Lung resistance protein (LRP) is a subunit of the major vault protein which has been identified in some anthracycline-resistant cell lines and appears to be involved in drug transport. LRP expression has been reported in 30–50% cases of AML in different series, but the majority of studies have been unable to show a correlation with response. MRP expression above normal can be found in 50% of patients with untreated AML, but there is no consensus on its impact on survival (see also Chapter 35).

The impact of prognostic factors on treatment choice

It is becoming routine to take into account the risk of relapse, as defined by some of the factors described, in order to target treatment. The most obvious example is the growing acceptance that transplantation is not required for patients with good-risk disease. Poor-risk patients must be identified promptly and offered either transplantation or some experimental approach since currently available chemotherapy is inadequate. Further data need regarding whether transplant, sibling or unrelated,

significantly benefits high-risk patients are needed. Similar information is also required about the significance of FLT-3 status with respect to the impact of transplantation. Children respond very well to intensive chemotherapy, with the majority enjoying prolonged remissions. Only the small number of children with high-risk features require a first-line transplant approach.

In older patients (> 60 years) either patients or doctors make a judgement at diagnosis as to whether intensive chemotherapy will be beneficial. Prognostic factors such as cytogenetics and performance score can inform this choice. Very poor-risk cytogenetics (e.g. complex changes) carries such a low prospect of success that the question arises as to whether such patients should receive intensive treatment even though they are considered fit enough.

Acute promyelocytic leukaemia

Acute promyelocytic leukaemia (APL) is a special case in which the presence of the t(15;17) predicts sensitivity to treatment with all-*trans*-retinoic acid (ATRA). It has been recognized for more than 20 years that this leukaemia subtype is sensitive to anthracyclines. Experience recently has clearly demonstrated that the combination of ATRA with chemotherapy has made a dramatic improvement, with survival now expected to exceed 80%. Even better prospects are becoming apparent when an anthracycline (idarubicin) and ATRA used together form the backbone of treatment. Simple maintenance with courses of ATRA with orally available agents such as methotrexate and 6-mercaptopurine has been shown in some studies to provide additional benefit. Since the molecular consequences of the t(15;17) are known, evaluation of the role of molecular monitoring is most developed in APL and provides a model for disease monitoring in AML.

Treatment in the older patient

Improvement in survival in older patients over the last 20 years has been much more elusive. With better supportive care, intensive chemotherapy can expect to achieve remission in 50–60% of cases. However, 80% of cases will relapse by 2 years. This result has been achieved with various combinations of induction and consolidation schedules and is not improved by maintenance to any great extent. There will be a greater interest in maintenance in future studies. Because the outcome is poor, two issues arise. Are there prognostic factors which confirm which patients will benefit from an intensive treatment approach? The data are less convincing than in younger patients, but younger age (60–70 years), higher performance score and favourable cytogenetic risk group can identify a minority of patients with a better than average outcome. However, several patients have adverse factors – older age, poorer performance score, complex cytogenetics or a chemoresistant phenotype. These patients will have a worse prognosis, which raises the issue of whether they should receive palliative care from the start. One modestly sized study compared a palliative treatment approach with conventional

chemotherapy. It demonstrated that the use of intensive chemo-therapy, because it achieved remission, was more beneficial in older patients, but to date no study has been large enough to ask that question within the risk groups.

One strategy for improvement is to target the function of P-gp. Only one out of several studies using cyclosporin or its analogue has managed to improve survival in relapsed disease, but other studies combining it with first-line treatment have been unsuccessful. This may be because P-gp is not the only resistance mechanism present in leukaemic cells, and once a cell has become resistant by one mechanism there are already other resistance routes.

Minimal residual disease detection (see also Chapter 34)

The assumption behind assessing minimal residual disease is that it will add greater definition to risk prediction by the prognostic factors already recognized. However, early detection will first have to be validated clinically and then interventions in these situations proved to be superior to intervention at the time of haematological relapse.

Morphology, cytogenetics and fluorescence *in situ* hybridization (FISH) are relatively insensitive techniques to detect residual disease. It is possible, using a large panel of monoclonal antibodies, to delineate in 85% of cases an 'aberrant' immunophenotype at diagnosis. This will be overexpression of an antigen, co-expression of antigens normally associated with different stages of maturation which does not occur in novel haemopoiesis, absence of myeloid antigen expression or expression of non-myeloid antigens.

This is complex and quite expensive technology, but it has been shown in modestly sized series that detection of cells with these phenotypes at a sensitivity of 1 in 10^4 or 1 in 10^5 is possible and can be predictive of relapse. That is, the persistent expression of the aberrant phenotype found at diagnosis is associated with a higher relapse risk. Up to about half of remission cases can have aberrant expression, which trebles the risk of relapse.

Nucleic acid-based approaches involving RT-PCR have been used particularly in APL. The cloning of a number of break-points (Table 31.1) provides the opportunity to utilize a PCR-based approach. Most experience has been gained in APL cases using the PML–RAR-α hybrid protein as the target, with assays with a sensitivity of 1 in 10^4. A number of conclusions have emerged which currently influence clinical practice. If the RT-PCR remains positive after consolidation chemotherapy, the risk of relapse is high (> 70%). However, most of the relapses that subsequently occur are in patients who were found to be negative after consolidation. The majority of patients are molecularly negative at this time point, but 20% will nevertheless relapse.

A strategy of regular monitoring of bone marrow (e.g. 3-monthly) is capable of detecting reappearance of molecular positivity about 3–6 months before haematological relapse. No randomized studies have compared the strategy of retreatment at the time of molecular relapse with intervention at the time of haematological relapse. As the risk of haematological relapse in a patient who was RT-PCR negative but then becomes positive is very high, early intervention in this disease seems justified.

Anecdotal evidence suggests that intervention at molecular relapse has a better outcome than intervention at haematological relapse. Less information is available about monitoring of the *AML–ETO* or *CBFβ–MYH11* fusion genes associated with the t(8;21) and inv(16) translocations. Longitudinal studies using the *AML–ETO* fusion have demonstrated that patients in long-term remission may have molecularly detectable 'disease'. This has been attributed to the presence of transcript in other lineages, e.g. monocytes. It seems probable that molecular data will have to be accumulated for each transcript before firm clinical decisions can be based on this information. The transcripts most amenable to monitoring occur in 20–25% of cases which have favourable-risk cytogenetics with fewer relapses, so large prospective trials will be required to accumulate enough patients, with enough events to clarify the situation. More sensitivity may be added to this approach using quantitative RT-PCR.

Although several other molecular targets are available, they individually represent small numbers of patients. It may be possible to use a more ubiquitously available molecular target. The Wilms' tumour (*WT1*) gene is overexpressed in the majority of AML cases compared with normal haemopoiesis and has been reported to have potential for molecular monitoring in the majority of cases. Mutations of the *RAS* or *FLT-3* genes are not likely to be useful in this context because some cases which have the mutation at diagnosis lose it at relapse and vice versa.

The management of relapse

The majority of patients will relapse. If this happens after a stem cell transplant procedure, the benefit of further therapy is questionable. This is, however, dependent on when the relapse occurs. Within 1 year, further treatment is unlikely to have sustained benefit and retransplantation is usually associated with a very high complication rate. If the relapse occurs later, further chemotherapy with retransplantation may save a few patients. The development of donor lymphocyte infusions has been a very effective approach for the treatment of post-allograft relapse in chronic myeloid leukaemia, but has a low rate of success in AML.

For patients who relapse after chemotherapy, three factors will dictate the clinical outcome – duration of first remission, age and cytogenetic risk group. Patients with good-risk disease have a high (75–80%) rate of second remission. Patients who are young with a long CR1 will have a reasonable survival, whereas older patients with a short CR1 will do poorly (Table 31.5). Since the second remission rate in good-risk disease defined by cytogenetics is relatively good, transplant is usually delayed till second remission. There is no clear 'best choice' chemotherapy for other risk groups, so this is often the setting for experimental therapy development.

Acute promyelocytic leukaemia is again a special case. Patients can respond again to retinoic acid and chemotherapy, but

Table 31.5 Outcome of relapse in patients over 60 years receiving reinduction treatment (*n* = 1529).

(a) Remission rate.

	15–59 years (%)	60–69 years (%)	> 70 years (%)
CR1 (months)			
< 6	15	11	13
6–12	33	29	26
> 12	56	67	53

(b) Survival from relapse at 2 years.

	< 35 years (%)	35–60 years (%)	60 + years (%)
CR1 (months)

6–12	16	14	8
>12	41	27	16

recently arsenic trioxide and the CD33-directed immunoconjugate (gemtuzumab ozogamicin) have been found to be effective. Remission rates of > 80% have been reported and, interestingly, following consolidation therapy, a similar proportion can be returned to RT-PCR negativity. This opens up the opportunity of autologous transplantation, the successful outcome of which depends on the autograft, and preferably the patient being molecularly negative. For patients who remain molecularly positive after reinduction, an allogeneic transplant is indicated.

For non-APL patients, whatever treatment is used to re-establish remission, it is unlikely to be durable without a transplant. Although prospective studies are rare, transplant registry data suggest that about 30% of patients can be salvaged with a transplant with little overall difference whether the source of stem cell is allogeneic or autologous.

Future developments

Classification

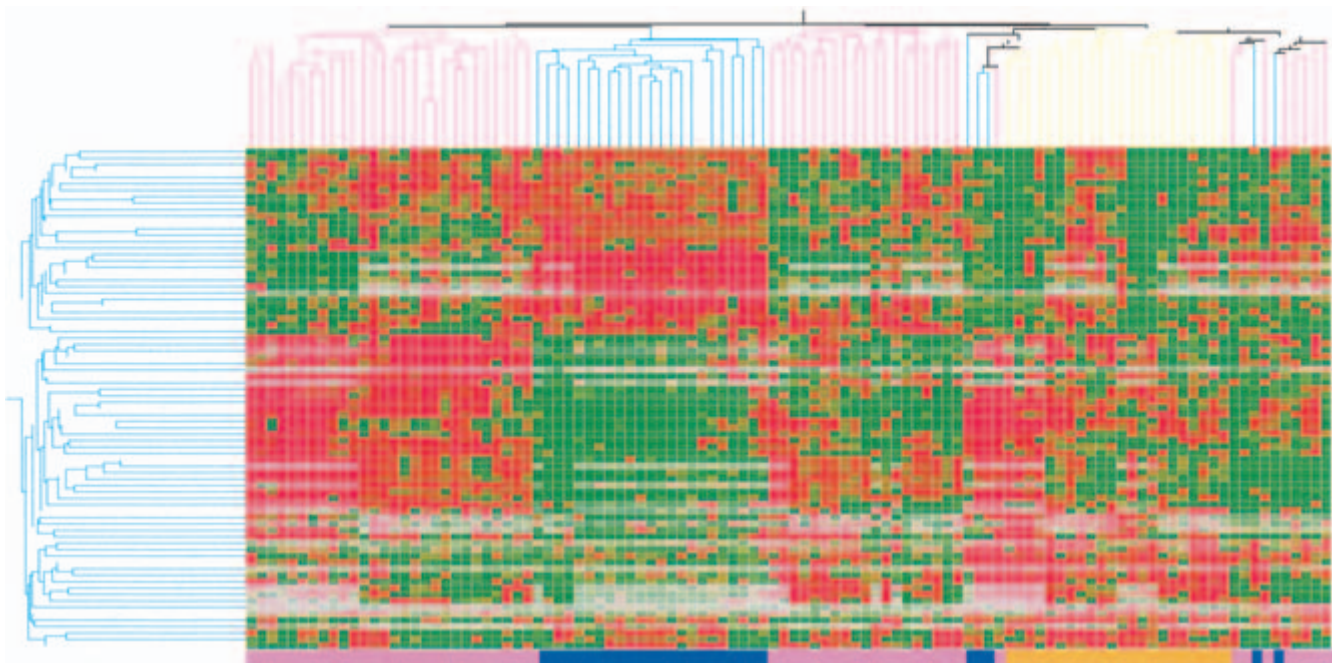
The classification of this disease will no doubt continue the trend of taking into account genetic and clinical features as well as


Figure 31.9 A gene and experiment cluster of AML samples. A gene list was identified from the 22 283-gene probe set on the Affymetrix U133A gene chip, which was capable of predicting cytogenetic risk group. This list was used to cluster the samples into similar groups and cluster genes showing similar expression profiles (within the cluster, red indicates high expression whereas green is low or absent expression). One group for each of the good- and poor-risk groups was obtained, but several clusters of standard-risk patients were identified, which may correlate with the diverse nature of this subgroup. Blue, good-risk patients; pink, standard-risk patients; yellow, poor-risk patients. Note that the right-hand cluster contains patients with good, standard and poor risk.

morphology. The technology could eventually allow subgroups to be identified on the basis of a gene expression signature such as is seen in Figure 31.9. High-density microarray chips representing genes can already distinguish major cytogenetic and FAB groups and the presence of a *FLT-3* mutation. This currently offers no advantage over currently available methods but is only at the developmental stage. It will throw light on associated molecular abnormalities which may eventually become targets for drug design and may be capable of predicting disease or toxicity response. The bioinformatics challenges are considerable given the enormous amount of information that these data produce.

Therapeutics

There is general acceptance that little further progress will be made by simply shuffling currently available drugs with respect to either scheduling or dosage. There may still need to be refinements with respect to toxicity. There is much interest in targeting treatment either by matching the treatment approach to the patient based on prognostic factors or by immunologically directing treatment to leukaemic cells and thereby enhancing the selectivity of treatment. Gemtuzumab ozogamicin is an immunotoxin which is being extensively explored in this respect. This is an immunoconjugate combining an IgG$_4$ anti-CD33 humanized monoclonal antibody with the highly potent antitumour antibiotic calicheamicin. The key to its utility is that, when the antibody combines with CD33 antigen, the complex is rapidly internalized to the cell, where the chemical linker between drug and antibody is lysed. A crucial property is that the linker is lysed only intracellularly and not in the circulation. CD33, although expressed on 90% of cases of AML, is not leukaemia specific. There is expression on haemopoietic precursors but not on stem cells or, as far as is known, other tissues. The conjugate is clearly active. As a single agent, it can achieve complete remission in relapse or as first-line treatment in older patients. Pancytopenia is not avoided and transient hepatotoxicity will be seen in some patients. It does not result in the alopecia or mucositis usually associated with chemotherapy. There are a number of areas for its use under investigation in AML, e.g. use in induction in older patients before chemotherapy; for induction in patients unfit for chemotherapy; as maintenance of remission; as first-line and relapse treatment in APL; as part of transplant conditioning; and in simultaneous combination with conventional chemotherapy. All of these approaches are still experimental.

Allogeneic transplant has proved over the years to be a highly effective immunological approach. However, as previously pointed out, the overall survival advantage is not always clear. Part of the reason is that, because it is only safely applicable to younger patients, it is competing with the group of patients with the most favourable responses to chemotherapy. Non-intensive transplants have demonstrated that it is feasible to achieve full

chimeric status, i.e. 100% donor cells in the bone marrow, without using intensive chemoradiotherapy. This can be done safely in older patients, but there remain concerns about the balance between avoiding relapse on the one hand and GvHD on the other. This could represent a consolidation option for older patients for whom conventional chemotherapy is less successful and where there is an anti-leukaemic effect of standard allograft. The approach presumes that there will be a significant GVL effect operating in AML. There are only preliminary data on this approach in AML, which is still experimental; assessment in a prospective clinical trial is required.

Many small molecules – particularly tyrosine kinase inhibitors – are becoming available for cancer treatment. So far none has matched the impact of Glivec in chronic myeloid leukaemia. The recognition of the *FLT-3* mutation as a common mutation in AML, which autophosphorylates the receptor and downstream molecules, has led to the discovery of a few agents with powerful – but not specific – FLT-3 inhibition. Preclinical models provide considerable encouragement for efficacy. Initial clinical studies show a response in about 50% of patients with relapsed disease, with occasional complete remissions. Because of lack of specificity, it is likely that these agents will need to be used in combination with each other, or with chemotherapy. Inhibitors of the RAS pathway molecules have also had preliminary assessments. Some responses have been seen, but it is also clear that the agents tested are not specific. Since many small molecules will be available for testing novel approaches to clinical trials will need to develop. Either a much greater international collaboration is needed to provide sufficient numbers of the patient subgroups or different statistical methods will be required.

Adult acute lymphoblastic leukaemia

32

Dieter Hoelzer and Nicola Gökbuget

Introduction

Acute lymphoblastic leukaemia (ALL) is a malignant disease characterized by the accumulation of lymphoblasts. In recent adult ALL trials – published between 1999 and 2002 – a trend towards higher complete remission (CR) rates of 80–85% and leukaemia-free survival (LFS) rates of 30–40% has been observed. Intensified consolidation, the extended use of stem cell transplantation (SCT), improvement in supportive care and more experience in treatment centres could have contributed to better outcome. Furthermore, a number of promising new treatment and management modalities for ALL came up including molecular targeting with BCR–ABL kinase inhibitors, antibody therapy and new approaches in SCT. In addition, risk-adapted treatment strategies have been developed over many years and risk models are continuously amended by new prognostic factors, e.g. by evaluation of minimal residual disease (MRD).

Diagnosis

Classification of blast cell phenotype in adult ALL requires morphological and cytochemical evaluation, immunophenotyping, cytogenetic and molecular genetic analysis. Morphology remains the method by which acute leukaemia is initially detected and, together with cytochemical reactions, is the major aid in distinguishing between ALL and acute myeloid leukaemia (AML). For more precise subclassification of ALL into B or T lineages, immunological techniques must be used to detect lineage-specific antigens as well as surface or intracytoplasmic molecules. Cytogenetic analysis is still a prerequisite for diagnosis of ALL because it has prognostic value, but molecular genetic techniques for identification of particular subsets of ALL (e.g. BCR–ABL-positive ALL) are of increasing importance. Molecular markers, particularly rearrangements of T-cell receptor (TCR) and immunoglobulin heavy-chain (IgH) genes, are presently used to evaluate therapeutic efficacy in individual patients by detection of MRD (see Chapter 34).

Morphology

The cytological features of leukaemic blast cells in ALL and their division into L1 to L3 according to the French–American–British (FAB) classification are discussed in Chapter 29. The distribution of L1 and L2 subtypes is of minor relevance for prediction of outcome in ALL. The subtype L3, observed in approximately 5% of adult ALL patients, should, however, be identified because it is indicative for mature B-cell ALL, which is subject to different treatment. The diagnosis should be confirmed by surface marker analysis.

Cell surface marker analysis

Acute lymphocyte leukaemia is divided into subtypes by immunological criteria based on the presence of specific receptors or antigens on the cell surface of leukaemic blast cells. Within the B- or T-lineage ALL, the subtypes are defined according to their stage of differentiation. For more details on the immunological

Table 32.1 Immunological classification, corresponding cytogenetic and molecular aberrations and frequencies in adult ALL.

	Adults (%)*	Surface marker	Cytogenetics**	Molecular genetics**
B-lineage		HLA-DR$^+$, TdT$^+$, CD19$^+$ and/or CD79a$^+$ and/or CD22$^+$		
Pro B-ALL	11	No further differentiation markers	t(4;11)	ALL1(MLL)-AF4
Common-ALL	50	CD10$^+$	t(9;22)	BCR-ABL
Pre B-ALL	12	CD10$^{+/-}$, cytoplasmic immunoglobulin (cyIgM$^+$)	t(9;22), t(1;19)	BCR-ABL; E2A-PBX1
B-ALL	5	CD10$^{+/-}$, surface immunoglobulin (sIgM$^+$)	t(8;14)	CMYC-IgH
T-lineage		TdT$^+$, cytoplasmic CD3 (cyCD3)$^+$ or surface CD3 (sCD3)$^+$		
Early T-ALL	6	cyCD3$^+$, CD7$^+$, CD5 $^{+/-}$, CD2 $^{+/-}$	t(11;14)	LMO1/–TCRa/d
Cortical T-ALL (Thy ALL)	10	cyCD3$^+$, CD7$^+$, CD1a$^+$, sCD3$^{+/-}$	t(10;14)	HOX-11-TCRa/d
Mature T-ALL	6	sCD3$^+$, CD1a$^-$

classification of ALL, see Chapter 29. The frequency and definition of subtypes in adult ALL is given in Table 32.1. The European Group for the Immunological Characterization of Acute Leukaemia (EGIL) has proposed a unified classification for ALL immunophenotypes.

B-lineage ALL

Pro-B ALL, also termed *pre-pre-B ALL* or early pre-B, is CD10 negative and lacks specific B- or T-cell differentiation markers but expresses human leukocyte antigen (HLA)-DR, TdT and CD19, and has rearranged immunoglobulin genes (Table 32.1). It occurs in approximately 9–11% of adult ALL.

Common ALL (c-ALL) is the major immunological subtype in adult ALL. It constitutes > 50% of cases of adult ALL. C-ALL is characterized by the presence of CD10 (Table 32.1). Blast cells do not express markers that characterize relatively mature B cells such as cytoplasmic or surface membrane immunoglobulins. The blast cells are positive for CD19 and TdT.

Pre-B ALL is characterized by the expression of cytoplasmic immunoglobulin, which is absent in common ALL, but is identical to common ALL with respect to the expression of all other cell markers (Table 32.1).

Mature B-cell ALL is found in approximately 5% of adult ALL patients. The blast cells express surface antigens of mature B cells, including surface membrane immunoglobulin. CD10 may be present, as well as, occasionally, cytoplasmic immunoglobulin (Table 32.1).

T-lineage ALL

Approximately 22% of adult ALL cases have blast cells with a T-cell phenotype. All cases express the T-cell antigen gp40 (CD7), and they may, according to their degree of T-cell differentiation,

express other T-cell antigens [e.g. the E rosette receptor (CD2) or the cortical thymocyte antigen T6 (CD1)] (Table 32.1). A minority of T-cell ALL blast cells expresses CD10 together with T-cell antigens. In most cases of T-cell ALL, one or more of the T-cell receptor genes are rearranged. These properties make it possible to classify T-cell ALL according to their stage of differentiation.

Early T-precursor ALL accounts for 6% of adult ALL. It shows characteristic T-cell markers (cyCD3 and CD7) but no further differentiation markers.

Thymic (cortical) T-ALL is the most frequent subtype of T-ALL (10%). It is characterized particularly by the expression of CD1a. Surface CD3 may be present. Since this subtype is associated with a better prognosis, its identification is of particular importance.

Mature T-ALL has a frequency of 6%. The blast cells do not express CD1a but they are positive for surface CD3.

Clinical relevance of cytogenetic and molecular genetic analysis in adult ALL

Cytogenetic abnormalities are independent prognostic variables for predicting the outcome of adult ALL. In three multicentre studies, clonal chromosomal aberrations could be detected in approximately 62–85% of adult ALL patients.

The Ph chromosome t(9;22)(q34;q11) results from a translocation involving the breakpoint cluster region of the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. PCR analyses revealed an incidence of 20–30% *BCR–ABL*+ ALL in adult compared with 3% in childhood ALL patients. One-third of adult ALL patients with a Ph chromosome show M-*BCR* rearrangements (resulting in a 210-kDa protein), similar to patients

with chronic myeloid leukaemia (CML), whereas two-thirds have m-*BCR* rearrangements (resulting in a 190-kDa protein). It is noteworthy that *BCR–ABL* is more frequently detected than the corresponding chromosome abnormality t(9;22) because of occasional difficulties in obtaining adequate material for cytogenetic analysis (see also Chapter 30).

The most frequent form of 11q23 abnormalities in ALL is t(4;11)(q21;q23). The translocation is frequently detected in infant leukaemia and in patients with the pro-B ALL subtype (CD10 negative). The overall incidence in adults is approximately 5%. Typical molecular aberrations in ALL with associated cytogenetic translocations and immunological subtypes are summarized in Table 32.1.

The role of cytogenetic analysis in adult ALL has to be re-evaluated critically. The most frequent cytogenetic aberrations and those with the largest prognostic impact can also be detected by the corresponding molecular genetic abnormalities, as mentioned above. These techniques are more reliable and have a greater sensitivity, e.g. a detection level of more than 10^{-6} for BCR–ABL. They are, therefore, more useful for initial detection of the aberrations and for follow-up analysis of minimal residual disease (see below). In addition, the observed incidence of the majority of cytogenetic aberrations is very low and therefore a correlation to clinical outcome and even more therapeutic consequences are limited. Nevertheless, cytogenetic analysis is still recommended as a routine diagnostic method in ALL.

Clinical manifestation

Most adult ALL patients initially present with clinical symptoms resulting from bone marrow failure. Physical findings such as pallor, tachycardia, weakness and fatigue are due to anaemia; petechiae or other haemorrhagic manifestations are attributable to thrombocytopenia; infectious complications are due to neutropenia. Clinical signs of leukaemia related directly to infiltration of typical organs with leukaemic blasts, such as lymphadenopathy, splenomegaly, and hepatomegaly, are present in most patients but are infrequently the problems for which the patient first seeks medical advice.

Symptoms and clinical manifestations of adult ALL patients, 15–65 years of age, entering two consecutive German multicentre trials are given in Table 32.2 according to their appearance in the different immunological subtypes. One-third had infection or fever at presentation, and one-third presented with haemorrhagic episodes. Weight loss was observed only occasionally. Approximately one-half of the patients presented at diagnosis with lymphadenopathy, splenomegaly and hepatomegaly, and hilar lymph node enlargement or a thymic mass (detected on chest radiographs or computerizd tomography scans) in approximately 14% of patients. Most patients (85%) with mediastinal masses had T-cell ALL. Massive thymic enlargement can cause dyspnoea, especially when associated with pleural effusions. Although 7% of ALL patients at presentation had central nervous system (CNS) involvement (as demonstrated by leukaemic blast cells in the cerebrospinal fluid), only 4% of these initially had CNS symptoms such as headache, vomiting, lethargy, nuchal rigidity and cranial or peripheral nerve dysfunction.

Virtually any organ can be infiltrated by ALL blast cells, and approximately one-tenth of the patients had such organ involvement but with a wide variation between subtypes (Table 32.2). Most often a pleural effusion was observed, and this occurred almost exclusively in those patients with mediastinal enlargement and T-cell ALL. Some of those patients also had a

*$n = 640$ patients of GMALL studies 03/87 and 04/89.

pericardial effusion. Bone or joint pain was rarely observed compared with childhood ALL; bone lesions could be found in only 1% of cases. Initial involvement of the testis was very rare (< 1%). Leukaemic infiltration of retina, skin, tonsils, lung, or kidney was observed only occasionally, particularly in mature B-cell ALL and to a lesser extent in T-cell ALL, all of them associated with a poorer outcome.

Laboratory evaluation

The peripheral blood cell values at diagnosis of the same cohort of patients are given in Tables 32.3 and 32.4, which again shows differences between the subtypes of adult ALL. Overall, the leucocyte count was elevated in 59% of the cohort, 14% had normal counts and 27% had leucopenia. In 92% of the patients, leukaemic blast cells were seen in the blood film. Thus, 'aleukaemic' leukaemias account for only a small proportion of cases of adult ALL. With automated blood counting, the diagnosis may be missed in patients with normal or decreased white blood cell (WBC) counts and with low or zero blast cells in peripheral blood. In any case, but also for this reason, microscopic examination of blood films in people suspected of having acute leukaemia is an absolute requirement. An elevated blood count $> 100 \times 10^9$/L was observed in 16% of the patients, and occasionally WBC counts $> 500 \times 10^9$/L occurred. In general, a high WBC count is found more frequently in T-cell ALL patients compared with those with B-lineage ALL (Table 32.3).

Neutrophils $< 500 \times 10^6$/L were seen overall in 23% of the patients. Severe neutropenia at diagnosis is observed more often in B-precursor ALL (28%). Thrombocytopenia $< 25 \times 10^9$/L occurred in one-third of adult ALL patients, corresponding roughly with the symptoms of infection and bleeding present at diagnosis. Anaemia at diagnosis is observed in most adult ALL patients, but only in a small proportion is it severe with haemoglobin < 8 g/dL (Table 32.3).

Bone marrow aspiration or biopsy is mandatory for diagnosis of ALL. In < 15% of patients, the bone marrow cannot be aspirated and a biopsy must be performed. Dry taps are due to densely packed blast cells, fibrosis, or inadequate technique; the first two resolve after therapy. Most patients have > 50%, or even > 90%, of blast cells in the bone marrow. In < 3% of cases, the blast cells constitute < 50% of the nucleated marrow cells.

A lumbar puncture should be done to determine whether the CNS is involved. If there is a risk of bleeding as a result of a very low platelet count, or of blast cell contamination due to a high leukaemic blast content in the peripheral blood, lumbar puncture should be postponed. When the leucocyte count in the spinal fluid is low or the morphological detection of blasts is inconclusive, demonstration of an immunologically defined blast cell population can confirm a diagnosis of CNS involvement.

The most frequent metabolic abnormality is an increased serum uric acid level in approximately one-half of the patients;

Table 32.4 Coagulation parameters at the time of diagnosis in adult ALL*.

	Value	Patients (%)
Fibrinogen (g/L)	< 1	4
	> 1	96
Prothrombin time (%)	< 50	7
	50–75	34

	40–50	11
	> 50	3

*$n = 640$ patients of GMALL studies 03/87 and 04/89.

hypercalcaemia is rare. Serum lactate dehydrogenase (LDH) is often elevated as a result of cell destruction in patients with a large tumour mass. In a small proportion of patients (Table 32.4), the initial fibrinogen level was < 1 g/L. Disseminated intravascular coagulation in ALL was rarely observed at diagnosis.

Differential diagnosis

Difficulty is rarely experienced in establishing the diagnosis of ALL. The differentiation from lymphocytosis, lymphadenopathy and hepatosplenomegaly in viral infections and other acute or chronic leukaemias can usually be done by lymphocyte surface markers.

Aleukaemic pancytopenic ALL patients without blast cells in peripheral blood (< 10%) have to be distinguished from those with aplastic anaemia, which may also be a preleukaemic syndrome. In contrast to ALL, in aplastic anaemia the bone marrow is hypocellular. In rare cases with low bone marrow infiltration, an arbitrary distinction between ALL and lymphoblastic NHL is usually chosen according to the degree of infiltration, above or below 25%.

Mixed or hybrid leukaemias are those in which blast cells express lymphoid as well as myeloid antigens; they may also be termed biphenotypic or bilineage leukaemias. Biphenotypic leukaemias are defined as those in which markers of lymphoid and myeloid lineages are co-expressed on the same leukaemic cells. The European Group for the Immunological Characterization of Leukemia (EGIL) has suggested a scoring system which is helpful for definition of biphenotypic leukaemia depending on the type and degree of expression of lymphoid and myeloid markers. Bilineage leukaemias are those with two populations of blast cells that have either lymphoid or myeloid antigens and might be allocated to a treatment strategy either for ALL or for AML. After start of therapy with either regimen, one population may disappear whereas the other is maintained and may require a shift of therapy (see also Chapter 31).

Occasionally, difficulties can occur in distinguishing Ph/ BCR–ABL-positive ALL from primary lymphoid blast crisis of CML. Sometimes final diagnosis can be done only after treatment initiation. In ALL patients achieving complete clinical remission (CR), the peripheral blood count shows normal values, whereas CML cases may revert to a chronic phase with pathological leftshift.

Initial evaluation and supportive therapy

Speed in clinical evaluation and diagnosis is important in order to initiate supportive measures and to decide on appropriate therapy. In only a few cases is the leukaemic process so advanced that immediate treatment is necessary (e.g. in patients with symptoms due to a large mediastinal mass and pleural effusion, a very high WBC or a rapidly progressing B-cell ALL).

A few general measures should be initiated at once. Sufficient fluid intake to guarantee urine production of 100 mL/h throughout induction therapy should be maintained to reduce the danger of uric acid formation. Patients should also receive allopurinol to reduce the formation of uric acid and avoid the danger of urate nephropathy. Allopurinol blocks the enzyme xanthine oxidase, which mediates the generation of uric acid from xanthine as a product of purine catabolism. Allopurinol should be given at a dose of 300 mg/day, which may be increased to 600 mg/day if high leucocyte counts or organomegaly persist. The dose of allopurinol has to be reduced when 6-mercaptopurine is given because it potentiates the action of 6-mercaptopurine. Rasburicase is a new recombinant uratoxidase enzyme which catalyses the oxidation of uric acid to allantoin. Rasburicase can reduce high uric acid faster and more safely than allopurinol, thereby preventing a tumour lysis syndrome in almost all cases. It might therefore be an alternative in patients with high risk of tumour lysis syndrome.

Parenteral fluid administration may be required when the patient's oral intake is inadequate because of nausea or difficulty in swallowing. Placement of an implantable port system is advantageous when anticipating a long period of induction therapy or when part of the therapy will be carried out on an outpatient basis (see also Chapter 36).

Blood substitution

In general, platelet transfusions should be given in response to bleeding episodes and to prevent bleeding when platelet counts fall to < 10×10^9/L and to < 20×10^9/L when there is a bleeding tendency or the patient is febrile. Most often, 4–8 units of platelets are given daily until bleeding ceases. HLA-matched platelets are given to patients who become refractory to random donor platelets. The incidence of fatal haemorrhage during induction therapy has been significantly lowered by these measures. Red cell transfusions have a lower priority than platelet substitution. They should be given according to haemoglobin value (always if haemoglobin below 8 g/dL) but depending on age, comorbidity (e.g. cardiac) and clinical symptoms. The clinical benefit of granulocyte transfusions in patients with severe infections is under investigation.

Infection management

The use of more intense cytostatic regimens has resulted not only in improved response rates of malignancies but also in higher infection-associated morbidity and mortality. Long-term neutropenia is the most important risk factor, but CD4 lymphopenia, antibody deficiency and multiple immunosuppression in allogeneic stem cell transplantation also lead to severe and lethal infections. Whereas formerly Gram-negative microorganisms were the leading cause of febrile neutropenia, in the last decade Gram-positive bacterial infections, mostly caused

by staphylococci, have increased and are frequently correlated with indwelling central venous access. Invasive fungal infections are, however, the most dangerous development, with increasing frequency particularly of mould infections. The successful management of febrile neutropenia is based on hygienic procedures including body hygiene, germ-reduced food, reverse isolation or high-efficiency particulate air filtration, antibiotic prophylaxis, sufficient diagnostics, and consequent empirical antimicrobial therapy.

For antibacterial prophylaxis, cotrimoxazole or fluorochinolones, both mainly directed against Gram-negative organisms, have mostly been used. Cotrimoxazole also reduces the incidence of *Pneumocystis carinii* pneumonia, which occurs in approximately 20% of ALL patients without prophylaxis. Although antifungal prophylaxis with oral amphotericin B solution or triazoles may successfully reduce *Candida* colonization and prevent local *Candida* infections, the prophylactic procedures for reducing systemic mycoses are disappointing. Fluconazole has been reported to reduce only systemic *Candida albicans* infections in SCT patients, but non-*albicans* infections, especially by fluconazole-resistant *Candida krusei*, are emerging. Because of its high mortality and difficulty in diagnosis, *Aspergillus* infection is a particular problem. Attempts to prevent aspergilloses have included prophylaxis with itraconazole, intravenous low-dose amphotericin B, liposomal amphotericin B and inhalation of aerosolized amphotericin B, but in randomized studies no clear benefit could be shown. In febrile neutropenia, early diagnostic procedures are necessary. They include physical examination, microbiological investigations, imaging procedures and biopsies. Cultures of blood, urine, sputum and other infected areas are mandatory. *Aspergillus* galactomannan antigen test (Platelia) may aid diagnostic efforts in suspected aspergillosis. Furthermore, PCR methods are investigated for early detection of fungal infections. Imaging procedures such as chest radiography and abdominal ultrasound are routine diagnostic tools. High-resolution computerized tomography of the lungs is one of the most important diagnostic steps for the early diagnosis of *Aspergillus* pneumonia. Fungal pneumonias also may be microbiologically proven with bronchoalveolar lavage or biopsy.

Successful treatment of febrile neutropenia is based on immediate empirical administration of broad-spectrum antibiotics. As initial therapy, combinations such as β-lactam antibiotics plus aminoglycosides or monotherapy (e.g. with carbapenems, piperacillin-tazobactam or cephalosporins of class 3 and 3a) are standard. In view of the increasing problems of invasive fungal infections, empiric antifungal treatment with amphotericin B or fluconazole for patients with refractory fever or pulmonary infiltration has been established. So far, conventional amphotericin B, amphotericin lipid formulations, 5-flucytosine, fluconazole and itraconazole represented antimycotic standard treatment in proven or suspected invasive mycoses. This standard, however, is nowadays changing by introduction of high-potency new antimycotics such as voriconazole (particularly effective in the treatment of aspergillosis, but also of fluconazole-resistant candidosis or fusariosis) and caspofungin (successful treatment for candidoses and aspergilloses).

Haemopoietic growth factors

The use of haemopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) is a valuable component of supportive therapy during the treatment of ALL (Table 32.5). There is no indication so far that these CSFs stimulate leukaemic cell growth in a clinically significant manner.

Most clinical trials demonstrate that the prophylactic administration of G-CSF significantly accelerates neutrophil recovery, and several prospective, randomized studies also show that this is associated with a substantially reduced incidence and duration of febrile neutropenia and of severe infections in ALL, and also reduced induction mortality.

The scheduling of G-CSF is of great importance. When G-CSF is first given at the end of a 4-week induction chemotherapy regimen, potential benefits are limited. Therefore, it is noteworthy that G-CSF may even be given in parallel with chemotherapy without aggravating the myelotoxicity of these specific regimens and that this scheduling is an important determinant of the clinical efficacy. On the other hand, after short consolidation cycles G-CSF treatment may be postponed.

A closer adherence to the dose and schedule of chemotherapeutic regimens should be theoretically possible by the use of G-CSF. A benefit in terms of long-term outcome by increased dose intensity achieved by the use of G-CSF has not yet been demonstrated in any trial.

Chemotherapy

Chemotherapy of ALL is usually divided into several phases, beginning with remission induction. The objective of induction chemotherapy is to achieve CR, i.e. eradication of leukaemia as determined by morphological criteria and, more recently, also by molecular markers. The post-remission therapy usually consists of intensification or consolidation cycles and maintenance treatment. Most often specific prophylactic CNS treatment is added (Table 32.6).

Remission induction therapy

Correct diagnosis and management of the initial complications are the prerequisites for successful induction therapy. A cautious cell reduction phase is often recommended for patients with a large leukaemic cell burden or a high leucocyte count. Patients with extreme leucocytosis ($> 100 \times 10^9$/L) have been treated initially with leukapheresis, but these patients can also be managed with steroids in combination with vincristine or cyclophosphamide. For mature B-cell ALL, initial treatment with

Table 32.5 Trials of G-CSF in adult ALL.

NR, no response.

cyclophosphamide and prednisone for 1 week usually results in a safe reduction of large tumour masses, in most cases without tumour lysis syndrome.

Standard induction therapy for ALL includes prednisone, vincristine, anthracyclines (mostly daunorubicin) and also L-asparaginase. Further drugs, such as cyclophosphamide, cytarabine (either conventional or high dose), mercaptopurine and others, are added in many protocols, sometimes named as early intensification.

Prednisone and prednisolone have been most frequently administered, although *dexamethasone* shows a higher anti-leukaemic activity *in vitro* and a better penetration of the cerebrospinal fluid. Extensive use of dexamethasone may, however, be associated with an increased risk of septicaemias and fungal infections which may be circumvented if treatment time and dose is reduced.

Anthracycline dose intensity and schedule may play an important role in induction therapy of ALL. In the past daunorubicin was mostly administered at a weekly schedule, but recently many trials include dose intensification with doses of 30–60 mg/m^2 at a 2–3 day schedule. Intensive anthracycline therapy may be associated with a higher induction mortality. Therefore, intensive supportive care and probably the use of growth factors is recommended with these types of protocols.

Asparaginase (A) does not affect the CR rate but improves LFS. If not used during induction therapy, it is often included as part of the consolidation treatment. Three different A preparations with significantly different half-lives are available: native *E. coli* A (1.2 days), *Erwinia* A (0.65 days) and PEG-L-A (5.7 days). The availability may vary between different countries. In order to reach equal efficacy, the application schedule has to be adapted and is generally daily for *Erwinia*, every second day for *E. coli* and 1–2 weekly for PEG-L-A.

The role of *cyclophosphamide* (C) – generally administered at the beginning of induction therapy – has been evaluated in several studies. A randomized study by the Italian GIMEMA group comparing a three-drug induction with or without C did not show a difference in terms of CR rate (81% vs. 82%). However, in several non-randomized trials, high CR rates (85–91%) were achieved with regimens including C pretreatment, particularly in adult T-ALL.

High-dose treatment

A more recent strategy is to add high-dose cytarabine (HDAC) before or after the standard induction therapy. This approach has resulted in a median CR rate of 79%, which is not superior to that obtained with conventional treatment, and it remains uncertain whether, and for which subgroups, it may be beneficial for LFS. Up-front treatment before conventional chemotherapy yielded higher CR rates than treatment afterwards, which was in part related to a higher induction mortality (reviewed in Gökbuget and Hoelzer 2002). Furthermore, any type of induction therapy with HDAC may lead to an increased incidence of severe neutropenias after subsequent chemotherapy cycles. The relatively high early mortality rate is now decreasing with better handling and improved supportive care. Overall, the aim of HDAC treatment is not only to improve the CR rate but, even more, to increase the quality of remission. This means that a lower tumour load should lead to a better LFS. So far, however, no convincing results are available to support this hypothesis.

In conclusion, all approaches for induction therapy including high-dose treatment result in a CR rate of approximately 80% in adult ALL. However, the molecular CR rate is clearly lower and the addition of new therapeutic approaches – other than chemotherapy – such as molecular targeting or antibody

Table 32.6 Overall treatment results in adult ALL in larger studies*.

treatment may be the future approach to increase the molecular CR rate.

Failure of induction therapy

Twenty per cent of adult ALL patients do not achieve CR after induction therapy, in contrast to < 3% of children with ALL. Mortality during induction is age dependent, increasing with age from < 3% in adolescents to 20% in patients > 60 years of age. The main cause of death in approximately two-thirds of the patients is infection, in part fungal infection. The remaining non-responders may achieve a partial remission or may be refractory to standard treatment. These patients have an extremely poor prognosis. They are therefore candidates for experimental treatment approaches or consideration for a SCT, even if not in CR but in good partial remission.

Consolidation therapy

Consolidation therapy refers to high-dose chemotherapy, to the use of multiple new agents, or to readministration of the induction regimen. These measures are aimed at eliminating residual leukaemia after induction chemotherapy and thereby preventing relapse as well as emergence of drug-resistant cells.

In adult ALL, intensification therapy can prolong LFS (see Table 32.6). Intensification schedules include teniposide, etoposide, m-amsacrine, mitoxantrone, idarubicin and HDAC, or intermediate- or high-dose methotrexate (HDMTX). Allogeneic SCT from sibling or unrelated donors or autologous SCT is now the major approach for intensive post-induction therapy in high-risk patients. But also, before SCT, consolidation therapy is usually given to achieve a CR of good quality.

High-dose chemotherapy

High-dose chemotherapy in consolidation has been used mainly to overcome drug resistance or to achieve therapeutic drug levels in the cerebrospinal fluid.

High-dose cytarabine

Although there is considerable experience with high-dose cytarabine (HDAC) for the treatment of ALL, it remains uncertain what dose is optimal; usually doses ranging from 1–3 g/m^2 every 12 h for 4–5 days are given within several combinations. HDAC has been included in several trials in adult *de novo* ALL as part of consolidation therapy or during induction and consolidation treatment. With a weighted mean for the LFS of 30% (26–50%), the results are not superior to trials without HDAC.

It seems that specific subgroups of ALL benefit from a HDAC treatment; thus, encouraging results are achieved for paediatric B-cell ALL. It remains uncertain to what extent HDAC contributes to the effects of HDMTX in these patients. Apparently also for adult pro-B ALL, HDAC is beneficial, since cure rates of 50% can be achieved. For other adult poor-risk groups, particularly Ph$^+$ ALL, HDAC is apparently not improving the outcome.

An additional argument for the use of HDAC might be its effectiveness in treating CNS leukaemia. There is evidence that in ALL and NHL, higher levels of AC triphosphate can be reached with 3 g/m^2 than with the lower dose of 1 g/m^2 AC; in addition, with the higher dose, the cerebrospinal fluid can be cleared of blast cells.

High-dose methotrexate (HDMTX)

The use of HDMTX has been extensively studied for the treatment of childhood ALL and, to a lesser extent, adult ALL. A wide range of doses (0.5–8 g/m^2) has been used. HDMTX appears to be effective in preventing systemic and testicular relapses.

The effect of HDMTX on CNS leukaemia may contribute to the favourable results reported with its use. Overall, the intensive use of HDMTX may have had a major in improvement of outcome in paediatric B-lineage ALL.

Several studies have investigated the efficacy of HDMTX in adult ALL – as consolidation or during consolidation and induction treatment. The weighted mean for LFS of six studies, which also comprised a variety of other drugs, is 41%, with a wide range (31–56%). Most favourable results have been achieved in small trials with HDMTX as part of intensive multidrug consolidation regimens.

The combination of cycles having HDAC with cycles having HDMTX during consolidation was reported from six trials with a weighted mean for LFS of 32% (17–48%). Thus, there is some evidence that the inclusion of HDAC and HDMTX as part of multidrug consolidation treatment may improve overall results.

Maintenance therapy

The aim of maintenance or continuation therapy is to eliminate minimal residual disease (MRD). The optimal form and duration of maintenance therapy remains open but can hopefully be better defined by tailoring according to MRD.

Currently maintenance therapy in adult ALL is being revised; according to MRD (e.g. none for MRD-negative patients), to ALL subtype (e.g. none for mature B-ALL) and including new therapeutic options (e.g. a tyrosine kinase inhibitor for BCR–ABL-positive ALL).

Prophylaxis of central nervous system leukaemia

Central nervous system leukaemia occurs in 6% (1–10%) of patients with adult ALL at diagnosis, with a higher incidence in T-cell ALL (8%) and mature B-cell ALL (13%).

Treatment and prophylaxis of CNS leukaemia may consist of intrathecal methotrexate alone or in combination with AC or prednisone, an intraventricular therapy, systemic treatment with HDAC or HDMTX or cranial irradiation.

Adult ALL patients who did not receive specific prophylactic CNS treatment in earlier trials have a CNS relapse rate of 30% (29–32%), similar to that observed in children without CNS prophylaxis. With intrathecal chemotherapy alone, the rate of

isolated and combined CNS relapses could be reduced to 13% (8–19%). Intermittent injections during maintenance therapy improves the efficacy compared with only a few doses during induction treatment. In most adult ALL trials, additional prophylactic CNS irradiation (24 Gy) has been included. Long-term toxicities are apparently less severe than in paediatric patients. This combined approach further reduces the CNS relapse rate to 9% (3–19%). There is some evidence that early irradiation after remission induction is superior to delayed irradiation during consolidation treatment. It is questionable whether systemic high-dose treatment alone provides sufficient CNS prophylaxis because the CNS relapse rate is approximately 14% (10–16%). In many recent trials, combined treatment approaches have shown high efficacy. For high-dose chemotherapy together with intrathecal therapy, the rate of CNS relapses was 7% (2–16%); with additional CNS irradiation, the relapse rate was 6% (1–13%). The efficacy of intensified CNS prophylaxis was also demonstrated in a retrospective analysis from the MD Anderson Cancer Center, where the lowest CNS relapse rate (2%) was achieved in a trial with early high-dose chemotherapy and intrathecal therapy for all patients.

Because the risk for CNS relapse is associated with other prognostic factors such as T-cell ALL, B-cell ALL, extreme leucocytosis, high leukaemia cell proliferation rate, high serum LDH levels, and extramedullary organ involvement, a risk-adapted CNS prophylaxis has been suggested. This approach, however, in contrast to childhood ALL, is not widely used in adults.

Therapy for relapsed and resistant leukaemia

Patients who fail to achieve CR or those who relapse subsequently have been treated with a variety of protocols. The use of regimens including vincristine, anthracyclines, and steroids, similar to standard induction treatment, led to CR rates of approximately 60% in earlier studies but these patients generally had no intensive first-line treatment.

High-dose AC has been extensively studied in relapsed adult ALL. From several small pilot studies comprising < 100 patients, the weighted mean CR rate was 37%. Higher CR rates (50–60%) were achieved with combination regimens that included HDAC and mitoxantrone, amsacrine or vincristine plus steroids. Because HDAC is increasingly administered during front-line treatment, its efficacy during relapse treatment may be impaired. Therefore, new combinations with idarubicin (46–64% CR rate) or fludarabine (67–83% CR rate) or other agents have been evaluated. Median remission duration did not exceed 5 months.

The most significant predictive factor for treatment response in relapsed patients is the duration of first remission. Patients with longer previous remission (> 18 months) have a higher CR rate and longer remission duration than those with a short previous remission (< 18 months).

For all chemotherapy regimens, the duration of second remission is usually short (< 6 months), and the long-term survival rate with chemotherapy alone is < 5%. Thus, the only curative chance for adult patients with relapsed or resistant ALL is SCT, and the major aim of relapse treatment is the induction of a second remission with sufficient duration to prepare SCT.

Stem cell transplantation

Stem cell transplantation (SCT) from peripheral blood and to a lesser extent from bone marrow is the major post-remission strategy for eradication of residual disease in adult ALL. Prognostic factors for remission duration after chemotherapy (i.e. age, WBC count, immunophenotype, BCR–ABL status) are also predictive for the outcome after SCT (see also Chapter 25).

Allogeneic SCT from sibling donors

The outcome of allogeneic SCT for ALL depends on the age and remission status of the patient. The best results have been obtained with patients transplanted during first remission, among whom the probability of survival is approximately 50% (Table 32.7). After allogeneic SCT in second remission, the LFS rate is 34% and in advanced ALL (refractory or in relapse), allogeneic SCT results in an 18% long-term survival rate (Table 32.7).

There is evidence that a graft-versus-leukaemia (GvL) effect is also present in ALL, as indicated by several observations, such as lower relapse rates in patients with acute and/or chronic GvHD, lower recurrence rates after matched unrelated donor (MUD) SCT, induction of remission by withdrawal of prophylaxis against GvHD or donor lymphocyte infusions (DLI) in single patients with relapsed ALL. However, DLI applied in patients with relapse after SCT in order to induce GvL have a response rate of only 15% in ALL, which is much lower than the 40% in AML or 70–80% in CML.

Matched unrelated SCT

The use of SCT from MUDs has constantly increased in recent years in order to overcome the limitations of sibling donor, but also to exploit GvL effects. It can result in long-term survival of about 40% for patients transplanted in first CR and 25% for patients in CR2 (Table 32.7). The low relapse rate of 10% for patients in CR1 strengthens the hypothesis of a GvL effect. The high rate of transplant-related mortality (TRM) of approximately 40% in CR1 patients is still the major obstacle in MUD SCT. This might be reduced by improved donor selection, less toxic preparative regimens, better management of GvHD and improved supportive care.

Overall, the results of MUD SCT in ALL seem encouraging, and it has become the treatment of choice for high-risk patients in CR1 if a sibling donor is not available. For patients with BCR–ABL-positive ALL the results of MUD SCT are already approaching those of sibling SCT. Mismatched or haploidentical

SCT in adult ALL is still experimental and an option only for rare cases; it is explored by few very experienced SCT centres.

Autologous SCT

The results for autologous SCT in first remission in adult ALL are surprisingly good, with an LFS of 42% and a low TRM of < 5%. Similar results with an LFS rate of 42% in standard-risk ALL (*n* = 280) and 40% in high-risk ALL (*n* = 174) have been reported for a large series from the European Bone Marrow Transplant Group (EBMT).

This type of SCT is associated with a higher relapse risk (> 50%) because of the risk of reinfusing residual leukaemic cells and even more so because of the lack of a GvL effect. Purging of bone marrow or peripheral blood to eliminate or reduce remaining leukaemic blast cells is feasible but has not become a routine measure. Maintenance treatment after autologous SCT may contribute to a reduction of relapse risk but is not widely used. With new treatment options available, such as molecular targeting with BCR–ABL kinase inhibitors or monoclonal antibodies, maintenance treatment after autologous SCT may be revisited.

With the increasing number of MUD transplants and the advantage of GvL effects, the role of autologous SCT may decrease. However, because of the low TRM, this is still a reasonable approach for elderly patients. In addition, autologous SCT can shorten overall treatment in adult ALL to 3 months instead of 2 years of chemotherapy and maintenance treatment. This approach is also supported by several prospective randomized trials in adult ALL showing equal outcome for chemotherapy consolidation and autologous SCT.

Non-myeloablative SCT

Non-myeloablative SCT or reduced-intensity conditioning regimens (NMSCT) are new approaches which deserve evaluation in ALL and may lead to an extension of indications for allogeneic SCT (see Chapter 25). In contrast to conventional SCT, which mainly relies on cell kill by high-dose chemotherapy and total body irradiation (TBI), NMSCT relies on the use of GvL effects. Immunosuppression, e.g. with purine analogues, other cytostatic drugs and/or low-dose TBI, is followed by the infusion of donor stem cells from siblings or MUD with adapted immunosuppression to establish host tolerance.

So far, in more than 100 adult ALL patients with high median age and poor prognostic features, the probabilities for survival after NMSCT was around 23% with relapse rate of 47% and TRM of 42 (Table 32.7). Overall, it seemed to be of some benefit in patients in CR1. In patients with advanced refractory or relapsed ALL, this form of SCT is at present not successful due to a high TRM rate.

Role of SCT in adult ALL

The question of whether all patients in first CR with suitable sibling donor should receive allogeneic SCT or whether it should be reserved for patients with high-risk features remains controversial. Several recent studies include early SCT (mainly from matched related donors), but so far it has not been demonstrated that this approach has a favourable impact on overall outcome. In addition, quality of life of transplanted patients has to be considered. There is agreement that all high-risk patients are candidates for SCT in first CR, including sibling and

Subgroup	Incidence (%)	n	CR rate (%)*	MDR* (months)	LFS (%)*

matched unrelated allogeneic SCT. Ongoing studies investigate whether allogeneic sibling SCT is also superior for standard-risk ALL; however, for this comparison, selection mechanisms, e.g. for age and comorbidity, have to be considered. The analysis of patients with and without donor may be a reasonable approach. Autologous SCT seems to be equal to chemotherapy, and whether the argument of shorter treatment duration compared with chemotherapy is valid remains to be determined. The role of new approaches such as NMSCT or new conditioning regimens remains open.

Outcome of ALL subtypes and prognostic factors

Major adverse prognostic factors for attaining a CR are advanced age and Ph$^+$ ALL. Prognostic factors are of greater importance for duration of remission and survival (Table 32.8). Appreciation of the impact of such risk factors (Table 32.9) can result in the generation of risk-adapted treatment protocols for adult ALL.

Age

There is a continuous decline in the CR rate from 95% in children to 40–60% in patients > 50–60 years of age. Most trials demonstrate that increasing age is also associated with a shorter survival (median 3–14 months) and a LFS of only 10–20%.

It is difficult to define an age limit where a change in prognosis

Table 32.9 Adverse prognostic factors for remission duration in adult ALL*.

Clinical characteristics	Higher age (> 50 years, > 60 years) High WBC (> 30 000/μL in B-lineage)
Immunophenotype	Pro B Early T Mature T
Cytogenetics/molecular genetics	t(9;22)/BCR-ABL or t(4;11)/ALL1-AF4
Treatment response	Late achievement of CR (> 3, 4 weeks) MRD positivity

*As they emerged from more than 3000 adult ALL patients treated in the GMALL (German Multicenter Studies for Adult ALL) trials.

occurs, but in almost all studies LFS is inferior in patients older than 50–60 years of age. This age limit seems to be practical because patients below this age are candidates for intensified treatment approaches such as SCT, whereas, for the older group, new strategies need to be explored, carefully weighing the gain in survival against quality of life. Thus, elderly patients > 50–55 years of age who have achieved a CR and are in good clinical condition are potential candidates for autologous SCT or NMSCT. One promising new strategy is to treat elderly patients with Ph/BCR–ABL-positive ALL with the BCR–ABL kinase

inhibitor imantinib during induction to avoid the complications of chemotherapy.

Adolescent patients (15–20 years) with ALL are treated either according to protocols for paediatric ALL or in adult ALL trials. There is increasing evidence that results with paediatric protocols are superior, albeit in these retrospective analyses it remains open whether identical adolescent cohorts were treated and particularly whether dose intensity of protocols was similar.

Immunophenotype and cytogenetics

The immunophenotype is an important independent prognostic variable in ALL. In ongoing trials, it is used to adjust treatment regimens accordingly, e.g. separate regimens for mature B-cell ALL. A further example for clinical application is the identification of patients for antibody therapy, e.g. anti-CD20 (Rituximab) in CD20-positive B-lineage ALL or B-cell ALL or anti-CD52 (Campath-1h) in CD52-positive ALL.

T-lineage ALL

Results for T-cell ALL have substantially improved compared with survival rates of < 10% 20 years ago. There is, however, a substantial difference in outcome for the T-ALL subtypes. Thymic T-ALL, which accounts for half of the adult T-ALL patients, has a favourable outcome, with CR rates of 85–90% and survival > 50% at 5 years. Early T-ALL and mature T-ALL have a poorer outcome, with CR rates of 70% and LFS rates of approximately 30%.

The addition of cyclophosphamide and cytarabine to the usual drugs for ALL is mainly responsible for this improvement. HDMTX contributed to the improvement of survival in children, as did HDAC. HDAC improved the prognosis for adult ALL patients with high WBC counts and T-cell ALL. For adults, the benefit of HDMTX in T-cell ALL has to be confirmed in larger trials. New treatment approaches in adult T-ALL include purine analogues such as cladribine and compound GW506U78 (nelarabine) or antibody therapy, e.g. anti-CD52. Also, SCT for early/mature T-ALL patients in CR 1 seems promising.

B-lineage ALL

In *common and pre-B-ALL*, CR rates in adult trials have improved to 80% or more, but patients in most studies still relapse over a period of up to 5–6 years, and only one-third survive. Within B-precursor ALL, prognostic factors are decisive for outcome; high-risk patients with adverse prognostic features such as high WBC ($> 30 \times 10^9$/L) and/or late achievement of CR (> 3–4 weeks) (Table 32.8) have a survival of 25% or less, whereas standard-risk patients without any of those features have a 5-year survival of > 50%.

Philadelphia chromosome/BCR–ABL-positive ALL has the worst prognosis in children as well as in adults. In adults, however, the adverse impact is much greater as the incidence in children is only 3% compared with 25% in adults or even > 40% in elderly

ALL patients. In 13 studies with a total of 384 patients, the weighted mean CR rate is 67% (44–76%). The median remission duration in all series is short (5–11 months) and the survival rate, from 0% to 16% at 3–5 years, is extremely poor.

Treatment options for Ph/*BCR–ABL*-positive ALL in adults include HDMTX or HDAC; so far, no convincing progress for this subgroup of patients has been reported. The only curative chance for adult Ph/*BCR–ABL*-positive ALL patients is therefore SCT. A promising new treatment modality for Ph/*BCR–ABL*-positive ALL is the use of the ABL tyrosine kinase inhibitor imantib (see also Chapter 37).

In the past, adults with the subtype *pro-B ALL* or the *t(4;11)* translocation had a poor prognosis, as did infant ALL patients. With intensive regimens including HDAC and mitoxantrone as consolidation therapy, the results in adults seem to have improved. Pro-B-ALL patients also benefit from allogeneic SCT in CR1, with survival rates of 60%, as well as from autologous SCT. The adverse impact of the translocation t(4;11) seems to have changed as well with new treatment modalities.

In *mature B-cell ALL*, CR remission rates were low (40%) two decades ago, and remission duration was short (11 months). A change was brought about by innovative childhood B-cell ALL studies that significantly improved outcome. The drugs responsible for the improvement were high doses of fractionated cyclophosphamide, ifosfamide, HDMTX (0.5–8 g/m^2) and HDAC in conjunction with the conventional drugs for remission induction in ALL, given in short cycles at frequent intervals over a period of 6 months.

The application of these childhood B-cell ALL protocols in original or modified form also brought a substantial improvement for adult patients with B-cell ALL. CR rate is now approximately 75% (62–83%) and the LFS 55% (20–71%). Adverse prognostic factors are late CR (more than two cycles of chemotherapy), high WBC ($> 30 \times 10^9$/L) and age > 50 years. Patients with these high-risk features are probably candidates for SCT. B-cell ALL has a higher incidence of CNS involvement at diagnosis, and of CNS relapse. Therefore, effective measures against CNS disease, such as HDMTX and HDAC as well as intrathecal therapy, are important components of treatment regimens. On the other hand, maintenance treatment has been omitted. Because relapses occur almost exclusively within the first year in childhood as well as in adult B-cell ALL studies, patients thereafter can be considered as cured. Recent treatment protocols include antibody therapy with anti-CD20 (rituximab) since more than 80% of the patients are CD20-positive, with quite promising preliminary results.

Minimal residual disease – practical application in adult ALL

In childhood ALL, it has been demonstrated that level and course of MRD are independent prognostic factors (Chapter 34). These

results have been confirmed by a considerable number of mainly retrospective studies in adult ALL. There are, however, some important differences. A very good response, as indicated by an early and rapid decrease of MRD during induction, may be associated with a very low relapse risk. However, in general, the decrease in MRD occurs more slowly in adults, and fewer patients reach a negative MRD status. This applies particularly for patients with low MRD immediately after induction, who still show a considerable relapse rate of approximately 50%. Thus, in adult ALL, MRD analysis immediately after induction provides a good tool for identification of high relapse risk but not of those with low risk. The longitudinal course of MRD may be more important in adults than in children. High MRD at any time-point after induction is associated with a higher relapse risk, and the predictive value increases at later time-points (months 6–9).

The predictive value of MRD evaluation depends on the technical quality, such as sensitivity (10^{-4} for negative results), number of targets (at least two) and the frequency of evaluations (3 monthly) in individual patients. In a retrospective study of the GMALL (German Multicenter Studies for Adult ALL), a broad spectrum of target genes (IgH, IgK and TCR rearrangements) was measured quantitatively with high sensitivity ($< 10^{-4}$). Based on these results, MRD-based risk groups could be defined; MRD low risk was defined as MRD negative at all time-points after induction therapy confirmed with two markers and a sensitivity $> 10^{-4}$. MRD high risk was defined as MRD above 10^{-4} at two time-points after induction therapy without subsequent decrease. There was, however, a surprisingly large intermediate-risk group of patients who could not be allocated to either subset. The major reasons for allocation to the MRD-based intermediate-risk group were lack of a second marker (58%), insufficient sensitivity (51%) and inconclusive course of MRD (28%). However, most patients in this group had combinations of several reasons, e.g. only one marker and insufficient sensitivity, which made a reasonable assessment of the relapse risk impossible. Fifty per cent of the patients were allocated to this group, which is also large in paediatric ALL. In the ongoing GMALL study in patients with low-risk MRD, treatment is stopped after 1 year, whereas in high-risk MRD patients, intensification with stem cell transplantation or experimental treatment is intended. It is unclear at present how to proceed with intermediate-risk MRD patients. In an ongoing GMALL trial, these patients receive maintenance therapy with six intensification cycles for 1 year or more.

Overall, in adult ALL, a variety of potential clinical applications for MRD evaluation are already apparent. One of them is the new definition of CR, which considers the molecular remission status in addition to remission status assessed by morphology. Another important issue is the definition of new MRD-based prognostic factors in addition to conventional risk factors and the definition of MRD-based treatment decisions as described for the GMALL study above. Finally, MRD analysis may be used for molecular monitoring of new treatment elements such as chemotherapy, antibody treatment, molecular therapy, SCT and others.

Treatment with monoclonal antibodies

Targeted therapy with monoclonal antibodies (MAbs) is a new treatment option in adult ALL. ALL blasts express a variety of specific antigens such as CD19, CD20, cyCD22 for B-lineage ALL or CD25, CD/CD3 for T-lineage ALL and CD52 or CD33 for both, which may serve as targets for treatment with monoclonal antibodies. The presence of the target antigen on at least 20–30% of the blast cells is generally considered as a prerequisite for MAb therapy. Anti-CD20 (rituximab) and anti-CD52 (Campath-1) are currently being explored in adult ALL. First results with the combination of chemotherapy and Rituximab are promising in mature B-ALL.

Other MAbs, such as B43(anti-CD19)–genistein, B43(anti-CD19)–PAP and anti-B4-bR(anti-CD19) in B-lineage ALL and anti-CD7–ricin in T-lineage ALL, have been investigated in phase I–II pilot trials in ALL.

Anti-CD20

Rituximab is a chimeric MAb to CD20 which is expressed on normal and malignant B lymphocytes. It exerts significant anti-tumour activity and has led to an improvement of results in B-cell non-Hodgkin's lymphoma (NHL). CD20, defined as expression on more than 20% of the blast cells, is, however, also present on one-third of B-precursor ALL blasts, particularly in the elderly patients (40–50%), and the majority of mature B-ALL blast cells (80–90%).

This provides a rationale to explore rituximab in B-precursor ALL, mature B-ALL and Burkitt's lymphoma. Favourable results were observed in two trials in which rituximab was used in combination with intensive chemotherapy. Nineteen patients with newly diagnosed Burkitt's NHL or mature B-ALL received anti-CD20 together with the hyper-CVAD regimen for a total of eight doses. Eighty-nine per cent complete remission (CR) was observed. In a GMALL study with 53 patients (mature B-ALL, Burkitt's and other high-grade NHL) the remission rate was 91% in mature B-ALL and in Burkitt's NHL a response rate of 96% (partial or CR) was achieved after two cycles. Although preliminary, these studies indicate that there was apparently no additional toxicity compared with the previous protocol with chemotherapy only. The GMALL study group has recently started prospective trials with a combination of anti-CD20 and chemotherapy also in patients with B-precursor ALL.

Anti-CD52

The CD52 antigen is expressed in most lymphatic cells and to a higher degree in T compared with B lymphoblasts. CD52 anti-

bodies were first used for *ex vivo* T-cell depletion of allogeneic bone marrow grafts in order to prevent GvHD. The humanized antibody Campath-1H showed anti-tumour activity in CLL, T-PLL and other T-NHL. In a few cases of relapsed adult ALL, clinical effects were observed, with reduction of WBC, clearance of peripheral blast cells and partial remission (PR). Although the experience with Campath-1H in overt relapse of ALL is limited, several studies are ongoing, in relapse (also in combination with chemotherapy), in CR with positive MRD or even in *de novo* ALL as consolidation treatment.

ABL tyrosine kinase inhibitors in Ph/BCR–ABL-positive ALL

In *Ph/BCR–ABL*-positive (Ph+) leukaemia the *BCR–ABL* fusion gene is causally involved in leukaemogenesis and is considered to be essential for leukaemic transformation. With a selective inhibitor of the ABL tyrosine kinase (STI571, imatinib, Gleevec®), cellular proliferation of *BCR–ABL*-positive CML and ALL cells can be inhibited selectively (see Chapter 37).

Clinical experience with imatinib in advanced Ph+ ALL

In a study of relapsed or refractory Ph+ ALL patients, monotherapy with imatinib at a daily dose of 600 mg orally produced a haematological response in 60%. A complete haematological remission with normalization of peripheral blood counts (ANC > 1.5/nL, platelets > 100/nL) was noted in 19% of patients. Rapid blast cell clearance occurred within 1 week of treatment in the majority of patients, but this peripheral blood response did not necessarily correspond with a bone marrow response. Median estimated time to progression for ALL patients was 2.2 months.

Haematological toxicity of grades III and IV was frequent but was rarely associated with serious infectious or haemorrhagic complications. Non-haematological toxicity attributed to imatinib consisted primarily of mild to moderate gastrointestinal discomfort, peripheral and facial oedema and muscle cramps, and was readily manageable. No patient discontinued therapy because of non-haematological adverse events and there were no imatinib-related deaths. Thus, imatinib was well tolerated even in heavily pretreated patients.

Imatinib and allogeneic stem cell transplantation in Ph+ ALL

The efficacy of imatinib was also explored in patients with Ph+ ALL who relapsed after allogeneic SCT. Twenty consecutive Ph+ ALL patients received single-agent imatinib (600 mg/day orally) after relapse subsequent to allogeneic SCT. Complete remission was seen in approximately 50%. Donor cell chimerism increased to above 96% in both bone marrow and peripheral blood within the first 4 weeks of imatinib in responding patients, indicating a selective expansion of Ph-negative donor cells over the leukaemic clone. Disease-free survival after 2 years was approximately 20% and overall survival 40%, owing to subsequent salvage therapy. Thus, imatinib as a single agent induces remissions in a substantial proportion of patients relapsing after allogeneic SCT, and in a few cases even a molecular remission can be achieved.

Current concepts for imatinib treatment in *de novo* Ph+ ALL

As a consequence of the encouraging results in relapsed/refractory ALL, imatinib soon entered trials in *de novo* ALL. Imatinib at a dose of 600 mg/day orally was given for 4 weeks after induction therapy in *de novo* Ph+ ALL with CR. The BCR–ABL level after induction therapy decreased by more than 0.5 log in half of the cases, remained unchanged or increased in 40% and approximately 10% of the patients achieved molecular CR. In a subsequent study, imatinib is now given in parallel to the second phase of induction therapy.

Preliminary encouraging results of a combination regimen have also been shown by the group at MD Anderson. Patients with Ph+ ALL received imatinib in parallel with intensive chemotherapy (HyperCVAD regimen) for several cycles without serious unexpected toxicity. Imatinib as 'up-front' therapy in patients with newly diagnosed Ph+ ALL is also currently being tested by the GMALL Study Group in a randomized trial in elderly (> 65 years) patients with *de novo* Ph+ ALL. First results show that this combination is safe, that complete remissions can be achieved by a imatinib monotherapy and that the combination of imatinib and chemotherapy is feasible.

The list of novel compounds that show activity against BCR–ABL expressing cell lines is rapidly growing, including new anti-leukaemic agents that translate insights from basic science into clinical application. Hopefully, these new modalities of molecular targeted therapies will soon improve the outcome of the so far worst ALL subtype – the Ph+ ALL.

Childhood acute lymphoblastic leukaemia

33

Der-Cherng Liang and Ching-Hon Pui

Introduction

Acute lymphoblastic leukaemia (ALL) is the most common childhood cancer. Remarkable progress has been achieved in its treatment such that the 5-year event-free survival rates in the most successful clinical trials now range from 75% to 83% (Table 33.1). With retrieval therapy for those who suffer a relapse, approximately 80% of patients can be cured (i.e. no evidence of disease for 10 or more years). This advance can be attributed to the risk-directed therapies developed through well-designed clinical trials and improved supportive care. Current efforts to further improve the cure rate include minimal residual disease detection, molecular genetic studies of lymphoblasts, pharmacogenetics studies, pharmacodynamic studies of anti-leukaemic agents, gene expression profiling and the development of targeted therapies. These studies promise to increase the precision of risk assessment, to optimize therapy, to circumvent drug resistance and to elucidate the mechanisms of leukaemogenesis. In this chapter, we review the current status of the

Table 33.1 Results of selected clinical trials in patients with acute lymphoblastic leukaemia.

biological studies and treatment of childhood ALL and suggest future directions.

Epidemiology

The incidence of ALL is higher in boys than in girls, except during infancy, when there is a slight female predominance. Age-specific incidence patterns are characterized by a peak between the ages of 2 and 5 years, followed by falling rates during later childhood, adolescence and young adulthood. There are substantial geographic differences in the incidence of ALL. The rates are higher among populations in northern and western Europe, North America and Oceania and lower among those in Asia, South America and Africa. In the industrialized countries, the incidence is higher among children of European descent than among those of African descent. In this regard, the annual rates (per million population) of childhood ALL from birth to 19 years of age for US whites, US blacks, UK and India are 32.9, 14.8, 29.7 and 11.0 respectively.

Only a small proportion (< 5%) of patients with childhood ALL have underlying hereditary genetic abnormalities. Children with Down's syndrome have a 10- to 20-fold increased risk of developing ALL. Other genetic disorders associated with an increased incidence of ALL include ataxia telangiectasia and Bloom's syndrome. The association between ALL and congenital immunodeficiencies, such as X-linked agammaglobulinaemia and common variable immunodeficiency, is not well established.

Fraternal twins of patients have a two- to fourfold increased risk of ALL during the first decade of life compared with that of unrelated children. When ALL occurs in one identical twin, the other twin has a 20% chance of developing the disease. If ALL is diagnosed in the index twin during infancy, the other twin almost invariably will develop leukaemia within a few months. Molecular studies have demonstrated that intrauterine metastasis of ALL from one twin to the other, via the shared placental circulation, is responsible for the concordant leukaemia.

Aetiology and pathogenesis

The causes of the vast majority of cases remain to be clarified but likely involve an interaction between the host inherited susceptibility, environment, haemopoietic development and chance.

Primary genetic abnormalities and cooperative mutations

Acquired genetic changes are considered to be central to the development of leukaemia. These changes affect the number (ploidy) and/or the structure of chromosomes, such as trans-

locations, inversions, deletions, point mutations, and amplifications. Transformation of haemopoietic stem cells requires subversion of the controls of normal proliferation, a block in differentiation, resistance to death signals (apoptosis) and enhanced self-renewal. The primary mechanisms of leukaemia induction include aberrant activation of proto-oncogenes (e.g. *MYC*, *TAL1*, *LYL1*, *LMO2* and *HOX11*) and generation of fusion genes encoding active kinases (e.g. *BCR–ABL*) or transcription factors (e.g. *TEL–AML1*, *E2A–PBX1* and *MLL* linked to one of many fusion partners).

Current multistep models of carcinogenesis predict that the oncogenic events triggered by chromosomal rearrangements are not sufficient by themselves to induce overt leukaemia. The spectrum of secondary mutations involved in the development of leukaemia and their role in the clinical heterogeneity of specific leukaemia subtypes remain to be clarified. These mutations involve both genetic and epigenetic changes in key growth regulatory pathways, including those controlled by the tumour suppressors RB (the retinoblastoma protein and related family members, p130 and p107) and p53. RB plays a critical role in controlling cell cycle entry. The hypophosphorylated RB inhibits the ability of the E2F family of transcription factors to induce the transcription of genes necessary for S-phase entry. Mitogenic signals induce the formation of active cyclin D-dependent kinases, which, together with cyclin E–Cdk2, phosphorylate RB and abolish its growth-inhibitory functions. The activity of cyclin D-dependent kinases is in turn regulated by the INK4 proteins (p16^{INK4a}, p15^{INK4b}, p18^{INK4c} and p19^{INK4d}), which specifically inhibit the activity of cyclin D-dependent kinases and prevent the phosphorylation of RB. Inactivating mutations or deletions of RB are rare in ALL. By contrast, functional silencing of p16^{INK4a} and p15^{INK4b} occurs in almost all cases of childhood T-cell ALL and in a small proportion of B-lineage ALLs. Although the loss of p16^{INK4a} and p15^{INK4b} expression may play a role in the development of leukaemia, it has no independent prognostic significance.

The p53 transcription factor functions as a sensor of aberrant cellular proliferation, DNA damage and hypoxia, and its activation results in either cell cycle arrest or apoptosis. The activity of p53 is negatively regulated by HDM2 (the human homologue of mouse Mdm2), which directly binds to p53 and induces its degradation. The p14^{ARF} tumour suppressor in turn binds HDM2 to antagonize its ability to negatively regulate p53. Silencing of p14^{ARF} is a frequent event in ALL, and overexpression of HDM2 or silencing of the p53 transcriptional target p21^{CIP1} is observed in approximately 50% of ALL cases. Importantly, p16^{INK4a} and p14^{ARF} are encoded by alternative reading frames in the same genetic locus. The high frequency of homozygous deletions that eliminate the expression of both gene products suggests that alterations of both the RB and p53 pathways collaborate in the pathogenesis of ALL. However, it is likely that additional key regulators will be identified as targets for genetic or epigenetic alterations in ALL.

Prenatal origin of some leukaemias

The retrospective identification of leukaemia-specific fusion genes (e.g. *MLL–AF4, TEL–AML1*) in the neonatal blood spots and the development of concordant leukaemia in identical twins indicate that some leukaemias have a prenatal origin. ALL with the t(4; 11)/*MLL–AF4* has a high concordance rate in identical twins (nearly 100%) and a very short latency period (a few weeks to a few months), suggesting that this fusion alone is either leukaemogenic or requires only a small number of cooperative mutations to cause leukaemia. By contrast, the concordance rate in twins with the *TEL–AML1* fusion or T-cell phenotype is lower, and the postnatal latency period is longer, suggesting that additional postnatal events are required for leukaemic transformation. This concept is supported by the identification of rare cells expressing *TEL–AML1* fusion transcripts in approximately 1% of cord blood samples from newborns, a frequency 100-fold higher than the incidence of ALL defined by this fusion transcript. However, clearly, not all childhood cases develop *in utero*. For example, the t(1;19)/*E2A–PBX1* ALL appears to have a postnatal origin in most cases.

Environmental factors and host pharmacogenetics

The *MLL* gene, located on chromosome 11q23, is frequently involved in infant leukaemias and in therapy-related acute myeloid leukaemia (AML) after treatment with topoisomerase II inhibitors. It is possible that transplacental fetal exposure to topoisomerase II inhibitors, such as flavonoids in food and drink, quinolone, benzene metabolites, catechins, podophyllin resin, and even estrogens, is a critical event in the generation of leukaemias with *MLL* rearrangements. A case–control study disclosed significant associations between *in utero* exposure to DNA-damaging drugs, herb medicines or pesticides and the development of infant leukaemias with *MLL* rearrangements. Conceivably, a reduced ability of fetuses or their mothers to detoxify these agents could underlie an enhanced susceptibility to ALL.

Genetic polymorphisms of carcinogen-detoxifying enzyme have been variously associated with the development of leukaemia. For example, deficiency of glutathione S-transferases (GST-M1 and GST-T1), enzymes that detoxify electrophilic metabolites by catalysing their conjugation to glutathione, is associated with infant leukaemias without *MLL* rearrangement and with ALL in black children. Polymorphisms of another enzyme, reduced nicotinamide adenine dinucleotide phosphate:quinone oxidoreductase, which converts benzoquinones to less toxic hydroxyl metabolites, has been associated with the development of infant and childhood ALL. Cytochrome P-450 CYP1A1*2A genotype has also been linked to an increased risk of childhood ALL. Recent studies suggest that folate pathways may play a role in the susceptibility to ALL, and that folate supplement may reduce the risk, observations warranting additional studies for confirmation.

Although environmental factors such as chemical mutagens have been implicated in the aetiologies of leukaemia, solid evidence is lacking. Previous studies have largely excluded residential exposure to magnetic fields as a major instigating factor in leukaemogenesis. Two hypotheses have suggested that abnormal response to common infections plays an important role in the development of childhood ALL. Because high socioeconomic status and social isolation are associated with an increased risk of childhood B-precursor ALL, one hypothesis proposes that many such cases, especially those diagnosed between 2 and 5 years of age, are the consequence of a delayed exposure to common infections to a time when there is increased lymphoid cell proliferation and hence increased chance of leukaemogenic genetic mutations. The other hypothesis suggests that transiently increased rates of leukaemia, sometimes in clear geographic clusters, are due to population mixing, resulting in infection in previously unexposed and hence susceptible individuals.

Clinical presentation

The presenting symptoms and signs are quite variable (Table 33.2). Most patients have an acute onset, while in others the initial signs and symptoms appear insidiously. Fever occurs in approximately 50–60% of patients. In at least two-thirds of these patients, fever is due to leukaemia and will resolve within 72 h after the start of induction therapy. Fatigability and malaise are common. Over one-third of the patients may present with a limp, bone pain, arthralgia, or refusal to walk due to leukaemic infiltration of the periosteum, bone or joint or to expansion of marrow by leukaemic cells. Children with prominent bone pain sometimes have nearly normal blood counts, which can lead to a delay in diagnosis. Many patients have manifestations of bleeding, especially epistaxis or oozing from gum. Occasionally, patients present with life-threatening infection or bleeding. Less common symptoms and signs include headache, vomiting, respiratory distress and anuria. Rarely, ALL is detected during routine examination.

Physical examination often reveals pallor, petechiae and ecchymoses in the skin or mucous membranes, and bone tenderness. Liver, spleen and lymph nodes are the most common sites of extramedullary involvement and are enlarged in more than half the patients. Facial and/or abducens nerve palsies are occasionally seen. Ocular involvement can manifest as leukaemic infiltration of the orbit, optic nerve, retina or anterior chamber of the eye (hypopyon). Epidural spinal cord compression is a rare but serious presenting finding and requires immediate treatment to prevent permanent sequelae.

Overt testicular involvement occurs in only 2% of patients, mostly infants or adolescents with T-cell ALL. Less common presenting features include subcutaneous nodules (leukaemia

Table 33.2 Presenting clinical and laboratory features of children with newly diagnosed ALL.

Feature	Percentage of white children (SJCRH)	Percentage of total (BFM)
Age (years)		
≤ 1	2.7	2.7
2–9	71.6	79.6

BFM, Berlin–Frankfurt–Münster 90 (1990–95, not including B-ALL; Schrappe *et al.* 2000b); SJCRH, St Jude Children's Research Hospital (1979–2002).
*CNS 3 status denotes the presence of leukaemic cells in a cerebrospinal fluid that contains ≥ 5 WBC/μL with identifiable blasts.

cutis), enlarged salivary glands and priapism. Finally, in some patients, infiltration of the tonsils, adenoids, appendix or mesenteric lymph nodes leads to a surgical intervention before leukaemia is diagnosed.

Patients with cerebellar ataxia who develop a lymphoid neoplasm should be suspected of having ataxia telangiectasia. Increased serum alpha-fetoprotein is a useful aid in the diagnosis. Recognition of ataxia telangiectasia is important because these patients have excessive and sometimes fatal complications from treatment with irradiation (leukoencephalopathy) and cyclophosphamide (haemorrhagic cystitis).

Laboratory findings

Anaemia, abnormal leucocyte and differential counts, and thrombocytopenia are usually present at diagnosis. The initial leucocyte counts range from 0.1 to 1500 × 10⁹/L (median 12 × 10⁹/L) and are increased (> 10 × 10⁹/L) in slightly over one-half of patients. Hyperleucocytosis (> 100 × 10⁹/L) occurs in 10–15% of patients. Profound neutropenia (< 0.5 × 10⁹/L) occurs in 40% of patients, rendering them at high risk of infection. The majority of circulating leucocytes are lymphocytes or lymphoblasts. In patients with low initial counts (< 2 × 10⁹/L), often there are no circulating lymphoblasts in blood smears. Hypereosinophilia, generally reactive, may be present at diagnosis.

Thrombocytopenia (median count 50 × 10⁹/L) is usually present at diagnosis and severe haemorrhage is uncommon, even when platelet counts are as low as 20 × 10⁹/L, provided that infection and fever are absent. Coagulopathy, usually mild, may occur in T-cell ALL and is only rarely associated with severe haemorrhage. More than 75% of patients present with anaemia; haemoglobin is commonly < 8 g/dL. Anaemia or thrombocytopenia is often mild (or even absent) in patients with T-cell ALL. Rarely, pancytopenia followed by a period of spontaneous haemopoietic recovery may precede the diagnosis of ALL.

Elevated serum uric acid levels are common in patients with a large leukaemic cell burden. Increased serum phosphorus or potassium or water retention may occur and is aggravated by renal impairment. Leukaemic cell lysis (or tumour lysis) syndrome occurs most frequent in mature B-cell ALL, but it may also happen in T-cell ALL or B-precursor ALL with large leukaemic cell burden. Although an enlarged kidney can be detected in 30–50% of patients, kidney size at diagnosis lacks prognostic or therapeutic implications. Approximately 0.5% of patients have hypercalcaemia because of the release of parathyroid hormone-like protein from lymphoblasts. Hypercalcaemia generally resolves rapidly with hydration and chemotherapy. Liver dysfunction due to leukaemic infiltration occurs in 10%–20% of patients, is usually mild and has no important clinical or prognostic consequences. The serum lactate dehydrogenase level is frequently elevated and correlates with the leukaemic cell burden and prognosis. Serum immunoglobulin levels are modestly low (mostly IgA and IgM) in approximately one-third of patients.

Betweeen 50% and 60% of cases with T-cell ALL present with an anterior mediastinal mass. Chest radiography is needed to detect a mediastinal mass or pleural effusion. A bulky mass that compresses the great vessels and trachea can lead to superior vena cava syndrome. Patients with this syndrome tolerate anaesthesia poorly. Abnormalities of the bone, such as metaphyseal banding, periosteal reactions, osteolysis, osteosclerosis or osteopenia, can be revealed by radiography in one-half of the patients. As these changes do not affect treatment and outcome, routine bone radiography is not indicated. Spinal radiography is helpful in patients suspected of having vertebral collapse.

Cerebrospinal fluid should be carefully examined. Lymphoblasts can be identified in as many as one-third of patients at diagnosis, the majority of whom lack neurological symptoms. Traditionally, central nervous system (CNS) leukaemia is defined by the presence of at least five leucocytes per microlitre of cerebrospinal fluid plus lymphoblasts in a cytocentrifuged smear, or by the presence of cranial nerve palsies. However, we contend that the presence of any amount of lymphoblasts in cerebrospinal fluid (even due to iatrogenic introduction from a traumatic lumbar puncture) at diagnosis portends an increased risk of relapse and should be treated with intensive intrathecal therapy. However, the presence of blasts cells in cerebrospinal fluid with a normal cell count during treatment may not be predictive of CNS relapse.

Diagnosis

Virtually all patients have abnormal physical finding(s), abnormal blood counts and/or differential counts, or both. With a clinical suspicion of leukaemia, bone marrow aspiration should be performed. Bone marrow biopsy is occasionally needed in patients with a very packed bone marrow or marrow fibrosis,

leading to difficulty in bone marrow aspiration. Touch preparations should be made from all specimens, to provide air-dried materials for stainings.

Differential diagnosis

Bone pain, arthralgia and occasionally arthritis may mimic juvenile rheumatoid arthritis, rheumatic fever, other collagen diseases or osteomyelitis. Infectious mononucleosis and other viral infections can be confused with ALL; detection of atypical lymphocytes or elevated viral titres aid in the diagnosis. ALL can be readily distinguished from immune thrombocytopenic purpura, as isolated thrombocytopenia is rare in leukaemia. Aplastic anaemia may also present with pancytopenia and complications associated with bone marrow failure, but rarely with hepatosplenomegaly and lymphadenopathy. Paediatric small round cell tumours, when they invade bone marrow, may mimic ALL. However, tumour cells often form clumps in marrow, and tumour can be found by imaging studies.

Morphology and cytochemistry

Morphological analysis of leukaemic cells in smears stained with Romanowsky stain distinguishes three subtypes (L1, L2 and L3) as classified by the French–American–British (FAB) cooperative group. Myeloperoxidase, Sudan black B and ASD-chloroacetate esterase are specific for myeloblasts and α-naphthyl butyrate (or acetate) esterase is specific for monoblasts, while periodic acid–Schiff reagent reacts positively in over 70% of ALL cases. Because of the subjective nature of distinction between L1 and L2 subtypes, and the poor correlation of these subtypes with immunological and genetic features, morphological classification system has not been useful in the clinical management of ALL. Contemporary classification of ALL relies on immunophenotyping, cytogenetics and molecular analyses.

Immunophenotyping

Table 33.3 summarizes antigen expression profiles that distinguish different subtypes of ALL. The most commonly used system divides ALL into early pre-B, pre-B, B-cell and T-cell subtypes. For therapeutic purposes, one needs only to distinguish B-cell and T-cell ALL from all other B-lineage (B-cell precursor) ALL (see also Chapter 29).

Early pre-B ALL

About 60% of ALL patients have an early pre-B immunophenotype. Although immunoglobulin heavy-chain genes are usually rearranged in these cells, immunoglobulins are not detectable.

Table 33.3 Immunological classification of childhood acute lymphoblastic leukaemia.

SJCRH classification		EGIL classification	
Immunological subgroup	Immunophenotypic profile	Immunological subgroup	Immunophenotypic profile
B-lineage ALL	CD19$^+$/CD22$^+$/cyCD3$^-$/MPO$^-$	B-lineage ALL	CD19$^+$ and/or CD79α$^+$ and/or CD22$^+$
Early pre-B	CD79α$^\pm$/CD10$^+$/Igμ$^-$	B-I (pro-B)	No B-cell differentiation antigens
		B-II (common B)	CD10$^+$
Pre-B ALL	CD79α$^+$/CD10$^+$/cyIgμ$^+$	B-III (pre-B)	cyIgμ$^+$
Transitional (late) pre-B	CD79α$^+$/CD10$^+$/cyIgμ$^+$/sIgμ$^+$		
Mature B	CD79α$^+$/CD10$^\pm$/cyIgμ$^+$/sIgμ$^+$/sIgλ$^+$ or sIgκ$^+$	B-IV (mature B)	cyIg$^+$ or sIgκ+ or λ+
T-lineage ALL	CD7$^+$/cyCD3$^+$/CD22$^-$/CD79a$^\pm$/MPO$^-$	T-lineage ALL	Cytoplasmic/surface CD3$^+$
Pre-T	sCD3$^-$/CD5$^-$/CD1$^-$/CD4$^-$/CD8$^-$/CD10$^-$	T-I (pro-T)	CD7$^+$
Early-T	sCD3$^-$/CD5$^+$/CD1$^-$/CD4$^-$/CD8±/CD10$^-$	T-II (pre-T)	CD2$^+$ and/or CD5+ and/or CD8+
Common-T	sCD3^{lo}/CD5$^+$/CD1±/CD4±/CD8±/CD10±	T-III (cortical T)	CD1a$^+$
Late-T	sCD3^{hi}/CD5$^+$/CD1$^-$/CD4+ or CD8+/CD10$^-$	T-IV (mature T)	Surface CD3$^+$, CD1a–
		α/β(group a)	TCRα/β$^+$
		γ/δ(group b)	TCRγ/δ$^+$

EGIL, European Group for the Immunological Characterization of Leukemia; Ig, immunoglobulin; cyIg, cytoplasmic immunoglobulin; sIg, surface immunoglobulin; SJCRH, St Jude Children's Research Hospital; TCR, T-cell receptor.

The blasts always express CD19. Almost all cases have cytoplasmic CD22 and CD79a; weak surface CD22 expression is also evident in many cases. CD10 and terminal deoxynucleotidyl transferase (TdT) are detectable in 90% of cases, and more than 75% of cases express CD34. CD20 is present on a minor proportion of blasts in one-half of cases. In 10–15% of cases, CD45 is very weakly expressed or undetectable; leukaemic cells with this feature are usually hyperdiploid. Early pre-B ALL includes patients with a wide variety of genetic abnormalities (discussed later).

Pre-B ALL

About 20–25% of ALL patients have a pre-B immunophenotype with cytoplasmic immunoglobulin mu heavy chains and no detectable surface immunoglobulins. Like early pre-B, this subtype expresses CD19, CD22 and CD79a. Rearrangement of immunoglobulin light-chain genes is evident in some cases, but kappa and lambda proteins are not detectable. More than 95% of cases express CD10 and TdT. Only two-thirds express CD34. In many cases, surface CD20 is absent or is weakly expressed. Between 20% and 25% of pre-B ALL patients exhibit the t(1;19)(q23;p13) or the der(19)t(1;19)(q23;p13) genotype.

Transitional (or late) pre-B ALL

Approximately 3% of ALL patients have this phenotype. The blasts express both cytoplasmic and surface immunoglobulin mu heavy chains without kappa or lambda light chains. The blasts express CD10, usually TdT, and sometimes CD34. Except for a high frequency of hyperdiploidy, > 50 chromosomes, there is no characteristic chromosomal abnormality in this subtype of ALL.

B-cell ALL

In 2% of ALL cases, blasts express surface immunoglobulin mu heavy chains plus either kappa or lambda light chains. L3 morphology is typical of, but not diagnostic of, B-cell ALL. Blasts express CD19, CD22, CD20 and frequently CD10; CD34 is negative. In rare cases, TdT is expressed. Often, these cases represent the leukaemic phase of Burkitt's lymphoma (see also Chapter 29).

The genetic abnormality of this subtype is the reciprocal translocation of chromosome 8 with one of the three chromosomes (most commonly number 14) containing an immunoglobulin gene. The critical event in these translocations, t(8;14)(q24;q32), t(2;8)(p12;q24) and t(8;22)(q24;q11), is the juxtaposition of the *MYC* proto-oncogene (at 8q24) with the mu (at 14q32), kappa (at 2p12) and lambda (at 22q11) genes respectively. These rearrangements dysregulate the expression of c-*MYC* encoding a transcription factor, resulting in altered cell proliferation and survival. Dysregulation of c-*MYC* expression, in the presence of other genetic alterations, resulted in B-lineage leukaemia/lymphoma in mice.

It should be noted that occasional patients with the t(8;14) and L3 morphology display a less differentiated B-precursor immunophenotype or lack surface or cytoplasmic immunoglobulin. Even less common is B-cell ALL with L1 or L2 morphology, expression of TdT, CD34 and CD20 (weakly) and no t(8;14),

t(2;8) or t(8;22). Clinically, the presence of the specific translocation is of greatest importance for assigning patients to receive therapy for B-cell ALL. Patients without the specific translocation can be treated with therapy for B-cell precursor ALL.

T-cell ALL

T-cell ALL accounts for 12–15% of ALL cases. Blasts express surface CD7 and cytoplasmic CD3 (cCD3). More than 90% of blasts express CD2, CD5 and TdT. Surface CD1a, CD3, CD4 and CD8 are detected in fewer than 45% of cases. HLA-DR is not commonly expressed, and 40–45% of cases are positive for CD 10 and/or CD21.

T-cell ALL can be subdivided according to the distinct stages of T-cell ontogeny: pro-T (CD7$^+$), pre-T (CD2$^+$ and/or CD5$^+$ and/or CD8$^+$), cortical T (CD1a$^+$), and mature T (membrane CD3$^+$, CD1a$^-$). However, as many as 25% of cases do not conform to any of these stages. Moreover, several studies have yielded conflicting results about the prognostic significance of the antigen(s) expression.

T-cell receptor (TCR) proteins are heterogeneously expressed in T-cell ALL. In approximately two-thirds of T-cell cases, membrane CD3 and TCR proteins are absent. In half of these cases, however, TCR proteins (TCRβ, TCRα, or both) are present in the cytoplasm. Most cases with membrane CD3 and TCR chains express the αβ form of the TCR, whereas a minority express TCRγδ proteins. T-cell cases can also be subdivided into prognostically distinct genetic subtypes (see below).

ALL with aberrant antigen expression

Many leukaemias express antigens associated with multiple haemopoietic lineages. There is no uniform terminology or diagnostic criteria for these type of leukaemias. They have been variously termed acute mixed-lineage, hybrid, chimeric or biphenotypic leukaemia. 'Biclonal' or 'oligoclonal' leukaemia, which consists of two or more morphologically or immunophenotypically distinct leukaemic cell populations, is very rare.

Expression of myeloid antigens in ALL has no prognostic significance but can be of value for assessing minimal residual disease by multiparameter flow cytometry. Cases with myeloid antigen expression have a higher frequency of *MLL* rearrangement or *TEL–AML1* (also termed *ETV6–CBFA2*) fusion than do other cases.

Cytogenetic and molecular classification

Leukaemia arises from a haemopoietic progenitor cell that has sustained specific genetic damage leading to malignant transformation and proliferation. Classification based on genetic abnormalities yields clinically and biologically more relevant information than other approaches. To date, 75% of childhood ALL cases have specific genetic abnormalities with therapeutic and prognostic significance. Karyotypically, ALL cases can be classified according to chromosome number (ploidy) or specific rearrangements. We will only review briefly here the most common abnormalities (see also Chapter 30).

Ploidy groups

Commonly recognized ploidy groups are hyperdiploidy > 50 chromosomes, hyperdiploidy 47–50, normal karyotype, pseudodiploidy (normal number of chromosomes with structural changes), hypodiploidy 45, hypodiploidy < 45 (including near-haploid 24–28 chromosomes), near-triploidy (69–81 chromosomes) and near-tetraploidy (82–94 chromosomes). Hyperdiploidy > 50 is associated with an age of 1–10 years, a low median leucocyte count, a tendency to accumulate increased amounts of methotrexate polyglutamates, increased sensitivity to antimetabolites, a marked propensity for spontaneous apoptosis *in vitro* and a favourable prognosis, even with treatment based on antimetabolites. Trisomies of chromosomes 4, 10 and 17 have been correlated with the most favourable outcome, but no distinguishing biological features have been identified in this subset.

Cases with near-triploidy have treatment response similar to that of non-hyperdiploid ALL; those with near-tetraploidy have a higher frequency of T-cell immunophenotype. Among cases with hypodiploidy < 45, there is a significant trend for progressively worse outcome with decreasing chromosome number, such that cases with near-haploidy have the worst prognosis.

t(12;21)(p13;q22)/*TEL–AML1* fusion

TEL–AML1 fusion from a cryptic t(12;21) is the most common specific genetic rearrangement in childhood ALL, and can be identified only by molecular analysis. It is identified in 20–25% of Caucasian patients in the USA and Western Europe but in only 15% of Chinese patients in Taiwan and 15% of Japanese patients. The prognosis of this genetic abnormality depends on the treatment. While it is generally associated with a good prognosis, it has no prognostic impact in some studies. ALL cells bearing this abnormality have an increased sensitivity to asparaginase *in vitro*. It has been postulated that increased expression of CD40 and HLA-DR may render these cells more susceptible to immune surveillance.

The *TEL* gene on chromosome 12 belongs to the *ETS* family of transcription factors. *TEL* functions as a sequence-specific DNA-binding transcription regulator. It is normally widely expressed and appears to have an essential role in yolk sac angiogenesis, neuronal development and the establishment of bone marrow haemopoiesis. *AML1* (*CBFA2*) on chromosome 21 encodes a transcription factor that binds DNA as a heterodimer with CBFB and is essential for development of definitive haemopoiesis. The TEL–AML1 protein represses AML1-mediated transcriptional

activation through a dominant negative mechanism. The non-translocated *TEL* allele is frequently deleted in cases with the t(12;21); this deletion seems to be crucial for leukaemogenesis.

E2A–PBX1 and *E2A–HLF* fusion

The t(1;19)(q23;p13) with *E2A–PBX1* fusion, found in 5–6% of childhood ALL, is one of the most common translocations and is primarily seen in patients with pre-B ALL. The negative prognostic impact once associated with this karyotype has been abolished with contemporary treatment. The affected genes are those encoding the E2A transcription factor on chromosome 19 and the PBX1 homeodomain-containing transcription factor on chromosome 1. The resulting E2A–PBX1 fusion protein contains the transactivation domains of *E2A* linked to the DNA-binding homeodomain of *PBX1*. *PBX1* is required for the maintenance of definitive haemopoiesis and contributes to the growth of subsets of haemopoietic progenitors through its interaction with major HOX proteins. Ectopic expression of the E2A–PBX1 chimeric protein in mice leads to the development of leukaemia. The leukaemogenic effect of E2A–PBX1 is mediated, at least in part, by the induction of cell differentiation arrest.

A second *E2A* fusion gene, identified in 0.5–1% of cases with early pre-B immunophenotype, is created by the t(17;19)(q22;p13), in which *E2A* is fused to the gene that encodes hepatic leukaemia factor (*HLF*) on chromosome 17. The E2A–HLF fusion protein contains the transactivation domains of E2A linked to the DNA-binding and protein–protein interaction motifs of HLF. This fusion protein appears to inhibit apoptosis. Though relatively infrequent, these cases are easily recognized by their association with hypercalcaemia and disseminated intravascular coagulation at diagnosis. The prognosis of this genetic subtype appears to be poor.

BCR–ABL fusion

The t(9;22)(q34;q11), found in approximately 3% of childhood ALL, encodes a chimeric gene consisting of the 5′ portion of *BCR* fused to the 3′ portion of *ABL*. In chronic myeloid leukaemia, breaks occur most often within the major breakpoint cluster region (BCR) and encode a 210-kDa BCR–ABL chimeric tyrosine kinase (see also Chapter 37). In ALL, breaks occur most often within the minor breakpoint cluster regions, forming a 190-kDa BCR–ABL. In each fusion protein, N-terminal sequences of ABL are replaced by BCR sequences. This alteration results in a constitutively active ABL tyrosine kinase that induces aberrant signalling and activates multiple cellular pathways. Expression of either chimeric protein results in malignant transformation of haemopoietic cells and causes leukaemia in murine models. As a group, ALL with *BCR–ABL* fusion has been consistently associated with poor response to therapy; allogeneic haemopoietic stem cell transplantation is the treatment of choice if there is a suitable donor.

MLL gene rearrangements

Translocations affecting 11q23 chromosomal region occur in 8% of childhood ALL and in 70–80% of infant cases. The gene involved at the 11q23 region is *MLL* (mixed-lineage leukaemia or myeloid–lymphoid), also known as *HRX*, *ALL1* or *HTRX1*. More than 40 chromosomal loci are known to participate in *MLL* rearrangements. The most common translocation is the t(4;11)(q21;q23), which produces a chimeric protein that contains the N-terminal portion of *MLL* linked in-frame to the C-terminal portion of *AF4*.

MLL is crucial for embryonic development and haemopoiesis. *MLL* normally maintains expression of specific *HOX* genes by binding to DNA and recruiting a histone acetylase that keeps chromatin in an open conformation, accessible to transcriptional activators. In addition to interacting with DNA, *MLL* also directly interacts with the antiphosphatase SBF1, which positively regulates kinase signalling pathways. The leukaemia-associated alterations in *MLL* directly disrupt both of these important activities.

MLL rearrangements are associated with a young age, large leukaemic cell burden and central nervous system (CNS) involvement. The blast cells usually have CD10-negative B-cell precursor immunophenotype and expression of myeloid-associated antigens such as CD13, CD15 and CD33 is frequent. However, cases with the t(11;19)(q23;p13.3) with *MLL–ENL* fusion may have a T-cell phenotype. Age is the most important prognostic factor: infants younger than 1 year fare significantly worse than patients 1 year of age or older. Among infants with the t(4;11), a poor prednisone response and age < 3 months confer an especially poor prognosis; a poor prednisone response also appears to be associated with a poor response in older children with the t(4;11). Among patients with the t(11;19) and *MLL–ENL* fusion, those with a T-lineage immunophenotype, who are generally over 1 year of age, have a better outcome than patients over 1 year of age with B-cell precursor ALL. Haemopoietic stem cell transplantation failed to improve outcome in patients with the t(4;11). Two large cooperative group studies are evaluating the efficacy of intensified therapy that includes high-dose cytarabine, which appears to be particularly effective *in vitro* for leukaemic cells with the t(4;11). The finding of high levels of *FLT-3* expression in *MLL*-rearranged leukaemic cells has led to an ongoing phase I trial of FLT-3-targeted tyrosine kinase inhibitors.

Genetic abnormalities in T-cell ALL

Up to a quarter of patients with T-cell ALL lack detectable cytogenetic abnormalities. The most common specific translocations involve T-cell receptor alpha/delta gene loci on chromosome 14q11 and beta locus on 7q32–36. The translocations juxtapose enhancer elements responsible for the expression of T-cell receptor genes next to a variety of oncogene loci, leading to

overexpression of specific genes and disruption of transcriptional pathways involved in normal T-cell development and survival. Genes that are dysregulated in T-cell ALL include *SCL*(*TAL1*), *LMO1*(*TTG-1*)*, LMO2*(*TTG-2*) and *HOX11*. As a result of the t(1;14)(p33;q11), *SCL* (a gene involved in early haemopoiesis) is inserted next to the *TCRAD* loci; *SCL* expression is associated with *TALd* rearrangement, a cryptic abnormality resulting in an internal deletion of a 90- to 100-kb DNA in the 5′-untranslated region of *SCL*, in an additional 25% of T-cell ALL cases. This deletion juxtaposes the promoter sequences of a nearby gene (*SIL*, for *SCL*-interrupting locus) with the *SCL* coding region, resulting in the expression of a fused *SIL–SCL* transcript that encodes a normal SCL protein. However, misexpression of *SCL* has been detected in up to 60% of T-cell ALL cases, a frequency far exceeding that predicted by karyotype or *TALd* rearrangement.

The t(11;14)(p15;q11) and t(11;14)(p13;q11) inserts *LMO1* and *LMO2* into the *TCRAD* loci, leading to inappropriate expression of the respective LMO1 and LMO2 proteins, which contain two zinc-binding domains and participate in multi-protein DNA-binding complexes. *LMO2*, like *SCL*, plays an essential role in the development of primitive and definitive haemopoiesis. *LMO1* is normally expressed in CNS development and its misexpression is thought to contribute to the development of T-cell ALL in much the same way as for *LMO2*.

Another change found in T-cell ALL is the deletion from chromosome 9p21 of the *INK4a* and *INK4b* genes, which encode the p16[INK4a] and p15[INK4b] inhibitors of the Cdk4 cyclin D-dependent kinase. This locus, which is deleted in more than 50% of cases, also encodes a cell cycle regulatory protein, p19[ARF], which arrests cell cycle progression through p53.

A recent study using gene expression-profiling technology grouped T-cell ALL cases based on overexpression of the oncogenes *HOX11L2, LYL1*, *HOX11, TAL1* and *MLL-ENL*. Only one of the oncogenic transcription factors was highly expressed in most of the cases. Overexpression of *LMO1* or *LMO2* was found in most cases overexpressing *TAL1*, and high levels of *LMO2* were noted in *LYL1*[+] cases. Microarray analysis revealed that *LYL1*[+] cases showed an expression of the genes corresponding to an undifferentiated stage of thymocyte development, *HOX11*[+] cases showed a pattern reflecting the early thymocytic differentiation, and *TAL1*[+] cases had late thymocytic differentiation. A very favourable prognosis was observed in *HOX11*[+] cases, whose cells also have gene expression associated with a propensity to apoptosis. Expression of *HOX11L2*, a transcriptional regulator closely related to *HOX11*, is frequently found in T-cell ALL. The prognosis of this subset depends on treatment and was poor in some studies (Ballerini *et al.*, 2002; Ferrando *et al.*, 2002).

Subtypes of B-cell precursor ALL defined by global gene expression

Using oligonucleotide microarrays, Yeoh *et al.* (2002) identi-fied gene expression patterns that distinguished B-lineage ALL from T-cell ALL, confirming the results of a smaller series (Golub *et al.*, 1999). Moreover, expression profiles clearly identified each of the prognostically important subgroup of B-cell precursor ALL, including hyperdiploidy > 50 chromosomes, *BCR–ABL, E2A–PBX1, TEL–AML1* and *MLL* gene rearrangement. Examination of the genes constituting the expression signatures provides important insights into the biology of the leukaemia subgroups. For example, dysregulation of *HOX* gene family members has been identified as a dominant mechanism of leukaemic transformation in *MLL*-rearranged leukaemia. Microarray analysis also demonstrated that lymphoid leukaemic cells of different molecular subtypes share common pathways of genomic response to same treatment, and that changes in gene expression are treatment specific, suggesting that gene expression profiling can serve as a new tool for assessing the interaction of anti-cancer agents and providing a basis for optimizing combination chemotherapy.

Prognostic factors and risk groups

Assessment of the relapse risk is an integral part of the approach to ALL therapy. Only high-risk cases are treated intensively, with less toxic therapy reserved for cases at lower risk of treatment failure. Treatment is the single most important prognostic factor. For example, T-cell ALL, B-cell ALL and B-precursor ALL with the t(1;19), once associated with a very poor prognosis, now have a cure rate of 70% or more in some treatment protocols. Likewise, the poor prognosis of adolescence and black race can be abolished with effective contemporary therapy, although in most studies black race is still associated with a poor prognosis.

Age and leucocyte count

In B-cell precursor ALL, age and leucocyte count are consistent prognostic factors. Based on the Rome/US National Cancer Institute criteria, among B-cell precursor ALL cases, the two-thirds with presenting age of 1–9 years and initial leucocyte count < 50×10^9/L are classified to have standard-risk ALL, and the other one-third high-risk. However, this classification has limited value because one-third of the standard-risk patients may relapse, while patients at very high risk cannot be reliably distinguished from the high-risk patients. Moreover, the prognostic impact of age and, to a lesser extent, leucocyte count can be explained partly by their association with specific genetic abnormalities. For example, the overall poor prognosis of infant ALL is due to the very high frequency of *MLL* rearrangement (70– 80%) in this age group, whereas the favourable outcome of patients aged 1–9 years is related to the fact that 70% of them have hyperdiploidy > 50 chromosomes or *TEL–AML1* fusion, both favourable genetic features.

Table 33.4 Current ALL risk classifications of childhood acute lymphoblastic leukaemia.

Risk group	Features
St Jude Children's Research Hospital	
Low	B-cell precursor phenotype and age 1–9 years with leucocyte count $< 50 \times 10^9$/L, DNA index $\geq$ 1.16 and $<$ 1.60, or *TEL–AML1* fusion; without CNS or testicular leukaemia, or a t(1;19), t(4;11), t(9;22), or *MLL* rearrangement; level of minimal residual leukaemia $<$ 0.01% at the end of 6-week remission induction
Standard	T-cell phenotype and B-cell precursor cases not classified as low or high risk
High	t(9;22) or *BCR–ABL* fusion, induction failure, or blasts 1% or more (by flow cytometry or polymerase chain reaction) at the end of 6-week remission induction
Children's Oncology Group (B-lineage cases)	
Low	1–9 years with leucocyte count $< 50 \times 10^9$/L, have either trisomies 4, 10 and 17 or *TEL–AML1* fusion, rapid early response, without CNS or testicular leukaemia, or a *E2A–PBX1* fusion, *BCR–ABL* fusion or *MLL* rearrangement
Standard	1–9 years with leucocyte count $< 50 \times 10^9$/L, without trisomies 4, 10 and 17 or *TEL–AML1* fusion, and those with one of these genetic features but slow early response
High	The remaining cases who have no features of very-high risk
Very high-risk	*BCR–ABL* fusion, hypodiploidy, DNA index $<$ 0.81 or initial induction failure
Berlin–Frankfurt–Münster Consortium*	
Standard	Prednisone good response; molecular remission at the end of induction; no t(9;22)/*BCR-ABL* or t(4;11)/*MLL–AF4*
Medium	Prednisone good response; morphological remission on day 33; no t(9;22)/*BCR–ABL* or t(4;11)/*MLL–AF4*; not fulfil other standard- or high-risk criteria
High	Prednisone poor response; M2 or M3 marrow on day 33; presence of t(9;22)/*BCR–ABL* or t(4;11)/*MLL–AF4*; or $\geq$ 0.1% leukaemic cells at the end of induction

*M Schrappe, personal communication.

Genetic abnormalities and immunophenotypes

Leukaemic cell genetic abnormality and immunophenotype (T-cell, B-cell and B-precursor) have been incorporated into most classification systems (Table 33.4). Although *HOX11* over-expression confers a favourable prognosis in T-cell ALL, this genetic feature has yet to be included in the current risk classifications.

Even genetic abnormalities can only account partly for the prognosis. For example, up to 20% of patients with hyper-diploidy > 50 chromosomes or *TEL–AML1* fusion relapse. On the other hand, a substantial proportion of the patients with *BCR–ABL* who are 1–9 years old and have low leucocyte counts or who have good early response to prednisone may be cured with intensive chemotherapy alone. Similarly, among patients

with *MLL* rearrangements, those 1–9 years of age with good early response to prednisone, or with *MLL–ENL* fusion and a T-cell phenotype, respond well to chemotherapy.

Pharmacodynamic and pharmacogenetics factors

One plausible reason for the unpredictable relation between biological features of leukaemic cells and response to therapy is that pharmacodynamic and pharmacogenetic factors can exert a crucial influence on the effectiveness of treatment. There is a wide variation in the rate of metabolism of anti-leukaemic agents. Low systemic exposure to methotrexate and low-dose intensity of mercaptopurine have each been associated with a poor treatment outcome. Thus, treatment is unsuccessful in some patients because they have received inadequate doses of

drugs, and not because their leukaemia is resistant to therapy. Some anticonvulsants, such as phenytoin, phenobarbital and carbamazepine, can induce cytochrome P450 enzymes, thereby increasing the systemic clearance of a number of anti-leukaemic agents and leading to a poor treatment outcome. In patients who require anticonvulsants, we recommend the use of gabapentin and valproic acid, which are less likely to induce the activity of drug metabolism enzymes.

Patients who have deficiency of thiopurine methyltransferase (TPMT), the enzyme that catalyses the S-methylation (inactivation) of mercaptopurine, tend to have better leukaemia-free survival, probably because they receive a higher dose intensity of mercaptopurine. The null genotype (absence of both alleles) for *GSTM1* or *GSTT1* and for *GSTP1 Val$_{105}$/Val$_{105}$* has also been linked with lower risk in some treatment protocols, probably because of the reduction in detoxification of cytotoxic chemotherapy.

Early response to therapy

Because response to therapy is determined by both leukaemic cell genetics and host pharmacogenetics, measurements of this response *in vivo* should have a better prognostic strength than that of any other individual biological or host-related feature. The independent prognostic significance of the early response to induction therapy, as measured by the initial decrease of blasts in blood or bone marrow, was first recognized by the investigators of the Berlin–Frankfurt–Münster (BFM) Study Group and the Children's Cancer Group. However, neither measure has great precision, since 20% of patients with a good initial response eventually relapsed, while a third of patients with a poor response survived.

Recent development of assays to measure minimal residual disease by polymerase chain reaction of clonal antigen–receptor gene rearrangements, or by flow cytometry of aberrant immunophenotype, has greatly improved the sensitivity and specificity of assessment of early treatment response. Patients who attain a molecular or immunophenotypic remission, defined as leukaemic involvement of less than 10^{-4} nucleated bone marrow cells after induction therapy, have a significantly more favourable prognosis than those who do not; patients who are in morphological remission but have a post-induction residual leukaemia of 1% or more fare as poorly as those who do not achieve morphological remission. Half the patients show a disease reduction to 10^{-4} or lower after only 2 weeks of induction therapy, and they have an exceptionally good prognosis. Sequential monitoring can further improve the precision. The persistence of minimal residual disease (MRD) is associated with an estimated 70% cumulative risk of relapse. Patients with residual leukaemia of 0.1% or more at 4 months have an especially dismal outcome. Tandem application of flow cytometry and polymerase chain reaction testing has allowed us to study MRD successfully in virtually 100% of cases. We have therefore incorporated MRD detection into our current risk classification system (Table 33.4) (see also Chapter 34).

Other factors

Leukaemia cell growth in model systems, such as mice with severe combined immunodeficiency, cultures on stromal cell layers, or semisolid/liquid culture system, correlates with an adverse prognosis and with resistance to chemotherapy. Other factors related to a poor prognosis include male gender, malnutrition and expression of transporters of xenobiotics of the adenosine triphosphate-binding cassette protein superfamily.

Supportive care

At diagnosis, all febrile patients should be given empiric broad-spectrum antibiotics until an infection can be excluded. Most patients require packed red blood cell transfusions. We transfuse patients who have circulating leukaemic blasts with platelets to keep count close to 100×10^9/L before diagnostic lumbar puncture to reduce the risk of traumatic tap. Patients with a traumatic tap and leukaemic blasts in cerebrospinal fluid require intensified intrathecal therapy. After the clearance of circulating blasts, intrathecal therapy can be safely performed without prophylactic platelet transfusion, especially during vincristine–prednisone–asparaginase induction therapy, which is associated with a hypercoagulable state. All blood products should be irradiated in patients who are receiving chemotherapy to prevent graft-versus-host disease.

Careful attention to fluid and electrolyte balance is essential, both at diagnosis and for 48–72 hours after the start of chemotherapy. All patients require intravenous hydration. Specific measures to treat or prevent hyperuricaemia include allopurinol (a xanthine oxidase inhibitor that can prevent uric acid formation) and rasburicase (a recombinant urate oxidase that breaks down uric acid to allantoin – a readily excretable metabolite with 5- to 10-fold higher solubility than uric acid). Rasburicase is a more effective agent than allopurinol, and also facilitates the excretion of phosphorus, partly because of its potent uricolytic effect, obviating the need to alkalinize urine, and partly because of improved renal function with its use. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency because hydrogen peroxide, a byproduct of uric acid breakdown, can cause haemolysis or methaemoglobinaemia in these patients. In many patients, a phosphorus binder is needed to treat or prevent hyperphosphataemia and corresponding hypocalcaemia. Rarely, dialysis is needed for acute renal failure.

For patients with extreme hyperleucocytosis, some investigators have advocated the use of leukapheresis or exchange transfusion (in small children) to reduce the morbidity and mortality from leukostasis or leukaemic cell lysis, whilst others questioned the need for these measures.

Other important supportive care measures include prophylactic use of trimethoprim–sulphamethoxazole or atovaquone (in patients with poor tolerance to trimethoprim–sulphamethoxazole) for *Pneumocystis carinii* pneumonitis, the placement of indwelling catheters and psychosocial support. Prophylactic use of granulocyte colony-stimulating factor after induction or during consolidation therapy shortened the duration of severe neutropenia but failed to reduce episodes of febrile neutropenia or improve treatment outcome. In one study, the growth factor appeared to increase the risk of therapy-related AML in the context of epipodophyllotoxin-based therapy. The role of colony-stimulating factors and granulocyte transfusion in the treatment of neutropenia in children with cancer was discussed in a recent review (Liang, 2003).

Principles of treatment

The identification of reliable prognostic factors in ALL and the recognition of ALL as a heterogeneous disease have led to the use of risk-directed therapy. B-cell ALL cases are treated separately with short-term intensive therapy including high doses of methotrexate, cytarabine and cyclophosphamide, as well as anthracycline and intensive intrathecal therapy. For all other patients, specific approaches to therapy differ but consistently emphasize remission induction followed by intensification or consolidation therapy to eliminate residual leukaemia, eradication of CNS leukaemia, and treatment to ensure continuation of remission. The major advances established and some lessons learned from the recently completed clinical trials are summarized in Tables 33.5 and 33.6. In most studies, patients are divided into three risk groups, even though there has not been a consensus on the most useful criteria or on the terminology. The Children's Oncology Group recently proposed a four-group classification: low risk, standard risk, high risk, and very high risk (Table 33.4).

Induction therapy

The goal of remission induction therapy is to induce a complete remission by eradicating more than 99% of leukaemic burden, and by restoring normal haemopoiesis. Induction therapy typically includes a glucocorticoid (prednisone, prednisolone or dexamethasone), vincristine and at least a third agent (asparaginase, anthracycline, or both). There are several forms of asparaginase, each with a different half-life and hence potency. Two preparations were derived from *Escherichia coli*: Leunase (Kyowa Hacco Kogyo, Japan) is more potent and toxic than Elspar (Merck Sharp & Dohme, USA). Elspar has a half-life of 1.28 ± 0.35 days (SD); when it is covalently bound to monomethoxypolyethylene glycol (PEG), it has a half-life of 5.73 ± 3.24 days. There is another product, derived from *Erwinia chrysanthemi*, with a short half-life of 0.65 ± 0.13 days.

The reported differences in efficacy and toxicity of the various preparations can be attributed to the use of unequivalent doses. In the randomized EORTC 58881 trial, children received *Erwinia* asparaginase had a poorer event-free survival than

Table 33.5 Major advances established from the recently completed clinical trials.

Advance established	Reference
CNS-directed treatment	
1 Early intensification of intrathecal therapy improved outcome	Pui *et al.* (1998)
2 Traumatic lumbar puncture with blasts at diagnosis was associated with an inferior outcome	Gajjar *et al.* (2000), Bürger *et al.* (2003)
3 Cranial irradiation 12 Gy provided adequate CNS prophylaxis	Schrappe *et al.* (2000a,b)
4 Extended intrathecal therapy could replace cranial irradiation in intermediate-risk cases	Pui *et al.* (1998), Conter *et al.* (2000)
5 Omission of cranial irradiation for all patients may be feasible	Manera *et al.* (2000), Vilmer *et al.* (2000)
Intensification/reinduction chemotherapy	
1 Prolonged asparaginase intensification and dexamethasone improved outcome.	Silverman *et al.* (2000, 2001)
2 Intensive asparaginase consolidation benefited T-cell ALL	Maloney *et al.* (2000)
3 Double reinduction improved outcome for high-risk or intermediate-risk cases	Lange *et al.* (2002), Aricò *et al.* (2002)
4 Prolonged reinduction/intensification (augmented BFM therapy) improved outcome of high-risk cases with poor early response	Nachman *et al.* (1998)
High-dose methotrexate	
1 High-dose methotrexate was superior to fractionated oral methotrexate for intensification	Mahoney *et al.* (1998), Harris *et al.* (2000), Mahoney *et al.* (2000)
2 Very high-dose methotrexate (5 g/m^2) benefited T-cell ALL	Schrappe *et al.* (2000a,b)

Table 33.6 Lessons learned from the recently completed clinical trials.

Lesson learned	Reference
Intensive chemotherapy blocks resulted in inferior outcome in high-risk cases	Schrappe *et al.* (2000a,b)
High-dose intravenous mercaptopurine failed to improve outcome	Mahoney *et al.* (2000), Vilmer *et al.* (2000), Silverman *et al.* (2001), Bostrom *et al.* (2003)
High-dose cytarabine given in limited doses failed to improve outcome	Millot *et al.* (2001)
Allogeneic transplantation did not benefit t(4;11) cases	Pui *et al.* (2003b)
Thioguanine treatment did not improve outcome and was associated with hepatic veno-occlusive disease and thrombocytopenia	Harms *et al.* (2003)
Intensive mercaptopurine therapy may potentiate the risk of cranial irradiation-associated brain tumour or epipodophyllotoxin-related acute myeloid leukaemia, especially in patients with thiopurine methyltransferase deficiency	Relling *et al.* (1999b), Pui and Relling (2000)
Erwinia asparaginase at the same dose was inferior to *E. coli* asparaginase	Duval *et al.* (2002)
Hyperfractionated cranial irradiation may be inferior to conventional cranial irradiation	Silverman *et al.* (2001)

those who received *E. coli* preparation at the same dosage of 10 000 IU/m^2 twice weekly. In the Dana-Farber Consortium Protocol 1991–2001, no difference in event-free survival was noted between patients randomly allocated to receive *E. coli* asparaginase 25 000 IU/m^2 weekly for 30 weeks and those who received PEG-asparaginase 2500 IU/m^2 every other week for 30 weeks. Notably, patients who received fewer than 25 weeks of asparaginase therapy had a worse outcome than those who received 25 or more weeks of treatment. In the Pediatric Oncology Group 9310 study of relapsed ALL, the reinduction rate was significantly higher in patients who received 4-weekly doses of PEG-asparaginase than in those who received two doses given every other week. In one randomized trial, one dose of PEG-asparaginase at 2500 IU/m^2 produced more rapid clearance of lymphoblasts in day 7 and day 14 bone marrow and more prolonged asparaginase activity than five doses of native asparaginase at 6000 IU/m^2 on days 3, 5, 8, 10 and 12.

Collectively, the data suggested that PEG-asparaginase at 2500 IU/m^2 for one dose, *E. coli*-derived preparation at 25 000 IU/m^2 per week for 2 weeks or 10 000 IU/m^2 three times a week for 2 weeks, and *Erwinia* product at 25 000 IU/m^2 twice a week for 2 weeks appear to be equally effective. In terms of leukaemia control, the dose intensity and duration of asparaginase treatment are more important than the type of asparaginase used. *Erwinia* asparaginase should be used in patients with allergic reactions to *E. coli* preparation because antibodies against *E. coli* asparaginase cross-react with PEG-asparaginase.

Although asparaginase is an indispensable agent in the treatment of ALL, its use in remission induction is being challenged. In one randomized trial comparing the relative efficacy and toxicity of asparaginase and epirubicin as a third remission-induction agent in patients with standard-risk (low-risk) ALL, patients treated with Leunase 10 000 three times a week for 3 weeks had a significantly lower induction rate owing to a

higher rate of fatal infection. Reducing the dose of Leunase to 5000 IU/m^2 improved the remission induction rate. Dana-Farber Consortium protocols and COALL studies using asparaginase in the post-induction phase had an excellent long-term outcome with low morbidities (especially in terms of thrombotic complications and hyperglycaemia). Hence, additional studies are needed to determine the optimal timing of asparaginase treatment.

Dexamethasone has substituted for prednisone or prednisolone in induction and/or continuation treatment in some regimens because of its better penetrance into cerebrospinal fluid and its longer half-life. Although this substitution improved outcome in one randomized trial, it has also been implicated with excessive life-threatening infections and septic deaths in another. A number of major randomized clinical trials are evaluating the efficacy and toxicities of dexamethasone treatment during remission induction. To this end, higher dose of corticosteroid was shown to abrogate relative drug resistance in an upfront single-agent window study.

An intensified induction therapy is generally used in high-risk and very high-risk cases on the premise that a more rapid and profound reduction of leukaemic burden may forestall the development of drug resistance. Intensive induction therapy, however, may not be necessary for standard-risk (low-risk) cases, provided that patients receive post-induction intensification therapy. Moreover, intensive induction therapy may lead to a poor overall outcome because of an increase in early morbidity and mortality.

With modern chemotherapy and supportive care, 97–99% of children attained complete remission. Approximately 1% of the failures are due to toxic deaths during remission induction and another 1% to drug-resistant leukaemia. Patients who fail to achieve remission have a short survival and, if remission is eventually achieved, a higher rate of relapse. Therefore, most

investigators offer these patients the option of allogeneic transplantation after extended induction treatment. As mentioned earlier, patients with 1% or more residual leukaemia at the end of induction had an outcome as poor as those with induction failure and may also be candidates for allogeneic transplantation.

Intensive chemotherapy has been associated with the development of sepsis, disseminated fungal infection and typhlitis. Oral candidiasis occurs frequently. For oropharyngeal candidiasis, it is preferable to use poorly absorbed clotrimazole than other azole compounds to avoid inhibiting cytochrome P450 enzymes, resulting in excessive vincristine toxicities. Foods that may be contaminated with pathogens should be avoided. Glucose intolerance should be monitored in patients at increased risk of hyperglycaemia – adolescents, obese patients and Down's syndrome patients – during early remission induction with asparaginase. Too much salt intake may cause hypertension and seizure, especially in patients with severe constipation. Patients with Charcot–Marie–Tooth hereditary neuropathy are at particularly high risk for vincristine-induced profound neuropathy. Behaviour changes are common owing to the prolonged hospitalization, disease and glucocorticoid treatment, especially dexamethasone.

Intensification (consolidation) and reinduction

Once normal haemopoiesis is restored, patients can tolerate intensification (consolidation) therapy. There is no consensus on the best regimens and their duration. Delayed intensification (or reinduction), pioneered by investigators in the BFM group, is perhaps the most widely used regimen. It is basically a repetition of the induction therapy at 3 months after remission induction. Investigators of the Children's Cancer Group confirmed its efficacy and subsequently showed that double delayed intensification started at week 32 further improved outcome of patients with high-risk (or so called intermediate-risk) ALL. Extended and more intensive intensification therapy also significantly benefited patients with high-risk ALL and a slow response to initial induction therapy, especially in younger children. Whether this approach will benefit standard-risk cases is now under investigation. Hence, reinduction or delayed intensification appears to be beneficial to all patients, whereas double or prolonged intensification appears to be beneficial to patients with high-risk or very high-risk ALL.

Effective components of intensification treatment include the intensive use of asparaginase and high-dose methotrexate. The need for very high-dose methotrexate (5 g/m^2) in T-cell ALL is consistent with the finding that T-lymphoblasts accumulate methotrexate and its active polyglutamates metabolites less avidly than do B-lineage blasts, so that higher serum concentrations of methotrexate are needed for adequate response. The optimum dose of methotrexate for various genetic subtypes of B-precursor ALL remains to be determined, but a dose of 2.5 g/m^2 should be adequate in most cases.

The most successful post-remission intensification regimens generally feature continuous therapy, whereas high-dose pulse therapy with long rest periods due to myelosuppression appears to be less effective. This observation is consistent with the concept of metronomic dosing for solid tumours, based on the idea that continuous or frequent administration of cytotoxic drugs may improve outcome by abrogating the ability of slowly proliferating endothelial cells, essential for survival of tumour cells, to repair and recover during the usual rest period. Angiogenesis has also been seen in ALL, and chemotherapy could affect the recovery of bone marrow mesenchymal and endothelial cells that provide essential survival factors for leukaemic cells.

CNS-directed therapy

Treatment for subclinical or overt CNS leukaemia is an integral part of successful therapy for ALL. Patients with one or more of the following features are at increased risk of CNS relapse and require more intensive CNS-directed therapy: large leukaemic cell burden, T-cell ALL, high-risk genetic abnormality, and the presence of leukaemic cells in cerebrospinal fluid, even if caused by iatrogenic introduction from a traumatic lumbar puncture.

Dexamethasone and intrathecal therapy were shown to improve CNS control. Whether triple (methotrexate, hydrocortisone and cytarabine) intrathecal therapy is more efficacious than intrathecal methotrexate alone remains to be determined. High-dose methotrexate is useful for preventing haematological or testicular relapse, but has only a marginal effect on controlling CNS leukaemia.

Cranial irradiation is effective CNS therapy. However, it can cause substantial neurotoxicity, endocrinopathy and occasional brain tumours. In a study with extended follow-up, prior cranial irradiation (18–24 Gy) was associated with a $20.9 \pm 3.9\%$ (SE) cumulative risk of second neoplasm at 30 years from remission induction, higher mortality rate than that of the general population, and increased unemployment rate. Although 12 Gy cranial radiation together with intrathecal methotrexate and effective systemic chemotherapy can provide adequate CNS control, the long-term sequelae of this approach is unknown. Three clinical trials tested the feasibility of omitting cranial irradiation. In one study, the omission of cranial irradiation was implicated with increased CNS and haematological relapse in T-cell ALL with a presenting leucocyte count of more than 100×10^9/L. The inadequate systemic chemotherapy may have contributed to the increased rate of relapse. Two other studies omitted cranial irradiation for all patients. The cumulative risks of isolated CNS relapse were 4.2% and 3.0%, and rates of any CNS relapse were 8.3% and 6.0% respectively. CD10-negative B-cell precursor (pro-B) phenotype, CNS2 or CNS3 status and a leucocyte count of greater than 100×10^9/L conferred an increased risk of CNS

relapse. It should be noted that patients with isolated CNS relapse who had previously not received cranial irradiation have a very high retrieval rate. Dutch and St Jude Children's Research Hospital investigators are testing the hypothesis that, in the context of intensive systemic and intrathecal therapy, cranial irradiation can be omitted for all patients. In these studies, cranial irradiation is now reserved for salvage therapy, thus sparing the vast majority of patients from its toxicities.

Continuation treatment

Children with ALL, except those with B-cell leukaemia, require long-term continuation treatment. Attempts to shorten the duration of treatment to 24 months or less resulted in a high rate of relapse. A study which intensified early therapy but shortened total treatment duration to 1 year also resulted in poor overall result. Many investigators prefer to extend treatment for boys to 3 years because of their generally poorer outcome compared with girls, although the benefit of this approach remains to be determined. There is no advantage to prolonging treatment beyond 3 years.

The standard 'backbone' of continuation treatment is the combination of methotrexate given weekly and mercaptopurine given daily. By its inhibiting effect on *de novo* purine synthesis, methotrexate is synergistic with mercaptopurine, enhancing the conversion of mercaptopurine to thioguanine nucleotide, the active metabolite. Pharmacokinetic studies of methotrexate and mercaptopurine have revealed wide intrapatient and interpatient variability in drug disposition. Accumulation of higher intracellular levels of the active metabolites, methotrexate polyglutamates and thioguanine nucleotides, has led to a better outcome. Taking mercaptopuine at bedtime with an empty stomach is advisable for good efficacy. Mercaptopurine should not be taken together with milk or milk products which contain xanthine oxidase, which can degrade the drug. Tailoring dose as indicated by neutrophil count has led to a better outcome. However, overzealous use of mercaptopurine, so that neutropenia precludes further use of chemotherapy and thus reduces overall dose intensity, is counterproductive.

Rare patients (1 in 300) are homozygous deficient for thiopurine-S-methyltransferase and have extreme sensitivity to mercaptopurine, requiring marked reduction in dosage. Approximately 10% of patients have heterozygous deficiency, and may also need dose reduction. Molecular diagnosis can identify the patients who have the enzyme deficiency and allow selective dose reduction of the responsible agent in patients with poor tolerance to antimetabolite-based therapy, leaving the other drugs in full doses. Patients with the enzyme deficiency are also at greater risk of developing radiation-induced brain tumours and therapy-related acute myeloid leukaemia.

The parenteral administration of methotrexate affords a way to overcome decreased bioavailability and poor compliance.

Adjusting the dose of intravenous high-dose methotrexate to account for the patient's ability to clear the drug improves the outcome of B-precursor ALL. Multiple fractionated lower dose oral methotrexate and high-dose intravenous mercaptopurine are ineffective. Notably, methotrexate may induce encephalopathy, even when given orally, when treatment is intensive and leucovorin rescue is insufficient. Patients with Down's syndrome tolerate methotrexate poorly. By inhibiting enzymes involved in folate homeostasis and by depleting cellular reduced folates, high-dose methotrexate treatment may cause transient hyperhomocysteinaemia, which may be responsible for the neurotoxicity.

The addition of intermittent pulses of vincristine and a glucocorticoid to the continuation treatment regimens improves results. Dexamethasone has been substituted for prednisone during continuation therapy in many clinical trials. However, studies to determine the optimum dose and duration of dexamethasone therapy are needed. Glucocorticoid treatment, especially with dexamethasone, often causes behaviour changes; the dose occasionally needs to be reduced or even held because of psychotic reactions. Extended use of glucocorticoid may result in stunted growth, obesity, osteoporosis and avascular necrosis of bone which can be debilitating. Several studies will determine if interrupted use of glucocorticoid, e.g. administration for 1 week and then discontinuation for 1 week during reinduction therapy, can reduce the side-effects but maintain the efficacy.

Allogeneic haemopoietic stem-cell transplantation

Because improvements in transplantation and chemotherapy are occurring in parallel, the indications for transplantation in newly diagnosed and relapsed ALL patients should be re-evaluated periodically. At present, Philadelphia-positive ALL, induction failure and early marrow relapse are clear indications for transplantation. Transplantation has not been shown to improve outcome in other types of very high-risk ALL, such as infant ALL with *MLL* rearrangement, whose outcome may be improved by intensive therapy containing high-dose cytarabine.

Future directions

The trend towards increasingly aggressive therapy is likely to reach a point of diminishing returns. The hope for the future probably is the development of therapies that target the fundamental biological processes. Advances in the molecular classification of ALL, through use of DNA microarrays or proteomic techniques, will almost certainly identify targets for more specific treatments. One precedent is imatinib mesylate (Glivec, Gleevec) for *BCR–ABL*-positive ALL. This agent, which inhibits

the BCR–ABL oncoprotein and Kit tyrosine kinases, has induced transient remissions of *BCR–ABL*-positive ALL, as well as partial responses in patients with other malignancies, and is regarded as the forerunner of a new generation of molecularly targeted anti-cancer drugs (see also Chapter 37). Other potentially useful agents still in development include inhibitors of FLT-3 tyrosine kinase for leukaemias having activating mutations of this kinase, and histone deacetylase inhibitors for leukaemias such as *TEL–AML1*-positive ALL. Further refinements in the molecular classification of ALL, together with the identification of genetic features that affect the efficacy and toxicity of anti-leukaemic therapy, will afford unique opportunities to devise treatment plans for individual patients, and thus to realize the ultimate goal of curing all children with ALL.

Minimal residual disease in acute leukaemia

34

Letizia Foroni, Paula M Gameiro and A Victor Hoffbrand

Basic aspects of detection of minimal residual disease in acute leukaemia

Patients with acute lymphoblastic or acute myeloid leukaemia may harbour up to 10^{12} malignant cells at presentation. With chemotherapy, the majority of both children and adults (below the age of 65 years) achieve complete clinical remission (CCR) following the first course of induction therapy. However, even in CCR, patients can still have as many as 10^{10} malignant cells in the marrow, and this is responsible for relapse in 15–20% of children and 50–60% of adults with acute lymphoblastic leukaemia (ALL) and in a varying proportion of patients with acute myeloid leukaemia (AML).

A variety of methods have been developed to detect malignant cells in patients in CCR, i.e. to detect 'minimal residual disease' (MRD) with higher sensitivity than morphology. This conventionally defines CCR by the presence of less than 5% blasts in the bone marrow. The goal of more sensitive techniques for MRD detection is to adjust patients' therapy in order to reduce both the risk of relapse and of overtreatment, particularly in children. It is also aimed at determining the quality of stem cell harvests for autologous stem cell transplantation (SCT) and prediction of early relapse in patients following allogeneic SCT, e.g. when donor leucocyte infusion may be particularly effective at eliminating residual disease.

MRD is defined as the lowest level of disease detectable in patients in CCR by the methods available. A reliable technique for MRD detection should be specific (discriminate malignant from normal cells), sensitive (able to detect up to one leukaemic cell in at least 10^4 normal cells), reproducible (widely applicable in different laboratories) and quantitative (provide a numerical estimate of positive cells).

Several tests have been developed. Among these, the detection of tumour-associated aberrant immunophenotypic patterns by flow cytometry and leukaemic cell DNA or RNA by the polymerase chain reaction (PCR) have become the two most extensively used (Figure 34.1). They combine the highest levels of sensitivity and specificity. Other techniques, including
Figure 34.1 Relation between MRD level, stage of treatment and clinical status.

cytogenetics, fluorescence *in situ* hybridization (FISH) and Southern blotting lack the sensitivity required for detection of MRD.

Minimal residual disease detection by immunology and flow cytometry

Acute lymphoblastic leukaemia

The use of muliparameter flow cytometry for the immunological measurement of MRD requires the identification of a leukaemic-specific pattern of antigen expression (or profile) at presentation which is then sought at follow-up. The various phenotypes that can be used for MRD detection have been summarized (Table 34.1).

Table 34.1 Main marker combinations used to study MRD in childhood ALL and AML.

Cell lineage	Marker combination	Applicability (%)*
T-lineage ALL	TdT/CD5/CD3	90–95
	CD34/CD5/CD3	20–25
B-lineage ALL	CD19/CD34/CD10/CD38	40–60
	CD19/CD34/CD10/CD58	40–60
	CD19/CD34/CD10/CD45	40–60
	CD19/CD34/CD10/TdT	40–50
	CD19/CD34/CD10/CD66c	30–40
	CD19/CD34/TdT/IgM	10–20
	CD19/CD34/CD10/CD22	10–15
	CD19/CD34/CD10/CD13	10–15
	CD19/CD34/CD10/CD15	10–15
	CD19/CD34/CD10/NG-2	5–10
AML	CD33/CD34/CD117/CD15	20–40
	CD33/CD34/CD117/CD13	20–40
	CD13/CD33/CD34/CD56	20–30
	CD13/CD33/CD34/CD133	20–30
	CD13/CD33/CD34/CD7	20–30
	CD13/CD33/CD34/CD38	15–20
	CD33/CD34/CD117/HLA-Dr	15–20
	CD13/CD33/CD34/CD15	15–20
	CD33/CD34/CD117/CD11b	10–15
	CD13/CD33/CD34/CD19	5–10

*Percentage of patients with each type of leukaemia in whom MRD could be studied with the listed antibody combination. Percentages were calculated by including only cases in which intensity of antigen expression was sufficiently different from that of normal bone marrow cells to afford a sensitivity of detection of 1 in 10^4 or greater for ALL and 1 in 10^3 or greater in AML (table kindly provided by D. Campana, Professor of Paediatrics, University of Tennessee College of Medicine, Memphis, USA).

The method requires fresh material for analysis and operators skilled in flow cytometry to achieve the identification of rare leukaemic cells in the background of normal bone marrow cells. In competent hands, it can achieve sensitivity of 1 in 10^4 and a result can be obtained in 2–3 hours.

In T cell precursor ALL (T-ALL) patients, for instance, the double expression of terminal deoxynucleotidyl transferase (TdT) and cytoplasmic CD3 (cCD3) antigens makes the identification of leukaemic cells reliable up to 1 in 10^4 since normal bone marrow does not contain cells of this phenotype. Flow cytometry tests in childhood T-ALL show that the test is a good prognostic indicator of outcome with comparable levels of MRD in peripheral blood and BM samples, suggesting that monitoring of T-ALL patients can be done using peripheral blood samples.

In B-precursor ALL, distinction of leukaemic cells from normal regenerative post-chemotherapy cells is more difficult and may vary with the stage of treatment. In childhood B-precursor ALL patients, flow cytometry shows that MRD at < 0.01% as early as day 19 post induction identifies patients with high leukaemic cytoreduction and high frequency of subsequent CCR (> 97%). By contrast, MRD between > 0.1% and 1% at week 14 post induction identifies patients with a poor outcome (> 68% relapse incidence compared with 7% in patients MRD negative at this stage). High relapse rates are also observed in patients with MRD at any level in bone marrow samples beyond 3 months from presentation. Peripheral blood is approximately 10-fold less sensitive than bone marrow in B-precursor ALL, so a positive MRD test in PB identifies patients at higher risk of relapse than patients with MRD only in the bone marrow.

Acute myeloid leukaemia

Multiparameter flow cytometry has also been extensively applied to AML. Cross-lineage antigen expression and ectopic expression or abnormal light scatter patterns identify up to 50% of AML cases suitable for MRD investigation with a sensitivity of 1 in 10^4 (Table 34.1). MRD levels post induction identify four groups of patients. Patients with MRD < $1:10^4$ show no relapse while relapse rates increase to 14% with MRD at $1:10^3$–10^4, 50% for MRD levels between $1:10^2$ and $1:10^3$ and 84% with MRD above $1:10^2$. These higher MRD values are more frequent in patients with other adverse prognostic factors such as unfavourable cytogenetics and high white blood cell counts. Nevertheless, MRD detection remains independently prognostic in a multivariate analysis.

Flow cytometry offers several advantages since it provides a direct measurement of the number of leukaemic cells present. It is rapid, measures size of cells and distinguishes between viable and dead cells. Immunophenotypic change of the leukaemic cells may give negative results. Complete phenotypic switches are, however, rare.

Minimal residual disease detection by polymerase chain reaction

Acute lymphoblastic leukaemia

Minimal residual disease investigation in ALL using PCR relies on the detection of one or other of two molecular targets that distinguish the leukaemic cell from normal lymphoid cells: (i) junctional regions that result from clonal immunoglobulin and T-cell receptor gene rearrangement and (ii) fusion transcripts due to specific chromosomal translocations. Antigen receptor gene rearrangements occur naturally in B and T cells as part of normal lymphocyte development (see Chapter 20) and, because their sequences are unique in each precursor cell, can be considered as cell/patient-specific targets. The fusion transcripts resulting from chromosomal translocations are leukaemia but not patient specific. The two targets have different biological, technical and clinical aspects and are discussed separately. The results are available in 24–72 h, depending on the technique used.

Antigen receptor gene targets for MRD detection

Both B and T cells have highly specific cell-surface receptors, the immunoglobulin (Ig) or B-cell antigen receptor (BCR) and the T-cell receptor (TCR) respectively, for structure, organization and gene rearrangement of IgH and TCR molecules.

PCR-based MRD detection using antigen receptor genes

Identification of a clonal marker in B-precursor ALL and T-ALL

The process of Ig and TCR rearrangement gives rise to a unique rearrangement in each B cell (involving the genes for Ig production) and T cell (involving the genes for TCR production). The Ig gene rearrangement for the heavy chain is illustrated in Figure 34.2. The same process of rearrangement applies for the TCR-β and -δ genes. For the Ig light-chain k and λ, TCR-λ and TCR-α genes, no D elements are present. Because of its unique size and basepair combination, the complementarity determining region (CDR) 3 segment is the unique element that distinguishes the rearranged IgH gene in different B cells. All the cells derived from a single B-cell precursor carry the same rearrangement.

Since ALL is a clonal proliferation of precursor lymphoid cells, all leukaemic cells in each patient share the same Ig rearrangement (in B-precursor ALL) or TCR rearrangement (in T-ALL).

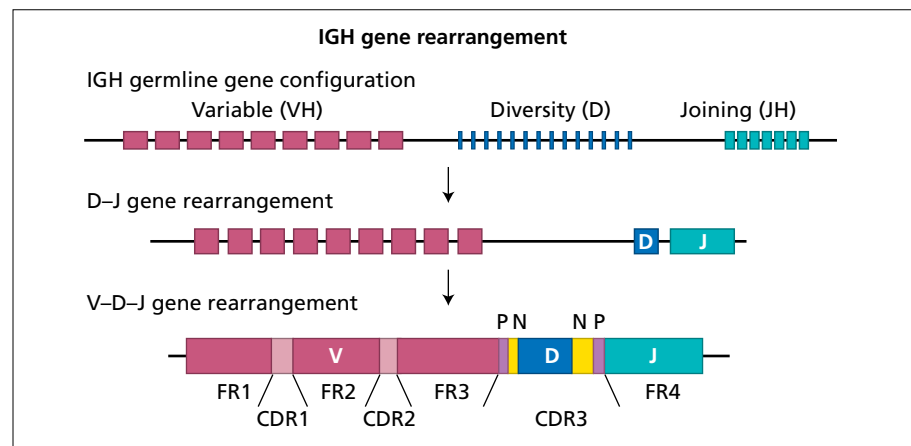
The presentation bone marrow or peripheral blood samples are processed for DNA extraction and the unique Ig or TCR gene rearrangement is identified using a combination of primers for the V, D and J segments of the different Ig heavy, Ig light genes and TCR-γ, TCR-β, TCR-δ and TCR-α genes. The primers are usually designed from regions of homology in the V or J segments to avoid having to use one primer for each one of the V,


Figure 34.2 VDJ gene rearrangement and identification of framework (FR), complementarity determining region (CDR), P and N nucleotides. FR and CDR regions are defined by the absence of contact with the antigen and lower mutation rate (FR) or direct contact with the antigen and higher incidence of mutations in the functional Ig protein (CDR). P nucleotides are novel basepairs complementary to the last germline nucleotides of the V and J elements while N nucleotides are *de novo* nucleotides added by terminal deoxynucleotidyl transferase (TdT) during the process of rearrangement. The joining element is referred to as FR4 region in the completed VDJ rearranged segment.
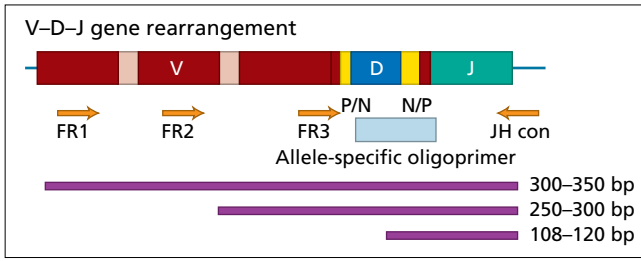

Figure 34.3 PCR strategy for the identification of clonal IGH gene rearrangement in B-precursor ALL. Family primers homologous to the FR1 or FR2 or FR3 regions are used in conjunction with a JH consensus primer. The primers are chosen from these regions which are less prone to be somatically mutated following the VDJ rearrangement (see legend to Figure 34.2). Different size fragments can be identified depending on the set of primers used.

D or J segments, which would be very labour intensive. An example of the strategy used for the amplification of the IgH genes is illustrated in Figure 34.3. The same strategy can be applied to TCR and Ig light-chain genes.

An example of amplification of clonal IgH rearrangement using primers for the FR1 and JH segments is illustrated in Figure 34.4.

The use of Ig and TCR gene rearrangements as MRD targets in precursor B- and T-cell ALL has the advantage of being widely applicable and being informative in 95–99% of patients (Table 34.2). Immunoglobulin genes are rearranged in more than 95% of precursor-B ALL cases: 98% for IgH (V_H–J_H and D_H–V_H), 50% for IgK (Vκ–Jκ and IgK–Kde) and 20% for IgL (Vλ–Jλ). In 5–10% of T-ALL cases, IgH genes are also rearranged. TCR-δ, TCR-γ and TCR-β clonal rearrangement occur
Figure 34.4 Example of a VH3 clonal population in a B-precursor ALL patient. DNA from a B-precursor ALL patient was screened with each of the FR1 primers for the six major VH family of genes (VH1 to VH6) and a JH primer, as illustrated in Figure 34.2. The major VH3 clonal marker can be easily seen as a specific band in the VH3 lane of approximately 350 bp size product. In this case a minor VH1 clonal band can also be seen. Amplification of the β-actin gene was carried out to control for quality and quantity of DNA loading. A PCR product of approximately 600 bp is visible in each lane.

in 70%, 90% and 50%, respectively, of the T-lineage ALL and also, as cross-lineage TCR gene rearrangements, in 50%, 70% and 10% of B-precursor ALL respectively (Table 34.2). Consequently, at least one (in 75% of patients), but often two (in 50% of cases) or three (in 40% of cases), rearrangements can

Table 34.2 Frequency of Ig and TCR gene rearrangements in precursor B- and T-lineage ALL.

Gene rearrangement	Precursor B-ALL (%)		Precursor T-ALL (%)	
	Adult	*Childhood*	*Adult*	*Childhood*
IgH	75–80	90–95	5–10*	5–10*
D_H–J_H	20		10	
V_H–D_H–J_H	>95		~2	
Igκ	40–50		0	
Vκ–Jκ	30			
Vκ–Kde	50			
Igλ	20		0	
TCR-β	10		50	
TCR-γ	70		60–70	>90
TCR-δ	50†		~70‡	

*Lineage IgH gene rearrangements in T-ALL are mainly incomplete D_H–J_H rearrangements and occur more frequently in CD3⁻ T-ALL (~20%) and TCR-γδ⁺ T-ALL (50%) compared with TCR-αβ⁺ T-ALL cases (< 5%).
†Predominantly Vδ2–Dδ3 and Dδ2–Dδ3 rearrangements.
‡Predominantly Vδ1–Jδ1 complete rearrangements and Dδ2–Jδ1 rearrangements.

be identified as molecular targets in ALL and used for MRD assessment.

The patient's leukaemic clone is then sequenced and the sequence of the CDR3 region identified. This region is unique for each patient and an oligoprimer is designed from its unique sequence and used in allele-specific oligonucleotide (ASO)-based MRD analysis (Figure 34.3 and text below).

PCR-based MRD detection

Fingerprinting gene analysis

Fingerprinting PCR-based MRD tests identify in remission marrow DNA the patient's original clone based on its unique size and migration mobility (Figure 34.5). Identification of residual leukaemia is carried out using the same combination of primers that yielded a signal in the presentation sample (for instance, VH3/JH and VH1/JH in Figure 34.4). The PCR reaction, however, is spiked with radiolabelled nucleotide ([α-^{32}P]dCTP) and the PCR product is then separated on a high-density acrylamide gel and autoradiographed to pick up the radiolabelled signal of the PCR product. In normal bone marrow, a 'ladder' of fragments is detected corresponding to the various IgH rearrangements in the heterogeneous B-cell population. In the follow-up sample, a signal identical in size to that from the original leukaemic presentation bone marrow sample will be observed if residual cells are present (Figure 34.5).

Alternatively, a fluorescence assay can be used (gene scanning analysis; Figure 34.6). Both techniques provide sensitivity of detection up to 1:10^3.

Allele-specific oligonucleotide (ASO) MRD detection

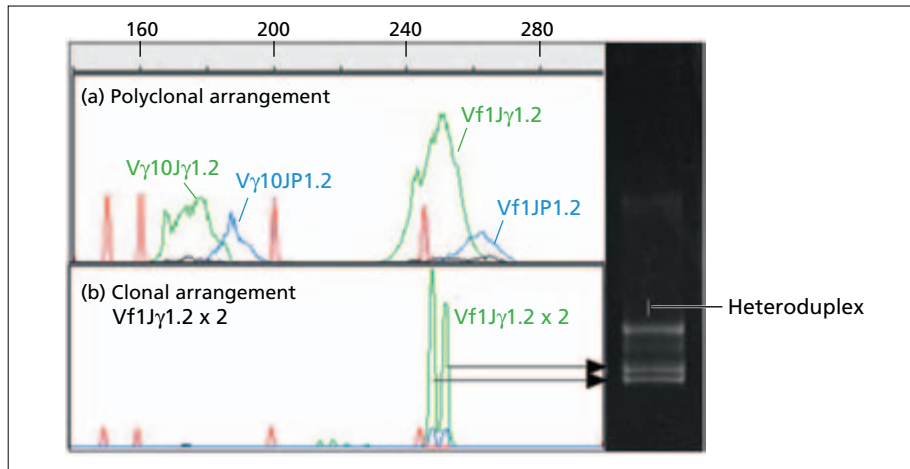
The ASO, designed from the CDR3 region (Figure 34.3), can be used to increase the sensitivity of MRD detection up to 1:10^4 or 1:10^5. The increase in sensitivity is due to the specificity for the leukaemic cell that this primer carries since the CDR3 region is unique to each rearrangement. Technically, the increase in sensitivity can be achieved by a variety of methods: (i) the ASO can be used in a radiolabelled PCR reaction as antisense primer (in place of the JH primer) in combination with the V family primer identified in the presentation sample (for instance a VH3 for the case in Figure 34.4); (ii) the ASO primer can be labelled and used as a probe in a hybridization experiment when the follow-up sample DNA is deposited on a filter paper (by dot-blot); or (iii) use as a sense or antisense primer in a quantitative PCR test using TaqMan or LightCycler technology (as described later) in combination with a JH or VH primer respectively. This is the most advanced technique and is replacing other approaches in many laboratories.
Figure 34.5 Example of fingerprinting analysis. A ladder of fragments corresponding to the various IGH rearrangements in polyclonal B cells is illustrated in (a) and (b) for DNA from normal bone marrow. This can be compared with the unique strong band detected in the bone marrow DNA of a patient with B-precursor ALL (c). The number above each lane in A and B indicates the VH gene family used for the PCR amplification (VH1 to VH6). (b) represents a longer exposure of (a), lanes 1, 2, 5 and 6.


Figure 34.6 Analysis of multiplex TCR-γ rearrangement by PCR from DNA using fluorescent primers and Genescan evaluation (left) compared with non-denaturing PAGE analysis of heteroduplex (HD) PCR products (right). (a) Polyclonal rearrangements. (b) Clonal biallelic rearrangement in a B-cell precursor ALL, analysed by gene scanning or heteroduplex. Slow-migrating clonal heteroduplexes are seen when both alleles undergo rearrangement with the same Vγ and Jγ segments. Homoduplexes are indicated by arrows. The use of differently labelled primers allows identification of the V and J segments used, as shown. Size markers are in red (diagram kindly provided by Kheïra Beldjord and Professor E. Mackintyre, Laboratoire d'Hématologie, Hôpital Necker Tour Pasteur, Paris, France).
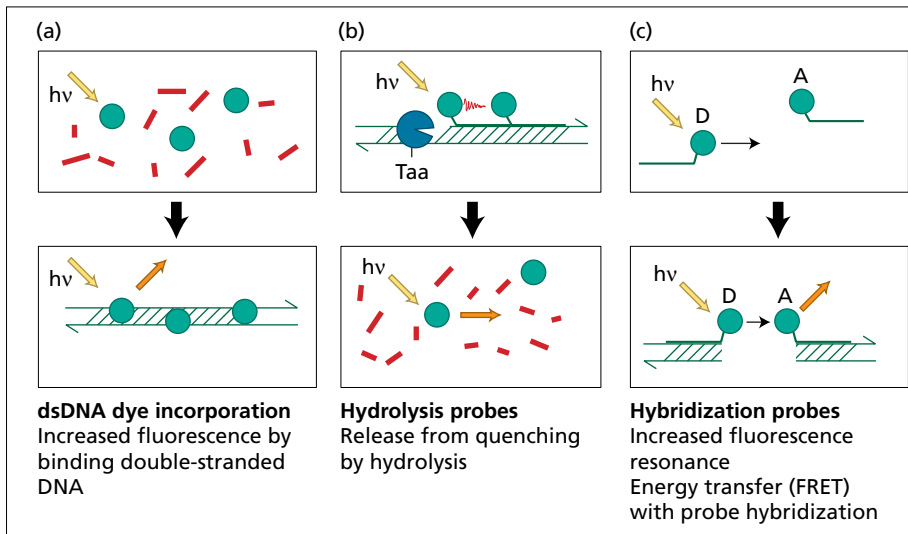

Figure 34.7 Real-time PCR techniques. (a) Incorporation of SyberGreen fluorescent dye as the PCR develops. (b) The hydrolysis probes are the basis for the TaqMan technology. (c) Hybridization probed with fluorescence resonance energy transfer (Roche) (courtesy of Dr Andreas Hochhaus, Heidelberg University, Mannheim, Germany).

Increased sensitivity can be achieved using cellular enrichment of lymphoid cells prior to PCR amplification or the amplification of multiple aliquots of DNA from remission BM samples.

Real-time PCR MRD detection

Real-time quantitative PCR (RQ-PCR) has been applied for the detection of *Ig/TCR* gene rearrangements in ALL. Whether using SYBR Green I hydrolysis probes or fluorescence resonance energy transfer (FRET), this technology provides rapid, repro-ducible and quantitative results for both *Ig/TCR* and gene fusion RT-PCR targets. The strategy used is illustrated in Figure 34.7.

Equipment and probe costs are becoming cheaper for application to large-scale studies. An extensive review of this technology has been published and we refer the reader to this for further information (Van der Velden *et al.*, 2003).

The technique of real-time PCR was pioneered in 1992 to detect PCR products as they accumulated by measuring the intercalation of ethidium bromide and hence increased fluorescence as the reaction proceeded (Figure 34.7a). The method was

subsequently improved by changing to a probe-based rather than intercalation-based detection system (Figure 34.7b). The probe carries a quencher that prevents the reporter dye fluorescing unless it is separated by the activity of the *Taq* polymerase as DNA is synthesized. Finally, the hybridization probe makes use of two sequence-specific oligonucleotides labelled with different fluorescent dyes. The light excites one primer which then transfers energy to the second oligoprimer and it is then converted into a quantified signal (FRET) (Figure 34.7c).

Quantitative PCR is visualized as the PCR cycles take place. It provides a signal comparison between different amounts of substrate and several samples can be tested simultaneously.

Clinical value of monitoring for antigen receptor gene rearrangements by PCR in ALL

Molecular investigation of antigen receptor gene rearrangements shows that targets for MRD can be identified in over 90% of childhood ALL and in 75–85% of adult ALL. These techniques are valuable for risk stratification of patients, based on their levels of residual disease at different time points.

Childhood ALL

In childhood ALL, single-point MRD assessment at day 28 post induction is a useful test for the identification of patients at increased risk of relapse. MRD PCR-based quantitative tests carried out as early as day 15 during induction therapy can identify patients with rapid molecular responses and an excellent prognosis, similar to flow cytometry tests on day 19, when lack of detectable residual leukaemic cells is associated with long-term disease-free survival.

At day 28, depending on the MRD level, patients fall within a high-, intermediate- or low-risk group. MRD $\geq 10^2$ identifies the group at highest risk of relapse. MRD level between 10^3 and 10^4 defines an intermediate-risk group and further monitoring should be performed to ensure complete conversion to MRD-negative tests in the following months. Sequential quantitative measurements of residual disease (at 12 and 20 weeks) identify patients with a fast decline in disease to undetectable levels that strongly correlate with durable CCR. Patients with no detectable disease or levels $< 10^4$ at day 28 represent a low-risk group and have the best outcome.

Any level of detectable disease beyond 3 months identifies patients at high risk. Examples of correlation between MRD tests and disease-free survival for samples collected during the first 24 months of treatment at our institution are illustrated in Figure 34.8. PCR-based MRD tests carry the most significant predictive value when compared with other criteria such as immunophenotype, age, sex, WBC count and cytogenetics. Tests in B- and T-lineage childhood ALL provide highly significant prediction of

outcome. MRD studies by PCR (but not by flow cytometry) show a higher incidence of disease in childhood T-ALL in remission than in B-precursor ALL, and this correlates with a poorer outcome of T-compared with B-precursor ALL in this age group.

Adult ALL

Results from the largest cohort (85 patients) so far studied showed, as observed in childhood, that MRD-PCR positivity at early time-points is predictive of outcome. The higher the level of MRD, the greater the chance of relapse (Figure 34.9). Over 50% of patients have detectable residual disease post induction, and residual disease decreases with time in patients destined to remain in CCR. In patients who eventually relapse, the disease is never fully eradicated and, in a proportion of patients (15–20%), relapse is associated with re-emergence of disease detected by PCR between 6 and 9 months post consolidation and during maintenance (Figure 34.9).

In T-ALL adult patients, data are more limited. In contrast to the strong predictive value of MRD tests in childhood T-ALL, in adults MRD tests appear to be best at predicting outcome only when carried out during maintenance therapy, i.e. beyond 6–9 months from presentation, rather than during the induction and consolidation phase, as seen in adult B-precursor ALL.

MRD detection at the end of treatment

Conversion from negative to positive MRD or the persistence of MRD-positive results to the end of treatment is associated with relapse in ALL patients irrespective of age. The aim must be to treat such patients before clinical relapse, as already practised in acute promyelocytic leukaemia (APL) and in chronic myeloid leukaemia (CML) post allogeneic SCT.

MRD detection in stem cell transplant ALL patients

In adult B-precursor ALL group, a close correlation has been observed between level of disease in harvested stem cells and clinical outcome in patients receiving autologous SCT (Figure 34.10). Similar observations have been made in non-Hodgkin's lymphoma and chronic lymphocytic leukaemia. On the other hand, outcome of adult ALL patients receiving allogeneic stem cell transplants appears to correlate with whether or not residual disease can be detected in the bone marrow after, rather than before, the procedure.

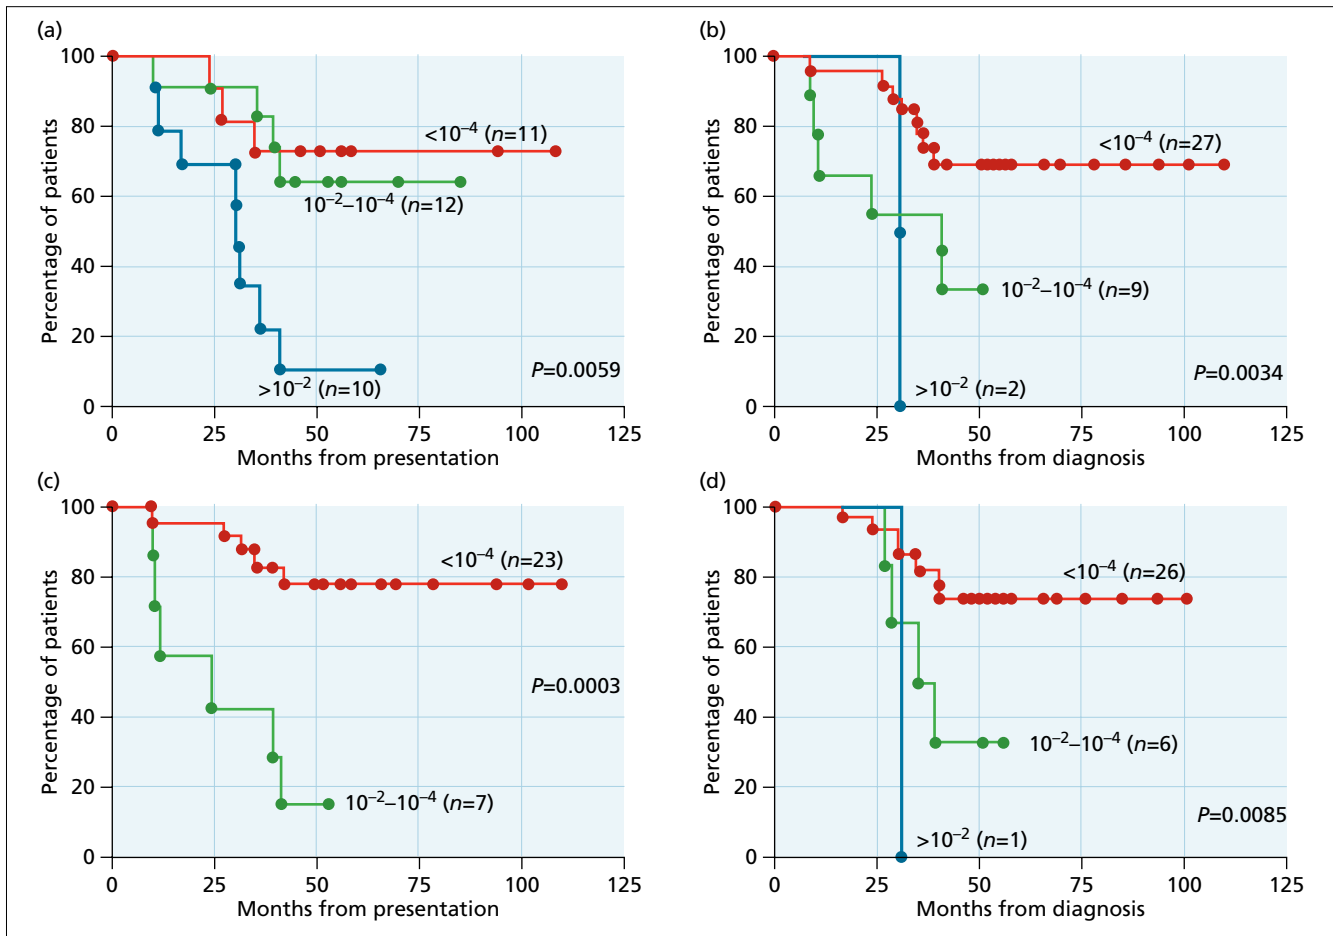
In childhood ALL, it is the MRD status before allo-BMT that affects outcome. This is probably because most children receiving SCT have extremely resistant disease and only the minority without such disease prior to SCT do well. In adults, SCT is often carried out in patients in first clinical remission, who may well also be in molecular remission.


Figure 34.8 Survival curves for childhood ALL patients according to MRD status and clinical outcome (from Gameiro *et al.*, 2002). The best survival is observed in patients with negative MRD at all time-points analysed. The higher the level of residual, the greater is the occurrence of clinical relapse. (a) Disease-free survival (DFS): day 28. (b) DFS: 2–5 months. (c) DFS: 6–9 months. (d) DFS: 10–24 months.

False-negative and false-positive MRD tests

Although PCR technology can in theory be sensitive to $1:10^5$ (Figure 34.1), false-negative results can still occur in ALL. First, they can arise when intervals between BM assessments are long, e.g. greater than 5 months. Monitoring at 3-month intervals (or more frequently) is recommended. Second, clonal evolution at relapse can result in negative tests. In rare patients, new clones emerge post treatment; this is associated with the emergence of resistant disease and, almost invariably, with poor outcome. Third, the presence of multiple (usually between two and six) B or T subclones at presentation (referred to as oligoclonality) can cause subsequent false-negative MRD tests. Oligoclonality arises primarily because the gene rearrangement machinery (i.e. TdT and recombination-activating genes, RAGs) is still active and functioning in precursor-B and T-cell leukaemia. Oligoclonality is seen in 20–30% of B-precursor ALL and 10–20% of T-ALL. It is, therefore, recommended that all B-cell subclones should be clearly identified at presentation and monitored during CCR. Fourth, PCR-negative tests in the bone marrow can in some cases accompany extramedullary relapses in the central nervous system, skin and testis. More frequently, extramedullary relapses are accompanied by positive MRD tests in the bone marrow. Finally, there may be heterogeneous distribution of the leukaemic cells in the bone marrow after treatment or patchy disease that may lead to false-negative tests. To avoid false-negative results during MRD-PCR monitoring in ALL, it is preferable that at least two molecular targets are used, and one of them, if possible, should be a gene fusion transcript.
Figure 34.9 Survival curves of adult ALL patients up to the beginning of maintenance therapy. (a) DFS: 0–2 months. (B) DFS: 3–5 months. (c) DFS: 6–9 months. MRD analysis of adult ALL patients reveals a strong correlation with clinical outcome, with the strongest correlation observed at 3–5 and 6–9 months (Mortuza *et al.*, 2002).
Figure 34.10 MRD analysis in patients receiving autologous SCT. A clear circle indicates a negative MRD test. A red circle indicates a positive MRD test, with a higher level (10^{-2} to 10^{-3}) being indicated by larger circles, while smaller circles illustrate levels at 10^{-4}. A black bar indicates haematological relapse and DFS is expressed in months from presentation. The vertical bar across the figure shows the time of SCT. The patients are separated into those who stayed in CCR (upper part of the figure) and patients who relapsed (lower part of the figure). The figure illustrates that residual disease prior to autologous SCT is associated with high incidence of relapse (cases in the lower part of the figure).

MRD detection in other lymphoid malignancies

MRD detection using antigen receptor genes

Non-Hodgkin's lymphoma (NHL) of B lineage is characterized by the clonal expansion of a lymphoid cell that has progressed through the B-cell development pathway. The clonal cells carry complete and functional IgH and IgL chain gene rearrangements. Clonal analysis of Ig genes and, in the cases of T-cell lymphomas, TCR genes can be used for monitoring residual disease in lymphoma patients following the identification of a B-cell clonal Ig

or TCR rearrangement at presentation. Indeed, in lymphoma patients the clone identified in the original lymph node biopsy can be sought in the peripheral blood and bone marrow for further staging of the disease.

MRD detection using lymphoma-specific translocations

In different histological subgroups of lymphomas, other markers can be identified. These derive from chromosomal translocations such as t(14;18) in follicular NHL, t(11;14) in mantle cell lymphoma, t(2;5) in anaplastic large-cell NHL or t(8;14) in Burkitt's lymphoma. The most frequent and widely investigated marker is t(14;18), which can be detected in up to 85% of follicular NHL patients. The translocation brings the *Bcl-2* gene adjacent to the IgH locus with breakpoint cluster regions (BCRs) either within the 3′-untranslated sequences of the *Bcl-2* gene (major BCR) or 20 kb downstream (minor BCR). As the breakpoints are localized within a restricted region of DNA, they are suitable for amplification by PCR for both the diagnostic and follow-up bone marrow or peripheral blood samples. Sensitivity up to $1:10^5$ cells can easily be achieved. It is particularly clinically important for patients to achieve molecular remission post SCT. As the translocation can be detected in lymphocytes of normal individuals, however, accurate quantification and time-point analysis is required, which will make future clinical studies more relevant.

There is at present limited information on the use of MRD for the monitoring of patients carrying t(11;14), t(2;5) and t(8;14). The heterogeneity of the breakpoints over a region sometimes larger than several thousand basepairs (bp) precludes the use of genomic DNA PCR for monitoring of MRD in these patients. In general, Ig and TCR rearrangement analysis, although rather more laborious, provides the most useful method for MRD investigation in lymphoma patients. The t(11;14) resulting in increased expression of cyclin D1 (on 11q13) can be detected using RT-PCR on RNA prepared from mantle cell lymphoma patients and is used for confirmation in diagnostic material.

Finally, although detectable in 65% of lymphoma patients, in 30–40% of CLL and multiple myeloma patients, Bcl-6 mutations (in the 5′ region of the gene, particularly 3′ of exon 1) have little or no application in the monitoring of MRD in patients with lymphoproliferative diseases.

Chromosomal translocations as molecular targets for MRD analysis

In acute leukaemias, chromosomal translocations result in two types of alteration, the production of gene fusions and the relocation of oncogenes to the vicinity of the transcription control elements of the Ig or TCR genes (see Chapter 30). Although both types of translocation result in the production of novel molecular targets, in practice only the gene fusions are suitable for the investigation of MRD. Moreover, the detection of fusion genes provides a method of MRD monitoring widely applicable in both ALL and AML.

The genes involved in these acquired aberrations are in general important for the normal development and function of haemopoietic cells. Typically, these genes encode transcription factors, cell cycle regulators or signal transduction molecules.

Clinical studies show that chromosomal rearrangements have prognostic value and can be used for risk stratification. For example, the t(9;22) and t(4;11) translocations in ALL are associated with a poor prognosis. On the other hand, the t(12;21) in ALL and the t(15;17), t(8;21) and inv(16) in AML are associated with a good prognosis. Therefore, the identification of such translocations at the molecular level not only identifies targets for MRD monitoring but also provides useful prognostic information in cases with failed cytogenetic analysis (see also Chapters 31 and 33).

Although, for Ig and TCR gene analysis, DNA is the preferred template for PCR, the detection of fusion genes relies exclusively on complementary DNA (cDNA) that is obtained by reverse transcription (RT) of RNA isolated from blood or bone marrow samples. This RT-PCR approach can be used when breakpoints lie within introns or small exons of the genes involved. Oligonucleotide PCR primers are designed from the exon sequences that flank the breakpoint region such that the amplified product contains the leukaemia-specific fusion sequence.

RT-PCR for MRD detection is quick (24–72 h), readily applicable to a wide range of patients, highly reproducible and very sensitive. Sensitivities average $1:10^4$ to $1:10^6$, depending on the target and whether nested PCR or real-time quantification is used. A major advantage in using fusion transcripts as PCR targets is their stability during the course of the disease. This safeguards against false-negative results that may arise in ALL due to continuing Ig or TCR rearrangement, as described above. Its main disadvantage is the risk of false-positive results due to cross-contamination by PCR products, especially if a nested approach is used. This risk may be reduced by the use of real-time quantitative PCR since its increased sensitivity can obviate the need for a nested procedure.

Acute lymphoblastic leukaemia

Approximately 40% of the ALL patients are positive for a recurrent chromosomal translocation. The most frequent chromosomal translocations and deletions in ALL are listed in Table 34.3.

t(1;19)(q23;p13): E2A-PBX1
The t(1;19)(q23;p13), resulting in the production of a chimeric basic helix–loop–helix (bHLH) transcription factor (E2A) – homeodomain (PBX1) protein – is most frequent in pre-B ALL expressing cytoplasmic Ig but is also sporadically detected in cytoplasmic Ig-negative B-precursor ALL, CD10[+] cALL or even

Table 34.3 Fusion genes suitable for MRD analysis in adult and childhood ALL.

Chromosomal translocation	Fusion gene	Relative frequency per type of leukaemia			
		Precursor B-ALL (%)		T-ALL (%)	
		Children	Adults	Children	Adults
t(1;19)(q23;p13)	E2A–PBX1	5–8	3–4	–	–
t(4;11)(q21;q23)	MLL–AF4	3–5*	3–4	–	–
t(9;22)(q34;q11)	BCR–ABL p190	3–5	15–30	< 1	< 1
t(9;22)(q34;q11)	BCR–ABL p210	1–2	10–15	< 1	< 1
t(12;21)(p13;q22)	ETV6–AML1	25–30	< 2	–	–
Del(1)(p32;p32)	SIL–TAL1	–	–	10–25	~10
Total		40–50	40–50	10–25	~10

*In infant ALL, the frequency of t(4;11) can be as high as 70% (adapted from van Dongen *et al.*, 1999).

T-ALL and AML. In most cases, the fusion transcript results from the splicing of exon 13 of *E2A* to exon 2 of *PBX1*. A variant fusion transcript is found in about 5–10% of the positive cases, owing to an additional stretch of 27 nucleotides in the junctional region resulting from alternative splicing.

Using a nested RT-PCR method, the *E2A–PBX1* transcript can be detected with a sensitivity of $1:10^4$ to $1:10^5$. MRD analysis using *E2A–PBX* fusion genes shows that persisting negative MRD predicts for CCR. Positive results, however, do not necessarily predict for future relapse. Whether quantification of MRD would have greater predictive value remains to be tested in a larger number of patients.

t(12;21)(p13;q22): ETV6-AML1

The t(12;21)(p13;q22) is a cryptic translocation not readily observed by conventional cytogenetics and the ETV6(TEL)–AML1(CBFA2) fusion transcript can be detected in patients with and without a cytogenetically visible chromosome 12 and/or 21 abnormality. FISH and PCR are therefore important techniques employed for its detection.

The t(12;21) is usually associated with a precursor cALL and more rarely pre-B ALL phenotype. It is rarely seen in adult ALL although it is the commonest translocation in childhood ALL (Table 34.3), with a peak incidence in the 2–5 year age group. The breakpoint region usually lies between exons 5 and 6 of the *ETV6* gene and between exon 1 and 3 of *AML1*. Fusion transcripts resulting from splicing of *ETV6* exon 5 to other AML1 exons can also be formed. The majority of the positive patients have the *ETV6* gene deleted on the non-translocated allele. It has been proposed that the translocation occurs during fetal development. The *ETV6–AML1* fusion transcript can be identified with a sensitivity of $1:10^{-4}$ to $1:10^{-5}$ using a nested RT-PCR approach. Accurate quantification of *ETV6–AML1* has shown that MRD measurements are a good prognostic indicator of future outcome.

11q23 abnormalities

Rearrangements involving the *MLL* (mixed leukaemia lymphoma) gene (also called *ALL1, HRX* or *Htrx1*) on chromosome 11q23 and multiple partner genes are found in precursor B-ALL, T-ALL, AML, myelodysplastic syndrome (MDS) and secondary leukaemia. The presence of *MLL* rearrangements is usually associated with a poor prognosis.

In ALL, the most common translocation partner of *MLL* is the *AF4* (*FEL*) gene on chromosome 4q21. Fifty to seventy per cent of infant ALL cases and approximately 5% of paediatric and adult ALL cases are *MLL–AF4* positive and associated with a pro-B-ALL ('null') phenotype (CD19+, CD34+, TdT+, cytoplasmic CD79+, CD10−). There is also frequent expression of myeloid antigens (CD15 and/or CD65).

The *MLL* and *AF4* genes are composed of 37 and 20 exons respectively, and at least 10 different fusion transcripts have been identified as a result of translocation breakpoints occurring in different introns of both genes. Breakpoints downstream of the *MLL* exon 9 in adult and paediatric ALL, but downstream of exon 11 in infant ALL and upstream of exon 4 of the AF4 gene, are commonly detected by PCR. Differential splicing is a common finding leading to more than one fusion transcript in some patients. All t(4;11)-positive cases transcribe the *MLL–AF4* fusion gene, whereas only 70% of cases transcribe the reciprocal, *AF4–MLL,* product. Interestingly, low levels of the *MLL1–AF4* transcript have been detected in some ALL cases without cytogenetically detectable t(4;11) and in haemopoietic tissues of healthy individuals.

Using a nested PCR strategy, the various *AF4–MLL* transcripts can be identified with a detection limit of $1:10^4$–$1:10^5$. MRD studies have shown that early conversion and persisting MRD negativity is consistently associated with CCR.

t(9;22)(q34;q11): BCR-ABL (p210 and p190)

The derivative chromosome 22, or Philadelphia chromosome

Chromosomal translocation	Subtype	Fusion gene	Relative frequency (%)	
			Children	Adults
t(8;21)(q22;q22)	M2	AML1–ETO	10–14	6–8
t(15;17)(q22;q21)	M3	PML–RARα	8–10	5–15
inv(16)(p13;q22)	M4Eo	CBFβ–MYH11	5–7	5–6
t(6;11)(q27;q23)		MLL–AF6	22	2–3[†]
t(9;11)(p22;q23)	M4, M5a/b	MLL–AF9		
t(10;11)(p11;q23)		MLL–AF10		
t(6;9)(p23;q34)	M1, M2, M4, M7	DEK–CAN		
t(9;22)(q34;q11)	M0, M1	BCR–ABL	Rare	Rare
Total			25–30	20–25*

Table 34.4 Fusion genes suitable for MRD analysis in AML.

*In AML patients > 60 years the total frequency of detectable fusion genes is only 10–15%.
[†]This frequency is higher in therapy related AML (~9%).

(Ph), of the t(9;22)(q34;q11) carries the *BCR–ABL* fusion gene encoding a chimeric protein of 190, 210 or 230 kDa, depending on the location of the breakpoint. This is the well-known hallmark of chronic myeloid leukaemia (CML) (see Chapter 37) but also occurs in 5–30% of ALL (Table 34.3) and rare cases of AML (Table 34.4).

Conventional nested RT-PCR can detect this transcript with a sensitivity of up to $1:10^{-5}$. Importantly, low levels of *BCR–ABL* transcripts have been detected in peripheral blood samples of a sizeable proportion of healthy individuals.

Quantitative monitoring of MRD shows that in PH$^+$ childhood ALL, a group of patients who are good responders clear residual disease during the first 5 months of treatment, whereas the poor responders have high levels of MRD and progress to haematological relapse. In adult ALL, persisting high levels of residual disease are usual and associated with haematological relapse. In the majority of cases, allogeneic transplant is the only treatment that achieves long-term molecular remission.

del(1)(p32;p32): SIL-TAL1

The *SIL–TAL1* fusion gene results from a site-specific deletion on chromosome 1 between the *TAL1* and *SIL* genes. As a result, in T cells, a normal TAL1 protein is expressed but under the control of the *SIL* gene promoter. *SIL–TAL1* transcripts are exclusively found in cases of T-ALL and the detection of *TAL1* deletions at the genomic level is not associated with particular clinical features. RT-PCR amplification of *SIL–TAL1* transcripts can reach the sensitivity of $1:10^5$, making it an excellent target for MRD investigation.

Acute myeloid leukaemia

Immunoglobulin and TCR rearrangements are rare in AML and therefore chromosome translocations provide the most important targets for MRD analysis by PCR. The most common

chromosomal translocations, detected in approximately 30–40% of AML patients, and their corresponding fusion transcripts are listed in Table 34.4 (see also Chapter 30).

t(8;21)(q22;q22): AML1-ETO

The t(8;21)(q22;q22) fuses the *AML1* (*CBFA2*) gene on chromosome 21 with the *ETO* (*MTG8*) gene on chromosome 8. Breakpoints localize between exons 5 and 6 of *AML1* and upstream of exon 2 of *ETO*. The translocation occurs mainly in *de novo* AML of FAB M2 subtype but may be seen also in AML cases with FAB M1 or M4 morphology.

Quantitative assessment of the *AML1–ETO* fusion gene shows a linear decrease (at least 2–4 logs) in copy number in most patients as a result of remission induction. The majority of patients remain positive at a low level during consolidation therapy. In patients destined to relapse, higher levels of MRD are observed before starting consolidation. Prior to relapse, an increase in level of MRD is observed in approximately 75% of patients. Patients with persisting level of MRD for many years have been identified but the incidence of relapse is not increased in a steady-state MRD status.

t(15;17)(q22;q21): PML-RARA

The t(15;17)(q22;q21) translocation, associated with acute promyelocytic leukaemia (APL)(FAB M3), fuses the *PML* gene, on 15q22, to the *RARA* gene on 17q21. The breakpoint cluster region on chromosome 17 localizes within *RARA* intron 2. Within *PML* there are three breakpoint cluster regions: breakpoint cluster region 3 (BCR 3) in intron 3, BCR2 in exon 6 (rarely in intron 5) and BCR1 in intron 6. At the messenger RNA level, BCR1, BCR2 and BCR3 are also called the long (L), variant (V) and short (S) isoforms, respectively. Alternative splicing within *PML* transcripts and the alternative use of two *RARA* polyadenylation sites are responsible for the production of additional *PML-RARA* transcripts of different sizes.

There are at least four variant translocations involving the *RARA* gene, with the same breakpoint, associated with the APL phenotype. These fusion partners are the *NPM* at 5q35, *PLZF* at 11q23, *NuMA* at 11q13 and *STAT5b* at 11q11.

As a consequence of the t(15;17)(q22;q21) translocation, both *PML–RARA* and *RARA–PML* fusions can be transcribed. While *PML–RARA* is consistently found in APL patients, *RARA–PML* is detectable in only 70% of cases. Thus, *PML–RARA* is most widely used for diagnosis and MRD monitoring in APL. This transcript can be detected by RT-PCR with a sensitivity of $1:10^4$.

At least 50% of patients with APL are MRD positive after the first cycle of chemotherapy. Most positive patients show a progressive decrease in MRD during the four or five chemotherapy blocks. Patients post consolidation who are in molecular remission have a high probability of CCR. Patients who revert to PCR-positive tests after the end of treatment, however, have a high probability of relapse. Patients with a low MRD level ($< 10^{-5}$) at the end of consolidation include a large proportion of relapse cases and monitoring should therefore continue at 2- to 3-month intervals for 1–2 years after completion of treatment.

The *PML–RARA* transcript can be detected with increased sensitivity by RQ-PCR compared with semiquantitative nested/two-round PCR techniques. Accurate quantification can identify patients with an increasing number of transcripts preceding haematological relapse. Patients treated at the time of molecular relapse have 2-year event-free survival (EFS) rates superior to those treated at the time of haematological relapse.

Inv(16)(p13;q22) and t(16;16)

The pericentric inversion of chromosome 16, inv 16(p13;q22), and the rarer t(16;16)(p13;q22) are recurrently associated with AML of the FAB subgroup M4 with abnormal eosinophils (M4Eo). These aberrations fuse the *CBFB* (*PEBP2b*) gene at 16q22 to the *MYH11* gene at 16p13. There is marked heterogeneity in the resulting *CBFB–MYH11* fusion transcripts owing to variability of genomic breakpoints in both *CBFB* and *MYH11* and to alternative splicing. Ten different types of fusion transcripts have been identified so far. The most common (> 85% of positive patients) is type A, resulting from ligation of *CBFB* exon 5 to exon 12 of *MYH11*. Although closely associated with AML M4Eo, the *CBFb–MYH11* fusion transcript has also been detected in AML patients in whom the cytogenetic abnormality could not be detected, including patients with AML M4 without eosinophils, M2, M5 and, less frequently M1, M6 and M7. The *CBFβ–MYH11* can be detected by RT-PCR with a sensitivity of $1:10^5$.

MRD monitoring shows that the mean *CBFB–MYH11* fusion transcript copy number is significantly higher in patients destined to relapse than in patients remaining in CCR. Moreover, in CCR patients, the copy number drops below the detection threshold after the treatment protocol is completed and MRD remains undetectable in subsequent analyses. In contrast, in patients who relapse, the copy number in CR never declines below the detection threshold. Both accurate quantification and a cut-off value for positive tests (as predictive of relapse) need to be established in large-scale studies in this group of patients.

FLT-3 internal tandem repeats, c-*KIT* mutations and WT1 levels

Additional changes in AML cells include the recently described internal tandem repeats (ITDs) and point mutations in both the *FLT-3* and *c-KIT* genes. *FLT*-3 ITDs and mutations occur in up to 30% of some AML subtypes (most frequently in M3/APL, but also in 35% of patients with a normal karyotype). They identify a poor prognostic group, except when detected in APL. Unfortunately, they are a poor target for MRD monitoring in AML because they are frequently associated with subclones at presentation and may appear *de novo* at relapse or vice versa.

Mutations in *c-KIT* (exon 8 and Asp816) are detected in 10–15% of AML patients with inv(16) and t(8;21), are mutually exclusive with *FLT-3* mutations and are associated with a poor prognosis. *C-KIT* mutations carry only a limited practical use for MRD detection, however, since they seem to be a secondary event in the disease progression and can be lost at time of relapse.

WT1 is overexpressed in over 60–70% of AML cases and in 50–60% of ALL regardless of the presence of other fusion transcripts. Quantitative analysis of *WT1* at presentation and during remission (fewer than 10^3 copies post induction and second consolidation) significantly correlates with better DFS and overall survival (OS). A rise in *WT1* levels and persistently high levels are associated with poorer outcome.

Conclusions

The application of flow cytometry and molecular techniques (including real-time quantification) has enabled us to detect and quantify MRD in acute leukaemia to levels of sensitivity of $1:10^4$ to 10^5. PCR techniques can be used to detect leukaemic cells among normal counterparts using both clonal changes in antigen receptor genes (IgH and TCR) and leukaemic-specific changes (translocations, point mutations). The predictive value of these tests has been found to be independent of other risk factors such as age, sex and presenting leucocyte count. Quantitative and semiquantitative assessment of MRD is becoming important in defining relapse risk as a function of MRD level immediately post induction and at later time points.

For both children and adults the challenge is to incorporate MRD analysis into prognostic indices in large randomized trials. Some studies have recently been initiated in Europe and the UK using MRD values at day 28 and during the first 3 months of treatment for ALL for risk stratification and change in treatment. The potential benefit would seem to be largest in 'standard-risk'

ALL as judged by conventional criteria (age, sex, presenting leucocyte count, chromosomal translocations). In this the largest category of patients, overall benefit has been obtained by treatment intensification, but this is at the expense of overtreating a substantial number of patients, especially children, who may be cured with less intensive protocols. A large number of adults appear to be cured by standard chemotherapy and could be spared invasive SCT procedures. The corollary to this is the potential for detecting a new group of high-risk patients, both adults and children, on the basis of slow MRD clearance. These could be candidates for further treatment intensification including SCT in first CR or alternative targeted treatment.

Multidrug resistance in leukaemia

35

Jean-Pierre Marie and Ollivier Legrand

Introduction

Chemotherapy is particularly effective in acute leukaemia, as is demonstrated by the detection of minimal residual disease: in childhood acute lymphoblastic leukaemia (ALL), the fraction of leukaemic cells that survive per week was estimated at 0.008 during the first 14 days of treatment, and, with an estimated number of leukaemic cells at diagnosis of 10^{12}, the mean size of the resistant population can be estimated as 10^7 cells at the end of induction treatment. These cells will be responsible for relapse if no further treatment (or despite this treatment) within 1–3 years.

Farber *et al.* (1948) were the first to describe drug resistance in ALL 55 years ago, and this obstacle is still the major cause of death in all types of acute leukaemia.

Mechanisms of drug resistance

Thirty-five years ago, Goldie and Coldman (1979) proposed a mathematical model for drug resistance, assuming that selected subclones of cancer cells eventually became resistant to chemotherapeutic drugs, owing to a high spontaneous mutation rate. These cells could escape the effect of cytotoxic drugs, through decreased uptake, increased catabolism, decreased transformation of a prodrug, modification of drug target, increase in DNA repair or resistance to drug-induced apoptosis.

Over the last 20 years, experimental models and clinical research have identified several causes of drug resistance in tumours. The most frequently observed phenomenon is the appearance of a broad spectrum of resistance, called 'multidrug resistance', or MDR.

Multidrug resistance

It was clinically observed that tumour cells resistant to a class of drug, are usually also cross-resistant to chemotherapy with a different target. This phenomenon, called MDR, was described *in vitro* by Biedler and Riehm during the 1970s in Chinese hamster ovary cells and is now recognized as a most frequent phenotype developed in cultured tumour cells exposed to anthracyclines or vinca alkaloids.

This MDR phenotype confers to the cells cross-resistance to a broad range of structurally and functionally unrelated cytotoxic agents, sharing common properties: all are plant or microbial products, known as xenobiotics. The resistant tumour cells maintain lower intracellular drug concentrations than do their sensitive counterparts, and in the large majority of cases express transport proteins of the ABC (ATP-binding cassette) superfamily, responsible for the active efflux of these drugs.

More recently, other mechanisms of resistance to a broad spectrum of drugs have been described: increase in DNA repair, and defects of drug-induced apoptosis, either due to strong survival signals delivered to the tumoral cells by microenvironment, or because of a defect in the apoptosis pathway (Figure 35.1). Unfortunately, very few confirmed data are available concerning these mechanisms in leukaemia, and the focus of this chapter will be on the ABC proteins.

ABC proteins

These transmembrane proteins are specialized in energy-dependent cellular transport. The encoding *MDR* genes are highly conserved between species, from bacteria to man. The
Figure 35.1 Mechanisms responsible for multidrug resistance in leukaemic cells.

Table 35.1 Classes of cytotoxic drugs expelled by P-gp. All of these drugs are from natural origin (xenobiotics).

Sources of cytotoxic drugs	Drugs expelled by P-gp
Streptomyces	Anthracyclines
	Daunorubicin,
	THP-adriamycin
	Idarubicin
	Mitoxantrone
	Amsacrine
Cantharanthus roseus	Vinca alkaloids
	Vinblastine
	Vincristine
	Navelbine
Taxus brevifolia	Taxanes
	Paclitaxel
	Taxotere
Mandrake plant	Epipodophyllotoxin:
	VP16
	VM26

role of these proteins is mainly protection against xenobiotics, including many hydrophobic cytostatics of natural origin (Table 35.1). The minimum structure of the protein is an ABC unit of 200–250 amino acids, consisting of consensus Walker A and B motifs and the ABC signature, located between the two Walker domains, for ATP binding, and six transmembrane domains (TMDs) (such as ABCG2). The more common structure consists of two ABC and 12 transmembrane domains (ABCB1 or P-glycoprotein), and a few members have five more transmembrane domains, with an external N-termination (ABCC1–2–3) (Figure 35.2).

A new classification of this family, with eight subgroups, is now adopted (see www.humanabc.org). The members responsible for drug efflux belong to several classes (Table 35.2), i.e. ABCB (P-gp), ABCC (MRPs family), ABCG (BCRP), the evidence for this being that the transfection of their cDNA in sensitive cell lines gives rise to the MDR phenotype. These proteins share resistance to anthracyclines, but have a variable spectrum of resistance to other natural compounds (vinca alkaloids, epipodophillotoxines, taxanes) (Table 35.3). Recently, it was shown that the presence of single-nucleotide polymorphisms in P-gp

Table 35.2 Classification of ABC proteins involved in multidrug resistance in cancer.

Nomenclature	Name	Localization/structure	Chromosomal location	MDR phenotype after transfection
ABCB1	P-gp/MDR1	Plasma membrane (TMD–ABC)2	7q21	++
ABCC1	MRP1	Plasma membrane TMD0(TMD–ABC)2	16q13.1	+ (if GSH)
ABCC2	MRP2(cMOAT)	Plasma membrane TMD0(TMD–ABC)2	10q24	+/– (if GSH)
ABCG2	BCRP/MXR1/ABCP	Plasma membrane (works as dimer) (TMD–ABC)	4q22	+

Taxanes	R	S	S
VP16	R	R	R
Methotrexate	S	R	S
Other		Cisplatin	Topotecan

(C3435T) or in BCRP (T/G482A) results in modification of drug efflux.

At present, the exact mechanism of drug binding to ABC pumps is unknown. In P-gp, mutagenesis showed that transmembrane domains 5, 6, 11 and 12 are crucial for drug efflux. It is suggested that a drug-induced conformational change creates a hydrophobic pocket, able to bind and transport the substrate out of the cell.

The ABC proteins are expressed in tissues that are highly exposed to xenobiotics, e.g. the gastrointestinal tract and the lung mucosa, and in organs involved in secretion processes like liver and kidneys. The presence of the three main ABC proteins involved in drug transport – P-gp, MRP1 and BCRP on endothelial cells – deserves attention: a blockade of these pumps would cause increased uptake of drugs from the bloodstream, decreasing the efficiency of the blood–brain barrier.

P-glycoprotein

The first – and probably most important – protein described in cell models of MDR resistance by Juliano and Ling in 1976 is P-glycoprotein (P-gp), encoded by the *ABCB1* (*MDR1*) gene. This heavily glycosylated protein of 170 kDa is expressed in many tissues which filter or expel toxins: gut, hepatocytes and renal tubules. It also protects the brain and testes (expressed on endothelial capillary cells of these organs). Progenitor cells (CD34[+]) expressed P-gp, as well as lymphocytes (NK > CD8 > CD4).

After several years of contradictory results concerning the frequency and value of P-gp expression in tumours, several workshops proposed a consensus on technical recommendations for measuring P-gp. Protein detection and, more importantly, functional tests by flow cytometry are recommended for leukaemic samples. Several monoclonal antibodies, recognizing an external epitope, are available for protein expression, and several fluorescent probes could be used (mainly Rhodamine 123), with and without specific inhibitors, for measuring the drug efflux.

The main recommendations are the following:
1 The tumour cell population in the sample must be as pure as possible, especially if 'bulk' techniques are used (RT-PCR).
2 Two different techniques should be used for validation, preferably with single-cell detection methods; protein detection and functional testing by flow cytometry are recommended for leukaemic samples.
3 Calibration controls (all assays must be positive, including one cell line with a low level of positivity, comparable to clinical leukaemic samples) and negative controls must be used. The same control cell lines have to be used by all centres working together.

4 A major confounding factor is the use of an arbitrary minimal cut-off for classifying samples as 'positive' or 'negative'. It is recommended that the data be reported as continuous variables, expressed as a ratio of MAb/control for protein, and as probe + inhibitor/probe alone for function.

P-gp in AML

Many studies have reported a high frequency of *MDR1* gene expression in adult acute myeloid leukaemia (AML). In large multicentre studies between one-third and one-half of cases are 'positive' at diagnosis, whatever the technique used, and usually a higher proportion of positive cases are described in elderly patients. The MDR phenotype is associated with poor prognosis, such as CD34 or CD7, and is more often expressed in AML with 'poor' cytogenetic features, as –7 or complex karyotype. In multivariate analysis, P-gp and karyotype have independent prognostic value.

Except for the promyelocytic subtype (AML M3), which is devoid of P-gp expression, all other AML subtypes are able to express the MDR phenotype. In the majority of cases, functional tests (dye efflux) correlate with P-gp expression, except in CD34⁻ cells, such as myelomonocytic and monoblastic leukaemias. For this reason, dye efflux appears to be more informative than quantification of P-gp itself in AML.

The correlation between *MDR1* gene expression and treatment outcome is well documented in AML: many studies have reported a relationship between either the absence of remission (refractory disease and death during aplasia) and the overexpression of P-gp, or between the overexpression of P-gp and refractory disease (Table 35.4).

Few studies are published on childhood AML. The global incidence of MDR1/P-gp (+) is lower than in adult AML (13–30%),

and no study has shown a correlation between MDR1/P-gp and prognosis (complete remission, overall survival, disease-free survival). Thus, it seems that P-gp expression does not have the same predictive value in childhood AML as it does in adult AML.

P-gp in childhood ALL

The main prognostic factor for long-term survival in childhood acute lymphoblastic leukaemia (ALL) is the sensitivity to corticosteroids. The cellular mechanisms of this resistance are not known, but the *in vivo* corticosensitivity test is highly predictive for long-term survival.

The incidence of *MDR1* overexpression in untreated patients with ALL is generally found to be low (< 10%) at diagnosis and even at relapse, except during the most advanced stage of the disease, when clinical drug resistance is usually observed. The MDR1 phenotype is not predictive for induction treatment failure, whatever the method of detection used.

P-gp in adult ALL

Few studies of ALL are conducted exclusively in adults, unlike AML. The frequency of positive cases is roughly 15–20%, and no studies have demonstrated a correlation between P-gp function and treatment failure.

The MDR phenotype in ALL is found only in ALL subgroups, such as CD7⁺ CD4⁻ CD8⁻ ALL, which are thought to originate from a haemopoietic stem cell, and has a worse prognosis.

In addition, half of all cases of adult T lymphoma–leukaemia (ATL) are positive for P-gp at diagnosis, and all patients with relapsed disease refractory to polychemotherapy are positive for P-gp. In this disease, the P-gp positivity could be due to the 'tax'

Table 35.4 Correlations between P-gp expression and clinical outcome in adult AML treated with standard chemotherapy (anthracycline + 100–200 mg/m² of Ara-C for 7–10 days with or without another drug).

protein of HTLV1, which is able to promote MDR1 expression in cells transfected with the viral gene.

P-gp in chronic lymphocytic leukaemia (CLL)

In CLL, several authors have described a large majority of patients expressing a low level of P-gp, either before or after chemotherapy. The MDR phenotype is also detected in normal B lymphocytes, and therefore is probably constitutively moderately expressed in CLL, but with no implication in clinical drug resistance.

P-gp in chronic myeloid leukaemia (CML)

During the chronic phase, P-gp expression does not differ from that in normal counterpart cells in CML. Blast cells of the acute phase could express P-gp, with the same prognostic value as in other acute leukaemias. Interestingly, imatinib mesylate (Gleevec®) is a substrate of P-gp.

MRP family (ABCC1–6)

The members of the ABCC family (*MRP1–6*; 'multidrug resistance-associated protein') have low homology (15%) with *MDR1*, and mainly act together with glutathione.

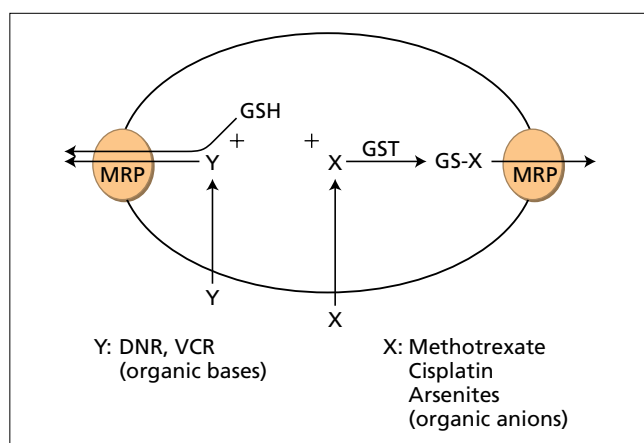
MRPs (but not P-gp) are transporters of organic anions such as methotrexate (itself an organic anion) and of neutral organic drugs conjugated to acidic ligands (GSH), such as cisplatin (MRP2) and arsenite (MRP1). Anthracyclines and vinca alkaloids, both weak organic bases, are conjugated with GSH, but are transported together with free GSH (Figure 35.3). MRP1 and -2 are particularly involved in the transport of chemotherapeutic


Figure 35.3 MRP1 and -2 mediated drug efflux. Two modalities of drug transport are shown: (i) the GS–X complex is expelled by MRP: organic anions such as methotrexate and cisplatin; (ii) Y is cotransported by MRP in the presence of GSH: organic bases such as anthracyclines and vinca alkaloids.

agents in human cancer cells. In leukaemia, monoclonal antibodies are used for measurement of MRP expression, and MRP1–2 efficiency could be checked by cytofluorimetry with a functional test, using calcein-AM as a probe and MK571 or probenicid as inhibitors.

Only MRP1 expression has been investigated on a large enough scale to generate enough data for objective analysis. In AML, compared with P-gp, discordant results have been published concerning the incidence of MRP1 expression; the range of MRP expression is narrow compared with P-gp, and a basal expression is found in all cases. One-third of the patients present with high expression. The prognostic value of MRP itself is not yet clearly determined, but both P-gp and MRP1 functions are of prognostic importance in adult AML. The role of other MRPs is still under investigation.

Few publications have concerned MRP in ALL, but all showed a measurable level of this protein at diagnosis, comparatively higher than in AML, and some cases showed an increase after treatment.

CLL cells express variable levels of MRP at diagnosis and after treatment, but the amount of MRP does not influence the course of the disease.

ABCG2 (Table 35.2)

Recently, a small ABC protein, ABCG2 (or BCRP), was described simultaneously by three different groups. It was described as a 'specific' ABC protein of the placenta (ABCP), as a new ABC protein expressed in a MDR1(–) MRP1(–) breast-resistant cell line (MCF7/Adr/Vp) ('BCRP'), and in a colon carcinoma cell line resistant to mitoxantrone (MXR1). This small protein, working as a dimer, is particularly active to efflux mitoxantrone, but also the other anthracyclines, bisantrene, and topotecan. It is expressed on side population (SP) cells, the pluripotent stem cells able to efflux the dye Hoescht 33342.

ABCG2 is expressed in a subset of leukaemic cells, but its role in clinical drug resistance is, to date, unknown.

Lung resistance protein/major vault protein

A wide variety of P-gp-negative multidrug-resistant cancer cell lines expressed the 'lung resistance-related protein' (LRP), identified as the major vault protein (MVP). Vaults are not ABC proteins, and are supposed to mediate the bidirectional transport of a variety of substrates between the nucleus and the cytoplasm. Until now, proof of the involvement of LRP/MVP in the MDR phenotype could not be demonstrated by transfection or antisense experiments.

In the majority of cases of AML, LRP/MVP is low, but detectable by RT-PCR, and the clinical significance of LRP
Figure 35.4 Efflux pumps involved in drug efflux in leukaemic cells. For LRP/MVP, the demonstration of drug efflux was, until now, not proven by transfection or antisense experiments.

expression is unclear. In relapsed childhood ALL, LRP expression (but not P-gp) was associated with an increased *in vitro* resistance to daunorubicin.

In summary, at least four ABC pumps and one non-ABC protein are able to expel several non-related cytotoxic drugs from the leukaemic cells, with probable redundancy (Figure 35.4).

Resistance to drug-induced apoptosis

The final effect of cytotoxic agents is apoptosis. Any factor able to reduce the amount of drug-induced apoptosis will increase cell survival, and therefore could be responsible for multidrug resistance. According to the known pathway of apoptosis involved in drug resistance (Figure 35.5), the role of several molecules has been investigated.

p53

p53 is activated in response to DNA damage, and stops the cell in the G_1 phase (via p21), permitting DNA repair, whereas apoptosis can be considered to be a failsafe mechanism to rid the organism of cells with severely damaged DNA. In cases of non-functional p53, the threshold of DNA damage leading to apoptosis increases, and this could contribute to drug resistance. In haematological malignancies, p53 is usually functional at diagnosis, but mutations have been described during progression of the disease in both lymphoid (mainly CLL) and myeloid leukaemias, and this progression corresponds mainly to highly resistant tumours.

Inhibitors of the cell cycle

Genetic alterations affecting the INK4 cell cycle inhibitors, p16^{INK4a} and p15^{INK4b}, which govern phosphorylation of the retinoblastoma protein (pRb) and control exit from the G_1 phase of the cell cycle, are frequently mutated in ALL (~ 30%), are present in high-risk ALL (relapse, T subtype), and are associated with an aggressive course of the disease.

In CLL, a high cell content of p27, a universal cyclin-cdk inhibitor, is correlated with a poor survival and an increased *in vitro* survival in the presence of a drug such as fludarabine.

Bcl-2 family

The anti-apoptotic properties of Bcl-2 and Bcl-x_L are well demonstrated *in vitro*, and their overexpression has been shown to protect tumour cell lines from the toxicity of several chemotherapeutic agents. AML cells with high Bcl-2 content correlated with a lower rate of complete remission. On the other hand, bax expression correlates with drug sensitivity to doxorubicin, cyclophosphamide and chlorambucil in CLL, and relapse in
Figure 35.5 Scheme of apoptosis. The cytotoxic drugs act mainly through mitochondria. AIF, apoptosis inducing factor; APAF1, apoptotic protease activating factor 1; Cyt C, cytochrome C; DISC, death-inducing signalling complex; IAP, inhibitor of apoptosis.

childhood ALL is associated with a decrease of the bax/Bcl-2 ratio.

BCR–ABL

The chimeric protein BCR–ABL, specific to CML and frequent in adult ALL, has been shown to confer resistance to genotoxic agent-induced apoptosis (Ara-C, daunorubicin, VP-16, etc.) *in vitro*, via a prolongation of cell cycle arrest at the G_2/M restriction point, without altering either the p53 pathway or DNA repair.

Imatinib, a specific anti-thyrosine kinase drug, is a very potent inhibitor of BCR–ABL effects, but resistance to this drug was quickly described in patients, due mainly to mutations in the chimeric BCR–ABL protein (see also Chapter 37).

Reversal of multidrug resistance

P-gp inhibition

Since the first observation of *in vitro* modulation of MDR phenotype by verapamil in 1981, it was recognized that several drugs already in use in the clinic inhibit P-gp efflux, and reverse MDR phenotype in experimental systems. This perspective to overcome clinical multidrug resistance has led to the strategy of concomitant administration of chemotherapy and a 'MDR modulator'. These compounds act mainly as competitive or non-competitive inhibitors, by competition with the drug for the binding site, or by binding to other P-gp sites that cause allosteric changes of the molecule, resulting in a decrease of cytotoxic drug binding.

Phase I and II trials

Several phase I and II trials were conducted in leukaemia, multiple myeloma, lymphoma and solid tumours using verapamil, amiodarone, quinine or cyclosporin A together with an anthracycline, VP16 or a taxane. These trials were not restricted to MDR(+) tumours, and it was difficult to know the benefit of these associations for the patients. The pharmacokinetics performed during these trials suggested evidence that verapamil and amiodarone had a minimum toxic dose (MTD) below the required dose for *in vivo* P-gp inhibition, and that quinine and cyclosporin A could be used as P-gp modulators with acceptable toxicity. Another interesting finding was the dramatic decrease of anti-cancer drug clearance when cyclosporin A was coadministered. This pharmacokinetic interaction led to a prolonged terminal half-life, and an increased area under the concentration curve (AUC) of the cytostatic, and therefore an increased toxicity. This interaction is less pronounced for quinine, probably because of the absence of inhibition of P450-mediated metabolism, observed when cyclosporin A is administered.

Phase III trials with quinine and cyclosporin A

To confirm the interest of such association, several randomized phase III trials, with or without these modulators, were tested (Tables 35.5 and 35.6). In the four trials published so far, the chemotherapy used as the reference (with or without modulator) included cytosine arabinoside (Ara-C), a non-P-gp substrate, at high dose, together with daunorubicin or idarubicin, or mitoxantrone. The use of these high doses of Ara-C, able to eradicate positive P-gp cells, reduced the chance of observing a difference between the two regimens. It is important to note that in none of these trials were the doses of anthracyclines reduced.

When quinine (30 mg/kg/day, given by continuous intravenous infusion) was added to an anthracycline and Ara-C, either in poor-prognosis adult leukaemia cases (relapsing/refractory/ secondary) or in untreated *de novo* AML, global results (rate of complete remission, overall survival) did not show any difference from the 'control' arm (same chemotherapy without quinine). It was noted that, in poor-prognosis patients: (i) clinical drug resistance was higher in the control group; and (ii) toxic death rate was higher in the quinine group, counteracting the potential benefit of MDR reversal. In *de novo* untreated patients, the addition of quinine benefited only the patients with functionally P-gp-positive AML cells, but did not influence the overall survival of such patients.

The addition of cyclosporin A at high dose (16 mg/kg/day) during the 3 days of continuous infusion of daunorubicin and high doses of Ara-C in relapsing/refractory AML patients significantly reduced the frequency of resistance and increased the relapse-free survival and the overall survival. The effect of cyclosporin A on survival was greater in the patients with P-gp(+) leukaemic cells than in the others. This interesting result could not be reproduced, with the same schedule, in patients experiencing a blast crisis of CML.

Quinine and cyclosporin A, molecules already on the market for a long time, were chosen for their ability to inhibit *in vivo* P-gp efflux. This was demonstrated by the potency of the serum from patients treated with high doses of these drugs to circumvent P-gp efflux in cell lines exposed to this serum.

Trials with PSC833 and other modulators in leukaemia

Several drugs were developed for the unique purpose of MDR reversal. The most advanced P-gp modulator is PSC-833, an analogue of cyclosporin D, 10-fold more potent than cyclosporin A, without any renal or immunosuppressive toxicity.

Extensive dose-finding trials of coadministered cytotoxic drugs (anthracyclines, VP16, and taxol in solid tumours) were conducted with this modulator used at the fixed dose of 10 mg/ kg/day, continuous intravenous infusion, after a loading dose of 2 mg/kg over 2 h. These phase I studies concluded that it was necessary to reduce the daily dose of mitozantrone by 30–50%,

*Patients treated with chemotherapy and modulator; **patients treated with chemotherapy alone.

the dose of daunorubicin by one-third, and the dose of VP16 by 40–60%, depending on the associations tested. When such adaptations of dose are used, the AUCs of these drugs are similar in both arms, and toxicities related to the cytostatics are also equivalent. The limiting toxicity of PSC833 alone was reversible ataxia and dysmetria, suggestive of a cerebellar dysfunction, possibly due to the inhibition of blood–brain barrier.

Several randomized phase III trials in AML (in elderly untreated patients and in relapsed/refractory younger patients) compared chemotherapy alone with chemotherapy (with lowered doses of anthracyclines and VP16) and PSC833, given intravenously by 24-h infusion during the administration of the anthracyclines and VP16. A higher rate of early mortality (despite the cytostatic dose reduction) was observed in the elderly patients treated with the addition of PSC833 (Table 35.6), raising the question of the consequences of the P-gp inhibition in normal tissues. The trial was stopped prematurely, but it is interesting to see that, in P-gp (+) patients, the increased number of toxic death due to the addition of PSC833 was compensated for by a particularly low proportion of resistant disease (19% vs. 41% without PSC833). Several large multicentre phase III trials testing PSC833 have been completed in relapsed and *de novo* AML, but not yet published, waiting for longer follow-up. Concerning the complete remission (CR) rate, no striking differences were observed between the two arms, tempering enthusiasm concerning the concept of P-gp inhibitors in drug-resistant leukaemia.

The failure of PSC833 to increase the CR rate in the whole population of AML patients could be explained, if higher toxicity is excluded, by the dramatic reduction of cytotoxic drugs, leading to a reduction of the maximum and/or steady-state concentration, detrimental to anti-cancer efficacy. The redundant role of the three major ABC pumps, often present together on the leukaemic cell surface, could also be explained.

The other drugs engineered for P-gp inhibition are less advanced, still in phase I and II, mainly in solid tumours. LY335979 is a quinoline derivative, specific to P-gp, and delivered orally, with a low effect on the pharmacokinetics of coadministered drugs. XR9576, an anthranilic acid derivative, delivered orally, is also being tested.

Reversion of other ABC pumps

Because of the failure of P-gp inhibitors to increase significantly the CR rate and overall survival in AML, and the putative role of other ABC pumps in drug resistance, it will be interesting to test inhibitors of several pumps. Two drugs are interesting in this setting: GG120918, a derivative of acridone carboxamide, that was developed as an inhibitor of P-gp, but was also described as a potent inhibitor of BCRP; and VX-710 (Biricodar®), a pipecolinate derivative, a modulator of P-gp and MRP1. The decision to develop GG120918 was, until now, not a priority, and Vertex Pharmaceutical is developing a phase II trial for Biricodar®.

Restoration of drug-induced apoptosis

Restoration of drug-induced apoptosis could be obtained *in vitro* with Bcl-2 antisense. The G3139, an 18-mer oligonucleotide complementary to the first codons of *Bcl*-2, was given subcutaneously during phase I, permitting the setting of the dose at a level able to give a high concentration of circulating Bcl-2 antisense without major toxicity, and a phase II trial is now completed in AML, together with chemotherapy. A randomized phase III trial is now running in untreated elderly patients with AML.

Ras inhibition

The membrane-associated G proteins encoded by the *ras* family of proto-oncogenes are potential targets for new therapeutic agents. Ras proteins are activated downstream of protein tyrosine kinases and, in turn, trigger a cascade of phosphorylation events through sequential activation of Raf, MEK-1 and ERKs. To be active, ras has to be farnesylated. Therefore, several inhibitors of farnesyl transferase (FTI) have recently been developed to counteract drug resistance due to activation of the phosphorylation cascade. A phase I trial with R115777 demonstrated a significant inhibition of ERK phosphorylation in blasts from acute leukaemia after treatment, and clinical responses, including few complete remissions, were observed. Several FTIs are now under investigation in AML and in CML.

Future directions

We have seen that a single mechanistic pathway cannot explain the genesis of resistance in leukaemia. Rather, drug resistance probably involves the altered expression of a diverse group of genetic factors influencing various biochemical pathways.

To determine the up- and downregulated genes responsible for drug resistance, the DNA microarray technology is particularly useful. Its capacity for simultaneous probing of the genome on high-density microarrays has enabled the analysis of the expression profiles of thousands of genes.

Such an analysis was conducted in doxorubicin-sensitive and -resistant cell lines and in clinical samples of AML, permitting the selection of cell cycle, signal transduction genes and transcription factor genes. The differential expression of only 28 genes (out of 23 040 tested) was the core of a 'drug response scoring' in adult AML set by Okutsu *et al.* (2002), allowing the prediction of the good and poor responders to a 'classical' induction therapy with 7 days of Ara-C (100 mg/m^2/day) and 3 days of anthracycline (idarubicin).

These analyses may ultimately enable us to use the signature expression profiles of drug-resistant leukaemia to predict response to drugs and to design targeted therapeutic regimens to circumvent drug resistance.

Supportive care in the management of leukaemia

36

Archibald G Prentice and J Peter Donnelly

Introduction

The outlook for patients with acute and chronic leukaemias has improved considerably in the past 40 years, mainly because of more effective therapy. Better understanding and management of the complications have also improved survival and quality of life. These complications vary with the pace of the disease (acute or chronic), with specific subtypes of myeloid and lymphoid leukaemias, and with the intensity and duration of therapy.

The effectiveness of support depends on the coordinated work of specialist doctors, nurses, therapists and pharmacists, working in facilities dedicated to the care of these patients. In the intensive care of patients with acute leukaemia, it is especially important that there should be clear rules about when and why nurses should ask medical staff to review their observations and equally clear rules about the doctors' responses. Timely and accurate communication between professional groups is essential, and all should be working to agreed written standards. Management of all the complications requires careful and regular recording of basic observations by nurses, most of whom should be registered and experienced in leukaemia care. This team needs a high skill mix, and an overall nurse–patient ratio above 1 to allow internal shift rotation that provides a continuous level of expertise.

Whatever the type of leukaemia, patients should be treated according to protocols as part of well-designed, multicentre, controlled trials.

The management of each group of complications is described both in general and with reference to specific types of leukaemia and forms of therapy. Complications requiring supportive care can be classified as:

1 psychological, due to loss of performance and self-determination and protracted treatment-related complications, such as the need for isolation as protection against infection;

2 reproductive due to the need to prevent pregnancy in female patients during intensive cytotoxic exposure and to preserve fertility in patients of childbearing age;

3 anaemia, due to failure of red cell production, bleeding or haemolysis;

4 bleeding, due to thrombocytopenia and lack of clotting factors, through either failure of production or excessive consumption (disseminated intravascular coagulation);

5 infections, due to failure of production of adequate numbers of functionally normal neutrophils, and monocytes/macrophages and failure of other components of the immune response, including the gut mucosal barrier;

6 metabolic, due to disturbances in fluid and electrolyte and acid–base balance, related to the disease or the treatment or both;

7 nutritional, when oral intake fails and loss of lean body mass is significant;

8 nausea and vomiting, due to chemotherapy and other drugs;

9 pain, due to involvement of specific anatomical sites in the disease or as a result of specific therapies;

10 palliative supportive care, necessary when cytotoxic therapy fails to induce or maintain lasting, complete remission; this does not exclude further cytotoxic therapy as part of other efforts to control distressing symptoms.

Psychological support

Regardless of the subtype of disease and form of therapy, this support starts with an explanation of the diagnosis and treatment by a senior haematologist accompanied by a specialist nurse, both of whom should be active and experienced in this type of care and communication. It is essential to gain the trust of the patients and their immediate families or partners from the outset so that they can understand and accept the need for the proposed intensity and duration of treatment and the risks of complications. As well as needing support for their distress on learning the diagnosis, most will also ask for detailed information including prognosis. Any relevant clinical trial can be described, and informed consent obtained for enrolment and randomization between different treatment options. A relationship of mutual and complete openness should be established as soon as possible, and questions and discussion encouraged.

Most patients may appear to be psychologically able to deal with these illnesses and all of their complications. But many patients find that loss of control of their normal daily activity is difficult to manage, particularly prolonged stays in hospital, including periods in protective isolation. Nearly all will suffer some loss of self-assurance and self-esteem, particularly if they fall ill at the peak of their responsibilities and abilities in their domestic and working lives. Fear of failure of therapy may be lessened if remission is achieved, but the patients' anticipation of the complications of subsequent cycles of therapy may add to their psychological problems.

Having little control over this cumulative experience, patients can develop significant neurotic or psychotic pathology, sometimes well after therapy is finished and as they attempt to resume a normal life. The clinical team must be alert to the development of any signs that such problems are impending and deal with them before patients suffer significant and lasting harm. In dealing with these problems, it is difficult for professional carers to maintain a balanced approach that suits each patient. It is as easy to be too intrusive with those patients who can cope without help as it is to fail to detect psychopathology in those who cannot. This area of supportive care underlines the need for integrated teamwork.

Regardless of age and subtype, patients with acute leukaemias present with a short history, are often seriously unwell due to acute marrow failure and require immediate admission to a haematology unit for intensive therapy. Their psychological complications are often more intensely expressed and require equally intensive support because their loss of function is so acute and severe. This type of supportive care should be an integ-

ral part of any therapy, whether it is given with the intention to achieve complete remission in younger patients or as palliation in the elderly and frail.

Reproductive issues

Before any chemotherapy is given to adolescents and young men, they should be counselled about the possibility of loss of fertility and offered the opportunity to store sperm. If therapy cannot be delayed, sperm should be collected as soon as possible to minimize the risk of damage to sperm already formed and stored and because of the potential infertility induced by any cytotoxic therapy, particularly intensive chemotherapy. Patients who opt to store sperm need expert counselling in all of the associated ethical issues before collection, particularly their wish to destroy or preserve the collection should the patient die. They and their partners may wish to conserve the sperm for future fertilization after the patient's death. Loss of fertility due to chemotherapy is much less likely in women, who should avoid falling pregnant while receiving such therapy because of likely damage to the embryo and fetus. Preservation *in vitro* of unfertilized ova is not yet possible and not undertaken routinely.

Impaired sexual function can be a problem in both sexes following intensive chemotherapy. Patients and their partners are often reluctant to discuss these problems with their specialist carers and are more likely to discuss them with nursing colleagues. Expert counselling or psychological care can be effective in restoring potency.

Anaemia and thrombocytopenia

In all types of leukaemias, and with all types of treatment, there is a risk of marrow failure leading to anaemia and thrombocytopenia. The pace at which they develop and their severity vary with the type of leukaemia and therapy, and many of the complications are seen whatever the intensity of therapy. As these causes and effects are most marked in the acute leukaemias, the support needed in that context is described in greater detail. By the time most patients present, their ability to produce red cells and platelets will be severely impaired and they will need regular and frequent transfusions of both. Administration of a wide range of intravenous therapies, including blood products, may be necessary simultaneously. Long-lasting, tunnelled, multilumen, central venous catheters (CVCs) facilitate rapid intravenous access for such multiple therapies, and also reduce the risk of blood-borne infection by reducing the need for multiple and repeated peripheral venous access. Sterile handling of these lines is therefore essential at all times. It is not necessary to transfuse either whole or fresh blood but there are some simple basic rules that should be followed regarding red cell and platelet transfusion (Table 36.1).

Table 36.1 Ten rules for transfusion and coagulation failure in acute leukaemia.

Rule	Reason	Exceptions
1 In younger patients use CMV-negative blood until CMV status known	High transplant-related CMV death risk	No transplant planned
2 Transfuse if Hb < 8 g/dL	Symptom control	Cardiac failure
3 Delay if white count > 100×10^9/L	Hyperviscosity risks bleeds and clots	None
4 Give platelets priority	Red cells dilute low count	Big bleeds; give both
5 Big volumes need diuretics	Circulatory overload	None but plan K^+ and Na^+ infusions too
6 Keep platelets > 10×10^9/L	Prevent bleeding	> 20×10^9/L during sepsis
7 Use ABO-identical platelets	Maximize effect	No clinical harm if only non-identical available
8 HLA-restricted platelets if refractory to donations	Loss of effect	May resolve allowing use of non-restricted donations
9 Use pethidine for allergic/febrile reactions	Avoid undetected cumulative steroid immunosuppression	None
10 Use only ABO-compatible plasma-derived products to correct clotting times	Avoid ABO haemolytic reactions	None; therapy determined by specific bleeding problems

Cytomegalovirus-negative blood products

As transfusion of both red cells and platelets may be required at the outset, it is important to establish immediately whether elective allogeneic stem cell transplantation (SCT) is likely as part of the care plan. If it is, those patients should always be transfused with blood products that are less likely to increase the risk of cytomegalovirus (CMV) transfusion, using leucodepleted or filtered donor blood or blood only from known CMV-negative donors until the patient's own CMV status is known. This applies to all patients under the age of 55 years who have potential sibling donors. CMV infection is a major cause of morbidity and mortality in allogeneic SCT and prevention is more effective than treatment.

Acute anaemia

Onset of anaemia is often rapid in patients with acute leukaemia so they are unable to compensate haemodynamically as in anaemia of slower onset. Because of their acutely reduced red cell mass and hence oxygen-carrying capacity, they are likely to be symptomatic and should be transfused as soon as they have been assessed clinically and the result of their blood count is known. This rule may need to be modified in the presence of symptomatic or treated cardiac disease (see Planning large volume transfusions, below). With chemotherapy red cell production remains suppressed and the patient remains dependent on repeated transfusions.

Conventional teaching is to try to maintain the haemoglobin level above 10 g/dL. This has been challenged recently and the Adult Leukaemia Working Party of the UK National Cancer Research Institute is planning a randomized trial to determine the risks and benefits of lowering the threshold of the haemo-

globin level at which red cell transfusion is indicated. There is evidence that patients in other critically ill categories will tolerate much lower levels (as low as 6 g/dL) and that transfusing at higher levels may be harmful. In practice, many leukaemia and transplant units already withhold red cell transfusion until the haemoglobin drops to 8 g/dL for patients whose cardiorespiratory function is not compromised.

Excessive red cell transfusion may lead to alloimmunization, with red cell blood group and white cell HLA antigens potentially creating difficulties for future transfusion and SCT. In the transplant patient (autologous and allogeneic), there is also the risk of iron overload, but this appears unlikely to be a problem with conventional chemotherapy.

Hyperviscosity of high white counts

Patients who present with acute leukaemias with very high white blood cell (WBC) counts, particularly over 100×10^9/L, should be given blood only if it is not possible to wait for reduction of the WBC either by leucapheresis or chemotherapy. These patients are already at risk of thrombotic and haemorrhagic events due to hyperviscosity, and transfusion will increase that risk, even if it is slow. It is probably safe to allow such patients to start their chemotherapy with a haemoglobin level as low as 8 g/dL. Patients with high WBCs in chronic myeloid leukaemia (CML) may develop hyperviscosity problems, but these are rare in chronic lymphocytic leukaemia (CLL).

Planning large-volume transfusions

When planning a large red cell transfusion, it is essential to estimate in advance the total intravenous fluid load these patients will receive over any following 24-h period. Most patients

with acute leukaemia are elderly and will already have some degree of cardiovascular pathology. Some chemotherapy, such as the anthracyclines commonly used in the remission induction of acute myeloblastic leukaemia (AML) and acute lymphoblastic leukaemia (ALL), are also unpredictably cardiotoxic below a total cumulative dose in individual patients. If a large intravenous fluid load is unavoidable and intravascular overload is likely, elective diuretic therapy should be prescribed, usually with small doses (20 mg) of intravenous furosemide (frusemide) at planned intervals throughout a prolonged infusion. The use of diuretics in this way may lead to electrolyte depletion, which requires correction (see Metabolic support, below). Careful observation of basic vital signs, more simply daily weights, will indicate whether there is an excessive intravascular fluid load contributing to compromised cardiac and respiratory function.

Platelets take priority

When these patients require both red cell and platelet transfusions, platelets should always be given first. Platelet production is compromised to such a degree that a large red cell transfusion will dilute the platelet count to a potentially dangerously lower level. Platelets for transfusion are provided in single packs known as an 'adult therapeutic dose' (ATD), which contains approximately 10^{11} platelets. These are obtained either by apheresis from a single donor or by pooling platelets harvested from the buffy coats of packs of blood from six donors.

Platelets can be given so quickly through a CVC, such that even with sudden and heavy bleeding it is seldom necessary to give red cells first, and red cells and platelets can be given simultaneously.

Minimum platelet level

The planned trial of restriction of red cell transfusions is partly based on the evidence that the previous threshold for the transfusion of platelets at 20×10^9/L or less was overcautious and a threshold of 10×10^9/L is equally unlikely to lead to significant bleeding. Platelet transfusions may also alloimmunize against red cell and HLA antigens.

In general, platelets are not given until the count falls below the lower limit, but there are exceptions to this rule. It is important to remember that a count just over this lower threshold is often obtained early in the morning and the count may drop below it within the following 24 h before a further count is undertaken. So the rate of fall in previous counts should prove a useful guide as to when platelet concentrate should be infused. Platelet function and survival may both be compromised in the presence of sepsis and some systemic antibiotics (particularly penicillins in high dose), so the higher threshold of 20×10^9/L should be used in patients with these risk factors. Whenever possible, platelet infusions should not be given temporally close to infusions of amphotericin B (see Infections, below) because of

the evidence that this drug will interfere with platelet function and thus reduce the effectiveness of the donation.

It has been suggested that patients who are stable and not infected may tolerate platelet counts as low as 5×10^9/L, provided the count is unlikely to fall further. This policy requires considerable faith in the accuracy and reproducibility of the laboratory technology of counting platelets.

'Compatible' platelets

Whenever possible, platelet concentrate of a red cell ABO group that is identical to that of the patient should be transfused. If non-identical platelets are used, there may be loss of platelet function and an inferior increment in the recipient's count. Whether this technical benefit is ever clinically significant has never been proven conclusively, but it seems reasonable to give patients the theoretical best possible donation if they need platelets at all, especially if one applies the policy of only transfusing at the lower count of 10×10^9/L.

Platelet 'increments'

Regular platelet counts are needed to plan platelet transfusions and will also reveal failure to obtain a satisfactory increment in the patient's platelet count following transfusion of an ATD. Such patients are described as 'refractory' to platelet transfusion because of the development of alloantibodies to the HLA antigens borne by platelets, and may manifest bleeding or bruising even before a failure of increment is detected. This refractory state should be confirmed with two platelet counts, one pre-transfusion and one taken 30-min post transfusion. On confirmation of this problem, the patient's HLA type should be determined immediately if this has not already been performed for the purposes of subsequent transplantation. The National Blood Service will then supply HLA-restricted, if not -identical, platelet donations until such time as a trial of HLA-unrestricted donations can be safely given again. Platelet refractoriness need not be permanent but can recur and is not necessarily heralded by a febrile reaction to transfusion.

Febrile reactions

During the course of treatment, patients will experience many episodes of fever for which there will be many potential explanations. Febrile reactions to blood and blood products are usually easy to identify as they occur during or immediately after the transfusion and should not be confused with the fever of infection (see Infections, below). If the reaction occurs during transfusion, transfusion should be slowed at first, or stopped if this does not reduce the severity of symptoms and signs. If that fails to abort the first febrile reaction, only then should a single intravenous injection of an antihistamine be given, such as chlorpheniramine 25 mg. If that is insufficient, many

haematologists will give hydrocortisone 100 mg intravenously, and some will give both hydrocortisone and chlorpheniramine simultaneously.

The frequency and severity of these reactions may lead to the prescription of these two drugs either 'as required' or as prophylaxis for these reactions, which leads, in turn, to their uncontrolled use by inexperienced junior doctors and nurses. The total cumulative dose of immunosuppressive steroids may go unseen, and the use of hydrocortisone in the management of these febrile reactions should be discouraged. Whether these reactions are due to blood products or drugs such as amphotericin B, the most effective treatment or prophylaxis is pethidine 12.5 mg intravenously. This drug is not immunosuppressive and this dose is neither sedating nor, on repetition, addictive, but it should not be used in fever that is probably due to infection.

Specific bleeding problems

In addition to the risk of bleeding because of low platelets, there are further specific coagulation problems that require early detection and planned management. Patients should be monitored for evidence of failure of coagulation, even when they are receiving regular platelet infusions. Clinical observation should include regular fundoscopy for retinal bleeding and testing for haematuria. During remission induction and consolidation therapy for acute leukaemia, platelet transfusion is unavoidable. Fresh-frozen plasma and cryoprecipitate are needed infrequently and should only be used for specific indications and in the absence of virally inactivated products. When correcting coagulation deficiency with plasma-derived products, ABO red cell group-compatible donations should be used to avoid ABO haemolytic reactions. The use of any blood products should follow best practice guidelines provided at present.

Asparaginase in the remission induction phase of the treatment of ALL can inhibit synthesis of coagulation factors, particularly fibrinogen, which should be replaced using fresh-frozen plasma or cryoprecipitate. Very rarely, asparaginase may cause superior sagittal vein thrombosis without warning, but especially in children with unsuspected genetic thrombophilia, for example factor V Leiden.

The hypergranular variant of acute promyelocytic leukaemia (M3) carries a very high risk of bleeding because of disseminated intravascular coagulation (DIC) or fibrinolysis. This can be present at diagnosis or is precipitated by chemotherapy, in either case because of the systemic prothrombotic action of the cytoplasmic granules released by the malignant blasts. The treatment, as in all cases of DIC, is to deal with the primary cause, in this case to lower the blast count as soon after diagnosis as possible. It may be accompanied by microangiopathic haemolytic anaemia. All-*trans*-retinoic acid (ATRA) is now a standard part of initial chemotherapy for these patients, as it induces maturation of granulocytes, reducing release of the prothrombotic contents of their granules and lowering the risk of DIC.

Many older adult patients are now anticoagulated with warfarin, aspirin and clopidogrel, or a combination of these, to lessen their risk of acute myocardial infarction or stroke. The physician who initiated this therapy should be identified, if possible, to discuss the risks of stopping these immediately after diagnosis and throughout the treatment of the leukaemia. All anti-platelet therapy should be stopped because protracted and severe thrombocytopenia will recur during the course of therapy. The long action of aspirin and clopidogrel make rapid reversal of their anti-platelet effect impossible if the platelet count drops suddenly. Low-molecular-weight heparin (LMWH) should replace warfarin in those patients who have a high risk of arterial or venous thrombosis, and should be stopped once the platelet count falls below 50×10^9/L. Long-term anticoagulation should not be restarted until all chemotherapy is finished and the patient is in a stable remission.

In patients with chronic and relapsed or refractory leukaemia, there may be chronic mucosal blood loss due to persistent and severe thrombocytopenia, which may be refractory to donor platelet transfusions. Oral tranexamic acid can reduce such blood loss and hormonal suppression can prevent endometrial bleeding. Persistent marrow failure without overt blood loss may require repeat red cell transfusions in patients with chronic leukaemias, particularly chronic lymphocytic leukaemia (CLL). These should be given to relieve symptoms and not according to any set level of haemoglobin. Red cell alloantibodies and iron overload complicate repeated transfusion. CLL patients can develop autoimmune haemolysis and thrombocytopenia. The management of these complications is described in Chapter 38. Erythropoietin is of little value in the treatment of chronic anaemia associated with chronic and relapsed/refractory acute leukaemias but may occasionally be of value following SCT if engraftment is slow.

In all SCT patients, all blood products must be irradiated before transfusion to avoid the risk of graft-versus-host disease (GvHD) mounted by donor lymphocytes against the immunocompromised host. The risk of transfusion-related GvHD is much lower in autografts than in allografts. Any transfusion given to those patients whose peripheral blood stem cells (PBSCs) are to be collected within the subsequent 2–3 weeks must also be irradiated, as transfused donor lymphocytes in the PBSC collection may remain alloreactive until post autograft, and lead to clinically significant GvHD.

Infections

Some infections occur with all types of leukaemia and therapy, whereas others show more specific associations. As a general rule, the greater the duration and severity of immunosuppression, the greater is the risk of life-threatening infection with a bigger range of organisms. During chemotherapy, patients with acute leukaemia have a high risk of life-threatening infections

Table 36.2 Origins of common potential bacterial pathogens.

	Endogenous	Exogenous
Gram-negative bacilli	*Escherichia coli*	*Pseudomonas aeruginosa*
	Klebsiella pneumoniae	*Enterobacter cloacae*
Gram-positive bacilli	*Corynebacterium* species	*Bacillus* species
	Clostridium species	
	e.g. *C. septicum*	
Gram-positive cocci	*Staphylococcus aureus*	*Enterococcus faecium*
	Coagulase-negative staphylococci	
	e.g. *Staphylococcus epidermidis*	
	Viridans streptococci	
	e.g. *Streptococcus mitis*	
	Enterococcus faecalis	
	Stomatococcus mucilaginosus	

because of the combination of neutropenia due to the disease and the chemotherapy, which also suppresses both humoral (B cell) and cell-mediated (T cell) immunity and worsens an already poor nutritional state. The risk is greatest with the profound and protracted immunosuppression required in allogeneic SCT from an unrelated donor.

Common causes of bacterial infection are depicted in Table 36.2. This limited range of bacteria accounts for most of the opportunistic infections identified during the course of neutropenia, despite the fact that the body is colonized with so many more. Strictly anaerobic bacteria are rarely the cause of systemic infection, although they outnumber other bacteria by several billion. Fungal infections tend to occur after bacterial infections. The body's surfaces, particularly in the oral cavity and gut, are inhabited by billions of bacteria spread over many hundreds of genera, and our environment contains hundreds more bacteria and fungi. But most remain harmless, or at least undetected as causes of fever during profound immunosuppression, despite leukaemic patients' close encounter with them.

All protocols for prophylaxis, investigation and treatment of infection should be agreed by haematologists and microbiologists. These protocols should be supplemented with regular discussion of individual patients' investigations and results, and by audits of responses to results and of effectiveness of the protocols.

Fever as evidence of infection during chemotherapy and stem cell transplantation

Although repeatedly neutropenic for prolonged periods, most patients with acute leukaemia will become febrile at some point. A minority of these episodes will be accompanied by symptoms and signs of localizing infection, such as dysuria and urinary frequency or inflammation of the CVC tunnel. Because of the perceived need to treat presumed bacteraemia promptly in most cases, the fever will be, at least initially, of unknown ori-

gin (FUO). This empiric approach may have some unfavourable consequences of excessive treatment, such as insufficient microbiological diagnosis, more adverse drug reactions, emergent bacterial resistance and increased costs. There are many other causes of fever in these patients, including blood products, drugs (chemotherapy and antibiotics), tumour lysis syndrome (TLS), DIC and, in SCT, total body irradiation (TBI) and GvHD. It is sometimes possible to identify one or more of these as the cause(s) of fever and thus avoid unnecessary antibiotic therapy.

Infections can go unnoticed because the inflammatory response is muted and no pus is formed because of neutropenia. Foci of infections can also be easily overlooked unless physical examination is frequent. Infections may start as fever with or without bacteraemia, followed by clinical evidence of localized infection, and constant vigilance is needed to detect the sequential development of systemic infection (Figure 36.1). Despite the meagre signs and symptoms of infection in an immunocompromised patient, it is still essential to conduct a careful physical examination, paying particular attention to the oropharynx, including the dentition, the lungs, the skin and exit sites of venous access devices, and the perianal region. Rectal examination is inadvisable in the severely neutropenic and thrombocytopenic patient because of the risk of bacteraemia. The most common sites of infection when present are the oral cavity, the lung and the skin, with its underlying soft tissues. Clinically detectable sources of infections occur in up to one in five cases and tend to be those in the skin and its structures or in the mucosal barrier, including the respiratory tract (Figure 36.2).

Microbiological proof of infection is found in only 20–30% of cases of neutropenic fever and a further 10–20% of cases can be defined as clinical infections.

All units treating these patients must have a clear written protocol that balances the risks and benefits of exact diagnosis against empiric therapy by making good use of all available evidence at the onset of FUO. This protocol must include a description of the specimens to be obtained by the microbiology
Figure 36.1 Common infections during neutropenia.
Figure 36.2 Sources of infection – the role of mucositis.

laboratory. Many diagnostic opportunities are missed if the laboratory is not clear about what is to be done with samples from these patients, and how results should be interpreted and reported. Obtaining specimens from some infectious foci may be difficult if this requires aspiration or biopsy during severe thrombocytopenia. Even when a specimen is obtained from a normally sterile site, the yield of pathogens is usually low,

interpretation is difficult and the results may not influence management. Failure to identify a focus of infection and to obtain appropriate samples may leave the fever unexplained. In most cases, microbiological diagnosis depends on identification of pathogens in blood cultures.

Laboratory investigation of neutropenic fever of unknown origin

Blood cultures

The utility of blood cultures depends on adherence to a few simple rules (Table 36.3). The specificity of blood cultures is increased if samples are taken from at least two separate sites, preferably including all lumina of a CVC. Blood should be drawn from a peripheral vein and from the CVC to confirm the significance of growing skin commensals in the culture medium, such as the Gram-positive coagulase-negative staphylococci. Other isolates including Gram-negative bacilli and viridans streptococci seldom colonize the lumen of a CVC. The total amount of blood sampled at any one time constitutes a single blood culture. Sensitivity and specificity are increased if at least 20 mL of blood taken from each sampling site at each time is

Table 36.3 Blood cultures.

When	At onset of fever
How	A sample of 20 mL blood from a peripheral vein and, when present, samples of 20 mL from each lumen of an indwelling vascular catheter
Method	Each sample divided between an aerobic and an anaerobic bottle
Time to positivity	Most organisms are detected within 24 h and 50% within 12 h
Time to identity	24–48 h, i.e. within the empirical phase
Utility	Identifies cause of fever in 20–30% of cases

divided between an aerobic and an anaerobic bottle to detect the majority of common pathogens.

Oral/rectal swabs

Viridans streptococci of the *mitis* group (*Streptococcus mitis* and *S. oralis*) are universal residents of the oral cavity and, with the exception of bacterial endocarditis, are seldom associated with infectious diseases. However, in the last two decades, these bacteria have been causing bacteraemia regularly in patients with severe oral mucositis. Similarly, *Clostridium* spp., for example *C. septicum*, are also normal commensal bacteria of the large bowel but can cause bacteraemia in patients suffering from a particularly severe form of gut mucositis, namely neutropenic enterocolitis (typhlitis). Given their presence in most individuals as part of the normal flora, it is pointless to obtain specimens from the oral cavity or rectum to detect these bacteria.

Specimens for pulmonary infection

Investigating pulmonary infection has become more demanding and involves obtaining blood samples as well as specimens from the respiratory tract. Bronchoalveolar lavage (BAL) specimens are advised for patients with pulmonary infiltrates and can yield the pathogen in 30–50% of cases. There are no standards for handling such specimens in the laboratory or in the diagnostic tests themselves. The residue of BAL samples after centrifugation is examined for *Pneumocystis jirovecii* (formerly *carinii*), the acid-fast bacilli and *Nocardia* spp., common bacteria, and moulds (*Aspergillus* spp.) and is subjected to culture for fungi and bacteria, including *Legionella* spp. and *Mycobacterium* spp. BAL may also be examined for the presence of *Aspergillus* galactomannan antigen, which is found frequently in cases of invasive pulmonary aspergillosis, and microbial DNA may be detected by PCR techniques.

Standards for virological investigations vary, but the influenza and parainfluenza viruses, adenovirus, respiratory syncytial virus and CMV may also be detected. When superficial pulmonary lesions are present, specimens might be obtained by percutaneous or open lung biopsy, provided that the benefit outweighs the risk, diagnosis is uncertain and treatment is not working. Although neutropenic patients do not produce sputum, they frequently expectorate mucous secretions, which should be sent for microscopy and culture. Recovery of moulds including *Aspergillus* on two or more consecutive occasions suggests that they are causative organisms from a patient with pulmonary infiltrates. The common practice of microbiology laboratories in discarding expectorated secretions without pus cells should not apply to these patients.

Skin lesions

Identifying the cause of a skin or soft-tissue infection is difficult because culturing superficial swabs of lesions rarely discriminates between pathogens and commensal flora. Culture and histological examination of skin punch-biopsy specimens is very helpful in diagnosing disseminated infections due to *Candida* spp., *Trichosporon* spp. and *Fusarium* spp., but aspiration of skin lesions is seldom successful as pus is usually absent.

Gut investigations

In oesophagitis, endoscopy occasionally distinguishes infection due to herpes simplex from that due to *Candida* spp. but clinical suspicion of infective oesophagitis rarely leads to endoscopy because appearances are usually non-specific and the procedure is hazardous. Persistent diarrhoea or abdominal pain requires a cytotoxicity assay on a stool sample for *C. difficile* toxin, and patients with right lower quadrant pain suggestive of typhlitis should have blood cultures taken to exclude the presence of *C. septicum* or *C. tertium*, as recovery of these bacteria usually indicates neutropenic enterocolitis. Although infections due to *Candida* spp., the Gram-negative bacilli, *Escherichia coli*, *Klebsiella pneumoniae*, and *P. aeruginosa*, *Clostridium* spp. and enterococci, including vancomycin-resistant enterococci (VRE), usually originate from the large bowel, there is no value in culturing faeces as there are many more patients colonized than infected.

Urinary tract

Urine should be obtained for standard culture when there are signs or symptoms of a urinary tract infection but not otherwise. Urine from SCT recipients with haemorrhagic cystitis should be tested for adenovirus and BK virus.

Non-cultural techniques

The role of non-cultural methods for diagnosis is small but expanding. *Legionella* antigen detection in urine is specific but detects only *L. pneumophila* type 1. Detection of CMV DNA by quantitative PCR may replace detection of the pp65 antigen in peripheral blood neutrophils among SCT recipients, and there is increasing expertise in using PCR to detect fungal DNA in blood and urine, but these remain investigational. Kits for the detection of *Aspergillus* antigen in serum, plasma and other sterile body fluids using an enzyme-linked immunosorbent assay (ELISA) are commercially available and can be used to screen patients at risk of aspergillosis. The specificity is generally high but the sensitivity has varied considerably, depending upon the nature of the specimen (blood, bronchial material, cerebral spinal fluid), the threshold employed (0.5–1.5), the frequency of sampling (once or twice weekly or less) and the prevalence of the disease in the population under study. Unlike PCR, the detection of the *Aspergillus* antigen by ELISA is considered equivalent to recovery by culture as mycological evidence.

Surveillance cultures

There is no point in undertaking surveillance cultures unless the results are used to guide therapeutic or prophylactic choice. Surveillance cultures of faeces are used if there is risk of emergent ciprofloxacin-resistant *Escherichia coli* or *Pseudomonas aeruginosa* when the drug is being used for prophylaxis. Testing

faeces for carriage of these bacteria is a prudent form of surveillance to permit early detection of rising resistance before there is a corresponding rise in the infections caused by resistant bacteria. Detection of *Candida* carriage can be used to start prophylaxis and, conversely, failure to detect the yeast or opportunistic Gram-negative bacilli in oral samples or faeces suggests that infection is highly unlikely as the negative predictive value of these cultures exceeds 95%.

Proven systemic infection during neutropenia

Surveys show that the rate of proven bacteraemia during periods of neutropenia has remained between 20% and 25% over many years. In adults, the range of bacteria identified has also altered very little but the ratio of Gram-positive to Gram-negative organisms has varied. In the 1970s, there were two to three times as many Gram-negative as -positive infections, in the late 1980s and early 1990s, this ratio was reversed and now the risks of Gram-negative and -positive infection are approximately equal. It is not entirely clear why this has happened, and it is important to emphasize that individual units can have a pattern of causative organisms that is unique and unlike this international spectrum. Therefore, it is important for each unit to monitor local rates of isolation of bacterial (and other) pathogens and their patterns of antibiotic susceptibility in liaison with the microbiologists, who should be members of the multidisciplinary team.

There have been changes in practice that have been widely applied and are blamed for the changing Gram-negative and -positive rates. For example, in the management of adult acute leukaemia there has been a trend towards more intensity of therapy, with an increasing risk of gut mucositis. In the presence of this complication, the use of blockade of gastric acid production increases the risk of streptococcal bacteraemia. The widespread use of indwelling CVC provides another portal of entry for Gram-positive staphylococci. The cause of greatest concern has been the indiscriminate use of oral quinolone antibacterials (ofloxacin, ciprofloxacin) as prophylaxis against Gram-negative bacteraemia, which has not reduced the overall risk rate but simply shifted towards the Gram-positive organisms. Such prophylaxis is justifiable in allogeneic SCT recipients, but it may not be appropriate in lower-risk patients who are receiving chemotherapy.

Recent studies suggest that the risk of Gram-negative bacteraemia has not diminished in many single centres and is on the increase in centres that have never used quinolones as prophylaxis, in those which have recently discontinued this use and even in those in which this use continues (Figure 36.3). The latest European data show that the risk of proven bacteraemia is now up to 28%, mainly due to a significant doubling of the risk of Gram-negative infections.

It is difficult to reconcile these data with a unifying explanation. But it does seem clear that, despite a relatively high risk of bacteraemia, there is insufficient evidence to support continuous prophylaxis against bacterial infections with broad-spectrum antibiotics during conventional chemotherapy. It is doubtful that this will substantially reduce the risk of such infections and may compromise the efficacy of these antibiotics when they are needed.

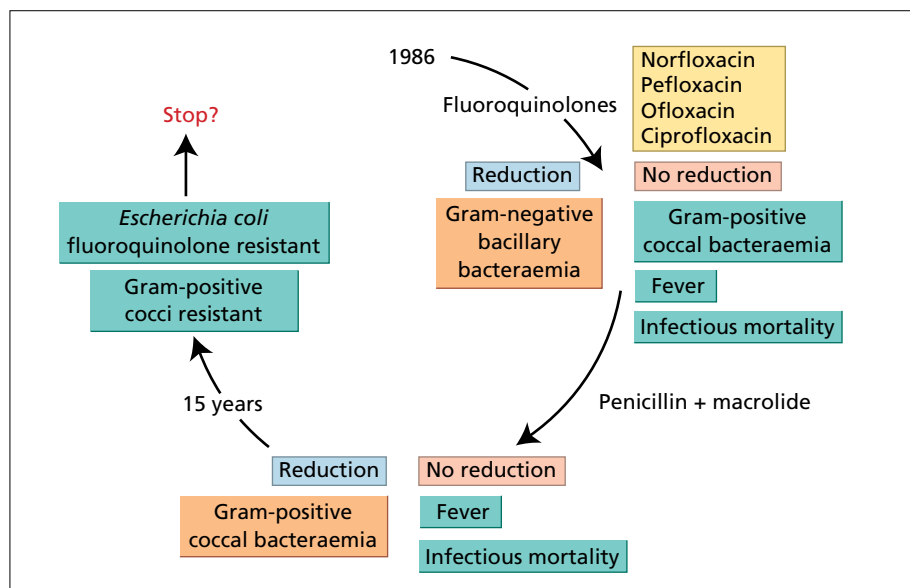
In bacteraemia associated with onset of fever, the most commonly identified organisms are the Gram-negative bacilli *E. coli*, *P. aeruginosa*, *Proteus*, *Klebsiella* and Enterobacter spp. and the Gram-positive cocci *Staphylococcus epidermidis*, *Staph. aureus* (increasingly the methicillin-resistant strains, MRSA), the viridans streptococci belonging to the *mitis* group *S. mitis* and *S. oralis*. Other species such as *Enterococcus faecalis* and *Clostridium* spp. occur only after 7–10 days' therapy with broad-spectrum


Figure 36.3 The life cycle of fluoroquinolone prophylaxis.
Figure 36.4 Antibiotic choices for prophylaxis during neutropenia.

antibiotics, in association with gut mucositis, including neutropenic enterocolitis (typhlitis).

The reported incidence of proven systemic fungal infection (SFI) is around 15% in SCT, and the risk rises in severe chronic GvHD requiring prolonged immunosuppression with steroids. The majority of these infections are now due to *Aspergillus* spp. and are seen more than 100 days after engraftment. The mortality rate of SFI is high in these patients. The rate of SFI during conventional chemotherapy is less clear but it is still a significant risk, particularly if T-cell suppression is induced by potent purine analogues such as fludarabine and high-dose cytosine arabinoside. The risk is low in the predictably brief duration of neutropenia with autologous SCT.

In allogeneic SCT, the rate of CMV seropositivity and clinical CMV infection vary according to the pre-transplant status of the donor and recipient. The post-transplant CMV-associated fatality rate is around 40%.

Prophylaxis of infections

Given that some infections occur frequently and arise from body sites harbouring an abundant normal commensal flora, it is not surprising that antimicrobial prophylaxis is advocated and adopted by many centres treating patients with acute leukaemia. Essentially, when adopted, prophylaxis is started just before chemotherapy is begun with the aim of suppressing or eradicating potentially opportunistic pathogens ahead of the anticipated neutropenia (Figure 36.4).

The early cocktails of non-absorbable antibiotics, such as framycetin, colistin and nystatin (FRACON) or gentamicin, vancomycin and nystatin (GVN), were superseded by cotrimoxazole and colistin and later by the fluoroquinolones, norfloxacin, pefloxacin, ciprofloxacin and ofloxacin. The need for antibacter-

ial prophylaxis is still in doubt. As described above, antibacterial prophylaxis had no impact on the overall incidences of fever or mortality over many years, and almost all patients given such prophylaxis will also be given further broad-spectrum antibiotics for FUO. Some institutes are now faced with patients harbouring fluoroquinolone-resistant *E. coli*, causing them to have to abandon prophylaxis altogether.

The risk of SFI varies with the intensity of therapy and its complications and is greatest in SCT patients with protracted GvHD. Non-absorbable polyenes, such as amphotericin B and nystatin, do not provide systemic protection. Fluconazole reduces the risk of *C. albicans* significantly in SCT, but not in conventional chemotherapy; it is not effective against certain yeasts, including *C. krusei* and *C. glabrata*, and it is inactive against moulds (e.g. *Aspergillus* spp.). Itraconazole is active against a broader spectrum of fungi than fluconazole. With the availability of interchangeable oral solution and intravenous formulations, this triazole is more effective than fluconazole in preventing a range of *Candida* spp. and *Aspergillus* SFI in SCT and conventional chemotherapy, provided that sufficient drug is given to achieve protective systemic levels. There is no evidence that newer triazoles (e.g. posaconazole and voriconazole) or lipid formulations of polyenes (e.g. liposomal amphotericin B) are as effective as itraconazole in prophylaxis of SFI.

There is no evidence to support antiviral prophylaxis during neutropenia that is induced by conventional chemotherapy, except in patients with CLL and a strong past history of herpes infection if they are given fludarabine. In allogeneic SCT, all patients are given aciclovir prophylaxis to reduce their risk of infection with a range of viruses, particularly CMV, which has a high fatality rate. Post-SCT CMV is best prevented by transplantation from a negative donor to a negative recipient, with exclusive use of leucodepleted blood products.
Figure 36.5 Initial empirical antibiotic options during neutropenia.

Empiric therapy of fever of unknown origin

In the 1960s, the combined mortality rate from Gram-negative and -positive bacteraemia during neutropenia induced by therapy for acute leukaemia was estimated at 90%. The introduction of the rapid, empiric use of broad-spectrum antibiotics with the onset of FUO was a major advance in supportive care. Now that this is routine practice (usually with a β-lactam and an aminoglycoside or else a β-lactam alone: see Figure 36.5). The mortality rate from proven bacterial infections is 7% overall, 10% for Gram-negative organisms and 6% for Gram-positive organisms at 30 days from onset of fever.

Each unit should establish and audit the application of rules for the use of these antibiotics in the treatment of FUO. Other causes of fever have been described above and the likelihood of them being the cause of any FUO should be carefully considered before antibiotics are given. There should be a working definition of when a FUO is likely to be due to bacteraemia or other systemic infection to justify systemic antibiotic therapy, including degree of neutropenia and height and duration of fever. A review of the literature shows wide variation in such definitions as they are applied to clinical trials. For patients receiving conventional chemotherapy for acute leukaemia, one practical suggestion is that once the neutrophil count drops below 0.5×10^9/L and the temperature reaches 38°C twice in 1 h despite the use of paracetamol, empiric antibiotic therapy should be given. Clearly, if the patient is shocked or shows early signs of haemodynamic and respiratory instability, a single temperature reading of 38°C is sufficient. The peripheral temperature may be normal or the patient may even be hypothermic on development of shock due to sepsis. Blood cultures should always be taken from both any CVC and a peripheral vein, and always before antibiotics are started.

Despite the dramatic reduction in mortality associated with the use of broad-spectrum antibiotics, they have their limitations. They have relatively poor activity against staphylococci (including MRSA) and streptococci, β-lactams must be given in multiple daily infusions occupying considerable access time through CVC, and the rate of Gram-negative organisms is increasing. The emergence of VRE associated with increased use of third-generation cephalosporins (e.g. ceftazidime) suggests that this class of antibiotics may not be appropriate for empirical therapy. The toxicity of the aminoglycosides requires frequent monitoring of levels and adjustment of dose or timing of administration.

Several randomized controlled trials have now shown that the rate of response of FUO is around 50%, whether an aminoglycoside is used in addition to a β-lactam or not. So initial empiric mono-therapy is sufficient using ceftazidime, cefepime, piperacillin–tazobactam, imipenem or meropenem. There is no need to add vancomycin or teicoplanin into the initial empirical regimen as no study to date has shown any difference in outcome or in the rate of defervescence, subsequent infections, use of additional antimicrobial agents or mortality.

Subsequent antimicrobial therapy

In some patients, when fever persists there may be no growth from culture samples, other microbiological results may be uninformative and there may be no clinical evidence that indicates the need for a switch to an alternative antibiotic. The assumption is often made that such patients have CVC-related staphylococcal infections, and vancomycin or teicoplanin is added empirically. Recent randomized placebo-controlled trials have shown that this makes no significant difference to response rates or mortality. This practice also encourages the emergence of VRE, so the value of such 'second-line' antibacterial empiric

therapy is unclear and only justifiable when there is clinical evidence of infection of the line tunnel.

Subsequently, antibiotic therapy may be modified, depending on the results of initial blood cultures or specimens taken from other sites or the development of new infections defined clinically or microbiologically. The empirical regimen should be continued and complemented with other drugs such as a glycopeptide (e.g. vancomycin) or an antifungal agent. There are individual infections which may be proven microbiologically (e.g. *Candida* in blood cultures) or may be suspected clinically or radiologically (e.g. invasive pulmonary aspergillosis or *Pneumocystis jirovecii* pneumonitis), which justify switching to alternative therapies or adding them to existing antibiotics. A willingness to perform early computerized tomography (CT) scanning of the chest may shorten the time to starting systemic antifungal therapy in suspected invasive pulmonary aspergillosis. Plain chest radiography is notoriously unreliable and should not be used to confirm or exclude this diagnosis.

Each unit should devise a protocol in which the criteria for adding subsequent therapy are defined, based on clinical and microbiological findings (Table 36.4) either given on the basis of the organism causing a microbiologically defined infection (Figure 36.6) or on the basis of the site involved in a clinically defined infection (Figure 36.7). There is little evidence to support precise times when additional or substitute antibiotics should be introduced. The superiority of any one therapeutic agent over any other active against proven *Aspergillus* spp. SFI or probable or possible SFI is based on relative toxicity. In presumed or proven *Pneumocystis* pneumonitis, the drug of choice is high-dose cotrimoxazole, with steroids to reduce the risk of postinfective fibrosis.

Table 36.4 Rules for additional therapy.

Related to primary infective event
• Clinical deterioration

• Initial bacterial pathogen resistant
• Non-bacterial infection
• > 5 days' fever

Related to subsequent infective event
• New microbiologically defined infection
    bacterial
    fungal
    viral
• New clinically defined infection
• New fever

Allogeneic stem cell transplantation patients

The febrile SCT recipient represents a special case of neutropenic FUO because of the increased risk of opportunistic infection with viruses, particularly those of the herpes group, herpes simplex and CMV. The procedures involved in SCT are very similar across units, as are the infective risks. Hence prophylaxis is very similar, e.g. valaciclovir or aciclovir for herpesviruses and a fluoroquinolone to suppress Gram-negative organisms.

An alternative approach is to only give these agents for prophylaxis when the patient is known to be a carrier of the particular organism. SCT recipients predictably develop fever shortly after the time of transplant and it is essential not to treat the immediate fever of total body irradiation with broad-spectrum

Figure 36.6 Microbiologically directed antibiotic treatment during neutropenia.
Figure 36.7 Clinically directed antibiotic treatment during neutropenia.

antibiotics. There is disagreement about whether broad-spectrum therapy should be started at a predetermined time post transplant on the assumption that FUO is imminent, or empirically at the onset of FUO. Whichever approach is followed, the pattern of infection during the neutropenia of SCT is predictable, justifying screening for CMV using a pp65 antigen ELISA or PCR, and *Aspergillus* infection using a galactomannan ELISA or PCR. Treatment may be pre-emptive if these organisms are detected.

By contrast with other neutropenic patients, the risk of infection to SCT recipients extends long after the neutropenia has resolved, particularly with chronic and severe GvHD treated with corticosteroids. These are now the major risk factors for SFI due to *A. fumigatus*, most cases occurring after 100 days, possibly as community acquired infections. These have a high case fatality rate, justifying prolonged prophylaxis. Bacteraemia due to certain Gram-negative bacilli, including *P. aeruginosa*, also occurs at this late stage. In addition, the hypogammaglobulinaemia of SCT persists for months or years after transplant with an increased risk of infection by the encapsulated bacteria *S. pneumoniae* and *Haemophilus influenza*. During the post-transplant period, prolonged prophylaxis against these bacteria may be justified as diagnosis and appropriate treatment may come too late, but there is limited evidence that prophylaxis is cost-effective. These patients need to be seen regularly and frequently, and have to be clear about when to present themselves to the transplant or follow-up unit if they are unwell.

Stopping antibiotics after neutropenic sepsis

Provided that fever has resolved and the temperature has been normal for at least 5 days, antibacterials can be stopped if there has been no bacterial growth on cultures. However, if significant

organisms are grown on blood cultures antibiotics should be given for at least 10 days following lysis of fever. Systemic infections (bacterial or yeast) related to colonization or infection of a CVC or the tunnel may require removal of the CVC to reduce the risk of recurrence. It is less clear when systemic antifungal therapy can be safely stopped in invasive aspergillosis, as radiological changes may persist well after eradication of the causative organism.

Infections specific to childhood and adult acute lymphoblastic leukaemia

The significant additional risk in these patients is *Pneumocystis jirovecii* pneumonitis, which may be lessened by cotrimoxazole 960 mg b.d. orally, twice weekly. The infection has a characteristically rapid onset and presentation with marked hypoxia, relatively few abnormal physical signs apart from increased respiratory effort and extensive pulmonary shadowing on chest radiography. Confirmation of the diagnosis is difficult as there are no reliable objective tests.

Growth factors and granulocyte infusions

Recombinant human granulocyte colony-stimulating factor (G-CSF) may reduce the severity and duration of neutropenia after chemotherapy or SCT, but only if the patient has enough stem cells that are able to be stimulated. The response will not be immediate and it is not clear that this reduces the risk of serious systemic infection, the mortality rate from these infections or the mortality rate overall. Infusion of high-dose granulocyte collections from donors stimulated by G-CSF may be indicated if infection is resistant to antimicrobials and delayed neutrophil recovery is expected. But there is little evidence to support their

use, and they should be avoided in patients with pre-existing HLA alloimmunization or requiring mechanical ventilation.

Infection risks in chronic leukaemias

In the CLLs there is a wide range of suppression of both humoral and cell-mediated immunity and, consequently, a wide spectrum of potential infecting organisms from the relatively low-risk superficial herpetic infection to potentially fatal bacterial pneumonia. These risks increase with progression of disease and intensity of therapy. The use of the more potent purine analogues, fludarabine and cladribine, intensify these risks not only by inducing short-term neutropenia, but also by profound suppression of T-cell function. Atypical infections such as *P. jeroveci* pneumonitis, *Listeria* and fungal infections have been reported, and prophylactic cotrimoxazole is indicated during and for 6 months after these drugs are given, to allow sufficient recovery of T-cell function. In hairy cell leukaemia, there is often neutropenia and monocytopenia with a major bacterial infection at presentation. These patients require the same prophylaxis as other CLLs if treated with purine analogues.

The infection risks of CML are similar to those of the acute leukaemias, although less severe in chronic stable phase. Since the introduction of imatinib, which induces rapid, smooth and lasting control of the disease, the risk of infection has been greatly reduced.

Metabolic complications

Fluid balance

Fluid intake and output must be monitored carefully in patients treated intensively. Accurate observation and recording of these data is the task of specialist nurses, and medical staff must review these regularly. Maintenance of fluid balance is a continuous problem in these patients, particularly the elderly, who have an increased risk of renal and congestive heart failure. The delivery of chemotherapy, blood and blood products, antibiotics and parenteral feeding needs large volumes which may exceed physiological requirements without oral intake. Fluid overload happens relatively quickly if monitoring is overlooked and it should be anticipated and avoided (Anaemia and thrombocytopenia, Planning large volume transfusions, above).

Vomiting, diarrhoea, sweating and insensible respiratory loss may singly, or in combination, lead steadily, sometimes rapidly, to dehydration. The vasodilatation and hypotension of sepsis will exacerbate hypovolaemia, which should be anticipated. Replacement of volume is achieved with normal saline solution alternating with 5% dextrose solution. Acute onset of these complications can require rapid infusion of colloid (polysaccharide solutions such as gelofusin) for expansion of intravascular volume particularly when a shift of body fluid is suspected from

the intravascular space into tissues as can occur in septic shock. However, polysaccharide solutions are metabolized quickly and solutions of albumin are preferable when loss of plasma osmotic pressure is due to chronic hypoalbuminaemia. Fresh-frozen plasma should not be used for this indication. Prolonged hypovolaemia will result in acute renal tubular necrosis (ATN), therefore an early decision is needed about the likely cause of oliguria, in case this is due to a 'renal' rather than the 'pre-renal' hypovolaemic cause of acute renal failure (ARF). Supporting a balanced throughput of volume of fluid is complicated by a number of electrolyte and metabolic problems.

Hyperuricaemia and tumour lysis syndrome

The rapid rate of cell proliferation and death in acute leukaemia increases the catabolism of nucleic acids, which terminates with the excess production of uric acid. Therefore, patients may present with biochemical hyperuricaemia (HU) or its clinical consequences or develop these once treatment starts. The most extreme form of this is the tumour lysis syndrome (TLS), in which severe HU, hyperphosphataemia, hyperkalaemia and hypocalcaemia are associated with supersaturation of the urine with uric acid, which is then deposited in crystals in the renal tubules and distal collecting system. These biochemical abnormalities result in a major increase in the morbidity and mortality of patients, including ARF, which requires haemodialysis.

Tumour lysis syndrome is a frequent complication of advanced stage Burkitt's lymphoma and B-cell ALL in childhood and of any adult leukaemia with a very high presenting blast count and, despite attempts to manage the metabolic problems, as many as 25% of such children develop ARF on starting chemotherapy. The precise incidence of clinical and subclinical TLS are not known. Subclinical TLS could cause unrecognized morbidity and adversely affect the efficacy and safety of other therapies, some of which are also nephrotoxic.

The standard management for HU is allopurinol (300 mg daily orally), hydration and attempted urinary alkalinization. Hydration is technically easy with CVCs, but the complexities of maintaining fluid balance and avoiding overload are described above. Urinary alkalinization is achievable but complicates the management of fluid and electrolyte balance and, in practice, it is difficult to maintain the urinary pH above 8. Allopurinol blocks the formation of uric acid by inhibition of xanthine oxidase, increasing plasma and urinary concentrations of hypoxanthine and xanthine. Xanthine is less soluble than uric acid in urine and occasional cases of nephropathy are described as a consequence of this therapy. Patients have a backlog of excess uric acid that they must excrete, particularly those with a high tumour burden, and allopurinol has no effect on that. Hypersensitivity to allopurinol is well recognized, especially in the elderly, and causes distressing allergic dermatitis that may exfoliate. Interaction with other medications (warfarin, thiazide diuretics, antibiotics such as ampicillin and amoxycillin and

chemotherapy such as mercaptopurine and azathioprine) is well described. Many patients have difficulty taking the drug orally; this may not be widely recognized and the alternative intravenous (i.v.) formulation is not sufficiently prescribed. Allopurinol reduces or makes normal the serum uric acid level in the great majority of adult and paediatric patients. The recombinant enzyme, rasburicase, produces a fall in uric acid concentrations within 1 h and is a safe and effective alternative for those patients who require rapid control of HU or cannot tolerate allopurinol. At present, recommended dosage schedules may be excessive and the drug is expensive, but rasburicase also avoids the need for hyperhydration and urinary alkalinization (see also Chapter 33).

Abnormalities of renal function and electrolyte balance

The hyperphosphataemia, hyperkalaemia and hypocalcaemia associated with TLS are described above, but other electrolyte problems occur more commonly. Hypokalaemia and hyponatraemia are the most frequent, and require regular intravenous supplements. Prolonged and copious diarrhoea will also result in hypokalaemia. Both hypokalaemia and hyponatraemia are also intrinsic to the disease owing to high plasma levels of lysosyme (particularly in the monocytic FAB subtypes M4 and 5), which interferes with proximal tubular function. Intravenous amphotericin B also induces renal tubular wasting of potassium and magnesium. This can be at least partially blocked by the diuretic amiloride (20 mg daily orally) but intravenous supplements of potassium, and less often of magnesium, are usually also required in patients receiving intravenous conventional amphotericin B. Oral replacement of these electrolytes is ineffective. Liposomal amphotericin B is less likely to create these electrolyte problems.

It is common practice to estimate urea and electrolyte levels daily during the aplastic phase of intensive chemotherapy, and magnesium levels should be estimated twice weekly. Otherwise, hypomagnesaemia may not be appreciated as the cause of confusion, neuropathy assumed to be due to hypocalcaemia and unexplained arrhythmia. Aminoglycosides and vancomycin are also toxic to renal tubules and can exacerbate these problems. Cyclosporin A therapy in SCT is also nephrotoxic. Regular and frequent monitoring of the levels of all of these drugs will reduce the risk of renal damage.

The same problems with electrolyte balance may occur in the ATN which results from hypotension due to sepsis, major blood loss and pulmonary capillary leak syndrome in acute respiratory distress syndrome (ARDS). ATN is accompanied by failure of glomerular filtration, with oliguria or anuria, and a rise in the levels of serum creatinine and urea. In these patients, if the primary insult is treated successfully, then ATN resolves with a compensatory diuretic phase and full recovery of renal function. It is important to keep pace with the diuresis with adequate fluid replacement.

Amphotericin B is also toxic to glomeruli and it should be discontinued or switched to the liposomal form once the creatinine has exceeded twice the level on starting the drug, assuming that was a normal figure. The renal toxicity of amphotericin B is almost always reversible and should not exclude its use if there is no pre-existing renal pathology or toxicity related to another drug. Before liposomal preparations were available, intravenous sodium loading was recommended to lessen the renal and electrolyte problems of amphotericin B. This is seldom used now although it has never been compared prospectively against liposomal amphotericin B.

Liver function abnormalities

In patients presenting with acute leukaemia, raised levels of lactate dehydrogenase are common because this is derived from bone marrow as well as liver. Some will also have non-specific elevation of alkaline phosphatase and transaminase levels. About one-half will develop abnormally high levels of one or all of these measures of liver function owing to the direct hepatocellular toxicity of chemotherapy with increased levels of serum bilirubin sufficient to cause clinical jaundice. It is seldom necessary to modify doses of remission induction drugs because of these abnormalities but, recently, there has been some concern about the hepatotoxicity of the antimetabolite purine analogue thioguanine, which is no longer available. Cytosine arabinoside, another purine analogue, also induces cholestasis and this hepatotoxicity may have been underestimated in the past.

Hyperbilirubinaemia with clinical jaundice is a frequent and sometimes overlooked complication of red cell transfusion which does not of itself indicate liver disease but is more obvious if liver function is impaired for any other reason. The hepatotoxicity of most chemotherapy is transient and resolves spontaneously with regeneration of normal marrow and induction of remission. It is usually asymptomatic and seldom progresses to severe liver failure, ascites, cirrhosis or portal hypertension except in specific cases described below. However, even minor impairment of liver function will affect other drugs that are dependent on liver metabolism to a degree that may require modification of doses.

Severe and fatal liver damage may occur with veno-occlusive disease in allogeneic SCT, which is described in detail in Chapter 24. This is thought to be a complication of preparatory or conditioning therapies prior to infusion of stem cells. A similar syndrome is seen with the new drug, mylotarg, which is now part of remission induction in the latest MRC AML 15 trial in adults. Mylotarg consists of the cytotoxic antibiotic, ozogamicin, which is linked to an anti-CD33 monoclonal antibody and is activated by hydrolysis once it is internalized following attachment of the antibody to leukaemic myeloblasts. The preceding phase II pilot study of this agent, given in association with therapy for induction and consolidation of remission, revealed the dose-limiting hepatic toxicity of this 'magic bullet'. As with the simultaneous

use of nephrotoxic drugs, careful monitoring of all potentially hepatotoxic drugs or any drugs which are metabolized by the liver will be necessary if they are used simultaneously. These drugs include the triazole antifungal group (fluconazole, itraconazole, voriconazole, posaconazole and ravuconazole), all of which impair liver function to variable degrees.

Chronic liver damage, including cirrhosis and the greatly increased risk of hepatocellular carcinoma, is now a well-recognized late effect of blood transfusion owing to infection with the hepatitis C virus. Attempts to eradicate or reduce the viral load of these patients, using ribavarine and interferon, have met with limited success. As UK blood donors are routinely screened for this virus, the problem should become less prevalent in the future among multiply transfused patients.

The iron overload of multiple transfusion during therapy for acute leukaemias appears to cause clinical liver problems only in transplanted patients and can be reduced subsequently by venesection with or without iron chelation. In patients who are transfusion dependent due to marrow failure associated with chronic leukaemias, myelodysplasia or failure of therapy for any form of leukaemia the inconvenience and side-effects of iron chelation usually outweigh any potential benefit, especially when life expectancy is short.

Nutritional support

During intensive therapy, anorexia persists, even if nausea and vomiting and the pain of mucositis can be controlled. Loss of total body mass is inevitable, the extent of which depends on the duration of anorexia and the impact of additional catabolic insults such as severe infection. All dietary supplementation should be managed by dietitians and pharmacists in order to calculate accurately the contents of the supplements, on the basis of regular blood results. Oral supplementation may be sufficient to maintain an adequate caloric intake in less severe cases. For patients with a predictable or actual 10% or greater reduction in pre-treatment weight, total nutrition is indicated. This is likely in the majority of patients receiving allogeneic haemopoietic stem cell transplantation (HSCT). This can be given through a nasojejunal, fine, silastic tube, provided that this is inserted before the onset of mucositis, otherwise nutritional support must be given by indwelling intravenous catheter. As soon as patients recover the will to eat, all such dietary supplements can be cautiously withdrawn.

Nausea and vomiting

There is a high risk of severe and acute emesis with intensive chemotherapy. Every effort should be made to prevent this distressing complication and to avoid the development of anticipatory emesis should prophylaxis be ineffective. If control fails early then the chances of later successful control are reduced. It must be remembered that emesis may be due to other drugs (e.g. analgesics and antimicrobials), to acute infection and to other complications of leukaemia and its treatment such as meningeal relapse, intestinal obstruction (e.g. secondary to hypokalaemia and gut or retroperitoneal bleeding) or intracranial bleeding.

There are three major groups of antiemetic drugs, the serotonin antagonists (e.g. ondansetron and granisetron), the steroids (mainly dexamethasone) and a wide range of drugs that are sedative as well as antiemetic (e.g. metoclopramide, domperidone, haloperidol, lorazepam, cannabinoids and phenothiazines). Of these three classes, the serotonin antagonists will control emesis induced by intensive chemotherapy completely in about two-thirds of patients. Additional dexamethasone may benefit a further 10–20% of patients. All the sedating antiemetic agents are of second choice in intensive therapy. Their dosage, route of administration and scheduling should be strictly controlled and they should not be given on an uncontrolled or 'as required' basis. Cumulative oversedation is a major risk in these patients, particularly if they need simultaneous opiates for mucositis and antihistamines for allergic reactions to blood and drugs and develop hypoxia of infection or heart failure. Many of these drugs can also cause distressing dyskinesias.

For nausea due to less intensive oral therapy of CLL oral or hydoxyurea for CML metaclopramide may suffice and many patients do not need any antiemetic drug. There is a very low risk of nausea with imatinib.

Pain

Bone pain is an uncommon presenting feature of acute leukaemia, is due to an expanded marrow cavity packed with blasts and can occur or recur on relapse. Such pain is relieved by remission induction but may need temporary control with opiates. G-CSF and granulocyte–macrophage colony-stimulating factor (GM-CSF) can cause the same problem by expansion of normal marrow cells due to excessive stimulation.

Avascular necrosis of bone is seen in less than 5% of patients with ALL and lymphomas, particularly in association with high-dose steroids and cyclophosphamide. It usually affects younger patients, involves the ends of long bones and can cause permanent bone death requiring subsequent joint replacement. The diagnosis is elusive and requires magnetic resonance image (MRI) scanning. The pain is often severe enough to need relief with opiates. High-dose cytosine arabinoside can cause a painful vasculitis severe enough to lead to necrosis of soft tissue and skin. The neuropathy of the vinca alkaloids (usually vincristine but occasionally vinblastine) may present as limb pain or as painful constipation. The serotonin antagonists may cause headache in susceptible individuals and headache may also be due to intracranial bleeding or infection. Any bleed in any confined compartment will be painful, for example chest wall pain following haemorrhagic insertion of a CVC.

In SCT, the use of TBI and high-dose chemotherapy make gut mucositis inevitable. The extent, duration and severity vary but most patients will need some level of opiate relief. In most patients, this starts in the second week after therapy and resolves spontaneously without lasting sequelae from the third to fourth week onwards. As with all causes of pain, this requires whatever level of controlled drug analgesia is necessary to make the symptoms bearable without inducing brain or respiratory failure. Continuous i.v. infusion of an opiate is often required in severe mucositis and additional continuous anti-emetic may be needed in the same infusion. Palifermin (recombinant human keratinocyte growth factor) has been shown to reduce oral mucositis after intensive chemotherapy. All units should have a written protocol for pain control, which is similar to that used by the local palliative care team.

Palliation

The above account of supportive care of the patient with leukaemia describes an holistic approach. It is common for patients who have experienced this to wish to remain with the same haematology team for their terminal care when there is no further prospect of control of their underlying disease. There should be choices at this stage, which include the transfer of the patient to the palliative care team and joint management by them with haematology in whichever unit the patient and their family feel most suits the patient's needs. These choices should include dying at home, an option that requires some help from the acute care unit to mobilize the resources available in some communities to support this option. Most of the issues which arise in this palliative phase of care are described above. There can be much more flexibility in the frequency and choice of blood support, in pain control and in the use of antibiotics. Wherever palliative care is given, the patient and family should not feel abandoned by the team who supported them during previous periods of treatment.

Chronic myeloid leukaemia

37

John M Goldman and Tariq I Mughal

Introduction

Chronic myeloid leukaemia (CML) (also known as chronic myelogenous leukaemia, chronic granulocytic leukaemia) is a clonal disease that results from an acquired genetic change in a pluripotential haemopoietic stem cell. This altered stem cell proliferates and generates a population of differentiated cells that gradually displaces normal haemopoiesis and leads to a greatly expanded total myeloid mass. One important landmark in the study of CML was the discovery of the Philadelphia (Ph) chromosome in 1960; another was the characterization in the 1980s of the *BCR–ABL* chimeric gene and associated oncoprotein and a third was the demonstration that introducing the *BCR–ABL* gene into murine stem cells in experimental animals caused a disease simulating human CML.

Until the 1980s, CML was generally assumed to be incurable and was treated palliatively – in the early days with radiotherapy, and more recently with alkylating agents, notably busulphan. CML can be permanently eradicated in the majority of patients who survive after haemopoietic stem cell transplantation (SCT), but the proportion of patients eligible for SCT is still relatively small. The introduction into clinical practice of imatinib in 1998 was an important therapeutic advance, as with this agent most patients achieve a complete cytogenetic response and may expect prolongation of survival compared with other methods of treatment.

Classification

The majority of patients with CML have a relatively homogeneous disease characterized at diagnosis by splenomegaly, leucocy-

tosis and the presence of a Ph chromosome in all leukaemic cells. A minority of patients have a less typical disease that may be classified as atypical CML, chronic myelomonocytic leukaemia or chronic neutrophilic leukaemia. Children may have a disease referred to as juvenile chronic myelomonocytic leukaemia. In none of these variants is there a Ph chromosome.

Epidemiology, aetiology and natural history

The incidence of CML appears to be constant worldwide. It occurs in about 1.0–1.5 per 100 000 of the population per annum in all countries where statistics are adequate. CML is rare below the age of 20 years but occurs at all decades of life, with a median age of onset of 50–60 years. The incidence is slightly higher in males than in females.

The risk of developing CML is slightly but significantly increased by exposure to high doses of irradiation, as occurred in survivors of the atomic bombs exploded in Japan in 1945, and in patients irradiated for ankylosing spondylitis but, in general, almost all cases must be regarded as 'sporadic' and no predisposing factors are identifiable. In particular, there is no familial predisposition and no definite association with HLA genotypes has been recognized. No contributory infectious agent has been incriminated.

Clinically, CML is a biphasic or triphasic disease that is usually diagnosed in the initial 'chronic', 'indolent' or 'stable' phase and then spontaneously evolves after some years into an advanced phase, which can sometimes be subdivided into an earlier accelerated phase and a later acute or blastic phase. There has been much debate about the duration of disease before the diagnosis is established, a question that is essentially unanswerable. If it

is assumed that the disease starts with a 'transforming event' occurring in a single stem cell, it could be 5–10 years before the disease becomes clinically manifest. This estimate depends on the assumption that the leucocyte doubling time in the prediagnosis phase is not fundamentally different from the doubling time after diagnosis (which may not be the case), and the observation that the latent interval between exposure to irradiation from atomic bombs and the earliest identifiable increased incidence of CML was about 7 years. One study concluded that a routine blood count might have identified CML on average 6 months before it was actually diagnosed in individual patients.

Patients are usually in the 'chronic' phase when CML is diagnosed. This chronic phase lasts typically 2–7 years but it may, in rare cases, last more than 15 or even 20 years. Even more rarely, spontaneous remissions have been described. In about one-half of cases the chronic phase transforms unpredictably and abruptly to a more aggressive phase that used to be referred to as 'blastic crisis' and is now usually described as acute or blastic transformation. In the other half of cases, the disease evolves somewhat more gradually, through an intermediate phase described as 'accelerated' phase, which may last for months or years, before frank blastic transformation supervenes, which may have myeloblastic or lymphoblastic features. Occasional patients have a disease that progresses gradually to a myelofibrotic or osteomyelosclerotic picture that is characterized by extensive marrow fibrosis and sometimes gross overgrowth of bony trabeculae; the clinical problems are then usually due to failure of haemopoiesis rather than to blast cell proliferation, but a predominantly blastic disease can still supervene. The duration of survival after onset of transformation is usually 2–6 months.

Staging

Many attempts have been made to subclassify or 'stage' chronic-

Table 37.1 Sokal index for predicting survival.

Prognostic indices	
Good prognosis	< 0.8
Moderate prognosis	0.8–1.2
Poor prognosis	> 1.2

phase CML at diagnosis, in a manner that would permit some prediction of the duration of chronic phase in individual patients. The most commonly used classification, devised by Sokal and colleagues (1984), is based on a formula that takes account of the patient's age, blast cell count, spleen size and platelet count at diagnosis (Table 37.1). A similar classification, which may or may not prove more useful than that of Sokal, was introduced by Hasford (1999), called the Hasford or Euro score (Figure 37.1), which makes use of eosinophil and basophil numbers in addition to the values included in the Sokal system.

In practice, patients who have a low leucocyte doubling time probably survive longer than those with more rapid doubling times. Moreover, the patient's response to initial treatment does give some information about duration of survival; for example, a relatively low requirement for cytotoxic drugs to control the leucocyte count in the first year after diagnosis or a complete cytogenetic response to interferon α (IFN-α) are both good prognostic factors. Conversely, other possible adverse prognostic factors, such as the presence of deletions in the der9q$^+$ chromosome and a rapid rate of shortening of telomeres in the leukaemia cell population, may in the future be integrated into systems for
Figure 37.1 Probability of survival and median survival values for a population of CML patients classified into three prognostic categories according to the Euro score devised by Hasford *et al.* (1999).

staging patients with CML. It is likely, however, that the results of gene expression profiling will eventually be the most informative approach for predicting overall duration of disease.

Cytokinetics

It is presumed that the leukaemic stem cell replicates and that its progeny give rise to increased numbers of myeloid progenitor cells and also of differentiated progeny. Thus, the normal marrow is gradually replaced by a leukaemic myeloid mass that expands to fill normal fat spaces and encroaches on areas of long bones that are normally devoid of haemopoiesis in the adult. The increased myelopoiesis involves primarily the granulocyte series, but megakaryocyte and platelet numbers are also usually increased. Obvious erythroid hyperplasia and polycythaemia occur only rarely.

In the absence of a convincing assay for human haemopoietic stem cells, a number of efforts have been made to quantify *in vitro* its nearest counterpart, variously designated 'long-term culture-initiating cells', 'high-proliferative capacity progenitor cells' or 'blast colony-forming cells'. In general, the numbers of such cells seem to be moderately increased (e.g. 3- to 10-fold) in CML marrow compared with normal marrow, but results are inconsistent. In contrast, the numbers of committed progenitors, i.e. CFU-GEMM, BFU-E and CFU-GM, are clearly increased compared with normal, and this increase is proportionately much larger in the blood than in the marrow of untreated CML patients. BFU-E and CFU-GM numbers in the blood are significantly correlated with the leucocyte count; their numbers are restored to normal or subnormal levels by appropriate treatment.

Theoretically, an apparently autonomous proliferation of myeloid progenitors could be due to increased responsiveness to one or more physiological stimulators of haemopoiesis or to loss of sensitivity to a normal inhibitor. As a consequence of this, many efforts have been directed to assessing the response of CML progenitors to haemopoietic growth factors, notably granulocyte colony-stimulating factor (G-CSF), granulocyte–macrophage colony-stimulating factor (GM-CSF), interleukin 3 (IL-3), stem cell factor (SCF) and erythropoietin. There is some evidence that the autonomous proliferation could be due to an autocrine loop involving G-CSF and IL-3. It may also be due to increased production of elastase by the leukaemia cells that inhibit the response of normal but not leukaemia cells to G-CSF.

CML progenitors in *in vitro* culture systems adhere less well to preformed marrow stromal layers than their normal counterparts. This may be due to an abnormality of an integrin or absence of a glycophosphatidyl inositol-anchored protein that has not yet been defined. Thus, it is possible that the excessive proliferation of CML progenitors is due in part to their premature escape from physiological inhibitory influences in the stem cell 'niche'.

Cytogenetics

The Philadelphia (originally designated Ph[1], now der22q⁻ or Ph) chromosome (see Chapter 29) is an acquired cytogenetic abnormality that characterizes all leukaemic cells in CML. It is formed as a result of a reciprocal translocation of chromosomal material between the long arms of one chromosome 22 and one chromosome 9, an event referred to as t(9;22)(q34;q11) (Figure 37.2). The (9;22) translocation generates the *BCR–ABL* fusion gene on the Ph chromosome (see below) and also a 'reciprocal' fusion gene, designated *ABL–BCR*, on the derivative 9q⁺ chromosome. Such translocations involving just two chromosomes are described as 'simple', whereas about 10% of patients have 'complex' translocations involving chromosomes 9, 22 and one or sometimes two other chromosomes.

In CML patients, the Ph chromosome is present in all myeloid cell lineages, in some B cells and in a very small proportion of T cells. It is found in no other cells of the body. This distribution is not altered by traditional treatment with busulphan or hydroxyurea. Although valuable since the 1960s as a marker of the leukaemic cell, its true pathogenetic significance remained uncertain until the identification of the *BCR–ABL* chimeric gene in the 1980s. About 15% of patients have small deletions of chromosomal material on der9q⁺, which usually include the reciprocal *ABL–BCR* gene. Such deletions are thought to occur contemporaneously with the formation of the *BCR–ABL* gene on the Ph chromosome and denote a relatively poor overall prognosis. A small proportion of patients with clinically classical CML lack the Ph chromosome; however, some of these also have a typical *BCR–ABL* gene expressed as a p210 oncoprotein (see below).

Some, but not all, patients acquire additional clonal cytogenetic abnormalities during the course of the chronic phase. There was suspicion that some such changes might be caused in part by administration of alkylating agents, but they can undoubtedly occur spontaneously. The observation of non-random changes, typically +8, +Ph, iso-17q or +19, sometimes means that such new clones will expand and that blastic transformation will manifest itself within weeks or months, but these new clones (other than iso-17q) can remain clinically unimportant for many years. In overt blastic transformation, 80% of patients have clonal cytogenetic changes in addition to the Ph translocation.

Molecular biology

It was shown in the early 1980s that the *ABL* proto-oncogene, which encodes a non-receptor tyrosine kinase, was located normally on chromosome 9 but was translocated to chromosome 22 in CML patients. In 1984 the precise positions of the genomic breakpoint on chromosome 22 in different CML patients were found to be 'clustered' in a relatively small 5.8-kb region to
Figure 37.2 The t(9;22) translocation and its products: the *BCR–ABL* oncogene on the Ph chromosome and the reciprocal *ABL–BCR* on the derivative 9q+ chromosome. In classic CML, *BCR–ABL* is transcribed into mRNA molecules with e13a2 or e14a2 junctions, which are then translated into the p210^BCR–ABL oncoprotein. This oncoprotein is a hybrid containing functional domains from the N-terminal end of BCR [dimerization domain (DD)], SRC-homology 2 (SH2)-binding and the Rho GTP–GDP exchange-factor (GEF) domains and the C-terminal end of ABL. [Only SRC-homology regions 2, 3 and 1 (SH2, SH3 and SH1 respectively) and the DNA- and actin-binding domains are shown.] Tyrosine 177 (Y177) in the *BCR* portion of the fusion gene and tyrosine 412 (Y412) in the ABL portion are important for the docking of adapter proteins and for BCR–ABL autophosphorylation respectively. P-S/T denotes phosphoserine and phosphothreonine.

which the name 'breakpoint cluster region' (BCR) was given. Later, it became clear that this region formed the central part of a relatively large gene now known as the *BCR* gene, whose normal function is not well defined, and the breakpoint region was renamed '*major* breakpoint cluster region' (M-BCR). In contrast, the position of the genomic breakpoint in the *ABL* gene is very variable, but it always occurs upstream of the second (common) exon (a2). Thus, the Ph translocation results in juxtaposition of 5′-sequences from the *BCR* gene with 3′-ABL sequences derived from chromosome 9 (Figure 37.3). It produces a chimeric gene, designated *BCR–ABL* that is transcribed as an 8.5-kb mRNA and encodes a protein with a molecular weight of 210 kDa. This p210^BCR–ABL oncoprotein has far greater tyrosine kinase activity than the normal *ABL* gene product.

In CML, there are two variants of the BCR–ABL transcript, depending upon whether the break in M-BCR occurs in the intron between exons e13 and e14, or in the intron between exons e14 and e15. A break in the former intron yields an e13a2 mRNA junction and a break in the latter intron yields an e14a2 junction. (It should be noted that exon e13 was previously termed exon b2 and exon e14 was previously b3; thus the two RNA junctions were known until recently as b2a2 and b3a2 respectively.) Most patients have transcripts with features of either e13a2 or e14a2, but occasional patients have both transcripts present in their leukaemia cells. The precise type of *BCR–ABL* transcript has no prognostic significance for CML

patients. Moreover, the reciprocal *ABL–BCR* gene on der9q+ is expressed in about 70% of patients, but its expression or lack of expression does not have prognostic significance.

A minority of patients with Ph-positive acute lymphoblastic leukaemia (ALL), more often adults than children, also have *BCR–ABL* fusion genes in their leukaemia cells (see Chapters 29 and 31). In about one-third of Ph-positive ALL patients, the molecular features of the *BCR–ABL* gene are indistinguishable from those of CML; in the remaining two-thirds the genomic breakpoint occurs in the first intron of the *BCR* gene (a zone designated 'minor breakpoint cluster region' or m-BCR) and the *BCR–ABL* gene results from fusion of the first exon (designated e1) of the *BCR* gene with the second exon (a2) of the *ABL* gene. The mRNA is designated e1a2 and encodes a protein of 190 kDa (p190^BCR–ABL). Very rare patients with CML have a p190 protein instead of the usual p210. Equally rare is the finding of a Ph chromosome in association with chronic neutrophilic leukaemia. Such patients may have an mRNA formed from an e19a2 fusion gene associated with a p230^BCR–ABL oncoprotein.

The *BCR–ABL* gene has been cloned and inserted into a retroviral vector that has been used to transfect murine haemopoietic stem cells; these transduced stem cells can generate a disease resembling human CML in mice. Thus, the *BCR–ABL* gene is thought to play a pivotal role in the genesis of chronic-phase CML.

The mechanism by which the BCR–ABL oncoprotein alters stem cell kinetics remains ill-defined. It undoubtedly aberrantly
Figure 37.3 The structure of the normal *BCR* and *ABL* genes and the fusion transcripts found in CML and Ph-positive ALL. The ABL gene contains two alternative 5'-exons (named Ib and Ia) followed by 10 'common' exons numbered a2 to a11 (orange boxes). Breakpoints in CML and Ph-positive ALL usually occur in the introns between exons Ib and Ia or between exons Ia and a2 (as shown by vertical arrows). The *BCR* gene comprises a total of 23 exons, 11 exons upstream of the M-BCR region, five exons in the M-BCR that were originally termed b1 to b5 and are now renamed e12 to e16, and seven exons downstream of M-BCR.

For convenience, only exons e1, e12 to e16 and e23 are shown. Breakpoints in CML usually occur between exons e13 (b2) and e14 (b3) or between exons e14 (b3) and e15 (b4) of the M-BCR (as shown by two vertical arrows placed centrally). The majority of patients with Ph-positive ALL have breakpoints in the first intron of the gene (between e1 and e2 (not shown), arrow at left). Three possible BCR–ABL mRNA transcripts are shown below. The first two (e13a2 and e14a2 respectively) are characteristic of CML. The bottom mRNA (e1a2) is found in the majority of patients with Ph-positive ALL (see text).

autophosphorylates and also phosphorylates a wide range of intracellular proteins that would not normally be phosphorylated, Crkl, Mek 1/2, Rac and Jnk. It may act by activating the RAS or STAT signal transduction pathways. Alternatively, it may activate the p13 kinase–AKT pathway involved in facilitating apoptosis (Figure 37.4). As an activated ABL opposes cellular apoptosis, the *BCR–ABL* gene might act by impeding 'programmed cell death' in target stem cells.

The molecular basis of disease progression is still obscure, but it seems reasonable to infer that one or more probably a sequence of additional genetic events occurs in the Ph-positive clone. When the critical combination of additional events is achieved, clinically definable transformation ensues. At this stage, the leukaemia cells usually harbour one or other of the additional cytogenetic changes referred to above. About 20% of patients with CML in myeloid transformation have point mutations or deletions in the coding sequence of the *p53* tumour-suppressor gene, a gene implicated in progression of a variety of solid tumours, notably colonic carcinoma. The retinoblastoma (*RB*) gene is deleted in rare cases of CML in megakaryoblastic transformation, and changes in the *LYN*, *EVI-1* and *MYC* genes are described. About one-half of the patients with lymphoid

blast transformations have homozygous deletions in the p16 gene, whose normal function is to inhibit cyclin-dependent kinase 4. Molecular changes underlying the non-random cytogenetic changes described above have not been identified.

Clinical features

In the past, the majority of patients presented with symptoms, usually attributable to splenomegaly, haemorrhage or anaemia. In recent years, CML has been diagnosed in almost 50% of patients before the onset of symptoms as a result of 'routine' blood tests performed as part of medical examinations in healthy persons, for pregnancy, before blood donation or in the course of investigation for unrelated disorders. When present, symptoms may include lethargy, loss of energy, shortness of breath on exertion or weight loss or haemorrhage from various sites. Increased sweating is characteristic. Spontaneous bruising or unexplained bleeding from gums, intestinal or urinary tract are relatively common. Visual disturbances may occur. Fever and lymphadenopathy are rare in chronic phase. The patient may have severe pain or discomfort in the splenic area, often
Figure 37.4 Signal transduction pathways affected by BCR–ABL. The cellular effects of BCR–ABL are exerted through interactions with various proteins that transduce the oncogenic signals responsible for the activation or repression of gene transcription, of mitochondrial processing of apoptotic responses, of cytoskeletal organization and of the degradation of inhibitory proteins. The key pathways implicated so far are those involving RAS, mitogen-activated protein (MAP) kinases, signal transducers and activators of transcription (STAT), phosphatidylinositol 3-kinase (PI 3-K) and MYC. Most of the interactions are mediated through tyrosine phosphorylation and require the binding of BCR–ABL to adapter proteins such as growth factor receptor-bound protein 2 (GRB-2), DOK, CRK, CRK-like protein (CRKL), SRC homology-containing protein (SHC) and casitas B-lineage lymphoma protein (CBL). As we start to dissect these various interactions, we can now design drugs aimed at disrupting specific branches of these pathways in an attempt either to kill the CML cell or to cause its phenotype to revert to normal. It is obvious that the best target is BCR–ABL proper, as this is the only protein that is exclusive to the leukaemic clone. The second-best approach is to target key downstream effectors of BCR–ABL; however, this approach might, in principle, adversely affect normal haemopoiesis as well. P denotes phosphate.

Haematology

Chronic phase

Patients with splenomegaly are usually anaemic, while the haemoglobin concentration may be normal in patients with 'early' disease. The leucocyte count at diagnosis is usually in the range of $20-200 \times 10^9$/L, but the diagnosis of CML can be established by appropriate investigations in patients with persistent leucocytosis in the range $10-20 \times 10^9$/L; at the other extreme occasional patients may present with leucocyte numbers in the range $200-800 \times 10^9$/L. The blood film shows a full spectrum of cells in the granulocyte series, ranging from blast forms to mature neutrophils, with intermediate myelocytes and neutrophils predominating (Figure 37.5). The percentage of blast cells is loosely related to the absolute number of leucocytes, but a value higher than 12% suggests that the patient may already be in acceleration or transformation. The percentages of eosinophils and basophils are usually increased, and the absence of basophilia casts doubt on the diagnosis. Absolute numbers of lymphocytes and monocytes are slightly increased, but both are

associated with splenic infarction, or may have noticed a lump or mass in the right upper abdomen. Visual disturbances may be due to retinal haemorrhages. Sudden hearing loss occurs very rarely. Patients may present with features of gout or priapism in males, both of which are also rare.

At diagnosis, 50–70% of patients have splenomegaly. The spleen varies from just palpable to being so large that it occupies all the left side of the abdomen and is palpable also in the right iliac fossa. The liver is frequently also enlarged but with a soft edge that is difficult to define. There may be no other abnormal findings. Ecchymoses of varying sizes and ages may be present and may form discoloured subcutaneous lumps. Some patients have asymptomatic retinal haemorrhages. Patients with very high leucocyte counts may have features of leucostasis, with retinal vein engorgement and respiratory insufficiency.

Patients presenting with more advanced disease nearly always have some of the features described above. In addition, they may have bone tenderness or signs of infection. In established blastic transformation, the spleen is frequently enlarged and may be painful. The liver may become very large. Patients may develop fever, lymphadenopathy or very rarely lytic lesions of bone.

Figure 37.5 Peripheral blood appearances of a patient with CML at diagnosis. Note increased numbers of leucocytes including immature granulocytes and occasional blast cells.

reduced as percentages in the differential count. Platelet numbers are usually increased in the range of $300-600 \times 10^9$/L but may be normal or even reduced. Occasional nucleated red cells are present in the circulation in some patients. The alkaline phosphatase content of the neutrophil cytoplasm is diminished or absent. BCR–ABL transcripts can be demonstrated in the blood with ease, using the reverse transcription polymerase chain reaction (RT-PCR). In a minority of patients, the leucocyte count, if left untreated, shows a cyclical variation, but the overall trend is upwards.

Examination of the bone marrow by aspiration or trephine biopsy is not necessary to confirm the diagnosis of CML, but is usually carried out to assess the degree of marrow fibrosis, to perform cytogenetic analysis and to exclude incipient transformation. The marrow aspirate may show multiple small hypercellular fragments or may be so hypercellular that fragments cannot easily be discerned. The trails show a cellular composition resembling that of the CML blood. Blast cells in chronic phase number from 2% to 10%. Eosinophils and basophils are usually prominent; megakaryocytes are small, hypolobated and very numerous. Occasionally, Gaucher-like cells are present. The marrow biopsy shows complete loss of fat spaces with dense hypercellularity. The reticulin content may be normal or modestly increased.

Advanced phases

The haematological picture in acceleration is very variable. It may differ little from chronic phase but blast cell numbers may be increased disproportionately (Table 37.2). There may be anaemia in the presence of a normal leucocyte count. Platelet numbers may be greatly increased ($> 1000 \times 10^9$/L) or reduced (below 100×10^9/L) in a manner not accounted for by treatment. The marrow also shows a picture no longer consistent with chronic-phase disease, often with increased numbers of blast cells or promyelocytes and/or increased fibrosis.

Blastic transformation is defined by the presence of more than 30% blasts or blasts plus promyelocytes in the blood or marrow. Frequently, this criterion is irrelevant because blast cell numbers

Table 37.2 Criteria to distinguish the chronic, accelerated and blastic phases of CML based on proposals published by the World Health Organization (2001).

Chronic phase
Ability to reduce spleen size and restore and maintain a 'normal' blood count with appropriate therapy

Accelerated phase
(defined by one or more of the following features)
– Blasts 10–19% of white blood cells in peripheral blood and/or of nucleated bone marrow cells
– Peripheral blood basophils ≥ 20%
– Persistent thrombocytopenia ($< 100 \times 10^9$/L) unrelated to therapy, or persistent thrombocytosis ($> 1000 \times 10^9$/L) unresponsive to therapy
– Increasing spleen size and increasing white blood cell count unresponsive to therapy
– Megakaryocyte proliferation in sheets or clusters in association with marked reticulin or collagen fibrosis

Blastic phase
(defined by one or more of the following features)
– Blasts > 20% of peripheral blood leucocytes or of nucleated bone marrow cells
– Extramedullary blast proliferation
– Large foci or clusters of blasts in the bone marrow biopsy

Note: In this classification, unlike some other classifications, the acquisition of new cytogenetic abnormalities in addition to the Ph chromosome is not by itself a criterion for 'promoting' a chronic phase patient to accelerated phase.

Figure 37.6 Peripheral blood appearances of a patient with CML in lymphoid blast cell transformation.

in both sites have risen abruptly to exceed 80%. Their morphology is very variable. About 70% of patients have blasts classifiable generally as myeloid, which resemble to a degree the cells that characterize acute myeloid leukaemia (AML) (see Chapter 29). Such cells may be predominantly myeloblastic, monoblastic, erythroblastic or megakaryoblastic, and blast cells of different myeloid lineages frequently co-exist. These cells are best defined by their cytochemical and immunophenotypic characteristics though they do not usually fit neatly into the FAB classification for AML. About 20% of patients have lymphoid blast cells; these may resemble the FAB-L1 cells that typify childhood acute lymphoblastic leukaemia (ALL) or, more commonly, have L2 appearances (Figure 37.6). Immunophenotyping shows the typical membrane markers of a precursor B-cell ALL, namely CD10 (CALLA) and CD19 positivity, and further studies may show nuclear positivity for terminal deoxynucleotidyl transferase (TdT). Molecular studies show clonal rearrangement of immunoglobulin (Ig) chains and occasionally of TCR genes. The remaining 10% of blast cell transformations have mixed myeloid and lymphoid characteristics.

The clinical features associated with advanced disease are quite variable. In some cases, the patient is initially entirely asymptomatic and the diagnosis is based entirely on blood and marrow findings. In other cases, the patient may develop fevers, excessive sweating, anorexia and weight loss or bone pain. Rarely, there are localized lytic lesions of bone, which may be single or multiple. Occasionally, patients present with generalized lymphadenopathy; biopsy shows nodal infiltration with blast cells that may be myeloid or lymphoid. Localized skin infiltrates may be seen. Discrete masses of immature leukaemia cells may develop at almost any site; these are sometimes referred to as 'chloromas' or 'granulocytic sarcomas'. Patients with lymphoid blast cells in the blood and marrow may have involvement of the cerebrospinal fluid at the same time, or central nervous system (CNS) involvement may become symptomatic only at a later stage.

Biochemical changes

The biochemical changes seen in CML are non-specific. Patients diagnosed in chronic phase may have a slightly raised serum uric acid but the level is frequently normal. The serum alkaline phosphatase is usually normal or slightly raised. The lactate dehydrogenase (LDH) is usually raised. Serum K^+ may be spuriously raised due to leakage of intracellular potassium from platelets or, less commonly, from leucocytes after the blood is drawn. In such cases, the K^+ level in freshly drawn citrated blood is usually normal, as is the electrocardiogram. The serum vitamin B_{12} and B_{12} binding capacity are greatly increased due to raised levels of transcobalamin I.

In transformation, the serum uric acid may be raised, sometimes substantially, and tests of liver function are usually moderately abnormal. Hypercalcaemia is present occasionally and is usually due to bone destruction; very rarely, it may be attributable to a parathormone-like material ectopically produced by the blast cells.

Management of chronic myeloid leukaemia in chronic phase

The management of the newly diagnosed CML patients has changed very greatly in the last few years. In the 1970s, it was conventional for the physician to start treatment soon after diagnosis with busulphan and then to await further developments. The patient received little information about prognosis. Today, in most, but not all, countries, the patient is informed of the diagnosis and given as much information as possible about the disease and its prognosis. The various options for treatment are usually discussed at this stage, which, for the younger patient, include the possible need for allogeneic SCT at some stage in the disease. This means that the patient, all siblings and other family members should be HLA typed. The issue of gonadal function is important and men who have not completed their families should be offered semen cryopreservation before any treatment is started.

There is no urgency to start treatment immediately in asymptomatic patients with leucocyte counts below 100×10^9/L. This means that leucapheresis with cryopreservation of blood stem cells can be performed before anti-leukaemia treatment is instituted. Such stored cells may be used for autografting at a later date. However, drug treatment should ideally be started soon after the diagnosis is confirmed. The best single agent at present for patients in chronic phase not destined for allogeneic SCT is imatinib, but a number of combinations of imatinib with other agents are being tested. Hydroxyurea is a reasonable alternative in the short term if imatinib is not immediately available. IFN-α, until recently the treatment of choice, and busulphan should both be reserved for special indications.

Imatinib mesylate

Imatinib mesylate (Glivec or Gleevec; previously known as STI571 or CGP 57148B), a 2-phenylaminopyrimidine compound, is an ABL tyrosine kinase inhibitor that entered clinical trials in 1998. It was thought originally to act by occupying the ATP-binding pocket of the Abl kinase component of the BCR–ABL oncoprotein, and thereby blocking the capacity of the enzyme to phosphorylate downstream effector molecules; it is now thought to act by binding to an adjacent domain in a manner than holds the Abl component of the BCR–ABL oncoprotein molecule in an inactive configuration (Figure 37.7). The drug rapidly reverses the clinical and haematological abnormalities and induces major cytogenetic responses in over 80% of previously untreated chronic phase patients. It is usually administered orally at a dose of 400 mg per day, although pilot studies suggest that initial treatment with 600 mg or even 800 mg daily may give better results.

Side-effects include nausea, headache, rashes, infraorbital oedema, bone pains and, sometimes, more generalized fluid retention. The rashes can from time to time be treated by temporarily interrupting imatinib and then re-instituting it under short-term corticosteroid cover. Hepatotoxicity characterized by raised serum transaminases is occasionally seen and may necessitate stopping the drug. Some caution must be also exercised in

the light of a recent report of potentially fatal cerebral oedema. An interesting non-sinister effect, hair repigmentation, has been reported in a small group of responders. The toxicity in general seems to be appreciably less than that associated with IFN-α.

A significant minority of patients experience neutropenia and/or thrombocytopenia within the first few months of starting treatment with imatinib at standard dosage (i.e. 400 mg per day). In some cases, isolated neutropenia may be managed simply by adding G-CSF (e.g. 300–480 μg subcutaneously on alternate days or less often) for a finite period, after which it may be possible to reduce or stop the drug. In other cases, G-CSF works less well and it may be necessary to reduce or stop imatinib. If thrombocytopenia develops, it may be necessary to reduce the dose, although some believe that the drug is relatively ineffective at daily doses below 300 mg. Conversely, thrombocytosis sometimes persists in a patient whose leucocyte count is well controlled by imatinib; in such cases, the addition of hydroxyurea or anagrelide usually controls the platelet count.

The issue of how long to continue imatinib remains unresolved. For the patient who has achieved a complete cytogenetic remission, available evidence suggests that stopping the drug leads to recurrence of Ph positivity and eventually leucocytosis in the majority of cases, although on occasion the cytogenetic remission continues without treatment for many months or even longer. At present, the best advice for the responding patient is to continue the drug indefinitely. Conversely, for the patient who has failed to achieve a major cytogenetic response (> 66% Ph negativity in the bone marrow) after 1 year of treatment, the case for continuing treatment with imatinib is weak and alternative approaches should be considered.

Even in patients who achieve complete cytogenetic remission, low numbers of BCR–ABL transcripts can usually be detected by RT-PCR, which means that one cannot conclude that imatinib as a single agent eradicates all evidence of CML. A prospective randomized phase III trial designed to compare imatinib as a single agent with the combination of IFN-α with cytarabine in previously untreated patients started in June 2000. The interim results showed that 74% of the patients treated with imatinib achieved a complete cytogenetic remission compared with 14% of those in the control arm. Progression-free survival was significantly better in the imatinib-treated cohort than in the IFN-α and cytarabine group (97.2% versus 90.3%; $P < 0.001$). It is still too early to ascertain whether patients treated with imatinib have superior overall survival but the impressive numbers of complete cytogenetic responses and low levels of residual BCR–ABL transcripts achievable in many patients mean that this agent is now the treatment of choice for all or almost all newly diagnosed patients.

Response to imatinib is best monitored by regular cytogenetic studies or bone marrow analysis, supported, if necessary, by fluorescence *in situ* hybridization studies for the *BCR–ABL* gene for patients not yet in complete cytogenetic remission. For patients who have achieved cytogenetic remission, a quantitative

Figure 37.7 The presumed mechanism of action of imatinib. The phosphorylation of a substrate is shown schematically in (a). ATP occupies the pocket in the ABL component of the BCR–ABL oncoprotein, whence it donates a phosphate (P) group to a tyrosine (Y) residue on an unspecified substrate. The substrate then detaches itself from the BCR–ABL oncoprotein and makes functional contact with a further downstream effector molecule. In (b) imatinib occupies the ATP binding site and thereby prevents phosphorylation of the substrate. This molecule in turn fails to make contact with the effector protein and the signal transduction pathway that would otherwise transmit the 'leukaemia signal' is interrupted.

RT-PCR for BCR–ABL transcripts is the only approach that can assess the degree of response and recognize incipient relapse, which may indicate the need for a revised therapeutic strategy, including in some cases allogeneic SCT.

The acquisition of resistance to imatinib appears to be rare in patients with CML in chronic phase within the first 2 years of diagnosis. It is more common in patients who start imatinib in 'late chronic phase' after prior treatment with other agents. Resistance to imatinib has been seen in up to 70% of those treated in myeloid blast crisis, and all of those in lymphoid blast crisis relapse within 6 months of their initial response. Resistance appears to result from a variety of diverse mechanisms, including the 'acquisition' of point mutations in the ABL kinase domain, overexpression of the BCR–ABL oncoprotein and overexpression of P-glycoprotein, which accelerates exit of the drug from individual cells. Thus far at least 20 point mutations have been identified in leukaemia cells obtained from patients with variable degrees of resistance to imatinib. They each code for different amino acid substitutions in the Abl kinase component of the BCR–ABL oncoprotein. Cells with one such substitution, the replacement of a threonine by an isoleucine at position 315 (referred to as the T315I mutation), seem to be especially resistant to the inhibitory action of imatinib. Cells with other substitutions are relatively less resistant. Recent evidence suggests that the finding of amino acid substitutions in one particular part of the Abl kinase domain, the phosphate-binding loop (the so-called P-loop), may predict for disease progression and thus relatively poor survival. It is probable that these subclones pre-exist the administration of imatinib but are allowed to expand when the wild-type molecule is inhibited by imatinib.

Hydroxyurea

Hydroxyurea is a ribonucleotide reductase inhibitor that targets relatively mature myeloid progenitors in proliferative cycle. Its pharmacological action is rapid and readily reversible. Treatment for patients in chronic phase is usually started with 1.0–2.0 g daily by mouth and continued indefinitely. The leucocyte count starts to fall within days and the spleen reduces in size. It is usually possible to reverse all features of CML within 4–8 weeks of starting treatment with hydroxyurea. The dosage can then be titrated against the leucocyte count, the usual maintenance dose being between 1.0 and 1.5 g daily. In a patient whose leucocyte count is controlled, any reduction in the dose leads to a rapid increase in the leucocyte numbers, a phenomenon that disturbs the patient but has no ominous significance. The drug has relatively few side-effects. At high dosage it may cause nausea, diarrhoea or other gastrointestinal disturbance. Some patients get ulcers of the buccal mucosa. Skin rashes are seen. Most patients develop megaloblastic changes in the marrow with macrocytosis in the blood. The drug remains useful today for rapid cytoreduction in the newly diagnosed patient and may also be useful in patients unable to tolerate imatinib.

Interferon-α

Interferon-α is a member of a large family of glycoproteins of biological origin with antiviral and antiproliferative properties. Studies in the early 1980s using material purified from human cell lines showed that it was active in reducing the leucocyte count and reversing all features of CML in 70–80% of CML patients. Of particular interest at the time was the observation that 5–15% of patients achieved major reduction in the percentage of Ph-positive marrow metaphases with restoration of Ph-negative (putatively normal) haemopoiesis. It raised the important question of whether these 'cytogenetic responders' would have their life prolonged by treatment with IFN-α, and prospectively randomized controlled studies were initiated. Compared with hydroxyurea, IFN-α offered a survival advantage that was maximal for those who achieved complete cytogenetic remissions. These observations meant that IFN-α replaced hydroxyurea and busulphan in the 1980s as primary treatment for CML in chronic phase, and remained so until the introduction of imatinib.

Interferon-α must be administered by subcutaneous injection at daily doses ranging from 3 to 5 megaunits per/m^2. There is no good evidence that the higher doses are clinically superior. Toxicity is common in older patients, but is generally mild and reversible. Almost all patients experience fevers, shivers, muscle aches and general 'flu-like' features on starting the drug; these last usually 2–3 weeks but may be alleviated by paracetamol. They recur when dosage is increased. A significant minority of patients cannot tolerate the drug on account of lethargy, malaise, anorexia, weight loss, depression and other affective disorders or alopecia. Autoimmune syndromes, such as thyrotoxicosis, may also occur. A long-acting form of IFN-α, pegylated IFN-α, has been introduced recently, but, other than ease of administration, it seems to have little advantage over conventional formulations.

Busulphan

Busulphan (1,4-dimethanesulphonyloxybutane) is a polyfunctional alkylating agent that is now infrequently used (except as conditioning before transplant procedures). It targets a relatively primitive stem cell and the effects of administration are prolonged for some weeks after stopping the drug. It was the mainstay of treatment for CML in the period 1960–80. Treatment was conventionally started with 8 mg daily by mouth and the dosage was reduced as the leucocyte count began to fall. It was essential to reduce the dosage substantially or to stop the drug before the leucocyte count fell below 20×10^9/L because profound and prolonged leucopenia might otherwise be produced.

Busulphan could be administered either in finite courses lasting up to 4 weeks or continuously at a maintenance dose between 0.5 and 2.0 mg per day. Occasional patients were 'hypersensitive' to the effects of busulphan and developed severe,

sometimes irreversible, pancytopenia with marrow hypoplasia on standard dosage. Overdosage could achieve the same effect in any patient. Gonadal failure (as mentioned above) invariably occurred within a few months of starting treatment and was almost always irreversible. Other toxic effects included cutaneous pigmentation, pulmonary fibrosis and a wasting syndrome resembling hypoadrenalism. These points notwithstanding, the drug may be useful in older patients whose compliance is uncertain as it can also be given orally in the clinic as a single dose of 50 or 100 mg, to be repeated as necessary after 4 weeks or longer.

Homoharringtonine

Another drug of interest for CML in chronic phase is homo-harringtonine, a semisynthetic plant alkaloid that enhances apoptosis of CML cells. It produces haematological responses in 60–70% of patients and major cytogenetic responses in 25% in small series of patients in chronic phase. The results appear to improve with the addition of IFN-α. For the moment, it remains an investigational agent.

Allogeneic stem cell transplantation

Younger patients with HLA-identical sibling donors may be offered the option of treatment by allogeneic SCT (see Chapter 24). Most specialist centres exclude from consideration patients who are over the age of 50 or 55 years. The major factors influencing survival are patient age, disease phase at time of SCT, disease duration, degree of histocompatibility between donor and recipient, and gender of donor. In general, patients are 'conditioned' for transplant with cyclophosphamide at high dosage followed by total body irradiation, or with the combination of busulphan and cyclophosphamide at high dosage. If all goes well, reasonable marrow function is achieved in 3–4 weeks

after the infusion of donor haemopoietic stem cells and the patient leaves the hospital.

The possible major complications include graft-versus-host disease, reactivation of infection with cytomegalovirus or other viruses, idiopathic pneumonitis and veno-occlusive disease of the liver. For patients with CML treated by SCT with marrow from HLA-identical siblings, the overall leukaemia-free survival at 5 years is now 60–80% (Figure 37.8). There is a roughly 20% chance of transplant-related mortality and a 15% chance of relapse. Patients surviving without haematological evidence of disease can be monitored by serial cytogenetic studies and by use of the much more sensitive RT-PCR, which can detect very low numbers of BCR–ABL transcripts in the blood or marrow. These studies suggest (but do not prove) that in the majority of long-term survivors the CML may truly have been eradicated.

The recognition that the graft-versus-leukaemia (GvL) effect plays a major role in eradicating CML after allografting led to the concept that the toxicity of the transplant procedure could be substantially reduced by decreasing the intensity of the pretransplant conditioning. The strategy is thus to focus predominantly on the use of immunosuppressive rather than myeloablative agents, to maximize the numbers of haemopoietic stem cells transfused and to exploit the GvL effect mediated by donor alloreactive immunocompetent cells to eliminate the leukaemia cells. Such procedures have been termed variously non-myeloablative SCTs (NSCTs), reduced-intensity conditioning SCTs or mini-SCTs, and reflect advances in our understanding of how SCT actually works (see Chapter 24). It is still too early to say whether such NSCTs will prove superior to conventional transplants in the longer term, but the technique could make SCT more widely available to higher risk and perhaps also to older patients.

The qualified success of conventional SCTs using matched siblings led in the late 1980s to increasing use of 'matched' unrelated donors for SCT for patients with CML. At present,

Figure 37.8 Probability of survival for patients with CML in chronic phase who received allogeneic stem cell transplants from HLA-identical sibling or matched unrelated donors according to whether or not the transplant was performed within 1 year of diagnosis. Data reproduced from the International Bone Marrow Transplant Registry (Milwaukee, WI, USA) with permission.
serologically matched unrelated donors can be identified for about 50% of white patients and for lower percentages of patients of other ethnic origins. However, molecular methods for typing HLA class I and II have now largely superseded serological techniques, and complete matches for a given patient for five gene pairs, HLA-A, -B, -C, -DR and -DQ, are relatively rare. Thus, in the absence of a 'perfect match' the clinician has to decide what degree of mismatch may be acceptable for a given transplant. In general, the results of transplants using such unrelated donors are less good at present than results of using HLA-identical siblings, but some patients will probably prove to be cured.

About 10–30% of patients submitted to allogeneic SCT relapse within the first 3 years post transplant. The relapse in usually insidious and characterized first by rising levels of BCR–ABL transcripts, then by increasing number of Ph-positive marrow metaphases and, finally (if untreated), by haematological features of chronic-phase disease. This provides some rationale for the recommendation that patients should be monitored post-transplant by regular RT-PCR and cytogenetic studies. Rare patients in cytogenetic remission relapse directly to advanced-phase disease without any identified intervening period of chronic-phase disease.

There are various options for the management of relapse to chronic-phase disease, including use of IFN-α, hydroxyurea, imatinib, a second transplant using the same or another donor or lymphocyte transfusions from the original donor. Such donor lymphocyte transfusions (donor lymphocyte infusion, DLI) have gained popularity in recent years, and are believed to reflect the capacity of lymphoid cells collected from the original transplant donor to mediate a 'GvL' effect, even although they may have failed to eradicate the leukaemia at the time of the original transplant. In practice, mononuclear cells are collected from the transplant donor in one or two leucapheresis procedures and transfused to the patient (who receives no other conditioning and usually no prophylaxis for GvHD). Within 3–6 months the leukaemia is restored to complete cytogenetic remission in about 80% of CML patients treated in this way and these responders also achieve PCR negativity. Some responding patients sustain marrow aplasia, which can be reversed by transfusion of marrow cells from the donor. However, severe GvHD may occur and can, on rare occasions, prove lethal. However, the incidence and severity of GvHD can be greatly reduced by starting the lymphocyte transfusions at relatively low cell dose and repeating the transfusion with a higher cell dose at intervals of 4–12 weeks as required, a technique usually referred to as 'escalating-dose' DLI.

At present, opinions are evenly divided on the optimal management of the patient who relapses with increasing BCR–ABL transcript numbers or increasing Ph positivity after allogeneic SCT. Some feel that escalating-dose DLI is the best approach, whereas others prefer to resume treatment with imatinib. It may be possible to resolve this issue with a suitably designed prospective study.

Treatment decisions for newly diagnosed patients in chronic phase

The success of imatinib has made it extremely difficult to decide how best to treat the newly diagnosed patient, especially a patient for whom a suitable donor for allogeneic SCT is available and who would routinely have been advised to proceed to transplant in the 'pre-imatinib era'. The problem is due quite simply to two facts: first, although a successful transplant can cure CML, the outcome for an individual patient cannot reliably be predicted and, second, though the short-term results of treating patients with imatinib look excellent, the extent to which this agent will in general prolong life is not yet clear. Moreover, it is likely that results of transplant will improve in the foreseeable future, and likely also that some of the newer agents now in development may be able to control CML in patients resistant to imatinib. For the present one may consider initial treatment by allogeneic stem cell transplant for any young patient with an optimal donor, but unquestionably the great majority of patients should start treatment with imatinib or with a trial combination including imatinib. Patients with possible transplant donors who fail imatinib should be considered for all-SCT (Figure 37.9).

For patients for whom transplant would not have been considered in the 1990s, initial treatment should be with imatinib or an imatinib-containing combination. Those who respond should presumably continue the drug indefinitely. Those who do not respond or who, having initially responded, then lose their response should be considered for alternative therapy, e.g. the substitution or addition of other agents or perhaps autografting. Some such patients could be suitable for a reduced-intensity conditioning allo-SCT.

The decision-making process is especially complicated when CML is diagnosed in an asymptomatic patient presenting to an antenatal clinic. For a woman in the first trimester of pregnancy it is probably best to delay treatment, avoiding if possible all forms of chemotherapy, including imatinib. Leucapheresis and/or blood transfusion could be undertaken if essential. The same might apply to patients in the second trimester of pregnancy, but administration of interferon-α is probably safe at this stage. The safety of imatinib is not yet established. In the third trimester the objective should be maintain the platelet count in the normal range, and this should be achievable with apheresis or interferon-α.

New therapeutic approaches

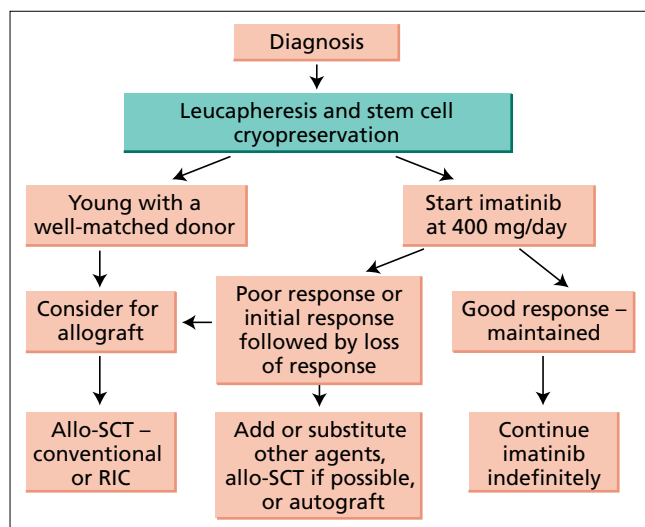
The demonstration that imatinib durably blocks the kinase activity of the BCR–ABL oncoprotein has provided a major incentive for the development of a second generation of kinase inhibitors. One such agent, BMS354825, has a chemical structure rather different from that of imatinib and appears to inhibit the kinase activity of both the *ABL* and *SRC* gene products.


Figure 37.9 Algorithm showing a possible approach to the management of a patient with newly diagnosed CML in chronic phase. A minority of young patients with HLA-identical siblings (or possibly well-matched unrelated donors) may be eligible for initial treatment by allografting. The great majority of newly diagnosed patients, including those with possible transplant donors, should probably be treated first with imatinib. Those who respond well and maintain their response should continue on the drug indefinitely. Patients who respond less well or who lose their response should be considered for other therapy. SCT, stem cell transplantation; RIC, reduced intensity conditioning.

Preliminary clinical experience suggests that it may be active against leukaemia cells from patients who have developed resistance to imatinib as a consequence of expanded clones with kinase domain mutations. Similarly, the new ABL/SRC inhibitor currently designated AMN107 (Novartis Pharma) may prove to be equally active in imatinib-resistant cell lines. It is likely that other analogous kinase inhibitors will become available before long. It would be logical to test such new agents in combination with imatinib.

The demonstration of a powerful GvL effect in CML has renewed interest in the possibility that some form of immunotherapeutic manipulation could be effective in CML. Some evidence suggests that patients vaccinated with oligopeptides corresponding to the junctional region of the BCR–ABL protein may generate immune responses that may be of clinical benefit. Other targets for vaccine therapy now under study include the Wilms tumour-1 protein and proteinase-3, both of which are overexpressed in CML cells.

Autografting in chronic phase

Because only a minority of patients are eligible for allogeneic SCT, much interest has focused on the possibility that life may be prolonged and some cures effected by autografting CML patients still in chronic phase. It is possible that the pool of leukaemic stem cells can be substantially reduced by an autograft procedure, and autografting may confer a short-term proliferative advantage on Ph-negative (presumably normal) stem cells. In practice, some patients have achieved temporary Ph-negative haemopoiesis after autografting. Preliminary studies have been reported in which patients have been autografted with Ph-negative stem cells collected from the peripheral blood in the recovery phase following high-dose combination chemotherapy; some such patients achieved durable Ph negativity.

Management of chronic myeloid leukaemia in advanced phase

Accelerated-phase disease

It is difficult to make general statements about the optimal management of patients in accelerated-phase disease as the criteria for this diagnosis are so very varied. Some patients can be managed merely with a minor alteration in their cytotoxic drugs regimen. Those who have not been treated previously with imatinib may obtain benefit from the introduction of this agent. Other patients may benefit from splenectomy or regular red cell transfusion. Patients whose disease seems to be moving towards overt blastic transformation may benefit from appropriate cytotoxic drug combinations. Allogeneic SCT should certainly be considered for younger patients if suitable donors can be identified. Reduced-intensity conditioning allografts are probably not indicated, as the efficacy of the GvL effecting advanced-phase CML is not clearly established.

Blastic transformation

Patients in blastic transformation may be treated with combinations of cytotoxic drugs in the hope of prolonging life but cure can no longer be a realistic objective. Conversely, it is not unreasonable to use a relatively innocuous drug such as hydroxyurea at higher dosage to restrain blast cell numbers and maintain the patient at home for as long as possible. If the patient has a myeloid transformation, he or she can be treated with drugs that are appropriate to the induction of remission in AML, namely daunorubicin, cytosine arabinoside with or without 6-thioguanine, or etoposide. The blast cell numbers will be reduced substantially in most cases but their numbers usually increase again within 3–6 weeks. Perhaps 20% of patients are restored to a situation resembling chronic phase disease and this benefit may last for 3–6 months. A very small minority, probably less than 10%, may achieve substantial degrees of Ph-negative haemopoiesis. This is most likely in patients who entered blastic transformation very soon after diagnosis.

Patients in lymphoid transformation may be treated, with a

little more optimism, with drugs applicable to the management of adult ALL (e.g. prednisolone, vincristine, daunorucibin and methotrexate with or without L-asparaginase). More than 50% of patients will be restored to 'second' chronic phase, at which point this status can be maintained with daily 6-mercaptopurine and weekly methotrexate. Because leukaemia involving the CNS is so relatively common in responding patients, those who achieve second chronic phase should have neuroprophylaxis with intrathecal methotrexate weekly for six consecutive weeks, but the administration of cranial irradiation is probably excessive. Some patients treated for lymphoid transformation of CML may sustain long periods of apparent 'remission'.

Imatinib may be remarkably effective in controlling the clinical and haematological features of CML in advanced phases in the very short term. In some patients in established myeloid blastic transformation, who received 600 mg daily, massive splenomegaly was entirely reversed and blast cells were eliminated from the blood and marrow, but such responses are almost always short-lived. Thus, imatinib should be incorporated into a programme of therapy that involves also use of conventional cytotoxic drugs and possibly also allogeneic SCT.

Allogeneic SCT using HLA-matched sibling donors can be performed in accelerated phase; the probability of leukaemia-free survival at 5 years is 30–50%. SCT performed in overt blastic transformation is nearly always unsuccessful. The mortality resulting from GvHD is extremely high and the probability of relapse in those who survive the transplant procedure is very considerable. The probability of survival at 5 years is consequently 0–10%. However, patients who can be restored to 'second' chronic phase by combination chemotherapy or by imatinib may have a relatively low risk of transplant-related mortality and may therefore be considered for allogeneic SCT with a view to eliminating both chronic disease and residual blastic disease provided that a suitable donor can be identified.

Variants of chronic myeloid leukaemia

Ph-negative chronic myeloid leukaemia

About 6% of patients with haematologically acceptable CML lack the Ph chromosome (see above). About one-half of these patients have a BCR–ABL gene that is molecularly identical to the BCR–ABL gene of Ph-positive CML; this gene is usually on the morphologically normal chromosome 22q but may occasionally be found on chromosome 9q. Such patients have a clinical course similar to those with Ph-positive disease. Conversely, the patients with no BCR–ABL gene frequently have haematological features that are subtly different from Ph-positive disease. They may lack basophilia, lack blast and myelocyte peaks in the leucocyte differential, or show dysplastic features. They are more likely to have some degree of monocytosis. These patients

respond poorly to imatinib, IFN-α or hydroxyurea, and overall their survival is inferior to that of Ph-positive patients.

Chronic myelomonocytic leukaemia

This is a rare myeloproliferative condition affecting predominantly elderly men but found at all ages (see Chapter 39). The patient may present with features of anaemia or haemorrhage. The spleen is typically enlarged and thus the clinical picture superficially resembles CML. However, the blood and marrow are quite different. Marrow cells lack a Ph chromosome. Blood monocytosis is prominent and monocyte numbers may be as high as 50×10^9/L. Thrombocytopenia is common. Basophilia and eosinophilia are absent. Dysplastic changes are usually present in the granulocyte and erythroid series. Consequently, the disease is included in the FAB classification of the myelodysplastic syndromes (see Chapter 39).

Very rare patients have been described with a chronic myelomonocytic leukaemia (CMML)-like blood picture associated with a consistent cytogenetic abnormalities in their leukaemia cells other than t(9;22). Most of these patients have either a t(5;12) associated with fusion of the *ETV* and *PDGFRB* genes or a t(8;13) associated with fusion of *ZNF198* and *FGFR1* genes but, in fact, other fusion partners have also been reported (Table 37.3). PDGFRB and FGFR1 are both receptor tyrosine kinases that are presumably 'activated' by mechanisms analogous to those that activate ABL gene in *BCR–ABL*-positive CML. The t(5;12) and t(8;13) leukaemias are both characterized by prominent eosinophilia but basophilia is usually absent. The t(5;12) leukaemias respond extremely well to low doses of imatinib but the t(8;13) leukaemias do not.

Chronic neutrophilic leukaemia

This is an exceedingly rare disorder that is usually diagnosed incidentally. The patient has a raised blood neutrophil count without immature granulocytes, and without basophilia or eosinophilia. The level of neutrophil alkaline phosphatase is usually raised. The marrow is hypercellular but cytogenetic studies are usually normal. The diagnosis is based largely on exclusion of other identifiable causes for the leucocytosis. Most patients have no symptoms referable to the neutrophilia and no physical signs, although some have minor degrees of splenomegaly. Treatment may not be required (see also Chapter 45).

Eosinophilic leukaemia

Most cases of raised eosinophil counts without identifiable primary cause have in the past been classified as examples of the 'hypereosinophilic syndrome' (HES) (see Chapter 45). However, it has been shown recently that some such patients respond well to treatment with imatinib, and some of these responding

CML, chronic myeloid leukaemia; CMML, chronic myelomonocytic leukaemia.

patients have evidence of a new fusion gene designated *FIP1L1–PDGFRA*, resulting from an interstitial deletion on chromosome 4 in their myeloid cells (see Table 37.3). In other cases in which no fusion gene has been identified, the number of immature cells in the blood and marrow is increased and the finding of a clonal cytogenetic abnormality in myeloid cells is strong evidence for a diagnosis of eosinophilic leukaemia (EL). It seems likely therefore that many, if not all, cases previously classified as HES may turn out to be due to a fusion gene and thus be classified more correctly as examples of EL. Occasional patients with EL progress to blastic transformation in a manner similar to Ph-positive CML. Patients with the *FIP1L1–PDGFRA* fusion gene usually respond well to relatively low does of imatinib.

Juvenile myelomonocytic leukaemia

Juvenile myelomonocytic leukaemia (JMML) is a rare disease affecting children under the age of 12 years. It represents about 2% of all childhood leukaemias. It includes a heterogeneous spectrum of myelodysplastic/myeloproliferative diseases that may be difficult to classify. Patients usually have symptoms of anaemia with lymphadenopathy and hepatosplenomegaly. There is a variety of skin rashes. Leucocyte numbers are increased with variable numbers of blast cells in the peripheral blood. Such cells are hypersensitive to GM-CSF *in vitro*. The haemoglobin F level may be elevated. The marrow is hypercellular but usually lacks chromosomal abnormalities, although monosomy 7 may be present. The disease responds poorly to standard cytotoxic drugs but patients may benefit from allogeneic SCT. Relapse after SCT is relatively common but relapses may be treated successfully with DLI.

Chronic lymphocytic leukaemia and other B-cell disorders

38

Daniel Catovsky

Introduction

Within the broad term of B-cell lymphoproliferative disorders we include a number of disease entities arising from mature B lymphocytes and which involve primarily the blood, bone marrow and other lymphoid organs such as the spleen. All of them are classified within the World Health Organization (WHO) proposals (see Chapter 43) on the basis of their histopathological appearances as this is often the key for their diagnosis. Their clinical course is often chronic and they affect mainly adults. All show, early in their course, circulating leukaemic cells in various degrees. Some of these conditions could be considered as primary leukaemias and these will be dealt with in this chapter. Others represent the leukaemic phase of low-grade non-Hodgkin's lymphomas (NHL) and their recognition is important for the purpose of differential diagnosis and patient management.

The study of lymphoid leukaemias has been enriched with the advent of monoclonal antibodies (MAbs) which define antigenic determinants that are specific for the B- and T-cell lineages. Characterization of these malignancies is not possible without the use of these reagents and/or other membrane markers which define the cell lineage and the maturation stage of the leukaemic cell. DNA analysis for the detection of immunoglobulin and T-cell receptor gene rearrangements has been incorporated as another diagnostic test for cell lineage and clonality and for monitoring minimal residual disease (MRD) after therapy. Chromosome abnormalities which characterise some of the genetic changes in the lymphoid leukaemias are now also important for diagnostic and prognostic purposes and are rout-

inely studied by fluorescence *in situ* hybridization (FISH) as it is not easy to obtain metaphases in slowly dividing lymphocytes.

The primary B-cell leukaemias include chronic lymphocytic leukaemia (CLL), which is by far the most common, the rare B-prolymphocytic leukaemia (B-PLL) and hairy cell leukaemia (HCL). The B-NHLs which most frequently affect the blood and bone marrow include splenic marginal zone lymphoma (SMZL) or splenic lymphoma with circulating villous lymphocytes (SLVL), mantle cell lymphoma (MCL), which not infrequently has lymphocytosis, particularly in the splenomegalic or non-nodal form, and follicular lymphoma which, in its generalized or systemic form (stage IV), regularly affects the bone marrow and may spill over to the peripheral blood.

Methodology for diagnosis

Examination of the morphology of leukaemic cells in well-prepared peripheral blood and bone marrow films stained with Romanowsky dyes is the first diagnostic procedure. Details which are helpful in the analysis of cell types are: cell size, nucleo-cytoplasmic (N/C) ratio, regularity or irregularity of the nuclear outline, the characteristics of the cytoplasm such as the presence and length of any villus formations, the degree of basophilia, the presence or absence of cytoplasmic granules, the degree of nuclear chromatin condensation and its pattern, and the prominence, frequency and localization of the nucleolus.

The second crucial element for the diagnosis of any type of lymphocytosis is to use a small battery of membrane markers to

Table 38.1 The immunophenotype of CLL: tests used as basis for a scoring system.

Marker (result)	Score
SmIg (weak)	1
CD5 (+)	1
CD23 (+)	1
FMC7 (−)*	1
CD79b (− or −/+)	1
Total	5

*Epitope of CD20 but CD20 not useful for scoring.

define the immunophenotype (B or T) and whether the process is clonal or polyclonal. Once a monoclonal B-cell proliferation is established by light-chain restriction, e.g. kappa or lambda, one can clarify the problem further by using a restricted panel of monoclonal antibodies to define a particular disease immunophenotype. Our group has, over a number of years, worked out a panel of reagents that help define the typical immunophenotype of CLL (Table 38.1). The original proposal by Matutes *et al.* (1994) was revised by replacing CD22 with CD79b, which is one of the components of the B-cell antigen receptor molecule. Table 38.1 indicates in brackets after each of the five markers used the expected result in CLL. Figure 38.1 illustrates the contrast between the flow cytometry profile of a case of CLL which scores 5 and one of follicular lymphoma presenting with lymphocytosis which scores 0.

Table 38.2 summarizes the results of applying the panel of markers of the CLL score to the B-cell disorders. High scores are, by definition, expected in CLL; low scores are the feature in the other B-cell leukaemias and B-cell NHL. The data refer mainly to results in peripheral blood samples. Figure 38.2 illustrates the almost complete lack of overlap between CLL and the B-NHLs evolving with lymphocytosis. There are, however, a number of issues which may present problems. First, as shown in Table 38.2, some cases of CLL with atypical morphology, e.g. clefted or cleaved nucleus, plasmacytoid features, and cases with more than 10% prolymphocytes (CLL/PL) may have scores lower

Table 38.2 CLL score in B-cell disorders.

Disease	Score
CLL	
Typical	4–5
Atypical; CLL/PL	3–5
B-prolymphocytic leukaemia	0–1
Hairy cell leukaemia	0–1
NHL with leukaemia*	0–2

*Follicular, mantle, splenic marginal zone.

than 4 or 5. Rare cases of NHL may approach scores of 2 or 3; thus, reliance only on the immunophenotype may be misleading. Second, the important distinction between CLL and MCL, another CD5-positive disease, may require other tests, e.g. FISH (see below). In our experience of 60 cases of MCL with lymphocytosis studied with this panel of MAb, the highest score was 2. Recently, we have also identified a group of patients with CD5-positive leukaemia in which MCL was excluded by FISH and which also gave scores of 1 or 2. We have provisionally described them as very atypical CLL as we are not sure of the exact nature of this condition.

An important consideration when using membrane markers is the distinction between CD20 and FMC7. FMC7 has now been recognized as binding to a conformational epitope of the CD20 molecule. Despite this, FMC7 does not correlate with CD20 staining in CLL. Most cases of CLL and other B-cell disorders express CD20, hence its value as a pan-B-cell marker and as a target for the monoclonal antibody rituximab. We have reexamined the possible use of CD20 instead of FMC7 for the scoring of CLL (as suggested by some authors) in close to 1000 cases and concluded that FMC7 is of greater diagnostic value to distinguish CLL (where it is negative) from the other B-cell disorders in which it is strongly expressed. The findings with CD20 and FMC7 are very similar only in the non-CLL B-cell disorders.

When considering the possibility of a diagnosis of NHL, it is essential to obtain tissue for histology to confirm this suspicion and facilitate the classification of the disease. When the WBC is high (e.g. above 50×10^9/L) and the blood film shows unequivocal features of CLL or B-PLL, lymph node histology may not be essential, and not infrequently it is not available.

Bone marrow trephine biopsies are always required as they provide important diagnostic and prognostic information. The pattern of bone marrow infiltration – paratrabecular, diffuse, nodular or interstitial – the cell morphology, the status of the normal haemopoietic elements, the presence of fibrosis, proliferation centres, etc., are all features which can help to confirm a diagnosis of CLL or NHL, provide indications about the mechanism of anaemia or thrombocytopenia and help predict the outcome of splenectomy. The pattern and degree of lymphocytic infiltration in CLL have been considered an important prognostic variable independent of the clinical stage. For disorders with an enlarged spleen, e.g. B-PLL, HCL, splenic lymphoma with circulating SLVLs and some forms of MCL, spleen histology is often of diagnostic value.

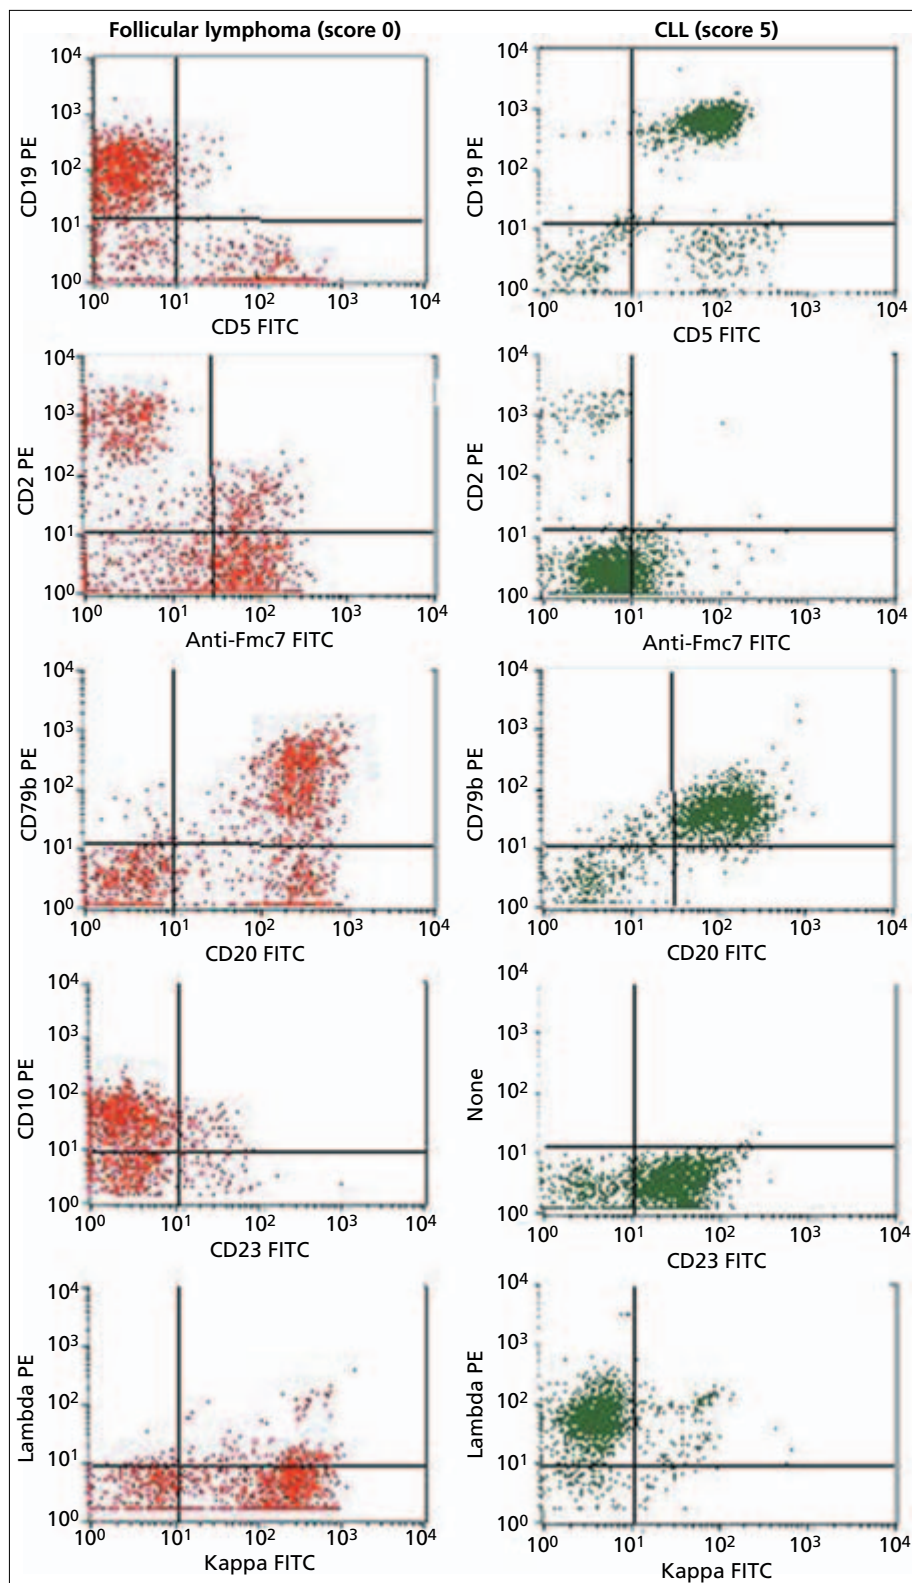
The difficulties in eliciting metaphases for cytogenetic analysis in CLL and other small lymphocytic disorders has emphasized the value of FISH analysis which can be assessed on interphase cells. There is, however, no specific genetic abnormality in CLL and the current FISH studies are valuable as prognostic indicators (see below). FISH is important to exclude the two NHLs which have characteristic abnormalities, MCL with t(11;14)(q13;q32) and follicular lymphoma with t(11;14)(q32;q21). Other abnormalities, e.g. deletions 6q21, 11q23, 13q14 and 17p21 (the p53


Figure 38.1 Flow cytometry analysis of peripheral blood samples from a case of follicular lymphoma with lymphocytosis (score 0) compared with a case of CLL (score 5) using the antibodies listed in Table 38.1.
Figure 38.2 Distribution frequency of scores in CLL (high scores) compared with cases of B-cell non-Hodgkin's lymphoma (B-NHL) with circulating lymphoma cells (low scores).

locus) and trisomy 12, are seen in variable degree in most types of B-cell NHL as well as in CLL.

Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia accounts for about 25% of all leukaemias. In adults over the age of 50 years it is the most common form, particularly in the West. In the Far East, its incidence is low. In our series of over 2000 samples with B-cell lymphocytosis, CLL represented two-thirds of cases and close to one-third were represented by NHL in leukaemic phase (or 'spillover'). CLL affects twice as many males as females, with a peak incidence between 60 and 80 years. In the MRC CLL trials, 70% of patients entered were aged 60 years or over, and 15% were below 50 years. There is a tendency for older patients to present with less advanced disease. CLL is rarely diagnosed below the age of 40 years and is even more rare below 30. In the last 10 years, we have seen several patients in their late 20s. In such cases, a diagnosis of follicular lymphoma needs to be excluded. Of all the leukaemias, CLL has the highest familial incidence, which can be documented in 5–10% of patients (see below).

Pioneering work by Dameshek and Galton in the 1960s introduced the concept of CLL as a progressive accumulation of lymphocytes, starting in lymph nodes and/or the bone marrow and gradually expanding to most haemopoietic organs. This concept of slow progression was the basis of the clinical staging system proposed by Rai *et al.* (1975) and will explain the progressive abnormalities of the immune system which result in hypogammaglobulinaemia and, not infrequently, autoimmune complications. The bone marrow, viewed by detailed histology, also reflects the progression of CLL from early interstitial and nodular infiltration to late diffuse lymphocytic replacement of normal haemopoietic elements.

Several factors may be involved in the pathogenesis of CLL, including antigen stimulation within specific microenvironments and failure to undergo apoptosis. The protein BCL2 is consistently overexpressed and prevents or delays the death of CLL lymphocytes. Stromal cells and activated CD4+ T lymphocytes may favour proliferation within tissue pseudofollicles (these are called proliferating centres and are the tissue hallmark of CLL).

Clinical and laboratory features

In approximately 50% of patients, the disease is diagnosed by chance following blood examination. In others, the presentation is prompted by symptoms of anaemia or by the discovery of painless lymph node enlargement. Systemic symptoms such as pyrexia, sweating or weight loss are rare. Not infrequently, prolonged chest infection or pneumonia is the first manifestation of CLL.

Lymph node enlargement is symmetrical and involves the neck, axillae and inguinal regions. Splenomegaly of variable degree is present in two-thirds of cases. Significant hepatomegaly is less frequent. It is possible to document lymph node enlargement in the hilar regions on routine radiographs, or in the retroperitoneal regions by ultrasound or computerized tomography (CT) scanning procedures. Although the latter investigations may not add significant prognostic information and are not used for staging purposes (see below), they are often useful for follow-up after treatment. An abdominal CT scan is important to document the extent of abdominal lymphadenopathy in patients presenting with palpable nodes. It is rare to find large para-aortic nodes in patients presenting without peripheral lymphadenopathy. Late in the disease process, however, this is not uncommon, and abdominal CT scans may be necessary to document progression.

The diagnosis of CLL requires evidence of lymphocytosis, at least 10×10^9/L, and lymphocytic infiltration in the bone marrow of at least 40%. With immunological methods, particularly the detection of monoclonal B-cell populations by light-chain restriction, it is possible to diagnose the disease with lymphocyte counts below this threshold. Morphologically, the lymphocytes in blood films are small and show scanty cytoplasm and a characteristic pattern of nuclear chromatin clumping; the nucleolus is inconspicuous and azurophil granules are seen only in a minority of normal T cells (Figure 38.3). The presence of smear cells, which correlates with the level of WBC, is of diagnostic value. A proportion of prolymphocytes (1–5%) are nearly always seen with counts > 30×10^9/L. If the proportion of prolymphocytes is greater than 10%, it represents a variant designated CLL/PL (Figure 38.4). As reported by the French–American–British (FAB) group, some patients have a mixed pattern of small and large cells and others have lymphoplasmacytoid features or even cells with nuclear clefts. These are often associated with other atypical features (see below).
Figure 38.3 Blood film of a typical case of CLL.

Figure 38.5 Low magnification of a trephine biopsy from a patient with CLL and heavy (packed) lymphocytic infiltration.

Figure 38.4 Blood film from a case of CLL/PL. Note the dual population of small lymphocytes and larger nucleolated prolymphocytes.
Figure 38.6 Higher magnification of the same case as Figure 38.5 showing scanty fat spaces and diffuse lymphocytic infiltration.

As stated above (Table 38.1), a combination of membrane markers is often diagnostic of CLL, distinguishing it not only from T-cell disorders but also from other B-lymphoproliferative disorders (Table 38.2). The diseases which are often confused with CLL are follicular lymphoma, splenic marginal zone lymphoma or SLVL and MCL when they present with lymphocytosis.

Anaemia and thrombocytopenia are important prognostic features in CLL and form part of the information used for staging. In advanced CLL, there is heavy lymphocytic infiltration resulting in bone marrow failure. The trephine biopsy shows heavy replacement of fat spaces and haemopoietic cells by lymphocytes (Figures 38.5 and 38.6). In an ageing population it is important always to exclude nutritional deficiencies (iron, folate), which can easily be corrected by appropriate supplements. The possible causes of anaemia in CLL are listed in Table 38.3. The current staging systems do not clearly distinguish the causes of anaemia as having different prognostic significance. This is

probably because marrow failure is by far the most common cause and there is an assumption that most haematologists will be able to detect the nutritional deficiencies. There is evidence, however, that autoimmune complications, e.g. anaemia or thrombocytopenia, which are rare at presentation, 7% and 1% respectively, do not necessarily confer a poor prognosis if adequately treated. It is important always to carry out the direct antiglobulin (Coombs) test at diagnosis in each patient. In a proportion of patients, autoimmune complications follow the initiation of therapy with alkylating agents or, as more recently recognized, after fludarabine. Therefore, the importance of the direct antiglobulin test is twofold: to document autoimmune haemolytic anaemia (AIHA) and to detect the triggering of AIHA after therapy. Not infrequently, patients have a positive Coombs test at presentation without overt haemolysis (e.g. no reticulocytosis or raised bilirubin). The documentation of autoimmune thrombocytopenic purpura (ITP) requires the demonstration of platelet-associated immunoglobulin. If this is not possible, one can still suspect peripheral destruction of platelets by examination of the bone marrow (see below).

Table 38.3 Causes of anaemia in CLL and their management.

Cause	Diagnostic test	Treatment	Significance
Bone marrow (BM) failure	BM aspirate and/or trephine biopsy	Corticosteroids; CLL therapy	Advanced CLL; stage III (Ral); C (Binet)
Haemolytic anaemia	Coombs test	Corticosteroids; immunosuppression; splenectomy	Does not affect prognosis but more frequent in active CLL
Red cell aplasia	BM examination	(See text)	Uncertain
Hypersplenism	BM; spleen size	Splenectomy; CLL therapy	Prognosis depends on stage after splenectomy
Fotate or iron deficiency	Indices, Fe and folate levels	Appropriate supplements	None; restage when anaemia corrected

Hypogammaglobulinaemia is the rule in advanced CLL and is responsible for the high incidence of upper respiratory tract infections. Small monoclonal (M) bands, often immunoglobulin M (IgM), are seen in less than 10% of cases. The appearance of an M band during the evolution of the disease or the discovery of free light chains in the urine (Bence Jones proteinuria) may indicate transformation.

Bone marrow examination (Table 38.4)

After the examination of peripheral blood films and the five markers for defining the immunophenotype, a bone marrow examination is the next most important test in CLL. Although it is common practice to perform an aspirate and a trephine biopsy, the latter is probably more informative. Aspirates are useful to confirm the cell morphology, to assess residual haemopoiesis and to ascertain any myelodysplastic features (in heavily treated patients). They are, however, not as informative as the core biopsy regarding overall cellularity and degree of infiltration.

The value of the biopsy is fourfold. The degree of infiltration is an important prognostic feature: a densely packed bone

Table 38.4 The value of bone marrow trephine biopsies in CLL.

- Prognostic feature
     Diffuse = packed BM has poor prognosis
- Clarify the nature of cytopenias
     Low platelets > megakaryocytes
     Red cell aplasia
- Differential diagnosis with low-grade NHL
     Paratrabecular pattern not seen in CLL
     > Proliferation centres in CLL/PL
- To assess response to treatment
     Nodular PR seen only on biopsy

marrow (or diffuse pattern) with little or no residual fat spaces (Figure 38.6) correlates with advanced CLL – stage C (Binet) or III–IV (Rai) (see below). A trephine needs to be at least 2 cm in length (Figure 38.5) to be informative. Other bone marrow patterns are interstitial, with relatively abundant fat spaces (Figure 38.7), and nodular (Figure 38.8). Both of these are seen alone or in combination (mixed pattern) in relatively early stages of the disease. A second value of bone marrow is to clarify the nature of the cytopenia. For example, an increased number of megakaryocytes in the presence of low platelets may suggest ITP (Figure 38.9). Absence of red cell precursors and a low reticulocyte count suggest red cell aplasia. When this is due to parvovirus infection, large basophilic erythroid precursors can be seen in the bone marrow aspirates. The pattern of bone marrow infiltration may also help in the differential diagnosis with other lymphomas. For example, true paratrabecular deposits are common in follicular lymphoma and may be seen in SLVL and MCL, but not in CLL. Proliferation centres, a classic feature of

Figure 38.7 Interstitial lymphocytic infiltration in a case of early CLL with preserved haemopoiesis and abundant fat spaces.
Figure 38.8 Nodular pattern of infiltration in CLL, early in the disease. A similar pattern described as nodular partial remission may be seen after chemotherapy in patients with previously diffuse involvement.
Figure 38.9 Diffuse infiltration in the bone marrow in a patient with CLL, a large spleen and thrombocytopenia. Note the large number of megakaryocytes which indicated that splenectomy will improve the low platelet count.

CLL and small lymphocytic lymphoma (SLL), are seen in lymph node biopsies, and in very active CLL also in bone marrow biopsies, not infrequently associated with an increased proportion of prolymphocytes (CLL/PL) in blood and bone marrow films. The proliferating centres have a high proliferation index as detected by immunocytochemistry staining for Ki-67 or MIB-1 and show prolymphocytes and blasts (para-immunoblasts). There is also a high expression of CD23 in the proliferating centres of lymph nodes and spleen greater than in the small lymphocytes. This may explain the high levels of soluble CD23 in the serum of patients with active CLL and its correlation with adverse prognosis. Proliferation centres are unique to CLL and SLL and are absent in NHL, particularly cases of MCL, which may otherwise resemble CLL.

With advances in treatment and with current targets aiming at maximum response, bone marrow biopsies are crucial to assess response. In particular, a nodular partial remission (PR), which is a very good clinical response, can only be defined by a bone marrow biopsy and not an aspirate. In such cases, the bone marrow aspirate may show less than 30% lymphocytes which, by the old criteria of response, could have been considered complete remission (CR). Immunostaining of the nodules is also important to assess response. If they are composed mainly of B cells (stained with CD20), they reflect residual CLL. If they are mainly T cells (stained with CD3) or a mixture, they may not represent residual CLL and are consistent with a true CR.

In patients with very early CLL with minimal lymphocytosis and otherwise normal blood counts, a bone marrow test may not be necessary and could be delayed until such a time when there is a suspicion of disease progression. Still, this information could be used to compare with a new bone marrow done when progression is suspected and the changes (e.g. greater infiltration) may facilitate a decision about the need to start therapy. Similarly, when assessing treatment responses, it is always useful to compare the pre-treatment bone marrow with the one at the end of therapy.

Staging systems

The two widely accepted systems are those of Rai *et al.* (1975) and Binet *et al.* (1981). Rai's staging system takes the view that CLL cells accumulate first in the blood and bone marrow, then in lymph nodes and spleen, finally leading to bone marrow failure. The chances of a patient surviving will depend largely on the stage at which he/she presents to the physician's attention. The Rai system has five stages: 0, no anaemia, thrombocytopenia or physical signs; I, lymphadenopathy only; II, splenomegaly and/or hepatomegaly with or without lymph node enlargement and without anaemia or thrombocytopenia; III, anaemia below 11 g/dL, irrespective of physical signs; and IV, thrombocytopenia below 100×10^9/L, with or without any of the above features. Binet modified this system following extensive multivariate analysis from two French studies. This system is simpler, has only three stages (A, B and C) and is probably more accurate with respect to the prognosis for patients with Rai stages I and II. For these patients, a subdivision according to the number of involved sites (as in Binet's staging) shows prognostic advantages over the subdivision in I and II. The Binet system groups together patients with anaemia (Hb < 10 g/dL) and thrombocytopenia (platelets < 100×10^9/L) as group C. The remainder of patients are staged according to the number of lymphoid organs involved, considering as one each of the following areas: neck, axillae and inguinal regions, spleen and liver. Group A patients have no organ enlargement or up to two areas; group B patients have 3–5 involved areas. The International Workshop on CLL proposed to retain the Rai stages as substages for group A, as A(0), A(I) and A(II), mainly with a view to preserving the

identification of the most benign group of Rai stage 0. From several studies, including early MRC trials, it appears that there is a distinct trend favouring A(0) compared with A(I) and A(II). More recently, the Rai staging has also been simplified and used in USA trials as follows: stages 0 (low grade), I and II (intermediate) and III and IV (advanced stage). Except for the difference in the level of haemoglobin (Hb) (10 or 11), Rai stages III and IV are the same as Binet C.

In practice, staging is necessary to predict prognosis, make decisions about which patients need treatment and facilitate allocation in randomized trials. There is little argument that stage C patients need therapy and also those with stage B, the majority of whom show features of disease progression – upward trend in the WBC, greater lymph node enlargement leading to symptoms of sweating and weight loss if the disease becomes bulky. There are also now conclusive data from several randomized trials that patients with stage A do not benefit from early treatment with chlorambucil. If anything, the approach of treating asymptomatic patients seems to have a deleterious effect.

The distribution of patients in the various stages, although variable, depending on whether from a retrospective study or a prospective randomized trial, is more or less as follows: A, 50%; B, 30%; and C, 20%. For both sexes, the proportion of stage A patients increases with age, with the highest proportion recorded over the age of 70 years. One of the important issues regarding which patients to treat is that staging, in particular stage A, appears to be a static definition and does not clearly predict whether patients will progress or not. The Spanish group has shown that a short lymphocyte doubling time (less than 12 months) in stage A correlates with poor prognosis. Similarly, the French group showed that those with Hb < 12 g/dL and/or lymphocyte count greater than 30×10^9/L (called A″) fared worse than those with Hb > 12 and lymphocytes < 30×10^9/L (A′). We examined both these factors in an observational study, MRC CLL3A, and found that both were strong indicators of prognosis and that the two criteria were independent of each other. We currently use a definition for stage A progressive for patients with short doubling times, downward trend in Hb and/or platelets, increasing organomegaly and systemic symptoms. Using these criteria, we have shown in both the CLL3 and CLL4 trials that stage A progressive fared the same as those with stage B, confirming the validity of the clinical criteria used. Both A progressive and B fared better than stage C.

New prognostic factors are now emerging in CLL (see below), and these will need to be tested against the relatively simple and well-established parameters. These will be relevant in particular to stage A but also perhaps to identify prognosis and good responders in the other stages. While these new tests are incorporated and tested in the clinic, the simple clinical observations, blood counts, symptoms and physical examination will remain as the best guideline on outcome. Stage is still very important as a starting point and, when considering the whole population with CLL, remains the best prognostic indicator. However, for randomized trials in which stage A non-progressive patients will not be entered, the prognostic value of staging loses its strength and other measures which assess the biology of the disease may become more relevant.

Prognostic factors

In a disease with such a variable pattern of survival it is important to examine critically the factors which determine survival. Most studies have shown that the best prognostic feature is the stage of the disease by either system. Individual features such as Hb, platelets, spleen size and number of lymph nodes enlarged are all important but are already incorporated in the stages. Now new categories of factors seem to add important prognostic information in addition to stage, age, sex and response to therapy. These reflect important biological features of the disease as assessed by molecular and flow cytometry methods. A number of studies have shown that some of these prognostic factors are independent of staging. Of the laboratory features, the level of the WBC, e.g. lymphocytes > 30×10^9/L in stage A, the proportion of prolymphocytes and the pattern of bone marrow involvement, e.g. diffuse involvement, have been shown to be important by several groups. Similarly, response to treatment seems to be an important independent feature. Although patients with early disease respond better than those with late disease, within each stage those who respond better will have a longer survival. Age is relevant in as much as, in the CLL age group, causes of death other than the disease itself are also very important. The influence of age is greater in stage A, in which up to 50% of patients may die of causes unrelated to CLL. Overall, one-third of patients may die of causes other than CLL, such as other neoplasms or cardiovascular accidents, and these are significantly influenced by age.

One biological factor which has emerged in all UK CLL trials for the last 25 years is sex. Female patients survive significantly longer than males and tend to respond better to treatment. In addition, females have a lower incidence of the disease and the M/F ratio is 2.5:1; this is higher in younger patients and lower in older ones. The M/F ratio is 3:1 in patients entered into treatment trials. The proportion of patients with stage A disease is higher in women than in men, i.e. 41% vs. 27%, whilst more men have stages B and C, i.e. 36% vs. 28%. When these favourable factors are taken into account and one considers that women tend to be older, sex remains as a prognostic factor independent of age, stage and response to treatment. The biology behind the better prognosis of women is not as yet obvious. The proportion of those with mutated immunoglobulin V_H genes is higher (see below), and this may provide a possible explanation.

Response to treatment has also emerged as an important prognostic variable. However, and disappointingly, large randomized trials have as yet failed to show a survival advantage for those treatments with higher response rates, e.g. fludarabine. One likely reason is that although treatment response matters, a

patient not responding to treatment A, e.g. chlorambucil, may then respond to treatment B, e.g. fludarabine (as shown in the MRC CLL3NR study) and, therefore, the patient changes from non-responder to responder. Only those non-responders to all treatments fare particularly badly.

The study of prognostic factors in CLL is currently undergoing a major revolution as new objective variables emerging from laboratory research may redefine more objectively the disease categories. The new prognostic factors include genetic markers, mutational status of the IgV$_H$ gene and surrogate markers such as CD38 and ZAP-70, the latter measured by flow cytometry. Other laboratory studies have been shown to have prognostic value but they were not easy to perform or were not shown consistently by all groups to have clinical value. This includes morphology, lymphocyte count, serum levels of β_2-microglobulin, lactate dehydrogenase (LDH), thymidine kinase and soluble CD23. It seems that the focus now is on new reproducible markers which relate to the underlying biology, proliferative potential and responsiveness to therapy.

Cytogenetics

It was known for many years that analysis of the karyotype of CLL lymphocytes stimulated to divide by a variety of mitogens elicited positive results in less than 50% of cases. This was due to two main reasons: the frequent observation of normal metaphases, which reflected the karyotype of the normal T cells, and the frequent lack of metaphases in cases with high WBC. Nevertheless, these early studies were important in identifying the abnormalities which can be found in CLL and which can now be studied more extensively by FISH analysis. This technique uses specific probes to detect these genetic changes on interphase cells. There is now a panel of at least five probes to study the most frequent abnormalities which can be detected in 80% of cases. Thus, we are now in a position in CLL similar to that of the acute leukaemias in which distinct chromosome abnormalities of prognostic significance can be detected in most patients. However, it is important to state that none of the abnormalities found are unique or specific for CLL and can be found in other B-cell leukaemias and NHL.

The most important contribution to the subject has been that of Dohner et al. (2000), who, in a study of 325 patients, proposed a hierarchical model for prognosis based on the genetic aberrations found in CLL (Table 38.5). This model is based on the prognostic value of such markers and it is necessary because some patients have more than one abnormality but the one which counts is the one listed higher in the table. It should be noted that deletions of 13q14 (Figure 38.10) confer a good prognosis (even better than no abnormality), but only provided they are found as a single change. Table 38.5 also shows that the incidence of the abnormalities is similar in cases entered thus far in the CLL4 trial. Of note is that there are few, if any, chromosome translocations in CLL; most changes are deletions or trisomy 12.

Table 38.5 Hierarchical model of chromosomal abnormalities in CLL.

Karyotype	Döhner	CLL4
No. of patients	352	223
17p deletion	7%	7%
11q deletion	17%	17%
12q trisomy	14%	10%
Normal karyotype	18%	26%
13q del as sole abnormality	36%	35%
Other abnormalities	8%	5%*

*6q21 deletion.

Table 38.6 Genetic abnormalities associated with progression and poor prognosis in CLL.

11q23 deletions (20% of cases)	• Younger age • Lymphadenopathy • Short survival
Trisomy 12 (15% of cases)	• CLL/PL • Disease progression • High proliferation rate
Abnormal 17p21 (p53 mutations/deletions 7% of cases)	• CLL/PL • Poor response to therapy • Transformation

Table 38.6 summarizes the main clinical and prognostic features associated with the three abnormalities which confer poor prognosis in CLL. The 17p deletion (Figure 38.11) has a much higher incidence (three or four times) in patients with advanced CLL, particularly after multiple treatments, than in those requiring treatment for the first time. The result of the 17p21 deletion
Figure 38.11 FISH analysis with a p53 probe (red) and a control 17 probe. Note many cells with only one (instead of two) red dot, indicating p53 deletion.

at the p53 locus often correlates with a point mutation in the other allele and this results in the total inactivation of the *p53* suppressor gene, the most common molecular change in cancer patients. Although the usual method for detecting p53 abnormalities is to use FISH to detect deletion of 17p, overexpression of the *p53* gene can be demonstrated by flow cytometry, immunocytochemistry and immunohistochemistry. The significance of *p53* overexpression is probably the same: although both abnormalities are not always detected at the same time, both tend to correlate with *p53* mutations.

The group with other abnormalities (Table 38.5) includes cases with deletion of 6q21 which, both in Dohner's series and in our current series, represents 6% of cases. These patients tend to present with high lymphocyte counts but apparently have an overall good prognosis. A rare translocation, t(14;19)(q23;q13), is found in less than 1% of cases. Although these patients were reported as having CLL, they seem to have atypical features and poor prognosis. This abnormality cannot, at present, be detected by FISH. In half of the cases, t(14;19) is associated with trisomy 12. We found two such cases within those described as very atypical CLL with scores of 1. Despite being CD5+, MCL was excluded by FISH and cyclin D1 staining.

The analysis of results of the CLL4 trial may clarify further the prognostic value of the five genetic markers in CLL and whether other features such as response to therapy can be predicted by means of FISH analysis.

VH mutations, CD38 and ZAP-70

The most interesting and exciting new findings relating to prognosis and which may underlie the clinical heterogeneity of CLL

Table 38.7 Mutational status of IgV$_H$ genes in CLL.

	Unmutated	*Mutated*
Incidence	45%	55%
M:F ratio	11:1	1.1:1
Morphology	Atypical	Typical
Trisomy 12	Frequent	Infrequent
Abnormal 13q14	Rare	Common
Stage (BiNet)	B&C (2/3)	Stage A (2/3)
Disease course	Progressive	Stable
CD38/ZAP70	Expressed	Negative
Therapy	Required	Not needed
Response	Poor	Normal
Survival	Short	Long

are the mutational status of the IgV$_H$ gene, and the expression of CD38 and of ZAP-70. Somatic hypermutation is a process by which B cells, after the initial recombination of the Ig genes, undergo further change in order to produce high-affinity antibodies. This event occurs within the germinal centre and gives rise to memory B cells and plasma cells.

CLL was, for many years, thought to be a disease of early or immature CD5+ B cells with unmutated IgV$_H$ genes. A similar hypothesis was made with MCL. More recent studies showed heterogeneity, and this was consolidated by two landmark papers in 1999 by Damle *et al.* and Hamblin *et al.* and demonstrated that just over half of the patients had mutated V$_H$ genes (Table 38.7), defined as < 98% homology to the nearest germline sequence, although in some studies < 97% is used as the cut-off level.

Many studies have confirmed the original finding, which suggested initially that there were two types of CLL: the unmutated type, associated with all the features of poor prognosis, and the mutated type, associated with stable disease and good prognosis (Table 38.7). Of interest is the finding that many of the features known to be of poor prognosis, such as stages B and C, male sex, atypical morphology, trisomy 12, 11q deletion, etc., are seen predominantly in unmutated cases whereas the opposite is true for the mutated ones. The early studies also showed that unmutated cases correlated with higher expression of the transmembrane glycoprotein CD38. This correlation is seen, however, in only two-thirds of cases. Therefore, and contrary to early speculation, CD38 could not be regarded as a surrogate marker for V$_H$ mutational status. Nevertheless, many studies have now shown that CD38 is an important prognostic marker. Low percentages correlate with stable disease, while a high percentage of CD38+ cells predicts a short time to disease progression and worse overall survival.

There are several caveats on the determination of CD38. Although assessed by flow cytometry and simpler than PCR and sequencing, which are used for V$_H$ mutations, CD38 testing should be only on the CLL B cells and exclude T cells which
Figure 38.12 Flow cytometry plots of ZAP70 in CLL Top left: ZAP70⁺, CD19⁺ lymphocytes; top right: control ZAP70+ T and NK lymphocytes (CD2+). Bottom left: a ZAP70⁻ case and the positive control T/NK cells (bottom right).

strongly express this antigen. This is currently done by triple labelling with CD5, CD19 and CD38 and appropriate gating. Another issue is the best threshold for CD38 positivity. The early reports suggest 30%, but more recent studies and our own experience suggest a lower figure, 7%, as being more likely to be accurate. In some reports, CD38 has prognostic value independently of V_H status, but it is likely that this relatively simple determination adds to the constellation of markers useful to assess prognosis in individual patients.

The heterogeneity in mutational status, which is, in fact, not unique to CLL, suggested two distinct origins for the disease: from unmutated naive B cells and from memory B cells. Subsequent data based on gene expression profiling showed unequivocally that CLL has a characteristic pattern of expression (or signature) which is independent of IgV_H mutation and is distinct from that of other B-cell lymphomas such as MCL, follicular lymphoma and diffuse large-cell B-cell NHL. The genotype of CLL was defined by a common pattern of expression of 12 000 genes, with only between 23 and 200 differentially expressed in mutated vs. unmutated cases. One notable difference is the high expression (four to five times higher) of ZAP-70 in unmutated cases. ZAP-70 encodes a protein tyrosine kinase and is of relevance in T-cell signalling. ZAP-70 can be demonstrated by flow cytometry, immunocytochemistry and Western blotting, and several studies have now shown a high concordance with the mutation status (~90%). Thus, ZAP-70 may be a better surrogate marker than CD38 to establish V_H mutational status without having recourse to molecular methodology. Studies using ZAP-70 have confirmed its prognostic value, particularly in patients with stage A disease, in whom an early assessment of the need for future therapy may be desirable. The

assessment of ZAP by flow cytometry (Figure 38.12) requires the exclusion not only of T cells (as for CD38) but also of NK cells, as both cell types express this cytoplasmic protein strongly. Thus, the determination of ZAP-70 requires cell permeabilization procedures and staining for CD3 and CD56 (for T and NK cells), CD19 and CD5 (for CLL cells) and ZAP-70 (Figure 38.12). Details are given in the report by Crespo *et al.* (2003).

The conclusion, from the gene expression profile and other studies, is that CLL derives from an activated, antigen-experienced B cell which resembles memory B cells and has a common pathogenetic pathway. The lack of balanced translocations which occur during Ig recombination and is seen in other B-cell NHL, e.g. MCL, follicular lymphoma, suggests that the mechanism of transformation in CLL is different and may not involve changes resulting from antigen exposure in germinal centres. A clear explanation for the differences in mutational status has not yet emerged.

Differential diagnosis

This was partly discussed in methodology for diagnosis. The main problem is when CLL has atypical features, more commonly morphology, less commonly immunophenotype, and, very rarely, both. We have provisionally described the latter situation as very atypical CLL. The most common change is the increased proportion of larger nucleolated lymphocytes or prolymphocytes. When there are more than 10% of these cells in blood films, the designation CLL/PL is used.

CLL/PL is a proliferative form of CLL, not infrequently associated with trisomy 12 or p53 deletion, high rate of cell divisions (as shown with the antibody Ki-67) and histologically

by proliferating centres in lymph nodes and bone marrow sections. Occasionally, lymph nodes seem totally replaced by prolymphocyte-like cells and we have used the term accelerated CLL. However, the peripheral blood films always show a dual population of small lymphocytes and larger prolymphocytes. CLL does not transform to B-PLL, which is a distinct clinico-pathological entity (see below).

When atypical features are present, including those of CLL/PL, it is important to consider the differential diagnosis with NHL in leukaemic phase, notably MCL which, like CLL, is CD5 positive. The best method to exclude (or confirm) MCL is to test for t(11;14) by FISH and/or to demonstrate expression of cyclin D1. Other NHLs can be excluded by histological criteria and the combination of immunophenotype and peripheral blood morphology.

Large-cell transformation or Richter's syndrome

'Immunoblastic' transformation or Richter's syndrome is well recognized in CLL. The change occurs usually in one or several lymph nodes which, when examined histologically, show the features of large-cell lymphoma. Richter's syndrome is associated with systemic symptoms (fever and weight loss) and with unexpected unilateral lymph node enlargement, not rarely in the retroperitoneal area. Richter's occurs in 3–5% of CLL cases, but the incidence may be higher if lymph node biopsies are performed when clinical changes with systemic symptoms develop in a patient with previously well-controlled disease. In rare cases, the transformation takes place in the bone marrow and is therefore seen in trephine biopsies and, rarely, is associated with 'spillover' to the blood. In such cases, the morphology resembles that of an acute leukaemia, with large blasts which are SmIg positive and some of the CLL markers (Figure 38.13). Richter's syndrome is often associated with monoclonal proteins in the serum or free light chains in the urine. Studies with Ig gene re-

arrangements are useful to demonstrate if the new malignant clone arose from a pre-existing CLL B cell or whether it is a new clone. The latter is seen in at least one-third of cases. Genetic imbalances are frequent in Richter's syndrome, the most common being p53 abnormalities (17p deletion, overexpression and/or mutation).
Current evidence suggests that intense immunosuppression with agents such as fludarabine and the subsequent CD4 lymphopenia may trigger Richter transformation in some cases, and, not infrequently, evidence of involvement of the Epstein–Barr virus (EBV) in the pathogenesis has been shown by demonstration of the EBV latent membrane protein (LMP), by immunohistology or of EBV-encoded RNA (EBER) by *in situ* hybridization. A role for EBV in the pathogenesis of Richter's syndrome has been reported in close to 15–20% of cases. In a minority of cases, the large-cell transformation induced by EBV has Reed–Sternberg-like cells, and in others the histology is identical to that of Hodgkin's disease. It is debatable whether cases of classic Hodgkin's disease should be considered a true transformation or a new event triggered, but not always, by EBV.

Hypercalcaemia with or without obvious osteolytic lesions is a well-recognized finding in very advanced CLL. It does not represent, in itself, transformation to a large-cell lymphoma as, often, the histology is that of heavy infiltration by small lymphocytes. Not infrequently, hypercalcaemia is a terminal event.

Familial CLL

Evidence from epidemiological and family studies supports the view that there is inherited susceptibility to CLL in a significant subset of patients. Case reports of leukaemia families, case–control and case cohort studies all showed that the relative risk of developing CLL in patients' relatives is 3–5 times higher than in the normal population.

A number of features seem to characterize the disease in familial CLL. One is the phenomenon of anticipation, manifested by early onset and more severe disease in successive generations. Several studies, including our own, have shown that the age at diagnosis of offspring is approximately 20 years earlier than in their parents. The phenomenon of anticipation is known in other hereditary conditions and is due to the expansion of trinucleotide repeats. However, this mechanism does not appear to be the case in CLL. Recent studies have also demonstrated a higher incidence of subclinical CLL, that is the detection of small B-cell clones by a very sensitive flow cytometry assay using CD5, CD19, CD20 and CD79b, in 'normal' relatives, with an incidence four times greater than in the general population. This incidence is even higher when looking at individuals under 40 years of age.

The search for CLL predisposition genes has been active in the last few years with the possibility of collecting DNA samples of familial cases. Figure 38.14 illustrates families with several affected members ascertained during our current study which

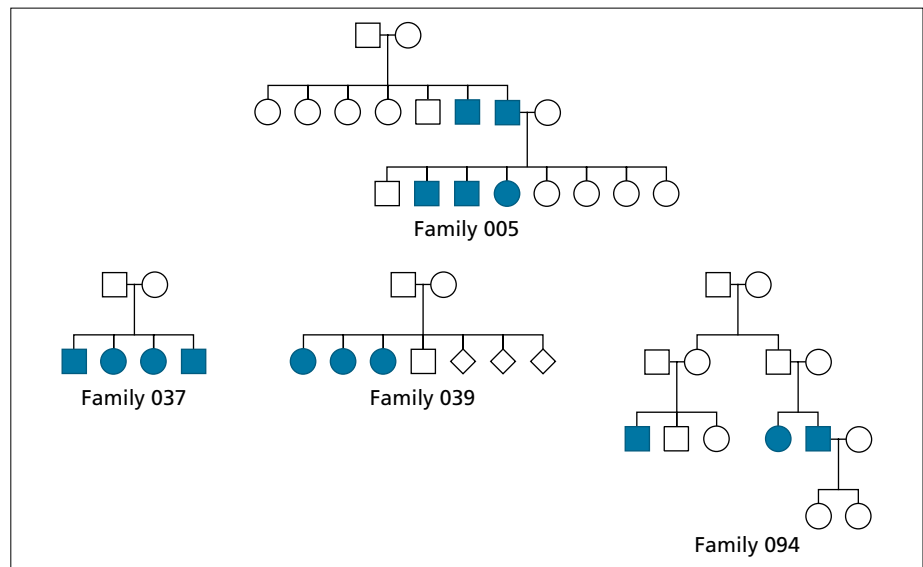
Figure 38.13 Blood film of a patient with Richter's syndrome with circulating large blast cells.


Figure 38.14 Four pedigrees of familial CLL cases with 3 or more affected per family.

has identified several families with three, four or five affected individuals. Through a family history questionnaire, we have determined that, in addition to CLL, other leukaemias and low-grade NHL can be found in such families. No clear-cut candidate gene has yet emerged, and several genes have been excluded as candidates. One of those excluded is the ataxia telangiectasia mutated (*ATM*) gene, which is mutated in ~20% of CLL samples, including some germline mutations. Other genes unlikely to play a role in linkage are the major histocompatibility complex (chromosome 6p21.3) and those in the pseudo-autosomal region (chromosomes Y and X). It will be possible in the next few years, through genome-wide linkage and association studies, to identify the gene(s) responsible for the inherited form of CLL. Most studies have suggested the vertical transmission of an autosomal gene with pleiotropic effects. A positive identification will also provide insights into the pathogenesis of the disease in general.

Monoclonal and polyclonal B-cell lymphocytosis

Improved flow cytometry technology has allowed the detection of small B-cell clones in 2.7% of normal individuals, particularly those over the age of 60 years. The significance of these clones which share immunophenotypic features with those of CLL is unknown. As mentioned above, such clones are found with higher frequency in healthy relatives of patients with CLL and an analogy has been made with the concept of MGUS (monoclonal gammopathy of unknown significance), therefore suggesting that some individuals with monoclonal B-cell lymphocytosis (MBCL) may evolve to CLL, but in others it may remain quiescent and not progress. It is also possible that MBCL may be the precursor state for other B-cell disorders, not just CLL.

In distinct contrast to MBCL, a rare abnormality described as polyclonal B-cell lymphocytosis (PBCL) has now been recognized. In affected patients, the absolute number of B cells is increased, not subclinical, but staining with anti-light chain antibodies shows lack of clonality and normal proportions of kappa- and lambda-staining cells. For several reasons, this entity, which appears not to be malignant in nature, needs to be recognized, not least because in some patients it may mimic CLL or other B-cell disorders. Features of PBCL are median age 40 years, lymphocyte count 3–15 (median 6.5), splenomegaly (15%) and mild BM infiltration. Ninety-five per cent of patients are smokers and 90% have HLA-DR7 in their genotype. The cell markers are non-clonal, CD19- and FMC7-positive, CD5 and CD23 are not expressed, and the patients have elevated levels of serum IgM (polyclonal). Despite the benign and non-clonal nature, a distinct abnormality has been shown in the B-lymphocytes: an extra copy of the long arm of chromosome 3 in the form of iso(3q). The blood picture is pleomorphic and frequently shows binucleated lymphocytes (Figure 38.15) which are characteristic of this condition. It is important to follow these patients closely and it is even more important not to institute any treatment.

Management

The indications for active treatment depend on the stage of the disease. For patients with stage A (Binet) or stages 0, I and II (Rai), a period of observation may be necessary to decide whether the pattern of the disease is stable or progressive. Most patients with stage B and two-thirds of those with Rai stage II will show progression within the first year or two after diagnosis. This is manifested by further organ enlargement, a downward trend in the Hb and/or platelets and a slowly rising WBC. As
Figure 38.15 Blood film from a case of polyclonal B-cell lymphocytosis showing a binucleated cell characteristic of this condition.

responses are better with less disease, some trials have compared early versus delayed therapy to see whether survival improves. Both a French trial and an MRC trial showed that early treatment with chlorambucil was, if anything, deleterious, with more deaths due to progression in the group treated early. This was confirmed in a large overview. Thus, the old wisdom of wait and see should continue to prevail for stage A patients, at least for the time being.

Nevertheless, the issue of early treatment in stage A patients with stable disease may now need to be revised, for two main reasons. First, it is now possible to identify better the patients likely to progress through some of the new prognostic factors defined above, e.g. unmutated V_H genes, CD38/ZAP70 expression, short doubling time, 17p or 11q deletions. It is in this group that randomized studies should be carried out to see whether early therapy may improve survival. Second, the purine analogues, alone or in combination, increase the proportion of remitters and the quality of the responses; therefore, there may be a potential benefit of their use early in high-risk cases. It should be remembered that most patients with stage A progressive can be identified by simple criteria: lymphocyte doubling time less than 12 months, downward trend in Hb and/or platelets, 50% or more increase in organomegaly and constitutional symptoms. In the CLL3 and CLL4 trials, the survival of these patients (who were entered with the above criteria) was similar to that of patients with stage B disease. It is also likely that in this group of patients one will find the poor prognostic factors defined by laboratory studies.

We should be aware that spontaneous clinical remissions may occur in CLL but these are not complete. We reported 10 patients (eight with stage A and two with stage B disease) who achieved remission without any therapy. Two had trisomy 12. Based on patients entered in MRC CLL trials, 1.5% of stage A patients may undergo a spontaneous reduction of the lymphocyte count greater than 50%.

Criteria for response

The definitions of response used in the UK for CLL3 and CLL4 trials are broadly similar to the National Cancer Institute (NCI) guidelines used in the USA. A bone marrow biopsy is required to define the new category of nodular partial remission (PR) by the presence of discrete or moderately large nodules of residual CLL. In this context, it is important to carry out immunohistochemistry as in some patients the nodules may contain mainly T cells rather than B cells. The former cases should be defined as achieving complete remission (CR). CR requires normalization of blood counts and the bone marrow whereas a PR requires the regression of at least 50% of organomegaly and lymphocyte counts (in the UK trials the requirement is a lymphocyte count less than 15×10^9/L). The NCI identifies rare groups of patients who may fulfil the criteria of CR except for persistent anaemia or thrombocytopenia. This may be due to persistent myelotoxicity or autoimmune phenomena. The NCI proposed that such cases be included as PRs. Another criterion for response proposed originally by the International Workshop on CLL but not widely used now is the downgrading of stages B or C to stage A for CR and from stage C to B for PR.

It has been shown recently that refinements in flow cytometry may contribute to defining minimal residual disease (MRD) with the same level of sensitivity or even greater than molecular methods (e.g. PCR). Flow cytometry requires at least two antibodies, CD5 and CD19, and gating on the B cells (CD19$^+$). A more sensitive quantitation can be achieved by means of four antibodies: CD5, CD19, CD20 and CD79b. This improves the criteria for CR which can now be subclassified as MRD$^+$ or MRD$^-$. MRD positivity, i.e. more than 0.05% bone marrow cells, predicts for a short event-free survival. Flow cytometry is also useful to monitor peripheral blood counts when lymphocyte counts are less than 1×10^9/L after therapy. The detection of MRD$^+$ cells in the PB usually correlates with persistence of at least 5% CLL lymphocytes in the bone marrow.

Treatment

Table 38.8 lists all the agents which can be used alone or in combination for the treatment of CLL. The list has been enriched with three nucleoside analogues and two monoclonal antibodies and illustrates the greater potential that now exists for achieving a greater number of good responses when these are used as first-, second- or even third-line therapy.

The role of corticosteroids as initial treatment for stage C patients is generally accepted. Platelets rise within 4–6 weeks; the Hb also rises; the WBC follows a characteristic curve, rising after 3 or 4 weeks, sometimes doubling the initial count and then gradually coming down. This is nearly always accompanied by a decrease in size and softening of lymph nodes and spleen. This beneficial effect facilitates the subsequent measures which employ agents having an effect on normal haemopoietic cells,

Table 38.8 Agents used alone or in combination for the treatment of CLL.

- Chlorambucil (oral)
- Cyclophosphamide (oral/i.v.)
- Prednisolone (standard/high dose)
- Fludarabine (oral/i.v.)
- Cladribine (2-CdA; i.v./s.c.)
- Pentostatin (DCF; i.v.)
- Rituximab (anti-CD20)
- Campath-1H (anti-CD52; i.v./s.c.)
- Genasense (BCL2 antisense)
- Zevalin (rituximab + yttrium-90)

and it seems more important when used before chlorambucil. Because of the side-effects associated with their use, it is advisable to retain steroids only for the early treatment of bone marrow failure and for autoimmune complications.

There is no evidence that chlorambucil given monthly in higher doses is more effective than a low dose administered continuously. However, the intermittent dose achieves the same effect with a smaller amount of the alkylating agent, and there is no evidence that adding prednisolone to the monthly courses of chlorambucil increases response rate or prolongs survival. It should be noted that the doses of chlorambucil (and of cyclophosphamide) have varied widely in different studies and there is clear indication of a dose–response curve. For example, the CALGB trial and the German CLL5 trial used chlorambucil at a dose equivalent to 40 mg/m^2 monthly and the reported CR rates were 3% and 5%, whereas the CLL3 trial used 60 mg/m^2 and the CR rate was 19%. In CLL4, the dose has been increased to 70 mg/m^2 (given as 10 mg/m^2 for 7 days every 4 weeks).

There have been several trials comparing chlorambucil with the combination COP (cyclophosphamide, oncovin and prednisolone); none showed an advantage for COP. It is apparent that the antimitotic agent oncovin (vincristine) has little role in CLL and in other similarly slowly progressive diseases. The value of prednisolone given monthly in COP is no better than when used with chlorambucil. Cyclophosphamide has no advantage over chlorambucil although it may be better as an immunosuppressive agent used continuously in patients with AHA.

The role of anthracyclines in the treatment of CLL is not clear but it is likely to be small. The combination of epirubicin with chlorambucil in CLL3 did not show an improved survival and only a marginally higher CR rate (22%). When used as the combination cyclophosphamide, doxorubicin, oncovin and prednisone (CHOP), it may be useful for patients with progressive disease who are poor responders to chlorambucil or fludarabine and for those who developed Richter's syndrome. The French version, or 'mini'-CHOP, uses more cyclophosphamide and half the dose of doxorubicin and in their large randomized trial proved better than the combination CAP (standard doses

as CHOP but minus oncovin). The complete haematological responses with mini-CHOP in previously untreated CLL were almost as good (33%) as with fludarabine (40%), but patients treated with the latter had a longer disease-free interval.

CLL lymphocytes are very sensitive to low-dose irradiation; splenic irradiation has been used in the early MRC trials and its general effect is sometimes manifested by a reduction in peripheral lymphadenopathy. The spleen size often regresses to become unpalpable and there is a dramatic fall in the WBC. This modality is now rarely used but the effect of irradiation is still exploited in transplantation protocols as total body irradiation (TBI).

Of the new generation of nucleoside analogues in the last decade, fludarabine has shown greatest promise for the treatment of CLL and low-grade NHL. Fludarabine has several modes of action which include inhibition of DNA synthesis and DNA repair and activation of the apoptotic pathways. These mechanisms enhance significantly the effect of this agent when used in combination with other drugs, e.g. cyclophosphamide and mitozantrone, and antibodies, e.g. rituximab. The main work carried out by Keating *et al.* in the 1990s at the MD Anderson Cancer Center showed that fludarabine has a high CR rate (~33%) in previously untreated patients, and still has high responses (15–20%) in those previously treated. This latter experience has been confirmed in the UK with evidence of lack of cross-resistance with chlorambucil or anthracycline-containing combinations. In the non-responders to chlorambucil or chlorambucil plus epirubicin in CLL3, the CR rate of single-agent fludarabine was 17%, with 64% PR.

The issue of first-line fludarabine and/or its combination with cyclophosphamide is currently being assessed in CLL4. Two large trials, French and American, showed a high response and prolonged disease-free survival but no overall survival advantage using first-line fludarabine against CAP or chlorambucil. Of interest is that the crossover of non-responders to chlorambucil in the CALGB study achieved 40% responses with fludarabine but, of the non-responders to fludarabine, only 7% responded to chlorambucil.

Using fludarabine in combination with other agents the CR rates have increased, e.g. from 20–35% when used alone in previously untreated patients to 30–45% with cyclophosphamide, 45% with rituximab and 65% with the combination FCR (fludarabine, cyclophosphamide and rituximab) in the MD Anderson experience. FCMR (adding mitozantrone) may be an even more powerful combination, but it has been used only in the salvage setting to improve on the already good responses achieved with FCM (without rituximab).

The downside of using strong combinations with fludarabine is that they are more myelotoxic (manifested as neutropenia) and immunosuppressive (manifested as lymphopenia) and care should be taken to take prophylactic measures such as using cotrimoxazole to prevent *Pneumocystis carinii* pneumonia (PCP) and aciclovir to prevent herpesvirus reactivations. On the positive

side is that responses may last longer and flow cytometry now shows many cases with negative MRD.

New studies will show whether patients with poor prognostic features also benefit from these more intensive regimens. Those in the worse category, represented by those with p53 abnormalities, do not respond to alkylating agents but may respond to high-dose methylprednisolone (HDMP) given in 5-day pulses monthly at 1 g/m^2 intravenously or by mouth and may respond to Campath-1H, a monoclonal antibody with activity against B and T cells. In our studies with HDMP, we relied on the prediction assessed by an *in vitro* cytotoxicity assay, or DiSC assay, and we observed good responses in 50% of cases with p53 abnormalities.

The introduction of Campath-1H (alemtuzumab) and rituximab has opened the door of more targeted biological agents with little or no myelotoxicity. Campath-1H (anti-CD52) acts through antibody- and complement-mediated cytotoxicity and can be used intravenously or by subcutaneous injection. It has potent activity in previously untreated CLL but requires prolonged periods (18 weeks) of treatment to achieve CR, according to a Swedish study, when given subcutaneously. In previously treated and fludarabine-resistant CLL the CR rate is 2%, but 31% achieve a PR. Its role in the management of CLL continues in active investigation, whether as first line, as consolidation to improve the quality of remission and MRD and/or as salvage therapy to rescue resistant cases. Currently, too, Campath is being tested in combination with fludarabine and with rituximab. The combination of Campath-1H with rituximab has been reported to achieve 8% CR and 44% PR (including 40% nodular PR) in relapsed and refractory CLL. The rationale is based, in addition to lack of overlapping toxicities, on the greater effect of Campath-1H in clearing blood, bone marrow and spleen and the greater effect of rituximab in reducing nodal masses.

Rituximab (anti-CD20) has potent activity in high- and low-grade NHL and CLL when used in combination with fludarabine, FC, FCM, chlorambucil and HDMP. Its mechanism of action is by complement-dependent cytotoxicity, activation of the intrinsic pathway of apoptosis and membrane-associated kinases. The lack of T-cell immunosuppression and its good tolerability makes it ideal for older individuals. Several studies are ongoing but it is likely that all will be positive, the limiting factor remaining its high cost. Different from Campath, too, is that rituximab has limited activity on its own, unless used in very high doses, therefore remaining as an effective potentiator of apoptosis in combination with cytotoxic drugs.

Two other purine analogues with good activity in CLL are cladribine (2-chlorodeoxyadenosine or 2-CDA) and pentostatin (2-deoxycoformycin or DCF). Cladribine, in particular, can achieve as good responses as fludarabine and, in previously untreated CLL, the CR rate of the combination cladribine plus cyclophosphamide has been reported as 29% and nodular PR 24%. Although cladribine and fludarabine have not been compared directly, cladribine appears to be the more myelotoxic of the two agents.

The role of splenectomy

Splenectomy is indicated for patients with a large spleen and in whom the initial treatment achieves only a moderate reduction of the spleen size. Patients with features of hypersplenism (peripheral cytopenias and an active bone marrow) benefit from splenectomy. Splenectomy is indicated for patients with autoimmune thrombocytopenia (ITP) or haemolytic anaemia (AHA) refractory to corticosteroids. In our experience, this procedure has been associated with no mortality and seems to have been of great benefit to patients with a large spleen and blood counts consistent with stage C disease. Provided patients are given long-term penicillin, this operation often has a beneficial effect on the disease, even if only as part of a debulking procedure. Prophylaxis with pneumococcal vaccines may not be effective in advanced CLL where antibody formation is reduced, although there is evidence of antibody responses to *Haemophilus influenza* B (HiB) vaccinations. Even in patients with very advanced CLL, splenectomy improves quality of life by raising Hb levels and improving platelet counts in about 50% of them. This operation generally prolongs life and facilitates the subsequent use of further chemotherapy. A rise in the lymphocyte count is often seen after splenectomy, but still one-third of patients do not require therapy for long periods. The post-splenectomy survival was 4.7 years in our series of 47 cases of CLL.

Stem cell transplantation (SCT)

The possibility of achieving a higher rate of CR in CLL and the fact that 15% of patients are diagnosed before the age of 50 years led investigators to explore ways of improving the duration of remission or even attempting a cure by means of high-dose therapy and SCT rescue. The number of autologous and allogeneic transplants for CLL has increased dramatically in Europe in the last decade. Three modalities are currently considered: autologous SCT, conventional allogeneic with high-intensity therapy and allogeneic with low-intensity procedures, or 'mini' allografts. There are no published randomized trials, but the overall picture is reflected in the statistics collected by the European Bone Marrow Transplant (EBMT) Organization.

The feasibility of autologous SCT in CLL was tested in the MRC pilot study, which registered just over 100 patients between 1996 and 2001. After remission with fludarabine and priming with cyclophosphamide, a peripheral blood stem cell harvest was planned in the good remitters (CR, nodular PR). Only two-thirds of patients were transplanted after high-dose cyclophosphamide and TBI. Failure to do so was because of inadequate remission in 20% and failure to harvest enough stem cells (CD34$^+$ cells) in those achieving remission. What is clear, from this and other autograft studies, is that high-dose therapy may prolong remission duration with little or no transplant-related mortality (TRM). The question of long-term benefits is currently being tested in a European intergroup study, which in the

UK is MRC CLL5. It is clear that this therapy does not provide a cure as ~50% relapse in the first 5 years. A German study showed that patients with unmutated V_H genes do significantly less well than those with mutated V_H genes. Comparison of unmutated cases with a matched group treated without autograft suggests that this therapy may, in fact, be more beneficial to the unmutated or poor prognostic cases than to the mutated ones.

Allogeneic transplants in CLL may offer the chance of a cure in a minority of patients. However, the TRM of conventional allografts is ~40% in the EBMT database. Even if these figures improve in selected centres, the high mortality is unacceptable. The new modality of 'mini' allograft has lower TRM of around 18%, which is still higher than with autografts (~5%). Long-term results are not available with mini allografts, but figures of overall survival at 3 years are encouraging, though no better than with autografts. The use of unrelated donors is still experimental, but currently the TRM is high, even with the low-intensity procedures.

Management of autoimmune complications

The most common immune complications in CLL are AHA, ITP and pure red cell aplasia (PRCA). Control of haemolysis can be achieved by corticosteroids (prednisolone or dexamethasone), but long-term management requires the direct antiglobulin test to become negative. This can be achieved with the addition of another agent, usually daily cyclophosphamide (e.g. 100 mg/day), cyclosporin A (e.g. 150 mg twice a day) or mycophenolate mofetil (e.g. 1 g twice a day). Rarely, in resistant cases, these agents may be used in combination. The advantage of cyclophosphamide is that it may provide a degree of control of the CLL. Rituximab has been reported to have beneficial effect when used in combination with cyclophosphamide and dexamethasone. AHA often needs long-term treatment and may require a splenectomy. When the direct antiglobulin test remains positive, the risk of haemolysis remains.

Immune thrombocytopenia, although less common, also requires active treatment as for AHA. High-dose gammaglobulin infusions over 5 days may improve the platelet count and are often a good guide as to the subsequent benefit of splenectomy. Cyclosporin A and rituximab are both effective in refractory ITP. Slow infusions of vinca alkaloids, e.g. 1 mg of vincristine, and danazol have been useful in some cases. ITP is usually more difficult to manage than AHA and, more often than in the latter, one needs to resort to splenectomy.

Pure red cell aplasia is an uncommon but well-recognized complication. Some cases are secondary to a parvovirus B19 infection. Rituximab and Campath-1H have been reported to be able to reverse this process which is sometimes very acute. It is paradoxical that rituximab and Campath-1H have occasionally been reported to facilitate parvovirus infection and cause PRCA. Rituximab has also been associated with delayed-onset neutropenia. On the other hand, fludarabine can occasionally induce

remission of PRCA and refractory ITP, although more commonly it has the opposite effect. The exact mechanism of the immune complications in CLL is still poorly understood and this explains the unusual, but well-documented, reports of the same agents causing or correcting these complications.

Supportive care

The main objective of treatment for CLL is to prolong survival with a good quality of life; therefore, care should be taken to prevent and/or treat promptly any complications arising from the immunodeficiency associated with the disease or its treatment. Thus, prompt antibiotic treatment for seemingly benign upper respiratory tract infections and antiviral measures to prevent the spread of herpetic infections are as important as the specific treatment for the disease. Patients with repeated infections and very low gammaglobulin levels may benefit from courses of intravenous gammaglobulin injections, e.g. 400 mg/kg every 4 weeks, particularly during the winter. Additional measures are the administration of allopurinol when starting therapy with a WBC $> 50 \times 10^9$/L, oral antifungals and H_2 blockers or proton pump inhibitors when using corticosteroids.

Causes of infection in CLL are multifactorial. Neutropenic episodes during chemotherapy require the use of G-CSF. Patients with long-term respiratory infections may require active prophylactic measures such as nebulized antibiotics to prevent Gram-negative infections. Cotrimoxazole is mandatory to prevent infections, particularly PCP, when fludarabine or Campath-1H are used. The latter requires regular monitoring for cytomegalovirus (CMV) and prompt treatment when such immunosuppressed patients, usually lymphopenic, become symptomatic and positive for CMV. The main factors predisposing to infections in CLL are the number of chemotherapy regimens and the activity of the disease more than the levels of serum immunoglobulins.

Erythropoietin (Epo) is now an accepted treatment for anaemia associated with cancer therapy. Patients with CLL and persistent anaemia (Hb < 10 g/dL) will benefit from Epo given three times a week or 40 000 units weekly. There is strong evidence for benefits, particularly an improvement in quality of life. Epo should be given for a minimum of 4 weeks before deciding that there is no response, and iron deposits need to be adequate. There is no evidence that Epo is useful in PRCA. Folic acid supplements are often useful in patients with macrocytic indices resulting from low folate levels. They should always be given in AHA.

Secondary MDS/AML

The increased intensity of treatments, in particular combinations of alkylating agents and purine analogues, may be responsible for an increased incidence of secondary myelodysplasia and acute myeloid leukaemia in CLL. Combinations with mitozantrone

and the use of TBI for stem cell transplants are also major risk factors for these secondary events. Single-agent therapy with chlorambucil or fludarabine is rarely associated with MDS/AML.

Prolymphocytic leukaemia

Prolymphocytic leukaemia (B-PLL) was considered a variant of CLL since its description by Galton *et al.* in 1974. In the last decade it has become apparent that there are important clinical and laboratory differences between these two disorders which, despite the existence of the group with CLL/PL discussed above, suggest that B-PLL is a distinct, but rare, disorder. This is supported by differences in the morphology and cell markers (Table 38.2), physical signs (almost exclusively splenomegaly in PLL) and clinical evolution. The key for diagnosis is the recognition of the prolymphocyte as the predominant cell in well-prepared peripheral blood films. The mean age of patients presenting with B-PLL is 70 years, which is 5 years older than the main age of CLL patients.

The main features of B-PLL are splenomegaly without lymphadenopathy, and a high WBC, usually over 100×10^9/L at the time of presentation. Anaemia and thrombocytopenia (as for stage C CLL) are seen in at least 50% of cases. Other laboratory findings are no different from high-count CLL – increased uric acid, low serum immunoglobulins – but the incidence of a monoclonal band appears to be higher than in CLL.

Differential diagnosis

The main diagnostic criterion is the identification of prolymphocytes as the predominant population in blood films. Usually, 55% prolymphocytes is the figure that discriminates B-PLL from CLL and CLL/PL, although the percentage of prolymphocytes in B-PLL is usually greater than 70%. The prolymphocyte is twice the size of a small CLL lymphocyte, has moderately condensed nuclear chromatin, a prominent central nucleolus and a lower nucleolus:cytoplasmic ratio than CLL cells (Figure 38.16). B prolymphocytes are more uniform and have a more regular nuclear outline than those of CLL/PL. They are larger and have clearer cytoplasm and a lower nucleolus:cytoplasmic ratio than T prolymphocytes. Using the scoring system depicted in Table 38.1, most B-PLL scored 0–1 and, rarely, 2 or 3. One-third of cases of B-PLL may be CD5 positive; this and other features may present a diagnostic problem with MCL with leukaemia.

The distinction from HCL variant is based mainly on the appearances of the cytoplasm; in HCL variant the cytoplasm is more abundant and distinctly villous, whereas in B-PLL it is generally smooth.

The issue of MCL was reviewed recently by us in eight cases diagnosed in the past as B-PLL but bearing the translocation t(11;14)(q13;32) characteristic of MCL. Detailed histology review and comparison with 13 cases of B-PLL without t(11;14) led us
Figure 38.16 Typical blood film from a case of B-prolymphocytic leukaemia with the characteristic large size, abundant cytoplasm and prominent nucleolus.

to the conclusion that the cases with t(11;14) and which overexpress cyclin D1 represent a splenomegalic form of MCL.

Treatment

Alkylating agents, e.g. chlorambucil or the combination COP, are of little value in the management of B-PLL. Response rates (partial responses and rare CRs) to splenic irradiation and/or the combination cyclophosphamide, doxorubicin, oncovin and prednisone (CHOP) have been recorded in up to one-third of cases. Splenectomy is often useful to remove a major proliferative focus which represents a considerable part of the tumour mass in this disease, to relieve hypersplenism and facilitate further therapy. Considering the older age group affected by B-PLL, splenectomy is not a practical proposition in some patients. Preliminary data suggest that 50% of patients may respond with partial or complete remission to fludarabine. There are insufficient data on the use of fludarabine combinations (FC, FCM, FCR) in B-PLL. One of the reasons for the poor response to therapy in this disease is the high frequency of p53 abnormalities, documented in 50–60% of cases.

Hairy cell leukaemia

Hairy cell leukaemia (HCL) is a well-recognized clinicopathological entity which affects males more frequently than females (M/F ratio 4:1), usually over the age of 40 years. The disease has, historically, elicited great interest, for different reasons: in the 1960s, in order to establish the diagnostic features of the newly described entity and subsequently, in the 1970s and 80s, advances in immunology led to the identification of the hairy cell as a B cell and demonstrated rearrangement of the heavy- and light-chain immunoglobulin genes. In the 1980s and 1990s,

HCL attracted considerable attention because of the significant advances in its treatment, first with alpha-interferon (IFN-α) and later with the purine analogues pentostatin and cladribine.

Clinical and laboratory findings

The main disease features result from the pancytopenia affecting most patients. HCL patients are moderately neutropenic and severely monocytopenic; thus, bacterial and opportunistic infections do occur. There is evidence that the incidence of typical and atypical mycobacterial infections is increased, but this was seen more frequently before the current treatments became available.

The main physical signs are splenomegaly and hepatomegaly. Lymphadenopathy is rare, but we have reported cases with massive abdominal lymphadenopathy and morphological features suggestive of transformation. A survey by routine CT scan showed a higher incidence than hitherto suspected of enlarged abdominal nodes. This is seen more often in relapsed patients and those with long-standing HCL and it tends to correlate with bulky disease.

Anaemia results from reduced bone marrow production and splenic pooling. Haemolysis is exceptional. The WBC may be low, normal or high (rarely above 20×10^9/L), but neutropenia and monocytopenia are constant. Some patients have no detectable hairy cells on blood films; two-thirds have 10–15% and others more than 50%. Patients with low WBC and no circulating hairy cells present diagnostic problems. Platelet counts are below 100×10^9/L in most cases.

Diagnosis

The recognition of typical hairy cells in peripheral blood films is useful for establishing or suggesting this diagnosis. Hairy cells are large – twice the size of a normal lymphocyte – and have abundant cytoplasm (low N/C ratio) which is characteristically villous in its outline (Figure 38.17). The nucleus is round, oval or slightly indented, and occasionally bilobed. A smooth nuclear chromatin, absence of a visible nucleolus and low N/C ratio are landmarks of typical hairy cells. Cells from the rare HCL variant have similar cytoplasmic features but have a round nucleolus with more condensed chromatin and a distinct nucleolus resembling prolymphocytes (Figure 38.18).

Bone marrow aspirates are, as a rule, unsuccessful as no fragments and few cells are obtained. Therefore, a trephine biopsy is essential. This shows diffuse interstitial infiltration of variable degree; occasionally the infiltration is focal. A typical feature is the arrangement of the cellular infiltrate, which is loose, leaving plenty of space between cells, often with a clear zone around each cell which is unique to this condition (Figures 38.19 and 38.20). This contrasts with the more dense infiltration in CLL and PLL or the paratrabecular involvement in NHL. Reticulin is always increased (Figure 38.21) and the cells stain strongly with

Figure 38.23 Staining for CD20 in a patient treated for HCL showing a cluster of residual CD20$^+$ cells, suggesting that the remission is incomplete.

anti-CD20 (Figure 38.22). The immunocytochemical staining for CD20 is crucial to demonstrate clusters of hairy cells following therapy, suggesting residual disease. This is otherwise difficult to assess on conventional sections (Figure 38.23).

Spleen histology, when available, shows distinct diagnostic features: infiltration by mononuclear cells with a blunt nucleus in the red pulp with little residual white pulp, and formation of pseudosinuses filled with erythrocytes ('red cell lakes'). Tartrate-resistant acid phosphatase (TRAP) demonstrated on hairy cells corresponds to a unique isoenzyme 5 and is specific for HCL. This enzyme is now tested by means of a MAb. Electron microscopy reveals ribosome–lamella complexes in one-third of the cases. Rarely, this intracytoplasmic inclusion can be seen on light microscopy.

Hairy cells are considered activated B cells with features of late maturation stages. SmIg is usually strong and characteristically shows several heavy-chain isotopes, often including IgA and IgG and sharing a single heavy chain. The cells of most cases of HCL variant express IgG as a single heavy chain. HCL cells are strongly FMC7, CD20 and CD22 positive but, in contrast to other B-cell disorders, they consistently express CD25, CD103 and CD123. In contrast to CLL, hairy cells are always CD5 negative and their score using the CLL panel is very low (Table 38.2).

The HCL variant is very rare and is characterized by high WBC (50–80 × 10^9/L) and splenomegaly. The cells do not express CD25 and CD123. They are often CD11c positive and, in half of the cases, CD103 is also positive. The bone marrow and spleen histology of the HCL variant closely resemble the typical disease. The main diagnostic difficulty in HCL variant is with splenic marginal zone lymphoma (or SLVL), except for the spleen histology which, in the former is mainly red pulp and in the latter predominantly white pulp.

Treatment

Many modalities have been tried in the past to improve the bone marrow function of patients with HCL. The prime objective of treatment should be the normalization of blood counts, as pancytopenia is the main source of complications, and to induce prolonged remissions. There are now two main agents, cladribine and pentostatin, which are widely used. In the past, only moderate success was seen with low-dose chlorambucil, splenic irradiation or even anthracyclines, and these are no longer indicated in HCL. Other treatments still used but for specific indications are splenectomy and IFN-α.

Splenectomy is a well-established treatment and has been shown to improve the quality of life and prolong survival in this disease. It should now be reserved for patients with very large spleens and some bone marrow reserve. In about 20% of successfully splenectomized patients, the counts remain normal for many years and no other therapy is thus indicated; some of them may never relapse although they may remain with little bone marrow involvement.

Interferon-α was used widely since the first report by Quesada in 1984. IFN-α induces a gradual normalization of blood counts, reduction of hairy cells in the blood and gradually from the bone marrow, return of monocytes and improvement of neutropenia. The improvements in the blood are not associated with a clearance in the bone marrow, and CRs are seen in only 20–30% of cases. The duration of response once IFN-α is discontinued is relatively short (median 15–18 months), although blood counts may remain normal for well over a year. The tendency once therapy has ceased is to relapse slowly. IFN-α is now reserved for problem cases and to help initial treatment in patients with severe cytopenias.

The two agents currently used in HCL, pentostatin (deoxycoformycin) and cladribine (2-chlorodeoxyadenosine), achieve CR in 80–85% of patients, with the remainder being partial responders. True resistance is seldom seen at first treatment. Long-term results are excellent, with very few patients actually dying of HCL. Ninety per cent of all patients and 95% of those with CR are alive at 10 years if one excludes non-HCL causes of death. About 30–40% tend to relapse once treatment is discontinued in the first 5–10 years (Figure 38.24). Relapses after 10 years are rare. Second CRs are obtained in 75% of patients and there is no evidence of cross-resistance between these agents. Despite this, a small group of patients tend to relapse every 2 or 3 years. For this group, plus the rare non-responders to purine analogues and those who achieve only PR, who in our experience have poorer survival than complete remitters, new modalities need to be developed.

Monoclonal antibodies against CD20 (rituximab) and CD22 (coupled with an immunotoxin) have now shown activity in HCL. Hairy cells express strongly CD20 and CD22, and these antibodies seem to achieve good responses in the group of relapsing patients, although, when rituximab is used alone in
Figure 38.24 Disease-free interval (DFI) in previously untreated patients with HCL treated with pentostatin or cladribine, showing a median DFI close to 10 years in those achieving a complete remission (CR1).

cladribine relapses, the CR rate is low (~15%). Its main role may be, as in other B-cell disorders, when used in combination with one of the purine analogues.

Patients with HCL variant respond less well to cladribine and pentostatin and not at all to IFN-α. Good palliation of symptoms and improvement of blood counts can be achieved with splenectomy which, in our experience, has been the most successful modality in this relatively resistant disease.

Supportive care for HCL is confined to patients undergoing therapy with nucleoside analogues, which can cause transient neutropenia in the early phases and prolonged lymphopenia later on. Long-term cotrimoxazole until lymphocyte counts rise above 1×10^9/L and also long periods on aciclovir are recommended. Major infections are only seen in untreated patients or those responding poorly to therapy.

The leukaemic phase of low-grade NHL

There are three types of NHL which not infrequently evolve with lymphocytosis which mimics and can be confused with, CLL. These are follicular lymphoma (FL), splenic marginal zone lymphoma or splenic lymphoma with circulating villous lymphocytes (SLVL) and mantle cell lymphoma (MCL).

Follicular lymphoma

Fifteen per cent of FL patients may have circulating lymphoma cells ($5–20 \times 10^9$/L), and this correlates with bone marrow involvement. A minority may present with WBC > 40×10^9/L (up to 200×10^9/L) and extensive disease, generalized lymphadenopathy and hepatosplenomegaly. Usually the circulating cells
Figure 38.25 Blood film of a patient with follicular lymphoma presenting with significant lymphocytosis (55×10^9/L). The cells show a cleaved nucleus, angular shape, homogeneous chromatin pattern, high N/C ratio and small size.

Figure 38.26 Electron microscopy of a circulating follicular centre lymphocyte showing a deep nuclear cleft.

are very small with almost no visible cytoplasm, the nuclear chromatin is smooth without clumps of heterochromatin and no visible nucleolus, and the nuclear shape is angular and has a small cleft (Figure 38.25). This is seen also at ultrastructural level (Figure 38.26). The differential diagnosis from CLL is supported by the immunophenotype. FL cells usually score 0 or

1 (Figure 38.1). Lymph node histology is essential to confirm a diagnosis of FL. Only patients with very high WBC may have poor prognosis; cases with a minor degree of spillover respond as cases without circulating cells. It is important to recall that late-stage FL may have circulating blasts (centroblasts) characterized by a peripherally located nucleolus and this corresponds with transformation to a large-cell lymphoma.

Splenic lymphoma

Splenic lymphoma with villous lymphocytes has now been recognized by the WHO classification as a distinct pathological entity described as splenic marginal zone lymphoma (SMZL). It is likely that at least two-thirds of patients with this lymphoma have circulating villous lymphocytes. A minority do not have frankly villous cells despite being clonal and in some the diagnosis can be suspected without circulating lymphocytes but can only be established after splenectomy. Therefore, the true incidence of this condition without circulating villous cells is unknown. A Spanish study of 60 patients, all splenectomized, described > 5% circulating abnormal cells in 68%, with a WBC greater than 4×10^9/L in 70%; their median lymphocyte count was ~8×10^9/L. Our own data on 129 patients with SLVL showed a median WBC of 16×10^9/L, median Hb of 11.8 g/dL and platelets 145×10^9/L.

Splenic lymphoma with villous lymphocytes is an indolent form of NHL. The median age of patients is 69 years and the majority present with splenomegaly. There is a slight female predominance. Anaemia and/or thrombocytopenia are seen in 40% of cases. One-third of patients have a serum monoclonal band, usually IgM below 30 g/L. Diagnosis is suspected on a typical blood film (Figure 38.27) showing small lymphocytes with an irregular membrane outline and short villi, often confined to
Figure 38.27 Lymphocytes from a case of splenic lymphoma with circulating villous lymphocytes.
Figure 38.28 Bone marrow trephine biopsy from a case of SLVL showing the characteristic intrasinusoidal infiltration seen in this disease highlighted by the anti-CD20 antibody.

one pole of the cells. A nucleolus is visible in half of the cases. Cytoplasmic basophilia is seen in ~10% of lymphocytes. The immunophenotype (Table 38.2) is different from CLL. SLVL cells can be distinguished from HCL and the HCL variant because they are negative with CD103 and CD123; they express CD25 and are always CD11c positive.

Bone marrow aspirates may show the same cells as in the blood, with variable degrees of infiltration. It has become apparent in the last few years that a distinct pattern of intrasinusoidal infiltration (Figure 38.28) is characteristic of SLVL and is highlighted with anti-B-cell antibodies (CD20, CD79a). This pattern of infiltration is rare in other types of NHL. In addition, the pattern of bone marrow infiltration can be nodular, interstitial and/or paratrabecular.

The spleen histology shows a characteristic bizoned pattern in the white pulp with a central zone of small lymphocytes with scanty cytoplasm and a peripheral zone of larger cells with more dispersed chromatin and more abundant cytoplasm. The red pulp is always infiltrated by both the smaller and larger cells. Plasmacytic differentiation may be seen.

There is no unique cytogenetic abnormality in SLVL but unbalanced translocations and deletions of 7q22–32 have been described in ~30%; 50% of cases have a monoallelic deletion at 13q14 but, in contrast to CLL, it affects mainly the RB1 locus. Trisomy 3, an abnormality seen in extranodal marginal zone lymphoma, has been found in 17% of cases. Abnormalities of p53 (mainly deletions) are found in 17% of cases and are associated with worse prognosis. Studies of the IgV$_H$ genes shows a heterogeneous pattern of mutations. Two-thirds of cases show V$_H$ mutations and one-third of cases are unmutated, currently without any apparent clinical or prognostic implications. Ongo-

ing mutations, a feature also seen in FL, has been observed in some cases.

An association with hepatitis C has been reported but the incidence of this event is unknown. Of interest is that IFN-α has been reported to induce CR in hepatitis C-positive SLVL patients. An association in hyper-reactive malaria and tropical splenomegaly has been described in African cases. Large-cell transformation is seen in 10% of cases, and this is related to p53 abnormalities.

Splenectomy is the treatment of choice in this disease, with splenectomized patients faring significantly better than those treated with chemotherapy only. Conventional therapies with alkylating agents and the combination CHOP are not very effective. Fludarabine has been recently reported to induce a high rate of complete remissions. The median survival in our series is 13 years, with 72% of patients alive at 5 years. Anaemia and lymphocytosis greater than 16×10^9/L seem to be associated with worse outcome.

Mantle cell lymphoma

Mantle cell lymphoma has been recognized as a distinct pathological entity for the last 12 years. Blood and bone marrow involvement are common. Possibly 40–50% of cases of MCL evolving with splenomegaly (non-nodal form) have significant lymphocytosis, sometimes mimicking CLL, CLL/PL or B-PLL (see above).

Morphologically, the cells are of medium size with a variable amount of cytoplasm, an irregular nucleus with nuclear cleft, a distinctly stippled chromatin pattern and an indistinct nucleolus (Figure 38.29). When the latter is seen in many cells, B-PLL is suspected. If the small lymphocytes predominate or if there is a mixture of small and large cells, CLL/PL is suspected. Rare cases, in our experience, have a high WBC count with cells resembling
Figure 38.29 Blood film from a patient with mantle cell lymphoma and lymphocytosis. The cells are medium size, slightly irregular in shape and have a speckled nuclear chromatin pattern.

those of SLVL. A lymphoblastoid form with blast-like cells has also been recognized.

Marker studies show that MCL cells are always CD5$^+$, CD19$^+$, CD20$^+$, thus raising the issue of CLL. In a series of over 60 cases which we studied, the majority (68%) scored 1, being CD5$^+$ but CD23$^-$ (in contrast to CLL), 17% scored 0 (CD5$^-$, CD23$^-$) and 15% scored 2 or 3 (CD5$^+$, CD23$^+$).

The bone marrow trephine biopsy shows a rather monotonous infiltration by slightly irregular cells. Crucially, and in contrast with CLL and particularly CLL/PL, no proliferating centres are seen in MCL (nor in the lymph node biopsies). The pattern of bone marrow infiltration is often diffuse in advanced cases, but in other cases is nodular and/or paratrabecular.

The characteristic translocation t(11;14)(q13;q32) is demonstrated in all cases by conventional cytogenetics or more easily by FISH analysis. The rearrangement of the *Bcl-1/PRAD*-1 gene at 11q13 results in the overexpression of cyclin D1, one of the proteins that controls the cell cycle. Cyclin D1 can be demonstrated in histological sections. Techniques for its demonstration by flow cytometry or by detecting cyclin D1 mRNA are also available but are less simple.

The correlation between cyclin D1 overexpression and t(11;14) is very high, in our experience. Studies on the mutational status of the IgV$_H$ genes has demonstrated, as in CLL and SLVL, molecular heterogeneity. About 30% of patients showed a mutated pattern and biased use of specific V$_H$ segments, particularly V$_H$3–21 and V$_H$3–34, which are seen also in mutated cases of CLL. A UK study showed different patterns of V$_H$ mutations in MCL presenting with lymphocytosis. Among a group described as non-nodal (76% had splenomegaly), 56% of patients had mutated V$_H$ genes, while 90% of the group with peripheral lymphadenopathy, described as nodal, had unmutated V$_H$ genes. There was a significant survival difference between these two groups: the non-nodal group had a median survival of 79 months whilst in the nodal group it was 30 months. Although the mutational status did not affect survival per se, a small group of long survivors were seen in the mutated group.

Therapy in MCL has been unsatisfactory, although improvements have recently been reported using fludarabine combinations such as fludarabine, cyclophosphamide and mitozantrone plus rituximab, as reported by a German study. A significant proportion of MCL patients have p53 abnormalities which underlie their poor response to therapy.

We reported good responses to splenectomy in MCL patients with leukaemia and splenomegaly. The average weight of the spleen in this group was 2.6 kg. Two-thirds of the patients benefited, with improvements in blood counts. A minority of the patients (4 out of 16) did not require further therapy for relatively prolonged periods, with improvements in the pre-existing cytopenias. It is possible that the group which most benefits from splenectomy is the one with mutated V$_H$ genes and described as non-nodal in the study by Orchard *et al.* (2003).

T-cell lymphoproliferative disorders

39

Estella Matutes

Introduction and classification

The chronic or mature T-cell lymphoproliferative disorders comprise a variety of disease entities which result from the clonal proliferation of post-thymic T lymphocytes. They should be distinguished from the immature or thymic derived T-cell neoplasms, i.e. T-cell acute lymphoblastic leukaemia (T-ALL) and lymphoblastic lymphomas as the disease course and therapeutic approaches are very different. The distinction between these two groups of T-cell malignancies is made on clinical grounds, immunophenotype and cell morphology [terminal transferase (TdT)-positive blasts in T-ALL compared with TdT-negative mature T lymphocytes in chronic T-cell disorders].

The incidence of the T-cell disorders varies around the world. Overall they are more common in Eastern and rare in Western countries, where they account for 10–15% of lymphoid malignancies. This different distribution may relate to both host and environmental factors. Advances in immunophenotyping and molecular cytogenetics together with a detailed analysis of the cell morphology and histopathology have significantly contributed to a more precise classification of the T-cell neoplasms. Further, the role of viruses in T-cell malignancies, essentially the Epstein–Barr virus (EBV) and the human T-cell leukaemia lymphoma virus type I (HTLV-I), has been well recognized. HTLV-I is the primary aetiological agent of adult T-cell leukaemia lymphoma (ATLL), and EBV has been shown to be involved in the pathogenesis of certain lymphomas such as the extranodal nasal angiocentric lymphomas.

These advances have not only shed some light onto the pathogenesis of these diseases but have also resulted in better approaches to managing these patients. Information on the gene profiles assessed by microarray analysis is scanty and still in its infancy. However, it is likely that in the near future they will have a major impact by allowing the devising of novel targeted therapies as well as helping to elucidate new genes or oncogenes involved in the pathogenesis of these disorders.

For classification purposes of the T-lymphoproliferative disorders, it is essential to compound the clinical features with laboratory investigations. The latter should include (i) lymphocyte morphology; (ii) histology of bone marrow and lymphoid tissues; (iii) immunological markers; (iv) cytogenetics using standard techniques or fluorescence *in situ* hybridization (FISH); (v) analysis of the T-cell receptor (TCR) chain genes by Southern blot or polymerase chain reaction (PCR) to demonstrate clonality of the T-cell population; and (vi) serology for HTLV-I and, if needed, DNA analysis to document the clonal integration of this retrovirus. Some of these investigations are key diagnostic tests while others may have prognostic or therapeutical implications. In addition, molecular analysis to search for certain oncogenes such as *TCL-1*, *p53*, etc. is relevant by giving some clues in the pathogenesis and/or progression of the disease.

On the basis of the clinical manifestations and origin of the neoplasm, the T-lymphoid disorders can be classified in three main groups: (i) primary leukaemias which arise in the bone marrow and evolve with a leukaemic picture; (ii) leukaemia/lymphoma syndromes or the leukaemic phase of T-cell lymphomas (T-NHL) in which the tumour arises in lymphoid tissues but a leukaemic picture is very common; and (iii) T-NHL, which originate in peripheral lymphoid tissues and very rarely involve the blood. Each of these groups includes disease entities distinguishable by their clinical and laboratory features and the majority have been recognized as such by the WHO classification (Table 39.1).

The disease features of the T-cell malignancies, the basis for diagnosis, their prognosis and management as well as the pathogenic events involved in disease initiation and/or progression will be described.

Primary leukaemias

This group includes two diseases: T-prolymphocytic leukaemia (T-PLL) and T-cell large granular lymphocyte leukaemia (T-LGL leukaemia).

Table 39.1 Classification of T-cell lymphoproliferative disorders.

Primary leukaemias
T-cell prolymphocytic leukaemia (T-PLL)
T-cell large granular lymphocyte (LGL) leukaemia

Leukaemia/lymphoma syndromes
Sézary's syndrome (SS)/mycosis fungoides (MF)
Adult T-cell leukaemia lymphoma (ATLL)

Peripheral T-cell lymphomas (T-NHL)
Unspecified
Specific variants
    Hepatosplenic γ/δ T-NHL
    Subcutaneous panniculitis-like T-NHL
    Angioimmunoblastic (AIL)
    Extranodal T/NK, nasal type
    Enteropathy T-NHL (intestinal)
    Anaplastic large-cell lymphoma (ALCL)

T-prolymphocytic leukaemia (T-PLL)

T-prolymphocytic leukaemia was first documented in a patient presenting with clinical features similar to B-PLL but in whom the cells had a T-cell phenotype. T-PLL is recognized in the WHO classification as a distinct T-cell disorder with three morphological variants. Despite the morphological heterogeneity, all these variants have a similar clinical course and identical molecular genetics.

Aetiology

T-prolymphocytic leukaemia is a rare disease and together with B-cell PLL accounts for around 2% of all mature lymphoid leukaemias. It is overall more frequent than B-cell PLL. T-PLL has been described in the West and East without a geographical or racial clustering. There is no evidence that radiation, carcinogenic agents and/or viruses play a role in the pathogenesis of T-PLL. However, there is a prevalence of T-PLL in patients with ataxia telangiectasia (AT) and it has been speculated, but not yet proven, that the AT mutated gene (*ATM*) may play a role in the development of T-PLL (see Pathogenesis).

Clinical features

T-PLL affects adults (median age 65 years) and is more frequent in males. Patients manifest with widespread disease and close to one-third with skin lesions. Main physical signs are hepatosplenomegaly and lymphadenopathy. Effusions are seen in 15% of patients but are frequent at a terminal and/or relapse phase of the disease; central nervous system (CNS) involvement is rare (Table 39.2). A few patients are asymptomatic and they manifest with non-specific symptoms and a slowly progressive lymphocytosis resembling the picture seen in stage A chronic lymphocytic leukaemia (CLL). This 'smouldering' form of T-PLL progresses in terms of months or rarely years. Lymphocyte counts range from 35 to 1000×10^9/L and a third of the cases have anaemia and/or thrombocytopenia. Serology and/or DNA analysis for HTLV-I/II are consistently negative. Liver function tests may be impaired and urate and sodium lactate dehydrogenase (LDH) raised. Bone marrow shows a variable degree of involvement and the most common pattern of lymphoid infiltration in the trephine biopsy is mixed (interstitial plus diffuse) or diffuse with reticulin fibrosis.

Diagnosis

Cell morphology and immunological markers are the key diagnostic tests. In two-thirds of cases, the lymphocytes have condensed chromatin, regular or irregular nuclear outline, prominent nucleolus and a deeply basophilic cytoplasm with

Table 39.2 Disease features of mature T-cell disorders.

Disease	Spleen/liver	Nodes	Skin	Others
T-PLL	+++/++	++	++	Effusions
T-cell LGL leukaemia	++/+	−	+	Cytopenias, PRCA
Sézary syndrome	−/−	+	+++	
ATLL	++/++	+++	+	Hypercalcaemia, HTLV-I
γ/δ T-NHL	+++/++	−	+	Extranodal sites
Subcutaneous panniculitic-like	−	−	+++	
AIL	++/++	+++	++	AHA, dysproteinemia
Extranodal nasal	+/+	+	+	Nasal, extranodal sites
Intestinal	−/−	+	−	Bowel
ALCL	+/+	++	+	

+++, > 70% of cases; ++, 40–70% of cases; +, 20–40% of cases; −, < 20% of cases.
AHA, autoimmune haemolytic anaemia; HTLV-I, human T-cell leukaemia lymphoma virus I; PRCA, pure red cell aplasia.

(a)   (b)
Figure 39.1 (a and b) Peripheral blood films from two cases of T-PLL showing medium-size lymphoid cells with prominent nucleolus and basophilic cytoplasm.

protrusions or blebs (typical T-PLL) (Figure 39.1). In the remaining, the lymphocytes are smaller in size and the nucleolus is small or not visible by light microscopy (small-cell variant of T-PLL) and/or have a cerebriform nucleus resembling Sézary cells (cerebriform variant). Although the small-cell T-PLL has been referred to as 'T-CLL', such designation may lead to confusion as these patients with small-cell T-PLL have an aggressive disease course and the immunophenotype and cytogenetics are similar to typical T-PLL. The two morphological T-PLL variants are formally recognized as T-PLL in the WHO classification.

Tissue histology is not essential for the diagnosis of T-PLL. The tissues which are more frequently available for review are spleen and skin. The spleen histology shows expansion of the white pulp extending to the red pulp and thus is different from T-cell LGL leukaemia. Skin histology is different from Sézary's syndrome (SS) and shows dermal infiltration preferentially around the appendages without epidermotropism.

Immunological markers show that T-prolymphocytes, unlike T-lymphoblasts, are negative with TdT and the cortical thymic marker CD1a while expressing CD2, CD5 and CD7, the latter with strong intensity. CD3 and anti-TCR-α/β are negative in the cell membrane from 20% of patients but are always expressed in the cytoplasm. The most common phenotype is CD4+CD8– (65% of cases), in ~ 10% cells are CD8+CD4–, and in 25% the cells co-express CD4 and CD8 (Table 39.3). T-prolymphocytes are negative with monoclonal antibodies (McAb) against natural killer (NK) cells, TIA-1 and HLA-DR; CD25 is negative or weak and CD52w (Campath-1H) is strongly expressed.

Pathogenesis

Chromosomal abnormalities are complex and essentially involve chromosomes 14, 8 and 11. The abnormality inv(14)(q11;q32) is characteristic of T-PLL and is detected in greater than two-thirds of the cases. This juxtaposes the TCR-α gene (14q11) to the oncogen TCL-1 (14q32.1) Few cases have rearrangement of the TCL-1 gene and most have TCL-1 overexpression, supporting the theory that this oncogen plays a role in the pathogenesis of this disease (Table 39.3). In some cases, the *TCR-α* gene (14q11) is juxtaposed to the *MTCP-1* gene (Xq28), resulting in the t(X;14)(q28;q11). The *MTCP-1* gene has homology with *TCL-1* and it has been shown to be expressed in two T-PLL patients who developed the leukaemia following a preceding phase of AT. Abnormalities of chromosome 8 involving both arms of this chromosome are frequent; although the c-*myc* oncogene (8q24) is not rearranged, overexpression of c-*myc* is found in cases with iso8q. 11q23 abnormalities are rarely detected by cytogenetics, but involvement of the *ATM* gene (11q23) by molecular analysis is common. There are genetic similarities between the sporadic T-PLL form and circulating T-lymphocytes from AT patients. These patients are at risk of developing lymphoid malignancies including T-PLL. T-cell clones in AT carry similar abnormalities to leukaemic T-prolymphocytes, and expression of TCL-1 transcripts occurs in both the preleukaemic and leukaemic phases in AT patients, as it does in the sporadic T-PLL phases. Further, mutations of the *ATM* gene (11q23) responsible for AT have been well documented in T-PLL. All these findings stress the close relationship between the sporadic form of T-PLL and the leukaemia that develops in AT patients.

Differential diagnosis

The differential diagnosis of T-PLL arises with B-PLL, T-ALL and other mature T-cell leukaemias and lymphomas. Distinction between T- and B-PLL and T-ALL can be made by immunophenotyping. The differential diagnosis between T-PLL and T-cell LGL leukaemia is not problematic except in cases of smouldering small-cell variant T-PLL. Immunophenotype and cytogenetics together with cell morphology allow the distinction between these two conditions. Cell morphology, clinical features, skin histology and HTLV-I status will differentiate T-PLL from T-cell lymphomas in the leukaemic phase, such as ATLL and SS.

Table 39.3 Immunophenotype and genotype in T-cell disorders.*

Disease	Immunophenotype	Genotype
T-PLL	CD7^{++}, CD4$^+$ or CD4$^+$/CD8$^+$	inv (14), iso 8q ATM, TCL-1
T-cell LGL leukaemia	CD7$^{+/-}$, CD8$^+$, CD57$^+$, CD16$^+$	Unknown
Sézary syndrome	CD7$^{+/-}$, CD4$^+$, CD8$^-$	Aneuploidy
Adult T-cell leukaemia lymphoma	CD7$^-$, CD4$^+$, CD25$^+$	HTLV-I
γ/δ hepatosplenic T-NHL	TCR-γ/δ$^+$, CD16$^+$, CD56$^+$, TIA-1$^+$	iso7q
Subcutaneous panniculitic-like	CD3$^+$, CD8$^+$, TIA-1$^+$	Unknown
Angioimmunoblastic T-NHL	CD3$^+$, CD5$^+$, CD10$^+$	+8, +5, del6q
Extranodal T/NK, nasal type	CD3epsilon$^+$, CD56$^+$, LMP-1$^+$	EBV
Enteropathy-type T-NHL	CD3$^+$, CD8$^+$, CD103$^+$	?EBV
Anaplastic large-cell lymphoma	CD30$^+$, CD3$^+$, CD25$^+$, EMA$^+$	t(2;5) NPM-ALK

*Refers only to the most relevant and distinct features.
ATM, ataxia telangiectasia mutated gene; EBV, Epstein–Barr virus; HTLV, human T-cell leukaemia/lymphoma virus; LMP-1, latent membrane protein; NPM-ALK, nucleolar phosphoprotein–anaplastic lymphoma tyrosine kinase.

Disease course and therapy

T-prolymphocytic leukaemia has an aggressive course and survival is short, estimated to be around 7 months in the historical series. Patients are resistant or achieve transient responses to most chemotherapies. A decade ago we showed that 2′-deoxycoformycin is effective in this disease with response rates of 45%, 10% of which were complete responses (CRs); this resulted in a survival improvement. Recently, we have documented the remarkable activity of the monoclonal antibody (MAb) Campath-1H either used as a first-line therapy or following 2′-deoxycoformycin. Over two-thirds of patients respond to this agent, and most achieve a CR. However, most patients following Campath-1H, eventually relapse, and therefore responses need to be consolidated with high-dose therapy and stem cell transplant. Such a schedule has been successfully used in some patients with encouraging results. A chart illustrating the response to Campath-1H in a T-PLL patient is shown in Figure 39.2.

Figure 39.2 Flow chart from a T-PLL patient illustrating a complete response to Campath-1H and subsequent consolidation with stem cell transplant.
Large granular lymphocyte leukaemia (LGL leukaemia)

Large granular lymphocyte leukaemia was described three decades ago and was at that time designated T-CLL, to contrast with B-cell CLL. A variety of designations, such as Tγ lymphoproliferative disorder, chronic T-cell lymphocytosis with neutropenia, T8+ T-CLL, natural killer (NK), cytotoxic and/or suppressor T-cell CLL, were used until Loughran (1993) coined the term of LGL leukaemia for this disease. Depending on the origin of the LGL cells, LGL leukaemia can be subdivided into two main groups: one group which is derived from T cells (CD3+) and another, more uncommon, group derived from NK cells (CD3−). However, in the WHO classification, only the T-cell LGL is considered as LGL leukaemia, while NK-LGL is included within the spectrum of the NK neoplasms. Therefore, we will strictly refer here to the T-cell LGL leukaemia.

Aetiology

The aetiology of T-cell LGL leukaemia is unknown. This disorder is more frequently seen in patients with autoimmune diseases, in particular those with rheumatoid arthritis and Felty's syndrome. The latter patients, as those with T-cell LGL leukaemia, have, with a high frequency, the DR4 haplotype. This suggests a common immunogenetic basis for all these conditions. In contrast, it is unlikely that DNA or RNA viruses play a major pathogenic role in T-cell LGL leukaemia. Although some reports have documented the presence of HTLV-I/II antibodies in a few cases, the data are questionable and have not been confirmed by molecular studies. Similarly, only occasional cases, particularly derived from NK cells, have been linked to EBV infection.

Clinical features

T-cell LGL leukaemia affects adults and is rare in children; it is slightly more frequent in females. Patients are asymptomatic or manifest with symptoms derived from cytopenias, essentially recurrent infections, autoimmune disease or rarely present as pure red cell aplasia; the disease may evolve as a pure lymphomatous form in a minority of cases. Physical examination shows splenomegaly in close to two-thirds of patients and hepatomegaly in one-half; skin lesions may be present but lymphadenopathy is exceedingly rare (Table 39.2). The lymphocyte count is normal or slightly raised, usually under 15×10^9/L, with the majority of cells being LGL; neutropenia is very common, and one-third of patients have anaemia and/or thrombocytopenia. In a few cases, a Coombs-positive haemolytic anaemia and autoimmune thrombocytopenia have been documented. Some patients test positive for rheumatoid factor (RA), antinuclear antibodies, circulating immune complexes and hypo- or hyper-gammaglobulinaemia. Bone marrow shows mild lymphoid infiltration, often with an interstitial pattern. It is not rare that marrow involvement is missed in both the aspirates and trephine biopsies but can be revealed by membrane markers or immunohistochemistry respectively. There may be erythroid and myeloid hyperplasia with maturation arrest.

Diagnosis

Cell morphology, immunological markers and molecular analysis investigating the configuration of the TCR-β or -γ chain genes are the key diagnostic tests. The circulating lymphocytes are medium in size, and have an eccentric nucleus with mature chromatin, no visible nucleolus and abundant pale cytoplasm with azurophilic granulation (Figure 39.3). The granules contain acid hydrolases, in particular acid phosphatase, perforin

(a)

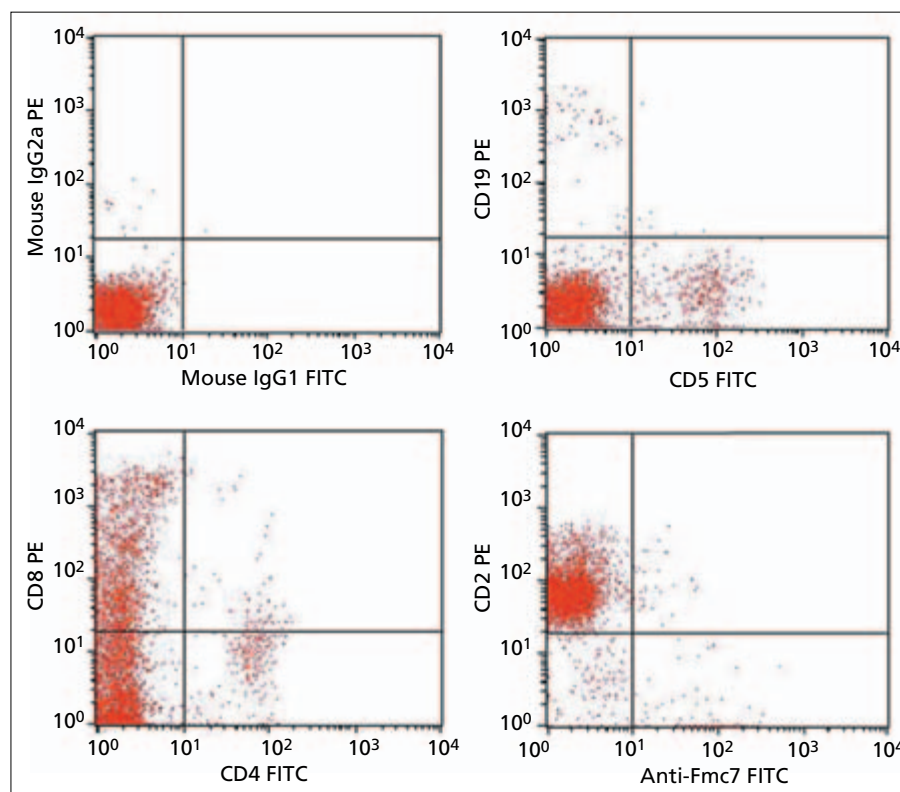
(b)
Figure 39.3 (a and b) Peripheral blood film from patients with T-cell LGL leukaemia showing lymphocytes with an eccentric nucleus, condensed chromatin and abundant pale cytoplasm with azurophilic granules.


Figure 39.4 Flow cytometry plots of lymphocytes from a T-cell LGL leukaemia illustrating that most cells are CD2$^+$ and CD8$^+$, but are CD4$^-$ and CD5$^-$.

and cytokines involved in the cytotoxic function of these lymphocytes. At the ultrastructural level, some of these granules may display a special configuration and are designated parallel tubular arrays (PTAs). Morphologically, the lymphocytes in T-cell LGL leukaemia cannot be distinguished from the minor circulating LGL population present in the blood from normal individuals.

Tissue histology is only available in some cases and is rarely essential for diagnosis. The spleen histology shows red pulp expansion with atrophic or a reactive white pulp resembling the pattern seen in hairy-cell leukaemia; however, pseudolake formation is not seen and the infiltrating cells have, unlike in hairy cell leukaemia, a T-cell phenotype. Sarcoid-like granulomas may be present in a few cases. The liver histology shows sinusoidal infiltration extending to the portal tracts.

Membrane markers in T-cell LGL leukaemia show that cells from most cases are CD2$^+$, CD3$^+$ TCR-α/β^+ whereas CD5 and CD7 are negative in around half of the cases. The most common phenotypic profile is CD8$^+$ CD4$^-$ CD57$^+$ CD16$^+$ TIA-1$^+$ (Table 39.3, Figure 39.4). A few cases have unusual phenotypes such as co-expression of CD4 and CD8 or a CD4$^+$ CD8$^-$ phenotype with or without co-expression of NK-associated markers. T-cell activation markers such as HLA-DR determinants and CD38 are expressed in a variable number of cases. Although the p55 α-chain of the interleukin 2 (IL-2) receptor (CD25) is usually absent in the cell membrane, LGL cells express the p75 inter-

mediate-affinity IL-2 receptor β-chain. LGL cells express both Fas (CD95) and its ligand but are resistant to apoptosis due to an impairment of the Fas apoptotic-induced pathway.

Southern blot and/or polymerase chain reaction (PCR) studies using primers specific for the variable regions of the TCR-β or -γ chain genes are essential to demonstrate the clonal nature of the expanded LGL population and distinguish them from reactive non-clonal LGL proliferations. In the majority of T-cell LGL leukaemia cases, the cells have a rearranged TCR-β chain gene, and only a few have rearrangements of the TCR-γ chain gene (Figure 39.5). It is now possible to demonstrate clonality by flow cytometry using a wide range of MAbs against the different variable regions of the TCR-β chain gene. Unlike in reactive LGL proliferations, in which different proportions of cells will stain with the various MAbs, in LGL leukaemia, cells will stain only with one of them.

Pathogenesis

There is no evidence for a recurrent chromosomal abnormality in T-cell LGL leukaemia. A number of cases may show normal karyotypes despite being clonal by DNA analysis. As outlined earlier, it is likely that T-cell LGL leukaemia has an immune or autoimmune basis. This hypothesis is supported not only by its association with autoimmune diseases but also by the evidence that immunosuppressive agents may control the disease manifestations in some patients. In addition, the cytopenias
Figure 39.5 PCR analysis on a case of T-cell LGL leukaemia showing a single rearranged band for the TCR-γ chain gene in the blood (second row) and bone marrow (third row). The first row is 1 kb ladder, the fourth a positive control and the fifth a negative control.

seem to be unrelated to bone marrow infiltration and/or hypersplenism and instead derived from an inhibitory effect of the LGL on the haemopoietic differentiation and maturation interfering with and/or arresting the physiological differentiation process.

Differential diagnosis

The differential diagnosis of T-cell LGL leukaemia arises with polyclonal T-cell lymphocytosis following splenectomy or reactive to viral infections, B-cell CLL and with other T-cell disorders. DNA analysis will allow to distinguish reactive from clonal LGL proliferations as in the former the TCR chain genes will be in germline configuration. Morphology and membrane markers distinguish T-cell LGL leukaemia from other B- and T-cell disorders.

Prognosis and therapy

The clinical course of T-cell LGL leukaemia is often stable or slowly progressive; only a few patients present with widespread and progressive disease. It has been suggested that cases whose cells express CD56 and/or CD26 behave more aggressively. Transformation into a large-cell lymphoma, a phenomenon similar to Richter's syndrome in CLL, is exceedingly rare.

The prognosis of LGL leukaemia is difficult to ascertain but overall is good compared with the other T-cell malignancies. Thus, data based on relatively large series of patients show that 80% of them survive at 4 years and the overall median survival is greater than 10 years. The main causes of death are infections and only in a few patients is death associated with progressive disease.

A substantial proportion of patients, e.g. those without cytopenias and stable blood counts, do not require treatment and only monitoring, e.g. 'watch and wait', a policy similar to that adopted in stage A B-CLL. Treatment is indicated in those with severe cytopenias, recurrent infections and/or progressive lymphocytosis or organomegaly. There is no gold-standard therapy to be used in LGL leukaemia. Overall, therapeutic strategies are based on the use of immunosuppressive agents as there is no evidence that high-dose therapy will benefit these patients by eradicating the clone. These treatments include cyclosporin A, low-dose cyclophosphamide (e.g. 200−300 mg/week) or weekly pulses of methotrexate (10 mg/m^2). There are no data concerning the disease features which will predict response to one or another immunosuppressive drug (Figure 39.6). There is limited experience of the use of haemopoietic growth factors, e.g. GM-CSF, G-CSF or erythropoietin. However, in the author's
Figure 39.6 Flow chart from a patient with T-cell LGL leukaemia with profound neutropenia (neutrophils: 0.1×10^9/L). The patient did not respond to cyclosporin A, but the neutropenia improved (neutrophils: 1×10^9/L) with weekly pulses of methotrexate.

experience, these may be considered as adjuvants to maintain or improve the blood cell counts. Few patients respond to 2′-deoxycoformycin, but this drug has not been extensively used in LGL leukaemia. Splenectomy does not correct the neutropenia or cytopenias and usually results in an increase of circulating LGL. Still, in patients with bulky spleen, this procedure may help by removing tumour burden. Patients with widespread disease, e.g. skin lesions, hepatosplenomegaly, rising WBC, should be managed with combination chemotherapy.

Leukaemia/lymphoma syndromes
(Table 39.1)

The leukaemia/lymphoma syndromes or leukaemic phase of T-NHL comprise T-cell neoplasms that arise in peripheral lymphoid tissues but with a high frequency present with blood involvement mimicking T-cell leukaemias. These include two diseases: Sézary's syndrome (SS) and adult-T-cell leukaemia lymphoma (ATLL).

Sézary's syndrome (SS)/mycosis fungoides (MF)

Aetiology
These are cutaneous T-cell lymphomas (CTCLs), with SS being considered the leukaemic manifestation of MF. Their aetiology is unknown. Although some studies have suggested a link between SS/MF with HTLV-I/II on the basis of the detection of retroviral sequences in the tumour cells, other studies have not confirmed these findings. In addition, HTLV-I antibodies are not detected in the patient's serum and a clonal integration of HTLV-I in the tumour cells has not been demonstrated in any case with 'bona fide' SS/MF. A cooperative study in more than 100 cases of CTCL using sensitive molecular tests, serology and cell culture has failed to show a single CTCL harbouring HTLV-I/II. Therefore, there is no robust evidence for the involvement of these retroviruses in SS/MF.

A relationship between MF and other T-cell conditions, chiefly lymphomatoid papulosis, has been entertained. Lymphomatoid papulosis is a recurrent skin eruption characterized by the presence of nodules with evidence by histology of anaplastic Reed–Sternberg-like cells infiltrating the skin. Although in the past its neoplastic nature had been debated, this issue was later settled as clonal. TCR rearrangements were documented in some patients. Such conditions may precede not only CTCL but also anaplastic lymphoma (ALCL) and/or Hodgkin's disease. The association between lymphomatoid papulosis and CTCL has been established in a case that presented with lymphomatoid papulosis and subsequently developed Hodgkin's disease and MF with evidence of the same clone in the three tumours. Currently, lymphomatoid papulosis is included in the group of primary cutaneous T-NHL by the WHO (see below).

Clinical features
Sézary's syndrome and MF affect elderly patients and are more common in males. Patients present with pruritus, and skin lesions either localized, e.g. nodules or plaques, or a generalized rash (Table 39.2). In patients with early-stage disease, the correct diagnosis is not always made at presentation and the manifestations are considered as reactive dermatitis even when skin histology is available. Physical examination shows generalized erythrodermia and/or nodules; organomegaly is rare. In SS, the WBC count is normal or raised with circulating atypical lymphocytes. Anaemia and thrombocytopenia are uncommon and bone marrow is usually not involved. Serology for HTLV-I is consistently negative even in cases originating from regions in which this virus is endemic.

Diagnosis
The diagnosis is based on cell morphology, skin histology and immunological markers.

The circulating blood lymphocytes are small to large size and exhibit a cerebriform nucleus often seen as a hyperchromatic nucleus (Figure 39.7); the cytoplasm is scanty or medium size and, in some cases, vacuolation is prominent. According to the cell size, two variants of SS had been recognized, the small- and large-cell variants. Small cells and/or a mixture of small and large cells are the predominant type in the peripheral blood. The nuclear configuration of the Sézary cells is best defined by ultrastructural analysis that reveals a serpentine nucleus with multiple narrow indentations.

Skin histology is a key diagnostic test in SS and in MF. This shows the presence of dermal lymphoid infiltrates which characteristically extend into the epidermis, a phenomenon designated epidermotropism; in some cases the infiltrates involve the subcutaneous fat. Pautrier microabcesses are typical but not unique to these conditions as they may be seen in T-NHL and ATLL.

Histology of other tissues is rarely available at diagnosis. The enlarged lymph nodes may show a reactive lymphadenitis or infiltration by lymphoma (Figure 39.8). Bone marrow, when involved, shows a mild interstitial infiltration.

Immunophenotyping demonstrates that the circulating neoplastic Sézary cells are positive for CD2, CD3 and CD5 whilst CD7 is negative in ~50% of cases (Table 39.3). The most common phenotype is CD4$^+$ CD8$^-$, but other unusual phenotypes, e.g. CD8$^+$ CD4$^-$ or co-expression of CD4/CD8, may be seen in a minority of cases. NK-associated markers are, as a rule, negative while expression of T-cell activation markers is variable. Unlike in ATLL, CD25 is rarely expressed in Sézary cells and, when positive, the reactivity is weaker than in ATLL cells. In the skin, the interdigitating Langerhans cells admixed with the neoplastic lymphocytes are CD1a$^+$ and S-100$^+$. Cases transforming into a large T-cell lymphoma display aberrant phenotypes with loss of pan-T markers and often expression of T-cell activation antigens such as CD30, CD25 and HLA-DR.

Pathogenesis

Chromosomal abnormalities are complex and have variable ploidy. Hyperploidy is frequent in the large-cell variant and aneuploidy or hypoploidy in the small-cell form. There are also differences in the DNA content between these two forms when analysed by flow cytometry. There is no evidence for a recurrent chromosomal abnormality in SS, but chromosomes 6, 2, 1 and 17q are the most commonly involved. Clonal evolution may be seen in some cases, particularly those transforming into large cell. Abnormalities of chromosome 17p have been documented in some cases, as well as p53 protein overexpression and p53 gene deletion; however, p53 mutations are rare in SS and there-

fore it has been postulated that the *mdm-2* gene may be, to some extent, responsible for the p53 inactivation in SS.

Differential diagnosis

The differential diagnosis arises with reactive dermatitis, T-PLL presenting with skin lesions, ATLL and cutaneous B-cell lymphomas. Cell morphology and immunological markers allow the distinction between SS and T-PLL and cutaneous B-NHL HTLV-I serology is the key test to distinguish SS from ATLL, essentially in cases presenting primarily with cutaneous forms of ATLL. The pattern and extent of skin infiltration and histochemistry usually allows the differentiation of SS from reactive dermatitis. However, in problematic cases, PCR analysis investigating the configuration of the TCR chain genes is needed; in SS this will show a rearranged T-cell band, unlike in reactive dermatitis where the pattern is polyclonal.

Clinical course, prognosis and treatment

The clinical course of MF/SS is usually relatively chronic. Thus, 87% of MF patients survive 5 years, whereas SS follows a more progressive course with shorter survival. The outcome for patients with abnormal clones seems to be worse than those with random heteroploidy. Transformation of SS or MF into a large-cell T-NHL is uncommon but has been documented in 8–19% of cases in retrospective studies. Transformation may be localized or systemic and chiefly is associated with advanced stages and a short survival. Only in a few cases has it been demonstrated that the tumour in the phase of transformation arises from the original clone. This is essential as SS/MF patients have an increased risk of secondary malignancies and, thus, the non-haemopoietic nature of the tumour needs to be excluded.

A variety of treatments, including topical and systemic agents, have been used in SS/MF. In patients, particularly the elderly

and those with localized skin disease, PUVA (psoralen with UVA irradiation), electron-beam and/or topical BCNU and steroids may alleviate and control the skin symptoms. Local radiotherapy is useful in patients with localized plaques. Systemic therapy is particularly indicated in young patients and/or those with widespread disease. This is based on either single-agent therapy with methotrexate, cyclophosphamide or etoposide or combination of drugs, e.g. CHOP (cyclophosphamide, hydroxydaunorubicin, oncovin and prednisolone). Over the last decade, new therapies have been employed, such as purine analogues, interferons, retinoids and immunotherapy with an anti-IL-2 MAb conjugated with the diphtheria toxin. Responses to purine analogues, either 2′-deoxycoformycin, 2-chlorodeoxyadenosine or fludarabine, range from 30% to 62%. Interferon-α alone or combined with retinoids (etretinate) is effective in cases with cutaneous disease but not in systemic disease. The MAb Campath-1H has been used in some patients with relapsed and refractory disease with encouraging results.

Adult T-cell leukaemia lymphoma (ATLL)

Aetiology and epidemiology

Adult T-cell leukaemia lymphoma is a unique malignancy in which the primary aetiological agent has been well established. This disease is caused by a retrovirus, HTLV-I, which is almost universally detected in all the patients. ATLL was first described as a distinct clinical entity in 1977. Its association with HTLV-I was demonstrated in the early 1980s almost simultaneously in USA and Japan, based on seroepidemiological studies and the isolation of HTLV-I from ATLL cells. ATLL is clustered in HTLV-I endemic areas such as Japan, the Caribbean, Africa, South America and the Middle East, and among immigrants from these countries to Europe and USA. In the UK, this disease is seen in immigrants of Afro-Caribbean descent. Familial cases of ATLL have been documented, and it has been suggested that a shared environment and perhaps a genetic background influence the development of ATLL in these families.

Clinical features

Adult T-cell leukaemia lymphoma affects adults without sex predominance. The disease manifests with leukaemia in over two-thirds of cases (leukaemia form), whereas approximately 25% have no blood involvement (lymphoma form). Within the leukaemia form, three subtypes are distinguished: acute, chronic and smouldering. Acute ATLL is the most common, accounting for 65% of cases. Patients present acutely with widespread disease, leucocytosis, opportunistic infections and/or hypercalcaemia. Physical examination shows lymphadenopathy, skin lesions and/or hepatosplenomegaly (Table 39.2). Chronic ATLL (5% of cases) presents with stable or slowly progressive lymphocytosis with the presence of atypical lymphocytes and minor or no lymphadenopathy or skin involvement. Smouldering ATLL (5% of cases) is characterized by normal blood counts with less
Figure 39.9 Peripheral blood film from a patient with ATLL showing lymphocytes with a polylobed nucleus (flower cells).

than 4% atypical lymphocytes and recurrent skin lesions or lung infiltrates. Hypercalcaemia by definition is not detected in chronic and smouldering ATLL. Both these forms progress in terms of months or rarely years into acute ATLL. A few ATLL patients have manifestations of conditions linked to HTLV-I infection such as tropical spastic paraparesis, arthritis, uveitis, etc. These either manifest concomitantly with, or precede the onset of, the T-cell neoplasm. Peripheral blood counts show a raised WBC with lymphocytosis in the acute and chronic leukaemia forms. Anaemia and thrombocytopenia is seen in close to a third of cases. Biochemistry shows a markedly raised LDH and the liver function tests may be abnormal. Hypercalcaemia is the most distinct biochemical abnormality, seen in 50% of cases at presentation and in up to two-thirds during the disease course. Rarely, it is associated with osteolytic lesions. The pathogenesis responsible for the hypercalcaemia is described below.

Diagnosis

The diagnosis of ATLL is based on cell morphology, immunophenotype and essentially by the demonstration of HTLV-I antibodies on the patient's serum or retrovirus sequences into the cell's DNA.

Morphological analysis of the peripheral blood films shows a pleomorphic picture with the presence of cells of different size and degree of nuclear irregularities in the acute and chronic leukaemia ATLL subtypes. The prototype cell, designated 'flower cell', is a medium-size lymphocyte with condensed chromatin and a convoluted or polylobated nucleus (Figure 39.9); a few cells may have a cerebriform nuclei and a minority show features of immunoblasts.

Immunological markers show that ATLL cells have a mature T-cell phenotype CD2+, CD5+. CD3 is expressed in the cytoplasm but, in some cases, cells lack expression of CD3 and TCR-α/β in the membrane. It has been suggested that the decreased
Figure 39.10 Flow cytometry plots of lymphocytes from an ATLL patient showing reactivity with CD5, CD4 and CD25 while CD7 is negative.

numbers of CD3 and TCR molecules in ATLL cells results from the cell activation by the retrovirus and that might play a role in the disease pathogenesis. Most ATLL cases have a CD4+ CD8− phenotype. Unusual cases with uncommon phenotypes such as co-expression of CD4 and CD8, or a CD8+ CD4− phenotype have been reported in Japan and appear to have a more aggressive disease. A distinct feature of ATLL cells is the strong expression of the p55 alpha chain of the IL-2 receptor (CD25) in the cell membrane (Figure 39.10). Soluble IL-2 receptors are detected in the patient's serum and the levels correlate with tumour burden and response to therapy. The possible role of the IL-2 and IL-2 receptor system has been entertained for a number of years and is discussed later. Other markers linked to T-cell activation such as HLA-DR determinants and CD38 are expressed in a variable proportion of cases.

Lymphoid tissue histology is not essential for diagnosis in patients presenting with leukaemia. In the lymphoma forms, tissue histology is an important diagnostic test; however, the histological pattern by itself does not allow the making of a diagnosis of ATLL as the pattern of infiltration might be similar to the other post-thymic T-NHL. Often, there is diffuse infiltration by pleomorphic lymphoid cells of different size, similar to what is seen in non-HTLV-I unrelated T-NHL; in a few cases, the pattern of involvement mimics AIL T-NHL or Hodgkin's disease. ATLL does not fit in a single category in the revised European-American classification of lymphoid neoplasms (REAL) and WHO classifications and it is only defined by the presence of HTLV-I. The pattern of skin infiltration is not specific either, as in half of ATLL cases it is identical to that of SS, with evidence of epidermotropism. Bone marrow biopsy shows mild or no lymphoid infiltration but bone resorption and proliferation of osteoclasts is not rare, particularly in patients with hypercalcaemia.

Demonstration of HTLV-I is the key test for the definitive diagnosis of ATLL. Serum antibodies to HTLV-I can be detected by ELISA or Western blot in virtually all ATLL patients. In a small minority of patients who have a clinical and laboratory picture characteristic of ATLL, the retrovirus cannot be detected by either serology or molecular analysis. This suggests that, in a few cases, the initiating event responsible for the development of ATLL is not HTLV-I, a scenario similar to that seen with EBV in endemic and non-endemic Burkitt's lymphomas. Still, when findings are negative for HTLV-I, one should question the diagnosis of ATLL.

Pathogenesis

Chromosome abnormalities with complex karyotypes and clonal evolution are frequent. Rearrangements of chromosome 14 at breakpoints q11 and q32, characteristic of T-PLL, are rare. In smouldering ATLL, clonal and non-clonal abnormalities have been documented and occasional cases show clonal evolution

from the smouldering to the acute phase. Sequential cytogenetic studies at the various phases of HTLV-I infection from carrier to acute ATLL might give some clues in the steps involved in the leukaemogenesis of HTLV-I-induced malignancy as the secondary factors involved in the neoplastic transformation of HTLV-I-infected lymphocytes are largely unknown.

The pathogenic role of IL-2 and its receptor had been suggested in the past on the basis of the independent growth of some HTLV-I-positive cell lines, the continuous transcription of the IL-2 receptor gene, the increased levels of IL-2 receptor mRNA and the fact that HTLV-I induces IL-2 receptor expression in normal T-lymphocytes when infected by this retrovirus. However, definitive evidence has not been proven as ATLL cells do not secrete IL-2, nor have increased mRNA levels for this cytokine.

The mechanism of hypercalcaemia seems to relate to the release of cytokines, chiefly a parathyroid-like hormone, IL-1 and tumour necrosis factor β by the tumour cells. These lead to bone resorption and release of calcium into the serum.

It is well established that HTLV-I is the primary aetiological agent of ATLL, shown by the presence of a mono-/oligoclonal integration of HTLV-I sequences into the leukaemic cell's DNA. Although HTLV-I infection constitutes the first step in the development of ATLL, it is not enough by itself to cause malignancy as only 0.5% of HTLV-I carriers will develop the disease and the life risk to develop the malignancy in a carrier is estimated to be around 5%. Infection in early life seems to be a risk factor. Concerning pathogenesis, HTLV-I does not carry an oncogene and the sites of integration vary from tumour to tumour. However, the retrovirus harbours various regulatory genes, e.g. *tax*, which code for proteins responsible for cell immortalization by activating some cellular genes relevant for proliferation and differentiation (trans-activation pathway). It is likely that disruption of other genes such as mutations of the tumour-suppressor genes *p53*, *p16* and *p15* are also implicated in the development of the neoplasm.

Differential diagnosis

The differential diagnosis of ATLL arises with primary T-cell leukaemias and T-NHL not associated to HTLV-I. In addition, smouldering ATLL raises diagnostic problems with carriers of the retrovirus. T-cell leukaemias and T-NHL can be distinguished from ATLL by clinical features, morphology and, essentially, by the presence or absence of HTLV-I. The HTLV-I test is essential, as the lymphoma. ATLL type or its cutaneous form cannot be distinguished, respectively, from pleomorphic T-NHL or MF/SS when only histology is considered. Further, in endemic areas and when the picture is not typical of ATLL, DNA analysis in addition to serology is needed to confirm that HTLV-I is clonally integrated in the leukaemic cells. Distinction between smouldering ATLL and carriers of the retrovirus is based on molecular analysis with probes specific for HTLV-I that will show a mono-/oligoclonal pattern of retroviral integration in smouldering ATLL versus a polyclonal pattern in the carriers.

Clinical course and therapy

Adult T-cell leukaemia lymphoma is an aggressive malignancy for which no successful treatment is yet available. Patients are refractory or transiently respond to chemotherapy or purine analogues. Survival ranges from 5 months to 13 months. Smouldering and chronic ATLL pursue an indolent course until the disease progresses and becomes refractory to therapy. The poor outlook of ATLL relates to both chemotherapy resistance and complications (hypercalcaemia and opportunistic infections) that make management difficult. Most patients have been treated with CHOP, similar schedules and/or single-agent therapy. Although partial remission (PR) or clinical complete responses have been achieved in some patients, these are short-lived. Results are not superior with immunotherapy with MAb against the IL-2 receptor. A combination of α-interferon and zidovudine seems to be effective, particularly when used after or combined with chemotherapy. Schedules combining chemotherapy plus anti-T-cell MAb may improve the outcome of these patients.

T-cell non-Hodgkin's lymphomas (T-NHL)

The tissue-based T-cell NHL encompasses a variety of entities that essentially affect lymphoid tissues and/or extranodal sites. Some of them are frequent in the East while very uncommon in the western countries. A minority of patients may develop or manifest with a leukaemic picture and, when the circulating cells are large blasts (Figure 39.11), present problems of differential diagnosis with acute leukaemias. According to the REAL and WHO, the T-NHL are classified as shown in Table 39.1.

Peripheral T-NHL (unspecified)

This term includes T-NHL difficult to classify by histology and molecular genetics. Problems in classifying these lymphomas
Figure 39.11 Bone marrow aspirate from a patient with T-NHL showing two large blasts.
Figure 39.12 Bone marrow trephine biopsy from a patient with peripheral T-cell lymphoma (unspecified) showing diffuse infiltration by pleomorphic lymphoid cells.
Figure 39.13 Bone marrow trephine showing infiltration by lymphoid cells with marked eosinophilia in a patient with T-NHL.

result from their rarity and the lack of objective criteria to better define them. Most peripheral T-NHLs are referred to as non-lymphoblastic TdT-negative T-NHL. Patients present with organomegaly, 'B' symptoms and some with extranodal disease; haemophagocytosis and/or impairment of the immune system are not uncommon. The term 'peripheral T-NHL with haemo-phagocytic syndrome' has been used to designate cases with prominent haemophagocytosis.

Lymph node histology shows diffuse effacement of the archi-tecture by atypical lymphocytes (Figure 39.12), or infiltration may be confined to interfollicular areas (T-zone variant) and/or the paracortical zone. There may be a background of eosinophils and histiocytes (Figure 39.13). The neoplastic cells express several T-cell markers CD2, CD3, CD5, CD7 with variable expression of CD4 and CD8. Aberrant phenotypes with lack of expression of pan-T markers are common. Bone marrow rarely is involved. There is no consistent chromosomal abnormality but complex
Figure 39.14 Bone marrow trephine section from a patient with hepatosplenic Tγ/δ lymphoma showing intrasinusoidal infiltration.

karyotypes are common. Most peripheral T-NHL should be considered high to intermediate grade. Treatment modalities based on combinations of agents such as CHOP, intensified CHOP plus etoposide or given at shorter intervals (e.g. every 2 weeks), followed or not by stem cell transplant, still remains the gold standard.

Peripheral T-NHL-specific variants (Table 39.1)

Six T-NHL have been considered by the WHO as distinct entities on the basis of the clinical and laboratory features. The most relevant features of these lymphomas are described below.

Hepatosplenic γ/δ T-NHL

This tumour derives from TCR-γ/δ$^+$ T-cells and affects preferen-tially young males. It is more common in immunocompromised patients. Hepatosplenomegaly is the main feature, but extra-nodal sites (e.g. skin) may be involved (Table 39.2). The histology is distinct, with an intrasinusoidal pattern of infiltration in all tissues affected such as spleen, liver and bone marrow (Figures 39.14 and 39.15). This mimics the pattern of distribution of nor-mal Tγ/δ lymphocytes which home preferentially in the spleen sinusoids while R-α/β lymphocytes migrate to the periarter-iolar sheets. The neoplastic cells have a CD2$^+$ CD7$^+$ CD3$^{+/-}$ TCR-γ/δ+ phenotype (Figure 39.16) and are usually negative with MAbs against TCR-α/β, CD5, CD4 and CD8 or expression of CD8 is weak. Often, the cells are positive with the NK-associated markers CD16 and CD56. A consistent feature is the expression of TCR-γ/δ and TIA-1, a MAb that identifies cytotoxic granule-associated proteins. Molecular studies show rearrange-ment of the TCR-γ/δ chain genes whilst the TCR-α/β are in the germ line. Cytogenetics have shown that some cases have iso7q and it has been suggested that this is a recurrent abnormality in this lymphoma (Table 39.3). EBV seems not to play a major pathogenic role. The clinical course is aggressive and median survival is less than 2 years despite intensive therapy.
Figure 39.15 Immunohistochemistry on the bone marrow from Figure 39.14 showing that most lymphocytes in the sinusoids express cytoplasmic CD3.

Subcutaneous panniculitis-like T-NHL

This manifests with skin nodules resembling a benign panniculitis; haemophagocytic syndrome is frequent and may be fatal. Skin histology shows lymphoid infiltrates admixed with adipocytes in the subcutaneous tissue with extension to the dermis. Fat and connective tissue necrosis and granulomas are common; angiocentricity unlike in angiocentric T-NHL is not

seen. The mitotic rate is high. The neoplastic cells are CD2$^+$, CD3$^+$, often CD8$^+$ and express granzyme B, perforins and TIA-1 suggesting that this lymphoma arises from cytotoxic T-cells. Molecular analysis shows rearrangement of the TCR-β chain gene. There are limited data on outcome and response to therapy but prognosis seems poor.

Angioimmunoblastic (AIL) T-NHL

Angioimmunoblastic (AIL) T-NHL had already been described in the 1970s. It affects adults and has an acute onset. 'B' symptoms, pruritus, cutaneous rash, organomegaly, effusions and immune disturbance either autoimmune phenomena, immunodeficiency and/or dysproteinemia are common (Table 39.2). Although the neoplastic nature of this lymphoma had been debated in the past, this issue has been settled by the demonstration of clonality by cytogenetics and DNA analysis. Cases of clonal AIL T-NHL evolving from reactive hyperplasia have been described, and this change may correlate with clinical progression. The diagnosis is based on clinical features and histology. The lymph node shows a diffuse pleomorphic infiltrate composed by lymphocytes, plasma cells, immunoblasts and eosinophils; proliferation of epithelioid post-capillary venules and increased numbers of dendritic cells is common. There is obliteration of the follicular structure described as 'burned-out' follicular centres. The bone marrow is often involved on the trephine biopsy and the aspirates may show reactive features with increase in
Figure 39.16 Flow cytometry plots of bone marrow cells from a patient with hepatosplenic γ/δ T-NHL showing that the lymphocytes express in the membrane TCRγ/δ, cytoplasmic CD3 and CD8 and are negative with anti-TCR-α/β and CD4.

polyclonal plasma cells. The lymphoma cells have a T-cell phenotype (CD2[+] CD5[+] CD3[+]), and often are CD10[+]; the proliferative rate is high. Complex karyotypes with multiple clones involving trisomy 3 or iso3q, trisomy 5 and del6q are common. DNA analysis of the TCR genes has firmly confirmed the T-cell clonality in AIL T-NHL. Most cases have rearrangement of the TCR-β and/or -γ chain genes and in a few cases, both immunoglobulin and TCR chain genes are rearranged. The pathogenic role of EBV is uncertain in this lymphoma, and it is likely that the presence of this virus in the tissues represents an epiphenomenon reflecting the polyclonal expansion of B-cells in an immunocompromised host. The clinical course is acute and prognosis is poor. Although transient spontaneous remissions have been documented, the lymphoma always recurs. Some patients initially respond to corticosteroids or combination chemotherapy but most relapse. A few reports on single cases have documented responses to fludarabine. The median survival ranges from 13 to 17 months. It is likely that more aggressive regimens including stem cell transplantation and/or combinations of chemotherapy with anti-T-cell monoclonal antibody will improve the dismal outcome of this lymphoma.

Extranodal T/NK lymphoma, nasal type

This type is significantly more frequent in China and Central/South America. Other designations for this lymphoma include lymphomatoid granulomatosis, polymorphic reticulosis, angiocentric immunoproliferative lesion or NK lymphoma. A workshop on angiocentric T-NHL outlined its peculiarities and stressed the differences between angiocentric nasal T/NK lymphomas and lymphomatoid granulomatosis. Lymphomatoid papulosis is now a well-recognized entity considered within cutaneous T-NHL. The term 'angiocentric' lymphoma was coined to define what represents different disease manifestations of related entities and to emphasize the angiocentricity of the lesions. Although the clonal T-cell nature of the lymphoid cells is not always demonstrated, the clinical course suggests that this is a neoplastic process. Patients present with extranodal disease, particularly a nasal mass; other tissues involved may be skin, testes, CNS, lung, bowel, bone, etc. The tumour histology shows lymphoid infiltrates admixed with histiocytes with a marked angiocentricity and angiodestruction (Figure 39.17).

It has been suggested that necrosis relates to the release of tumour necrosis factor overexpressed by the tumour cells and likely induced by EBV. Three grades (I–III) have been recognized on the basis of the cell size and degree of atypia and necrosis; it has been suggested that these histological subtypes may correlate with the clinical course, the best for the small-cell type. Immunophenotype shows that a proportion of cases have a T-cell phenotype often CD4[+] CD8[−] while the remaining have an NK phenotype with lack of specific T-cell markers and expression of CD56 (Figure 39.18); these later cases still express in the cytoplasm the epsilon chain of the CD3. HLA-DR determinants, CD38, CD30 and CD25 may be positive, indicating that the
Figure 39.17 Section from a nasal mass of a patient with extranodal T/NK lymphoma, nasal type, showing infiltration by lymphoid cells with angiocentricity.
Figure 39.18 Immunohistochemistry of the tissue from Figure 39.17 showing a strong reactivity with CD56.

tumour cells are activated lymphocytes. The latent membrane protein (LMP-1) of EBV can be demonstrated by immunohistochemistry in most cases. Cytogenetic information is scanty, but abnormalities involving iso6p, del(6q), iso1q, are common. Rearrangement of the TCR-chain genes has been documented in only a minority of cases, while most have germline TCR genes despite the fact that the features are of a malignant neoplasm and the epsilon chain of the CD3 is expressed. This has led to the speculation that the nature of the neoplastic cells is close to the NK lineage. The pathogenic role of EBV in this lymphoma has been well established by both serology and molecular analysis, the latter showing single clonal episomal bands in the tumour cells and, thus, demonstrating the clonal nature of the cells despite the germline configuration of the TCR-chain genes. Therefore,

detection of EBV RNA (EBERs) is useful to distinguish this lymphoma from cases with benign or inflammatory nasal lymphoid infiltrates. Patients with stage I/II grade lesions may respond to single agents or combination chemotherapy, but those with more extensive disease or grade III pursue an aggressive course. Prognosis is poor when dissemination occurs.

Enteropathy-type T-NHL (intestinal)

Intestinal lymphomas are often B-cell derived but a minority have a T-cell phenotype. This lymphoma seems to arise from a CD3$^+$ CD8$^+$ CD103$^+$ T lymphocyte present in the normal epithelial intestinal mucosa. Some of these patients have a previous history of coeliac disease and/or a gluten-sensitive enteropathy. The relationship between intestinal T-NHL and coeliac disease is supported by the higher frequency of this lymphoma in geographical regions where gluten enteropathy is common; diet may improve symptoms and patients have the HLA genotype seen in coeliac disease. The main manifestations are abdominal pain, chronic diarrhoea and/or weight loss; rarely bowel perforation or obstruction is the first manifestation. Histology shows intraepithelial and subepithelial lymphoid infiltration of the mucosa and villous atrophy with reactive eosinophils and histiocytes. Three histological subtypes considering the presence or not of enteropathy have been documented. These appear to correlate with outcome, the worst for patients with enteropathy associated T-NHL. The lymphoma cells express T-cell markers (CD7$^+$, CD3$^{+/-}$) and rarely are CD8 or CD4 positive. The expression of HML-1 (CD103), a marker present in normal intestinal lymphocytes, is a consistent finding supporting the theory that this lymphoma arises from the intraepithelial mucosa T-cells. The TCR-β/γ chain genes are rearranged. A high prevalence of EBV has been documented in Mexican but not in European patients. The clinical course is aggressive, with survival estimated to be less than 1 year. Patients with localized bowel disease have longer survival than those with generalized disease. Surgery is often the diagnostic procedure and the first therapeutical approach. Problems in the patient's management are the intolerance to chemotherapy due to poor nutrition, low performance status and low albumin. The outcome is significantly worse than that of low-grade intestinal B-NHL, in which the disease is controlled with minor intervention.

Anaplastic large-cell lymphoma (ALCL)

Anaplastic large-cell lymphoma was first recognized by Stein and is now considered as a distinct clinicobiological entity with characteristic molecular features and expression of Ki-1 (CD30), a marker also present in Reed–Sternberg cells. Because of the undifferentiated morphology, it was originally designated ALCL. It has a bimodal age of presentation (childhood and elderly) without clear sex predominance. Lymphadenopathy and cutaneous lesions are the most frequent manifestations while extranodal disease is rare (Table 39.2). There are two forms – systemic and primarily cutaneous ALCL – and it is controversial whether
Figure 39.19 Bone marrow film from a patient with CD30$^+$ ALCL showing infiltration by large bizarre anaplastic cells.

these forms are biologically different. In the WHO classification, the cutaneous CD30$^+$ ALCL is considered within the group of primary cutaneous T-NHL together with lymphomatoid papulosis and 'borderline lesions'. In addition, there is a secondary ALCL which develops in patients with lymphomatoid papulosis, MF and Hodgkin's disease and the prognosis in this group is worse than in *de novo* ALCL.

Lymph node histology shows lymphoid infiltration of the T zone and paracortical areas, with or without intrasinusoidal involvement. Capsular thickening and fibrous tissue deposition are common. The skin shows infiltration of the dermis and subcutaneous tissue but epidermotropism is rare. Morphologically, ALCL is heterogeneous. The typical morphology is that of very large lymphoid cells, sometimes multinucleated, resembling Reed–Sternberg cells (Figure 39.19). Several morphological variants of ALCL have been recognized: monomorphic, Hodgkin's-like, histiocytic rich or small cell. Despite this morphological heterogeneity, all these variants bear the t(2;5). Most cases have a T-cell phenotype and often lack expression of some T-cell markers; a few cases have a 'null' (non-B, non-T) phenotype.

ALCL cells universally express CD30 (Ki-1), the hallmark of this lymphoma (Table 39.3). Lymphocyte activation markers such as CD25, HLA-DR determinants and CD71 and the epithelial membrane antigen (EMA) are often positive while the cells are cytokeratin negative. Unlike Reed–Sternberg cells, ALCL cells are, as a rule, CD15 negative. This is important to consider as diagnostic problems of this lymphoma frequently arise with Hodgkin's disease. Recent studies have shown that ALCL cells express perforin and granzyme B, molecules present in cytotoxic and NK cells, and thus suggested that ALCL cells derive from activated cytotoxic T cells. The chromosomal abnormality t(2;5)(p23;q35) is characteristic of ALCL. This leads to the

rearrangement of the nucleolar phosphoprotein gene (*NPM*) on 5q35 with the anaplastic lymphoma tyrosine kinase (*ALK*) gene on 2p23 (Table 39.3). This fusion generates a chimeric transcript, NPM–ALK, which can be detected by FISH or by reverse transcriptase PCR using specific primers and by immunohistochemistry with an antibody against the *ALK*-encoded p80 protein. The expression or absence of p80 protein appears to have a prognostic impact. The NPM–ALK transcripts are detectable in most cases of nodal Ki-1[+] ALCL, but in only a few with the pure cutaneous form. This reinforces the fact that the latter represent a different entity, as regarded by the WHO.

It is unlikely that viruses such as EBV or HTLV-I play a pathogenic role in the development of this lymphoma. All the studies documenting the presence of these viruses are not solid and probably included some cases with other diagnosis.

The clinical course of ALCL is variable. Patients with early stages (I/II) and/or primary ALCL fare relatively well compared with those with advanced stages, bulky disease and/or secondary ALCL. The main prognostic factor in multivariate analysis is advanced stage (III/IV). There is no gold standard therapy for ALCL, and therapy should be tailored considering age, performance status and extent of the disease. Localized skin lesions may respond to radiotherapy but in advanced stages combination chemotherapy should be recommended. Unlike other T-NHL, ALCL patients have sensitive disease and usually respond to chemotherapy with an overall response rate of 55–100% in different series reported; however, most patients relapse. Autologous transplant has been successful in relapsed or newly diagnosed patients and this is the choice for young patients with advanced stages.

Differential diagnosis of peripheral T-NHL

The differential diagnosis arises with: (i) B-cell lymphomas, essentially T-cell rich B-NHL; (ii) reactive non-neoplastic lymphadenitis; and (iii) rarely, with Hodgkin's disease or acute leukaemias. Histology and immunohistochemistry allow distinguishing B- from T-cell lymphomas. In difficult cases, markers should be complemented with TCR and immunoglobulin chain gene analysis. The latter, in addition, will exclude cases of reactive lymphadenitis with difficult histology. Immunophenotype allows the distinction between large-cell T-NHL and acute myeloid leukaemia.

Diagnostic problems with other diseases may also arise with specific T-NHL subtypes. For instance, subpanniculitis-like T-NHL should be distinguished from benign skin conditions or histiocytosis, AIL T-NHL from reactive disorders, CD30[+] ALCL from Hodgkin's disease, and peripheral T-NHL, with marked haemophagocytic component, from histiocytic tumours or a reactive haemophagocytic syndrome. In such a setting, it is important to compound clinical features with the histopathology and, if required, with molecular analysis of the TCR chain genes.

Conclusions

The mature or chronic T-cell lymphoproliferative disorders comprise a variety of disease entities with distinct clinical and laboratory features. They can be classified on the basis of the clinical presentation and disease manifestations into primary leukaemias, leukaemia/lymphoma syndromes and T-cell lymphomas. The precise diagnosis is important in terms of patient management, prognosis and therapy. Most of these disorders have an aggressive clinical course and are considered as high- to intermediate-grade lymphomas. The application of molecular techniques together with immunological markers has greatly helped the understanding of their pathogenesis by the identification of genes or oncogenes responsible for disease initiation or progression and has allowed defining disease entities. This, in turn, has provided the basis for the development of novel and specific therapies for certain conditions, with improvement in survival. However, further research is needed to define a number of disorders which at present have not emerged as distinct entities. In this context, gene microarray analysis may allow us to establish new lymphoma entities, shed further light on their pathogenesis and devise gene-targeted therapies.

The myelodysplastic syndromes

40

David G Oscier and Sally B Killick

Introduction

The myelodysplastic syndromes (MDS) are clonal disorders of haemopoiesis. They share characteristic morphological abnormalities of the blood and bone marrow and a risk of evolution to acute leukaemia which varies depending on the subtype of MDS. The majority of patients are elderly and present with symptoms of marrow failure despite increased marrow cellularity. The nomenclature used to describe this syndrome has changed over the last 70 years. In the 1930s, the term 'refractory anaemia' was used to describe anaemic patients who were unresponsive to iron, vitamin B_{12} or folic acid. While some had 'anaemia of chronic disorders' others had features typical of MDS. A subgroup of patients with refractory anaemia was subsequently shown to have ring sideroblasts in the bone marrow. In the 1950s, it was appreciated that acute leukaemia in the elderly was often preceded by a 'pre-leukaemic' phase of peripheral blood cytopenia associated with either normal or a slightly increased percentage of bone marrow blasts. In 1982, the French–American–British (FAB) group proposed a morphological classification based on the percentage of blasts and ringed sideroblasts in the bone marrow and the presence or absence of a peripheral blood monocytosis which divided MDS into five subgroups. Patients with > 30% blasts in the bone marrow were considered to have acute leukaemia. In 2001, the World Health Organization (WHO) published a new classification of MDS incorporating morphological, genetic and clinical features; key differences from the FAB classification were the lowering of the blast threshold for the diagnosis of acute myeloid leukaemia (AML) to 20% and the

creation of a new category of mixed myelodysplastic and myeloproliferative diseases for patients with both proliferative features and dysplastic morphology. This chapter will utilize the WHO classification but includes a separate section on childhood MDS, which has some distinctive features.

Adult myelodysplastic syndromes

Incidence

Data on the incidence of MDS classified according to FAB criteria are derived mainly from European studies. Overall annual incidence rates are 3–4 per 100 000, but the rate increases dramatically with age, exceeding 30 per 100 000 for patients over the age of 80 (Figure 40.1). Data from the Italian registry show that 60% of patients are over the age of 70 years at diagnosis. The male to female ratio is 1.4:1. The most accurate epidemiological data on MDS come from the town district of Dusseldorf, where the incidence of MDS rose from 1.0 to 4.1 per 100 000 per year between 1976 and 1986. Subsequently, the incidence has remained stable and the early rise in incidence almost certainly reflected improvements in the diagnosis of MDS and an increasing tendency to investigate elderly cytopenic patients.

Aetiology

The aetiology of most cases of primary MDS remains unknown. Data from case–control studies are not always consistent but suggest modest associations with ionizing radiation, exposure to
Figure 40.1 Age distribution of patients presenting with MDS in Bournemouth, 1981–1990.

benzene, solvents and pesticides, and with smoking. There is current interest in the possibility that polymorphisms in genes which encode proteins which interact with environmental factors may be associated with an increased susceptibility to MDS. Examples include enzymes responsible for the metabolism of carcinogens, defence against oxidative stress and DNA repair. In approximately 15% of patients, secondary or therapy-related MDS (TR-MDS) develops after exposure to cytotoxic chemotherapy and/or wide-field radiotherapy. The cytotoxic agents most commonly implicated are alkylating agents, nitrosoureas and procarbazine but not topoisomerase II inhibitors. The maximum incidence of TR-MDS occurs 5–7 years, with a range of 1–10 years, following exposure to chemotherapy. The risk increases with age and with prolonged exposure to low-dose chemotherapy. The risk of developing TR-MDS or acute myeloid leukaemia (AML) following autologous transplantation for lymphoma, myeloma or solid tumours varies widely between series (1–12%). Most cases develop within 5 years of transplantation and risk factors include increasing age, the duration and quantity of pretransplant chemotherapy and the use of total body irradiation as part of the conditioning regimen.

As discussed below, TR-MDS is associated with a higher incidence of trilineage dysplasia, genetic abnormalities, evolution to AML and poor response to treatment than is primary MDS.

Clinical and laboratory features

Clinical features
Twenty per cent of primary adult MDS patients are diagnosed from an incidental blood count, but the majority of the remainder present with features of bone marrow failure; 80% complain of fatigue due to anaemia while 20% present with infections or bleeding. Bacterial pneumonias and skin abscesses are the most common infections, occurring particularly in patients with a neutrophil count $< 1 \times 10^9$/L. Lymphadenopathy, hepatomegaly and splenomegaly are rarely found. There is an association

between MDS and several rare disorders that seem to have an immunological basis. These include febrile neutrophilic dermatosis (Sweet's syndrome), pyoderma gangrenosum, cutaneous vasculitis and relapsing polychondritis.

Blood count
Most patients are anaemic at presentation; 30–50% are pancytopenic, while 20% have anaemia in combination with either neutropenia or thrombocytopenia. Approximately 5% have isolated neutropenia or thrombocytopenia. Rarely, the diagnosis of MDS may be suspected because of macrocytosis or abnormalities in the blood film in the presence of a normal blood count. Parameters such as the myeloperoxidase index of granulocytes (MPXI), erythrocyte distribution width (RDW) and platelet distribution width (PDW) generated by automated cell counters are frequently abnormal and may become useful as markers for early MDS.

Blood and marrow morphology
The ability to diagnose MDS is critically dependent on optimal staining of blood and marrow slides with a Romanowsky stain. The accuracy of the marrow differential increases with the number of cells counted, which should be a minimum of 500. Less than 0.5 ml of marrow should be aspirated for morphological assessment to avoid excessive dilution with peripheral blood cells. The main morphological abnormalities found in MDS are summarized in Table 40.1 and examples are shown in Figure 40.2. The presence of hypochromic red cell fragments, particularly when accompanied by basophilic stippling, is strongly suggestive of refractory anaemia with ring sideroblasts. Rarely, male patients may present with or develop a pronounced dimorphic picture due to acquired haemoglobin H disease. Interobserver variation is a problem in diagnosis of MDS and is lowest for the detection of ring sideroblasts, micromegakaryocytes and increased blasts, and highest for mild dyserythropoiesis and neutrophil hypogranularity. It is important to recognize that

dysplastic morphology may also be seen in healthy elderly individuals (affecting < 10% of marrow cells) and in a variety of non-clonal disorders including vitamin B_{12} and folic acid deficiency, heavy metal and alcohol poisoning, HIV and parvovirus infections and exposure to treatments such as anti-tuberculous therapy and granulocyte colony-stimulating factor (G-CSF).

Marrow histology

Bone marrow histology can provide additional diagnostic and prognostic information not obtainable from a marrow aspirate alone and should be routinely undertaken whenever bone marrow examination is performed in proven or suspected cases of MDS. Although the marrow is frequently hypercellular in MDS,

Table 40.1 Morphological abnormalities in MDS.

Lineage	Blood	Bone marrow
Erythroid	Oval macrocytosis	Erythroid hypoplasia
	Aniso-poikilocytosis	Multinuclearity
	Hypochromic red cell fragments	Dyskaryorrhexis
	Basophilic stippling	Cytoplasmic vacuolation
	Nucleated red cells	Ringed sideroblasts
Myeloid	Hypogranular neutrophils	Hypogranularity
	Hypolobation of neutrophil nuclei (Pelger cells)	Increased eosinophils and/or basophils
	Coarse nuclear chromatin clumping	Increased blasts
Megakaryocytes	Agranular platelets	Micromegakaryocytes
	Giant platelets	Large mono- or binuclear megakaryocytes
		Megakaryocytes with widely dispersed nuclei

hypocellularity, defined as cellularity < 30% of normal by reference to age-matched control subjects, is found in between 10% and 20% of cases. The precise incidence of hypocellularity is difficult to define since studies using magnetic resonance imaging have shown that marrow cellularity may be patchy, particularly in cases with no increase in marrow blasts. A slight increase in reticulin is seen in 50% of MDS cases, but marked fibrosis occurs in < 10%. Marrow hypocellularity, increased fibrosis and an inflammatory infiltrate comprising plasma cells, eosinophils, lymphoid aggregates and areas of oedema are more common in TR-MDS than in primary cases.

Marrow topography is frequently abnormal in MDS. In health, immature myeloid precursors are seen close to bony trabeculae and around blood vessels, whereas developing erythroid cells and megakaryocytes are seen in intertrabecular spaces. In MDS, myeloid precursors are displaced from trabecular margins and small clusters of myeloblasts and promyelocytes are sometimes seen in intertrabecular spaces. The clusters are called ALIPS (abnormal localization of immature precursors) and may develop due to autocrine production of vascular endothelial growth factor. The presence of ALIPS is considered to be an adverse prognostic factor in patients with less than 5% marrow blasts, but they are difficult to recognize and quantify and their presence is not specific to MDS. Clustering of megakaryocytes and the presence of both erythroid cells and megakaryocytes in paratrabecullar areas are also features of MDS.

Cytogenetic, genetic and epigenetic abnormalities

Clonal cytogenetic abnormalities are found on direct or short-term culture of bone marrow in between 10% and 50% of cases of primary MDS, depending on the subtype, and 90% of cases of TR-MDS; the most common abnormalities are shown in

Table 40.2 Incidence (%) of chromosome abnormalities in MDS.

Abnormality	Primary MDS	TR MDS
del 5q/monosomy 5	10–20	30
del 7q/monosomy 7	10	40
trisomy 8	10	10
t(11q23)	6	3
del 17p	3	8
del 20q	5	< 1
Complex karyotype	10–20	90

Table 40.2. The use of fluorescence *in situ* hybridization (FISH) in interphase cells, using probes to detect the common cytogenetic abnormalities in MDS, enables clonal abnormalities to be detected in up to 10% of patients with a normal karyotype. Patients with higher blasts counts are more likely to have complex karyotypic abnormalities. Serial studies show that karyotypic evolution occurs in approximately 15% of cases. Apart from the 5q-minus syndrome, which is discussed in more detail later, cytogenetic abnormalities are not specific for particular subtypes of MDS. In contrast to *de novo* AML, chromosome translocations are rare in MDS and most cytogenetic abnormalities involve the gain or loss of genetic material. Although the genetic consequences of the common cytogenetic abnormalities remain unknown, minimally deleted regions have been defined for the deletions associated with the 5q-minus syndrome, for 5q deletions occurring in TR-MDS and AML, and for the deletion on chromosome 20q. A number of separate deleted regions have been identified on chromosome 7q. Deletions of classical tumour-suppressor genes are accompanied by mutations or epigenetic silencing of the remaining allele. There is no evidence for mutation or loss of function of any gene on the remaining allele within the minimally deleted regions on chromosomes 5, 7

and 20, suggesting that a dosage effect resulting from the loss of a single allele (haploinsufficiency) may contribute to the malignant phenotype.

Further progress in defining key genes in the pathogenesis of MDS should come from genetic engineering studies in which the common chromosomal deletions in MDS are reproduced in mice.

Gene expression profiling using cDNA microarray analysis has been performed on both purified CD34-positive cells and neutrophils from patients with MDS. A characteristic expression profile has been identified for patients with trisomy of chromosome 8 and differences have been observed between myelodysplastic and normal CD34-positive cells and between patients with good-risk and poor-risk MDS.

Mutations of oncogenes and tumour-suppressor genes important in other haematological malignancies and in solid tumours have also been identified in MDS. *RAS* mutations, usually involving N-*RAS*, are found in up to 20% of cases depending on the subtype. Mutations of *RAS* may occur early in MDS and persist throughout the course of the disease or may be lost or first appear at the time of leukaemic transformation. Mutations of the *p53* gene, *CSF*-1R gene and *AML1* gene and internal duplication of the *FLT-3* gene are found in less than 10% of cases. It is increasingly recognized that methylation of CpG islands in the promoter region of genes may result in gene silencing in malignancy in the absence of mutation or deletion. Hypermethylation of the *p15* gene, which encodes an inhibitor of cell cycle progression, is found in 50% of patients with MDS, particularly in patients with raised blast cell counts. There is a correlation between clinical response to both 5-azacytidine

and 5-aza-2-deoxycytidine, both potent inhibitors of cytidine methylation, and demethylation of the *p15* gene.

Shortened telomeres, increased telomerase activity and microsatellite instability have also been described in MDS.

Detailed cytogenetic and genetic studies of patients with TR-MDS have identified patterns of associated abnormalities. Patients with monosomy 5 or deletion of 5q frequently have complex karyotypic abnormalities, a high incidence of *p53* mutations and a very poor prognosis. Abnormalities of chromosome 7 are associated with hypermethylation of the *p15* gene while tandem duplications of the *FLT-3* gene are most commonly found in the minority of patients with a normal karyotype.

Other investigations

Immunophenotyping of blood or bone marrow cells is not routinely performed in MDS, but abnormalities such as low sidescatter, downregulation of antigens normally expressed on myeloid cells, and abnormal patterns of cell marker expression are commonly found in MDS. In addition, blast cells are more frequently CD34-positive and myeloperoxidase-negative than in *de novo* AML and the expression of additional markers on blast cells such as CD7 may have prognostic significance. *In vitro* colony growth is frequently defective in MDS, particularly in patients with increased marrow blasts, but the techniques are too cumbersome and poorly standardized for routine use.

Further laboratory tests frequently abnormal in MDS are shown in Table 40.3.

Table 40.3 Laboratory findings in MDS.

Investigation	Abnormality
Ferrokinetics	Ineffective erythropoiesis
Haemoglobin F	Frequently raised in JMML
Haemoglobin H	Raised in acquired haemoglobin H disease
Ham's test	Rarely positive
NAP score	Frequently low
Serum lysozyme	Increased in CMML
Granulocyte function	Reduced motility, adherence phagocytosis and bacterial killing
Platelet function	Prolonged bleeding time, reduced aggregation with adrenaline and collagen
Platelet-associated immunoglobulin	May be raised in the absence of immune-mediated thrombocytopenia
Lymphocyte populations	Reduced CD4 and natural killer cells
Immunoglobulins	Polyclonal gammopathy in 30%
	Hypogammaglobulinaemia in 20%
	Paraprotein in 5–10%
Autoantibodies	Found in 50% of cases of CMML

Table 40.4 The FAB classification of MDS.

Subtype	Blood	Bone marrow
Refractory anaemia (RA)	< 1% blasts	Dysplasia < 5% blasts
Refractory anaemia with ringed sideroblasts (RARS)	< 1% blasts	As for RA and > 15% ringed sideroblasts
Refractory anaemia with excess blasts (RAEB)	< 5% blasts	Dysplasia 5–19% blasts
Refractory anaemia with excess blasts in transformation (RAEBt)	< 5% blasts	Dysplasia 20–29% blasts or Auer rods
Chronic myelomonocytic leukaemia (CMML)	$> 1 \times 10^9$/L monocytes	Dysplasia < 30% blasts

Table 40.5 The WHO classification of MDS.

Subtype	Blood	Bone marrow
Refractory anaemia (RA)	Anaemia	Erythroid dysplasia only
Refractory anaemia with ringed sideroblasts (RARS)	Anaemia	Erythroid dysplasia only > 15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Bi- or pancytopenia	Dysplasia in > 10% of cells in two or more cell lineages
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)	Bi- or pancytopenia	Dysplasia in > 10% of cells in two or more cell lineages > 15% ringed sideroblasts
Refractory anaemia with excess blasts-1 (RAEB-1)	Cytopenias; < 5% blasts	Uni- or multilineage dysplasia 5–9% blasts
Refractory anaemia with excess blasts-2 (RAEB-2)	Cytopenias or 5–19% blasts or Auer rods	Uni- or multilineage dysplasia 10–19% blasts or Auer rods
Myelodysplastic syndrome unclassified (MDS-U)	Cytopenias	Myeloid or megakaryocytic dysplasia
MDS associated with isolated del (5q)	Anaemia; normal or increased platelets	Megakaryocytes with hypolobated nuclei < 5% blasts

Classification of MDS

The FAB and WHO classifications of MDS and their interrelationship are shown in Tables 40.4–40.6.

The FAB classification (Table 40.4)

The FAB classification divides MDS into five subgroups with differing prognoses. The typical case of refractory anaemia (RA) presents with anaemia and a hypercellular marrow showing dyserythropoiesis but minimal granulocytic or megakaryocytic abnormalities. However, this group is clinically heterogeneous and includes patients with varying degrees of dysplasia and also patients with neutropenia and/or thrombocytopenia without anaemia. The diagnosis of refractory anaemia with ring sideroblasts (RARS) is made when ring sideroblasts forming a complete or partial ring around the nucleus make up more than 15% of erythroid cells, although small numbers of ring sideroblasts are found in over 60% of cases of MDS regardless of the subtype. Patients with an increase in marrow blasts are subdivided into those with refractory anaemia with excess blasts (RAEB) when the marrow blasts range between 5% and 19% and those with refractory anaemia with excess blasts in transformation (RAEBt) with a blast percentage between 20% and 29%. The latter term was introduced in recognition of the minority of patients with an increase in marrow blasts whose disease follows a more indolent course than is typically seen in AML. Chronic

Table 40.6 Relationship between the FAB and WHO classifications.

FAB	WHO
RA	RA (unilineage)
	RCMD

RARS	RARS (unilineage)
	RCMD-RS
RAEB	RAEB-1
	RAEB-2
RAEBt	AML with multilineage dysplasia
	AML and MDS, therapy related
CMML	Myelodysplastic/myeloproliferative diseases

myelomonocytic leukaemia (CMML) encompasses all cases with more than 1×10^9/L circulating monocytes. This subgroup was also recognized to be heterogeneous and includes patients with a high monocyte count and splenomegaly more typical of a myeloproliferative disorder as well as patients with a modest monocytosis and a clinical course similar to that seen in refractory anaemia or refractory anaemia with excess blasts.

The WHO classification (Table 40.5)

The WHO classification is a modification of the FAB classification incorporating more recent clinical and genetic data. Following the observation that patients with less than 5% marrow blasts had a poorer prognosis if multilineage dysplasia was present, the terms refractory anaemia and refractory anaemia with ring sideroblasts are confined to patients with unilineage erythroid dysplasia. New terms, refractory cytopenia with multilineage dysplasia(RCMD) and refractory cytopenia with multilineage dysplasia and ring sideroblasts, have been introduced for cases with bi- or pancytopenia and dysplastic features in more than 10% of cells in two or more myeloid lineages. It is recognized that patients with unilineage erythroid dysplasia, or in whom dysplasia is seen in < 10% of cells in two lineages, may be difficult to diagnose as having MDS in the absence of a clonal karyotypic abnormality. It is recommended that such patients are re-evaluated at 6 months. MDS associated with an isolated deletion of chromosome 5q is considered to be a separate subgroup based on the uniformity of clinical and laboratory features of cases with this cytogenetic abnormality. The majority of patients are elderly women who present with a macrocytic anaemia, normal white cell count and a normal or raised platelet count. The marrow aspirate shows erythroid hypoplasia and large mono- or binuclear megakaryocytes. Most

patients present with or develop a red cell transfusion requirement and the risk of leukaemic transformation is low.

The WHO classification recognizes the prognostic importance of the percentage of bone marrow blasts in MDS and includes myeloblasts, monoblasts, promonocytes and megakaryoblasts, but not erythroblasts, within the definition of a blast cell. CD34-positive cells defined immunophenotypically are not considered to be synonymous with the blast cells.

The term refractory anaemia with excess blasts is retained but subdivided into two subgroups based on the previous observation that patients with 10–19% of marrow blasts or more than 5% of circulating blasts (RAEB2) had a poorer prognosis than patients with < 10% of marrow blasts or fewer than 5% circulating blasts (RAEB1) (Table 40.6). The significance of Auer rods within blast cells remains uncertain in MDS, but all patients in whom Auer rods are seen are categorized as having RAEB2. In view of clinical and biological similarities, such as cytogenetic abnormalities, a high expression of multidrug-resistant glycoprotein and poor response to chemotherapy, between patients with dysplastic features and 20–29% marrow blasts and those with 30% or more blasts, the term refractory anaemia with excess blasts in transformation was abolished and all cases with dysplasia and more than 20% of blasts are classified as acute myeloid leukaemia with multilineage dysplasia. In addition, cases with the typical chromosome translocations found in *de novo* AML such as the t(15:17), t(18:21) and in(16) are considered to have AML regardless of the percentage of marrow blasts.

A new subgroup of MDS unclassified has also been introduced specifically for patients with unilineage, myeloid or megakaryocytic dysplasia and not as a depository for inadequately investigated cases.

Chronic myelomonocytic leukaemia is now included in a new classification of mixed myeloproliferative and myelodysplastic disorders.

Although the various WHO subgroups have differing clinical and biological features (Table 40.7), the use of quantitative criteria such as marrow blast percentage to define subgroups is of necessity arbitrary, and while some patients may remain within a single WHO subgroup others may progress through two or more subgroups during the course of their disease. It cannot be assumed that the clinical course of a patient presenting with RAEB will be the same as that of a patient with a preceding history of RCMD.

Pathogenesis

The pathogenesis of primary adult MDS is poorly understood. Genetic and functional abnormalities of haemopoietic stem cells, immunological abnormalities and increased apoptosis of bone marrow cells are all well documented, as discussed below (Figure 40.3).

Subtype	% of MDS	Cytogenetic abnormalities (%)	Median survival (months)
RA	5–10	25	66
RARS	10	< 10	72
RCMD	24	50	33
RCMD-RS	15	50	33
RAEB	40	30–50	10 (RAEB-1)
			18 (RAEB-2)
Isolated del 5q	5	100	116

Table 40.7 WHO classification – clinical and laboratory features.

Figure 40.3 Pathogenesis of myelodysplasia.

multiple cytogenetic abnormalities, point mutations in onco-genes and epigenetic abnormalities, particularly in TR-MDS but also in primary MDS, clearly demonstrates the multistep pathogenesis of MDS.

In addition to abnormalities of the nuclear genome, mito-chondrial DNA mutations are also found in up to 50% cases. In patients with ringed sideroblasts, iron deposition occurs within mitochondria, and it has been suggested that mitochondrial DNA mutations may impair the function of the mitochondrial respiratory chain, leading to oxidation of ferrous to ferric iron with the consequent accumulation of ferric iron within mitochondria. Support for this model comes from the study of Pearson's syndrome, which is a rare congenital disorder charac-terized by large lesions of mitochondrial DNA and a refractory anaemia with ringed sideroblasts in the bone marrow.

Immunological abnormalities in MDS

Aplastic anaemia and hypocellular MDS have many features in common. Both disorders are characterized by a clonal expan-sion of T cells (the clones are antigen driven and not neoplastic), over-representation of HLA-DR15, the presence of mutations in the *PIG-A* gene characteristic of paroxysmal nocturnal haemo-globinuria (PNH) and clinical response to immunosuppressive therapy. In addition, patients with aplastic anaemia frequently present with a macrocytosis and dyserythropoiesis. Clonal cyto-genetic abnormalities are occasionally found at presentation but develop in up to 30% of patients within 3 years of follow-up, and, following successful immunosuppressive therapy, 12% of patients develop MDS within 12 years. A current hypothesis suggests that aplastic anaemia and hypocellular MDS are closely related disorders (Figure 40.4) in which damage to a haemopoietic stem cell results in an immune response directed against both transformed and normal haemopoietic stem cells. The clinical outcome depends on the vigour of the immune response and the resistance of the neoplastic clone to immune-mediated damage. PNH clones, which are present in small numbers in normal mar-rows, appear able to expand in marrows rendered hypocellular by T-cell mediated damage. The expanded T cells in MDS may occasionally become neoplastic, resulting in T-cell large granular lymphocytic leukaemia.

MDS: a stem cell disorder

The presence of trilineage dysplasia and cytogenetic abnormalit-ies provides irrefutable evidence for involvement of a multipotent haemopoietic stem cell in MDS. The nature of the initiating event is unknown but is likely to be heterogeneous and include both inherited and acquired DNA damage. Insight into the nature of the target cell in MDS has come from recent studies utilizing interphase FISH. In normal marrow, haemopoietic stem cells reside in the CD34-positive, CD38-negative cell fraction. Interphase FISH studies in patients with the 5q-minus syndrome show that this cytogenetic abnormality is found in both CD34-positive, CD38-negative and CD34-positive, CD19-positive pro-B cells, suggesting that the disease originates in a lymphomyeloid stem cell. Similar studies in patients with tri-somy 8 show that this abnormality originates in a more mature myeloid stem cell but CD34-positive, CD38-negative cells which lack trisomy 8 are still functionally defective, implying that trisomy 8 is not an initiating event in the pathogenesis of MDS. It is currently unclear whether cases in which morphological abnormalities are confined to a single lineage arise in a lineage-committed or multipotent stem cell. The frequent finding of

Figure 40.4 Interrelationship between aplastic anaemia, myelodysplasia, paroxysmal nocturnal haemaglobinuria and T-cell large granulocytic leukaemia.

Apoptosis in MDS

A long-recognized paradox in MDS has been the association between a hypercellular bone marrow and peripheral blood cytopenias. In patients undergoing leukaemic transformation, cytopenias probably result from a failure of maturation of the neoplastic clone. However, there is increasing evidence that the ineffective haemopoiesis seen in patients without increased blasts is due to an increased susceptibility of CD34-positive MDS cells to apoptosis. Apoptosis is more prominent in early MDS (RA, RARS) than in advanced MDS (RAEBt and AML). In keeping with this finding, small studies have shown that Bcl-2 expression is lower in early MDS than with disease progression to AML, and patients with early MDS seem to have higher ratios of proapoptotic than of antiapoptotic proteins. There does not seem to be a correlation between CD34+ apoptosis and age, sub-type of MDS, peripheral cytopenias or marrow cellularity. Apoptosis may be triggered by a variety of factors, including intrinsic DNA damage, mitochondrial dysfunction, cytotoxic T cells, overexpression of the cytokine TNF-α with subsequent upregulation of the FAS/FASL pathway and abnormalities of marrow stromal cells. A recent study has shown that erythroid precursors in MDS spontaneously release cytochrome C from mitochondria, leading to activation of caspase 9 and apoptosis. G-CSF inhibits cytochrome C release, and this may provide an explanation for the use of G-CSF in conjunction with eryth-ropoietin in treating the anaemia of patients with RA, RARS and RCMD. Other agents targeted at proapoptotic pathways, e.g. amifostine or pentoxifylline, have not fulfilled their early promises.

Natural history and prognostic factors

The median survival of adult patients with primary MDS is approximately 20 months and the prognosis for each WHO sub-group is worse than for age- and sex-matched control subjects. The marked heterogeneity in outcome in MDS was illustrated by
Figure 40.5 Hypothetical model of evolution patterns in patients with MDS, based on growth advantage instability of the malignant clone (from Tricot *et al.* 1985, with permission).

a study of 46 patients, which correlated the morphological and cytogenetic changes that occurred during the course of the dis-ease with survival (Figure 40.5). Forty-eight per cent of patients (group A) had a stable course over many years. The initial FAB diagnosis in these cases was RA, RARS or CMML, and the majority were ALIP negative. Additional chromosome abnorm-alities rarely occurred during the course of the disease, and many patients died from incidental causes. Twenty-four per cent of patients (group C) had a gradual increase in the percentage of marrow blasts. These patients were often ALIP-positive at diag-nosis and rarely showed karyotypic evolution. They frequently succumbed to infections or haemorrhagic complications with or without evolution to acute leukaemia. A further type of evolu-tion (group B or D), found in 28% of patients, was characterized by a rapid increase in blast cells. The majority of these patients already had an abnormal karyotype at presentation, and most were ALIP positive. The sudden increase in blasts was frequently accompanied by additional chromosomal abnormalities. Another form of evolution not shown in Figure 40.5 is characterized by increasing pancytopenia without an increase in marrow blasts. Dysplastic changes may become more pronounced, and occa-sionally increasing anaemia may be due to red cell aplasia. It is unclear whether these changes reflect clonal expansion or clonal evolution.

This heterogeneity in clinical course has stimulated an ongo-ing quest for prognostic factors. A list of factors with adverse prognostic significance is shown in Table 40.8. Since the WHO classification incorporates known prognostic factors such as cytopenias, increased marrow blasts, the presence of trilineage dysplasia and the isolated loss of chromosome 5q, it is not sur-prising that it has prognostic significance. A different approach has been to devise prognostic scoring systems incorporating a number of known prognostic factors, and is suitable for use in all patients with MDS regardless of their subtype. In 1997, an International Prognostic Scoring System (IPSS) was published

Table 40.8 Adverse prognostic factors in MDS.

Leukaemic growth pattern

based on the retrospective evaluation of a clinical, morphological and cytogenetic data from 816 patients who were either untreated or had received only short courses of low-dose oral chemotherapy or haemopoietic growth factors. The study included patients classified as having MDS according to the FAB criteria except that patients with proliferative CMML with a white blood count of $> 12 \times 10^9$/L were excluded. The IPSS is shown in Table 40.9, and patients may be allocated into one of four risk groups – low,

intermediate I, intermediate II or high – whose median survival according to age at diagnosis is shown in Table 40.10. The clinical value of a single prognostic factor or a scoring system is critically dependent on the type of treatment a patient receives. The IPSS has been validated in patients undergoing allogeneic transplantation, but the outcome of patients receiving intensive chemotherapy is more dependant on cytogenetic data than the percentage of marrow blasts and the IPSS appears to be less useful in this setting. Different sets of predictive factors for response to haemopoietic growth factors and to immunosuppressive therapy have also been developed and these are discussed later.

It is likely that newer prognostic factors, including data from gene expression profiling, will be incorporated into scoring systems and will improve the prognostic power.

Management

The management of MDS is generally unsatisfactory. The literature abounds with small uncontrolled studies, usually detailing the short-term response to a wide variety of agents. There is also a dearth of randomized trials such that the relative merit of various forms of treatment remains unclear. This lack of good trial data in a relatively common disorder with a short median survival reflects both the difficulty of trial design and the disappointing preliminary results obtained with most currently available treatments but is largely due to the advanced age of most of the patients, whose general health, social situation and own wishes and expectations are major factors in determining appropriate treatment. Management options range from observation only, supportive care, a variety of treatments (cytotoxics, transplantation, growth factors, immunosuppression), to only symptom relief for patients whose general health is so poor that an improvement in their haematological status would confer no corresponding improvement in quality of life. Identification of risk factors for disease progression and use of the IPSS score to predict outcome may help guide the clinician in deciding patient management. However, there are two caveats: in asymptomatic patients, a period of observation to determine the rate of disease progression can be helpful before formulating a management plan, and it is unwise to base treatment on the results of blood

Table 40.9 International Prognostic Scoring System (IPSS).

Score value	0	0.5	1.0	1.5	2.0
BM blasts (%)	< 5	5–10	–	11–20	21–30
Karyotype*	Good	Intermediate	Poor		
Cytopenias	0/1	2/3			

*Good: normal, –Y, del(5q), del(20q); poor: complex (> 3 abnormalities) or chromosome 7 anomalies; intermediate: other abnormalities.
Cytopenias defined as haemoglobin concentration < 10 g/dL, neutrophils < 1.5×10^9/L and platelets < 100×10^9/L.

Table 40.10 Median survival of primary myelodysplastic syndrome using the IPSS score.

Risk group	IPSS score	Median survivial			
		< 60 years	*> 60 years*	*< 70 years*	*> 70 years*
Low	0	11.8	4.8	9	3.9
Intermediate 1	0.5–1.0	5.2	2.7	4.4	2.4

High	> 2.5	0.3	0.5	0.4	0.4

and marrow findings taken during an acute infective episode as transient increases in the neutrophil count and percentage of marrow blasts may be seen.

Supportive care

The mainstay of supportive care is the use of red cell transfusions in patients who are symptomatically anaemic. Blood transfusions, however, do have certain risks associated, including iron overload in multitransfused patients. Although iron chelation, with desferrioxamine, is generally recommended in good-risk MDS, there are few data in the literature to suggest that this expensive and inconvenient treatment improves overall survival. Recommendations on when to commence chelation are therefore difficult. It would be reasonable to consider chelation once a patient has received 5 g iron (approximately 25 units of red cells), but limited to those patients with a good prognosis according to the IPSS score, have no other significant comorbidities and are at an age that would clinically benefit. Vitamin C in low dose increases iron excretion and should be started after 4 weeks of commencing chelation. Desferrioxamine is generally given as a subcutaneous infusion over 10–12 h; alternatively, it can be given via an indwelling catheter. The use of oral iron chelators have not been routinely used in MDS.

Platelet transfusions are indicated in thrombocytopenic patients in the treatment of acute bleeding episodes, or as prophylaxis prior to surgery or following chemotherapy. However, their long-term use, for example in the prevention of recurrent epistaxis or mouth bleeding in elderly patients with persistent thrombocytopenia, presents major logistic (and financial) problems. The potential clinical importance of platelet and neutrophil dysfunction in patients whose counts may be normal or minimally depressed should not be forgotten when deciding on the need for platelet support prior to surgery or the choice between oral and intravenous antibiotics in an infected patient. The potential role of growth factors in supportive care is discussed below.

Growth factors

Erythropoietin (Epo)
Anaemia represents one of the major clinical problems for patients with MDS. The aim of recombinant Epo is to improve the overall quality of life by avoiding fluctuations in the haemo-

globin concentration. It also has the added benefit of avoiding the risks associated with red cell transfusions. Unfortunately, those who would benefit most are least likely to respond. Predictors of response include low serum Epo level of < 200 U/L (usually raised in MDS), non-RARS subtype and no or low transfusion requirements (two or less units/month). It is generally well tolerated and studies have shown a benefit of Epo over placebo, with overall response rates (100% reduction in transfusion requirements) of 16–24%.

There is some synergism between Epo and granulocyte colony-stimulating factor (G-CSF). The effect is most marked in patients with RARS (approximately 50% response rates), who have a very low response rate to Epo alone (approximately 8% response). In some patients the response to combination therapy can be maintained with Epo alone, whereas others require both Epo and G-CSF. A prototype predictive model for response to Epo + G-CSF has been described (Figure 40.6), based on the serum Epo level and pretreatment transfusion need. This approach could be useful to the clinician when deciding whether or not to embark on this treatment to avoid unnecessary cost and patient inconvenience. It is thought that growth factors in MDS work by reducing haemopoietic progenitor cell apoptosis, leading to more effective erythropoiesis.

Granulocyte colony-stimulating factor (G-CSF)
Over 90% of MDS patients receiving short-term G-CSF show a dose-dependent neutrophilia, with an improvement in neutrophil function but no increase in eosinophils, monocytes or lymphocytes. In a minority of patients the haemoglobin and/or platelet count is increased. Its use is usually reserved for patients with severe sepsis or as part of intensive chemotherapy.

Immunosuppression

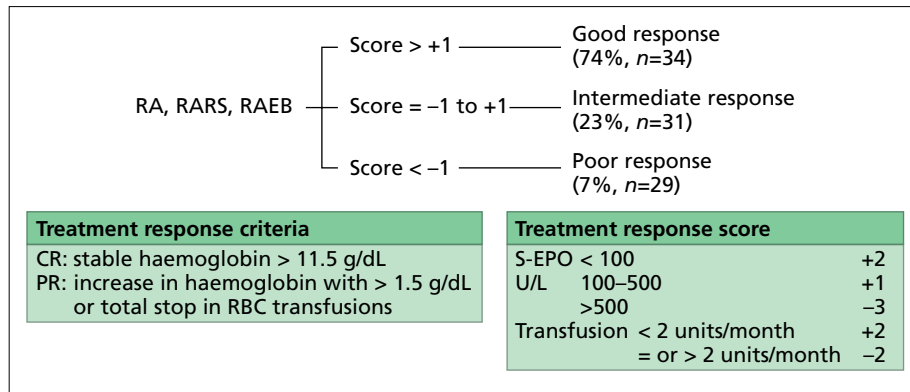
Accumulating evidence suggests that there is an immunological process involved in the pathogenesis of MDS. For this reason, as in aplastic anaemia, several groups have had success in treating 'low-risk' MDS (RA, RARS) with anti-thymocyte globulin. It is expected that 30–50% of patients will have a response to treatment, evident by an improvement in blood counts and a reduction or cessation of blood products. There seems to be a trend towards better response rates in those patients with hypocellular MDS or who have HLA-DR15. The treatment is not curative


Figure 40.6 Predictive model for response rates to therapy with Epo plus GCSF based upon pretreatment Epo concentration and transfusion need (reproduced with permission from Hellstrom-Lindberg *et al.*, *British Journal of Haematology* 2003; **120**: 1037–46).

but durable responses have been noted. Cyclosporin, probably acting by a similar mechanism, has also been shown to have an effect in one small study. The results of large randomized trials of immunosuppression in MDS are awaited.

Intensive chemotherapy

Typically, treatment of MDS with intensive chemotherapy is marked by low remission rates and high relapse rates, often complicated by prolonged chemotherapy induced hypoplasia. The reason that the disease is difficult to treat is thought to be the high drug resistance of the malignant clone. Complete remission (CR) rates are generally accepted as being lower than in patients with *de novo* AML; however, these comparisons are valid only if the patient groups are of similar age and those with apparently *de novo* AML are rigorously assessed for the presence of trilineage dysplasia.

The CR rates for high-risk MDS from studies in the mid- to late 1990s are 38–79%. Factors associated with a higher chance of CR include early treatment (within 3 months of diagnosis), young age (< 50 years), normal karyotype and the presence of Auer rods (Table 40.11). Remissions are typically short-lived (5–15 months), which provides the rationale for consolidating induction chemotherapy with transplantation in suitable patients. It is now generally accepted that among those MDS patients with complex karyotypes, particularly involving loss of chromosome 5 or 7, the CR rate is lower and remission duration even shorter. These factors should be borne in mind when deciding whether a patient should receive intensive chemotherapy.

Table 40.11 Positive predictors for response to intensive chemotherapy.

Age < 50 years
Normal karyotype
Auer rods
Treatment within 3 months of diagnosis

In vitro studies have shown that fludarabine is an effective DNA terminator and increases the intracellular concentration of Ara-C; this is the rationale behind the combination FLA. The addition of G-CSF (FLAG) is thought to increase the sensitivity of the blasts to Ara-C; however, this observation has not been translated into a clinical benefit as CR rates are similar with FLAG and FLA. Overall, studies have shown CR rates of approximately 66% with the two regimens.

Finally, patients with treatment-related MDS have a particularly poor prognosis. CR rates are lower and duration of remissions shorter.

Stem cell transplantation (SCT)

It is apparent that intensive chemotherapy alone in high-risk patients with MDS does not produce durable remissions and therefore consolidation is needed. This can be either allogeneic or autologous SCT. There is no place for SCT in patients who do not achieve CR with induction chemotherapy. Transplantation is also offered to appropriate patients with early MDS, although these patients do not usually require chemotherapy before transplant (if marrow blasts < 5%).

Allogeneic SCT

Data from the International BMT Registry (IBMTR) show that the best results following allo-SCT occur in patients under 40 years old with short disease duration and < 5% bone marrow blasts. Patients with RA/RARS receiving an HLA-identical sibling SCT have an overall 3-year survival of 53%, compared with 36% 3-year survival in those with RAEB, RAEBt or CMML (1991–1997). Data from the European BMT group (EBMT) show similar results (1983–1998), with 3-year actuarial disease-free survival of untreated RA/RARS and RAEBt/sAML of 55% and 28% respectively. Thus, the status of the underlying disease is a major contributing factor to disease-free survival (Table 40.12).

The value of giving pretransplant chemotherapy in advanced MDS remains debatable. European BMT centres favour intensive chemotherapy prior to SCT in an attempt to reduce relapse rates,

Table 40.12 Poor prognostic factors for outcome following allo-SCT in MDS.

Older age
Poor-risk cytogenetics
High IPSS score
Advanced disease (RAEB, RAEBt)
Treatment-related MDS
Prolonged disease duration
Marrow fibrosis

whereas most patients in North America are transplanted without induction chemotherapy. Pretransplant chemotherapy has the added advantage of selecting out those who do not enter CR, as these will have a worse overall survival following transplantation.

As MDS is more common with advancing age and transplant-related mortality (TRM) is high in this group of patients, interest has been shown in non-myeloablative SCT. Conditioning (fludarabine, busulphan, Campath) is highly immunosuppressive but not myeloablative, so TRM is reduced. Disease control depends on a graft-versus-MDS effect and donor lymphocyte infusions can be given post transplant in patients with a mixed chimera. Early results suggest that TRM is significantly reduced when compared with standard SCT, but this benefit is offset by high relapse rates seen 1–2 years post transplant. Longer follow-up and larger numbers of patients are needed to establish whether this will be an effective form of treatment in MDS.

Autologous SCT

For those patients ineligible for allo-SCT, autologous SCT (bone marrow or PBSCs) may be a viable alternative. Polyclonal CD34$^+$ progenitors can be harvested from the blood of MDS patients in the recovery phase of intensive chemotherapy and used to achieve rapid and stable engraftment following high-dose chemotherapy. Although the feasibility of autologous bone marrow and PBSC SCT in MDS is well established, the efficacy remains to be determined. Data from EBMT on autologous BMT in first CR show 2-year survival, disease-free survival and relapse rates of 39%, 34% and 64% respectively. MDS patients have higher relapse rates than matched AML controls, suggesting higher residual disease burden in the graft.

Novel therapies

Improvement in our understanding of the underlying mechanisms in the pathogenesis of MDS has led to identification of a variety of potential therapeutic targets.

Thalidomide and its analogues

Exactly how thalidomide acts in MDS is unclear, but it is thought that it inhibits TNF-α production, has an antiangiogenic effect and modulates the immune system. There have now been many small studies, particularly in low-risk MDS. Response rates have been described in up to half the patients treated, although only a minority of these patients have become independent of transfusions. The use of thalidomide has been limited by unacceptable toxicities. Considering that many of these patients are elderly and quality-of-life issues are paramount, it is interesting to note that even patients having a major haematological response (off transfusions) have elected to come off treatment due to side-effects. Thalidomide analogues are now in trial (CC-5013, Revimid). CC-5013 seems to have a lower toxicity profile, and response rates (transfusion independence) have been seen in about one-third of non-5q– patients. Those with the 5q– syndrome have higher response rates and this may represent an effective new treatment option for this subgroup of patients.

Demethylation agents

Methylation in MDS was discussed in detail earlier in the chapter. The epigenetic therapeutic approach with either 5-azacytidine or 5-aza-2'-deoxycytidine induces demethylation of hypermethylated genes. Silverman's group has investigated 5-azacytidine, a pyrimidine nucleoside cytosine analogue. The results of a randomized study of azacytidine versus observation in MDS patients show an overall response rate of 63% in the azacytidine arm; 6% achieved a complete response and median time to leukaemic progression was 22 months (compared with 12 months in the observational arm). A significant improvement in median survival has not been shown, although quality of life in the treatment group was reported as better.

Therapeutic strategy

Deciding the best approach for the treatment of patients with MDS can be difficult. It is helpful to use the IPSS score to guide treatment, in addition to the patient's age, performance status and, most importantly, the patient's own wishes.

Management of anaemia

Red cell transfusions should be given to any patient with symptomatic anaemia. Alternatives to blood transfusions should be considered in suitable patients, including growth factors, immunosuppression and newer agents such as the thalidomide analogues. Figure 40.7 outlines a reasonable approach.

IPSS low

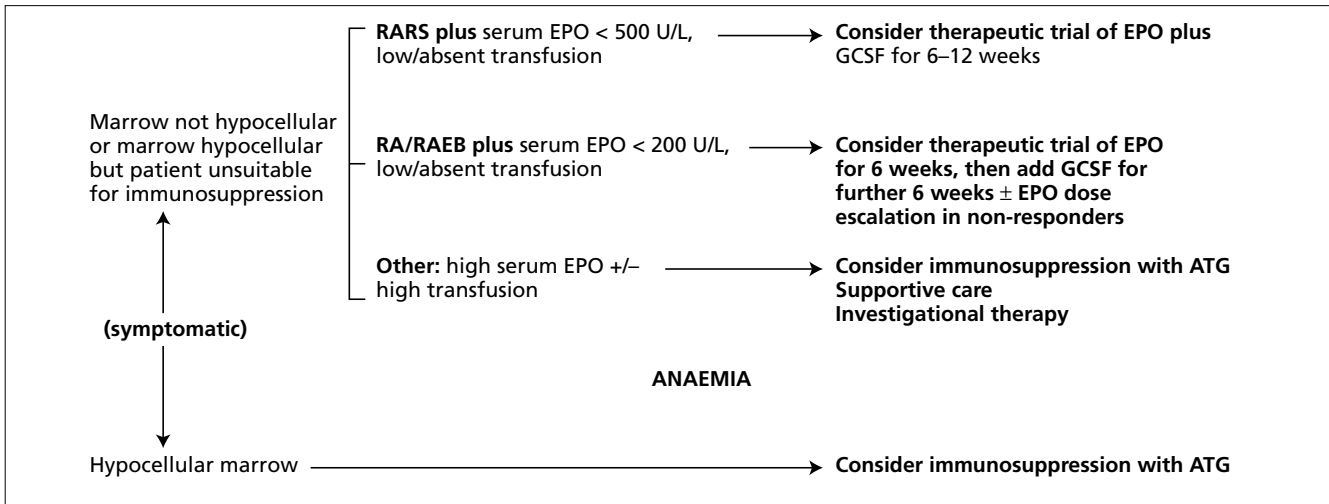
As the median survival without treatment is 4.8 years (> 60 years) to 11.8 years (< 60 years), the morbidity and mortality from intensive chemotherapy or SCT cannot be justified. It is more appropriate to monitor these patients for disease progression.


Figure 40.7 Guidelines for the management of symptomatic anaemia in MDS patients (reproduced with permission from Bowen *et al.*, *British Journal of Haematology* 2003; **120**: 187–200).

IPSS Intermediate-1

It is reasonable to consider SCT in this group of patients, particularly in those < 50 years with a sibling donor available, as the outcome after SCT is improved if performed early in the disease. However, with the median survival for patients < 60 years being 5.2 years, and a known significant TRM, the decision to transplant these patients is difficult, particularly in those with mild cytopenias and a normal karyotype. These patients could be left under close observation. Patients < 65 years with severe cytopenias or showing disease progression should be discussed with the local transplant unit.

IPSS Intermediate-2/High

Patients in this poor prognostic group who are less than 65 years should be considered for chemotherapy plus SCT. When making this decision, it is useful to consider the predictive factors for response to chemotherapy (Table 40.11) and outcome following SCT (Table 40.12). In addition, SCT should be performed only in those patients who achieve a complete or good partial response to chemotherapy. The flow chart in Figure 40.8 gives an overview of recommendations for SCT consolidation by the UK MDS guideline group.

It is difficult to give recommendations for the treatment of patients with high-risk MDS over the age of 65 years. These patients are eligible for the elderly NCRI AML trial (AML 14); however, much will depend on patients' performance status, comorbidities and own wishes. It is reasonable to await the result of the karyotype before deciding on treatment, as patients with poor-risk karyotypes have low response rates to intensive AML-type induction.

The place for novel therapies

With the advent of more new agents for the treatment of MDS, such as the thalidomide analogues and azacytidine, the decisions become even more complex. However, as with all investigational therapies, patients should be treated within clinical research protocols.

Myelodysplastic/myeloproliferative diseases

The WHO classification of myelodysplastic/myeloproliferative diseases (MDS/MPD) is shown in Table 40.13 and includes patients with both proliferative features characterized by marrow hypercellularity and increased numbers of circulating cells in one or more lineages, as well as dysplastic features characterized by abnormal cell morphology and cytopenia(s).

Chronic myelomonocytic leukaemia

Chronic myelomonocytic leukaemia (CMML) constitutes 15–20% of cases of MDS, defined according to FAB criteria. There is

Table 40.13 WHO classification of myelodysplastic/myeloproliferative diseases.

Chronic myelomonocytic leukaemia	CMML
Atypical chronic myeloid leukaemia	aCML
Juvenile myelomonocytic leukaemia	JMML
Myelodysplastic/myeloproliferative disease	Unclassifiable

Table 40.14 Diagnostic criteria for CMML.

Persistent monocytosis of $> 1 \times 10^9$/L
No BCR-ABL fusion gene
< 20% blasts in blood or marrow
Dysplasia in one or more lineages

a male predominance and median age of presentation is 72 years. Only 10% of cases present under the age of 60. The aetiology is unknown and therapy-related CMML is extremely rare.

The diagnostic criteria are shown in Table 40.14. If dysplastic features are minimal or absent, the diagnosis of CMML is still tenable if a clonal cytogenetic abnormality is present or if monocytosis persists for at least 3 months in the absence of other causes of monocytosis.

Clinical and laboratory features
Approximately 50% of patients have splenomegaly at presentation. Patients with high monocyte counts may develop a maculopapular skin infiltrate or monocytic pleural or pericardial effusions. Mild anaemia and thrombocytopenia are common and the white cell count may vary from normal to over 80×10^9/L. Monocytes may have normal morphology or may have agranular cytoplasm and/or abnormal nuclear lobation. The bone marrow is usually hypercellular and typical trilineage dysplastic

features are found in over 80% of cases. Cytochemical studies may aid the distinction between monocyte and granulocyte precursors. Cytogenetic abnormalities are found in 30–40% of cases and are not specific for CMML. Deletions of 5q are rare in CMML. The incidence of *RAS* mutations is higher than in other forms of myelodysplasia and is found in up to 40% of cases. Hypermethylation of the *p15* gene and reduced expression of p15 protein in marrow trephines is found in approximately 50% of patients with CMML. A minority of patients with either CMML or atypical chronic myeloid leukaemia present with chromosome translocations which disrupt either the fibroblast growth factor receptor-1 gene on chromosome 8p11 or the platelet-derived growth factor receptor B gene on chromosome 5q31. These translocations involve multiple partners and result in the expression of tyrosine kinase fusion proteins. These patients usually present with marked eosinophilia and are important to identify as they respond well to imatinib mesylate but not to conventional chemotherapy.

Natural history and prognosis
CMML has been subdivided into dysplastic and proliferative subtypes, but there are no clinical, morphological or biological features which reliably separate the two groups, and patients presenting with low monocyte counts and dysplastic features may subsequently acquire proliferative features during the course of the disease. The clinical course is variable, with a median survival of approximately 2 years. Adverse prognostic features include

Table 40.15 Differential diagnosis of proliferative MDS.

	CML	CMML	Atypical CML
Dysplasia	< 10% except in transformation	+	++

Immature granulocytes	Myelocyte peak	< 15%	> 15%
Basophilia	+	−	±
BCR–ABL rearrangement			
± Ph chromosome	Yes	No	No
RAS mutations	No	40%	?

CML, chronic myeloid leukaemia; CMML, chronic myelomonocytic leukaemia.

anaemia, thrombocytopenia, lymphocytosis, a raised serum lactate dehydrogenase (LDH) and an increased percentage of bone marrow blasts. The importance of the marrow blast percentage in predicting outcome is highlighted in the WHO classification which subdivides CMML into cases with < 10% marrow blasts (CMML-I) and those with 10–19% blasts (CMML-II).

Treatment

The majority of patients with CMML are elderly (> 60 years), and when the proliferative phase prevails oral chemotherapy with hydroxyurea would be the treatment of choice. In a multicentre European randomized trial of hydroxyurea versus etoposide in adult CMML, the response rate and median survival was 60% and 20 months for hydroxyurea, and 36% and 9 months for etoposide.

Younger patients with adverse features should be considered for more intensive treatment. The EBMT data for allogeneic (related and unrelated) SCT in adult patients with CMML, however, show poor long-term outcomes, with 5-year estimated overall survivals of only 21%. As with other types of MDS, patients have a better outcome if transplanted early in their disease. Alternatively, AML-type induction can be given, consolidated with autologous SCT.

Particularly in young patients, treatment options for CMML are not optimal, and, therefore, wherever possible, patients should be put into clinical trials .

Atypical chronic myeloid leukaemia

Atypical chronic myeloid leukaemia (aCML) is a poorly defined entity characterized by a leucocytosis, more than 10% circulating immature myeloid cells that are rarely more than 5% blasts, and prominent dysgranulopoiesis. A subset is characterized by neutrophils and myeloid precursors with pronounced clumping of nuclear chromatin. The distinguishing features between CMML, aCML and CML are shown in Table 40.15.

Most patients present with anaemia and/or thrombocytopenia and splenomegaly is common. Eighty per cent of cases have a cytogenetic abnormality but, as with CMML, none is specific for aCML. The prognosis is poorer than for CMML,

with a median survival of < 20 months. The response to intensive chemotherapy is generally poor (see also Chapter 37).

Myelodysplastic/myeloproliferative disease, unclassifiable

This category includes patients with one or more myelodysplastic features, less than 20% blasts in the bone marrow and either a platelet count of more than 600×10^9/L or a white cell count of more than 12×10^9/L with or without splenomegaly. There should be no preceding history of a well-defined chronic myeloproliferative disorder and patients should lack a BCR–ABL fusion gene, a deletion of chromosome 5q or a translocation of chromosome 3q21.

Within this subgroup are patients who present with both a thrombocytosis and more than 15% of ringed sideroblasts in the bone marrow.

Paediatric myelodysplasia

Myelodysplastic syndromes are rare in childhood, with an overall incidence between 1.35 and 3.6 per million, making up less than 5% of childhood malignancies. In contrast to adult MDS, which is commoner in the elderly, most cases of paediatric MDS develop in children less than 5 years old. A classification based on the WHO classification has recently been proposed by an international working group and is shown in Table 40.16.

Juvenile myelomonocytic leukaemia

Juvenile myelomonocytic leukaemia (JMML) is a disorder with both myelodysplastic and myeloproliferative features. The incidence is 1.2 per million per year and the median age at presentation is 1.8 years. Ninety-five per cent of cases occur in children under 5 years old. The condition is twice as common in boys. The incidence of JMML is increased in children with neurofibromatosis type I (NFI) and with Noonan's syndrome. Diagnostic criteria for JMML are shown in Table 40.17. Typically, there is a leucocytosis comprising neutrophils, immature myeloid cells

Suggestive clinical features
Hepatosplenomegaly
Lymphadenopathy
Pallor
Skin rash

Laboratory features
Essential
    No *BCR–ABL* fusion gene
    Monocytes $> 1 \times 10^9$/L
    Marrow blasts $< 20\%$

Plus at least two of the following
    Increased HbF
    Circulating myeloid precursors
    WBC $> 10 \times 10^9$/L
    Clonal cytogenetic abnormality
    Hypersensitivity of myeloid precursors to GM-CSF

and monocytes. Blasts usually constitute less than 5% of blood cells. The marrow is hypercellular and dysplastic features are often minimal. Approximately 30% of patients have monosomy 7, and 10% have other chromosomal abnormalities, whereas chromosome analysis is normal in 60% of cases.

Monocyte–macrophage colonies derived from either blood or bone marrow from patients with JMML are characterized by hypersensitivity to granulocyte–monocyte colony-stimulating factor (GM-CSF). This hypersensitivity is due to defects in the RAS–MAP kinase signalling pathway resulting from mutations in either a *RAS* gene, the *NFI* gene (the cause of neurofibromatosis type I) or the *PTPNII* gene (the cause of Noonan's syndrome).

The prognosis of JMML is variable, with survival ranging from 5 months to 4 years without treatment. Poor prognostic factors include age of more than 2 years, thrombocytopenia and elevated haemoglobin F levels. Blast transformation occurs in 10–20% of cases, and most patients die from organ failure, espe-cially respiratory failure, due to leukaemic infiltration. Although responses may be achieved with regimens containing cytosine arabinoside and/or *cis*-retinoic acid, the only curative therapy is allogeneic transplantation. The relapse rate following transplantation approaches 50% in some series, but further responses have been obtained with donor lymphocyte infusions. Novel therapies targeting the RAS–MAP kinase pathway are currently in trial (see also Chapter 37).

Myeloid leukaemia in Down's syndrome

Ten per cent of children with Down's syndrome develop a transient abnormal myelopoiesis neonatally. The majority of cases spontaneously remit by 3 months, but 25% develop megakaryoblastic leukaemia 1–3 years later. Dysplastic features are common and the percentage of marrow blasts has no biological or prognostic significance. These patients respond well to intensive chemotherapy.

Myelodysplastic syndromes

Myelodysplastic syndromes may develop in previously healthy children, in association with congenital bone marrow failure syndrome such as Fanconi's anaemia, following chemotherapy and/or radiotherapy, or be familial. Most patients present with pancytopenia, and the marrow shows characteristic dysplastic features with or without an increase in blasts. Ringed sideroblasts are extremely rare in a child with MDS, and their presence should instigate a search for other causes of sideroblastic anaemia, such as a mitochondrial DNA defect or a disorder of haem synthesis. An abnormal karyotype is found in 60–70% of cases, the commonest abnormality being monosomy 7, found in 30% of cases. Patients presenting with refractory cytopenia may pursue an indolent course for several years, but disease progression is inevitable. The value of prognostic scoring systems is less clear than in adult MDS. Allogeneic transplantation is the treatment of choice for all forms of childhood MDS, but there is still debate whether patients with increased blasts should receive prior intensive chemotherapy.

Myeloma

Evangelos Terpos and Amin Rahemtulla

Definition and epidemiology

Multiple myeloma is a B-cell malignancy characterized by a monoclonal expansion and accumulation of abnormal plasma cells in the bone marrow compartment. The clinical manifestations of myeloma are heterogeneous, and include bone complications, symptoms of impaired haemopoiesis and hyperviscosity, renal dysfunction, infections, peripheral neuropathy and extramedullary disease.

Myeloma belongs to a group of disorders called plasma cell dyscrasias that also include benign monoclonal diseases such as monoclonal gammopathy of undetermined significance (MGUS), indolent lymphomas such as lymphoplasmacytic lymphoma (Waldenström's macroglobulinaemia), and rare, biologically interesting disorders, such as heavy-chain diseases. All disorders share common plasma cell morphological features and most are associated with the production of abnormal immunoglobulins. Indolent/smouldering or asymptomatic myeloma has an intramedullary tumour cell content of > 10% but none of the other complications, such as lytic lesions, characteristic of multiple myeloma, nor symptoms from any complications. Myeloma may rarely involve extramedullary sites, such as blood, pleural fluid and skin. Extramedullary myeloma seems to be more aggressive, and when plasma cells are present in the blood at a proportion of greater than 20% of the white blood cells the condition is known

as plasma cell leukaemia. Table 41.1 summarizes the criteria for the definition of multiple myeloma, indolent or asymptomatic myeloma and MGUS.

Myeloma constitutes 1% of all cancers, but it is the second most common blood cancer after lymphomas and accounts for 10% of haematological malignancies. Myeloma has an annual incidence in the UK of 60 per million; at any one time there will be 10–15 000 patients with the condition. Cancer Research UK statistics show that there were 3730 new cases of myeloma in the UK in 2000 and there were 2600 deaths from this condition in 2002. The median age at diagnosis is 60–65 years; fewer than 2% of myeloma patients are under 40 years old at diagnosis. There are various theories about the age at onset and these include: (i) a reduction in ability of immune system of the elderly to eliminate potential myeloma precursors; (ii) the cumulative impact of environmental exposures with age; and (iii) hormonal effects of ageing. However, recent statistics indicate that myeloma is increasing in incidence and occurring more frequently in individuals aged below 55 years. Myeloma seems to be more common in men than women. The reasons for this are unclear but may include both hormonal effects and job-related exposure. Myeloma has a higher incidence in Afro-Caribbean ethnic groups compared with Caucasians in the UK, and in the USA the incidence also varies by race: from about 1/100 000 population/year for Asians, to about 4/100 000 population/year for Caucasians and 8–10/100 000 population/year for Afro-Americans.

Table 41.1 Criteria for the diagnosis of multiple myeloma, indolent myeloma and MGUS.

(A) Multiple myeloma

Major criteria	I	Plasmacytoma on tissue biopsy
	II	Bone marrow infiltration with > 30% plasma cells
	III	Monoclonal globulin spike (paraprotein) on serum electrophoresis (IgG > 35 g/L, IgA > 20 g/L), or on concentrated urine electrophoresis (> 1g/24 h of κ or λ light chains)
Minor criteria	a	Bone marrow infiltration with 10–30% plasma cells
	b	Paraprotein less than the level defined above
	c	Lytic bone lesions
	d	Normal IgM < 0.5 g/L, IgA < 1 g/L or IgG < 6 g/L

The diagnosis of multiple myeloma requires a minimum of two major criteria or one major criterion + one minor criterion, or three minor criteria always including a and b.

(B) Indolent (or asymptomatic) multiple myeloma

Same as multiple myeloma except:
  No bone lesions or one asymptomatic lytic lesion (X-ray survey)
  Paraprotein level: IgG < 70 g/L and IgA < 50 g/L
  No symptoms:
    Haemoglobin > 10 g/dL
    Serum calcium normal
    Serum creatinine < 170 μmol/L
    No infections

(C) MGUS

Paraprotein present, but at levels   IgG < 35 g/L, IgA < 20 g/L, Urinary light chains < 1 g/24h

Furthermore:
  Normal level of residual polyclonal immunoglobulins
  Bone marrow plasma cells < 10% (and without cytological abnormalities)
  No bone lesions
  No symptoms
  No evidence of other B-cell proliferative disorder

A variety of genetic and environmental factors have been proposed to explain the increased incidence in individuals of African descent. Differences in hormone receptors, immune reactivity and toxin metabolism have been evaluated. The diversity of possible exposures and genetic susceptibility factors make proof difficult. Although there is a tendency for myeloma to occur in families (3–5%), the likelihood of inheritance is low and no inherited genes have been identified.

Pathogenesis

Origin of the malignant plasma cell

Multiple myeloma is a malignant condition caused by clonal proliferation of plasma cells. These plasma cells are usually confined to the bone marrow but may be seen in the peripheral blood in end-stage myeloma (Figure 41.1). The precise stage at which malignant change occurs in myeloma cells has not yet been clarified. Current evidence suggests, however, that myeloma cell is a long-lived plasma cell, which has been exposed to antigen having undergone the B-cell maturation processes. Maturation of normal B-cell precursors to mature plasma cells involves rearrangement of the immunoglobulin (Ig) genes with subsequent somatic mutation of the variable (V) region. The myeloma cell is a post-germinal centre plasma cell which has undergone immunoglobulin gene recombination, class-switching and somatic hypermutation, and homes to the bone marrow (see Chapter 20). Molecular analysis of the peripheral blood mononuclear cells in myeloma has clearly demonstrated the presence of circulating clonal B cells with the same Ig gene rearrangement and the same somatic hypermutation as the marrow malignant plasma cells.

Myeloma cells proliferate at a low rate. The plasma cell labelling index typically detects less than 1% of tumour cells that are actively synthesizing DNA until late in the course of the disease, and is a better prognostic indicator than plasma cell infiltration of the bone marrow. Plasma cells may be identified by high CD38, high CD138 and low CD45 expression by flow cytometry. Myeloma cells are also CD19$^-$ or CD19$^+$/CD56$^+$, whereas normal plasma cells are consistently CD19$^+$/CD56$^-$. In myeloma, the proliferative cells usually express CD45 and the level of expression of this gene is higher than that observed in the non-proliferative compartment. Better clarification of the myeloma cell compartments will help to better understand the biology of the disease.

Environmental exposure

The cause of myeloma is unknown as no single factor has been consistently associated with it. Exposure to chemicals, such as dioxins, solvents and cleaners, and to radiation may be associated with the development of myeloma in predisposed individuals. Studies of atomic bomb survivors have shown an increased incidence of myeloma 15–20 years after exposure to radiation. Viral infections have also been implicated in the pathogenesis of myeloma. Several studies have suggested a link between myeloma

(a)

(b)

(c)

(d)

and herpesvirus infections (especially herpesvirus 8), Epstein–Barr virus, human immunodeficiency virus, hepatitis viruses, as well as to new 'stealth adapted' viruses such as mutated cytomegalovirus. However, epidemiological studies attempting to establish definite associations between myeloma and certain infections or autoimmune diseases have, so far, remained inconclusive.

Increased karyotypic instability

Increasing evidence suggests that the development of myeloma is a multistep process that includes the progressive occurrence of multiple structural chromosomal changes. Karyotypes of myeloma are more similar to those of epithelial tumours and the blast phase of chronic myeloid leukaemia than to those of other haemopoietic malignancies. However, the number of unbalanced translocations (translocations that generate a derivative chromosome(s) that has lost sequences from the involved chromosomes) is greatly increased in myeloma compared with epithelial tumours, as revealed by comparative genomic hybridization (CGH).

Monosomy 13, translocations into the switch regions of the IgH genes involving a large array of chromosomal partners (switch translocations), chromosome 8q (c-*myc* oncogene) abnormalities, and other numerical chromosomal changes (monosomy, trisomy) are detected in up to 80–90% of myeloma cases. Monosomy 13 is discussed below, while the common chromosomal partners in switch translocations and the involved candidate oncogenes in the pathogenesis of myeloma are shown in Table 41.2. Hyperdiploidy, with chromosome counts of greater than 50, has been reported in 30–45% of abnormal cases by conventional cytogenetics and CGH. Deletions of chromosome

Table 41.2 Frequent chromosomal partners and candidate oncogenes in switch translocations [t(partner chromosome;14) (involved region;q32)] involved in the pathogenesis of multiple myeloma.

Chromosomal partners	Frequency in myeloma patients	Candidate oncogene	Localization	Distance between breakpoints and oncogenes	Function
11q13	15–20%	Cyclin D1	der(14)	100–330 kb	Cell cycle regulator
		Myeov	der(11)		Unknown
4p16	12–17%	FGFR3	der(14)	50–100 kb	Growth factor receptor tyrosine kinase

6p25	< 5%	MUM1/IRF4	der(14)	Immediately adjacent	Transcriptional regulator of IFN and IFN-stimulated genes

FGFR3, fibroblast growth factor receptor 3; MMSET/WHSC1, multiple malformation syndrome/Wolf–Hirschhorn syndrome gene 1; MUM1/IRF4, multiple myeloma oncogene 1/interferon-responsive factor 4.

13q, 6q and 16q have also been described. Hypodiploidy is also a common finding, with loss of chromosomes 8, 13, 14 and X observed by conventional cytogenetics.

Chromosome 13q loss

Monoallelic loss of 13q sequences is one of the most frequent abnormalities in myeloma. Monosomy of chromosome 13 occurs more commonly (92%), while the interstitial deletion or translocation of 13q occurs less frequently. Loss of 13q is detected in 15–20% of cases by conventional cytogenetics and in 50% of cases using interphase fluorescence *in situ* hybridization (FISH) analysis. Chromosome 13q loss has also been detected in 20–40% of MGUS cases. There seems to be a higher incidence of monosomy 13 in myeloma patients with pre-existing MGUS (70%) than in those patients without such a history. Moreover, the frequency of chromosome 13q loss increases with disease stage, reaching 70% in plasma cell leukaemia. On the other hand, in most MGUS patients, only a subset of myeloma cells have the 13q abnormality, while in multiple myeloma almost all tumour cells have this defect. Thus, these data raise the possibility that monosomy 13 is an early event in the pathogenesis of the disease. The genes that are located on chromosome 13 and implicated in the pathogenesis of myeloma have not yet been recognized.

Prognostic significance of cytogenetic abnormalities

Several studies have demonstrated that monosomy 13, detected by conventional cytogenetics, is a predictor for survival. However, the high incidence of this cytogenetic abnormality in MGUS patients and its co-existence in many cases with a large variety of other chromosomal aberrations, revealed by molecular

cytogenetics, makes the prognostic value of monosomy 13 alone difficult to ascertain. Conventional karyotyping has also demonstrated a poor prognosis associated with chromosome 11q translocations, including t(11;14) and reciprocal translocations with chromosomes 8, 9 and 12. However, this was not confirmed by molecular cytogenetics, and the possibility that conventional karyotyping technique has selected cases which are hyperproliferative must be considered. Gene expression profile from microarray technology may provide a more accurate and comprehensive assessment of molecular changes, and is currently used to characterize myeloma at a molecular level and correlate with response rates in trials of novel agents.

Bone marrow microenvironment in myeloma

The pathogenesis of multiple myeloma is complex and includes mutual interactions that affect the number and function of both malignant cells and normal bone marrow stromal cells (BMSCs). Bone marrow microenvironment includes the extracellular matrix and at least five types of stromal cells: fibroblasts, osteoblasts, osteoclasts, vascular endothelial cells and lymphocytes. Reciprocal positive and negative interactions among these cells are mediated by a variety of cytokines and adhesion molecules. The homing of myeloma cells to the bone marrow seems to involve selective adhesion to bone marrow endothelial cells, transendothelial migration and adhesion to stromal cells through the production of stromal-derived factor 1 (SDF-1) and insulin-like growth factor 1 (IGF-1), which are secreted by bone marrow endothelial and stromal cells and have a chemoattractant effect on myeloma cells. Adhesion of myeloma cells to BMSCs, through the $\alpha_4\beta_1$-integrin/vascular cell adhesion molecule 1 (VCAM-1) interaction, induces the paracrine secretion of cytokines such as interleukin 6 (IL-6), IL-1β, IL-11, tumour necrosis factors (TNFs), transforming growth factor-

Figure 41.2 The bone marrow microenvironment in multiple myeloma. The multiple interactions between myeloma, stromal and endothelial cells and osteoclasts reflect the vital role of the bone marrow microenvironment in the biology of the disease. The production of different cytokines by both stromal and myeloma cells enhances myeloma proliferation and growth, osteoclast activation and vessel formation. Furthermore, the inhibition of T-lymphocytes, through mechanisms which are unclear, increases the immunodeficiency in myeloma, while the suppression of osteoblasts in combination with osteoclast activation leads to bone loss.
beta (TGF-β) and receptor activator of nuclear factor-kappa B ligand (RANKL) by BMSCs (Figure 41.2). The production of IL-6 by BMSCs, which is via activation of the nuclear factor-kappa B (NF-κB), triggers the proliferation of myeloma cells, and protects them against dexamethasone-induced apoptosis. The activation of NF-κB, which is a transcriptional factor, is responsible for the production of other growth factors and adhesion molecules, such as vascular endothelial growth factor (VEGF), VCAM-1 and E-selectin, by the BMSCs and myeloma cells. Inactivated NF-κB is located in the cytoplasm of the cell bound to its inhibitor IκB The activation of NF-κB involves the following sequence of events: activation of IκB-kinase → IκB phosphorylation → ubiquitination and degradation of IκB by the proteasome → dissociation of NF-κB from IκB → nuclear translocation of NF-κB → production of molecules that are crucial for myeloma survival. The value of this pathway for myeloma cell growth is evident by the anti-myeloma effect of drugs, such as dexamethasone, thalidomide and bortezomib (proteasome inhibitor), which inhibit NF-κB.

Angiogenesis is also increased in some cases of myeloma and correlates with disease activity and survival. Secreted VEGF from myeloma cells interacts with receptors on endothelial cells to enhance their migration and proliferation. Additional factors, such as the basic fibroblast growth factor (bFGF), produced by either myeloma or stromal cells, also induce angiogenesis (Figure 41.2). However, the precise role of angiogenesis in myeloma remains to be established. In myeloma, there is also an inhibition of T-lymphocyte function through mechanisms, which are not clear but may include production of inhibitory molecules, such as interferon-alpha (IFN-α) at high concentrations and reduction of interferon-gamma (IFN-γ).

Biology of bone disease

Bone destruction in myeloma is related to increased osteoclastic activity which is not accompanied by a comparable increase in osteoblast formation. This uncoupling of resorption and formation leads to rapid bone loss, osteoporosis, lytic lesions and fractures. The enhanced and uncontrolled osteoclastic activity has been confirmed consistently in several animal models and is also reflected by the increase in markers of bone resorption, including N- or C-terminal cross-linking telopeptide of type I collagen (NTX or ICTP/CTX respectively) and tartrate-resistant acid phosphatase type 5b (TRACP-5b), in the serum of myeloma patients. A number of cytokines and growth factors that are produced by either myeloma cells or BMSCs have been implicated in the increased osteoclast formation and activity in myeloma. These cytokines include IL-6, IL-1β, IL-11, TNF-α, TNF-β, bFGF, IGF and, more recently, macrophage inflammatory protein 1 alpha (MIP-1α), hepatocyte growth factor and the RANKL pathway. The recently characterized RANKL interacts with a cellular receptor activator of NF-κB (RANK), and a soluble decoy receptor of RANKL, named osteoprotegerin (OPG). Following activation of RANK on osteoclasts by its ligand, RANKL, differentiation, proliferation, and survival of osteoclasts is enhanced. OPG is reduced in patients with myeloma, while the levels of soluble RANKL (sRANKL) are increased; thus, the ratio sRANKL/OPG is increased, allowing greater interaction between RANKL and RANK. This correlates not only with the extent of lytic lesions but also with survival in myeloma. The induction of release of the different cytokines, such as IL-6 and IL-1β, TNFs, bFGF and IGFs, due to the adherence of myeloma cells to stromal cells, modifies the bone marrow microenvironment, enhancing
Figure 41.3 The interactions in the bone marrow microenvironment, which influence the development of bone disease in multiple myeloma.

RANKL expression by osteoblasts. IL-6 also acts as a growth factor for osteoclasts, and as survival factor for myeloma cells. In addition, IL-11 is also produced by both myeloma and stromal cells and exerts its effect through RANKL/RANK/OPG pathway, inducing osteoclastogenesis while inhibiting osteoblast formation. More recently, gene expression profiling studies have revealed that myeloma cells produce dickkop-1 protein, which inhibits Wnt-mediated osteoblast differentiation, leading to reduced bone formation. MIP-1α, a low-molecular-weight chemokine which belongs to the RANTES family, is also produced by myeloma cells and activates the osteoclasts. MIP-1α levels are elevated in bone marrow plasma of patients with myeloma and correlate with the presence of lytic lesions. Figure 41.3 summarizes the currently available data about osteoclast activation in myeloma, reflecting the role of the bone marrow microenvironment in the development of myeloma-related bone disease.

Clinical features

Plasma cell infiltration of bone marrow results in bone marrow failure and bone lesions. Patients therefore present with symptoms due to bone disease, hypercalcaemia, impaired haemopoiesis, immune paresis and renal failure. In a minority of patients, plasma cell infiltration of soft tissues is seen at presentation. Plasmacytomas may spread extradurally or may cause spinal cord compression. High serum paraprotein may result in hyperviscosity, and high levels of light chains (Bence Jones protein) in the urine may result in renal failure. The clinical features may be due to the following.

Bone disease

Bone pain is the most common symptom and results from osteolytic lesions and pathological fractures – mainly wedging or collapse of vertebral bodies with or without osteoporosis (Figure 41.4). In advanced disease, pathological fractures of the long bones, ribs and sternum may occur. Skull lesions, in general, very rarely cause pain.

Immune paresis and impaired haemopoiesis

A large proportion of patients with multiple myeloma have reduced serum levels of normal immunoglobulins. In some of these patients, the immune paresis is severe enough to make them susceptible to bacterial infections, and levels of immunoglobulin rarely return to normal levels following chemotherapy even if the disease has responded well and paraprotein levels have fallen. Immune paresis, renal failure, neutropenia and anti-myeloma therapy can combine to cause severe immunodeficiency, and infections are a major cause of death in these patients.

Normochromic, normocytic anaemia is a common finding in myeloma, and symptoms related to this may be a presenting feature at diagnosis. Anaemia may be due to the infiltration of the bone marrow by myeloma cells, due to chronic inflammation or the use of cytotoxic drugs. Serum erythropoietin levels are usually appropriately raised in those patients with good renal function and inappropriately low in those patients with poor renal function. Thrombocytopenia and neutropenia may also occur due to bone marrow infiltration by malignant plasma cells or to the use of chemotherapy.

(a)

(b)

(c)

Hypercalcaemia

There is an imbalance between bone formation and bone destruction resulting in a continuing loss of calcium from the skeleton. At presentation, around a quarter of all patients have hypercalcaemia with associated lytic bone lesions and/or osteoporosis. Patients may be symptomatic, with polydypsia, polyuria and constipation. Hypercalcaemia may be severe enough to cause life-threatening dehydration and renal failure.

Nephropathy

Patients with multiple myeloma may present with uraemia which may or may not be corrected by rehydration and chemotherapy. Renal dysfunction occurs when the tubular absorptive capacity of light chains is exhausted, resulting in interstitial nephritis with light-chain casts. Other causes of renal dysfunction are hypercalcaemia with hypercalciuria, amyloid light-chain (AL) amyloidosis associated with λ-light-chain disease, immunoglobulin light-chain deposition, infection, hyperuricaemia and the use of anti-inflammatory drugs. The infiltration of the kidneys by myeloma cells may also occur but is rare.

Neurological complications

Neurological abnormalities are mainly caused by tumour growth compressing the spinal cord or cranial nerves. Peripheral neuropathy is frequently due to perineuronal amyloid deposition. Polyneuropathy may also be observed as a part of POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy and skin changes). Plasma cell leukaemia may involve the meninges, while intracerebral mass lesions are very rare.

Hyperviscosity

Hyperviscosity occurs in less than 10% of patients and usually associated with an IgM paraprotein. The intrinsic viscosity of IgM, which usually exists as a 900-kDa pentamer, is relatively high compared with IgA or IgG, and the hyperviscosity syndrome therefore occurs at relatively lower concentrations, typically 40–50 g/L. Patients with IgA myeloma present more often with hyperviscosity syndrome than those with IgG myeloma because of the greater tendency of IgA to form multimers. Among patients with IgG myeloma, those who have IgG3 subclass paraprotein are more likely to develop this syndrome. It leads to

Figure 41.4 (*left*) Characteristic bone lytic lesions and pathological fractures in multiple myeloma. (a) Typical 'punched-out' lytic lesions in the skull (plain radiograph). (b and c) Magnetic resonance imaging in multiple myeloma; mixed diffuse/focal abnormalities and fractures involving the thoracic and lumbar spine.

cerebral, pulmonary and renal dysfunction as well as a haemorrhagic tendency. Patients may present with visual, cardiovascular and neurological symptoms, often accompanied by fatigue, malaise and weight loss. Visual dysfunction may range from mild visual disturbance to sudden loss of vision. Fundoscopy may show progression from retinal vein distension to increasing vessel tortuosity, with arteriovenous 'nipping', areas of beading and dilatation of small venules ('string of sausages' appearance) to full-blown retinopathy with florid haemorrhages and exudates. The neurological symptoms of hyperviscosity syndrome include headache, fluctuating level of consciousness, mental slowing, dizziness, ataxia, vertigo, neuropathies, convulsion and coma. The increased viscosity also increases plasma volume and may compromise cardiac function.

Coagulopathy

Coagulopathy in multiple myeloma is well documented but is rarely a clinical problem. Bleeding may be the result of hyperviscosity, perivascular amyloidosis, acquired coagulopathy, or thrombocytopenia. An acquired coagulopathy due to interference of fibrin aggregation by the paraprotein or an acquired inhibitor of factors VIII or X has been documented. The bleeding tendency may also be due to the coating of platelets by the paraprotein. This may result in chronic, recurrent bleeding of the gums and the upper respiratory and gastrointestinal tracts. The bleeding time is usually prolonged and *in vitro* platelet function is abnormal. Some patients may develop thrombosis as a result of hyperviscosity or secondary to acquired deficiency of protein C or due to lupus anticoagulant.

Amyloidosis (see also Chapter 42)

Amyloidosis results from the abnormal extracellular deposition and accumulation of protein and protein derivatives and is clinically evident in around 5% of patients with multiple myeloma. The amyloid deposit shows green birefringence when stained with Congo red and viewed under polarized light. The disease becomes clinically significant when its diffuse form affects organ function by replacing the normal cells. The extracellular deposit is invariably made up of three components. The fibrillar protein is the component that defines the type of amyloidosis and depends on the underlying disease. It is made of fibrils arranged primarily in a β-pleated sheet secondary structure. The other two components are the serum amyloid P and charged glycosaminoglycans, which are ubiquitous in all types of amyloidosis and probably contribute to the formation of the β-pleated sheet structure. In primary amyloidosis, which is usually associated with multiple myeloma, the characteristic fibrillar protein is a fragment of the variable immunoglobulin light (and/or rarely heavy) chain and thus is different from patient to patient. This type of amyloidosis is referred to as AL amyloidosis.

The common presentations of AL amyloidosis include carpal tunnel syndrome, congestive cardiac failure, macroglossia, gastrointestinal disturbances, neuropathies (peripheral and autonomic) and lesions of the skin, subcutaneous tissues, tendon sheaths and fasciae. The most commonly involved organ system in AL amyloidosis is the gastrointestinal system, with the colon being the most frequently involved organ. Oesophageal and gastric involvement usually manifests as dysmotility, wall thickening and gastro-oesophageal reflux disease. These result from amyloid infiltration of the muscularis and/or destruction of the Auerbach plexus. When the small intestine is involved, the most common finding is diffuse or nodular wall thickening. Abdominal pain, malabsorption, haemorrhage and perforation are rare complications. Colonic biopsy specimens are positive in 80% of patients with systemic amyloidosis. Splenomegaly is the only finding associated with splenic involvement. This causes increased fragility, and spontaneous rupture may occur. Diffuse infiltration of the liver results in hepatomegaly, but abnormal liver function is rare. If liver dysfunction is present then the prognosis is very poor. Macroglossia may result from amyloid infiltration of the intrinsic muscles and could interfere with swallowing and respiration.

Cardiac involvement is common in AL amyloidosis and can remain silent until it manifests as progressive cardiac failure exacerbated by conduction disturbances and coronary arterial insufficiency. Pulmonary involvement in amyloidosis is relatively rare. Patients present with recurrent pneumonia which is responsive to antibiotic treatment. This is due to obstruction of the associated bronchus or bronchiole either by interstitial thickening, resembling bronchiolitis obliterans or, more rarely, a focal amyloidoma. Renal infiltration may also occur but renal dysfunction is rare, usually manifesting as nephrotic syndrome. Peripheral neuropathy with autonomic failure may also occur in primary amyloidosis. Initial neuropathic symptoms include distal sensory loss with elevated temperature thresholds. Autonomic symptoms and signs are prominent and affect multiple systems. Orthostatic symptoms with near-syncope or syncope are quite common. Constipation alternating with diarrhoea is due to infiltration of the myenteric and submucosal plexus. Infiltration of the oesophagus causes dysphagia. Widespread anhidrosis with compensatory sweating is commonly observed. Impotence is frequent in men.

Laboratory findings

Diagnosis

The criteria for the diagnosis of multiple myeloma are shown in Table 41.1, while the work-up for the diagnosis of myeloma is described in Table 41.3. The diagnostic work-up may reveal a normochromic, normocytic anaemia, hypercalcaemia, hyper-

Table 41.3 The work-up for myeloma.

Full blood count, film and ESR

Evaluation of kidney function, serum calcium, CRP, β_2-microglobulin, LDH, uric acid levels and liver function tests.

Protein electrophoresis and paraprotein quantitation

Quantitative analysis of the normal immunoglobulins

24-hour urine collection for light chain (Bence Jones protein) excretion

Coagulation screen

Bone marrow aspiration and trephine biopsy for morphology, immunophenotyping (CD 138, CD79a, kappa, lambda, CD20) and cytogenetics

A complete skeletal survey. Patients with symptoms or signs of cord compression would require further investigation with computerized tomography (CT) or magnetic resonance imaging (MRI)

Table 41.4 The Durie–Salmon staging system.

I	*All of the following*
	Haemoglobin > 10.5 g/dL
	Serum calcium normal
	X-rays show normal bone structure or solitary bone plasmocytoma only
	Low paraprotein levels
	IgG < 50 g/L
	IgA < 30 g/L
	Urinary light chain < 4 g/24 h
II	*Fitting neither stage I nor stage III*
III	*One or more of the following*
	Haemoglobin < 8.5 g/dL
	Serum calcium > 3 mmol/L
	Advanced lytic bone lesions (> three lytic lesions)
	High paraprotein levels
	IgG > 70/L
	IgA > 50 g/L
	Urinary light chain > 12 g/24 h

Subclassification

A	Serum creatinine < 170 μmol/L
B	Serum creatinine ≥ 170 μmol/L

uricaemia, low serum albumin or abnormal coagulation. In most patients with myeloma, the malignant plasma cells secrete an abnormal immunoglobulin (paraprotein), but around 1% of patients have non-secretory disease. Nearly 60% of the patients have detectable IgG paraprotein, 20% have IgA paraprotein, 15–20% light-chain only paraprotein, and less than 1% have IgD or IgE paraprotein. Suppression of the normal immunoglobulins is a typical finding in most cases. Other biochemical findings include increased levels of urea and creatinine in renal dysfunction, elevated serum levels of C-reactive protein and β_2-microglobulin, which are associated with poor prognosis, increased levels of lactate dehydrogenase, increased levels of markers of bone resorption (TRACP-5b and collagen degradation products: NTX, ICTP, CTX), and decreased levels of markers of bone formation (bone alkaline phosphatase and osteocalcin). Skeletal survey would indicate the extent of lytic bone lesions. If there are symptoms or signs of spinal cord compression then further imaging with computerized tomography (CT) or magnetic resonance imaging (MRI) is recommended. Isotope bone scans are of limited value because of decreased osteoblast function. Positron emission tomography (PET) is not useful because of the small size of the infiltrates in the bone marrow and lower metabolic rate of the tumour compared with normal tissue but may be useful in cases of macroscopic plasmacytomas. Measurement of bone density with DEXA scan may be useful to monitor progress of the disease in patients with osteoporosis.

The differential diagnosis includes MGUS, which is associated with lower paraprotein levels, less plasmacytosis in the bone marrow, and no anaemia, renal dysfunction or lytic lesions (see Table 41.1). Patients with solitary plasmacytoma may have no evidence of systematic disease, while AL amyloidosis can be dis-

tinguished by renal or rectal biopsy, or fine-needle aspiration of subcutaneous fat and staining the tissue with Congo red. Amyloidosis may be suspected in cases with carpal tunnel syndrome, macroglossia, renal dysfunction, or cardiomegaly associated with arrhythmias, low-voltage and conduction defects on electrocardiogram. Scintigraphy with radiolabelled serum amyloid P component (SAP) scan can be used to quantitate and document the distribution of amyloid.

Staging and prognosis

Once the diagnosis of multiple myeloma has been established, staging of the disease should be performed. Salmon–Durie staging system is the standard system for staging a myeloma patient and is shown in Table 41.4. A number of prognostic indices have been proposed to date using different risk factors. In all these indices, β_2-microglobulin remains the most powerful prognostic marker, while CRP, albumin, LDH, and chromosome 13q loss have also been shown to be of prognostic value. Recently, the International Myeloma Working Group has proposed a novel prognostic index (International Prognostic Index; IPI) for the staging of multiple myeloma. This system, based on almost 8500 patients, includes only two parameters, β_2-microglobulin and albumin, and is described in Table 41.5.

Table 41.5 International Prognostic Index for multiple myeloma.

Staging	Parameters	Number of patients	Median survival (months)
Stage 1	β_2-m < 3.5 ALB ≥ 35	2401	62
Stage 2	β_2-m < 3.5 ALB < 35 or β_2-m 3.5–5.5	3278	44
Stage 3	β_2-m > 5.5	2770	29

β_2-m, serum β_2-microglobulin (mg/L); ALB, serum albumin (g/L).
Factors that predict for lower risk:
Age < 60 + β_2-m < 3.5 mg/L + ALB > 35 g/L
Factors that predict for higher risk:
β_2-m > 10 mg/L + ALB < 35 g/L
Low platelet count
Cytogenetics do influence outcome; however, chromosome 13 deletion and complex chromosome abnormalities do not seem to add to the impact of age, β_2-m and ALB.

Treatment

Asymptomatic/indolent multiple myeloma

Patients with no symptoms, normal renal function and absence of bone lesions, classified as stage I (according to Salmon–Durie criteria), may remain stable for a long time without any chemotherapy. These patients account for about 20% of myeloma patients, and have a median time to disease progression of 2–3 years. The survival is similar when treatment (melphalan and prednisolone) is administered just after diagnosis or at disease progression in stage I patients. However, the disease needs to be evaluated at regular intervals (every 2–3 months) to separate the stable, asymptomatic patients who do not need treatment from patients with progressive, symptomatic disease. Signs of disease progression, such as rising paraprotein levels, falling haemoglobin levels, radiological evidence of bone disease, or an increase in bone marrow infiltration in non-secretory myeloma, are indications to start treatment. Asymptomatic patients with at least one lytic lesion visible on radiographs have a median time to progression of 8 months, whereas abnormal marrow appearance on magnetic resonance imaging (MRI) is also associated with higher risk of disease progression.

Conventional chemotherapy (Table 41.6)

Conventional doses of chemotherapy rarely result in complete remission (CR) and cure is not achieved. Initial chemotherapy for patients with symptomatic multiple myeloma includes melphalan and prednisolone (MP), vincristine, doxorubicin and dexamethasone (VAD), alkylator-based combinations, cyclophosphamide with or without prednisolone, dexamethasone alone, idarubicin with dexamethasone and many other steroid-containing regimens. The response to treatment is assessed by a number of criteria described in Table 41.7.

Melphalan and prednisolone

This classical anti-myeloma regimen includes melphalan given at a dose of 6–8 mg/m^2/day combined with prednisolone at a dose of 40–60 mg/day for 4–7 days at 4- to 6-week intervals. It induces partial remission (PR) in approximately 50% patients, while CR is very rare. Patients who respond to treatment show a progressive fall in the paraprotein until a plateau phase (stable paraprotein level for at least 3 months together with transfusion independency and minimal symptoms) is reached. Further treatment of these patients with conventional doses of drugs does not result in improvement of outcome. The median duration of survival is around 3 years in most series, and the plateau phase usually has a duration of 18–24 months before progression. The role of prednisolone in the MP regimen is controversial. A number of trials have shown that the addition of standard dose of prednisolone to oral melphalan is not superior to melphalan alone with respect to overall survival, although the response rates may be higher with the combination. This should be kept in mind, particularly when dealing with patients who are at a high risk of steroid-related side-effects. Melphalan alone is usually given at a dose of 7–12 mg/m^2/day for 4 days every 3–4 weeks. Melphalan alone and MP are usually well tolerated and side-effects include mild nausea and myelosuppression, while alopecia is rare.

Various combination regimens, described below, have been used in an attempt to improve the outcome in myeloma patients. A meta-analysis of 6633 patients in 27 randomized trials comparing combination chemotherapy with MP confirmed that outcome after treatment with these regimens is very similar and they offer no advantage over MP. However, MP must be avoided in patients who are going to be treated with autologous stem cell transplantation (ASCT) owing to its toxicity to bone marrow stem cells. Previous treatment with melphalan is associated with a significantly lower yield of CD34$^+$ cells.

VAD and VAD-associated regimens

The combination of vincristine and doxorubicin administered by continuous 4 days infusion with the addition of high-dose oral dexamethasone is the most frequently used first-line chemotherapy regimen for myeloma. This regimen produces quick and high response rates (up to 80%) with a CR rate of 10–25%. The administration of liposomal doxorubicin (40 mg/m^2 intravenously, over 1 h, on day 1 only) instead of the 'classical' doxorubicin in the VAD regimen produces similar efficacy with fewer episodes of alopecia, and less frequent hospitalization. The

Table 41.6 Regimens for treatment of myeloma.

Drug regimen	Dose	Days
MP (many variations)		
M = Melphalan	7 mg/m^2/day p.o.	1–5
P = Prednisolone	60 mg/day p.o.	1–5
Cyclophosphamide	400 mg/m^2 p.o. once a week for 12 weeks	Weekly
Prednisolone	60 mg p.o. alternate days for 6 weeks	Alternate days
VAD regimen (28-day cycle)		
V = Vincristine	0.4 mg/day c.i.v.	1–4
A = Doxorubicin (adriamycin)	9 mg/m^2/day c.i.v.	1–4
D = Dexamethasone	40 mg/day p.o.	1–4 (and 9–12, 17–20 in the first cycle)
VAMP (28-day cycle)		
V = Vincristine	0.4 mg/day c.i.v.	1–4
A = Doxorubicin (adriamycin)	9 mg/m^2/day c.i.v.	1–4
MP = Methylprednisolone	1.5 g i.v./p.o.	1–5
C-VAMP (28-day cycle)		
C = Cyclophosphamide	500 mg i.v	1, 8, 15
V = Vincristine	0.4 mg/day c.i.v.	1–4
A = Doxorubicin (adriamycin)	9 mg/m^2/day c.i.v.	1–4
MP = Methylprednisolone	1.5 g i.v./p.o.	1–5
Z-Dex (21-day cycle)		
Z = Idarubicin (Zavedos)	10 mg/m^2/day p.o.	1–4
Dex = Dexamethasone	40 mg/day p.o.	1–4 (and 8–11, 15–18 in the first cycle)
VMCP (21-day cycle)		
V = Vincristine	1 mg i.v.	1
M = Melphalan	5 mg/m^2/day p.o.	1–4
C = Cyclophosphamide	110 mg/m^2/day p.o.	1–4
P = Prednisolone	60 mg/m^2/day p.o.	1–4
VBAP (21-day cycle)		
V = Vincristine	1 mg i.v.	1
B = Carmustine	30 mg/m^2 i.v.	1
A = Doxorubicin (adriamycin)	30 mg/m^2 i.v.	1
P = Prednisolone	60 mg/m^2/day p.o.	1–4
ABCM (28-day cycle)		
A = Doxorubicin	30 mg/m^2 i.v.	
B = BCNU	30 mg/m^2 i.v.	1
C = Cyclophosphamide	100 mg/m^2/day p.o.	22–25
M = Melphalan	6 mg/m^2/day p.o.	22–25
Thalidomide	100–600 mg/day p.o.	Daily
CTD (21-day cycle)		
C = Cyclophosphamide	500 mg p.o.	1, 8, 15
T = Thalidomide	100–200 mg/day p.o.	Daily
D = Dexamethasone	40 mg/day p.o.	1–4 and 12–15
CVAD (21-day cycle)		
C = Cyclophosphamide	500 mg p.o. or i.v.	1, 8, 15
V = Vincristine	0.4 mg/day c.i.v.	1–4
A = Doxorubicin (adriamycin)	9 mg/m^2/day c.i.v.	1–4
D = Dexamethasone	40 mg/day p.o.	1–4 and 12–15

replacement of dexamethasone with methylprednisolone (VAMP) and the addition of cyclophosphamide to this regimen (C-VAMP) results in the same response rate as the VAD regimen. However, there are no randomized trials comparing VAMP and C-VAMP with VAD chemotherapy. All these regimens produce no durable remissions and they offer no advantage in overall survival over MP. They are suitable for patients in whom high-dose chemotherapy (HDT) and ASCT are planned as the treatment does not damage the haemopoietic stem cells. These regimens may also be used in patients with renal failure as they do not cause increased toxicity in such patients. There is evidence that high-dose dexamethasone is responsible for much of the efficacy of VAD chemotherapy. Intermittent courses of dexamethasone produce an overall response rate of near 45%, similar overall survival as with VAD chemotherapy, and less serious complications (4% vs. 27% for patients receiving dexamethasone alone or VAD respectively). These results suggest that dexamethasone alone, 40 mg daily for 4 days every 2 weeks until response and then monthly, offers advantages over other regimens in respect of the absence of myelotoxicity, simplicity, suitability in pati-

ents with renal failure or in patients who require simultaneous radiotherapy. The addition of oral idarubicin to high-dose dexamethasone for 4 days every month, for 4 months (Z-Dex), produces an overall response rate of 75–80%, with 17% of patients achieving CR. Myelosuppression is seen in 70% of the patients while gastrointestinal toxicity and alopecia are infrequently reported. Furthermore, stem cells can still be harvested after treatment with this regimen. However, randomized trials comparing Z-Dex with VAD have not been carried out.

Alkylator-based combination regimens

These regimens generally include a combination of steroids (mainly prednisolone; P), cyclophosphamide (C) and melphalan (M) with agents such as vincristine (V), doxorubicin (A) and carmustine (BCNU; B). There is no advantage of these regimens over MP, even in patients with a poor prognosis. Furthermore, alkylator-based combination chemotherapy regimens are more myelotoxic than MP, affect subsequent stem cell mobilization and frequently cause vomiting, alopecia, cardiotoxicity and infection.

Table 41.7 EBMT criteria or response to anti-myeloma treatment.

Response	Criteria for response
Complete remission (CR)	*Requires all of the following* • Disappearance of the original monoclonal protein from the blood and urine on at least two determinations for a minimum of 6 weeks by immunofixation studies • < 5% plasma cells in the bone marrow on at least two determinations for a minimum of 6 weeks • No increase in the size or number of lytic bone lesions • Disappearance of soft tissue plasmacytomas for at least 6 weeks
Partial remission (PR)	*Requires all of the following* • ≥ 50% reduction in the level of serum monoclonal protein for at least two determinations 6 weeks apart • If present, reduction in 24-h urinary light-chain excretion by either 90% or to < 200 mg for at least two determinations 6 weeks apart • ≥ 50% reduction in the size of soft tissue plasmacytomas (by clinical or radiographic examination) for at least 6 weeks • No increase in the size or number of lytic bone lesions
Minimal response (MR)	*Requires all of the following* • 25–49% reduction in the level of serum monoclonal protein for at least two determinations 6 weeks apart • If present, a 50–89% reduction in 24-h urinary light-chain excretion, which still exceeds 200 mg/24 h for at least two determinations 6 weeks apart • 25–49% reduction in the size of soft-tissue plasmacytomas (by clinical or radiographic examination) for at least 6 weeks • No increase in the size or number of lytic bone lesions
No change (NC)	Not meeting the criteria for MR or PD
Progressive disease (PD) (for patients not in CR)	*Requires one or more of the following* • > 25% increase in the level of serum monoclonal paraprotein, which must also be an absolute increase for at least 5 g/L and confirmed on a repeat investigation • > 25% increase in 24-h urinary light-chain excretion, which must also be an absolute increase of at least 200 mg/24 h and confirmed on a repeat investigation • > 25% increase in plasma cells in a bone marrow aspirate or on trephine biopsy, which must also be an absolute increase of at least 10% • Definite increase in the size of existing lytic bone lesions or soft-tissue plasmacytomas • Development of new bone lesions or soft tissue plasmacytomas • Development of hypercalcaemia (corrected serum calcium > 2.8 mmol/L not attributable to any other case)
Relapse from CR	*Requires one or more of the following* • Reappearance of serum or urinary paraprotein on immunofixation or routine electrophoresis confirmed by at least one follow-up and excluding oligoclonal immune reconstitution • < 5% plasma cells in a bone marrow aspirate or on trephine biopsy • Definite increase in the size of residual lytic bone lesions or soft-tissue plasmacytomas • Development of new bone lesions or soft tissue plasmacytomas • Development of hypercalcaemia (corrected serum calcium > 2.8 mmol/L not attributable to any other case)

Induction chemotherapy plus interferon-alpha

Interferon-alpha (IFN-α) alone is not effective as part of induction therapy in myeloma patients. Two large meta-analyses studies of 4802 patients showed a slight benefit in both progression-free survival and overall survival (6 and 2 months respectively) in patients treated with chemotherapy plus IFN-α.

However, the Nordic Myeloma Study Group has shown no benefit in survival in patients treated with IFN-α during induction chemotherapy, while there is a significant reduction in quality of life for patients receiving IFN-α during the first year of treatment. Therefore, it seems that there is no role for IFN-α in induction treatment.

Thalidomide and dexamethasone

The combination of thalidomide and dexamethasone produces response rates up to 65% in newly diagnosed patients, which is similar to VAD-like regimens. Unfortunately, venous thromboembolism is seen in 10% of patients, a side-effect that suggests that this combination is not suitable for induction treatment. Trials studying the effect of thalidomide and dexamethasone in combination with chemotherapeutic agents, including cyclophosphamide, are being carried out at present.

Autologous stem cell transplantation

In the absence of any significant progress in conventional chemotherapy, HDT with ASCT has become one of the most widely explored strategies to improve anti-myeloma treatment. ASCT has become the treatment of choice for symptomatic eligible patients with multiple myeloma. It is usually given after initial cytoreduction with VAD-related regimens. Peripheral blood stem cells (PBSCs) are harvested after mobilization with a combination of chemotherapy and growth factors.

High response rates with CR up to 30% can be achieved after ASCT, even in patients refractory to conventional treatment, leading to longer progression-free and overall survival. Two large randomized trials have been carried out to study the role of HDT and ASCT in myeloma. The first was conducted by the Inter-Groupe Francophone du Myélome (IFM 1996) in newly diagnosed patients with stage II or III myeloma. Patients received four to six cycles of VMCP/BVAP induction followed by randomization to additional conventional chemotherapy for a total of 18 cycles or high-dose melphalan and total body irradiation followed by ASCT. ASCT was superior to chemotherapy in terms of response rate (38% CR plus good PR vs. 14%), the 6-year event-free survival (25% vs. 14%) and overall survival (43% vs. 28%). This result was confirmed by a large MRC trial (2003) in which 407 patients with previously untreated myeloma received either standard conventional chemotherapy alone or conventional chemotherapy followed by HDT and ASCT. The CR rate was higher in the transplant group (44% vs. 8%) and so was the overall survival (54 vs. 42 months) and progression-free survival (32 vs. 20 months). Therefore, HDT and ASCT is considered the treatment of choice for patients below 70 years of age. Although some elderly patients may also benefit from the procedure, ASCT is not recommended for elderly myeloma patients who are not fit.

The median overall survival from the time of ASCT is approximately 50 months. The procedure is safe, and the transplantation-related mortality (TRM) is below 2%. The recommended dose of melphalan is 200 mg/m^2. Addition of total body irradiation does not lengthen progression-free or overall survival but adds significantly to toxicity. Low levels of β_2-microglobulin at diagnosis, and the achievement of CR post ASCT, are associated with a better prognosis and seem to be the most important factors in predicting the final outcome.

The issue of early versus late ASCT has been studied and, although there is no difference in overall survival between these treatment modalities, patients who receive an early ASCT have a longer period without symptoms, treatment and treatment-related toxicity. CD34 selection or purging of harvested stem cells does not influence survival and the role of tandem transplants remains unclear. A recent randomized IFM trial showed better survival in those patients with myeloma who were treated with tandem transplants than in those treated with a single transplant. Unfortunately, the patients in the single transplant group received HDT with 140 mg/m^2 melphalan and 8 Gy total body irradiation. This combination has already been shown to result in inferior survival when compared with HDT with 200 mg/m^2 melphalan alone. Future trials will need to compare tandem transplants with single transplants after HDT with 200 mg/m^2 melphalan. HDT may also be carried out in patients with renal failure if they are otherwise fit. The TRM for patients with creatinine levels of above 170 μmol/L is around 6% and the probability of survival at 5 years is 55%.

Allogeneic stem cell transplantation

Allogeneic bone marrow transplantation is too risky to be considered for most patients, but the possibility of a potentially curable graft-versus-myeloma (GvM) effect gives this procedure the best chance for long-term disease control. Registry data show that in patients who have undergone allogeneic matched sibling-donor transplantation, the long-term survival is around 25%. However, the median survival is similar to that in patients who receive ASCT, mainly because of the high TRM rate of between 20% and 40%, which seems to be higher in male patients. Allogeneic transplantations with matched unrelated donors have an even higher TRM and may be considered only in exceptional cases and carried out at specialist centres in the context of a clinical trial. Patients who survive the procedure have a 60% chance of achieving CR and a 50% possibility of achieving molecular remission compared with 7% of patients who have a molecular remission after ASCT. However, only around 20% of allografted patients are in continued CR 5 or more years post transplant. Chronic graft-versus-host disease (GvHD) correlates with CR in allotransplant patients and provides further evidence of an allogeneic GvM effect. There are a number of small studies in the literature showing a direct GvM effect of donor lymphocyte infusions (DLIs). The GvM effect of DLI is often accompanied by severe GvHD. In order to harness this GvM effect, current research is focused on allogeneic transplantation from HLA identical sibling after conditioning with a non-myeloablative or reduced-intensity conditioning regimens followed by DLI to eradicate residual tumour. These 'mini-transplants' have the theoretical advantage of low TRM (near 20%) while maintaining the GvM effect. However, further studies are required to fully evaluate this procedure.

Maintenance therapy

Interferon-alpha

Interferon-α as maintenance therapy following induction chemotherapy results in a slight improvement in progression-free and overall survival of nearly 5–7 months. The addition of chemotherapy (VAD, MP, CP) to the IFN-α maintenance does not seem to improve survival when compared with IFN-α alone. Meta-analysis by the Myeloma Trialists' Collaborative Group showed slightly increased survival in myeloma patients who were given IFN-α as maintenance treatment after conventional chemotherapy but not in those who had undergone ASCT. Taking into consideration the benefit of IFN-α and considerable toxicity, consisting mainly of flu-like symptoms and malaise, the decision to treat individual patients would depend on how well IFN-α is tolerated. The dose of IFN-α has varied among different studies, ranging between 1.5–3 MU/m^2, subcutaneously, three times per week.

Other regimens

Dexamethasone alone, 20 mg/m^2 orally each morning for 4 days, monthly until relapse, offers no advantage over IFN-α. The role of new agents, such as thalidomide or bortezomib, as maintenance treatment post ASCT is under investigation.

Treatment of refractory and relapsed disease

Primary refractory disease

Patients with disease refractory to VAD may respond to alkylating agents and vice versa. Patients with alkylating agent- or VAD-refractory disease may still respond to high-dose melphalan followed by ASCT. Refractory patients have a better outcome after transplantation than after chemotherapy, although patients with prolonged (> 1 year) primary resistant disease gain only minimal benefit from HDT and ASCT.

Relapsed disease

The therapeutic options include repeating initial chemotherapy or, alternatively, using another combination of chemotherapeutic agents mentioned above, followed by HDT and ASCT. Patients who have been treated with MP initially may respond well to the same treatment (response of about 50%) or to VAD-related regimens. Weekly oral or intravenous cyclophosphamide may also be effective. A second ASCT may be performed in patients who relapse after an initial autograft. In these patients, β_2-microglobulin levels, the disease status at transplantation and bone marrow plasma cell infiltration correlate with response and overall survival. Allogeneic transplantation may be an option in some patients, with response rates of around 40% but confers no advantage in term of overall survival compared with ASCT.

Thalidomide

Thalidomide, which was removed from widespread clinical use in 1962 because of severe teratogenicity, has been shown to produce response rates of 30% in patients with refractory or relapsed disease. In the first report by Singhal *et al.* (1999), thalidomide was given at a starting dose of 200 mg/day, increasing in 200-mg increments every 2 weeks to a maximum dose of 800 mg/day. However, the optimal dose of thalidomide remains uncertain, and this issue can be resolved only by appropriate prospective clinical trials. The combination of thalidomide with dexamethasone seems to increase the response rate to around 50%. The combination of thalidomide with chemotherapy and dexamethasone (CDT: cyclophosphamide, dexamethasone and thalidomide; hyper-CDT: cyclophosphamide, dexamethasone, and thalidomide; TCED: thalidomide, cyclophosphamide, etoposide, and dexamethasone; DT-PACE: dexamethasone, thalidomide, cisplatin, doxorubicin, cyclophosphamide and etoposide) has produced overall response rates of 30–80% in patients with advanced myeloma. The precise role of these combinations in the management of myeloma has not yet been clarified.

Venous thromboembolism has emerged as the single most important complication of thalidomide. The frequency of thromboembolic disease is less than 5% when thalidomide is used alone but is increased to near 15% when thalidomide is given with dexamethasone and almost to 30% when thalidomide is given in combination with chemotherapy. To date, no identifiable prothrombotic abnormality has been found to be predictive of thrombosis in these patients. Other side-effects of thalidomide include peripheral neuropathy, somnolence, constipation, tremor, xerostomia, neutropenia, hypothyroidism, rash and bradycardia. Peripheral neuropathy is a major potential problem with thalidomide as it can be irreversible if the drug is not promptly withdrawn. Thus, patients need to be followed up very closely for the first few months of thalidomide administration.

Bortezomib

Bortezomib (formerly PS341) is a small molecule that is a potent and selective inhibitor of the 26S proteasome, which is the primary component of the protein degradation pathway of the cell. Bortezomib inhibits proliferation and induces apoptosis of human myeloma cell lines. It also inhibits the NF-κB activation, overcomes drug resistance and adds to the anti-myeloma activity of dexamethasone *in vitro*. In a recent trial of 202 refractory myeloma patients who had received more than three lines of previous treatment, the response rate to bortezomib was 35% (CR and very good PR almost 10%). The median overall survival was 16 months, with a median duration of response of 12 months. A phase III trial comparing bortezomib and high doses of dexamethasone is in progress. This drug has recently been approved by the United States Food and Drug Administration on the basis of the encouraging phase II results and the UK licence application is pending.

Revimid

Revimid is an immunomodulatory agent that exhibits no sedative side-effects but occasionally causes neurotoxic side-effects. Responses have been reported in one-third of patients with advanced and refractory myeloma. Many of these patients had been previously exposed to thalidomide, although true thalidomide resistance was infrequently established. Unlike thalidomide, Revimid causes myelosuppression, which in the setting of compromised bone marrow reserve due to extensive prior cytotoxic drug exposure, may not be fully reversible. Trials are currently under way to investigate the dosing schedules and responses in combination with dexamethasone.

Management of bone disease and hypercalcaemia

The clinical manifestations of myeloma include osteolytic bone destruction and hypercalcaemia. The initial therapy of patients with hypercalcaemia consists of vigorous hydration with intravenous saline and diuresis with frusemide once the patient is rehydrated. Corticosteroids are very effective in hypercalcaemia through their anti-tumour effect, anti-osteoclast activity and reduction of gastrointestinal absorption of calcium. If the patient remains hypercalcaemic after rehydration and diuresis, a specific intravenous anti-osteoclast agent such as pamidronate or zoledronic acid should be used. The majority of the patients achieve normal serum calcium levels within 7 days. In resistant cases, parenteral mithramycin or calcitonin may be indicated. Calcitonin causes a reduction in calcium levels within 12–24 h, but the response is moderate and brief. Mithramycin is effective but toxic, causing myelosuppression, hepatitis and renal damage. Progression of skeletal disease is often not affected by chemotherapy even in patients who seem to be responding. Therapeutic options include the use of bisphosphonates with or without local radiotherapy or surgery.

Bisphosphonates

Bisphosphonates inhibit osteoclast activity by preventing the osteoclast differentiation, inducing osteoclast apoptosis and interrupting their attachment to the bone. They also induce apoptosis of human myeloma cells *in vitro*, reduce IL-6 secretion by bone marrow stromal cells and cause expansion of γδ T-cells with anti-myeloma activity, suggesting a possible anti-tumour effect of these agents. The effects of bisphosphonates have been evaluated in randomized trials. Oral clodronate (1600 mg, orally, daily) reduces skeleton-related events (SREs), such as pathological fractures, surgery for fracture or impending fracture, radiotherapy to the bone, spinal cord compression and hypercalcaemia. Patients without overt skeletal disease at diagnosis benefit the most, an observation that supports the use of bisphosphonates early in the management of the disease. The second-generation aminobisphosphonate pamidronate, given monthly at a dose of 90 mg intravenously, also reduces SREs and improves pain and quality of life. It may also extend survival in a subgroup of patients with advanced disease, while it decreases paraprotein, IL-6 and bone resorption markers in myeloma patients, including those in plateau phase. A large meta-analysis, which included 11 randomized trials with 2183 patients, showed that the addition of bisphosphonates (pamidronate or clodronate) to the specific anti-myeloma treatment reduces pathological vertebral fractures and pain. However, there is no effect on mortality, the incidence of non-vertebral fractures or the incidence of hypercalcaemia. No randomized trials have been carried out between the different doses of clodronate or between clodronate and pamidronate to evaluate the differences between these two efficacious bisphosphonates in the management of myeloma bone disease. Ibandronate, a new third-generation bisphosphonate, does not seem to be effective at the doses of 2 mg and 4 mg. Zoledronic acid is a novel third-generation bisphosphonate, which produces the greatest osteoclast inhibition *in vitro,* inhibits the development of osteolytic bone disease and increases progression-free survival in murine myeloma models. It is administered intravenously, in a 15-min infusion, at a dose of 4 mg, and is superior to pamidronate in the treatment of hypercalcaemia of malignancy. However, no superiority over pamidronate has been established in terms of SREs in myeloma. Evidence suggests that long-term bisphosphonate treatment with pamidronate, zoledronic acid or clodronate is necessary for all myeloma patients with lytic bone disease.

Radiotherapy

Radiotherapy may be required in patients who have extramedullary plasmacytoma, in those who have painful destruction of a vertebral body or a pathological fracture, or in whom there is computerized tomography (CT) or MRI evidence of spinal cord compression. Percutaneous vertebroplasty has only recently been introduced as a treatment for osteolytic lesions and osteoporotic compression fractures of the vertebrae. Early results in 187 patients with metastases, myeloma or osteoporotic compression fractures are very promising as approximately 80% of patients with pain unresponsive to medical treatment experience a significant degree of pain relief.

Surgery

Surgery has a role in the management of selected myeloma patients with spinal cord compression or those with unstable vertebral fractures.

Drug resistance

Drug resistance is a major obstacle to successful drug treatment of multiple myeloma. Several mechanisms of drug resistance have been identified (see also Chapter 35). Previous studies had suggested that P-glycoprotein overexpression was responsible

for chemotherapy resistance in myeloma cells. Attempts in many clinical studies to reverse multidrug resistance by downregulating P-glycoprotein have not been successful so far.

Another mechanism is related to resistance to apoptosis (programmed cell death), induced by cytotoxic drugs or radiation, of myeloma cells. The proteins involved in this mechanism include B-cell leukaemia/lymphoma protein 2 (Bcl-2), Bcl-XL, Mcl-1 and mutations in the p53 protein. Although switch translocations leading to the activation of multiple partners play an important part in the pathogenesis of myeloma, these translocations do not involve Bcl-2 family members. However, Bcl-2 is expressed in many myeloma cell lines and plasma cells from myeloma patients. Bcl-XL is expressed more often at the time of patient relapse and correlates with resistance to chemotherapy. Mcl-1 is expressed in virtually all cell lines and patient samples examined thus far. Whether these proteins have overlapping functions or work independently to promote myeloma cell survival is unclear. Investigators have started to target these proteins to overcome drug resistance. Some laboratories have been able to correlate induction of apoptosis with decreased expression of Mcl-1. *In vitro* studies have shown that inhibition of Mcl-1 expression with antisense oligonucleotide results in rapid apoptosis and this killing is potentiated by the addition of dexamethasone.

More recently, increased activity of the transcription factor nuclear factor kappa B (NF-κB) has been implicated in the mechanism of chemotherapy resistance of myeloma cells. NF-κB activity protects cells from apoptosis induced by cytotoxic drugs, TNF, IL-1 and many other stimuli. It can activate the expression of TNF receptor-associated factors (TRAF) 1 and 2 and cellular inhibitors of apoptosis genes (cIAP), thereby inhibiting caspase-8 activation and apoptosis. It also inhibits apoptosis by activating cFLIP as well as Bcl-XL and XIAP. Inhibition of C activity in both melphalan-sensitive and melphalan-resistant myeloma cell lines resulted in increased apoptosis. Newer agents such as bortezomib have, therefore, been specifically designed to block NF-κB activation and thus promote apoptosis in chemotherapy-resistant myeloma cells.

Future drug development will likely result in drugs which, either alone or in combination with chemotherapy and radiation, lower the threshold for apoptosis of myeloma cells and overcome chemotherapy resistance.

Supportive therapy

Anaemia

Traditionally, symptomatic anaemia has been managed by red cell transfusion. There is now increasing evidence that recombinant human erythropoietin (rHuEpo) is useful in the management of anaemia in myeloma. In a randomized trial that included 121 transfusion-dependent patients with low-grade non-Hodgkin's lymphoma or myeloma without renal impairment, a response rate of 60% was achieved when a daily dose of 5000 U was given

s.c. (subcutaneously). Another double-blind, placebo-controlled trial in 145 anaemic myeloma patients with normal renal function showed that rHuEpo at a dose of 150 IU/kg, s.c., three times weekly, produces a reduction in transfusion requirements, a mean increase in haemoglobin of 1.8 g/dL and an improvement in quality of life. Although there are no reliable predictors of response to rHuEpo, low endogenous erythropoietin concentration seems to be the most helpful predictive factor for response. These data suggest that a therapeutic trial of rHuEpo should be considered in any myeloma patient with symptomatic anaemia.

Renal failure

A degree of renal impairment occurs in up to 50% of myeloma patients at some stage of their disease, while advanced renal failure requiring haemodialysis occurs in 3–12%. In the majority of the patients, renal function will improve in response to simple measures such as rehydration, correction of hypercalcaemia with bisphosphonates, fluid rehydration and administration of glucocorticoids, or discontinuation of nephrotoxic drugs such as non-steroidal anti-inflammatory drugs (NSAIDs) and treatment of any infections. The risk of renal failure, which may be precipitated by the use of intravenous X-ray contrast media, can be reduced by ensuring adequate hydration and by using dyes of reduced osmolality. Allopurinol should be prescribed with the cytotoxic chemotherapy. Half of those who recover do so in the first 6 weeks but late recovery is still possible. Renal impairment is most likely to be reversed in patients with mild impairment, independently of the underlying myeloma.

The efficacy of plasma exchange in patients with hyperviscosity is well established. However, evidence of its usefulness in the treatment of cast nephropathy is equivocal, and therefore it should be used only in the context of a clinical trial. Plasma exchange is effective at removing light chains from the blood, and one retrospective case study suggests that plasma exchange may offer some benefit in preventing initiation of dialysis, as well as preventing acute renal failure progressing to chronic renal failure. It may be necessary to biopsy the kidney to differentiate between cast nephropathy, amyloidosis, light-chain deposition disease and acute tubular necrosis. Renal dialysis may be required to manage the renal failure in some patients. Both peritoneal and haemodialysis have been used successfully in newly diagnosed patients presenting with acute renal failure. Dialysis should be offered to patients in renal failure to allow time for a trial of anti-myeloma chemotherapy. It is the control of the underlying disease rather than the reversal of renal failure, which determines survival benefit. VAD chemotherapy or dexamethasone alone is recommended for initial treatment of patients with renal impairment. Cyclophosphamide is excreted in the urine and therefore a dosage reduction is needed. Patients with multiple myeloma and renal failure have been treated with high-dose therapy with melphalan with some success. There is no consensus concerning the dosage of melphalan in patients with impaired renal function. Melphalan undergoes spontaneous

degradation in the blood, and most of the inactive metabolites are excreted in the faeces and some in the urine. Some case reports suggest that the dose of melphalan should be reduced to prevent severe mucositis while others found no change in the pharmacokinetics of high-dose melphalan in patients with renal failure. Patients treated with standard-dose melphalan even when they were on haemodialysis had a treatment-related mortality of less than 5%.

Conclusion and future prospects

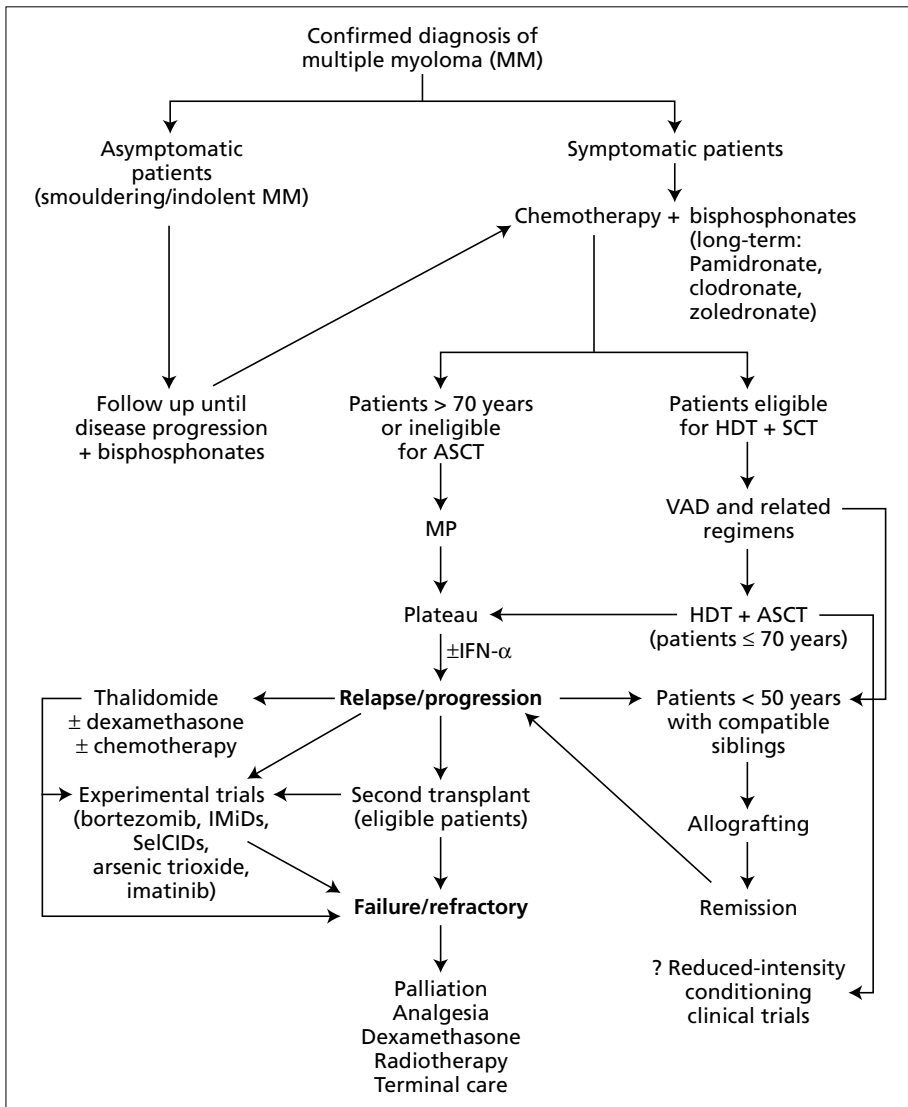
Figure 41.5 summarizes the management of patients. The use of HDT and ASCT has improved quality of life and survival and is now considered the standard therapy after initial chemotherapy with VAD or VAD-related regimen. For patients not suitable for ASCT, MP remains the treatment of choice. Unfortunately, most patients die from their disease, and strategies to improve the outcome of ASCT such as tandem transplantation and manipulation of the graft have not been helpful. Allogeneic SCT may be curative in a proportion of patients and should be considered in younger patients with HLA-compatible siblings. Current transplantation trials involve 'debulking' with an ASCT followed by reduced-intensity conditioned allogeneic sibling transplant. This strategy is aimed at harnessing the GvM of the donor graft while maintaining a low TRM. Further progress in management may come from clinical trials which are currently being carried out with other potential agents, including thalidomide analogues [selected cytokine inhibitory drugs (SelCIDs) and immunomodulatory drugs (IMiDs)], arsenic trioxide and proteasome inhibitors, such as bortezomib.


Figure 41.5 Algorithm for the management of patients with myeloma.

Monoclonal gammopathy of uncertain significance

The term 'monoclonal gammopathy of undetermined significance' (MGUS) indicates the presence of a paraprotein in patients without evidence of multiple myeloma, Waldenström's macroglobulinaemia, AL amyloidosis or a related plasma cell proliferative disorder. MGUS is characterized by the following: a serum paraprotein concentration less than 35 g/L; less than 10% plasma cells in the bone marrow; or no Bence Jones protein in the urine; absence of lytic bone lesions; and no related anaemia, hypercalcaemia or renal insufficiency (see Table 41.1). Paraproteins occur without myeloma or Waldenström's macroglobulinaemia in approximately 3% of persons older than 70 years. A monoclonal increase in immunoglobulins results from a clonal process that is malignant or potentially malignant, whereas a reactive or inflammatory process causes a polyclonal increase in immunoglobulins. It is, therefore, essential to distinguish between monoclonal and polyclonal proliferation of plasma cells. It is important to determine whether the monoclonal gammopathy remains stable and benign or progresses to myeloma or a related disorder. Long-term follow-up of a group of 1384 MGUS patients from Minnesota showed that 8% of patients developed myeloma, primary AL amyloidosis, lymphoma with an IgM paraprotein, Waldenström's macroglobulinaemia, plasmacytoma or chronic lymphocytic leukaemia. The cumulative probability of progression to one of these disorders was 10% at 10 years, 21% at 20 years and 26% at 25 years. Although the risk of progression was only 1% per year, patients were at risk of progression even after 25 years or more of stable MGUS.

The sequence of events responsible for malignant transformation of MGUS to myeloma or a related plasma cell proliferative disorder is poorly understood. Alterations, including cytogenetic changes, expression of cytokines and expression of adhesion molecules, occur in both the myeloma cell and the bone marrow microenvironment during this transformation, but the specific pathogenetic role of these alterations is unclear. FISH studies show that 60% of patients with myeloma have IgH (14q32) translocations. Of note, these studies have indicated that these translocations are not unique to myeloma but are also present in MGUS. In one series, 46% of patients with MGUS had IgH translocations, with t(11;14)(q13;q32) being the most common. Because IgH translocations occur in both MGUS and myeloma, their primary role probably lies in the initiation of the clone rather than progression of MGUS to myeloma. Deletions of chromosome 13, which have been in myeloma also occur in MGUS. However, it is not clear if this accelerates the rate of progression from MGUS to myeloma. Aneuploidy appears to occur in some patients with MGUS. Hyperdiploidy has also been noted in bone marrow plasma cells of patients with MGUS.

Changes in the bone marrow microenvironment have also been described. Angiogenesis increases progressively along the spectrum of plasma cell disorders, from the more benign MGUS stage to advanced myeloma, suggesting that angiogenesis may be related to disease progression. It is likely that progression of MGUS to myeloma involves the dysregulation of various cytokines in plasma cells and stromal cells, leading to osteoclast activation and lytic bone lesions. However, none of the findings, including plasma cell morphology, made at diagnosis of MGUS distinguishes between patients whose condition will remain stable and those in whom a malignant condition will develop. When multiple myeloma or Waldenström's macroglobulinaemia develops, the type of paraprotein is the same as that of the MGUS. The initial concentration of paraprotein is an important risk factor for progression to a plasma cell disorder. In one study, the risk of transformation to myeloma or a related disorder 20 years after the diagnosis of MGUS was 14% for patients with an initial paraprotein level of 5 g/L or less, 16% for 10 g/L, 25% for 15 g/L, 41% for 20 g/L, 49% for 25 g/L and 64% for 30 g/L. There is no significant difference in survival between patients with MGUS and age-matched control subjects. No one factor can differentiate a patient with a benign monoclonal gammopathy from one in whom a malignant plasma cell disorder subsequently develops although attempts are currently being made, through gene expression profiling, to determine if a pattern of gene expression can be identified to predict progression to myeloma. These patients need to be followed up regularly and serum paraprotein level must be measured every 6–12 months to determine whether their condition has transformed.

Lymphoplasmacytic lymphoma/Waldenström's macroglobulinaemia

Lymphoplasmacytic lymphoma/Waldenström's macroglobulinaemia (LPL) is a B-cell lymphoma that shows maturation to plasmacytoid lymphocytes and plasma cells and is associated with an IgM paraprotein with hyperviscosity or cryoglobulinaemia. It is discussed in greater detail in Chapter 45.

Solitary plasmacytoma

Solitary bone and extramedullary plasmacytomas are rare. Their diagnosis is based on histological confirmation of monoclonal plasma cell infiltration of a single disease site and on the exclusion of multiple myeloma. The treatment of choice for both entities is localized radiotherapy. Using modern radiotherapy and at a total dose of 4000–5000 cGy, the risk for local recurrence is less than 5%. There is no role for systemic chemotherapy in the management of these disorders. The prognosis of patients with solitary extramedullary plasmacytoma appears to be better than for patients with solitary bone plasmacytoma, as approximately 70% of patients with solitary extramedullary plasmacytoma

remain disease free at 10 years compared with 30% of patients with bone plasmacytoma.

Plasma-cell leukaemia

In 2% of the cases of myeloma, plasma cells may be present in peripheral blood. Plasma cell leukaemia is defined as a level of plasma cells in the peripheral blood that exceeds 2×10^9/L or > 20% of the white cells. It may occur at the time of diagnosis, when it is known as primary plasma cell leukaemia, or evolve as a terminal complication during the course of multiple myeloma, when it is called secondary plasma cell leukaemia. Plasma cell leukaemia is more frequent in light-chain (Bence Jones protein) or IgD myeloma. It is seen less frequently in IgA or IgG myeloma. Osteolytic lesion and bone pain are less frequent and lymphadenopathy, organomegaly and renal failure more frequent in plasma cell leukaemia. It is an aggressive disease associated with short survival.

Non-secretory myeloma

About 1% of multiple myeloma patients have plasma cells that synthesize but do not secrete immunoglobulin molecules, resulting in absence of paraprotein. Monoclonal cytoplasmic immunoglobulin is demonstrated in the malignant plasma cells by immunohistochemistry. In rare cases, no cytoplasmic immunoglobulin is detected. The clinical features are very similar to secretory multiple myeloma except for a lower incidence of renal complications. The diagnosis can be missed because of the lack of serum or urine monoclonal immunoglobulin unless bone marrow biopsy with immunohistochemistry is carried out.

Osteosclerotic myeloma (POEMS syndrome)

Osteosclerotic myeloma is often a component of the rare POEMS syndrome, which includes polyneuropathy (sensorineural demyelination), organomegaly (hepatomegaly, splenomegaly), endocrinopathy (diabetes, gynaecomastia, testicular atrophy, impotence), monoclonal gammopathy and skin changes (hyperpigmentation, hypertrichosis). It is characterized by a plasma cell infiltrate in the marrow accompanied by thickened bone trabeculae and often lymph node changes resembling the plasma cell variant of Castleman's disease. Patients may present with polyneuropathy and symptoms related to endocrinopathy, skeletal lesions or lymphadenopathy. They usually have either IgAλ or IgGλ paraprotein. The level of paraprotein in the serum and urine is usually low. Anaemia, hypercalcaemia, renal dysfunction and pathological fractures are rare. Bone marrow trephine shows a characteristic osteosclerotic plasmacytoma

which may occur singly or multiply. The lesion shows thickened trabecular bone with closely associated peritrabecular fibrosis with entrapped plasma cells. The rest of the bone marrow away from the lesions is relatively normal with less than 5% plasma cells. Lymph node biopsy shows a follicular proliferation with regressed and reactive follicles and interfollicular plasma cell accumulation, consistent with the plasma cell variant of Castleman's disease. One study showed that the survival may be better than that for typical multiple myeloma.

Heavy-chain diseases

These are B-cell neoplasms that produce monoclonal heavy chains but no light chains. There is considerable heterogeneity in the morphology and clinical features. The heavy chain is either a μ or γ or α which is truncated and not capable of full assembly and would therefore be of varying size. The deletions are located mainly in the Fab fragment with a normal Fc portion. It may therefore not have the characteristic 'spike' on serum electrophoresis and requires immunoelectrophoresis or immunofixation to confirm heavy-chain specificity. These diseases probably represent variants of lymphoma. In γ-heavy-chain disease (γ-HCD) and α-HCD there is a reduction in the synthesis of light chains, whereas in μ-HCD, light chains are produced in moderate quantities but are not incorporated into immunoglobulin molecules.

α-Heavy-chain disease is a variant of extranodal marginal zone B-cell lymphoma of the mucosa-associated lymphoid tissue (MALT) type in which defective α-chains are secreted. It occurs in young adults with a peak incidence in the second and third decades. It is endemic in areas bordering the Mediterranean, including Israel, Egypt, Saudi Arabia and North Africa. It is associated with low socioeconomic status and consequential poor hygiene, malnutrition and frequent intestinal infections. It involves the gastrointestinal tract, mainly the small intestine and mesenteric nodes, resulting in malabsorption, diarrhoea, hypocalcaemia, abdominal pain, wasting, fever and steatorrhoea. It is also known as immunoproliferative small intestinal disease (IPSID). The serum protein electrophoresis is usually normal because of the variation in the IgA molecular forms or it shows hypogammaglobulinaemia. Anti-IgA antibody is therefore required to make the diagnosis by immunofixation. Serial studies of patients who are diagnosed early in the course of their disease suggest that the lamina propria of the duodenum and jejunum and regional mesenteric nodes and retroperitoneal nodes are initially infiltrated by small lymphocytes and plasma cells. As the disease progresses, the lamina propria becomes more heavily infiltrated with plasma cells with extension into the submucosa and the muscularis mucosa. Further progression results in the appearance of immunoblastic tumours of the small bowel and mesenteric nodes. Initially the entire length of the small intestine is diffusely involved, but later on in the course of

the disease pleomorphic immunoblastic tumours may develop with intestinal obstruction, intussusception or perforation. The plasma cells and marginal zone cells express monoclonal cytoplasmic α heavy-chain without light chains, express pan-B-cell antigens but not CD5 or CD10. If α-HCD is treated with antibiotics at an early stage of disease, then complete remission may be achieved. Many patients may undergo transformation to large B-cell lymphoma with fatal result.

μ-Heavy-chain disease is an extremely rare disease of adults resulting from a B-cell neoplasm resembling chronic lymphocytic leukaemia (CLL) and involving the spleen, liver, bone marrow and peripheral blood, in which a defective μ-chain lacking a variable region is produced. Most patients present with a slowly progressive chronic lymphocytic leukaemia. μ-HCD can be differentiated from CLL by the high frequency of hepatosplenomegaly and absence of lymphadenopathy. Routine serum protein electrophoresis is usually normal but immunoelectrophoresis may show m-polymers of varying sizes. Light chains, particularly κ-chains, are commonly found in the urine. Bone marrow biopsy shows a mixture of characteristic vacuolated plasma cells and small, round lymphocytes similar to CLL cells. The cells show monoclonal cytoplasmic m-chain without light chain, express pan-B cell antigens but do not express CD5 or CD10.

γ-Heavy-chain disease is a lymphoplamacytic lymphoma that produces a truncated γ-chain, which does not bind to light chains to form a complete immunoglobulin molecule. It is a rare disease with a median age of onset at 60. Most patients have systemic symptoms such as anorexia, weakness, fever, weight loss and recurrent bacterial infections or may exhibit autoimmune processes such as haemolytic anaemia, autoimmune thrombocytopenia. These patients have lymphadenopathy, splenomegaly, hepatomegaly and peripheral eosinophilia. Serum protein electrophoresis may be normal, but the diagnosis may be made by demonstration of IgG without light chains by immunofixation. There is usually very little light chain production with urinary light chain less than 1 g/24 h. Lymph nodes show a mixture of lymphocytes, plasmacytoid lymphocytes, plasma cells, immunoblasts and eosinophils. When plasma cells predominate, it may resemble multiple myeloma. The neoplastic cells have monoclonal cytoplasmic γ-chains and express pan-B cell markers, but do not express CD5 or CD10. The clinical course is variable but it can be rapidly progressive with a median survival of 12 months.

Amyloidosis

Hugh JB Goodman and Philip N Hawkins

42

Introduction

Amyloidosis is a disorder of protein folding in which normally soluble proteins are deposited in the extracellular space as insoluble fibrils that progressively disrupt tissue structure and function. Some 20 different unrelated proteins can form amyloid *in vivo*, and clinical amyloidosis is classified according to the fibril protein type (Table 42.1). Although the term amyloid is derived from the Greek for starch-like, the misnomer was recognized over 100 years ago and has remained unchallenged.

Amyloid deposition may be systemic or localized, hereditary or acquired, life-threatening or an incidental finding. Organ involvement varies within and between fibril types and clinical phenotypes overlap greatly. Systemic amyloidosis may involve virtually any tissue and is often fatal, although its prognosis has been improved by haemodialysis, kidney, liver and heart transplantation, and by increasingly effective treatment of the various conditions that underlie it. Localized amyloid deposits are confined to specific foci or to a particular organ or tissue, and can be clinically silent through to causing serious disease such as haemorrhage in local respiratory or urogenital tract AL amyloid. In addition to the amyloidoses *per se*, local amyloid deposition is a hallmark pathological feature of uncertain significance in other important diseases including Alzheimer's disease, the prion disorders and type II diabetes mellitus.

The chapter is devoted mainly to describing the clinical features, diagnosis and management of AL (monoclonal immunoglobulin light chain) amyloidosis, which is the most common and serious form of systemic amyloidosis in industrialized societies. The differential diagnosis and other amyloid fibril types that can mimic AL type are also discussed.

Pathogenesis of amyloid

Amyloidosis breaks the dogma that tertiary structure of proteins is determined solely by their primary amino acid sequence. Amyloid-forming proteins can exist in two completely different stable structures, the transformation evidently involving massive refolding of the native form into one that can autoaggregate in a highly ordered manner to produce the characteristic predominantly β-sheet, rigid, non-branching fibrils of 10–15 nm in diameter and of indeterminate length. Acquired biophysical properties common to all amyloid fibrils include insolubility in physiological solutions, relative resistance to proteolysis, and ability to bind Congo red dye in an ordered manner that gives the diagnostic green birefringence under cross-polarized light.

Amyloid deposition can occur in three circumstances. The first is when there is a sustained abnormally high concentration of certain normal proteins, such as serum amyloid A protein (SAA) in chronic inflammation and β_2-microglobulin in renal failure, which underlie susceptibility to AA and Aβ_2M amyloidosis respectively. The second situation is when there is a normal concentration of a normal, but inherently amyloidogenic, protein over a very prolonged period, such as transthyretin in senile amyloidosis (ATTR) and β-protein in Alzheimer's disease. The third situation is the production of an acquired or inherited variant protein with an abnormal structure, such as amyloidogenic monoclonal immunoglobulin light chains or the amyloidogenic variants of transthyretin, lysozyme, apolipoprotein AI, fibrinogen Aα chain, etc. The genetic and environmental factors that influence individual susceptibility to and timing of amyloid deposition are unclear, but once the process has begun amyloid deposition is unremitting as long as the supply of the respective precursor protein remains undiminished.

Table 42.1 Classification of amyloidosis.*

Type	Fibril precursor protein	Clinical syndrome
AA	Serum amyloid A protein	Systemic amyloidosis associated with acquired or hereditary chronic inflammatory diseases. Formerly known as secondary or reactive amyloidosis
AL	Monoclonal immunoglobulin light chains	Systemic amyloidosis associated with myeloma, monoclonal gammopathy, occult B cell dyscrasia. Formerly known as primary amyloidosis
ATTR	Normal plasma transthyretin	Senile systemic amyloidosis with predominant cardiac involvement
ATTR	Genetic variants of transthyretin (e.g. ATTR Met30, Ala60, Ile122)	Familial amyloid polyneuropathy (FAP), with systemic amyloidosis and often prominent amyloid cardiomyopathy
$A\beta_2M$	β_2-Microglobulin	Dialysis related amyloidosis (DRA) associated with renal failure and long-term dialysis. Predominantly musculoskeletal symptoms
$A\beta$	β-Protein precursor (and rare genetic variants)	Cerebrovascular and intracerebral plaque amyloid in Alzheimer's disease. Occasional familial cases
AApoAI	Genetic variants of apolipoprotein AI (e.g. AApoAI Arg26, Arg60)	Autosomal dominant systemic amyloidosis. Predominantly non-neuropathic with prominent visceral involvement, especially nephropathy. Minor wild-type ApoAI amyloid deposits may occur in the aorta
AFib	Genetic variants of fibrinogen α chain (e.g. AFib Val526)	Autosomal dominant systemic amyloidosis. Non-neuropathic usually with prominent nephropathy
ALys	Genetic variants of lysozyme (e.g. ALys His67)	Autosomal dominant systemic amyloidosis. Non-neuropathic with prominent renal and gastrointestinal involvement
ACys	Genetic variant of cystatin C (Gln68)	Hereditary cerebral haemorrhage with cerebral and systemic amyloidosis
AGel	Genetic variants of gelsolin (e.g. Asn187)	Autosomal dominant systemic amyloidosis. Predominant cranial nerve involvement with lattice corneal dystrophy
AIAPP	Islet amyloid polypeptide	Amyloid in islets of Langerhans in type II diabetes mellitus and insulinoma

*Amyloid composed of peptide hormones, prion protein, and unknown proteins, not included.

Amyloid deposits consist mainly of amyloid fibrils, but they also contain some common minor constituents, including certain glycosaminoglycans (GAGs) and the normal circulating plasma protein serum amyloid P component (SAP), as well as various other trace proteins. SAP binds in a specific calcium-dependent manner to a ligand that is present on all amyloid fibrils but not on their precursor proteins, and studies in knockout mice indicate that SAP contributes to amyloidogenesis.

Amyloid fibril-associated GAGs mainly comprise heparan and dermatan sulphates. Their universal presence, restricted heterogeneity and intimate relationship with the fibrils suggest that they may also contribute to the development or stability of amyloid deposits, a possibility that has lately been supported by the inhibitory effect of low-molecular-weight GAG analogues on the experimental induction of AA amyloidosis in mice.

Many of the pathological effects of amyloid can be attributed to its physical presence. Extensive deposits, which may amount to kilograms, are structurally disruptive and incompatible with normal function, as are strategically located smaller deposits, for example in glomeruli or nerves. Amyloid fibrils may also be cytotoxic. However, the relationship between the quantity of amyloid and degree of associated organ dysfunction differs greatly between individuals, and there is a strong impression that the rate of new amyloid deposition may be as important a determinant of progressive organ failure as the amyloid load itself.

Systemic AL amyloidosis

Systemic AL (formerly known as 'primary') amyloidosis occurs in a small proportion of individuals with monoclonal B-cell dyscrasias. AL fibrils are derived from monoclonal immunoglobulin light chains, which are unique in each patient, underlying the remarkable broad clinical picture in this particular form

of amyloidosis. Virtually any organ or combination of organs other than the brain may be directly affected, commonly including the heart. However, symptoms are often non-specific and screening techniques frequently fail to detect the underlying monoclonal gammopathies leading to delayed diagnosis, by which time the deposits are often very extensive and the prognosis poor.

AL fibrils and monoclonal light chains

AL fibrils are composed of part or sometimes the whole of the variable (V_L) domain of monoclonal immunoglobulin light chains. The molecular weight of the fibril subunit protein therefore varies between about 8000 and 30 000 Da. The inherent 'amyloidogenicity' of certain monoclonal light chains has been elegantly demonstrated in an *in vivo* model in which purified Bence Jones proteins were injected into mice. Animals receiving light chains from patients with AL amyloid developed typical amyloid deposits composed of the human protein, whereas animals receiving light chains from myeloma patients without amyloid did not. AL fibrils are more commonly derived from λ than κ light chains, despite the fact that κ isotypes predominate among both normal immunoglobulins and monoclonal gammopathies. Some amyloidogenic light chains have distinctive amino acid replacements or insertions compared with non-amyloid monoclonal light chains, including replacement of hydrophilic framework residues by hydrophobic ones, changes that can promote aggregation and insolubility. Certain light-chain isotypes, notably $V_{\lambda VI}$, are especially amyloidogenic, and there is a degree of concordance between some isotypes and their tropism for being deposited as amyloid in particular organ systems. For example, the $V_{\lambda VI}$ isotype often presents with dominant renal involvement whereas the $V_{\lambda II}$ isotype frequently involves the heart.

The plasma cell dyscrasia

Although almost any dyscrasia of differentiated B lymphocytes, including multiple myeloma, Waldenström's macroglobulinaemia and other malignant lymphomas/leukaemias, may produce a monoclonal immunoglobulin that can sometimes form AL amyloid, well over 80% of cases are associated with low-grade and otherwise 'benign' monoclonal gammopathies. Histological studies indicate that amyloid deposition occurs in up to 15% of cases of myeloma, but usually in small and clinically insignificant amounts, and that it probably occurs in less than 5% of patients with 'benign' monoclonal gammopathy of undetermined significance (MGUS).

Clinical features

AL amyloidosis accounts for more than 1 in 1500 deaths in Britain and occurs equally in men and women. The median age at presentation is 65 years, but it can occur in young adults and is

probably much underdiagnosed in the elderly, in whom it would be expected to have the highest incidence. It is the most serious and commonly diagnosed form of systemic amyloidosis, and presently outnumbers referrals of AA amyloidosis to the UK National Amyloidosis Centre by a factor of 8:1.

Common organ-related features at presentation are proteinuria and nephrotic syndrome, renal impairment, symptomatic cardiac involvement, neuropathy and hepatomegaly. Dysfunction of a single organ may dominate the clinical picture. Fatigue, weight loss and malaise are frequent. The heart is affected pathologically in up to 90% of patients, in 30% of whom restrictive cardiomyopathy is a presenting feature, and in up to half of whom it is fatal. Rarer cardiac presentations include arrhythmias and angina, the latter sometimes due to coronary amyloid angiopathy. Dominant renal amyloid is the presenting feature in one-third of patients, typically presenting with nephrotic syndrome and/or renal impairment. Gut involvement may cause motility disturbances, which can also be secondary to autonomic neuropathy, and malabsorption, perforation, haemorrhage or obstruction. Macroglossia occurs in 5–10% but is almost pathognomonic of AL amyloidosis (Figure 42.1). Hyposplenism is not infrequent in both AA and AL amyloidosis but is rarely documented. Painful sensory polyneuropathy with early loss of pain and temperature sensation followed later by motor deficits occur in 10–20% of cases and carpal tunnel syndrome occurs in 20%. Autonomic neuropathy leading to impotence, orthostatic hypotension and gastrointestinal disturbances may
Figure 42.1 Macroglossia in AL amyloidosis.

occur alone or together with peripheral neuropathy, and has a poor prognosis. Involvement of dermal blood vessels is common and may cause purpura, most distinctively in a periorbital distribution ('raccoon eyes'). Direct skin involvement takes the form of papules, nodules and plaques, usually on the face and upper trunk. Articular amyloid is rare but the symptoms can be severe and superficially mimic an inflammatory polyarthritis. Soft-tissue infiltration may occur, characteristically involving the lower face or the glenohumeral joints and surrounding tissues to produce the 'shoulder pad' sign. An uncommon but serious manifestation of AL amyloid is an acquired bleeding diathesis that may be associated with deficiency of factor X and sometimes also factor IX, or with increased fibrinolysis. It does not occur in other amyloidoses, although in both AL and AA disease there may be serious bleeding in the absence of any identifiable factor deficiency.

Natural history/prognosis

Systemic AL amyloidosis is a progressive systemic disease with a prognosis far worse than AA and hereditary types. Median survival in historical series is only 12–15 months. Half of deaths are due to cardiac involvement, and in patients in whom heart failure is evident at presentation median survival is only about 6 months. Autonomic neuropathy and liver involvement with hyperbilirubinaemia are also associated with a very poor prognosis, whereas dominant renal involvement or peripheral neuropathy has a better outlook.

The traditional impression that amyloid deposition is irreversible and inexorably progressive largely reflects the persistent nature of the acquired or hereditary conditions that underlie it. It is now clear that amyloid deposits generally exist in a slowly dynamic state, and that they often gradually regress if the amyloid fibril precursor protein supply can be reduced. Under favourable circumstances organ function may improve and prolonged survival can occur. This knowledge has encouraged a much more aggressive approach to patient management in recent years.

Diagnosis and investigation of AL amyloidosis

Amyloid should be considered in the differential diagnosis of renal failure, nephrotic syndrome, restrictive cardiomyopathy, peripheral or autonomic neuropathy and hepatomegaly, etc., but early symptoms are often very non-specific and insidious, such as malaise or weight loss. The index of suspicion should be high in patients known to have clonal B-cell dyscrasias, but in practice the diagnosis of amyloidosis is usually an unexpected finding following biopsy of an organ with disturbed function. The approach to diagnosis is outlined in Table 42.2, and essentially comprises confirmation of the presence of amyloid, determination of fibril type, characterization of the underlying plasma cell dyscrasia, and evaluation of the extent, distribution and function of involved organs.

Confirming the presence of amyloid

Histology
In systemic forms of amyloidosis, deposits occur in blood vessels and as small interstitial foci throughout the body, providing the basis for 'screening' biopsies of abdominal fat or rectum which are diagnostic in 50–80% of cases. Diffuse parenchymal amyloid deposits may occur in few or many organs, and biopsy of a clinically affected organ, for example of kidney, heart, liver or gastrointestinal tract, is likely to give positive results in more than 95% of cases. The appearance on H&E-stained tissue of pink amorphous material should raise suspicion of amyloid and prompt further more specific stains. Many cotton dyes, fluorochromes and metachromatic stains are used, but Congo red staining giving green birefringence under cross-polarized light is generally accepted to be the diagnostic gold standard in amyloidosis (Figure 42.2). False-positive and -negative interpretation of the Congo red stain is not rare but can be minimized by using the alkaline–alcohol method (Puchtler et al., 1962), fresh reagents, tissue sections of optimal 5–10 μm thickness, inclusion of positive control tissue and high-quality polarizing filters. Some Congo red techniques stain connective tissues quite strongly and produce white or very pale-green birefringence that can cause diagnostic errors.

Electron microscopy
Amyloid fibrils cannot always be convincingly identified ultrastructurally, and a diagnosis of amyloidosis made through electron microscopy alone should be regarded with caution since other pathological processes involve deposition of fibrillar material.

SAP scintigraphy
Radiolabelled SAP scintigraphy is a specific nuclear medicine imaging technique that demonstrates the presence and distribution of amyloid deposits in vivo in a quantitative manner. It was developed and is used routinely at the UK National Amyloidosis Centre, but is not available commercially. ^{123}I-SAP localizes rapidly and specifically to amyloid deposits, of all fibril types, in proportion to the amount of amyloid present. SAP scintigraphy confirms the presence of amyloid in most patients with AL type, and virtually all with AA type. The scans provide information that is different and complementary to biopsy histology, notably including data on the whole body and individual organ amyloid load in serial follow-up studies, for example following chemotherapy in AL amyloidosis (Figure 42.3). The organ distribution of amyloid on SAP scintigraphy can be indicative of the fibril type, for example bone uptake occurs only in AL amyloidosis. Unfortunately, amyloid in the moving heart and in small or diffuse hollow structures such as nerves and the gut is not adequately visualized by SAP scintigraphy. Various other tracers, including conventional bone-seeking agents and radiolabelled aprotinin, sometimes localize non-specifically to amyloid deposits but do not have any defined clinical role.

Table 42.2 Approach to the investigation and monitoring of suspected AL amyloidosis.

	Confirmation of amyloid	*Determination of amyloid type*	*Evaluation of organ involvement*	*Investigation of Plasma cell dyscrasia*	*Monitoring*
Pathology	Biopsy and Congo red histology of affected organ, screening tissue (e.g. fat aspirate or rectum) or any available specimen	Immunohistochemical staining of tissue sections with a panel of antibodies to amyloid fibril proteins (often not definitive in AL) amyloidosis)	Biopsy of affected organ (but subsequent biopsies merely to determine the extent of amyloid involvement are not recommended)	Bone marrow aspirate and biopsy with light-chain immunophenotyping	Follow-up biopsies usually not helpful in monitoring amyloid load
Haematology, biochemistry, immunology		Identification of a monoclonal gammopathy supports AL type but may be an incidental finding	Serum creatinine and creatinine clearance, albumin, 24-h urine protein Liver function tests Coagulation screen	Full blood count, urea and electrolytes, creatinine, calcium Immunoglobulins Electrophoresis and immunofixation of serum and urine Quantitative serum free light chain assay	Serum free light chain and paraprotein concentration
Imaging	SAP scintigraphy	SAP scintigraphy (evidence of marrow involvement is indicative of AL type)	Echocardiogram, ECG SAP scintigraphy	Skeletal survey	SAP scintigraphy
Other		DNA analysis Amyloid fibril protein sequencing	As otherwise indicated, e.g. nerve conduction studies		Serial assessment of organ function, e.g. liver and renal function tests, echocardiogram and other investigations as indicated

Identifying fibril type

It has been common practice to diagnose apparently 'primary' cases of amyloidosis as AL type, especially when a monoclonal gammopathy can be demonstrated. However, the underlying chronic inflammatory disease process is clinically covert in 5–10% of patients with AA amyloidosis, and a family history is quite often absent in patients with hereditary amyloidosis caused by variant forms of fibrinogen Aα chain and transthyretin, due to low penetrance and late onset of symptoms. The coincidental presence of a monoclonal gammopathy can therefore be gravely misleading and lead to inappropriate use of cytotoxic agents. The combination of immunohistochemical staining and DNA analysis usually allows confirmation of fibril type or exclusion of hereditary forms.

Immunohistochemistry
Immunohistochemical staining of amyloid containing tissue sections using a panel of antibodies against known amyloid

proteins is the most accessible method for characterizing fibril type. However, definitive results often cannot be obtained in AL amyloid due to a combination of background staining of normal immunoglobulin and failure of antibodies to bind to κ or λ light chains in their abnormal amyloid conformation. In contrast, antibodies against serum amyloid A protein can confirm or exclude AA amyloid in virtually all cases, and, with optimization, antibodies are similarly useful in most hereditary forms. Reliable interpretation of immunohistochemical stains is not possible unless positive and negative controls have been used, and the specificity of staining by absorption with appropriate antigens has been demonstrated in each run.

DNA analysis
Sequencing of the genes associated with hereditary amyloidosis is now performed routinely in our centre to exclude hereditary amyloidosis when presumed AL type cannot be confirmed definitively, as well as in all patients in whom familial disease is suspected. Corroboration by other methods (e.g. immunohistochemistry)

(a)

(b)
Figure 42.2 Appearance of amyloid in a bone marrow biopsy (×40, 6-μm section). (a) Congo red stain showing amorphous pink material in the interstitium and small blood vessel (arrow). (b) Same section under high-intensity cross-polarized light showing diagnostic apple-green birefringence.

is necessary to confirm that identified mutations are indeed the cause of the amyloid.

Assessment of the plasma cell dyscrasia

A monoclonal whole paraprotein or free light chains can be identified by electrophoresis and immunofixation of serum and urine in only 80% of patients with AL amyloid. However, a new fully quantitative high-sensitivity immunoassay (Freelite™, The Binding Site, Birmingham, UK) can demonstrate and monitor a clonal excess of serum free light chains in about 98% of cases.

Bone marrow aspiration and trephine biopsy are required to characterize the underlying B-cell dyscrasia, which comprises a subtle plasma cell infiltrate in about 80% of cases. The presence of amyloid in a bone marrow specimen is highly suggestive of AL

type. Immunophenotyping and cytogenetic findings in AL amyloidosis are similar to those in myeloma, which can be diagnosed concurrently according to standard criteria (e.g. Jaffe *et al.*, 2002). Immune paresis occurs frequently in AL amyloidosis, but lytic lesions or hypercalcaemia are strongly suggestive of myeloma.

Assessment of organ involvement

Organ involvement by amyloid can be ascertained clinically, histologically, according to function and by SAP scintigraphy, but the clinical significance of these findings may differ substantially. Various criteria and methods for evaluating organ involvement are presently in use (Table 42.3). ECG and two-dimensional Doppler echocardiography are vital tools for evaluating cardiac involvement, and variously show reduced standard lead voltages, poor R-wave progression in the chest leads ('pseudo-infarct' pattern) along with small, concentrically thickened ventricular walls, dilated atria and homogeneously thickened and echogenic valves. Cardiac amyloidosis is a restrictive cardiomyopathy and diastolic dysfunction is easily missed and difficult to quantify. The status of other organs can be assessed either through routine tests of liver and renal function, etc., or by specialist investigations as indicated, for example autonomic function and nerve conduction tests, high-resolution pulmonary CT scanning, etc.

Differential diagnosis

Alternative diagnoses that frequently need to be considered include amyloidosis of non-AL types, principally AA and hereditary forms, localized forms of AL amyloidosis, non-amyloid light chain deposition disease, and non-amyloid paraprotein-associated neuropathies.

Management of AL amyloidosis

Therapy is not yet available that can specifically inhibit the formation of amyloid or enhance its clearance, although both strategies are being pursued experimentally. The objective of treatment at present is to suppress production of the amyloidogenic monoclonal light chains in the hope that progression of the disease will be slowed down, halted or reversed. However, few clinical trials have been performed, clinical benefit is typically much delayed, and many patients have advanced multisystem disease at diagnosis and therefore tolerate chemotherapy poorly. Quantitative measurements of circulating free immunoglobulin light chains are often the most effective means for guiding treatment in individual patients, and, although it is generally desirable to suppress the underlying clonal disease as rapidly as possible, reduction in the concentration of the amyloidogenic class of free light chain by just 50–75% is often sufficient to confer substantial survival benefit, regardless of the type of chemotherapy used. More intensive suppression of the clonal disease may be unneces-

(a) (b) (c)
Figure 42.3 Radiolabelled ^{123}I-SAP whole-body scintigraphy, anterior images. (a) The tracer has localized virtually exclusively to amyloid deposits in the bones in this particular patient, a distribution that is pathognomonic for amyloid of AL type. (b) and (c) Serial scintigraphs in a 56-year-old woman with AL amyloidosis. At presentation in 1998 (b) she had massive uptake in the spleen and liver, obscuring any renal signal. She underwent high-dose chemotherapy, and the follow-up scan in 2002 (c) shows that the deposits have regressed very substantially.

sary, and efforts to minimize toxicity from chemotherapy should be paramount.

Certain organs affected by amyloid tend to fare better than others following treatment. Kidney function, particularly proteinuria, in the absence of renal impairment often improves when the clonal disease is adequately suppressed, whereas cardiac and peripheral nerve function tend to improve extremely slowly if at all.

Melphalan and prednisolone

Efficacy of cyclic oral melphalan with or without prednisolone has been demonstrated in a randomized controlled trial in which colchicine was effectively used as a placebo. However, benefits of treatment were very slow and were substantial in only 20% of cases, and one-fifth of responders developed myelodysplasia

or leukaemia. Although dose-intensive chemotherapy regimens have not been tested as rigorously as low-dose oral melphalan and prednisolone, the evidence that they may be much more efficacious is compelling.

Vincristine, doxorubicin (Adriamycin) and dexamethasone (VAD)

VAD and similar regimens are well established as infusional induction regimens in myeloma, associated with response rates of 60–80%, complete response rates of 10–25% and rapid reduction in tumour burden. They do not deplete stem cell reserve, keeping open the option for subsequent PBSCT. Problems with the use of VAD/C-VAMP (see also Chapter 41) in AL amyloidosis include exacerbation of peripheral and autonomic neuropathy by vincristine, induction or worsening of fluid retention in renal

Table 42.3 Non-invasive diagnostic criteria of amyloid-related major organ involvement.*

Organ involvement	Comenzo et al. (1998)	Dispenzieri et al. (2001)
Heart	Mean left ventricular wall thickness on echocardiography > 11 mm with no history of hypertension or valvular heart disease *or* Unexplained low voltage (< 0.5 mV) on ECG	Cardiac interventricular septum > 12 mm and/or infiltrative cardiomyopathy and/or diastolic dysfunction determined by echocardiography
Kidney	Proteinuria > 0.5 g/24 h	Proteinuria > 0.5 g/24 h
Liver	Hepatomegaly with an alkaline phosphatase > 200 U/L	Hepatomegaly (> 4 cm below costal margin) with an alkaline phosphatase > 1.5 × upper limit of normal
Nerve	Based on clinical history, autonomic dysfunction with orthostasis, gastric atony by gastric emptying scan or abnormal sensory and/or motor findings on neurological examination	Peripheral neuropathy (other than carpal tunnel syndrome) or autonomic neuropathy

*In patients in whom a positive diagnosis has been made by tissue biopsy.

or cardiac amyloidosis by dexamethasone/methylprednisolone, which can also cause bone fractures and vertebral collapse. Doxorubicin has not been shown to exacerbate amyloid cardiomyopathy, but caution is recommended. There have been no randomized controlled trials of VAD in AL amyloidosis, but in our experience the clonal disease response rate is approximately 63% (based on a fall in the aberrant serum free light-chain values by > 50%), and organ function improves in about half of VAD-treated patients.

Intermediate-dose intravenous melphalan (IDM)

The variable absorption of melphalan from the gastrointestinal tract led investigators to trial intravenous intermediate-dose melphalan (25 mg/m^2) and oral dexamethasone in patients with untreated multiple myeloma. This regimen has been used as first-line therapy in patients with AL amyloidosis at the National Amyloidosis Centre, who were selected on the basis that they were not fit enough to receive VAD-based treatment, because of age, poor performance status, severe amyloid cardiomyopathy or neuropathy. Dexamethasone was omitted in patients with significant fluid retention. Efficacy, in terms of both clonal disease and organ response, was similar to VAD. It is prudent to harvest stem cells from patients who might subsequently benefit from PBSCT since IDM depletes stem cell reserve.

Autologous peripheral blood stem cell transplantation (PBSCT) (see also Chapter 41)

Use of high-dose melphalan therapy (HDT) and PBSCT in AL amyloidosis was first reported in 1996, and several series have reported clinical benefit in up to about 60% of patients who survive the procedure. However, treatment-related mortality (TRM) has been consistently and substantially higher than in multiple myeloma, ranging from 14% to 39%, reflecting the compromised function of multiple organ systems by amyloid. Refinement of patient selection and improvement of peritransplantation management are therefore urgent priorities. Causes of death include cardiac arrhythmias, intractable hypotension, multiple organ failure and gastrointestinal bleeding. Measures that can reduce morbidity and mortality of PBSCT in AL amyloidosis include omitting substantial prehydration, administering the melphalan in two divided doses, and not using granulocyte colony-stimulating factor (G-CSF) to enhance engraftment. TRM is higher in patients with clinical involvement of three or more organ systems, those aged above 55–65 years and those with chronic renal failure. Even stem cell mobilization has significant risks in AL amyloidosis.

The efficacy of PBSCT in AL amyloidosis has not been determined in any controlled comparative study, and its apparently good outcome may reflect selection of fitter good-prognosis patients (Dispenzieri, 2001). The role of PBSCT therefore remains unclear, and because of its special problems in AL amyloidosis it is recommended that such patients are treated in units with expertise of this particular disease. It seems reasonable to restrict PBSCT to younger patients with one or two involved organs who have not had previous amyloid-related gastrointestinal bleeding and who do not have severe cardiomyopathy, advanced renal failure or are dialysis dependent. Our own practice is rarely to recommend PBSCT as first-line therapy, but to consider its role in patients who have not responded adequately to VAD and/or IDM in terms of their clinical status or serum free light-chain values.

Allogeneic bone marrow transplantation

Successful allogeneic BMT for AL amyloidosis was reported in 1998 and 3 years post BMT was associated with complete clinical recovery. TRM in this setting would probably be inordinately high, and there are currently no data on reduced-intensity conditioning in AL amyloid.

Thalidomide

Early impressions on the potential role of thalidomide in AL amyloidosis are that the degree and rate of response of the underlying clonal plasma cell disease are similar to those in multiple myeloma. Adverse effects including somnolence, constipation, development of irreversible neuropathy and risk of venous and arterial thrombosis limit its application to AL amyloidosis.

Supportive treatment and organ transplantation

Supportive therapy remains a critical component of management, whereas therapy directed against the underlying clonal disease can be instituted. Renal dialysis may be necessary, and is usually both feasible and well tolerated. Renal, cardiac and other transplants have a role in selected patients who have otherwise well-preserved organ function and in whom adjunctive chemotherapy before or after surgery has either already been successful or remains realistic. Rigorous control of hypertension is vital in renal amyloidosis. Surgical resection of amyloidotic tissue is occasionally beneficial but, in general, a conservative approach to surgery, anaesthesia and other invasive procedures is advised. Should any such procedure be undertaken, meticulous attention to blood pressure and fluid balance is essential, especially in patients with renal and/or cardiac involvement. Amyloidotic tissues may heal poorly and are liable to haemorrhage. Diuretics are the mainstay of treatment in cardiac amyloidosis, and vasodilating drugs are generally best avoided. Dysrhythmias may respond to conventional pharmacological therapy or to pacing.

Localized AL amyloidosis

Localized deposits of AL amyloid can occur almost anywhere in the body, characteristic sites including the skin, airways, conjunctiva and urogenital tract. They may be nodular or confluent and are associated with a usually inconspicuous focal infiltrate of clonal B-cell producing amyloidogenic light chains. Local AL amyloid rarely progresses into a truly systemic disease, and conservative management is usually appropriate. Orbital AL amyloid presents as mass lesions which can disrupt eye movement and the structure of the orbit. Localized laryngeal AL amyloidosis is a well-recognized syndrome that is often amenable to direct or laser excision, but hereditary systemic ApoAI amyloidosis can also present in this manner. Amyloidosis in the bronchial tree is virtually always of localized AL type, as are solitary or multiple amyloid nodules within the lung tissue. In contrast, diffuse alveolar septal parenchymal deposition is commonly a manifestation of systemic AL amyloidosis. Lichenoid and macular forms of cutaneous amyloid are thought to be derived from keratin or related proteins, whereas nodular cutaneous amyloidosis deposits are generally of AL type, and can sometimes be a manifestation of systemic AL amyloidosis. Localized urogenital AL deposits usually present with haematuria or, less commonly, obstruction, and can occur anywhere from the renal collecting system to the urethra.

Other forms of systemic amyloidosis

Among more than 1500 patients with systemic amyloidosis who have been referred for evaluation at the National Amyloidosis Centre, approximately 80% have had AL type, 10% AA (reactive systemic) type, and the remainder have had a variety of hereditary, localized and other types. Although some features of systemic AL amyloidosis are very characteristic of this particular type, such as macroglossia, periorbital purpura and certain permutations of organ involvement, the clinical phenotypes of AA, AL and hereditary systemic amyloidosis can be completely indistinguishable. Furthermore, the underlying chronic inflammatory disease process is clinically covert in 5–10% of patients with AA amyloidosis, and a family history is often absent in patients with hereditary TTR and fibrinogen Aα chain amyloidosis, which are the most common familial forms.

AA amyloidosis

Reactive systemic AA (secondary) amyloidosis occurs in 1–5% of patients with chronic inflammatory diseases that evoke a substantial acute phase response, after a median latency of about 10 years. AA amyloid fibrils are derived from the circulating acute phase reactant, serum amyloid A protein (SAA), the serum concentration of which can increase from the healthy reference range of less than 10 mg/L to over 1000 mg/L during active inflammation. The commonest associated diseases in the developed world include rheumatoid arthritis, juvenile idiopathic arthritis and Crohn's disease. Familial Mediterranean fever (FMF) and chronic infections remain important causes in some parts of world. Castleman's disease of the solitary plasma cell type is probably the commonest underlying condition that can remain clinically covert.

Most patients present with nephropathy, particularly proteinuria, but liver and gastrointestinal involvement may occur at a late stage. Clinical involvement of the heart and nerves occurs very rarely. Diagnosis of AA amyloid is usually achieved by

rectal or renal biopsy, and the AA fibril type can be confirmed immunohistochemically using anti-SAA antibodies in most cases. SAP scintigraphy virtually always shows involvement of the spleen and kidneys; hepatic involvement is a late feature associated with a poor prognosis. Treatment in AA amyloidosis should be guided by frequent estimation of SAA concentration and will depend on the nature of the underlying inflammatory disease, ranging from anti-TNF agents in rheumatoid arthritis and colchicine in FMF to surgical resection of Castleman's disease tumours. Any therapy that reduces SAA production to healthy baseline levels prevents further deposition of AA amyloid, frequently leads to the regression of existing amyloid deposits with improvement in amyloid-related organ dysfunction, and significantly improves long-term survival.

β₂-Microglobulin amyloidosis (Aβ₂M)

β_2-Microglobulin amyloidosis, also known as dialysis-related amyloidosis (DRA), occurs due to the accumulation of β_2-microglobulin in renal failure and predominantly affects articular and periarticular structures in patients with end-stage renal failure who have been on dialysis for at least 7–10 years. Susceptibility factors include older age and the use of 'non-biocompatible' dialysis membranes. Carpal tunnel syndrome is often the first clinical manifestation, and large joint arthralgias, tenosynovitis, spondyloarthropathies and periarticular bone cysts are common. Although $A\beta_2M$ is a systemic form of amyloidosis, deposits outside the musculoskeletal system are seldom of clinical significance. The disabling arthralgia may respond partially to non-steroidal anti-inflammatory drugs or corticosteroids, but the only really effective treatment for this condition is normalization of β_2-microglobulin levels through renal transplantation. Carpal tunnel syndrome is amenable to surgery but may recur.

Transthyretin amyloidosis

Normal transthyretin (TTR) is inherently but weakly amyloidogenic, and minor TTR amyloid (ATTR) deposits are common in elderly individuals. Clinically significant involvement is almost completely restricted to the heart, and senile cardiac amyloid derived from wild-type TTR occurs in up to 25% subjects over 80 years of age. This syndrome is extremely rare before 65 years of age. There is no specific treatment but patients may survive for many years with reasonably good quality of life managed with diuretics alone.

Hereditary systemic amyloidoses

Hereditary systemic amyloidosis is caused by deposition of genetically variant proteins as amyloid fibrils, and is associated with mutations in the genes for transthyretin, fibrinogen Aα chain, cystatin C, gelsolin, apolipoprotein AI, apolipoprotein

AII, and lysozyme. These disorders are all inherited in an autosomal dominant manner with variable penetrance, and usually present in adult life.

Familial amyloidotic polyneuropathy (FAP) associated with mutations in the gene for TTR is the most common type of hereditary amyloidosis. It is characterized by progressive and disabling peripheral and autonomic neuropathy, often along with cardiac involvement; vitreous amyloid deposits may also occur and are virtually pathognomonic of the syndrome. Symptoms typically present between the third and seventh decades. More than 80 TTR variants are associated with FAP, the most frequent of which is the substitution of methionine for valine at residue 30 (TTR Met30). There are well-recognized foci of this in Portugal, Japan and Sweden, but FAP has been reported in most ethnic groups. TTR Ala60 is the most frequent cause of FAP in the British population, typically presenting after age 50 years and usually with marked cardiac involvement. TTR Ile122 occurs in 3–4% of black Africans and is associated with a phenotype indistinguishable from senile (wild type) cardiac amyloidosis other than often presenting about 10 years earlier. The majority of TTR is produced by hepatocytes, and liver transplantation is the only effective treatment for this disorder. Although the visceral amyloid deposits frequently regress following liver transplantation, the neuropathy is often irreversible and established cardiac amyloidosis may paradoxically progress due to on-going fibril formation by wild-type TTR in this particular organ. Combined heart and liver transplantation has been performed successfully in a small number of cases.

The syndrome of non-neuropathic hereditary systemic amyloidosis is caused by mutations in the genes for fibrinogen Aα chain, lysozyme, apolipoprotein AI and AII. Most such patients present with renal impairment and/or proteinuria, but substantial deposits in the liver and spleen are frequent in hereditary lysozyme and apolipoprotein AI amyloidosis, and the heart may be involved in hereditary apolipoprotein AI amyloidosis. Prominent neuropathy occurs in some patients with apolipoprotein AI Arg26. Although kindreds with hereditary amyloidosis are rare, 10% of patients referred to the National Amyloidosis Centre with apparently sporadic amyloidosis do in fact have hereditary forms of the disease. About half of these are associated with TTR mutations, and most of the remainder are associated with variant fibrinogen Aα chain Val526. Penetrance of this particular mutation is extremely low in most families, thus obscuring the genetic aetiology, but the renal histology is characteristic showing substantial accumulation of amyloid within enlarged glomeruli, but none in blood vessels or the interstitium. Hereditary cystatin C amyloidosis manifests in Icelandic families as cerebral amyloid angiopathy with recurrent cerebral haemorrhage, and gelsolin variants are associated with predominant cranial neuropathy, most often in Finnish patients.

DNA analysis is now performed routinely at the UK National Amyloidosis Centre on patients with systemic amyloidosis in whom AA or AL fibril type cannot be definitively verified.

Conclusion and future directions

Improved understanding of the aetiology and pathogenesis of amyloid has led to numerous recent improvements in the characterization and management of amyloidosis. Chemotherapy in systemic AL amyloidosis can now be guided by its early effect on serum free light-chain concentration, and routine DNA analysis can prevent patients with otherwise unrecognized hereditary amyloidosis from receiving inappropriate cytotoxic treatment. Clinical improvement following successful treatment of the various conditions that underlie amyloidosis is always delayed, and supportive measures are of great importance.

Novel therapeutic strategies include small molecules, peptides and GAG analogues that bind to fibril precursors and stabilize their native fold, or interfere with refolding and/or aggregation into the common amyloid conformation. Immunotherapy approaches and SAP depletion are being explored as specific therapies directed at promoting regression of amyloid. Several of these new therapeutic approaches are already being tested in patients with the hope that they may be effective in a diverse spectrum of amyloid related disorders.

The classification of lymphoma

43

Peter G Isaacson

Introduction

The aim of any lymphoma classification is to provide an international language allowing communication between those with a special interest in this group of diseases. The classification must be reproducible and clinically relevant, so that treatment results can be compared world-wide, and sufficiently flexible to permit the incorporation of new data. Finally, the classification must be histopathologically based since it is the histopathologist who, in most instances, makes the initial diagnosis. Traditionally, Hodgkin's disease (Hodgkin's lymphoma) and non-Hodgkin's lymphomas have been classified separately. This is a reflection of the specific identifying cell and limited morphological range of Hodgkin's disease together with its distinctive clinical features. In comparison, the clinicopathological features of the non-Hodgkin's lymphomas are much more wide-ranging and less distinct for any given entity. Not surprisingly, therefore, there have been only two classifications of Hodgkin's disease proposed since 1925, whereas more than 25 classifications of non-Hodgkin's lymphoma have appeared in the same period.

To the early pathologists the histological appearances of all non-Hodgkin's lymphomas were alike, consisting of replacement of the normal lymph node architecture by sheets of small or sometimes larger dark-staining cells. However, it was quite clear that not all cases behaved the same; the survival of patients with non-Hodgkin's lymphoma varied from a few months to many years. Pathologists were, therefore, increasingly asked by their clinical colleagues whether they could predict the natural course of an individual case. Following the emergence of therapeutic successes with Hodgkin's disease, more effective means of

therapy for the non-Hodgkin's lymphomas began to be developed. The effectiveness of these therapies was not homogeneous within the non-Hodgkin's lymphomas as a whole but clearly varied with the histology and, consequently, clinicians began to demand much more precise and clinically relevant histological diagnoses. In response to this, Rappaport (1966) formulated the first clinically relevant histological classification of the non-Hodgkin's lymphomas. The Rappaport classification, broadly speaking, divided lymphomas into those composed of small cells and large cells, each of which could be further subdivided into those with a follicular (or nodular) growth pattern and those that were diffuse. The follicular and small-cell tumours were clinically less aggressive; a better survival could, therefore, be expected and, importantly, less potent and less toxic therapy was suitable for these cases. The converse applied to cases with a diffuse growth pattern especially if composed of large cells.

As histological techniques improved, allowing finer morphological discrimination between cells, so more detailed classifications emerged. In parallel with these improvements it was becoming possible to establish the phenotype of the lymphoma cells using immunological techniques. It soon became evident that the lymphoma cells were closely related to normal lymph node cells and that the cells of many non-Hodgkin's lymphomas recapitulated the cytology of normal lymphocytes, particularly the B cells of the follicle centre. It was also clear, however, that there were an alarmingly wide variety of lymphoid neoplasms, and a whole host of classifications based on these new concepts sprung up. This caused so much confusion that a series of special international meetings was convened to decide on a single clinically relevant classification that could be used throughout the world. In the absence of any consensus, The United States

National Cancer Institute convened a study to evaluate the competing classifications and the result was the compromise 'Working Formulation for Clinical Use' (Non-Hodgkin's Lymphoma Classification Project, 1982). It was stressed at the time that this 'formulation', although based on histopathological appearances, was a language for translation between the competing classifications and not a classification in its own right. However, it was rapidly accepted as such by pathologists, particularly in the USA, where it became the classification of choice. The working formulation divided lymphomas into three grades based on their clinical behaviour, assessed using therapy current in the late 1960s and early 1970s, and thereafter used imprecise collective morphological terms such as 'large cell' and 'mixed small and large cell' to characterize individual entities. The result was that different clinicopathological entities were lumped together and as new entities were described, they merely became absorbed into this inflexible system. The Working Formulation was incapable of incorporating the rapidly expanding amount of immunophenotypic data on which pathologists were increasingly relying for lymphoma diagnosis. The Working Formulation thus soon lost its main reason for existence, namely its clinical relevance.

The majority of European pathologists never accepted the Working Formulation and preferred to use the Kiel classification. This classification and its updated editions (Stansfeld *et al.*, 1988) was based on modern immunophenotypic data dividing lymphomas into B and T-cell types and, thereafter, into individual entities based largely on the similarity of their cells to normal lymphocyte variants. According to their cytological characteristics, rather than their predetermined clinical behaviour and in keeping with established schemes for other tumours, the lymphomas were designated low or high grade. Unlike the Working Formulation, the Kiel classification had a sound biological basis and could easily be updated, thus maintaining its clinical relevance. Criticisms that could be levelled at the Kiel classification included its over-reliance on establishing the normal cell counterpart for each type of lymphoma, illogical over-splitting of some entities, and its failure to take into account the extranodal lymphomas.

The use of different lymphoma classifications on either side of the Atlantic, and the inherent defects in each, defied the basic requirement of a classification, namely that of providing a language for international communication, and threatened a return to the chaos of the 1970s. Moreover, new techniques and new concepts were emerging that urgently needed to be incorporated into the principles underlying lymphoma classification. Developments in immunohistochemistry meant that a cell lineage could confidently be assigned to most lymphomas and that many distinctive functional properties of the neoplastic cells could be determined. Distinctive molecular genetic properties of the different disorders also began to emerge, and some of these could be identified using simple immunohistochemical techniques. Another important development was the recognition

that many lymphomas arose in extranodal sites and that site of origin was often a significant clinical determinant.

The Revised European American Lymphoma (REAL) classification

In 1991, a group of pathologists from both sides of the Atlantic and the Far East formed an International Lymphoma Study Group (ILSG) which met annually to discuss research. Not surprisingly, this group soon found itself addressing the problems of lymphoma classification as outlined above and the need for a new approach to these problems soon became evident. Of the three alternative approaches that emerged, namely to update either the Working Formulation or the Kiel classification or to produce an entirely new classification, a decision was made to adopt the latter course. The basis for what was to become the Revised European American Lymphoma (REAL) Classification was the construction of a list of neoplastic lymphoproliferative disorders each defined as far as possible according to a set of five properties, namely morphology (histology), immunophenotype, genotype, normal cell counterpart and clinical features. The degree to which these properties contribute to the classification of each entity varies. For some such as mantle cell lymphoma each property is highly distinctive, perhaps reflecting its basic distinctive genotype, while for others such as nasal type NK-cell lymphoma clinical features together with immunophenotype are the most important.

The World Health Organisation (WHO) classification

In 1995, under the auspices of the WHO, the (American) Society for Hematopathology and the European Association for Haematopathology undertook a joint project to produce a comprehensive classification of all haematological neoplasms including those of myeloid lymphoid and histiocytic lineage. Recognizing that the REAL classification had only recently been proposed and was in the process of clinical evaluation, the brief for lymphoid neoplasms was to update and revise the REAL classification with input from additional experts in order to broaden the consensus. The formation of the steering committee and 10 subcommittees, each charged with the review of a specific group of neoplasms, involved 52 expert histopathologists and haematologists. In recognition of the importance of clinical relevance, a clinical advisory committee of 35 experts in the fields of leukaemia and lymphoma from around the world was convened. The subcommittees and the clinical advisory committee met separately, the former on many occasions, and recommendations were fed to the steering committee prior to a joint meeting of all committee members that was held in November 1997 at Airlie House in Virginia. The purposes of this

final 'grand' meeting were to iron out particular controversies, most of which had arisen consequent to actual use or, in effect, field testing of the REAL classification, to ensure that there was common ground between pathologists and clinicians and to agree on the final format. The agenda of the Airlie House meeting comprised a series of topics and questions that had been proposed by members of the subcommittee and the clinical advisory committee. In the case of the lymphomas, discussion of these topics served to refine and update the REAL classification which could then be subsumed into the WHO scheme.

The basis of the REAL and WHO classifications

Morphology

Morphology is, in effect, the collective expression of the immunophenotype, genotype and normal cell counterpart and as such remains the mainstay of lymphoma diagnosis. Once an entity has been defined on the basis of its collective properties, morphology on its own is often sufficient for a definitive diagnosis. However, lymphomas of identical morphology, but arising in different sites, may constitute different disease entities and some single disease entities may be morphologically heterogeneous. For example, anaplastic large-cell lymphoma (ALCL) arising in lymph nodes behaves much more aggressively than the morphologically identical tumour arising in the skin while the cytological features of enteropathy-type T-cell lymphoma are highly variable and do not influence its clinical behaviour. Histological grade alone, which should not be confused with clinical aggressiveness, is no longer considered a basis for the separation of lymphomas into broad groups. Many entities may transform from low- to high-grade disease as part of their natural history and can present *de novo* as either low- or high-grade lesions.

Immunophenotype

The immunophenotype of lymphomas was first used for broad grouping of lymphomas into B-cell and T-cell types in the Kiel classification. With the specific inclusion of the natural killer (NK) cell phenotype into the T-cell group, this distinction remains a fundamental consideration in the REAL classification and serves as a primary step in the separation of the lymphomas into two broad groups. Within these broad groupings the detailed immunophenotype is useful in helping to define individual entities but in only a few instances does a combination of immunophenotypic properties alone serve to define an entity that cannot be distinguished by other means. This is true of mantle cell lymphoma where the defining genotype, t(11;14), results in expression of cyclin D1, the defining immunophenotype.

Genotype

With increasing recognition that cancer is a genetic disease, the genotype of lymphomas is assuming greater significance in their classification. For some entities, such as follicular lymphoma, [t(14;18)] and mantle cell lymphoma [t(11;14)], the genotype is indeed the defining property. However, genotyping is beyond the capability of most laboratories and, fortunately, the genotype finds expression as reproducible morphological and/or immunophenotypic features that allow confident and reproducible diagnoses.

Normal cell counterpart

The normal cell counterpart, when known, is a useful aid to classification as it helps to characterize the morphology and phenotype of the lymphoma and, importantly, to understand its clinical behaviour, which may relate to the physiological pathways of the normal cell. This property has more significance for B-cell than T-cell lymphomas, largely because more is known about the B-cell subtypes and their functional characteristics.

Clinical features

The inclusion of clinical features, including site of origin, aggressiveness and prognosis, as an integral and practical part of the definition of lymphomas as distinct diseases is one of the more novel aspects of the REAL and WHO classifications.

Site of origin

Neither the Working Formulation nor the Kiel classification acknowledged the fact that a high percentage of lymphomas do not arise in lymph nodes. In the USA extranodal lymphoma accounts for some 25% of all cases, while in the Far East the percentage is much higher, amounting to 45% in Japan and 60% in Korea. The importance of the site of origin of lymphomas should not be underestimated. The distribution of lymphoma types shows a markedly different bias in different sites. Thus, extranodal Hodgkin's lymphoma is altogether rare, and follicular lymphoma, one of the commonest lymph node tumours, occurs only infrequently as a primary tumour in the gastrointestinal tract despite its high content of native lymphoid tissue. In some organs and/or tissues, such as the skin, gastrointestinal tract and, to a lesser extent, the spleen, lymphomas more or less specifically characteristic of that site alone occur. Examples include cutaneous follicle centre cell lymphoma, enteropathy-type T-cell lymphoma and splenic marginal zone lymphoma. For clinical purposes it is sometimes useful to group together the lymphomas that arise in specific sites and to approach the diagnosis of lymphoma arising in those sites in this way rather than in the purest sense of an overall lymphoma classification. This is best exemplified by lymphomas arising in the gastrointestinal tract and the skin. However, the use of entirely separate

classifications for lymphomas arising at different extranodal sites is to be discouraged.

Clinical aggressiveness

The REAL and WHO classifications make a clear distinction between histological or cytological grade and clinical aggressiveness. Histological grade is based on cell and especially nuclear size, density of nuclear chromatin and the proliferation fraction as assessed by the number of mitotic figures or the proliferation fraction determined by Ki-67 immunostaining. Thus, low-grade lymphomas are composed of small cells with dense nuclear chromatin and a low proliferation fraction; the converse is true for high-grade tumours. The REAL and WHO classifications, unlike the Kiel classification, do not separate lymphomas according to grade in recognition of the fact that low-grade lymphomas may transform to a high-grade tumour without changing the disease 'entity'. By and large, histological grade correlates with clinical aggressiveness but this is not always the case. Mantle cell lymphoma is histologically low grade but clinically aggressive, as are some T-cell lymphomas such as angioimmunoblastic T-cell lymphoma. Both the Working Formulation and the Kiel classification stressed the fundamental importance of 'grade', although using the term in a different sense, in determining treatment. The REAL and WHO classifications instead lay stress on the disease entity. Thus, not all 'low-grade' B-cell lymphomas are necessarily treated alike as exemplified by hairy cell leukaemia for which highly specific therapy has evolved (see also Chapter 38). It is likely that as the different entities are better defined and recognized clinically, more disease specific therapies will emerge.

Prognosis

Clinical aggressiveness is not the same as prognosis, with which it is often confused. For example, ALCL, a high-grade neoplasm, is clinically aggressive but has a good prognosis since it responds excellently to therapy. A variety of prognostic factors within each disease influence the clinical outcome. One of these is histological grade but clinical features are also important. The more important of these have been collected together to form the International Prognostic Index (IPI), the measurement of which is a powerful predictor of clinical outcome in any given patient.

The structure of the WHO classification
(Table 43.1)

Like the Kiel classification, the lymphomas, defined according to the principles described above, are primarily divided broadly into B- and T-cell groups. A modification is the inclusion of lymphomas with a natural killer (NK)-cell phenotype in the T-cell group. In each group the precursor cell, or lymphoblastic, lymphomas are separated from the larger group of peripheral

Table 43.1 The World Health Organization classification of lymphoid malignancies.

B-cell neoplasms
Precursor B-cell neoplasm
B-cell lymphoblastic lymphoma/leukaemia

Mature B-cell neoplasms
Chronic lymphocytic leukaemia/small lymphocytic lymphoma
Prolymphocytic leukaemia
Lymphoplasmacytic lymphoma
Splenic marginal zone lymphoma

cell tumours. The order in which the different entities are cited is not fixed and can be changed according to the convenience of the user. The B-cell lymphomas are grouped into those with peripheral blood involvement, plasma cell neoplasms, extranodal lymphomas, nodal lymphomas and lymphoproliferative disorders of uncertain malignant potential. The T/NK-cell lymphomas are similarly grouped into those that tend to involve the peripheral blood, cutaneous lymphomas, other extranodal lymphomas, nodal lymphomas and a single entity of uncertain lineage.

Hodgkin's lymphoma

Breaking with tradition, the authors of the REAL classification took the decision to include Hodgkin's disease in the lymphoma classification albeit as a separate table. This concept was continued in the WHO classification with the modification that Hodgkin's disease is designated as Hodgkin's lymphoma (HL), in recognition of the compelling evidence for the B-cell derivation of Hodgkin's disease. Despite this evidence, there is still preference for maintaining the 'Hodgkin' eponym. In this way the unique features of HL, including, importantly, its specific therapy and good prognosis, will continue to be recognized. Not surprisingly, the classification of this disorder is little changed from those of 1947 and 1966. The only changes in its classification are the implicit recognition that lymphocyte-predominant HL is a different disorder from classical HL and the addition of the category 'lymphocyte-rich HL'. It is hoped that the inclusion of this new category will serve to prevent misdiagnosis of these cases as lymphocyte-predominant HL, especially when they present with nodular or follicular histology. It could be argued that Hodgkin's lymphoma eventually will be listed in the table of B-cell lymphomas.

Reproducibility and clinical relevance

The value of any lymphoma classification is only as good as its histopathological reproducibility and its clinical relevance. In this respect, the validity of the REAL and WHO classifications had already been tested to a certain extent prior to their publication since many of the entities had been subject to detailed clinicopathological analysis in the medical literature. Shortly after its publication, moreover, the reproducibility and clinical relevance of the REAL classification were formally evaluated.

The Lymphoma Classification Project
(Lymphoma Classification Project, 1997)

Following its publication, an international study was convened to determine whether the REAL classification could be readily applied by a group of six expert haematopathologists, who, with one exception, were not associated with the original proposal. The specific aims of the project were to judge whether the classification could be used in practice, to test its inter-observer reproducibility, to assess the need for immunophenotyping in making a diagnosis (one of the criticisms following its publication having been that the REAL classification was not cost-effective in this respect!), to determine whether the constituent diseases were clinically distinctive either at presentation or in terms of clinical outcome, and to determine the relevant frequency of these diseases in the study populations. The participating pathologists, assisted by clinicians and statisticians, studied 1400 cases of lymphoma comprising 80–210 cases in each of eight centres in North America , Europe, Asia and Africa.

The participants found that the REAL classification was highly practical, allowing the ready classification of 95% of cases. Inter-observer reproducibility was greater than 85% for most categories, which was a substantial improvement over previous studies using other classifications, in which reproducibility was frequently in the region of only 60% or less. Immunophenotyping was not necessary for the classification of certain diseases including follicular lymphoma and lymphocytic lymphoma/chronic lymphocytic leukaemia but essential for the classification of T-cell lymphomas and particularly helpful for some B-cell disorders, including mantle cell lymphoma and diffuse large B-cell lymphoma.

In making clinicopathological correlations, the Lymphoma Classification Project showed that the different diseases recognized by the REAL classification did indeed differ in terms of clinical presentation and survival supporting the contention that they were distinct biological entities. However, an important finding of the study was that classification is not the only predictor of clinical outcome of any individual case. In this respect, the power of the IPI was confirmed. For example, patients with follicular lymphoma and an IPI score of 1–3 have a median survival of 7–10 years, while the median survival for the minority with an IPI of 4 or 5 is significantly reduced to 1.5 years.

The relative frequency of the different lymphomas

When discussing lymphoma classification there tends, inevitably, to be greater emphasis on the rare and difficult conditions than is necessarily warranted by their frequency. Because of

epidemiological differences and regional bias, it is difficult to generalize about the distribution of the different lymphomas. However, extrapolating from previous studies that preceded the REAL classification, and the results of the Lymphoma Classification Project it possible to obtain some sort of perspective. Thus, in North America and Europe B-cell lymphomas account for some 85% of all lymphomas. The Lymphoma Classification Project found that, together, large B-cell lymphoma (30.6%), follicular lymphoma (22.1%), MALT lymphoma (7.6%), lymphocytic lymphoma/chronic lymphocytic leukaemia (6.7%) and mantle cell lymphoma (6.0%) constituted 73% of all lymphomas. Given that Asian and African patients were represented by only two of the eight centres, these relative incidence figures are less valid for Asia or Africa, where overall there is a much lower frequency of follicular lymphoma, and in parts of Asia, a higher frequency of T-cell lymphoma.

Updating the classification

Previous experience, especially with the Working Formulation, has shown the folly of considering any lymphoma classification a permanent entity. New concepts and consequently newly recognized diseases are constantly arising and demand to be included in any classification. The REAL classification recognized this both tacitly and overtly by the inclusion of provisional entities. The question of how to address the problem of updating the classification was left hanging, however. In this respect it was a fortunate coincidence that, shortly after the publication of the REAL classification, the WHO commenced the ambitious project with the aim of formulating a new comprehensive classification of both lymphoma and leukaemia. In terms of the lymphomas, the WHO classification project has essentially addressed the immediate problem of updating and refining the REAL classification. However, the problem of continuous updating of the WHO classification still remains to be addressed.

Issues relating to individual entities in the WHO classification

As with any new classification, when the WHO lymphoma classification was presented to the haematologists and oncologists who would be using it in the clinic, several contentious issues arose that deserve special consideration and clarification.

Precursor cell neoplasms

With respect to the relationship of the solid precursor cell tumours with the leukaemias, the FAB terms L1, L2 and L3 are no longer relevant since L1 and L2 do not predict immunophenotype or clinical behaviour and L3 is equivalent to Burkitt's lymphoma in a leukaemic phase. Lymphoblastic lymphomas

and leukaemias are the same disease in different stages (see also Chapters 29, 32 and 33).

The mature B-cell leukaemias

The term 'mature' is preferable to 'peripheral' to describe the majority of the lymphomas. Chronic lymphocytic leukaemia and lymphocytic lymphoma are clearly the same disease although they tend to be seen by different clinicians. However, prolymphocytic leukaemia is distinctly different (see also Chapter 38).

Follicular lymphoma

Grading of follicular lymphoma is a contentious issue, but it is now agreed that grading should be carried out according to the method proposed by Mann and Berard (1982), who described three grades based on the number of large cells (centroblasts) per high-power field. Grade 3 follicular lymphoma is divided into 3a and 3b, the latter used for tumours comprising sheets of centroblasts. In practice, only grade 3 (more than 15 centroblasts per high-power field) is clinically significant, being indicative of more aggressive disease that may require doxorubicin-containing therapy. The presence and percentage of diffuse areas should also be commented on, although the clinical significance of this point is not yet clear.

Cutaneous follicle centre lymphoma

This rather poorly defined skin tumour tends to occur in the upper half of the body and appears to be unrelated to follicular lymphoma but rather a variant of diffuse large B-cell lymphoma. Its importance lies in its remarkably indolent clinical behaviour.

Marginal zone lymphomas

Three separate entities constitute this group of lymphomas. The first two, marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma) and nodal marginal-zone lymphoma +/– monocytoid B-cells are closely related, but the third, splenic marginal-zone lymphoma is a quite different disease.

Marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)

This type of lymphoma arises in extranodal sites and recapitulates the histology of the Peyer's patch. The stomach is the commonest site. MALT lymphomas are, by definition, low grade. Transformation to a diffuse large B-cell (high-grade) lymphoma can occur, and this phenomenon is clinically significant and should be documented in the histology report. However, the term 'high-grade MALT lymphoma' should not be used for these cases. In particular, diffuse large B-cell lymphomas arising *de novo* at extranodal sites where MALT lymphomas occur, such as the stomach, should not be called high-grade MALT

lymphomas since this terminology may bias the clinician towards inappropriate therapy.

Nodal marginal zone lymphoma with or without monocytoid B-cells

The lymph node histology of this entity is identical to that of lymph node involvement by MALT lymphoma so that the possibility of a cryptic MALT lymphoma should always be borne in mind when a diagnosis of nodal marginal zone lymphoma is entertained.

Splenic marginal zone lymphoma (SMZL)

The constituent cells of SMZL bear only passing resemblance to splenic marginal zone cells and do not share their immunophenotype. Patients typically present with splenomegaly, often accompanied by anaemia and thrombocytopenia. Peripheral blood involvement is often, but not always, present, and in some of these cases the circulating neoplastic lymphocytes have a villous appearance. These cases were previously termed 'splenic lymphoma with villous lymphocytes'. The use of this somewhat imprecise term will not only fail to include those cases without circulating villous lymphocytes but, more importantly, tends to include other cases of B-cell lymphoma with peripheral blood spillover since the cells of various lymphomas may sometimes adopt a villous appearance, either real or artefactual, in the peripheral blood. This is an important consideration since SMZL tends to respond favourably to splenectomy alone in contrast to its poor response to chemotherapy (see also Chapter 38).

Diffuse large B-cell lymphoma (DLBCL) and Burkitt-like lymphoma

The classification of large B-cell lymphomas as a single group has been controversial. Various morphological subtypes have been recognized, including centroblastic, immunoblastic and T-cell rich, but the clinical significance of subclassifying DLBCL in this way is of doubtful significance and they do not appear to constitute separate diseases. There are, however, three rare large B-cell lymphomas that do appear to merit the designation as distinct diseases, namely primary mediastinal (thymic) large B-cell lymphoma, intravascular lymphoma and primary effusion lymphoma. There is little doubt that within the category of DLBCL there are at least several more distinct entities that might benefit from different therapies. Their recognition is one of the challenges facing haematopathologists and several promising approaches, including gene profiling, have already been identified.

The borderline between DLBCL and Burkitt's lymphoma (BL) is not always clear-cut. The WHO clinical advisory meeting took the decision that those DLBCL with Burkitt-like morphology, c-*myc* rearrangement and a proliferation fraction of 100% are best described as having 'atypical Burkitt lymphoma' and should receive therapy tailored for BL. Thus, they represent a subtype of BL, the others being endemic BL, non-endemic BL and immunodeficiency-associated BL.

Mature T- and NK-cell lymphomas

Clinical syndromes rather than cytomorphological features form the principal basis for the identification of real diseases within this difficult group. Several provisional disorders listed in the REAL classification are now recognized as defined entities but, despite many attempts to recognize distinct diseases, most T-cell lymphomas end up being classified as 'T-cell lymphoma unspecified'. This is clearly unsatisfactory and is partly due to the rarity of T-cell lymphomas as a whole. It is to be hoped that the adoption of the new principles of classification will, as new data accumulate, lead to the rationalization of this group.

Anaplastic large-cell lymphoma

Previously defined on the basis of its cytology and expression of CD30 (Stein *et al.*, 1985), it has become clear that more than one 'real' disease can exhibit these features. The discovery of the t(2;5) translocation, which results in the expression of anaplastic lymphoma kinase (ALK) protein, has helped to define a form of T/null-cell ALCL that tends to occur in children and young adults and which, although aggressive, carries a good prognosis with appropriate therapy. It seems likely that the somewhat similar, but t(2;5) (ALK)-negative, cases are a different disorder, but this awaits confirmation. It is clear, however that primary cutaneous ALCL which is always ALK negative and, moreover, lacks a cytotoxic phenotype, is an entirely different entity. Cutaneous ALCL is closely related to the benign disorder lymphomatoid papulosis, and the term 'cutaneous lymphoproliferative disorder' has been suggested for those cases with overlapping features. Whether such a term is appropriate in a lymphoma classification is a moot point.

Conclusions

The WHO classification of lymphoid neoplasms represents a major step forward in our understanding of these tumours. Moreover, in building on the REAL classification it has pointed the way to practical methods of further updating which will be essential if the classification is to endure and to continue to serve the needs of clinicians. Implicit in the classification are signposts for further research, particularly with respect to diffuse large B-cell lymphoma and T-cell lymphoma, unspecified. The formulation of the WHO classifications must be counted as a considerable achievement. By contrast with previous attempts to classify this difficult group of tumours, a large number of pathologists, 19 for the REAL classification and over 50 for the WHO scheme, has been involved and to have achieved consensus within this group is remarkable! Perhaps even more remarkable is to have maintained this consensus in presenting such radically new concepts to the clinicians who treat patients with lymphoma.

Hodgkin's lymphoma

Lynny Yung and David Linch

44

Introduction

Hodgkin's lymphoma is an uncommon tumour, although it is one of the more frequent malignancies in young people. Traditionally, radiation therapy was the primary treatment agent, and the first successful combination chemotherapy regimen was introduced in the 1960s. Since then, combined-modality therapy has developed allowing reduction of both chemotherapy and radiation doses. The outcome of patients with Hodgkin's lymphoma has improved greatly over the last few decades such that is should now be considered curable in the large majority of cases. With the excellent cure rates now attainable, the late effects of treatment have become more apparent. Current therapeutic strategies must aim to maintain the high cure rates while minimizing these late effects.

Epidemiology

Hodgkin's lymphoma is relatively uncommon with an incidence of approximately 2.3/100 000 per annum. Hodgkin's lymphoma is a disease of young adults, and in the 15–34 years age group it is the second most common malignancy in men and the fourth most common in women. The incidence in women peaks in the third decade and then falls, but in men the incidence remains fairly constant thereafter. The overall incidence is stable, which contrasts with the non-Hodgkin's lymphomas, whose incidence appears to be rising.

Histological classification (see also Chapter 43)

The diagnosis of Hodgkin's lymphoma (HL) is based on the finding of Hodgkin/Reed–Sternberg cells in an appropriate cel-
Figure 44.1 Low-power view of lymph node biopsy of classical Hodgkin's lymphoma showing nodularity and sclerosis.

lular background of reactive T cells and eosinophils with varying degrees of fibrosis. Hodgkin's lymphoma is broadly classified into two distinct entities, nodular lymphocyte predominant Hodgkin's lymphoma (NLPHL) and classical Hodgkin's lymphoma (Figures 44.1–44.8). NLPHL represents about 5% of all cases of Hodgkin's lymphoma. It is more common in males and frequently presents with limited nodal disease of the neck without constitutional symptoms.

Classical Hodgkin's lymphoma is divided into four subtypes (Table 44.1). In the developed world nodular sclerosing Hodgkin's lymphoma accounts for the majority of cases. 'Diffuse lymphocyte-predominant Hodgkin's disease' is now known as
Figure 44.2 High-power view of classical Hodgkin's lymphoma showing abundant Reed–Sternberg cells and occasional eosinophils.
Figure 44.4 CD15 immunostain of classical Hodgkin's lymphoma.
Figure 44.3 CD30 immunostain of classical Hodgkin's lymphoma showing clear membranous and Golgi apparatus staining of the Hodgkin/Reed–Sternberg cells.
Figure 44.5 Low-power view of lymph node biopsy of nodular lymphocyte predominant Hodgkin's lymphoma showing nodular features and slight mottled appearance of the follicles.

lymphocyte-rich classical HL, and most cases of lymphocyte-depleted Hodgkin's lymphoma have been reclassified as cases of nodular sclerosing disease or anaplastic large-cell lymphomas. Histological appearances have been studied in relation to prognosis. A new grading system for advanced-stage disease with nodular sclerosis in which risk is assigned on the basis of four histological features (eosinophilia, lymphocyte depletion, cellular atypia and necrosis) has been proposed. This system requires validation as currently all subtypes of classical Hodgkin's lymphoma are treated in the same way.

Pathogenesis

The pathogenesis of Hodgkin's lymphoma is not yet fully understood; however, the nature of the Hodgkin/Reed–Sternberg (H/RS) cell has now been elucidated. The pathognomonic H/RS cell is derived from a B lymphocyte with clonal rearrangements in the V, D and J segments of the IgH chain locus in the majority of patients. The malignant cells in NLPHL have both the immunophenotype and genotype of post-germinal centre B-cells
Figure 44.6 High-power view of nodular lymphocyte-predominant Hodgkin's lymphoma showing many convoluted lymphocytic and histiocytic (L&H) or 'popcorn' cells.

Figure 44.7 CD20 staining of nodular lymphocyte predominant Hodgkin's lymphoma. Note that the L&H cells are typically surrounded by a rosette of CD20 negating, reactive T-cells.

including immunoglobulin production and high expression of pan-B cell antigens such as CD20 (Table 44.2 and Figures 44.7 and 44.8).

In classical Hodgkin's lymphoma, however, mature B-cell antigen expression may be low or absent and there is no immunoglobulin production despite the immunoglobulin gene rearrangements and subsequent somatic mutations. In some cases the lack of immunoglobulin production is due to crippling mutations in the immunoglobulin gene (e.g. creation of stop codons), but in other cases there is dysregulation of the transcriptional machinery involved in immunoglobulin gene expression.

Figure 44.8 J-chain immunostaining of nodular lymphocyte predominant Hodgkin's lymphoma demonstrating immunoglobulin production of L&H cells, a feature not seen in classical Hodgkin's lymphoma.

Table 44.1 WHO classification of Hodgkin's lymphoma.

Nodular lymphocyte-predominant Hodgkin's lymphoma
Classical Hodgkin's lymphoma
    Nodular sclerosis classical Hodgkin's lymphoma
    Mixed-cellularity classical Hodgkin's lymphoma
    Lymphocyte-rich classical Hodgkin's lymphoma
    Lymphocyte-depleted classical Hodgkin's lymphoma

The octamer motif is an important element in the regulation of immunoglobulin promoter and enhancer function. The absence of the transcription factor Oct2 or its coactivator BOB1/OBF1 from Reed–Sternberg cells has been demonstrated in cases of classical Hodgkin's lymphoma, whereas Oct2 was found to be highly expressed in the malignant cells of NLPHL.

It seems likely that the Hodgkin/Reed–Sternberg cell has mechanisms in place that protect it from apoptosis. The immunoglobulin receptor complex provides important survival signals to developing B cells and the absence of immunoglobulin expression could put Hodgkin's cells at a survival disadvantage. Hypermutation of rearranged immunoglobulin genes is characteristic of normal germinal centre activity. B-cells that acquire unfavourable mutations are negatively selected and thus eliminated, primarily via Fas-mediated apoptosis. Constitutive expression of C-FLIP, a downregulator of Fas, has been detected in Hodgkin/Reed–Sternberg cells and may represent an antiapoptotic pathway.

The NF-κB pathway is another mechanism by which H/RS cells might escape apoptosis. NF-κB is a family of transcription factors involved in the regulation of multiple processes including

Table 44.2 Comparison of phenotypes of classical and lymphocyte-predominant Hodgkin's lymphoma.

	Classical Hodgkin's lymphoma, Reed–Sternberg cells	Nodular lymphocyte-predominant Hodgkin's lymphoma, atypical lymphocytic and histiocytic (L&H) cells
CD30	Positive	Negative
CD15	Usually positive	Negative
Immunoglobulin expression	Absent	Present
CD20	Occasionally positive	Negative
Other B-cell antigens	Usually negative	Usually positive

apoptosis and oncogenesis; NF-κB itself is regulated via a number of upstream elements including CD40 ligand and TNF receptor-associated factors. In resting cells NF-κB resides in the cytoplasm bound to its inhibitor IκB. Activation of the cell by various routes such as via CD40 ligand or LMP1, leads to the activation of IκB kinase and the phosphorylation of IκB and subsequent ubiquitination with degradation by the 26S proteasome. The liberated NF-κB is then able to move into the nucleus, where it activates transcription of a number of target genes involved in the prevention of apoptosis. NF-κB activity has been shown to be upregulated in H/RS cells of the majority of cases of classical Hodgkin's lymphoma, and mutations of the *IKK* gene family have been detected and are associated with nuclear translocation of NF-κB, thus leading to upregulation of its target genes.

There are several other events such as infection by the Epstein–Barr virus (EBV) which may be important in the survival of the H/RS cell. EBV nuclear proteins such as EBNA and LMP1 have been detected in around 40% of cases of classical Hodgkin's lymphoma, with the highest frequency in mixed cellularity disease. LMP1 is known to have oncogenic potential by triggering Bcl-2 expression and acting via the CD40 cell signalling pathway, thus allowing cells to evade apoptosis. The association with EBV varies with age; the majority of childhood and elderly Hodgkin's lymphoma is EBV associated however, around only 25–50% of young adults have EBV-positive tumours. This age group (15–34 years) represents the peak incidence of the disease, and the possibility of alternative lymphotropic viruses being involved in the pathogenesis of EBV-negative cases has been suggested but not yet demonstrated. It is well recognized that the incidence of Hodgkin's lymphoma in HIV-positive patients is increased by around sevenfold and almost all cases are associated with EBV infection. Hodgkin's lymphoma associated with organ and bone marrow transplantation and with congenital immunodeficiency syndromes has also been shown to be usually EBV associated.

Clinical presentation

The presenting features of Hodgkin's lymphoma are numerous. The majority of patients present with an enlarged but otherwise

Figure 44.9 Chest radiograph showing enlarged superior mediastinum.

asymptomatic lump(s), most often in the lower neck or supraclavicular region. Mediastinal masses are frequent and are sometimes discovered after routine chest radiography (Figure 44.9). Less commonly, patients complain of chest discomfort with a cough or dyspnoea. Around 25% of patients will have systemic symptoms at presentation. Typical symptoms are fatigue, fever, weight loss and night sweats. Pruritus and intermittent fevers (so-called Pel–Ebstein fever) often associated with night sweats are classical symptoms of Hodgkin's lymphoma.

An important feature of Hodgkin's lymphoma is contiguous spread, with disease most commonly starting above the diaphragm in the cervical nodes and spreading to involve adjacent nodes and less commonly non-lymphoid tissue.

Splenomegaly may occur without involvement by disease; however, hepatosplenomegaly invariably indicates disease infiltration. Peripheral blood manifestations are common but non-specific, with lymphocytopenia and anaemia being indicators of advanced disease. Eosinophilia is frequently reported,

although opinion differs as to whether this has prognostic significance.

Staging

The Ann Arbor staging system was developed over 30 years ago to define those patients who could be treated by radiotherapy, and it is still valuable in defining the extent of therapy even though radiation alone is less frequently employed. The Cotswolds modification (Table 44.3) made in 1989, takes into account the importance of bulky disease and the fact that laparotomy and splenectomy are no longer recommended as staging procedures as they have been shown to have no effect on overall survival, and are associated with significant morbidity and occasionally mortality.

Lymphangiography is now rarely performed and computerized tomography (CT) scanning is the major means of staging both intrathoracic and intra-abdominal disease (Figure 44.10). Magnetic resonance imaging (MRI) scanning is largely restricted to the evaluation of specific situations such as bony involvement and spinal cord compression. Fluorodeoxyglucose positron emission tomography (FDG-PET) scanning may also have a role, relying on the uptake of 2-fluoro-2-deoxy-D-glucose by metabolically active tissues possibly revealing disease in sites difficult to image by CT scanning (Figure 44.11). Current practice, however, does not include PET scanning as part of the staging investigations although this may change with the increased availability of this technology.

Table 44.3 Ann Arbor staging system with Cotswolds modifications for Hodgkin's lymphoma.

Stage

I Involvement of a single lymph-node region or lymphoid structure (e.g. spleen, thymus, Waldeyer's ring)
II ≥ 2 lymph node regions on the same side of the diaphragm
III Lymph nodes on both sides of the diaphragm
III1 With splenic hilar, coeliac or portal nodes
III2 With para-aortic, iliac, mesenteric nodes
IV Involvement of extranodal site(s) beyond that designated 'E'

Modifying features

A No symptoms
B Fever, drenching night sweats, weight loss > 10% in 6 months
X Bulky disease: > one-third widening of mediastinum
   > 10 cm maximum diameter of nodal mass
E Involvement of single, contiguous or proximal extranodal site
CS Clinical stage
PS Pathological stage

Prognostic factors

In 1985, the British National Lymphoma Investigation (BNLI) published a prognostic index in localized Hodgkin's lymphoma which was based on an analysis of over 2000 patients. This was a complex index and therefore was not widely adopted, although risk stratified therapy is now an established principle of management. The EORTC (European Organization for Research and Treatment of Cancer) have identified a number of features indicative of a worse prognosis in stage I and II disease and used these to stratify therapy (Table 44.4). In more advanced disease the International Prognostic Score (or Hasenclever index) was developed (Table 44.5) based on an analysis of over 5000 patients treated initially with an anthracycline-containing

Table 44.4 EORTC risk factors in localized disease.

Favourable
Patients must have *all* of the following features
    Clinical stage I and II
    Maximum of three nodal areas involved
    Age < 50 years
    ESR < 50 mm/h without B symptoms or ESR < 30 mm/h with
      B symptoms
    Mediastinal/thoracic ratio < 0.35.

Unfavourable
Patients have *any* of the following features
    Clinical stage II with involvement of at least four nodal areas
    Age > 50 years
    ESR > 50 mm/h if asymptomatic or ESR > 30 mm/h if
      B symptoms
    Mediastinal/thoracic ratio > 0.35

Table 44.5 Hasenclever index.

Age > 45 years
Male gender
Serum albumin < 40 g/L
Haemoglobin level < 10.5 g/dL
Stage IV disease
Leucocytosis (white cell count $\geq 15 \times 10^9$/L)
Lymphopenia ($< 0.6 \times 10^9$/L or < 8% of the white cell count)

chemotherapy regimen. Seven factors were identified, each of which reduced the predicted 5-year freedom from progression rate by around 8%.

Response assessment

Complete response (CR) following therapy is often difficult to determine in patients with Hodgkin's lymphoma as residual masses are very common (Figure 44.12). The entity of CRu (unconfirmed/uncertain) was therefore introduced, and refers to those patients in whom there is uncertainty about the remission status due to persisting radiological abnormalities particularly in the mediastinum. Gallium scanning techniques have been used in the assessment of residual masses and comparative studies between gallium scanning and PET are under way. Gallium is predominantly excreted via the gastrointestinal tract which may limit its use in the assessment of abdominal disease.

PET scanning is likely to play an important role in clarifying remission status in this group of patients as the 2-fluoro-2-deoxy-glucose is taken up by residual metabolically active
Figure 44.12 CT scan of the chest showing large residual mass at end of treatment.
Figure 44.13 PET-CT scan of same patient as in Figure 44.12 showing FDG avidity of large residual mass.

tumour cells and not fibrotic tissue. FDG-PET has higher sensitivity, specificity, positive and negative predictive values for disease-free survival (DFS) than CT scanning. In some centres, PET-CT is available to produce images which enable comparison of areas of FDG avidity with lesions seen on the CT scan (Figures 44.13 and 44.14). The optimal timing of a PET scan has yet to be determined as recent chemotherapy may result in a positive scan due to ongoing macrophage activity. Patients with suspicious symptoms or a residual mass at the end of treatment may be monitored with PET scans and offered further therapy as indicated. However, PET may be less discriminating in the evaluation of inflammatory or extranodal disease and it is currently recommended that unusual lesions are biopsied.
Figure 44.14 PET-CT scan showing FDG-'cold' residual mass.

Therapy

The outcome in both localized and advanced Hodgkin's lymphoma has improved greatly over the last 30 years such that the disease is now considered curable in the large majority of cases. Unlike many other forms of cancer, it is often possible to effect a cure even if first-line treatment fails and this creates the dilemma of whether it is better to use more extensive/intensive therapy initially to cure the maximum number of individuals possible with that course of therapy, or whether it is better to use lesser therapy initially and rely on more intensive salvage therapy in a greater proportion of patients. The decision must be based on the analysis of long-term survival rates with the different strategies and the consideration of short- and long-term side-effects of treatment including the psychological trauma associated with relapse when a less intensive initial therapy is used.

Nodular lymphocyte predominant Hodgkin's lymphoma

NLPHL is a distinct entity and needs to be considered separately from the therapeutic standpoint.

There have been no prospective randomized trials carried out specifically in NLPHL. As the disease is usually localized, it is most often treated with surgical excision and involved-field radiotherapy, although if the surgical excision is complete the radiotherapy may be unnecessary. Complete response rates of 96% with 8-year disease-free survival of 99% or 98% in stage I and II, respectively, have been reported by the European Task

Force on Lymphoma. The treatment of advanced disease is generally the same as for classical Hodgkin's lymphoma, i.e. combination chemotherapy. However, NLPHL tends to relapse as a large-cell lymphoma and relapse may occur 10–15 years after the initial diagnosis. It is important therefore to correctly diagnose and stage this entity accurately as the outcome in patients with advanced-stage NLPHL approaches that of patients with classical disease.

Recently, groups from Stanford, USA, and Germany have reported the use of the CD20 monoclonal antibody rituximab in patients with NLPHL The therapy is well tolerated and results have been encouraging. Longer follow-up is required, but rituximab should certainly be considered for patients failing combination chemotherapy.

Classical Hodgkin's lymphoma

All forms of classical Hodgkin's lymphoma are usually treated in the same way, with anatomical stage being the most important factor in determining therapy. In some centres specific histological subtypes are used as prognostic factors and could therefore modify the risk group and the therapy prescribed.

Localized disease, i.e. stage I and stage IIA

A plethora of trials have been conducted in localized Hodgkin's lymphoma but it is difficult to compare directly the results from different trials. Entry criteria vary, with some groups stratifying localized disease into a number of different risk groups. The EORTC, for instance, has considered localized disease in two risk groups (favourable and unfavourable, see Table 44.4). In the UK, the usual practice is to have only one category of localized disease, and patients with stage IIB or IIIA disease are considered as having advanced disease.

The traditional therapy for localized disease was radiotherapy alone. This resulted in high rates of complete remission but relapse was frequent. The more extensive the radiation fields, the lower the relapse rate; this has been shown in a randomized trial conducted by the BNLI in which 'mantle' or 'inverted Y' radiation fields resulted in an approximately 11% higher time to treatment failure rate than involved-field radiotherapy. In Europe, even more extended radiation fields have been routinely used, but despite this, the relapse rate is still of the order of 20–30%. Interestingly, more extensive radiation fields have not translated into improved survival attesting to the success of chemotherapy in those patients relapsing after radiation. Nonetheless, such high relapse rates are now considered to be unacceptable.

The relapse risk can be reduced by the use of combined-modality therapy (CMT) incorporating both chemotherapy and radiotherapy. There is little evidence again that this improves survival, but within the context of CMT it is possible to use shorter courses of chemotherapy than are used in advanced

disease and more restricted radiation fields. In unfavourable risk disease, the EORTC H7 CMT trial showed that four cycles of chemotherapy were as effective as six and involved-field radiation as effective as subtotal nodal irradiation (STNI). Even in this poor-risk group the 6-year failure-free survival and overall survival rates were 89% and 90% respectively. Even shorter courses of chemotherapy are adequate in patients with better-risk disease. Three cycles of a MOPP/ABV hybrid regimen plus involved-field radiotherapy have been shown to be more effective than STNI, resulting in a 4-year event-free survival of 99% in the EORTC/GELA H8F trial. Three cycles of combination chemotherapy (usually ABVD) plus involved-field radiotherapy should thus be considered the standard for treatment in favourable-risk localized disease. A number of even shorter chemotherapy regimens have been combined with involved-field radiotherapy and, although they may be less efficacious than three cycles of MOPP/ABV or equivalent, they probably have less short- and long-term toxicity. As well as reducing the radiation field and dose in CMT, it may also be possible to reduce the amount of chemotherapy. In the German HD8 trial for intermediate-stage patients (stage I or II disease with at least one risk factor) treated with four courses of alternating COPP and ABVD, no difference in survival or freedom from treatment failure rates were shown between those receiving involved-field radiotherapy and those receiving extended-field radiotherapy; however, side-effects were more common in patients receiving extended-field radiotherapy. The current HD10 trial explores the use of reduced doses of radiation as well as restricted fields.

Concern over radiation-induced second malignancies has raised the issue of whether localized disease should be treated with chemotherapy alone, and this issue is addressed in the current Canadian National Cancer Institute HD6 phase III study which randomizes patients with clinical stage I–IIA to ABVD chemotherapy or STNI.

It may be that shorter courses of chemotherapy alone are adequate, especially when the length of chemotherapy is guided by interval PET scanning, and this will be tested in the forthcoming UK NCRI trial.

Advanced disease

The introduction of the MOPP (mustine, vincristine, procarbazine and prednisolone) combination chemotherapy regimen was a major landmark in the treatment of advanced Hodgkin's lymphoma. In the following few years a number of modifications to this regimen were made which maintained the efficacy but reduced the toxicity associated with MOPP. The next most important step was the development in the 1970s of the ABVD regimen (doxorubicin, bleomycin, vinblastine and dacarbazine). This was originally introduced as a salvage regimen for patients who had failed MOPP chemotherapy and was designed as far as possible to contain non-cross-resistant drugs to those in MOPP. This was later used as first-line therapy, particularly because the

drugs in ABVD were far less likely to induce infertility and secondary leukaemia than those in MOPP. ABVD was also combined with MOPP or MOPP-like therapy in either alternating or hybrid regimens so as to introduce a large number of drugs over a short time period in the hope of reducing the development of tumour resistance. A seminal trial was reported in 1992 by the Cancer and Leukaemia Group B (CALGB) comparing MOPP, ABVD and alternating MOPP/ABVD as the first chemotherapy in patients with stage III and IV disease. This showed that ABVD and alternating MOPP/ABVD were superior to MOPP in terms of response rate and failure-free survival (Table 44.6). Several studies compared MOPP alternating with ABVD with a MOPP/ABV hybrid and showed no significant differences. The CALGB trial had been too small to determine whether MOPP alternating with ABVD was superior to ABVD alone, but ABVD became widely accepted as the treatment of choice because of its lesser long-term toxicity. This practice was substantiated in the follow-up CALGB 8952 trial, which compared a MOPP/ABV hybrid against ABVD in patients with stage III or IV disease or after radiotherapy failure. At 5 years, the failure-free survival in the two arms was 63% and 66% respectively, with an overall survival of 81% and 82%. This trial was stopped after 856 patients had been randomized because of an excess of treatment-related deaths and second malignancies in the hybrid arm (Table 44.6).

Encouraging results have been reported using some alternative regimens. The Stanford V regimen is a 12-week regime of seven active agents with radiotherapy to sites of initial bulk; this is summarized in Table 44.6. A small randomized Italian study, however, found the Stanford V regimen to be inferior to ABVD and randomized trials comparing Stanford V against ABVD therapy are still ongoing.

A new hybrid regimen BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide vincristine, procarbazine, and prednisone) developed by the German Hodgkin's Study Group has been compared with their standard alternating regimen (COPP/ABVD) and a dose-intensified version of BEACOPP (escalated BEACOPP). The escalated BEACOPP requires the routine administration of G-CSF. The COPP/ABVD arm was closed early because it was found to result in a significantly inferior freedom from treatment failure (FFTF) compared with the BEACOPP arms at the first interim analysis. The final analysis has revealed significant improvement in the FFTF at 5 years in the BEACOPP arm compared with the COPP/ABVD arm (76% vs. 69%) and a further significant improvement in the escalated BEACOPP arm, in which the FFTF at 5 years is 87%. Both BEACOPP arms showed an advantage in overall survival at 5 years over the standard COPP/ABVD arm; however, there was no significant difference between baseline BEACOPP and escalated BEACOPP. The rate of early disease progression was lower in the escalated dose BEACOPP arm than in the baseline BEACOPP and COPP-ABVD arms. The initial concern of an increased incidence of AML/MDS in the escalated dose arm has not been confirmed in later analyses. In addition, it must be noted that

†Escalated BEACOPP therapy requires the routine administration of G-CSF.

there is considerably more chance of infertility with a pro-carbazine-containing regimen than with ABVD. At the very least this study demonstrates that there is a clear dose–response relationship within the dose range possible without haemopoietic stem cell support. Selected studies of treatment of advanced disease are summarized in Table 44.6.

There is an argument that high-risk patients may benefit from more intensive regimens such as BEACOPP. In the UK, the ChlVPP/PABLOE alternating regimen has been widely used, and an analysis of 326 patients is summarized in Table 44.6. This study also suggests that a significant proportion of the patients failing alternating therapy could be rescued with alternative approaches. In the approximately 20% of patients with an IPS of 4–7, the FFS at 5 years was expectedly lower at 71% and fewer failures were rescued so that the OS was only 74%. It may therefore be that regimens such as escalated BEACOPP may be most beneficial in high-risk patients and this will be explored in a European Intergroup trial. The strategy of high-dose therapy with stem cell transplantation in first remission has also been tested in a randomized trial, which failed to show any benefit of early high-dose therapy. It should be noted that in this trial the patients receiving continued conventional dose therapy had an excellent 5-year failure-free survival of 83%, thus illustrating the difficulty in defining a poor-prognosis group once a good response to initial therapy has been obtained.

Radiotherapy in advanced Hodgkin's lymphoma

The use of consolidation radiotherapy in patients with advanced Hodgkin's lymphoma is common, especially if a CRu is attained and there was bulky disease at presentation. The evidence for this practice is not strong. The Groupe d'Etude des Lymphomes de L'Adulte (GELA) designed a complex study (H89) comparing six cycles of two different chemotherapy regimes with a second randomization to two more cycles of the same chemotherapy or to subtotal or total nodal irradiation (Table 44.6). There was no advantage to radiotherapy consolidation when a doxorubicin-containing regimen had been used. The EORTC 20884 trial of involved-field radiotherapy in patients with advanced Hodgkin's lymphoma showed no advantage to consolidation radiotherapy for those achieving CR after MOPP/ABV chemotherapy. Interestingly, however, patients only achieving a partial remission after MOPP/ABV had a similar overall outcome if they were given additional radiotherapy (Table 44.6). A meta-analysis comparing chemotherapy with combined-modality therapies concluded that, providing the amount of chemotherapy was adequate, the addition of radiotherapy did not improve tumour control and might be associated with a reduced survival attributable to long-term effects of treatment. Despite these negative conclusions about consolidation radiotherapy it must be noted that two of the most recent regimens reported to date both use radiotherapy consolidation in the majority of patients.

In Stanford V, 85% of patients received radiotherapy and in escalated BEACOPP radiotherapy was given to the majority of patients.

Treatment of childhood Hodgkin's lymphoma

Hodgkin's lymphoma in children and adolescents is curable in over 90% of cases. With rising numbers of long-term survivors, the impact of long-term effects becomes increasingly important. A number of specific childhood regimens have been developed which aim to maintain these excellent remission rates but reduce the likelihood of developing late effects. These regimens encompass the same general principles, namely avoidance of laparotomy staging to reduce the risk of fulminant sepsis, risk-adjusted therapy to avoid overtreatment of favourable-risk patients, combined modality treatment at all stages of the disease, avoidance of procarbazine in boys to protect future fertility and minimization of radiation dose and field and anthracycline dose. Many of these principles are now also being applied in adult patients with Hodgkin's lymphoma.

Relapsed disease

A proportion of patients receiving chemotherapy, either *de novo* or after radiation failure, will have refractory disease or will relapse from remission. Occasional patients can be cured by radiotherapy if the persistent or relapsed disease is localized, but the majority of patients will require systemic therapy. In patients with long first remissions, a significant proportion of patients may be cured by further standard dose chemotherapy, but the results of such approaches are poor if the remission has been short or the disease was refractory to initial chemotherapy. In the report of the long-term follow-up of the initial cohort of patients treated with MOPP at the NCI, there were no survivors beyond 10 years in those who had not achieved a remission.

High-dose chemotherapy and autologous stem cell transplantation was first pioneered in relapsed Hodgkin's lymphoma over 40 years ago, but it is only in the last two decades that it has become an established modality of treatment. In the last decade peripheral blood stem cells have replaced the use of bone marrow as the source of haemopoietic stem cells. In the early 1980s the procedure-related mortality associated with an autograft was in the order of 10%, but with improved patient selection and better supportive care this has fallen to 3% or less. In large single-centre series and in registry reviews, the overall survival rates of patients receiving autologous transplantation for relapsed or resistant disease are approximately 40–50%. A number of different conditioning regimens have been used, and high-dose chemotherapy is generally preferred to total body irradiation (TBI). This is because chemotherapy is logistically easier to administer, appears as effective as TBI and may be associated with less pneumonitis, although high-dose chemotherapy is also associated with pneumonitis, particularly in patients who have

received mediastinal radiation in the preceding year. Following high-dose therapy it is common practice to irradiate persistent masses or sites of previous large volume disease, although there are no trial data to substantiate this practice.

Prior to high-dose therapy, standard-dose chemotherapy is usually given to reduce disease bulk and demonstrate chemosensitivity. In patients with progressive disease despite standard-dose chemotherapy, or who have persistent B symptoms or a raised lactate dehydrgenase (LDH), the results of high-dose therapy are probably too poor to justify proceeding to this course of action. It must be noted, however, that in some cases a mass will not immediately shrink in size and failure to achieve a formal response (complete or partial remission) should not disqualify a patient from receiving an autograft.

The BNLI carried out a small randomized trial of BEAM (carmustine, etoposide, cytarabine and melphalan) followed by autologous stem cell transplantation or mini-BEAM (the same drugs at lower doses) in patients with refractory or relapsed disease. There was a highly significant progression-free survival advantage in the high-dose therapy arm, and similar results have subsequently been reported from a larger German study. Neither study demonstrated an overall survival benefit and this may, in part, be due to the small size of these trials, but may also be because some patients failing standard dose salvage therapy can still be rescued by high-dose therapy at a later time. This raises the issue of when is the optimal time to consider an autograft procedure. It is widely recommended for all patients below the age of 65 years who fail first-line chemotherapy, although this may not be appropriate if there has been a first complete remission lasting more than 3 years.

The value of allogeneic transplantation in Hodgkin's lymphoma is unclear. High transplant-related mortality rates have been reported in several series. However, there may be a reduced relapse rate in those patients surviving an allogeneic transplant, suggesting a graft-versus-lymphoma effect. There is current interest in the use of less toxic non-myeloablative allogeneic transplants in Hodgkin's lymphoma, particularly in patients who have failed a previous autograft, and in a UK study involving 24 patients with relapsed or refractory HL there were only two procedure-related deaths. Interestingly, several patients who subsequently relapsed responded to donor lymphocyte infusions. Further follow-up and larger trials will be required to ascertain the role of this modality of therapy.

Late effects of Hodgkin's lymphoma and its treatment

As the cure rate for Hodgkin's lymphoma has increased and longer-term follow-up data have become available, the significance of the late effects of treatment have become more apparent (Table 44.7). In a study of young adults aged 29 years or less at diagnosis, and who achieved a stable complete remission after

Table 44.7 Late effects of Hodgkin's lymphoma and its treatment.

Second malignancies
Cardiac disease
Endocrine dysfunction
Psychological trauma
Lung damage (usually subclinical)
Hyposplenism (following splenectomy or splenic irradiation)

first- or second-line therapy, the actuarial overall survival at 20 years was 93% and 85% respectively, compared with 98.5% in the age-matched general population. In some patients treated for favourable-risk disease it has been shown that, at 12–15 years after therapy, the mortality risk related to therapy exceeds the risk of dying from Hodgkin's lymphoma. The two most frequent causes of excess deaths are second malignancies and ischaemic heart disease.

The commonest second malignancy is lung cancer. This is mainly attributable to radiotherapy, although chemotherapy also contributes to the risk. Patients who have had thoracic irradiation must be warned of the risk of developing secondary lung cancer and must be strongly discouraged from smoking. The risk of developing secondary myeloid leukaemia is related to the cumulative dose of alkylating agents received and, therefore, occurs predominantly in patients who have had remitting and relapsing disease. The risk of secondary breast cancer is greatest in adolescent females or young women who received mediastinal or axillary irradiation. There is a clear dose–response relationship, which emphasizes the use of the minimal radiation dose required for tumour control. The risk in such patients of ever developing breast cancer is in the region of 1 in 4, and patients at such high risk must be made aware of this fact and offered access to a screening programme. Other malignancies that occur in excess in patients treated for Hodgkin's lymphoma include non-Hodgkin's lymphomas, cancers of the colon, stomach, head and neck and thyroid, and malignant melanoma. Advice should be given regarding early consultation for suspicious symptoms and the avoidance of sunburn.

The Stanford group reported a threefold increase in relative risk of cardiac death in Hodgkin's lymphoma survivors representing a major risk as the incidence of cardiac disease in the general population is so high. The major contributory factor is mediastinal irradiation, especially if a dose in excess of 30 Gy is used. Whether the increasing use of anthracyclines will have a long-term impact on cardiac disease is not yet clear.

The most common endocrine disorders are hypothyroidism following radiotherapy to the lower neck and infertility. Around half of patients receiving neck radiation will develop hypothyroidism, and these patients should be monitored accordingly. Infertility is caused by irradiation of the gonads and the use of drugs such as procarbazine and alkylating agents. It is their repeated use that is most damaging, and young female patients

receiving an autologous transplant will often remain fertile if they are still menstruating prior to the high-dose therapy. Sperm cryopreservation prior to chemotherapy should be offered to men who have not completed their families. Artificial insemination has a relatively low success rate per cycle; however, intracytoplasmic sperm injection may be more successful. Hodgkin's lymphoma may often be slow growing, and this permits the harvesting of eggs, *in vitro* fertilization and embryo storage in those young women who have an established partner. Oocyte cryopreservation and ovarian tissue banking are currently in development and remain experimental.

The psychological trauma associated with contracting a malignant disease, receiving radiotherapy and chemotherapy and coping with the risk or eventuality of relapse is considerable. A significant proportion of patients report lower perceived levels of overall health, dissatisfaction in their personal relationships and difficulties in obtaining life assurance and financial loans as a result of the disease and/or its treatment.

Current strategies must therefore aim to give the minimal therapy without jeopardizing the high rates of cure that are now possible with front-line therapy. This will require large randomized trials with long follow-up.

Novel therapies

Cytotoxic drugs

Gemcitabine, an analogue of cytarabine, has been found to have anti-tumour activity in Hodgkin's lymphoma. It is well tolerated with a favourable toxicity profile, and response rates in excess of 35% in heavily pretreated patients can be achieved. Future studies will explore the use of gemcitabine in combination with other active cytotoxic agents.

As NF-κB has been shown to be activated in Hodgkin's lymphoma cells, this pathway is an important target for new drug development. Particular attention is focused on proteasome inhibitors which prevent degradation of IκB and thus minimize the liberation of active NF-κB.

Immunotherapy

Limited success has been seen following the reinfusion of EBV-specific cytotoxic T lymphocytes (CTLs) in patients with Hodgkin's lymphoma. H/RS cells have been shown to evade destruction by EBV-specific CTLs by downregulating the T-cell receptor response and by the secretion of cytokines, which may prevent the generation of an effective cell-mediated response. Strategies aiming to generate LMP-selective CTLs, possibly with the use of autologous dendritic cells may prove more efficacious.

One of the most promising antigens for targeted immunotherapy is the CD30 antigen. Studies investigating anti-tumour activity of an anti-CD30 monoclonal antibody and radioimmunotherapy with ^{131}I-labelled anti-CD30 antibody are ongoing.

Use of bispecific antibodies such as CD30/CD25 and CD30/CD3 are currently the subject of phase I/II trials and may be more effective than the single agent alone.

Conclusion

Much progress has been made in recent years regarding both the cellular aspects of the Hodgkin/Reed–Sternberg cell and the treatment of the resultant tumour. The results of therapy are extremely good, and attention must be paid to minimizing late effects of treatment. In many cases the same ultimate survival can be achieved using different therapeutic approaches. The choice of approach depends on an appreciation of short- and long-term side-effects, and increasingly the patient must be involved in an informed decision-making process.

Aetiology and management of non-Hodgkin's lymphoma

45

Irit Avivi and Anthony H Goldstone

Epidemiology

Frequency

The incidence of non-Hodgkin's lymphoma (NHL) has dramatically increased since the 1950s, in both the UK and the USA (from 6.9 per 100 000 person-years in 1947–50, up to 17.4 per 100 000 in 1984–88), becoming the fifth most common cancer in the USA. This is only partially accounted for by HIV-related lymphomas, and there is suggestive, although not definitive, evidence that the role of environmental factors may be also essential.

Non-Hodgkin's lymphoma is slightly more common in males than in females, and in the USA it is more common in white people than in black people. Although NHL can occur at any age, the incidence rises considerably with age.

Geographical variations

Proportions of cases in different histological categories vary markedly from one country to another and among different racial groups. Although some of these variations may be spurious, reflecting local specifics of medical practice, real differences undoubtedly exist. For example, follicular lymphoma (FL), one of the most common NHLs in Europe and the USA, is rare in Japan and other Far Eastern countries. In contrast, HTLV-1 is much more common in the Far East (Japan) and in the Caribbean islands than Western countries.

These differences are perhaps not surprising, given the role of the immune system (from which these neoplasms arise) in constantly monitoring and reacting to antigenic factors in the environment. This must cause variations between different parts of the world in the degree to which individual cell populations in lymphoid tissue are activated, which is likely to be reflected in the frequency variations of different lymphomas.

Aetiology

In the majority of cases of NHL, the cause is not identified, although several factors are known to play a role in lymphomagenesis. A small number of lymphomas originate from chronic antigenic stimulation; for example, *Helicobacter pylori* (HP) infection appears to be a possible causative agent for the development of gastric mucosa-associated lymphoid tissue (MALT) lymphoma. Eradication of HP with antibiotics appears to be initial effective therapy for localized gastric MALT lymphoma. Similarly, infection with *Campylobacter jejuni* has been suggested recently to be associated with the development of immunoproliferative small intestinal disease (IPSID).

Viruses

Several viruses have been implicated in lymphoma pathogenesis, although none of them is directly causative in the way similar to that of the oncogenic virus inducing neoplasia in animals.

Epstein–Barr virus

Epstein–Barr virus (EBV) was first thought to be associated with lymphomagenesis following its isolation from endemic Burkitt's lymphoma tissue, but it is now known to be a major factor causing development of NHL in immunosuppressed individuals [e.g. HIV patients or those post solid-organ/allogeneic stem cell transplantation (SCT), in whom it is called post-transplant lymphoproliferative disease]. There are two forms of cellular infection by EBV: latent and replicative. In latent infection, the virus enters the cell and remains in the DNA; B cells become immortalized and acquire neoplastic potential. In replicative infection, viral particles are released from cells, whereas the cells themselves die.

It is the latent type of infection that transforms infected resting B cells into proliferating blasts. The mechanism of this remarkable effect depends on the expression of several viral latent proteins that are under control of a master transcription factor, EBV nuclear antigen 2 (EBNA-2). The pattern of viral gene expression that derives this process is called the growth programme (Table 45.1).

This process can happen in the presence of the following conditions: first, the EBV-infected cells that express the growth programme must be unable to exit the cell cycle and become resting memory B cells, and second, the cytotoxic T-cell response must be impeded, so that lymphoblasts would not be killed. Post-transplant lymphoproliferative disease (PTLD) may therefore develop when B cells (other than naive B cells) become infected and express the growth programme without being able to exit it, and continue to proliferate in the absence of effective cytotoxic T-cell response.

Epstein–Barr virus is also associated with the development of the endemic (African) type of Burkitt's lymphoma (BL), in which it is expressed by 98%. However, the exact mechanism of EBV involvement in BL development is unclear. None of the growth promoting latent genes is expressed, whereas the only detected latent protein of the virus is EBNA-1. Burkitt's lymphoma is characterized by deregulated activation of c-*MYC* oncogene (Table 45.2), resulting in a sustained proliferation mode, in which cells express EBNA-1 only. EBV may therefore have a role in the development of BL. However, given the multistep process of tumorigenesis, it is actually impossible to be sure whether the final cellular or viral phenotype of BL is related to the original infected precursor.

Human T-cell leukaemia virus type I

Adult T-cell leukaemia/lymphoma (ATLL) is a T-cell malignancy that occurs after a 40- to 60-year period of clinical

Table 45.1 Transcriptional programmes used by EBV to establish and maintain infection.

Type of infected B cells*	Programme	Genes expressed	Function of the programme
Naive cell	Growth	EBNA-1 through EBNA-6, LMP-1, LMP-2A, LMP-3B	Activated B cell
Germinal centre cell	Default	EBNA-1, LMP-1, LMP-2A	Differentiate activated B cells into memory cells
Peripheral blood memory cell	Latency	None	Allows lifetime persistence
Dividing peripheral blood memory cell		EBNA-1 only	Allows viral DNA in latency programme cell to divide
Plasma cell	Lytic	All lytic genes	Replicates virus in plasma cell

*Except where indicated, the types of cell are primarily restricted to the lymphoid tissues of Waldeyer's ring.
EBNA, EBV nuclear antigen; LMP, latent membrane protein.

Table 45.2 Chromosomal translocations found in non-Hodgkin's lymphoma.

Translocation	Gene involved	Type of lymphoma
t(8;14)(q24;q32)	c-*MYC* and IgH	Burkitt's lymphoma
t(8;2)(p11/2;24)	c-*MYC* and Igκ	Burkitt's lymphoma
t(8;22)(q24;q11)	c-*MYC* and Igλ	Burkitt's lymphoma
t(11;14)(q24;q32)	*BCL-1* (cyclin D1) and IgH	Mantle cell
t(14;18)(q32;q21)	*BCL-2* and IgH	Follicular lymphoma
t(3;4)(q27;q32) and variants	*BCL-6* and various partners	Large B cell
t(2;5)(p23;q35)	*NPM* and *ALK*	T-cell anaplastic large cell

latency in about 3–5% of human T-cell leukaemia virus type I (HTLV-1)-infected individuals. ATLL cells are monoclonally expanded and harbour an integrated provirus. A persistent oligo/polyclonal expansion of HTLV 1-bearing cells has been shown to precede ATLL, supporting the fact that in ATLL tumour cells arise from a clonally expanding non-malignant cell.

Tax protein, encoded and expressed by an activated form of HTLV-1, rescues virus-expressing T cells from apoptotic death. This suggests that Tax protein can rescue the host cells of the activated virus from the ultimate apoptotic death, contributing to tumorigenesis.

Kaposi sarcoma-associated virus

Kaposi sarcoma-associated virus (KSHV) is the causative agent of both Kaposi sarcoma (KS) and primary effusion lymphoma (PEL). KSHV, called also HHV-8, appears to have an important role in the pathogenesis of both KS and primary effusion lymphoma (PEL), elaborating growth factors and cytokines that promote tumour growth. It encodes putative oncogenes and genes that stimulate angiogenesis and cell proliferation, including G-protein-coupled receptor-promoting cell transformation and angiogenesis and 'interleukin 6 (IL-6) homologous cytokine', preventing cell apoptosis in IL-6-dependent cell lines.

The KSHV G-protein-coupled receptor (vGPCR) is a homologue of the human IL-8 receptor that signals constitutively, activates mitogen- and stress-activated kinases, and induces transcription via multiple transcription factors, including AP-1 and nuclear factor kappa B (NF-κB). Furthermore, vGPCR causes cellular transformation *in vitro* and leads to KS-like tumours in transgenic mouse models.

KSHV also encodes a cyclin D homologue, K cyclin, which is thought to promote viral oncogenesis. The expression of K cyclin in cultured cells not only triggers cell cycle progression, but also engages the p53 tumour-suppressor pathway, which probably restricts the oncogenic potential of K cyclin.

Immunosuppression

Lymphomas, almost always of the histologically aggressive variety, have become more common in immunosuppressed patients with the discovery of AIDS and increase in solid organ and SCT. Lymphoma has been reported to occur in 4–10% of patients with AIDS and the pathogenesis is almost certainly multifactorial. The increased risk of infections with viruses such as EBV, chronic antigen exposure and cytokine stimulation arising from repeated infections result in polyclonal B-cell activation and, therefore, a greater chance of mutations that develop randomly during mitosis. Almost all cases of central nervous system (CNS) lymphomas and Hodgkin's lymphoma diagnosed in immunosuppressed patients are EBV+.

Lymphomas develop in < 1% of allogeneic SCT recipients, although the risk is higher in the patients receiving rigorous T cell-depleted transplants followed by heavy post-graft immunosuppression (e.g. anti-thymocyte globulins, applied for graft-versus-host disease). In heart or lung transplants, the incidence of lymphomas is as high as 4–7%. Most post-transplant lymphomas are EBV related (see previous discussion on EBV-related lymphomas). At early stages, they may be polyclonal or oligoclonal and only later become monoclonal, but the clonal nature of the proliferation does not appear to predict closely the response to immunosuppression withdrawal, which may result in spontaneous remission.

Genetic and occupational factors

Several studies reported an increased risk of NHL in first-degree relatives of lymphoma (HD/NHL) probands compared with the general population. The temporal proximity of HD/HD and NHL/NHL sibling pairs argues for environmental as well as genetic aetiology.

An increased incidence of NHL has been reported in people working in agriculture, forestry, logging industries, as well as in those involved in metalworking machinery, printing and publishing industry, motor vehicles and telephone communications. The risk seems to increase with employment duration and vary by histological type.

Occupational exposure to specific chemicals, such as benzidine, mineral, cutting or lubricating oil, pesticides, herbicides and wood dust seem to play an important role in the development of NHL. However, the exact impact of these factors is still debated and their contribution to pre-existing genetic factors is not totally clear.

Cytogenetics and oncogenes

Cytogenetic analysis in non-Hodgkin's lymphoma can be difficult, given the problem of isolating neoplastic cells from tissue biopsy samples for karyotypic analysis. However, several large studies suggest that nearly all cases have a cytogenetic abnormality. It may be either numerical or structural but a number of translocations are particularly interesting because of their association with specific types of lymphoma and the insights they have provided into the process of lymphomagenesis. Rearrangements frequently involve T-cell receptor (TCR) or immunoglobulin (Ig) genes, which rearrange as part of the normal process of lymphoid differentiation (Chapter 28). In some cases, the aberrant recombination may be due to structural similarities between the regions close to the breakpoints and the heptamer/nonamer recombinase-recognition sequences bordering the normally rearranging genes. The rearrangements typically cause deregulation (usually upregulation) of oncogenes brought under the influence of immunoglobulin TCR promoter and enhancer sequences (see Table 45.2).

There is some disagreement concerning the frequency of the t(14;18) in FLs, but most studies report its presence in about 85% of patients. Some of the discrepancies may reflect true geographical variation; for instance, in Japan the reported incidence is only 33%. The breakpoints on chromosome 18 occur at two sites, approximately 20 kb apart, within or near the transcriptional unit of the BCL2 gene. Approximately two-thirds of the breakpoints occur within 150 basepairs, known as the 'major breakpoint region', in the 5′-untranslated region of the BCL-2 gene, and most of the remaining breakpoints occur 3′ to this in the 'minor cluster region'. The BCL-2 gene codes for a protein localized in the inner mitochondrial membrane, which is involved in the inhibition of apoptosis rather than the induction of proliferation. This blockage of cell death in neoplastic germinal centre cells may account for the fact that the FLs are, at least initially, slow growing.

The usual cytogenetic abnormality in Burkitt's lymphoma is a translocation involving the c-MYC gene on chromosome 8 and the Ig heavy-chain gene on chromosome 14, which is found in over 80% of cases. Although both the endemic and sporadic forms of Burkitt's lymphoma have the same gross translocations, there are subtle differences at the molecular level. Variant translocations involve chromosome 8 and either chromosome 2 or 22, where the breakpoints involve, respectively, kappa and lambda light-chain genes. In all cases, there is upregulation of c-MYC, a nuclear transcription factor involved in cell proliferation and the control of apoptosis.

The t(11l;14) translocation is found in mantle cell lymphomas. The oncogene on chromosome 11 is known as BCL-l or PRAD-l, and encodes a D-cyclin involved in cell cycle control (Table 45.2).

The BCL-6 gene is a transcription factor of the zinc finger family, whose precise function is unknown. It has recently been suggested to maintain B cells in a germinal centre-like state, inhibiting B-cell differentiation. Rearrangements of BCL-6 occur in over one-third of large-cell lymphomas and in an even higher number of cases mutations within the gene are found. The presence of BCL6 rearrangement has been suggested to predict favourable prognosis, although not confirmed in all studies (Table 45.2).

T-cell lymphomas are less frequent than B-cell lymphomas and have been less extensively studied at the molecular level. T-cell lymphoblastic lymphomas may have abnormalities similar to those found in T-cell acute lymphoblastic leukaemia (ALL), such as abnormalities of the TAL-1 gene on chromosome 1, the HOX11 gene on chromosome 10 and the RHOMB2 gene on chromosome 11.

Anaplastic Ki-1 (CD30)-positive large-cell lymphomas are usually of T-cell origin, and in at least one-half of the cases there is a t(2;5)(p23;q35) translocation (see Figure 45.1 and Table 45.2). The genes involved in this translocation encode a receptor tyrosine kinase called anaplastic lymphoma kinase (ALK) on chromosome 2, and nucleophosmin on chromosome 5. The resulting hybrid gene encodes a hybrid protein in which about 40% of nucleophosmin is fused to the entire cytoplasmic portion of ALK. The nucleophosmin moiety not only induces ALK expression (as nucleophosmin is a ubiquitously expressed nuclear protein), but also activates the kinase through cross-linking.
Figure 45.1 Anaplastic large-cell lymphoma of T-cell type.
Figure 45.2 Large B-cell lymphoma. The cells are larger than normal lymphocytes and have a round nucleus with prominent nucleoli, some adjacent to the nuclear membrane ('centroblasts').

When a chromosomal translocation is frequently found in a particular lymphoma type, e.g. t(14;18) in FL, and if the breakpoint falls within a well-defined and limited region(s), polymerase chain reaction (PCR) analysis may be used either to assist in diagnosis or to detect minimal residual disease. However, the clinical significance and value of such studies have yet to be determined, as it is not completely clear what the prognostic importance may be of small numbers of cells carrying this translocation in patients who are in clinical remission.

Recently, DNA microarray technology has opened new avenues for the understanding of lymphomas. By hybridization of cDNA to arrays containing > 10 000 different DNA fragments, this approach allows simultaneous evaluation of the mRNA expression of thousands of genes in a single experiment. These data can then be used for identification of lymphoma subgroups, with a defined gene expression pattern, not previously identified by morphology, cytogenetics or molecular techniques.

This approach has already provided novel insights into different entities of B-cell NHLs; measurement of the expression of only six genes was found to be predictive of overall survival in diffuse large B-cell lymphoma (Figure 45.2) and the prognosis of FL has been related to the molecular features of tumour-infiltrating cells.

Clinical features

The median age of presentation of low-grade lymphomas and large-cell lymphomas is around 55–60 years, with a slight male predominance. In FL (Figure 45.3), the marrow is involved in about 50% of cases at diagnosis (Figure 45.4). Burkitt's lymphoma often presents with extranodal disease, appearing in the jaw in Africa, and as gastrointestinal disease or in other intra-abdominal sites in the West. Hypercalcaemia is frequent.
(a)
(b)

Figure 45.3 Immunostaining of follicular lymphoma showing its typical nodular appearance: (a) CD20 is expressed by the tumour cells, whereas (b) CD3 is confined to reactive T cells. (Paraffin sections: APAAP immunoalkaline phosphatase stain.)

Widespread painless lymphadenopathy is more common at presentation in NHL than in Hodgkin's disease (HD) and contiguous spread is not so apparent. Superior vena cava syndrome caused by a bulky mediastinal mass is also more frequent in NHL than in Hodgkin's lymphoma. Hepatosplenomegaly is frequent at diagnosis.

Patients with indolent histology are less likely to have B symptoms (unexplained fever of 38°C or higher, night sweats and loss of more than 10% of body weight in 6 months) than those with an aggressive histology, but this is not invariable. Some patients present with systemic symptoms without peripheral lymphadenopathy, which can result in considerable delays in diagnosis. Symptoms and signs may be due to the involvement of particular organs (e.g. skin, gastrointestinal tract, salivary glands, lungs, renal tract and central nervous system).

Lymphoblastic lymphoma usually occurs in children and young adults, often with thymic mass, systemic symptoms and bone marrow failure.
Figure 45.4 Non-Hodgkin's lymphoma in the marrow: paratrabecular localization.

Table 45.3 Prognostic factors for aggressive lymphoma: International Prognostic Index (IPI) (reproduced from *New England Journal of Medicine* (1993) **329**: 987 with permission).

Age > 60 years
Ann Arbor stage III or IV
Increased lactate dehydrogenase concentration
Performance score of > 2
Involvement of more than one extranodal site

Table 45.4 Ann Arbor staging system.

Stage I	Involvement in a single lymph node region or single extralymphatic site
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm; localized contiguous involvement of only one extralymphatic site and lymph node region (stage IIE)
Stage III	Involvement of lymph node regions on both sides of the diaphragm; may include spleen
Stage IV	Disseminated involvement of one or more extralymphatic organs with or without lymph node involvement

Laboratory investigations

Histological diagnosis from biopsy of a lymph node, bone marrow or extranodal mass is essential (Figures 45.1–45.8). Fine-needle aspiration may help to exclude or suggest lymphoma, but histological examination is essential to complete the diagnosis. Immunocytochemistry is now performed and, in specialized units, cytogenetic and immunoglobulin or TCR rearrangement analysis, as well as, more recently, DNA microarray testing.

Anaemia at diagnosis is usually indicative of widespread disease and may reflect a non-specific manifestation of malignancy. However, it can also be due to hypersplenism or bone marrow infiltration. Occasional patients, most often those with indolent histology, have an autoimmune haemolysis. The white count is variable. Overspill of lymphoma cells into the blood is relatively frequent in late stages of indolent lymphoma and can infrequently be seen by light microscopy at diagnosis. It can be detected much more frequently using PCR technique. Hypo-albuminaemia is another non-specific feature associated with a systemic disturbance and is indicative of a poor prognosis. A raised level of lactate dehydrogenase (LDH) is usually associated with advanced disease and is an important independent prognostic factor (Table 45.3). Paraproteins are found in about 15% of indolent lymphomas and in a little less than 5% of histologically aggressive lymphomas.

Staging

The Ann Arbor staging system, initially developed for Hodgkin's disease, is used in adults with NHL (Table 45.4). Inspection of Waldeyer's ring is particularly important, and a bone marrow biopsy should be performed in all patients. Although a laparotomy may sometimes be required to relieve a gut obstruction, stop a GI haemorrhage or make a diagnosis of a disease restricted to the abdomen, there is widespread agreement that a staging laparotomy is not justified. In children, the St Jude staging system is usually used. Radiography, computerized tomography (CT), magnetic resonance imaging (MRI) or positron emission tomography (PET) scanning are used for initial staging of the disease and are of value in monitoring response to therapy and detection of residual disease or relapse.

Treatment

Treatment of NHL is mainly based on the histological findings, dividing patients into two major groups: patients with indolent versus aggressive NHL. However, therapeutic decisions are also taken with regard to patient's age, performance status and disease extension (Table 45.3). There are also some special subtypes

of lymphoma (e.g. CNS lymphoma, MALT lymphoma) that will be discussed separately.

Follicular lymphoma

Localized disease

Approximately 20% of follicular lymphoma (FL) patients present with non-bulky localized disease. Almost one-half of them may be cured with localized radiotherapy. MacManus and colleagues from Stanford University reviewed in 1996 the outcome of 177 FL stage I/II patients treated with radiotherapy only: 64% of these patients approached 10-year actuarial survival, whereas 44% remained disease free. Similar results were reported by the MD Anderson group, in which tumour size and Ann Arbor stage have significantly affected progression-free survival (PFS) (15-year PFS = 49% for tumour < 3 cm versus 29% for mass 3.0 cm, $P = 0.04$, and Ann Arbor stage; 66% versus 26% for stages I and II, respectively, $P = 0.006$). Ann Arbor stage has also affected the cause-specific survival ($P = 0.01$), but overall survival was apparently unaffected by the extent of the radiation field. It seems that radiotherapy can cure approximately one-half of patients with stage I and one-quarter of those with stage II FL. Patients with localized disease should therefore receive involved-field radiation without undue delay, aiming not only to eliminate their symptoms, but also to achieve disease cure.

Adding adjuvant chemotherapy to radiotherapy for localized disease

As most relapses following radiotherapy occur outside the radiation field, a reasonable approach would be to combine radiotherapy with systemic chemotherapy, aiming to reduce relapse risk and improve cure rate.

The British National Lymphoma Investigation (BNLI) has prospectively compared the outcome of 148 patients with localized low-grade lymphoma, treated with radiotherapy, with/without adjuvant continuous chlorambucil (CHL). There were no significant differences either in overall survival (OS) or in disease-free survival (DFS) between the two treatment groups (maximal follow-up = 18 years). Intensification of chemotherapy (e.g. CHOP, Table 45.5) also failed to improve patients' outcome.

However, there were some retrospective and prospective non-randomized trials that reported an improved PFS in patients treated with combined modality treatment compared with radiotherapy alone. In the MD Anderson Cancer Center, patients with low-grade lymphoma, stage I/II, were treated with 10 cycles of COP–Bleo/CHOP–Bleo (Table 45.5), followed by involved-field radiation. The 10-year PFS and OS approached 76% and 82%, respectively, which were higher than previously reported results with involved-field radiotherapy alone (Seymour et al., 2003). These findings have encouraged the development of a joint phase III study by the Trans Tasman Radiation Oncology Group (TROG) and the Australasian Leukaemia and Lymphoma Group (ALLG) in which patients with clinical stage I/II FL are randomized to involved-field radiotherapy with or without six cycles of cytotoxic chemotherapy (TROG 99.03 trial – started recruitment in early 2000). However, at present there are no proven data to support the addition of chemotherapy; chemotherapy should therefore be used in such patients after relapse.

Table 45.5 Chemotherapy protocols used in NHL.

CVP	Cyclophosphamide, vincristine, prednisolone
FMC	Fludarabine/cyclophosphamide/mitoxantrone
CHOP	Cyclophosphamide, doxorubicin, vincristine, prednisolone
MACE–CYTABOM	Doxorubicin, etoposide, prednisolone, cytarabine, bleomycin, vincristine, methotrexate
MACOP B	Methotrexate, doxorubicin, cyclophosphamide, vincristine, bleomycin
m-BACOD	Methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, dexamethasone
ESHAP	Etoposide, cytarabine, methylprednisolone, cisplatin
Mini-BEAM	BCNU, etoposide, cytarabine, melphalan
ICE	Ifosfamide, carboplatin, and etoposide
DHAP	Dexamethasone, high-dose cytarabine and cisplatin
DVIP	Dexamethasone, etoposide, ifosfamide and cisplatin
CODOX–M/IVAC	Cyclophosphamide, doxorubicin, high-dose methotrexate/ifosfamide, etoposide and high-dose cytarabine
Hyper CVAD	Hyperfractionated cyclophosphamide, vincristine, doxorubicin and dexamethasone
ACVBP	Doxorubicin, cyclophosphamide, vindesine, bleomycin, prednisolone

Is there any place for radiotherapy in relapsed disease?
Low-dose (4 Gy) involved-field radiotherapy appears to provide a high response rate (92% overall response rate, with 61% complete responses) with durable remissions (> 1 year) in patients with relapsed disease. Low-dose radiotherapy should therefore be considered in patients with recurrent, localized disease, irrespective of their initial presentation.

Advanced disease

Patients with FL tend to have a highly variable outcome. Although some patients experience early progression and die of their disease in less than 5 years, others may have an indolent course and live for 15 years or longer. Conventional chemotherapy is, however, unable to prolong long-term survival compared with observation. In the absence of a specific therapy for an indolent disease (50% survival at 10 years), management is mainly targeted to reduce symptoms and prolong time to progression (TTP), rather than prolong survival.

Patients' quality of life and treatment-related side-effects should be carefully considered, especially in the background of an incurable disease, which occurs mainly in elderly patients whose life expectancy irrespective of diseases may be less than 20 years.

Management therefore ranges from a 'watch-and-wait' approach through different kinds of chemotherapy regimens (monoclonal antibodies applied in symptomatic patients) as far as experimental intensive therapies (autologous/allogeneic SCT) considered in younger patients aiming to prolong survival and achieve cure.

What is required is a series of complementary structured randomized studies that will give proper data over a number of years. Unfortunately, newer modalities such as monoclonal antibodies with some sort of stem cell transplant will inevitably be introduced during the lifetime of an incidental patient's disease and 'skew' the findings. It is almost impossible to study a patient over 10–15 years without allowing him/her to potentially benefit from new treatments emerging during that period.

Chemotherapy for follicular lymphoma

As mentioned above, historically treatment has been unable to prolong long-term survival. Therefore, it is mainly offered to reduce symptoms and signs of the disease and improve quality of life.

A large number of patients are asymptomatic at diagnosis. Deferral of treatment in such patients seems to have no adverse impact on survival. The BNLI has recently reported the outcome of 309 patients with asymptomatic advanced stage III/IV low-grade lymphoma, who were randomly assigned to receive oral chlorambucil 10 mg/m^2 continuously ($n = 158$) versus observation until disease progression ($n = 151$) (local radiotherapy to symptomatic enlarged lymph nodes was permitted in both arms). There was no significant difference in OS and cause-specific survival (CSS) between the two arms. However, age below 60 years and stage III versus IV conferred a significant survival advantage. The actuarial chance of not requiring chemotherapy at 10 years was almost 20%, supporting the strategy of 'watch and wait' in these 'advanced' patients. Similarly, the Groupe d'Étude des Lymphomes Folliculaires (GELF) found no differences in overall survival between low-tumour burden patients randomized to prednimustine/interferon versus observation only. As a rule, conservative management should be considered in asymptomatic patients, keeping their quality of life without having unnecessary toxicity.

Alkylating agents
Those individuals who have symptoms can receive either oral or intravenous therapies.

Oral chlorambucil and cyclophosphamide, both alkylating agents, remain good therapies for those who do not need rapid debulking of their tumour mass. Combination chemotherapy with CVP (cyclophosphamide, vincristine, prednisolone – see Table 45.5) does not improve either overall survival or TTP compared with chlorambucil. However, with chlorambucil, response is faster, making this regimen a preferable option for patients with large tumour mass and/or significant symptoms.

Doxorubicin-containing regimens
The role of doxorubicin-containing regimens for indolent lymphoma remains unproven. The Southwestern Oncology Group (SWOG) reviewed survival data of 415 low-grade lymphoma patients treated with CHOP (see Table 45.5). Median survival in these patients approached 6.9 years, which was not higher than reported previously with less aggressive therapies. However, although several studies suggest that patients with high-grade histology (> 15 centroblasts per high-power field) do benefit from doxorubicin-containing regimens, achieving a prolonged TTP with improved overall survival, others failed to confirm this strategy.

It should be noted that part of these inconclusive results reflects changes in definitions in lymphoma grading over the last three decades, making these studies difficult to compare.

Nevertheless, there are still some patients for whom doxorubicin-containing regimens may be appropriate, although the data to support this approach remain controversial. Patients with grade III FL and those presented with constitutional symptoms, high tumour burden and elevated LDH (all parameters suggesting a more aggressive disease, despite the indolent histology) may be more appropriate for doxorubicin-containing combination.

Purine analogues
The more recent purine analogues – fludarabine, 2-chlorodeoxyadenosine (cladribine) and deoxycoformycin (pentostatin) – present a group of potently lymphotoxic antimetabolite agents, non-cross-resistant to alkylating agent therapy. Their activity in

the indolent NHLs, particularly in the follicular subtype, may be due to their unique ability as antimetabolites to inhibit resting as well as dividing cells.

Several retrospective studies suggested a higher response rate with single-agent fludarabine (FLU) compared with alkylating agent-based regimens. However, prospective randomized trials failed to confirm these results, suggesting CVP/CHVP interferon to be as good as single-agent fludarabine.

Several retrospective/phase I studies have suggested that fludarabine-containing combinations (e.g. FC, fludarabine, cyclophosphamide; FND, fludarabine, mitoxantrone, dexamethasone) are superior to traditional alkylating regimens or fludarabine only, providing a higher complete response (CR) rate in both therapy-naive and relapsed patients. Other studies, however, failed to repeat these results, emphasizing the need for prospective randomized trials.

The Bologna prospective randomized trial compared the outcome of 'treatment-naive' LGL/MCL patients, treated with FLU for 5 days versus fludarabine–idarubicin (FLU–ID) (FLU for 3 days, idarubicin, ID, 12 mg/m^2 on day 1). There was no difference in response rate between the two arms, but remission duration was significantly longer in those who received FLU–ID therapy ($P = 0.021$). However, it is unclear if this improvement translates into an improved survival, and it may increase treatment-related toxicity, particularly opportunistic infections that may sometimes be extremely severe. A phase III ECOG trial comparing fludarabine (25 mg/m^2, days 1–5) and cyclophosphamide (1000 mg/m^2, day 1) with CVP was prematurely closed as a result of excess deaths in the fludarabine arm.

Fludarabine does cause immunosuppression – resulting in increased incidence of opportunistic infection necessitating prophylaxis against *Pneumocystis carinii*. It may also cause myelosuppression and adversely affect stem cell harvesting. However, it is usually well tolerated and, as the introduction of an oral formulation, its use has become much easier. Several studies performed in patients with chronic lymphocytic leukaemia (CLL) and low-grade lymphoma, confirmed oral fludarabine to be as effective as the intravenous formulation.

Side-effects of chemotherapy

Chemotherapy-related side-effects should be seriously considered, taking into account the historical inability of chemotherapy to improve patients' survival. Chemotherapy may adversely affect quality of life, causing myelosuppression and immunosuppression with increased risk of infections. Myelodysplastic changes and increased risk of leukaemia were mainly reported with alkylating agents; however, these may also be associated with fludarabine. For young patients, infertility may be a primary concern of treatment.

Interferon

Recombinant interferon-alpha (IFN-α) has been used simultan-

eously with initial cytotoxic chemotherapy or as a maintenance therapy in patients who responded to initial chemotherapy aiming to enhance immunological response and prolong survival.

Interferon with induction chemotherapy

Several prospective randomized trials have compared the activity of IFN-α-containing regimens versus chemotherapy. Two studies only, both using anthracycline-containing regimens, revealed a statistically significant improved time to treatment failure (TTF) and DFS in those who received IFN as part of induction chemotherapy. A meta-analysis presented at the meeting of the American Society of Clinical Oncology in 1998 showed a statistically significantly longer survival in patients with high tumour mass, treated with anthracycline-containing regimens and high-dose IFN (5 megaunits, three times per week).

Interferon maintenance therapy

Although several prospective trials failed to show any survival advantage with IFN-α maintenance therapy, two observed a significantly prolonged remission duration ($P > 0.001$) and improved OS in patients who received IFN compared with those who had no maintenance treatment ($P > 0.001$). Both of these studies used a relatively high dose of IFN (5 megaunits, three times per week) for at least 1 year, suggesting that high-dose and long maintenance therapy is effective. IFN therefore remains a consideration for therapy but the optimal dose and duration of treatment are still unclear and, given the potential side effects, usage at present may be less attractive than other options.

Monoclonal antibodies

Although response rates and PFS may have improved slightly, the overall survival has not increased, and advanced indolent NHL remains essentially incurable without allogeneic bone marrow transplant. A number of new ways of outcome improvement are being investigated, including monoclonal antibodies (MAbs) targeted against specific antigens expressed by lymphoma cells (Table 45.6).

The cell-surface antigen CD20 is in many ways an ideal target as it is expressed by 95% of B-cell NHL cases but not on haemopoietic stem cells; it has a functional role in B-cell growth and also does not normally circulate as a free antigen in plasma, so the free antigen does not compete for antibody binding.

Rituximab is an anti-CD20 chimeric MAb which was the first approved for NHL treatment. Response is achieved through several mechanisms, including complement-dependent cytotoxicity (CDC), antibody-dependent cellular cytotoxicity (ADCC) and induction of apoptosis. Rituximab is also able to sensitize lymphoma cells to the cytotoxic activity of chemotherapy.

Previously untreated low-grade lymphoma

Single-agent therapy with rituximab appears to be effective in previously untreated low-grade NHL patients, yielding a high response rate of 62–73%, including 20–44% CRs.

Table 45.6 Monoclonal antibodies in NHL.

Antibody	Antigen	Conjugate
Rituximab (IDEC-C2B8: rituxan)	CD20	None
Alemtuzumab (Campath-1H)	CD52	None
HII2 (Epratuzumab)	CD22	None
Hu1D10 (Apolizumab Remitogen)	HLA-DR	None
Ibritumomab tiuxetan (IDEC-Y2B8: Zevalin)	CD20	^{90}Y
Tositumomab (Bexxar)	CD20	^{131}I
Immunotoxins	CD19, CD22	*Pseudomonas*
Ricin A, Shiga toxin		Exotoxin A (PE38)

Extended therapy has been suggested to be better than rituximab induction alone. A phase III trial comparing rituximab maintenance therapy with observation only (following rituximab induction) showed a significantly improved PFS in those who received rituximab maintenance, with no increase in treatment-related adverse events (Gianni *et al.*, 2003). Whether maintenance with rituximab to these complete responders can prolong survival remains to be seen.

The single-agent activity of rituximab, coupled with its distinct mechanisms of action, non-overlapping toxicity and ability to sensitize lymphoma cells to cytotoxic activity, has encouraged researchers to evaluate its combinations with chemotherapy. In a phase II trial, rituximab plus chemotherapy (CHOP or CVP) has demonstrated significant activity, achieving a high response rate of 97% (including 57% CR) in 82 patients with previously untreated FL.

A characteristic chromosomal translocation t(14;18), leading to an overexpression of *bcl-2*, an anti-apoptotic gene that may serve as a survival factor for lymphoma cells, is carried by 85% of patients with FL, and it can be detected by PCR. Achievement of molecular remission post therapy (clearance of *bcl-2*$^+$ cells) appears to be associated with prolonged PFS and may even predict a longer OS. Various chemotherapy regimens (e.g. FND–R, fludarabine, novantrone, dexamethasone; CHOP–R) have yielded similar results, reporting molecular remissions with prolonged PFS. Rituximab-containing chemotherapy regimens appear to increase both clinical and molecular remission rates when compared with those usually achieved with chemotherapy only, giving grounds for optimism.

An open multicentre randomized phase III study, comparing CVP (cyclophosphamide, vincristine, prednisolone) with CVP–rituximab (R-CVP) in previously untreated patients with FL stage III/IV, has recently confirmed R-CVP to be superior to CVP only, providing a significantly higher overall response rate (81% versus 57%, with 40% CRs versus 10% respectively: $P < 0.0001$) and prolonged TTF and TTP compared with CVP alone ($P < 0.0001$ for both parameters).

Relapsed low-grade lymphoma

Single-agent rituximab is also effective in relapsed disease, providing responses in 38–59% of patients, including CR in up to 28%. The pivotal trial in this setting reported an overall response rate (ORR) of 48%, with a median TTP of 13 months in responders (McLaughlin *et al.*, 1998). Nevertheless, responses are not durable and patients eventually relapse. Attempts to improve PFS by extending rituximab treatment or combining rituximab with chemotherapy are being undertaken at present. A study by the German Low-Grade Lymphoma Study Group is comparing the combination of fludarabine, cyclophosphamide and mitoxantrone (FCM) with rituximab plus FCM in patients with relapsed follicular and mantle cell lymphoma (MCL). Interim analyses showed an ORR of 83% in the immunochemotherapy arm compared with 53% for FCM alone, indicating that combined modality treatment may be superior to chemotherapy alone.

Many studies now suggest that combination immunochemotherapy may be more effective than single-agent rituximab or chemotherapy alone and thus this treatment may be offered to patients with relapsed disease who can tolerate a combined regimen. Results of prospective comparative trials are still needed, however, to confirm the superiority of this strategy.

New unconjugated antibodies and combinations of monoclonal antibodies

New MAbs directed at different antigens expressed by lymphoma cells are being investigated at present (anti-CD22, hLL2, epratuzumab; anti-DR, Hu1D10, remitogen, apolizumab and anti-CD19 MAbs; see Table 45.6). Hu1D10 is a humanized MAb, directed at a polymorphic determinant (1D10 antigen) on the HLA-DR β-chain expressed by normal and malignant B cells. A recent study found that it was well tolerated and effective in some patients with FL who did not respond to rituximab. Response occurred on day 100+ and was occasionally accompanied by development of new anti-lymphoma antibodies, detected months after Hu1D10 had cleared.

Alemtuzumab (Campath-1-H*)*, directed against CD52, may be used in both B- and T-cell NHL. An increased risk of opportunistic infection (related to T-cell depletion) may limit its use.

Combination of monoclonal antibodies

Combined MAbs directed at different antigens may have a synergistic effect, leading to increased response rate. Various combinations are being investigated (e.g. rituximab and alemtuzumab, rituximab and anti-CD22: epratuzumab). Data are still too limited to draw final conclusions about their potential toxicity and efficacy. In summary, there is little doubt about the efficacy of rituximab in FL, but there is still doubt as to whether

Table 45.7 Characteristics of currently available radioimmunoconjugates used in NHL.

Characteristics	^{131}I	^{90}Y
Emission	β and γ	β
Half-life	8 days	2.5 days
Energy	–	× 5
Imaging	Can be used for radioimmunoscintigraphy	Cannot be used for radioimmunoscintigraphy by conventional methods*
Stability	Rapid degradation after endocytosis	Retained stable by tumour cells after endocytosis
Hospitalization	Hospitalization	Outpatient*

*As a result of having no γ emission.

Table 45.8 Potential problems for using radioimmunoconjugates.

Needs a special knowledge and can be given by an expert only
Treatment with ^{131}I (emitting γ-particles) hospitalization for isolation
Accumulative toxicity may limit future stem cell harvesting
Long-term toxicity unknown (possibility of secondary malignancies)

any treatment significantly modifies the ultimate duration of disease.

Radiolabelled monoclonal antibodies (radioimmunoconjugates)

Lymphoma cells are sensitive to radiation, which makes them an ideal target for immunoradiotherapy. The radioimmunoconjugates kill tumour cells predominantly by radioactive emission and can therefore be effective in patients who do not respond to unconjugated antibodies (e.g. rituximab). The β-particles emitted by ^{131}I and ^{90}Y radioisotopes have high penetration (over many cell diameters), allowing eradication of tumour cells that are not expressing the targeted antigen but are adjacent to target CD20$^+$ cells; this is known as 'crossfire' effect.

The most common radioisotopes are ^{131}I (β/γ-emitter) and ^{90}Y (a pure β-emitter) (Table 45.7). Although ^{131}I is inexpensive and easily conjugated, ^{90}Y has five times more energy, a longer path length and a shorter half-life than ^{131}I (2.5 days versus 8 days). A potential problem with pure β-emitters (e.g. ^{90}Y) is that dosimetry is relatively complicated. However, pure β-emitters can be given to outpatients, as there is no radiation risk for those who come into contact with them. This risk is substantially higher with γ-particles (^{131}I) (Table 45.8).

Radioimmunoconjugates in patients with relapsed disease

During the past decade, two products directed against CD20 antigen – ^{131}I-labelled tositumomab and ^{90}Y-labelled ibritumomab tiuxetan – have been studied. Both products have produced response rates of 70–80% in patients with relapsed/treatment-naive low-grade lymphoma, and 50–60% in low-grade lymphoma that has transformed into an intermediate or high-grade lymphoma. Median duration of response to a single course of treatment approached 1 year. The treatment was well tolerated. However, prolonged myelosuppression with a potential risk of long-term myelodysplastic syndrome/myelogenous leukaemia was noted (Witzig *et al.*, 2003). A phase III trial, comparing rituximab with ^{90}Y-labelled ibritumomab tiuxetan in patients with relapsed/refractory low-grade lymphoma/transformed B-cell NHL, confirmed the efficacy of radioimmunoconjugates, showing a higher response rate in those who received ^{90}Y-labelled ibritumomab tiuxetan. There was no difference in median TTP, but durable responses (≥ 6 m) were more frequent in the radioimmunotherapy arm. Radioimmunoconjugates can even be effective in those who failed to respond to non-conjugated MAbs.

Radioimmunoconjugates in therapy-naive patients

The Southwest Oncology Group (SWOG) has recently reviewed the outcome of 90 previously untreated FL patients (Press *et al.*, 2003), treated with six cycles of CHOP followed by tositumomab/^{131}I-tositumomab (SWOG, Phase II trial, S9911). ORR was 90% (including 67% CRs) and 2-year PFS and OS were 81% and 97% respectively. Based on these encouraging results, SWOG has recently conducted a phase III prospective randomized trial, comparing CHOP–R with CHOP–tositumomab/^{131}I-tositumomab (S0016, ongoing trial).

Immunotoxins

Immunotoxins are specific antibodies connected to toxins through a linker that is easily cleavable on the malignant cell surface but stable while the toxin circulates in the blood. For the immunotoxin to be effective, the antigen should be expressed extensively on the surface of the targeted cell, and should be able to be internalized in response to antibody binding so that the toxin can kill the cell. The most commonly used toxins – ricin A, diphtheria, *Pseudomonas* exotoxin A (PE) and Shiga-like toxin-1 – kill by inhibiting protein synthesis. The efficacy and safety of most of these immunotoxins have yet to be proven. However, an

anti-CD22 immunotoxin (RFB4 (dsFv)-PE38 (BL22)) has been recently reported to be extremely potent in hairy cell leukaemia (HCL) patients who failed 2-CDA. As CD22 antigen is expressed by other lymphoproliferative disorders (i.e. MCL and DLCL), BL22 immunotoxin may also be applied in these patients.

Stem cell transplantation in low-grade non-Hodgkin's lymphoma

Autologous stem cell transplantation

There are increasing data suggesting autologous stem cell transplantation (ASCT) to be valuable in FL patients beyond CR1. The only prospective trial that compared SCT with observation in patients who obtained CR/PR following second-line chemotherapy, revealed an improved PFS and OS in transplanted patients (Schouten *et al.*, 2003). Bierman and colleagues (2003), on behalf of the EBMT/EBMTR and ABMTR, have recently reported increased survival in NHL patients treated with syngeneic SCT compared with allogeneic transplantation, suggesting high-dose therapy (HDT) to be highly effective. Furthermore, FL patients who received unpurged autografts had a five-times higher risk of relapse ($P = 0.008$) than recipients of syngeneic transplants, and recipients of unpurged autografts had a significantly increased relapse risk ($P = 0.0009$) compared with patients who received purged autografts, indicating SCT purging to be potentially valuable in these patients. DFS and OS were significantly better with purged versus unpurged autograft, $P = 0.003$ and $P = 0.04$ respectively.

Despite these encouraging results, there is still need for data from prospective randomized trials to confirm the beneficial effect of HDT and SCT purging on OS and DFS. The optimum timing of SCT (CR1 or beyond) remains to be determined by the ongoing randomized multicentre trial of the German Low-grade Lymphoma Study Group.

Non-conjugated monoclonal antibodies, radioimmunoconjugates and autologous stem cell transplantation

It is well established that conventional chemotherapy does not prolong survival in patients with low-grade lymphoma. However, ASCT may improve PFS, and most FL patients will eventually relapse due to contamination of the harvest product with lymphoma cells or re-growth of malignant cells that survived the HDT. Molecular remission before transplant appears to be linked to increase PFS. Therefore, it is tempting to try to purge the stem cells before transplantation, to minimize harvest contamination and reduce relapse risk. Similarly, it might be a reasonable approach to add rituximab post transplant (mopping up), aiming to eradicate residual cells that survived high-dose chemotherapy (ongoing EBMT Lym1 study). The efficacy of both stem cell purging/post-transplant 'mopping-up' is still debated, and results from prospective randomized trials are awaited.

Radioimmunoconjugates may also be used as part of ASCT in NHL, enabling the delivery of higher radiotherapy doses without significantly increasing treatment-related toxicity. Major studies were mainly performed in patients with high-grade lymphoma. However, there will be a role in low-grade lymphoma if proven to be effective and safe.

Allogeneic stem cell transplantation in low-grade lymphoma

Advanced low-grade lymphomas are usually incurable with conventional-dose chemotherapy. It is uncertain whether cures are possible with HDT and bone marrow transplant from a human leucocyte antigen (HLA)-identical sibling. Recent data from several studies suggest that allogeneic SCT is potentially curative (Bierman *et al.*, 2003), although the existence of a strong graft-versus-leukaemia (GvL) effect remains uncertain and treatment-related mortality (TRM) remains high.

Low-intensity stem cell transplantation (LI SCT) is being increasingly used for various kinds of haematological malignancies, aiming to exploit the curative potential of ASCT by inducing graft-versus-tumour effect without the morbidity and mortality associated with conventional transplantation. Several studies have recently suggested this approach to be less toxic and potentially curable in patients with low-grade lymphoma. However, data are still premature and need further evaluation with a longer follow-up.

Suggested algorithm for therapy of low-grade non-Hodgkin's lymphoma (mostly follicular lymphoma)

At diagnosis
Localized disease
Use of involved-field radiation.

Disseminated disease (stage III/IV)
Asymptomatic patient In asymptomatic patients a 'watch and wait' policy is generally appropriate. Younger patients with advanced asymptomatic disease my be considered for clinical trials (e.g. BNLI trial: rituximab in patients with stage III/IV asymptomatic FL).

Symptomatic patient Use of chemotherapy and/or immunotherapy to relieve symptoms. Treatment regimen should be chosen according to patient's performance status and age. Data regarding upfront SCT (performed in CR1) are still scanty, but there is some evidence to suggest that it may have a role, although this has to be confirmed in prospective randomized trials.

Relapsed disease At the time of relapse it is important to evaluate patients' symptoms and rule out biological progression as identified by histological evidence of progression, asynchronous

growth in prior disease sites, appearance of B symptoms and high LDH. Patients who have previously achieved a prolonged response to alkylating agents may be retreated, whereas those who failed to respond or progressed quickly may benefit from purine analogue-based therapies. The addition of MAbs may improve results even further. Histological evidence of transformation or clinical suspicion of more aggressive disease indicates the need for anthracycline-containing regimens.

Further intensification of treatment ASCT should be particularly considered in those who have an histological evidence of transformation. ASCT may be valuable in patients beyond CR1, providing a prolonged DFS and OS. Younger patients with progressive disease may be considered for allogeneic SCT, the only potentially curative therapy for patients with advanced disease. Useful outcomes have been seen in patients undergoing allogeneic SCT after failure of autograft but TRM remains an issue.

Marginal zone B-cell lymphoma (Figure 45.5)

The term 'marginal zone lymphoma' (MZL) is actually referring to three closely related lymphoma subtypes, including nodal, primary splenic and extranodal lymphomas of mucosa-associated lymphoid tissue (MALT) (see Chapter 43).

These lymphomas are characterized by mature B cells, lacking expression of CD5 and CD10. MALT lymphoma is described below in 'extranodal disease' (Figure 45.5).

(a)   (b)
Figure 45.5 Marginal zone lymphoma of a salivary gland. (a) Sheets of marginal zone B cells and formation of a lymphoepithelial lesion. (b) Immunoperoxidase stain for low molecular weight cytokeratin (MNF116) shows positive staining of normal epithelial cells infiltrated by lymphoma.

Splenic marginal zone lymphoma (with or without villous lymphocytes) and nodal variant

Splenic MZL often presents as splenomegaly with bone marrow and peripheral blood involvement, whereas lymph nodes/extranodal sites are usually spared. Splenic MZL is characterized by micronodular infiltration of the spleen with marginal-zone differentiation; the immunophenotype is usually IgM^+ $IgD^{+/-}$ cytoplasmic$^-$ $Ig^{-/+}$pan B antigens$^+$ $CD5^-$ $CD10^-$ $CD23^-$ $CD43^{-/+}$ cyclin D1$^-$. It generally tends to have an indolent course; however, autoimmune complications are often associated with tumour progression, with increase of blastic forms and shorter survival. To date, no definitive curative therapy has been established.

Splenectomy is considered to be the treatment of choice for symptomatic patients (pain, cytopenias), resulting in correction of pancytopenia and improvement of life quality (see Chapter 38).

The utility of purine analogues and anti-CD20 antibodies has to be clarified in prospective trials, although retrospective data suggest those modalities to be effective.

Waldenström's macroglobulinaemia

Waldenström's macroglobulinaemia (WM) represents a clonal expansion of post-germinal centre lymphoid cells expressing IgM, CD19 and CD20. High IgM levels may cause hyperviscosity syndrome, manifested with shortness of breath.

Patient management ranges from 'wait and see' for asymptomatic patients, through various types of chemotherapy agents (e.g. alkylating agents with/without steroids, purine nucleoside analogues), monoclonal antibodies (e.g. rituximab) and immunomodulators (e.g. thalidomide), to autologous/allogeneic SCT. Patients presenting with hyperviscosity also need adjuvant plasmapheresis.

Chemotherapy of Waldenström's macroglobulinaemia

Treatment of WM has been dependent on alkylating agents (e.g. chlorambucil) for years, resulting in 60% response rate with a median survival of about 60 months. Purine analogues (e.g. fludarabine and cladribine) appear to be active in both previously untreated patients and those who fail to respond to alkylating agents/relapsed disease, providing response rates of 38–85% and 30–50% respectively.

The only prospective randomized trial comparing an alkylating containing regimen (cyclophosphamide, doxorubicin, prednisolone – CAP) with fludarabine for patients with relapsed/primary refractory disease, observed an improved PFS in those

who received fludarabine. There are still no prospective random-ized data comparing these strategies as first-line therapy.

Monoclonal antibodies

Waldenström's macroglobulinaemia is a low-grade lympho-plasmacytoid lymphoma characterized by CD20 expression on malignant cells. Several studies have shown rituximab to be active in WM, providing responses in up to 35% of previously untreated patients. However, rituximab can cause a sudden rise in serum IgM and viscosity levels in certain patients, which may lead to complications; therefore, close monitoring of these parameters and symptoms of hyperviscosity is recommended during therapy. Similarly, Zevalin (^{90}Y-ibritumomab tiuxetan) is likely to be effective and a phase I trial evaluating this MAb in patients with WM is ongoing.

Stem cell transplantation for Waldenström's macroglobulinaemia

Several small studies reported encouraging results with ASCT in heavily pretreated patients, providing high response rates (95%), with improved PFS in some patients. Allogeneic SCT does produce prolonged remissions with potential cures com-pared with autograft, but TRM approaches 40%. Future strat-egies in WM will include a plan to evaluate the role of HDT along with biological agents (e.g. rituximab purging), mainten-ance strategies (including immunotherapy) and evaluation of non-myeloablative regimens containing fludarabine to achieve higher response rates and improve survival.

Novel therapies

The accumulating evidence regarding the efficacy of thalido-mide in myeloma encouraged investigators to explore its activity in WD. Dimopoulos and colleagues reported a response rate of 25% in heavily pretreated patients, treated with thalidomide, whereas combination therapy with thalidomide, dexametha-sone and clarithromycin resulted in a higher response rate, approaching 40–83% (Coleman et al., 2003).

The potential role of immune modulatory drugs (revimid, actimid) is being investigated at present. However, the number of patients included in these studies was small and further studies are needed to confirm thalidomide activity in WM. Several emerging therapies, including the proteasome inhibitor PS-341; inhibitors of the heatshock protein 90 (hsp90) molecu-lar chaperone (e.g. geldanamycin and its analogues); histone deacetylase inhibitors (e.g. suberoylanilide hydroxamic acid) are all being explored as potential agents for WM. These agents induce growth arrest and apoptosis of WM cells. A combination of these agents with chemotherapy may increase treatment effi-cacy, inhibiting diverse pathways that are important for tumour growth and survival.

Guidelines for Waldenström's macroglobulinaemia

The International Workshop on WM has recently published its recommendations for the treatment of patients with WM (Gertz et al., 2003).

1 Alkylating agents, nucleoside analogues (e.g. cladribine and fludarabine) and rituximab are reasonable choices for first-line therapy of WM. Combinations of alkylating agents, nucleoside analogues or rituximab should at this time be encouraged in the context of a clinical trial.

2 Patients with relapsed disease can be treated with an altern-ative first-line agent or re-use of the same agent. Thalidomide with/without chemotherapy can also be considered at relapse.

3 ASCT may be considered for patients with refractory or relapsing disease. (However, patients considered for ASCT may fail mobilization following treatment with alkylator or nucleo-side analogue.)

4 Allogeneic transplantation should only be undertaken in the context of a clinical trial. Plasmapheresis should be considered as interim therapy until definitive therapy can be initiated.

5 Splenectomy is rarely indicated but has been used to manage painful splenomegaly and hypersplenism.

Hairy cell leukaemia (see also Chapter 38)

Hairy cell leukaemia (HCL) is an uncommon B-cell chronic lymphoproliferative disorder characterized by an indolent course. The majority of patients do require therapy, having life-threatening infections due to pancytopenia or symptomatic splenomegaly. During the last 20 years, remarkable progress has been made in the treatment of HCL. Splenectomy, which used to be the treatment of choice, is rarely being used since the intro-duction of interferon alpha (IFN-α) in 1984. However, most interferon-induced responses are partial and not durable.

Purine analogues (cladribine, pentostatin) provide durable complete responses in the majority of patients, making these agents the treatment of choice, whereas IFN-α is reserved at pre-sent for those who fail to respond to purine analogues. Purine analogues are capable of re-inducing complete remissions in many of those who relapse.

Patients who fail to respond to purine analogues/IFN can be successfully treated with unconjugated/conjugated MAbs (recombinant immunotoxins), targeted against various antigens expressed by tumour cells. Rituximab has been recently shown to have variable activity in patients with relapsed/refractory HCL, providing responses in 25–80% of them. Two recom-binant immunotoxins, BL22 and LMB-2, targeting CD22 and CD25 respectively, have demonstrated to be active in patients with HCL resistant to purine analogues. BL22 was reported to induce complete remissions (CRs) in the majority of patients with cladribine-resistant HCL.
Figure 45.6 Irregular small lymphoid cells (small cleaved cells; centrocytes) typical of mantle cell lymphomas.

Mantle cell lymphoma (Figure 45.6)

Conventional chemotherapy regimens do improve PFS, but can rarely lead to cure. None of the following chemotherapeutic regimens – CVP, CHOP, fludarabine – seems to be significantly better than any other, providing an OS of only 3–4 years. The addition of rituximab to these regimens appears to result in increased remission rate. In a recent publication, CHOP–rituximab yielded a response rate of more than 90%, including 48% CR rate. However, PFS remains unsatisfactory, similar to that reported with CHOP.

Autologous ASCT in first CR may be beneficial, although a high proportion of patients will still relapse following transplant. Pretransplant immunological *ex vivo* purging has been suggested to improve patient outcome. Results were disappointing and the chances for patients to achieve molecular remission (MR) in the bone marrow harvest product were less than 15%.

Magni and colleagues (2000) have reported encouraging results with *in vivo* purging in mantle cell lymphoma (MCL) patients. Fifteen patients with NHL (including seven with newly diagnosed MCL and eight with relapsed FL/other low-grade lymphoma) were prospectively treated with two cycles of intensive chemotherapy, each one followed by two doses of rituximab. This regimen included two sessions of stem cell harvest and four sessions of stem cell re-infusion, carried out between chemotherapy courses. Results were compared with those of 10 matched patients who were treated concurrently with the same regimen, but without rituximab; 14 out of 15 patients in the 'high-dose rituximab' group achieved PCR-negative harvests, compared with 40% in the control group ($P = 0.007$). A recent update of this study (Gianni *et al.*, 2003) confirmed durable remissions (median follow up at 54 months), with an OS and EFS of 89% and 79%, respectively, compared with 42% and 18% in 35 age-matched historical control subjects, treated with chemotherapy only. Other groups have reported similar results.

Mopping up post transplant may also be useful, increasing the MR rate achieved with an autograft. The feasibility of both methods is being studied at present, with newly diagnosed MCL treated with CHOP–rituximab, followed by an autograft with post-transplant rituximab. An update of this ongoing phase II study has suggested increased molecular remission (MR) rate following rituximab maintenance (Mangel *et al.*, 2002). Pre- and post-transplant rituximab increases the MR rate obtained with autograft; however, the follow-up is still too short to confirm any survival advantage with both strategies.

The optimal timing for pretransplant purging/post-transplant rituximab, as well as the duration of the treatment are under investigation. New intensified chemotherapy regimens that include rituximab but preclude HDT–autograft, may provide the same response rate as observed with 'rituximab–HDT' regimens. Longer follow-up is needed to confirm the role of rituximab–HDT as part of the management of MCL.

Aggressive B-cell NHL

Treatment of diffuse large-cell lymphoma (DLCL) is mainly based on anthracycline-containing combinations, with or without adjuvant radiotherapy. However, there are some variations in treatment related to patient's age, performance status, number of poor prognostic factors at presentation (Table 45.3) and the presence of extranodal involvement (e.g. testis, Waldeyer's ring, bone marrow).

A large international trial suggested that in patients under 60 years of age, the presence of two of the following risk factors – raised LDH, stage III or IV and poor performance status

– predicts a lower chance to achieve CR and increased risk of relapse (Table 45.5).

Stage I disease

Overall survival in patients with 'laparotomy-confirmed' non-bulky localized disease (stage I/II) approaches 80% at 10 years from diagnosis. Local radiotherapy can be curative in up to 90% of patients with 'laparotomy-confirmed' stage I/IE disease. The majority of patients with 'clinically confirmed stage I/IE' do have occult disease in other areas (undetected without laparotomy), however, causing disease relapse outside the radiation field. The British National Lymphoma Investigation (BNLI) reported a 10-year DFS and OS of 45% and 67% respectively, in 243 patients who were treated with local radiotherapy for stage I/IE disease. In patients younger than 60 years ($n = 140$), the actuarial cause specific death approached 80%. It is therefore quite clear that local radiotherapy is insufficient and systemic treatment such as chemotherapy is necessary.

Shenkier and colleagues (2002) have suggested treating such patients with a brief chemotherapy course (three cycles of anthracycline-containing regimen) followed by radiotherapy, reporting a 10-year actuarial overall and progression-free survival rates of 63% and 74%, respectively, which is higher than previously reported with radiotherapy only. A prospective randomized trial, comparing both strategies, has also reported a significantly improved DFS and OS in patients who received combined modality treatment.

Stage II–IV disease

Patients with more advanced stages of disease should receive combination chemotherapy. It is now over 30 years since the doxorubicin-containing CHOP regimen was first introduced. Despite a CR rate of 60–70%, less than 40% remain disease free at 5 years from diagnosis. Since that time, different chemotherapy regimens have been introduced (e.g. MACOP–B, m-BACOD; Table 45.5), however, none of them has proved to be superior to CHOP. Several prospective studies have failed to show any advantage of intensified regimens over CHOP, supporting the continued usage of CHOP in B-cell DLCL. A study performed by the Eastern Cooperative Oncology Group (ECOG), comparing CHOP with m-BACOD in patients with stage III/IV disease, showed no difference in CR rate or OS between the two arms, whereas m-BACOD was more toxic. Similarly, a collaborative study of the Southwestern Oncology Group/Eastern Cooperative Oncology Group, comparing CHOP with three different intensified regimens (MACOP–B, m-BACOD and Pro–MACECytabom) showed no survival advantage of any of these regimens compared with CHOP.

Mature data from the BNLI trial, comparing CHOP with PACEBOM, have shown a survival advantage of PACEBOM in patients younger than 50 years ($P = 0.002$) and in those who had stage IV disease ($P = 0.02$), suggesting that an etoposide-containing multiagent weekly regimen may be superior to CHOP (Linch et al., 2000).

However, it should be noted that most of these phase III studies compared CHOP with various chemotherapy regimens that contained a lower dose of doxorubicin and/or cyclophosphamide – two of the most potent drugs in diffuse large B-cell lymphoma (DLCL) therapy, which may partially explain the inferiority of these combinations.

In contrast, intensified CHOP (escalated dose of cyclophosphamide/doxorubicin and/or shorter duration between cycles, with/without additional drugs; e.g. MTX/cytarabine) appears to increase CR rate and improve DFS. Several phase II studies have recently suggested these regimens to be highly potent and well tolerated, indicating the need for a phase III study to confirm its superiority compared with conventional CHOP. It is still unclear whether biweekly CHOP is preferable to dose-escalated CHOP; however, recent data from the Japanese Clinical Oncology Group prospective trial suggest both variants to be effective, but biweekly CHOP may be less toxic (Itoh et al., 2002).

Adjuvant immunotherapy has been suggested to improve patients' outcome. A prospective randomized trial in 399 elderly patients with previously untreated DLCL demonstrated a significant advantage for CHOP–R over CHOP alone (Coiffier et al., 2002). Patients in the CHOP–R group had a higher CR rate (75% versus 63%, $P = 0.005$), improved PFS (2-year disease progression of 9% versus 22%, $P = 0.007$; 2-year relapse rate of 14% versus 25%, $P = 0.002$) and increased OS (2-year OS 70% versus 57%, $P = 0.007$), with no significant increase in treatment-related toxicity. This study identified CHOP–R as the gold standard therapy in elderly patients with DLCL.

In contrast, the intergroup 4944 trial, comparing CHOP–R versus CHOP followed by rituximab (R) maintenance for elderly patients with DLCL, failed to show any differences in overall response rate or in early progression (6 months) between the two arms of induction (CHOP and CHOP–R). However, induction with CHOP–R (followed by R maintenance or observation) significantly prolonged time to treatment failure (TTF), whereas R maintenance also significantly prolonged TTF in responders. This advantage appeared limited to patients induced with CHOP alone. There was no significant difference in OS at 2.7 years' follow-up. It should be noted that this trial, in contrast to the GELA study, was not designed to directly compare CHOP–R with CHOP. Furthermore, rituximab in induction was applied differently, which might explain the differences between the two studies. Results of a similar ongoing study, comparing CHOP with CHOP–R in younger patients, are awaited.

Prophylactic therapy to the central nervous system

Patients with DLCL who present with a high International Prognostic Index (IPI) (particularly those with high LDH

and/or extranodal disease) are at higher risk for CNS relapse and should therefore receive CNS prophylactic therapy (see CNS prophylaxis, below).

Adjuvant radiotherapy

The role of adjuvant radiotherapy in DLCL remains controversial. Although this kind of radiotherapy is recommended at present for patients with stage I/II disease, it is unclear if adjuvant radiotherapy has any benefit in patients with advanced (stage III–IV) bulky disease, who had completed six to eight cycles of systemic combination chemotherapy. Several retrospective and one prospective randomized study, addressing this issue, suggested that adjuvant radiotherapy may be valuable, providing that an improved DFS and OS compared with chemotherapy alone.

Nieder and colleagues (2003) have recently proposed guidelines for radiotherapy in DLCL, based both on their experience and on the available literature. According to their recommendations, a tumour of less than 3.5 cm (possibly < 6 cm) can be treated with 30 or 30.6 Gy after achieving CR. Tumours of 7–10 cm may need a higher dose, i.e. 40 Gy, whereas larger masses may need up to 45 Gy. Adjuvant radiotherapy may improve both PFS and OS, reducing relapse rate in the irradiated field. Radiation may cause short/long-term side-effects; therefore, minimal effective doses should be delivered, aiming to minimize toxicity (salivary glands, orbital structures, lung, heart, etc.).

'Up-front' autologous stem cell transplantation

The role of up-front ASCT (performed in CR1 in patients with very high risk DLCL) is still controversial. The UKLG LY02 prospective randomized trial compared the outcome of poor-risk DLCL patients, treated with three courses of CHOP followed by BEAM/ASCT versus further cycles of CHOP. There was no significant difference in OS between the two arms. In contrast, the LNH87–2 prospective randomized trial observed improved survival in high-risk patients treated with up-front transplantation (with ASCT, 8-year DFS and OS were 55% and 64% versus 39% and 49% with conventional consolidation respectively). Improved results with ASCT were recently reported by another French group (Milpied *et al.*, 2004). Tandem transplant does not appear to add any survival advantage compared with a single transplant. Today, the potentially improved response to CHOP of adding rituximab, must cast future doubts on the value of up-front ASCT as consolidation.

Autologous stem cell transplantation in relapsed and primary refractory disease

Once a patient has failed initial chemotherapy, the prognosis is poor and long-term overall survival is less than 10%. High-

dose therapy followed by ASCT is effective only in those who have shown some response to conventional dose second-line chemotherapy prior to ASCT (PR or responsive relapse). Patients who progressed on first-line salvage therapy have a very low chance of responding to a second-line salvage regimen and should therefore be considered for experimental therapies, whereas those who respond could go ahead and have an ASCT. The prospective randomized multinational Parma trial confirmed the superiority of intensified treatment in patients with sensitive relapse, providing a significantly longer event-free survival.

The subgroup of patients that fails to respond to induction is defined as 'primary refractory disease'. Attempts to overcome this biological resistance, by early ASCT, have failed to achieve better results than conventional chemotherapy. ASCT should therefore be limited to those who respond to second-line chemotherapy.

Allogeneic stem cell transplantation in aggressive non-Hodgkin's lymphoma

Some patients are likely to have a very poor prognosis with conventional therapy, including those who failed ASCT, those presenting with a very high IPI and those with special subtypes of aggressive NHL (e.g. γδ T-cell NHL). Such patients may be considered for allogeneic SCT.

Several reports suggested allogeneic SCT to be potentially curative in high-risk patients with chemosensitive disease. There is no certainty regarding the existence of a strong graft-versus-leukaemia (GvL) effect in intermediate/high grade of the disease, whereas mortality following transplantation remains high, indicating that this treatment should be reserved for selected patients only. Data available at present regarding the role of low intensity SCT in aggressive NL appear to be even less promising because of a high relapse rate and a relatively high TRM (37%). The majority of patients included in these studies had very advanced disease, which might have adversely affected study results. Further studies that explore low-intensity SCT in earlier stages are awaited.

Aggressive T-cell lymphoma

Peripheral T-cell non-Hodgkin's lymphoma otherwise unspecified (Figure 45.7)

Peripheral T cell lymphomas (PTCL) derive from post-thymic T cells at various stages of differentiation. Several studies have suggested T-cell phenotype to be an independent prognostic factor associated with decreased DFS and OS. Treatment of T-cell lymphomas is based on multi-agent chemotherapy (e.g. CHOP); however, patients' outcome remains disappointing and the majority of patients die of their disease. At present, no chemotherapy regimens have been found to be superior to CHOP. The
Figure 45.7 Peripheral T-cell lymphoma. Expansion of the paracortical region of a lymph node, with wide separation of germinal follicles.

ability of upfront ASCT (performed in CR1) to improve long-term outcome remains controversial. Further studies evaluating new combination chemotherapies, HDT (both up-front ASCT and allogeneic SCT) are required.

CD30⁺ anaplastic large-cell lymphoma

Two entities of systemic ALCL have been identified: ALCL ALK (anaplastic lymphoma kinase)⁺ and ALCL ALK⁻. ALK expression is caused by chromosomal translocations, most commonly t(2;5), causing the *NPM* gene, located at 5q35 to fuse with gene at 2p23⁻ encoding the receptor tyrosine kinase ALK. The *ALK* gene comes under the control of the *NPM* promoter, resulting in a permanent transcription of the *NPM–ALK* hybrid gene into a 80-kDa chimeric protein named NPM–ALK or p80. The new protein appears to have mitogenic activity, promoting T-cell transformation and tumour growth.

Systemic ALCL ALK⁺ occurs mainly in young males and is characterized by an aggressive course without therapy. Combination chemotherapy (e.g. CHOP) does improve survival; however, long-term outcome in those who present with intermediate/high-risk IPI is disappointing (5-year OS: 41% versus 94% in patients with low-risk IPI), emphasizing the need for new therapeutic modalities in this subgroup of patients. These patients should probably be enrolled into clinical trials, looking

at the value of more intensified regimen with or without up-front ASCT. Specific therapies such as MAbs directed against CD30 and/or specific inhibitors of NMP–ALK (Bonvini *et al.*, 2002) should also be explored.

Unfortunately, patients with ALCL ALK⁻ appear to be less responsive to combination chemotherapy, achieving a 5-year OS of less than 50% (15–45%). The role of HDT followed by up-front autologous/allogeneic SCT is under investigation.

Secondary central nervous system lymphoma in aggressive non-Hodgkin's lymphoma

It is established that less than 2% of low-grade lymphoma patients develop CNS involvement, compared with 5% in DLCL patients and 80% in those who have Burkitt's/Burkitt-like/lymphoblastic lymphoma and do not receive prophylactic therapy.

Secondary central nervous system lymphoma in patients with diffuse large-cell lymphoma

About 5% of DLCL patients may develop CNS relapse within 1 year, with or without a simultaneous systemic relapse. Several risk factors for CNS involvement have been suggested, which include advanced stage of disease (III, IV), elevated LDH, involvement of more than one extranodal site, involvement of testis/bone marrow/paranasal sinuses/Waldeyer ring, B symptoms and high IPI (Table 45.9).

Haioun and colleagues (2000) from the Groupe d'Etudes des Lymphomes de l'Adulte have reported the outcome of 1373 patients with aggressive NHL (excluding patients with lymphoblastic/Burkitt's lymphoma), treated with chemotherapy regimen including CNS prophylactic therapy with IT MTX with each cycle and two pulses of 2 g/m² of MTX. Despite receiving CNS prophylactic therapy, 22 patients developed CNS relapses (16 isolated). Multivariate analysis showed increased LDH and more than one extranodal involvement to be independent risk factors for CNS relapse.

Table 45.9 Risk factors for CNS involvement.

High IPI score
Extranodal sites involved (0 or 1 versus > 1)
Raised LDH level
Age < 60 years
Specific involvement of the following organs: bone marrow, testis, paranasal sinuses and Waldeyer's ring
Low albumin level
Retroperitoneal glands

Further analysis proved high IPI to be the only independent parameter associated with increased risk for CNS disease (low and low-intermediate versus high-intermediate and high IPI, relative risk = 7). The outcome of those who developed CNS relapse was extremely poor, with a median survival of less than 6 months.

The Norwegian study, which is the largest study ever published on CNS involvement in patients with DLCL, confirmed high IPI to be strongly associated with increased risk for CNS relapse (Hollender *et al.*, 2002).

What is the best prophylactic therapy and who should receive it?

Patients with FL or other lymphocytic lymphoma, having a very low risk to develop CNS relapse (< 1%), should not receive any CNS prophylactic therapy. Patients with DLCL and those with 'peripheral T-cell lymphoma not otherwise specified' (PCTL-NOS) appear to have a higher risk for CNS relapse and may therefore need CNS prophylactic therapy. Patients presenting with a high IPI score (particularly those who have a high LDH level or involvement of more than one extranodal site) have the highest risk for CNS relapse.

The question of the best CNS prophylactic therapy remains unclear. It seems that CNS prophylactic therapy based on intrathecal therapy (IT) only should be relatively prolonged (> 6 ITs), otherwise it is unable to eliminate relapse risk completely, but can only reduce it.

The efficacy of systemic methotrexate (MTX) in the absence of IT MTX is being investigated at present by the joint study of Southwestern Oncology Group and Eastern Cooperative Oncology Group (SWOG/ECOG), which compares m-BACOD, MACOP–B CHOP and PROMACE–CYTABOM, using different doses of MTX (200 mg/m^2, 400 mg/m^2 and 1500 mg/m^2). It is worth noting that the highest dose only has a significant CNS efficacy.

High-dose cytarabine (10 g/m^2 or higher) may also be a reasonable option for CNS prophylaxis, reducing CNS relapse rate in ALL patients (who are at higher risk for CNS involvement). Incorporation of high-dose cytarabine/MTX (> 2–3 g/m^2) may be particularly useful in patients with a high IPI. Further studies evaluating prospectively long-term toxicity and efficacy of each of these strategies are required.

Suggested algorithm for therapy of aggressive non-Hodgkin's lymphoma (summary)

At diagnosis
• Anthracyclines containing combination chemotherapy, with/ without rituximab (CHOP–rituximab) are already proven to be superior to CHOP in patients who are more than 60 years old).
• Patients with intermediate-high/high IPI (particularly those

who present with raised LDH and/or extranodal involvement) should receive CNS prophylactic therapy.
• Adjuvant radiotherapy may be considered in patients with bulky disease.
• No clear role for up-front ASCT (performed in CR1).

At relapse
• Second-line regimens (e.g. ESHAP, DVIP, DHAP, mini-BEAM), followed by ASCT.
• Allogeneic SCT may be considered in patients who failed ASCT/special subtypes of NHL (e.g. γδ lymphoma).

High-grade lymphoma

Burkitt's lymphoma and small non-cleaved Burkitt's-like lymphoma (Figure 45.8)

These are highly aggressive forms of non-Hodgkin's lymphoma, frequently involving extranodal organs (e.g. CNS, in 20%) but usually without tumour cells detected in the peripheral blood and characterized by dysregulation of c-*MYC* oncogene.

Treatment of these patients is based on multidrug combination chemotherapy, including drugs which highly penetrate CNS (e.g. CODOX–M/IVAC regimen, hyper CVAD) (Table 45.5). Approximately 50–80% of adult patients can be cured with these intensive chemotherapy regimens, and in paediatric populations the cure rate is even higher.

The risk for tumour lysis syndrome (TLS), especially after initiating chemotherapy, is relatively high, reflecting the high proliferation rate of tumour cells. Vigorous hydration with alkalinization, accompanied by administration of uric acid synthesis inhibitor (e.g. allopurinol)/recombinant urate oxidase (rasburicase), are very important in preventing/reducing the severity of this complication (see also Chapter 36). Hypercalcaemia is also frequent at presentation and needs appropriate therapy with, for example, hydration and biphosphonate.
Figure 45.8 Burkitt's lymphoma. Sheets of lymphoblasts and 'starry sky' tangible body macrophages.

Lymphoblastic lymphoma

These are actually derived from early B/T cells, and should therefore be treated as ALL (see Chapters 32 and 33). High-dose therapy with total body irradiation–autograft in first remission gives as good an outcome as extended chemotherapy, whereas the role of allogeneic SCT is probably spared for the relapsed patients. Allogeneic SCT provides a lower relapse rate compared with autograft; however, long-term survival is not necessarily higher due to increased TRM as observed with allograft.

Extranodal lymphomas

At least 25% of NHLs arise from tissues other than lymph nodes, including sites that normally contain no lymphatic tissue. The incidence of NHL, particularly primary extranodal lymphoma (ENL), is gradually increasing (e.g. primary CNS/gastrointestinal/breast), most probably due to the increase in viral infections, especially HIV, and exposure to environmental factors.

Primary gastrointestinal lymphoma

Gastrointestinal (GI) lymphoma is the most common form of extranodal lymphoma, accounting for 30–40% of cases.

Mucosa-associated lymphoid tissue and marginal zone lymphoma

Helicobacter pylori infection appears to be a possible causative agent for development of gastric malt lymphoma. Eradication of *H. pylori* with antibiotics appears to be initial effective therapy for localized gastric mucosa-associated lymphoid tissue (MALT) lymphoma. Preliminary analysis of the LY03 trial (International Extranodal Lymphoma Study Group, the United Kingdom Lymphoma Group and the Groupe d'Etude des Lymphomes de l'Adulte) confirmed that at least one-half of the cases treated with antibiotics achieve histological CR (Zucca *et al.*, 2002). Median time for optimal response is 6 months, but some patients require even 24 months to achieve CR. Response rate is the highest in those whose disease is restricted to mucosa (78%), and in those who have no nodal involvement by endoscopic ultra-sonography. The extent of tumour penetration into the gastric wall is inversely correlated with CR rate.

Based on these data it seems reasonable to treat localized disease with antibiotic therapy, followed by a strict endoscopic follow-up, including multiple biopsies 2 months after therapy to confirm eradication of bacteria, with repeated endoscopies and biopsies at least twice per year for 2 years to confirm histological regression of the tumour.

Histological complete remission (hCR) does not necessarily predict cure: PCR for the detection of monoclonality remains positive in approximately one-half of those who achieved hCR, suggesting a suppression, but not eradication of the lymphoma clone. In cases of unsuccessful eradication of *H. pylori* (PR/resist-

ance disease), a second-line high-dose anti-*H. pylori* therapy should be addressed, containing three or four drugs, omeprazole being one of them (e.g. omeprazole, bismuth citrate, metronidazole, tetracycline). Those patients whose tumour fails to regress despite second-line therapy frequently express t(11;18) and those who present with *H. pylori*-negative localized gastric lymphoma may still respond to chemotherapy (e.g. oral cyclophosphamide/chlorambucil), radiotherapy, surgery or combinations of these treatments (e.g. surgery with chemotherapy). At present there are no prospective randomized trials comparing these modalities. Recent data suggest low-dose radiotherapy to be effective for patients with stage I/II disease, providing a 5-year DFS of 93%.

Surgery may offer excellent control of disease, but without a total gastrectomy, there is no guarantee for cure, as disease tends to be multifocal, involving areas that may look macroscopically normal. Patients with advanced-stage disease are unlikely to be cured with antibiotics only and are therefore treated with systemic chemotherapy/immunotherapy up front.

Diffuse large-cell lymphoma of the stomach

Advanced gastrointestinal DLCL tends to behave like a primarily nodal advanced disease. These tumours were traditionally treated with gastrectomy, however, recent data suggest that this strategy is unnecessary in most cases, where combination chemotherapy with or without adjuvant radiotherapy provides high response and cure rates. At present, the International Extranodal Lymphoma Study Group is investigating the role of short-course chemotherapy, followed by involved-field radiotherapy, in patients with localized gastric DLCL.

In some cases, histological transformation of mucosa-associated lymphoid tissue (MALT) lymphoma might occur and therefore it may be reasonable to add an anti-*H. pylori* therapy, aiming to eradicate the bacteria and avoid potential relapses. Furthermore, anti-*H. pylori* therapy applied in these '*H. pylori*-positive cases' yielded a high response rate, indicating a 'pathogenic dependency' on *H. pylori* infection.

Diffuse large-cell lymphoma of the intestine

At present, there are no studies that demonstrate surgery to be unnecessary, and management is therefore based on surgical resection followed by systemic chemotherapy.

Immunoproliferative small intestinal disease

Immunoproliferative small intestinal disease (IPSID) (also known as α-chain disease) arises in small intestinal mucosa-associated lymphoid tissue (MALT) and is characterized by the expression of a monotypic truncated Ig α-heavy chain without an associated light chain. IPSID is mostly found in young adults of low socioeconomic class in developing countries. The aetiology of this disease is unclear, although various causative pathogens (e.g. *Campylobacter jejuni*), and genetic and toxic mechanisms have been proposed.

One-half of all IPSID patients present with concurrent intestinal B-cell lymphoma, whereas most of the remaining patients develop frank lymphoma within a few years. Whereas patients with early-stage disease may respond to antibiotics, those who present with more advanced disease should be treated with chemotherapy.

Enteropathy-associated T-cell lymphoma

Enteropathy-associated T-cell lymphoma (EATCL) arises in the setting of gluten-induced enteropathy and evolves from reactive intraepithelial lymphocytes through a low-grade lymphocytic neoplasm to a high-grade tumour, which is usually the cause of the presenting symptoms. A gluten-free diet appears to markedly reduce the risk for lymphoma; those who have already developed EATCL should receive specific therapy (e.g. CHOP), although there are no specific guidelines on how to treat these patients.

Non-gastric mucosa-associated lymphoid tissue lymphoma (non-gastric MALT)

Mucosa-associated lymphoid tissue (MALT) lymphoma can also occur in salivary glands, skin, thyroid, conjunctiva, orbit, larynx, lung, breast, kidney, liver and prostate; in these cases it tends to have an indolent course. Treatment should be 'patient-tailored', considering the site of disease and the patient's symptoms. Management therefore ranges from a 'watch and wait' policy, through various kinds of therapy, including chemotherapy, monoclonal antibodies (e.g. rituximab) to radiotherapy and surgery.

Primary cutaneous lymphoma

Primary cutaneous B and T lymphomas represent a heterogeneous group, characterized by isolated accumulation of malignant lymphocytes originating in the skin, without extracutaneous manifestations at presentation and during the first 6 months thereafter.

Cutaneous T-cell lymphoma

Cutaneous T-cell lymphoma represents a group of skin lymphomas, characterized by a dominant filtration of clonal T cells (see also Chapter 39).

Mycosis fungoides (MF), the most common form of CTCL, has an indolent course, unless nodal/visceral involvement exists. The treatment is mainly palliative and is based on 'skin targeted modalities', including PUVA, electron beam radiation, narrowband UVA (NB-UVA), topical steroids, nitrogen mustard, carmustine and vitamin D. PUVA and NB-UVA remain the gold standard therapy at early stages (IA/IIA), whereas systemic therapies are reserved for more advanced stages. Treatment options in these cases may include chlorambucil, methotrexate, doxorubicin, etoposide, retinoids, rexinoids, interferon, extracorporal photopheresis, interferon alpha/gamma, or conjugated monoclonal antibodies (e.g. anti-CD52) and immunotoxins (e.g. IL-2 receptor-specific fusion protein combined with diphtheria toxin, which selectively target the IL-2 receptor on malignant and activated T cells). Systemic therapies are frequently combined with topical agents. INF-α with or without phototherapy appears to be highly effective in advanced disease, providing responses in up to 80% of patients. Other immunomodulatory agents, such as recombinant human IL-2, anti-adiotype vaccines and gene therapies, are under investigation.

Young patients with biologically aggressive disease who failed conventional therapies may be considered for allogeneic SCT.

Sézary's syndrome

Sézary's syndrome (SS) is an aggressive CTL, characterized by erythrodema, lymphadenopathy and circulating malignant T cells with ceribriform nuclei. Therapy is usually based on a combination of systemic and topical therapy; chemotherapy agents (e.g. alkylators, including temozolomide), IL-2 diphtheria toxin, retinoids/rexonoid, accompanied with topical steroids or PUVA. Extracorporal photopheresis may also be effective, especially in those who present with a low number of circulating Sézary cells. Several groups have recently reported a dramatic response to anti-CD52 MAbs.

CD30+ large-cell lymphoma is the most common form of non-MF primary CTLC that appears to have an indolent course, with a 5-year survival in 90% of cases. These patients are usually treated successfully with spot radiation or surgical excision, and only those who progress are considered for systemic treatment. On the other hand, patients with CD30− T-cell large-cell lymphoma tend to have aggressive disease with poor prognosis and should therefore receive multi-agent systemic chemotherapy at diagnosis, irrespective of disease stage.

Cutaneous B-cell lymphoma

Primary cutaneous B-cell lymphoma (CBCL) presents a group of lymphomas characterized by dominant infiltration of clonal B cells in the skin. Follicle centre lymphoma (FCL), the most frequent CBCL, is characterized by a localized slowly progressive lesion in the neck/head or trunk and is associated with an excellent prognosis (5-year OS > 90%). Local radiation remains the preferred therapy for patients with localized disease (localized with regional satellites), whereas those who present with disseminated skin disease may be observed or treated with systemic chemotherapy with or without MoABs (e.g. rituximab).

Immunocytoma (marginal zone lymphoma), the second most common CBCL, is also considered to have an indolent course with a 5-year OS approaching 97%. Patient management is similar to that of patients with FCL. A more aggressive type of CBCL, represented with nodules/tumours on one or both legs, is called '*large-cell lymphoma of the leg*'. Despite its less indolent nature, the treatment of choice for early stages remains local (local radiation or excision), whereas those who present with disseminated disease are treated with systemic chemotherapy with or without adjuvant MAbs.

In summary, primary cutaneous lymphomas present a heterogeneous group of B- and T-cell lymphomas with a variety of clinical presentations and prognoses. Accurate diagnosis and assessment of prognostic factors determine patients' management. The majority of patients should be considered for conservative palliative therapy (e.g. local or topical treatments), unless they present with histologically aggressive lymphoma (e.g. large-cell CTCL) or disseminated stage of an 'indolent' disease (extracutaneous involvement), for which they should receive systemic therapy. New emerging therapies (MAbs, topical and systemic rexinoids, recombinant toxins and immunomodulators) may succeed in improving long-term outcome; however, further studies are needed.

Primary central nervous system lymphoma

Primary CNS lymphoma is defined as lymphoma arising in the cranial–spinal axis (brain, spinal cord, leptomeninges and eye). It is usually disseminated within the nervous system at presentation (in 50% of immunocompetent patients and in nearly 100% of AIDS patients). The histology in most cases is compatible with DLCLs (90%) or non-cleaved cell lymphoma.

Age, poor performance status, involvement of deep structures, high LDH level and a high protein level in cerebrospinal fluid (CSF) appear to predict poor prognosis. Until recently, the traditional therapy was based on whole-brain radiation. Unfortunately, the relapse rate within/outside the radiation field approached 90% and 5-year survival was less than 10%, suggesting that radiotherapy is insufficient. Combination therapy, however (chemotherapy with radiotherapy), appears to be more effective, providing a 5-year OS of 30–50%, but may cause delayed neurotoxicity, especially in patients older than 60 years. Several studies suggested 'high-dose methotrexate (MTX)-containing regimens' to be as good as combined modality treatment, but less neurotoxic. Therefore, chemotherapy should become the standard therapy in elderly patients, whereas radiotherapy should be reserved for those who relapse or fail to respond to chemotherapy.

Chemoradiotherapy is at present the standard treatment in younger patients. However, further attempts to reduce long-term neurotoxicity in this group, delivering lower doses of radiotherapy/omitting radiotherapy, but providing intensified chemotherapy regimens such as up-front ASCT, should be explored.

Lymphoma in the immunocompromised patient

Most frequently the disease is diagnosed in patients with *acquired* immunodeficiency, caused by HIV infection (AIDS-related lymphoma) or immunosuppresive drugs (e.g. post-transplant lymphoproliferative disorder).

Post transplant lymphoproliferative disorders (PTLDs) range from polyclonal plasmacytic hyperplasia, up to monoclonal B-cell proliferation, polymorphic hyperplasia/lymphoma, immunoblastic lymphoma or myeloma. EBV virus causes the majority of these disorders: impaired T-cell function leads to proliferation of EBV latently infected polyclonal B cells, whereas subsequent genomic mutations result in monoclonal PTLD.

Prevention of EBV infection/reactivation may therefore be essential. Antiviral agents (e.g. aciclovir, ganciclovir), passive immunotherapy and pre-emptive immunotherapy, using cytotoxic T lymphocytes targeted against EBV, are all applied to prevent PTLDs, with variable success. Patients who develop PTLD may respond to reduction in immunosuppressive therapy, especially those who develop PTLD within 1 year from transplant (ORR = 80% versus 10% in patients who developed PTLD beyond 1 year).

Anti-B cell MAbs (e.g. anti-CD20, anti-CD21 and anti-CD24) are also effective, providing responses in 65% of patients. IFN-α, being an antiviral and anti-tumour agent, was shown to induce prolonged remissions when combined with reduction in immunosuppression. Chemotherapy is usually reserved for those patients who have failed to respond to previous modalities. Lower doses of chemotherapy (e.g. reduced CHOP) appear to be highly effective but less toxic than conventional regimens. Adoptive immunotherapy following allogeneic SCT may also be effective. Donor lymphocyte infusion (DLI) may cause severe GvHD, limiting their use. In contrast, antiEBV cytotoxic T lymphocytes do provide a more specific effect, but are less available, being produced over weeks to months by expert laboratories.

AIDS-related non-Hodgkin's lymphoma

The histological diagnosis in the majority of such patients is DLCL (60%) or Burkitt's lymphoma (30%). Combination chemotherapy is the treatment of choice. Treatment-related toxicity might be higher than observed in non-HIV patients, especially in those with advanced AIDS disease. Therapy should be individually tailored; therefore, those who have advanced AIDS and limited anti-retroviral therapeutic options should receive a palliative chemotherapy (e.g. oral prednisolone, bleomycin)/radiotherapy, whereas those who have early disease/good performance status may tolerate curative chemotherapy regimens (e.g. reduced dose/conventional dose of CHOP/m-BACOD/CDE/EPOCH/CODOX–M/IVAC) with or without rituximab. Recent publications indicate that concurrent treatment with highly active anti-retroviral therapy (HAART) significantly improves the outcome of HIV-related NHL, providing an OS and DFS similar to that of non-HIV patients.

Lymphoma in elderly patients

DLCL accounts for 50% of lymphomas in patients older than 60 years. Unfortunately, the outcome in this population is worse

than that observed in younger adults, partly because of the high incidence of co-existing medical problems, affecting organ function. Attempts to improve patients' outcome, providing intensified chemotherapy regimens (compared with CHOP), ended with increased toxicity without improvement in survival, whereas less toxic regimens were often less effective. However, the prospective randomized GELA study, comparing CHOP with CHOP–rituximab (CHOP–R), has recently reported an improved DFS and OS in elderly patients (> 60 years) treated with CHOP–R, with no increase in treatment-related toxicity.

The addition of granulocyte colony-stimulating factors (G-CSF) can shorten duration of neutropenia, enabling the delivery of chemotherapy at the planned time and dose intensity. Several studies have recently reported encouraging results with HDT/ASCT in patients older than 60 (4-year OS in patients with chemosensitive relapsed disease approached 40%), indicating the feasibility of this treatment in selected patients.

Myeloproliferative disorders

George Vassiliou and Anthony R Green

Introduction

For the purposes of this chapter, the term myeloproliferative disorders (MPDs) will refer to clonal disorders of haemopoiesis that lead to an increase in the numbers of one or more mature blood cell progeny. The chronic myeloid leukaemias would fit this definition and share pathogenetic features with some of the MPDs, but have, historically (since the discovery of the Philadelphia chromosome), been studied separately from the MPDs and are described in Chapter 37. The myelodysplastic syndromes (MDS) can also, in a minority of cases, fit our working definition of MPD, in being associated with increased numbers of mature cell progeny, but dysplasia is a major feature and there are, usually, co-existing cytopenias. Not surprisingly, a small number of patients do not fit neatly into a single category and exhibit features of both MPD and MDS (see also Chapter 40).

This chapter will focus on the classical MPDs: polycythaemia (rubra) vera (PV), essential thrombocythaemia (ET) and idiopathic myelofibrosis (IMF), three related disorders originally grouped together by Dameshek in 1951. These disorders share clinical, morphological and molecular features and can transform, in their course, into one another. They are believed to be clonal disorders of the pluripotent haemopoietic stem cell and all have, albeit to varying degrees, the potential to transform into acute myeloid leukaemia (AML). Secondary (non-clonal) polycythaemias and thrombocytoses will also be described in this chapter, as they often enter the differential diagnosis of their clonal counterparts.

In addition, some of the less common MPDs will be described, namely mastocytosis and its variants, the clonal eosinophilic syndromes and chronic neutrophilic leukaemia (CNL) (see also Chapter 37). The ontogeny of the target cell for transformation is less well established in these disorders, but there is accumulating evidence implicating the pluripotent haemopoietic stem cell in at least some cases.

The polycythaemias

True polycythaemia refers to an absolute increase in total body red cell volume (or mass), which usually manifests itself as a raised haemoglobin (Hb) concentration and/or packed cell volume (PCV). A raised Hb (or PCV) can also be secondary to a reduction in plasma volume, without an increase in total red cell volume; this is known as apparent (or relative) polycythaemia.

True polycythaemia is further subdivided into primary polycythaemia (polycythaemia vera), a clonal haematological disorder, and secondary polycythaemia, which results from an increased erythropoietin drive, either in the presence or in the absence of hypoxia (Figure 46.1).

Polycythaemia vera

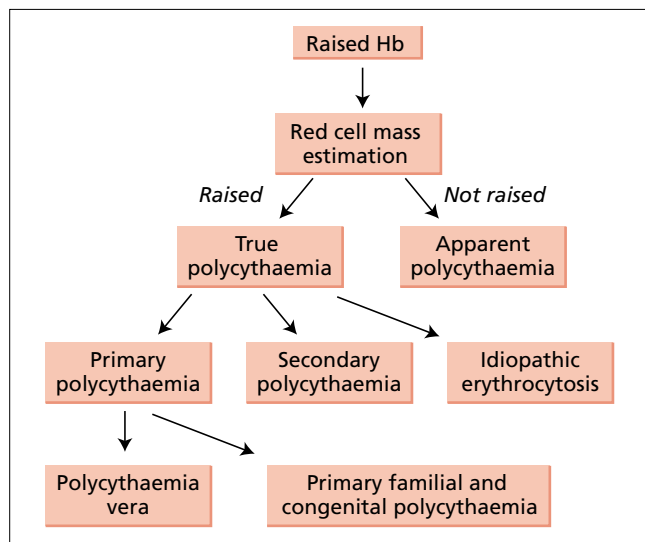
The central pathological feature of PV is an expansion in the total red cell mass, although elevations in the platelet and/or


Figure 46.1 An aetiological classification of polycythaemia.

neutrophil counts are relatively common. The first description of PV was by Vaquez in 1892. Oscier, in 1903, published the first series of patients, identifying salient clinical features setting PV apart from other erythrocytoses. Considerable information has been gathered about PV since the work of these pioneers, much of it due to the work of the Polycythaemia Vera Study Group (PVSG), which was set up in 1967 with the aim of optimizing diagnosis and management of PV.

Pathophysiology

PV is a stem cell disorder characterized by hyperplasia of all three major haemopoietic cell lineages. The first line of evidence in support of the stem cell origin of PV came in the form of clonality studies. Using X-chromosome inactivation patterns (XCIPs) in the mid-1970s, Fialkow and colleagues showed that neutrophils, erythrocytes and platelets originated from the same clone. Subsequent studies have confirmed these findings in large groups of patients.

Erythropoiesis is autonomous and does not appear to rely on erythropoietin. Plasma levels of this hormone are reduced in PV patients and PV progenitor cells, unlike normal ones, can survive *in vitro* and give rise to erythroid colonies (BFU-E) in the absence of added erythropoietin (endogenous erythroid colonies, EECs). Increased sensitivity of PV erythroid progenitors to several growth factors including erythropoietin, insulin-like growth factor 1, thrombopoietin, interleukin 3 (IL-3), and granulocyte/monocyte colony-stimulating factor has also been documented.

The precise molecular basis of PV, however, remains elusive and this is in large part due to the absence of pathognomonic chromosomal abnormalities. Chromosomal abnormalities do, however, occur in about 20–30% of patients with PV. The com-

monest such abnormalities are in decreasing order of incidence: deletion of part of the long arm of chromosome 20, trisomy 8, trisomy 9, duplication of part of the long arm of chromosome 1 and deletion of part of the long arm of chromosome 13. It remains unclear if these abnormalities are causative, if they are sufficient to cause PV or if they are acquired during its course. Abnormalities of chromosomes 5 and 7 are usually seen in association with disease progression, usually in the context of prior exposure to genotoxic therapy. As regards recurrent chromosomal deletions a significant amount of effort has gone into the delineation of the common deleted regions (i.e. the minimum regions deleted in all cases) in an attempt to identify critical target genes. In the case of chromosome 20q, the common deleted region has been narrowed to two megabases of genomic DNA, but no specific causative genes have been identified as yet.

Elsewhere in the genome, a number of molecular abnormalities have been observed. In particular, the mRNA of the gene *PRV-1*, which encodes neutrophil antigen NB1, was found to be overexpressed in granulocytes from PV patients when compared with normal control subjects or patients with secondary erythrocytoses, an observation which may provide a useful diagnostic tool. PV erythroid progenitors have been reported to overexpress the anti-apoptotic protein Bcl–xL but the significance of this observation remains obscure. In addition, expression of the thrombopoietin receptor in platelets is markedly reduced or absent in PV patients, as in patients with ET and IMF, and this is associated with impaired protein phosphorylation in response to thrombopoietin, while the response to thrombin is maintained. All of these abnormalities are likely to represent secondary changes but the primary causal event remains unknown.

Clinical features

Epidemiology

The annual incidence of PV is reported to be around 2–3 per 100 000 of the population with a male–female ratio of 0.8:1.2. The median age at onset is 55–60 years and although incidence increases with age, PV can occur at any age even, rarely, in childhood.

Thrombotic complications

Thrombosis is the most common serious complication of PV. Untreated PV patients run a greatly increased risk of thrombosis, which can be arterial, venous or microvascular. The increased PCV leads to an increased blood viscosity, rheological abnormalities and abnormal platelet–endothelial contact. Additionally, procoagulant changes in platelets (e.g. decreased response to prostaglandin D_2), thrombocytosis and pre-existing vascular disease can all conspire to dramatically increase thrombotic risk.

Arterial occlusions can lead to myocardial infarcts, strokes, transient ischaemic attacks, amaurosis, scotomata, mesenteric
Figure 46.2 Polycythaemia vera presenting with the Budd–Chiari syndrome in a 28-year-old man: contrast computerized tomography showing reduced enhancement of the right lobe of the liver (arrow) with characteristic sparing of the caudate lobe (arrowhead). On this occasion, the left lobe was also relatively spared. Marked ascites and a bulky spleen are also seen.

Figure 46.3 Blood film from a case of post-polycythaemic myelofibrosis after splenectomy. Note the presence of nucleated erythrocytes, giant platelets and features of splenectomy including target cells, spherocytes and acanthocytes (×20).

and limb ischaemia. Less commonly, microvascular occlusions affecting the extremities and erythromelalgia can occur.

In the venous circulation, unusual sites such as the splanchnic vessels are often involved. As a result, mesenteric, splenic and hepatoportal thromboses (Figure 46.2) are not uncommonly presenting features of PV. Superficial thrombophlebitis, conventional deep venous thromboses and pulmonary emboli are also seen.

Neurological features
Over and above the consequences of occlusive vascular lesions, the sluggish cerebral blood flow secondary to the increased PCV is thought to underlie features such as headaches, drowsiness, insomnia, amnesia, tinnitus, vertigo, chorea and even depression. Transient visual disturbances also occur.

Pruritus
This symptom occurs in about one-quarter of PV patients and in some it may be severe. It is characteristically aquagenic, precipitated by warm baths and can be associated with erythema, swelling or even pain. Pruritus is often relieved by controlling the PCV, but its aetiology remains elusive. Hyperhistaminaemia and iron deficiency may have a role and there is an increased incidence in patients with a lower mean corpuscular volume (MCV).

Skin
Plethora, dilated conjunctival vessels and rosacea-like facial skin changes are not uncommon at presentation. Brown discolora-tion of the skin, erythromelalgia and, rarely, Sweet's syndrome may be seen.

Splenomegaly
Palpable splenomegaly is seen in 30–50% of cases of PV. It is unclear if its presence carries prognostic implications, but it may be associated with an increased risk of progression to myelofibrosis.

Hypertension and gout
Hypertension is probably more common in patients with PV as is hyperuricaemia, with gout seen in about 5% of cases.

Leukaemic transformation
Leukaemogenesis is perhaps the most feared complication of PV, but the risk of developing acute leukaemia in PV patients treated only with venesection is very small (1–3%). This risk, however, increases dramatically (more than 10-fold) when radioactive phosphorus (^{32}P), chlorambucil or irradiation are used as treatment. The median time interval between first starting such therapy and developing acute leukaemia is 5–8 years.

Myelofibrosis
Progression to myelofibrosis (Figure 46.3) occurs in around 10–20% of PV cases at 15 years after diagnosis. This figure is approximate, not least because different studies have used distinct criteria to define myelofibrotic transformation. Transformation often occurs gradually over many years and is thought to be associated with an increased risk of leukaemic conversion. The management of these patients is similar to that of idiopathic myelofibrosis.

Table 46.1 Diagnostic criteria for polycythaemia vera.

A1	Raised red cell mass (> 25% above predicted, or PCV ≥ 60 in men or 0.56 in women)*
A2	Normal arterial oxygen saturation (> 92%) and no elevation of serum erythropoietin
A3	Palpable splenomegaly
A4	Acquired clonal genetic abnormality in haemopoietic cells (excluding *BCR–ABL* fusion)
B1	Thrombocytosis (platelets > 400 × 10⁹/L)
B2	Neutrophilia (neutrophils > 10 × 10⁹/L; > 12.5 × 10⁹/L in smokers)
B3	Radiological splenomegaly
B4	Endogenous erythroid colonies or low serum erythropoietin

A1 + A2 + either another A or another two B establishes polycythaemia vera.

*These PCV values are invariably associated with a raised red cell mass in an adult population.

Modified from Pearson *et al.* (2000).

Investigations

The diagnosis of PV requires both the exclusion of secondary and apparent polycythaemia, and the identification of positive criteria in support of PV (Table 46.1). In some circumstances the exclusion criteria are met but positive criteria are not and the syndrome is referred to as idiopathic erythrocytosis. The latter diagnosis is becoming less common as specific diagnostic markers for PV and other polycythaemias become available.

The PVSG diagnostic criteria for PV in the 1970s have been subsequently refined (see Table 46.1) to take into account new diagnostic markers (e.g. BFU-E assays, serum erythropoietin levels) and to discard older less reliable tests (e.g. serum B_{12} levels). Alternative diagnostic criteria have been proposed recently as part of the 'WHO classification of tumours'. However, these criteria have been criticized on a number of grounds and particularly for the suggestion that an Hb concentration of > 18.5 g/dL for men or > 16.5 g/dL for women is equivalent to a raised red cell mass.

Treatment

In the absence of thrombocytosis, regular venesection remains the mainstay of treatment for PV in patients who can tolerate it. A target haematocrit of 0.45 is widely used, following the demonstration that, in patients with PV, higher haematocrits are associated with a significantly increased risk of thrombosis. With repeat venesections, iron deficiency often ensues, which reduces the frequency of further venesections but may be associated with a reactive thrombocytosis.

Cytoreductive therapy is recommended for patients with thrombocytosis, in view of the probable increased risk of thrombosis, as well as for patients unable to undergo venesection. Hydroxyurea (hydroxycarbamide) is the most commonly used drug. It is orally bioavailable and generally very well tolerated. It will reduce both the haematocrit and the platelet count. The commonest complications are leucopenia or thrombocytopenia, which are dose dependent and can usually be avoided by close monitoring of the blood count when the drug is first introduced. In susceptible patients it can cause photosensitivity, painful leg ulcers and gastrointestinal side-effects. The usual dose is 1–2 g daily.

It has been suggested that hydroxyurea may increase the inherent leukaemogenic risk associated with PV. This concern is largely based on studies involving small numbers of patients or patients who have also required other cytotoxic agents (and may therefore represent a subgroup with more aggressive disease). At present, there are no convincing data to show that hydroxyurea, when used as a single agent, significantly increases the risk of leukaemia, although a small effect cannot be excluded. Preliminary data from studies of hydroxyurea in sickle cell disease are reassuring, but longer follow-up is required.

Interferon-alpha (IFN-α) is effective in controlling both the platelet count and the PCV. It is not widely used because of its cost, route of administration (subcutaneous injection) and its side-effects (including fatigue, flu-like symptoms, depression). It can be useful, however, in young patients who are reluctant to take other cytotoxic agents, in pregnancy and in patients with intractable pruritus. The usual dose range is 3–5 mU three times per week.

Anagrelide is a newer agent that lowers the platelet count by inhibiting megakaryocyte differentiation. It can be useful in controlling the platelet count of patients being treated with venesection and can also be combined with hydroxyurea to allow the use of lower doses of both agents. Approximately 10% of patients are completely refractory to anagrelide. The usual dose is 1–2 mg daily, but occasional patients may require doses of up to 8 mg daily. Its side-effects are mainly secondary to its inotropic and vasodilatory properties and include headaches, palpitations and fluid retention.

Busulphan is sometimes used in elderly patients or when all other treatments are not tolerated. It is very convenient as it need only be administered intermittently, but may increase the risk of leukaemia. The usual dosage is 25–75 mg as a single dose every 2–3 months.

Low-dose aspirin (100 mg daily) reduces thrombotic complications in PV and is used in most patients without contraindications to this drug.

Pruritus often improves with control of the PCV but paroxetine, antihistamines and aspirin (in some cases) can be of help and there is evidence suggesting that IFN can be useful in intractable cases.

In view of the age of most patients and the relatively benign natural history of treated PV, bone marrow transplantation is not advocated for stable disease. The role, if any, of transplants employing reduced-intensity conditioning regimes is not yet clear.

Prognosis

In the first half of the twentieth century, untreated polycythaemia had a dismal prognosis with a 50% survival of less than 2 years. However, adequately treated PV now has a relatively benign natural history with a life expectancy of over 11 years, bearing in mind that the average age of onset is 60 years.

Other causes of polycythaemia

All disorders with an increased red cell mass which are not due to a clonal proliferation of haemopoietic progenitors are included under this heading. They are most conveniently subclassified into primary and secondary causes. In primary polycythaemia, the defect is intrinsic to the red cell precursors, which are hypersensitive to erythropoietin. In secondary polycythaemia, the defect is upstream of the red cell precursors. The latter group can be further subdivided into polycythaemias in the presence or in the absence of systemic hypoxia. A small group of patients do not fall into any of these categories and are given the diagnosis of idiopathic erythrocytosis (IE) (Table 46.2). The clinical management of many of these syndromes is not well defined.

The term apparent polycythaemia refers to a raised haematocrit in the absence of a raised red cell mass and is discussed later in this chapter.

Primary polycythaemia

Primary familial and congenital polycythaemia

Primary familial and congenital polycythaemia (PFCP) is a rare disorder in which erythropoiesis is intrinsically overactive. The disorder is usually transmitted in an autosomal dominant manner with some cases appearing sporadically. Clinical features include the presence of isolated erythrocytosis without evolution into leukemia or other myeloproliferative disorders, absence of splenomegaly, normal white blood cell and platelet counts, low or normal plasma erythropoietin (Epo) levels, normal haemoglobin–oxygen dissociation curve/P_{50}, and hypersensitivity of erythroid progenitors to Epo. Mutations in the gene encoding the erythropoietin receptor (EpoR) have been described in several (but not all) families with PFCP. In most

Table 46.2 Causes of polycythaemia other than polycythaemia vera.

Primary polycythaemia (intrinsic defect in red cell progenitors)	Primary familial and congenital polycythaemia		
Secondary polycythaemia	Polycythaemia in the presence of systemic hypoxia	Chronic hypoxia	Lung disease
			Hypopnoea
			High altitude
			Congenital cyanotic heart disease
		Defective oxygen transport	High-affinity haemoglobins
			Red cell metabolic defects (low 2,3-BPG)
			Methaemoglobinaemia
			Heavy smoking (carboxyhaemoglobinaemia)
	Polycythaemia in the absence of systemic hypoxia	Inherited/congenital polycythaemia	Chuvash polycythaemia
		Abnormal erythropoietin secretion	Renal tumours
			Cystic/polycystic kidney disease
			Renal transplantation
			Renal hypoxia (e.g. renal artery stenosis, hydronephrosis)
			Cerebellar haemangioma
			Hepatocellular carcinoma
		Endocrine syndromes	Administration of androgenic steroids
			Cushing's syndrome
			Conn's syndrome
			Phaeochromocytoma (rarely)
			Bartter's syndrome
Idiopathic erythrocytosis			

cases, the mutations lead to a C-terminal truncation of the EpoR protein, with increased sensitivity to Epo.

Secondary polycythaemia

Polycythaemias in the presence of systemic hypoxia

Chronic lung disease and hypopnoea

Lung disease is the predominant cause of chronic systemic hypoxia at sea level. Hypoxaemic chronic obstructive pulmonary disease (COPD) is the commonest syndrome, but any lung–airway disease leading to chronic hypoxia could cause polycythaemia. Syndromes such as obstructive sleep apnoea and hypoventilation due to muscle weakness or paralysis can also occasionally be associated with secondary polycythaemia.

Where possible, hypoxia should be ameliorated by treating the lung disease or with home oxygen therapy. Polycythaemia has opposing effects on oxygen delivery as it increases the oxygen-carrying capacity while also increasing blood viscosity. Unfortunately, there is little evidence from clinical trials to guide management. In practice, many specialists suggest that venesection should be performed for haematocrits above 0.55.

High altitude

Residents at altitudes above 4000 m compensate for the ambient hypoxia by multisystem adaptation, including mild polycythaemia, increase in capillary perfusion and lung diffusion capacity as well as biochemical changes in metabolic enzymes and myoglobin. Cardiac work does not need to increase in most well adapted individuals. Excessive altitude polycythaemia (PCV > 0.65) is seen in a proportion of cases and is often accompanied by hyperuricaemia and proteinuria. Some of these individuals eventually decompensate and develop chronic mountain sickness (Monge's disease). Such people deteriorate steadily and develop extreme polycythaemia (sometimes PCV > 0.75), arterial desaturation and right heart failure. Symptoms range from mental slowing, headaches and lethargy to breathlessness, dry cough and signs of right heart failure. Many of the cases described were miners with coincidental pulmonary disease and the latter may play a significant role in the process of decompensation. Resettlement at lower altitudes halts disease progression and can partly reverse it.

Treatment with angiotensin-converting enzyme (ACE) inhibitors has been shown in randomized studies to reduce the haematocrit and proteinuria that are seen in excessive altitude polycythaemia.

Congenital cyanotic heart disease

Congenital heart defects leading to a right-to-left shunt can cause dramatic polycythaemia (up to PCV > 0.80). Surgery to correct the cardiac defect should be undertaken when possible. A few inoperable patients survive to adulthood and the management of their polycythaemia is not straightforward. As in
Figure 46.4 Haemoglobin–oxygen dissociation curves from a 27-year-old man with a raised red cell mass and a normal person (HbA) showing the presence of a high-affinity Hb ('left shift'). Mass spectrometric analysis showed the man to be heterozygous for Hb San Diego, a high-affinity β-chain variant.

patients with chronic lung disease, the increase in oxygen-carrying capacity afforded by polycythaemia is countered by an increased viscosity and associated haemodynamic changes. Here, however, we are often dealing with young patients with responsive vasculatures, which can usually accommodate such changes. Some experts advocate venesection when the PCV is greater than 0.60, whereas others allow the haematocrit to rise further and venesect for symptoms such as recurrent haemoptysis, marked fatigue or deteriorating exercise tolerance.

High-affinity haemoglobins

High-affinity haemoglobins release less oxygen for a given oxygen partial pressure, and may therefore give rise to tissue hypoxia. This leads to an erythropoietin-driven polycythaemia, which tends to re-normalize erythropoietin levels. The pathognomonic anomaly is a left shift in the oxygen dissociation curve (Figure 46.4). The precise variant can be identified by mutational screening at the DNA level or by protein mass spectrometry.

There are over 40 haemoglobin variants with an increased affinity for oxygen, all dominantly inherited. Most are due to mutations in β-globin, with a small number due to mutations in α-globin. Mutations are clustered in regions of the globin chains that are involved in the regulation of the transition between tense (T) and relaxed (R) states of haemoglobin. Normally, oxy-HbA is in the T state and has low affinity for oxygen, and deoxy-HbA is in the R state and has a high affinity for oxygen. Thus, mutations at the αβ contact site (e.g. Hb San Diego, Hb Radcliffe), the C-terminus (e.g. Hb Bethesda) and the 2,3-BPG (2,3-bisphosphoglycerate) binding site (e.g. Hb Helsinki) are the commonest.

Most people with a high-affinity Hb are in good health and are either diagnosed coincidentally or after being noticed to be plethoric. Some experience excessive muscle fatigue after vigorous

exercise. Hyperviscosity is rarely a problem and surveys have failed to identify increased cardiovascular morbidity or mortality. Pregnancy is not adversely affected, even in mothers with haemoglobin affinity that exceeds that of HbF.

Red cell metabolic defects

Very rare cases of polycythaemia are due to abnormalities in red cell metabolism that lead to a reduction in intra-erythrocytic 2,3-BPG. The best characterized defect is a mutant 2,3-BPG mutase. The only well characterized family with this disorder showed an autosomal recessive inheritance, although heterozygous family members had a decreased P_{50} and, in some cases, a moderate polycythaemia. This disorder is excluded by the finding of a normal P_{50} in a fresh blood sample.

Methaemoglobinaemia

Oxidation of haem iron converts it from its normal ferrous (Fe^{2+}) to the ferric (Fe^{3+}) form and, correspondingly, haemoglobin (HbA) becomes methaemoglobin (Met-HbA). This constitutes an important antioxidant mechanism for the red cell, and conversion of Met-HbA back to HbA requires the generation of NADH from glycolysis. The rate of HbA auto-oxidation is about 20 times slower under normal circumstances than the rate of Met-HbA reduction, thus preventing Met-HbA accumulation.

Methaemoglobin has an increased affinity for oxygen and a left-shifted oxygen dissociation curve. Pathological acquired methaemoglobinaemia can result from exposure to strong oxidants (e.g. dapsone, paraquat, benzocaine) and can be life-threatening when severe but is rarely sufficiently long-lived to give rise to polycythaemia.

Hereditary methaemoglobinaemias can be due to haemoglobin mutations involving amino acids around the haem pocket (haemoglobin M disease), or secondary to enzymatic deficiencies that interfere with the generation of NADH which is required for day-to-day methaemoglobin reduction (namely NADH reductase and cytochrome b5 reductase). In view of the chronic nature of the methaemoglobinaemia in these disorders, secondary erythrocytosis can develop in the same manner as for high-affinity haemoglobin mutants.

Heavy smoking

Heavy smoking can lead to mild polycythaemia in the absence of hypoxic lung disease. The underlying cause of this is a raised carboxyhaemoglobin (CO-Hb) level resulting from chronically raised carbon monoxide (CO) levels. CO-Hb levels in urban dwelling non-smokers are rarely higher than 2%, with levels ranging from 3% to 20% in smokers. The short half-life of CO in the body (3–5 h) leads, in smokers, to a rise in CO-Hb during the day and a fall during sleep, making it difficult to compare measurements taken at different times. Binding of CO to Hb, as well as displacing O_2, leads to a conformational change similar to that seen in methaemoglobinaemia, with a similar left shift in the oxygen dissociation curve and a fall in P_{50}.

Polycythaemia in the absence of systemic hypoxia

Inherited/congenital polycythaemia

Chuvash polycythaemia

Chuvash polycythaemia (CP) is an autosomal recessive condition that is endemic in the Russian mid-Volga river region of Chuvashia. Patients have increased levels of circulating erythropoietin but do not carry mutations of the Epo receptor. CP was recently shown to be associated with a C → T mutation at nucleotide 598 (leads to an Arg200Trp substitution) in the von Hippel–Lindau (VHL) gene. The *VHL* gene is pivotal for ubiquitination and subsequent degradation of HIF-1 transcription factor, which is central to the oxygen-sensing pathway. This *VHL* mutant leads to a reduced rate of degradation of HIF1 and upregulation of downstream targets including Epo, leading to polycythaemia. Recently, some of the rare non-Russian families with inherited polycythaemia were also shown to carry *VHL* mutations.

Abnormal erythropoietin secretion

Abnormal Epo secretion is a well-recognized cause of secondary polycythaemia and is most commonly secondary to renal pathologies such as renal tumours (benign and malignant), polycystic kidney disease and diseases associated with local hypoxia such as renal cysts, hydronephrosis and renal artery stenosis. The polycythaemia usually responds to treatment of the underlying renal pathology.

Erythrocytosis occurs in 20–30% of patients after renal transplantation. The biggest risk to such patients is hypertension, strokes and cardiovascular complications. In many cases, the erythrocytosis and associated hypertension respond to ACE inhibitors. Theophylline may also be effective in some cases. Patients who remain polycythaemic despite such treatments should be treated with repeated venesections to maintain their haematocrit below 45%; 30–40% of cases resolve spontaneously.

Non-renal tumours can rarely be associated with polycythaemia. The commonest reported ones are hepatocellular carcinoma, cerebellar and other haemangiomata and large uterine fibromyomata. Polycythaemia responds to removal of the tumour in most of these cases.

Endocrine disorders

The mechanism underlying the development of polycythaemia in most endocrine disorders lies in the overproduction of androgens, which can produce polycythaemia by increasing Epo levels and also, probably, through a direct action on bone marrow progenitors.

Idiopathic erythrocytosis

In a small proportion of patients with polycythaemia the criteria for the diagnosis of PV are not met and no other aetiology for the

raised red cell mass can be identified. This group is heterogeneous and likely to include patients with germline mutations causing polycythaemia as well as some that will go on to develop overt PV. With the advent of increasingly sophisticated diagnostic tests and the identification of the molecular lesions in many inherited forms of polycythaemia, idiopathic erythrocytosis is becoming a rare entity.

Apparent polycythaemia

Apparent polycythaemia refers to a raised PCV (> 0.51 in males, > 0.48 in females) in the presence of a normal red cell volume (less than 25% above the predicted mean normal value). The raised haematocrit is due to a reduction in the plasma volume. Smoking, hypertension, obesity, excessive alcohol and diuretic therapy have all been associated with apparent polycythaemia. Pathogenesis is uncertain and almost certainly heterogeneous. Some cases of high-affinity Hbs have been reportedly associated with apparent rather than true polycythaemia, but this may simply reflect the moderate nature of the elevation in red cell volume in such cases.

It is not clear whether apparent polycythaemia is associated with increased rates of thrombosis, but it seems sensible to encourage affected individuals to avoid known predisposing factors. There are no convincing data that routine venesection is beneficial but some authorities advocate venesection at PCV > 0.55, particularly for individuals at risk for vaso-occlusive events.

Essential thrombocythaemia

The central pathological feature of essential thrombocythaemia (ET) is a persistent elevation in the platelet count to above 600×10^9/L. However, ET remains poorly understood largely because of a lack of positive diagnostic criteria, together with the fact that cases labelled as ET are likely to be pathogenetically heterogeneous. In 1934, Epstein and Goedel first described a patient with persistent elevation of the platelet count in association with megakaryocyte hyperplasia and tendency for venous thromboses and haemorrhage. Subsequently, Ozer and Gunz independently described two series of patients in 1960, thus confirming ET as a specific clinical entity.

Pathophysiology

No clear pathogenetic abnormality has been found in ET, the pathobiology of which remains as elusive as it is fascinating. X-chromosome inactivation patterns (XCIPs) provided the first evidence that ET may be a clonal stem cell disorder involving granulocytes, platelets and red cells but not T cells. The hope that this finding could provide a much-needed diagnostic tool has been confounded by two observations. First, the fact that around 25% of normal elderly females have acquired skewing of

XCIP in myeloid cells. Second, the evidence that myelopoiesis can be polyclonal in many cases of ET. Taken together, these findings demonstrate that XCIP analysis cannot be used as a routine diagnostic test for ET.

A significant obstacle to understanding the pathogenesis of ET is the fact that it is likely to be heterogeneous. Further insights will require the identification of target genes and a number of candidates have been studied.

Thrombopoietin (TPO) mutations leading to increased TPO levels have been described in families with familial thrombocytosis. No such mutations have been identified in patients with ET, and TPO levels in patients with ET are similar to those in patients with reactive thrombocytosis. TPO levels are not therefore of diagnostic value in ET. Expression of the TPO receptor c-mpl is reduced in ET, PV and IMF. There are no associated mutations in the *c-mpl* gene and the significance of this observation remains unclear. Unfortunately, there is significant overlap between *c-mpl* levels in reactive thrombocytosis and ET and so this assay is also not diagnostically useful. It has been suggested that megakaryocyte c-mpl levels may be more helpful, but this requires confirmation.

Endogenous erythroid colonies (EECs) or megakaryocyte colonies (EMCs) can be grown from the blood or bone marrow of most patients with ET, but not from those with reactive thrombocytosis or normal subjects. Expression of the gene *PRV-1* in blood granulocytes is raised in a significant proportion of cases of ET and this seems to be associated with reduced Epo levels, clonal granulopoiesis and the presence of EECs.

Mutations in *p53* are rare in chronic-phase ET but become more common in cases transforming to AML, suggesting a role for this gene in the transformation process.

Clinical features

Epidemiology
The annual incidence of ET is similar to that of PV at around 1.5–2.0 cases per 100 000 of the population. The median age at onset is 50–55 years and, although it can occur at any age, it is rare in childhood.

Thrombotic complications
As with PV, thrombotic complications are the main cause of morbidity and mortality in ET. Thromboses are present in around 15–20% of patients at presentation and may be arterial or venous. The range of clinical syndromes is similar to that of PV, but the frequency of splanchnic thromboses is probably lower in ET.

A number of risk factors are associated with an increase in the risk of thrombosis in patients with ET. The best characterized are age over 60 years and a prior history of thrombosis. Other risk factors for thrombosis in ET are likely to include high platelet count (> 1000), hyperlipidaemia, hypertension and cigarette smoking. More recently, provisional data suggest that

male gender, monoclonal haemopoiesis, the presence of antiphospholipid antibodies, spontaneous megakaryocyte or erythroid colonies and inheritance of the factor V Leiden polymorphism may also increase the risk of thrombosis. Platelet function abnormalities do not correlate with thrombotic risk.

Haemorrhagic complications

Bleeding is less common and less well studied than thrombosis in ET, but can be dramatic when it happens. Efforts to correlate the thrombotic risk to platelet function abnormalities have generally been fruitless and this investigation is also unable to predict haemorrhagic risk. Bleeding is, however, more common in patients with platelet counts above 1000 and, in at least some cases, this is due to an acquired von Willebrand disease, with a decrease in high-molecular-weight multimers.

Splenomegaly and hyposplenism

Splenomegaly is present in about 20–25% of ET patients at diagnosis and it is rarely more than moderate. Progressive enlargement of the spleen during the course of ET should raise suspicion of evolving myelofibrosis. It has been suggested that over time, some patients with ET develop splenic atrophy secondary to silent microinfarcts in the splenic microcirculation. Frank hyposplenism and its complications are rare however.

Transformation to myelofibrosis or polycythaemia vera

Transformation to myelofibrosis and, more rarely, to PV, are recognized complications of ET. Some, but not all, cases of apparent polycythaemic transformation may represent resolution of prior iron deficiency, as can happen with iron supplementation and after the menopause. The insidious onset of myelofibrotic transformation and the reluctance to serially study bone marrow trephine biopsies have hampered attempts to define its nature and frequency. From the limited available data, myelofibrotic transformation occurs in less than 10% and polycythaemic transformation in less than 1–2% of ET patients over 10 years.

Leukaemic transformation

ET can evolve into a myelodysplastic syndrome (MDS) or AML even in untreated cases, but only rarely. The presence of cytogenetic abnormalities and treatment with alkylating agents increase this risk. Approximately 3% of patients treated with hydroxyurea alone develop MDS or AML if followed for a median time of 8 years. As with PV, there are no data that demonstrate that hydroxyurea as a single agent significantly increases the risk of leukaemia inherent to this disease, but a small effect cannot be excluded.

Investigations

Essential thrombocythaemia is a diagnosis of exclusion

The lack of pathognomonic features and the existence of many other causes of a raised platelet count pose significant hurdles in the diagnosis of ET. Save for the one positive diagnostic require-

ment of a platelet count persistently raised above 600×10^9/L, ET remains a diagnosis of exclusion and can only be made after other clonal blood disorders and reactive thrombocytosis are ruled out. The PVSG criteria, as last modified in 1997, are summarized and updated in Table 46.3. Bone marrow histological features such as giant, multilobated megakaryocytes and megakaryocyte clustering (Figure 46.5) are suggestive of ET.

Table 46.3 Diagnostic criteria for essential thrombocythaemia.

Platelet count $> 600 \times 10^9$/L for at least 2 months

No cause for a reactive thrombocytosis, including normal inflammatory indices

No evidence of polycythaemia vera: haematocrit < 0.48 or normal red cell mass ($< 125\%$ of predicted value)

No evidence of iron deficiency: stainable iron in the marrow or normal red cell mean corpuscular volume*

No evidence of chronic myeloid leukaemia: no Philadelphia chromosome or *BCR–ABL* gene rearrangement

No evidence of myelofibrosis: no collagen fibrosis, minimal or no reticulin fibrosis

No evidence of a myelodysplastic syndrome (MDS): no significant dysplasia, no cytogenetic abnormalities suggestive of MDS

All of the above must be met to make a diagnosis of essential thrombocythaemia.

*If these measurements suggest iron deficiency, PV cannot be excluded unless a trial of iron therapy fails to increase the red cell mass into the polycythaemic range.
Figure 46.5 Bone marrow trephine section (haematoxylin and eosin, H&E) from a 60-year-old man with essential thrombocythaemia. Note the hypercellularity and marked increase in megakaryocyte numbers, consisting largely of clusters of mature, multilobated forms.

    Recovery from chemotherapy
Drugs
    Vincristine

Bone marrow cytogenetic abnormalities are encountered in less than 5% of cases at diagnosis and, when present, are similar to those seen in PV.

A small number of cases of apparent ET are found to carry the Philadelphia (Ph) chromosome. These cases are sometimes reported as Ph-positive ET but are probably best considered as variant presentations of CML and should be managed as such.

A further modification of the PVSG criteria has been proposed as part of the 'WHO classification of tumours'. However, this requires interpreting megakaryocyte morphology and other trephine features to make a positive diagnosis of ET and to distinguish ET from other conditions, including a controversial entity termed 'pre-fibrotic myelofibrosis'. These histological criteria do not appear sufficiently robust to be used in routine diagnosis.

Reactive thrombocytosis

Thrombocytosis is most commonly reactive and secondary to increased levels of circulating cytokines that stimulate thrombopoiesis. Inflammatory, vasculitic and allergic disorders, acute and chronic infections, malignancies, haemolysis, iron deficiency and blood loss can all lead to an increased platelet count (Table 46.4). Reactive thrombocytosis can sometimes be marked and, rarely, the platelet count can be greater than 1000×10^9/L. There is usually evidence of on-going inflammation in the form of a raised erythrocyte sedimentation rate (ESR) or C-reactive protein but this is not always the case.

Other clonal thrombocytoses

A number of other haematological malignancies can be associated with thrombocytosis. CML can be excluded by demonstrating the absence of the *bcr–abl* fusion transcript. If the Hb or haematocrit is near the upper limit of normal, it is useful to

measure the red cell mass in order to exclude PV, remembering that iron deficiency can mask a raised red cell mass. IMF can be excluded by the absence of significant bone marrow fibrosis.

Lastly, myelodysplastic syndromes can also in a minority of cases be associated with a thrombocytosis, but are usually associated with cytopenias, dysplastic features or specific cytogenetic abnormalities (e.g. deletion 5q).

Treatment

When considering the management of patients with ET, it is helpful to stratify patients into risk groups, according to their risk of vascular complications, and take treatment decisions on this basis. Patients may be assigned to a high-, intermediate- or low-risk category.

High-risk patients

High-risk patients are those over 60 years old, and those with one or more high-risk features, i.e. a platelet count $> 1500 \times 10^9$/L, a prior history of thrombosis or significant thrombotic risk factors, such as diabetes or hypertension. In high-risk patients control of the platelet count with hydroxyurea reduces thrombotic events. The MRC PT-1 trial has recently compared treatment with hydroxyurea plus low-dose aspirin with anagrelide plus low-dose aspirin. Patients receiving anagrelide plus aspirin were significantly more likely to reach the composite primary endpoint (arterial thrombosis, venous thrombosis or major haemorrhage) and more likely to discontinue their allocated treatment. Compared with hydroxyurea plus aspirin, treatment with anagrelide plus aspirin was associated with a significantly increased rate of arterial thrombosis, major haemorrhage and myelofibrotic transformation but a decreased rate of venous thromboembolism. These results suggest that hydroxyurea plus aspirin should remain first-line therapy for high-risk patients. Anagrelide is a useful second-line agent, but the decision to use concurrent aspirin should depend on the relative risks of arterial thrombosis and haemorrhage in each individual patient.

IFN-α can give good control of the platelet count in ET but, as discussed under PV, its significant side-effect profile, subcutaneous administration and cost prevent its widespread use. It has a clearer role in the management of ET in pregnancy (see below) and some favour it in young patients. Busulphan can achieve good control of the platelet count but is only rarely used because of concerns over its long-term leukaemogenic potential. This is true for other alkylating agents and for radioactive phosphorus (^{32}P).

Intermediate-risk patients

Intermediate-risk patients are those between 40 and 60 years old who lack any of the high-risk features listed above. It is not clear whether it is beneficial to lower the platelet count in this group of patients. Most receive either aspirin alone, or hydroxyurea and aspirin.

Low-risk patients

Low-risk patients are those younger than 40 years old who lack any high-risk features. Low risk patients are usually given low-dose aspirin alone unless there is a contraindication such as previous peptic ulceration, ET-associated haemorrhage or allergy to salicylates. Anti-platelet agents such as dipyridamole, ticlopidine or clopidogrel should be considered in these cases.

Prognosis

Few studies have directly addressed survival in ET and these have reached different conclusions. Some suggest that mortality at 10 years is that of age-matched control subjects, whereas others found it to be worse. In high-risk patients, hydroxyurea reduces the incidence of vaso-occlusive events from 10.7 to 1.6 per 100 patient-years.

Essential thrombocythaemia and pregnancy

ET is the MPD encountered most frequently in women of child-bearing age. Fertility is probably reduced in women with ET, but data are lacking on this issue. In pregnancy, the commonest complication of ET is first-trimester miscarriage, which occurs in up to 30% of pregnancies. This is thought to be secondary to placental microinfarcts and placental insufficiency. The reported increased incidence of antiphospholipid antibodies in ET may contribute to this. Other less frequent complications include intrauterine death, growth retardation, premature delivery and pre-eclampsia. The risk of maternal thrombosis and haemorrhage is higher than in normal pregnancy, nonetheless a successful outcome (live birth) is achieved in around 60% of cases and no maternal deaths were seen in a recent review of 220 pregnancies.

The optimal management of ET in pregnancy has not yet been fully defined. There is conflicting evidence about the effectiveness of aspirin but, given the good documentation of its safety in a large unrelated study of pre-eclampsia, it should probably be given to most patients who are pregnant or planning a pregnancy. Pregnancies deemed at high risk of thrombosis either on the basis of a prior history of thrombosis or a platelet count of over 1000×10^9/L should be considered for therapy with a combination of IFN and aspirin. Hydroxyurea and anagrelide should not be used on account of their teratogenic potential. In addition to lowering the platelet count, cases at the highest risk of thrombosis, such as those with previous thrombosis, hypertension or diabetes, should be considered for antithrombotic prophylaxis normally in the form of low-molecular-weight heparin.

The platelet count may rise dramatically in the post-partum period but can normally be controlled with hydroxyurea or anagrelide. Hydroxyurea and anagrelide are excreted in breast milk so that breast-feeding is contraindicated while a patient is receiving either of these agents. Although IFN-α is also excreted in breast milk, it is unlikely to be absorbed intact by the baby and there are anecdotal reports of successful breast-feeding while the mother was receiving IFN.

Idiopathic myelofibrosis

Also known as agnogenic myeloid metaplasia, idiopathic myelofibrosis (IMF) has the poorest prognosis of the MPDs. PV and ET can develop into a condition that resembles IMF, usually after a latency of many years. The first reported case of IMF is probably that reported by Hueck in 1879 as a 'peculiar leukaemia'. It was not until Dameshek's seminal work in 1951 that IMF was recognized as a myeloproliferative disorder.

Pathophysiology

Idiopathic myelofibrosis is a clonal myeloproliferative disorder of the pluripotent haemopoietic stem cell, in which a clonal proliferation of multiple cell lineages is accompanied by progressive bone marrow fibrosis. The marrow fibrosis is thought to be secondary to the release of proinflammatory cytokines from abnormal clonal cells (primarily megakaryocytes), which act to stimulate fibroblast proliferation and fibrosis. In support of this premise, transgenic mice expressing high levels of TPO rapidly develop myelofibrosis in association with increased megakaryocyte numbers. Additionally, mice expressing reduced levels of the transcription factor GATA-1, which impairs the ability of their megakaryocytes to differentiate into platelets, also develop myelofibrosis in association with increased expression of cytokines such as transforming growth factor β1, platelet-derived growth factor and vascular endothelial growth factor in the bone marrow.

In the peripheral circulation there is an increase in the number of CD34-positive cells together with increased numbers of progenitors capable of giving rise to a variety of haemopoietic colonies. As with PV and ET, erythroid and megakaryocytic colonies can also be derived in the absence of exogenous growth factors in many cases.

The genetic changes underlying the pathogenesis of IMF are, as with other MPDs, poorly defined. Cytogenetic abnormalities are commoner than in other MPDs and are found in up to 60% of cases. The commonest are deletions of 20q and 13q, trisomy 8 and abnormalities of chromosomes 1, 5, 7 and 9. Oncogene mutations are rare and include point mutations in N-*RAS*, c-*KIT* and *p53*. Recently, deletion or downregulation of the retinoic acid receptor-beta (RARβ) has been reported in the majority of cases of IMF studied. The significance of this finding awaits clarification.

Clinical features

Epidemiology

The estimated annual incidence of IMF is around 0.5–1.5 per 100 000 of the population, with most patients diagnosed in the

Figure 46.6 Massive splenomegaly in a 53-year-old man with an 8-year history of idiopathic myelofibrosis (IMF).

sixth decade of life and roughly equal involvement of the two sexes. Up to one-third of patients with IMF are asymptomatic at diagnosis and many of these are discovered after unrelated blood tests show modest abnormalities such as anaemia and thrombocytopenia.

Splenomegaly

An enlarged spleen is found in almost all patients at presentation and splenic pain/discomfort is a common presenting symptom of IMF. Most cases develop moderate to marked splenomegaly during the course of the disease and about 10% of cases develop massive splenomegaly, with the spleen extending to the right iliac fossa (Figure 46.6). This dramatic increase in splenic mass (up to 20–30 times normal) can lead to a substantial increase in splenic blood flow which, in the most severe cases, can lead to portal hypertension with oesophageal varices and ascites. Painful and painless splenic infarcts are common sequelae of splenomegaly in IMF.

Extramedullary haemopoiesis

The spleen is the commonest site of extramedullary haemopoiesis in IMF. The liver is also usually involved and this can lead to significant hepatomegaly. Unusual sites can sometimes be affected, leading to haemopoietic tumours surrounded by a capsule of connective tissue. Such sites include lymph nodes, central nervous system, skin, pericardium, peritoneum, pleura, ovaries, kidneys, adrenals, gastrointestinal tract and lungs. Many such cases remain asymptomatic, but involvement of the central nervous system can be a cause of serious morbidity. Treatment with radiotherapy or surgery, when required, almost always leads to resolution of these masses.

Systemic symptoms

A hypermetabolic state presenting with fevers, anorexia, weight loss and night sweats develops in many cases of IMF, sometimes

early on in the disease. The presence of such symptoms is associated with a poor prognosis.

Anaemia

Mild to moderate anaemia is found in most patients at presentation and worsens as myelofibrosis progresses. The anaemia is in large part due to reduced erythropoiesis, but may be compounded by hypersplenism, bleeding and iron or folate deficiency. Acquired HbH disease is a rare complication.

Platelet abnormalities

Platelet counts are raised in up to one-half of the cases at presentation and can be associated with thrombotic complications. However, progressive thrombocytopenia is a frequent occurrence and becomes increasingly troublesome as the disease progresses. Dysmegakaryopoiesis and abnormal platelet function further add to the risk of haemorrhagic complications.

White cells and leukaemic transformation

The presence of immature myeloid as well as erythroid progenitors is a characteristic feature of IMF (Figure 46.7). Neutrophilia is common, as are modest elevations in basophil and eosinophil counts. As the disease progresses, leucopenia increases in frequency and is believed to be secondary to progressive hypersplenism, dysmyelopoiesis and progressive replacement of the

bone marrow by fibrotic tissue. In end-stage IMF, myeloid precursors become increasingly common relative to mature cells, as do circulating blasts. Transformation to AML occurs in 5–10% of cases of IMF and is usually rapidly fatal.

Investigations

Diagnostic criteria for IMF are shown in Table 46.5. Other causes of bone marrow fibrosis are listed in Table 46.6.

Peripheral blood
The presence of myeloid and erythroid precursors in the peripheral blood (leucoerythroblastic blood picture) is common in IMF (Figure 46.7). Other causes of a leucoerythroblastic blood film include bone marrow infiltration, severe sepsis, severe haemolysis and a sick neonate. Teardrop poikilocytes (dacryocytes), basophilic stippling, macrocytosis (which may or may not be secondary to folate deficiency), giant platelets and megakaryocyte fragments may also be present.

Bone marrow
Attempts at bone marrow aspiration often yield a dry-tap or a haemodilute sample, making aspirate morphology of limited diagnostic value. Sufficient material can often be obtained from either bone marrow or peripheral blood to assess the karyotype, which can help exclude diagnoses such as CML. Other chromosomal abnormalities may be found in up to 60% of cases as detailed above. Abnormalities of chromosomes 5 and 7 are usually found in patients with prior exposure to genotoxic agents and are associated with a poor prognosis.

Bone marrow trephine biopsy is essential to make a diagnosis of IMF. Initial stages are characterized by an increase in bone marrow cellularity in association with a disorganization of marrow architecture and the presence of abnormal large megakaryocytes often occurring in clusters (Figure 46.8). Bone marrow fibrosis becomes increasingly dominant and progressively replaces haemopoiesis. Intrasinusoidal haemopoiesis can sometimes be seen at this stage (Figure 46.9). The degree of fibrosis is best demonstrated using silver impregnation, which stains reticulin fibres (Figure 46.8). Collagen fibres are best demonstrated using a trichrome stain. The degree of fibrosis can be graded from I to IV according to severity. In a minority of cases of advanced IMF (less than 10%), osteosclerosis ensues with thickening of the trabecula and extensive deposition of osteoid. Such changes may be evident on plain radiography.

(a)

(b)
Figure 46.8 Bone marrow trephine sections from a patient with early-stage IMF. The H&E stain (a) shows hypercellularity, disorganized architecture, increase in megakaryocyte numbers and prominent sinusoids. The silver stain (b) also shows a marked increase in reticulin fibres.
Figure 46.9 Bone marrow trephine section in IMF (H&E). Note the presence of two dilated sinusoids (arrows) containing immature haemopoietic cells, including megakaryocytes.

Treatment

The only curative treatment for IMF is allogeneic stem cell transplantation, but this is only appropriate for a small proportion of patients. In most cases, therapy is supportive and aimed at alleviating symptoms.

Conventional allogeneic bone marrow transplantation is only a realistic option in young patients who represent perhaps 10% of all cases. The decision to proceed to transplantation should always be made in light of the patient's specific prognosis, age and general fitness. Only small series have been reported and the long-term survival of patients < 45 years is approximately 50%, with a 30% transplant-related mortality. For patients > 45 years,

outcomes are much worse, with long-term survival of 10–20%. Small numbers of reduced-intensity transplants have been reported, which show that this modality is feasible and safe in patients over 50 years old, although its efficacy is not yet clear.

Anaemia responds to treatment with androgens in up to one-third of cases, with the best responses seen in patients without massive splenomegaly and with a normal karyotype. The drugs most commonly used are oxymethalone (50–150 mg daily) and danazol (400–600 mg daily). Both of these can have virilizing effects and can lead to abnormal liver function. Patients with a reduced red cell survival may respond to treatment with corticosteroids. Human recombinant erythropoietin has recently shown promise in small clinical studies of anaemia in IMF. Splenectomy also has a role (see below). Despite these treatments, most patients become transfusion dependent eventually.

Cytoreductive therapy can be useful in the management of some aspects of IMF, such as hepatosplenomegaly, constitutional symptoms and troublesome thrombocytosis. Hydroxyurea is the most widely used agent but anagrelide has also been used for thrombocytosis.

The indications for splenectomy include splenic pain/discomfort, constitutional symptoms, portal hypertension and transfusion-dependent anaemia. In contrast, there is no good evidence that thrombocytopenia responds to splenectomy. The procedure has significant mortality (around 10%) and morbidity, particularly in elderly patients. Problems include perioperative bleeding, infection and thrombosis as well as rebound thrombocytosis and progressive hepatomegaly. It is particularly important to correct any coagulation abnormalities prior to surgery.

Splenic irradiation is an alternative to splenectomy in some cases and it can significantly reduce splenic size, albeit transiently. This procedure is not without complications as it can lead

Table 46.7 Prognostic scoring systems in myelofibrosis: the Lille scoring system.

Number of adverse prognostic factors	Risk group	Cases (%)	Median survival (months)
0	Low	47	93
1	Intermediate	45	26
2	High	8	13

From Dupriez *et al.* (1996).

to life-threatening cytopenias. Radiotherapy can also be useful for treating pockets of extramedullary haemopoiesis involving vital organs or bodily cavities.

The antiangiogenic drug thalidomide has been reported to improve anaemia, thrombocytopenia or splenomegaly in approximately one-half of the patients, but these changes are clinically significant only in a small proportion (< 20%). Thalidomide is poorly tolerated at conventional doses (> 100 mg per day) with more than one-half of the patients being unable to tolerate it beyond 3 months and it increases the risk of extreme thrombocytosis and probably that of venous thrombosis. Trials of lower doses of the drug alone or in combination with prednisolone are under way and preliminary data suggest that such doses are better tolerated and may be similarly efficacious.

Imatinib mesylate has at most a modest effect in reducing splenic size in IMF, but other tyrosine kinase inhibitors are under investigation. Bisphosphonates can be useful in patients with bone pain.

Prognosis

The median survival is 3–5 years, but the range is very wide. As a result, efforts have been made to devise algorithms to individualize prognosis. The two most widely used algorithms are shown in Tables 46.7 and 46.8. More recently, an elevation in the circu-

Table 46.8 Prognostic scoring systems in myelofibrosis: The Sheffield prognostic system.

Age (years)	Hb (g/dL)	Karyotype	Median survival months (95% CI)

lating CD34$^+$ cell count above 300×10^6/L was identified as an additional adverse prognostic feature.

Mastocytosis

Mastocytosis comprises a rare group of disorders characterized by a pathological increase in mast cells in tissues, including the skin, bone marrow, liver, spleen, lymph nodes and the gastrointestinal tract. Mastocytosis can be an isolated finding or can form part of other haematological disorders, including myelodysplastic syndromes, myeloproliferative disorders or AML. Some cases of mastocytosis involve just the skin (cutaneous mastocytosis) whereas others involve multiple tissues and are associated with systemic symptoms (systemic mastocytosis). A proposal for the classification of mast cell diseases was recently put forward (Table 46.9).

The first case of urticaria pigmentosa (a form of cutaneous mastocytosis) was described in 1869 by Nettleship, and systemic disease due to increased mast cells was first documented by Ellis in 1949. The observation that stem cell factor (SCF) is an essential growth factor for mast cell development has led to significant advances in our understanding of this group of diseases.

Pathophysiology

After a search for abnormalities of SCF failed to identify any pathological changes, researchers turned to c-Kit, the tyrosine

Table 46.9 Classification of mastocytosis.

kinase receptor for SCF. A c-*kit* point mutation leading to a single amino acid substitution (Asp816Val) was thus identified. This mutation leads to ligand-independent phosphorylation of c-Kit and a consequent clonal expansion of mast cells.

Asp816Val was originally identified in cases of mastocytosis with associated haematological disorders but is now known to be present in the majority of adults presenting with urticaria pigmentosa or indolent systemic mastocytosis. More recently, other activating mutations affecting the same codon have been identified in a minority of adult cases of cutaneous mastocytosis (Asp816Tyr, Asp816Phe). A different mutation has been reported in a small number of cases of paediatric mastocytosis, namely Lys839Glu, which surprisingly gives rise to a dominant-negative (inactivating) form of c-Kit; the significance of this observation remains unresolved.

Recent reports have suggested that in some cases of mastocytosis the c-*kit* mutation is found in other haemopoietic cells such as B cells, myeloid cells and T cells. These results suggest that mastocytosis, as with the classical MPDs, may be a clonal disorder of the haemopoietic stem cell.

Clinical features

Cutaneous manifestations

Urticaria pigmentosa is the usual presenting feature in children and adults with isolated mastocytosis. Yellowish-brown lesions, usually macular and sometimes papular, appear in a patchy distribution. Less commonly, there is diffuse involvement of the skin, which becomes thickened and darker brown (Figure 46.10). Pruritus is common, as is flushing, and some cases develop haemorrhagic bullous disease. Whealing of lesions upon rubbing is known as Darier's sign.

Systemic disease

Systemic manifestations are very heterogeneous and are thought

Figure 46.10 Urticaria pigmentosa in a 55-year-old woman. Note the widespread pink or brownish macules that become confluent in areas.

to be largely secondary to mast cell mediator release. Episodes of flushing, angioedema, or even anaphylaxis with or without any specific trigger, can arise as a result of systemic histamine release. Gastrointestinal symptoms include abdominal pain, diarrhoea, nausea and vomiting. Gastritis and peptic ulceration may occur secondary to hyperhistaminaemia and severe cases may develop malabsorption. Osteoporosis is well recognized and can sometimes lead to pathological fractures. Peripheral blood cytopenias may arise secondary to mast cell infiltration of the bone marrow. Hepatosplenomegaly is more common in cases associated with another clonal haematological disorder. Fever, fatigue and weight loss can sometimes ensue and may result from the release of cytokines such as tumour necrosis factor-alpha (TNF-α) and IL-1.

Symptoms of organ failure due to organ infiltration are characteristic of aggressive systemic mastocytosis. Depending on the organs involved, cytopenias, pathological fractures, impaired liver function, ascites and malabsorption can all be seen as part of this syndrome.

Investigations

Clinical features of mastocytosis can be highly suggestive of the disease but diagnosis usually requires histological and biochemical confirmation. An algorithm has been proposed for the diagnosis of systemic mast cell disease and is shown in Table 46.10.

Routine investigations should include a full blood count, liver function tests and a random serum tryptase. Tests for histamine metabolites in 24-h urine specimens are probably no more useful than measurements of serum tryptase. Plasma levels of soluble CD25 and CD117 (kit) have shown promise as novel markers of mast cell disease.
Figure 46.11 Systemic mastocytosis involving the bone marrow (H&E). Malignant whorls of rounded and spindle-shaped mast cells are seen infiltrating the bone marrow in a paratrabecular distribution (arrow). A lymphoid aggregate and areas of hypocellularity are seen interspersed between the mast cell infiltrate and neighbouring haemopoietic islands (arrowhead) (courtesy of Dr Wendy Erber).

Bone marrow aspiration and trephine biopsy allow assessment of bone marrow involvement. Mast cell aggregates can be visualized on conventional haematoxylin and eosin-stained sections (Figure 46.11) but stand out much more clearly with stains such as toluidine blue (Figure 46.12). Immunochemistry using antitryptase antibodies can also be very useful, being highly specific for mast cells. Flow cytometry to look for expression of CD2 and CD25 in bone marrow mast cells may be useful as this phenotype is not seen in normal mast cells.

Abdominal ultrasound or computerized tomography (CT) scanning should be performed to look for hepatosplenomegaly and lymphadenopathy. Plain radiography and bone densitometry can be used to assess bone involvement and the presence of osteoporosis. Endoscopy and biopsy can be useful if gut involvement is suspected.

Treatment

Despite significant advances in the understanding of its pathophysiology, no curative treatment exists for mastocytosis, the management of which remains symptomatic.

There are four main components to the management of mastocytosis:
1 avoidance of factors that can trigger mediator release from mast cells;
2 treatment of acute mediator release;
3 treatment of chronic mediator release;
4 reduction of the mast cell burden/organ infiltration.

Avoidance of triggers of mast cell mediator release is primarily an exercise in patient education. Severe reactions due to systemic mast cell mediator release are difficult to predict in patients with
(a)
(b)

Figure 46.12 Toluidine blue stain of bone marrow aspirate (a) and trephine biopsy section (b) in systemic mastocytosis. Abnormal spindle-shaped mast cells containing metachromatic granules are seen.

mastocytosis and do not correlate well with disease category, mast cell burden or severity of other symptoms. All patients and relevant health-care workers should be warned of particular triggers, including general anaesthesia, contrast radiography and insect stings. Known mast cell activators such as morphine and dextran should only be introduced with great caution. Patients with previous anaphylaxis or severe hypotension should carry injectable adrenaline and they, their family and friends should be instructed in its intramuscular administration. Local mediator release in cutaneous mastocytosis can be moderated by avoidance of triggering factors such as friction and heat.

Acute systemic mast cell mediator release should be treated in much the same way as other forms of anaphylaxis. Treatment with adrenaline and intravenous fluids should be started as soon as possible, with early involvement of intensive care specialists in severe cases. Antihistamines (H_1 and H_2 blockers) should be introduced and continued long-term if the episode was particularly severe or recurrent.

Symptoms of chronic mediator release are the commonest clinical problem in mastocytosis. Symptomatic cutaneous disease should be managed with the help of a dermatologist. Treatments include H_1 and H_2 blockers, topical corticosteroids and PUVA for severe disease. Non-life threatening systemic symptoms such as flushing, abdominal pain and diarrhoea should be treated with H_1 and H_2 blockers, sodium cromoglycate and corticosteroids. Inhibitors of prostaglandin synthesis, such as aspirin and non-steroidal anti-inflammatory drugs, can also be useful. Aspirin should always be started with caution as it can initially lead to acute mediator release. Such drugs can be used prophylactically if symptoms recur frequently. Gastrointestinal disease usually responds to the drugs used to treat chronic systemic symptoms. Leukotriene antagonists anecdotally help with abdominal cramps and diarrhoea. Peptic ulcer and reflux disease should be treated with proton pump inhibitors. Osteoporosis should be treated with bisphosphonates and may be prevented with bisphosphonates or calcium and vitamin D supplementation. Bone density should be recorded and monitored according to the severity of osteoporosis. Radiotherapy can help with severe localized pain.

In patients in whom adequate symptomatic control cannot be achieved and in cases of aggressive mastocytosis, treatment with IFN-α, usually given in combination with oral corticosteroids, should be considered. Splenectomy may help reduce the mast cell burden and associated systemic symptoms. Cladribine was reported to be effective in isolated cases of systemic mastocytosis.

Treatment with chemotherapy is usually reserved for cases of rapidly progressive aggressive mastocytosis, mast cell leukaemia and mast cell sarcoma, but published data are not encouraging. Mast cell sarcoma may also respond to local radiotherapy when appropriate. Allogeneic bone marrow transplantation should also be considered. Treatment of any associated haematological disorder should be undertaken as appropriate for that disorder and the overall prognosis is usually that of the latter.

Future treatments

Treatments that target the mutant c-kit tyrosine kinase have attracted a lot of interest recently. Imatinib was known to inhibit wild-type c-kit in *in vitro* studies and be active against juxtamembrane mutants of c-kit found in gastrointestinal stromal tumours. By contrast, the drug does not have the same effect on malignant mast cells carrying codon 816 mutations, probably because the mutant c-kit does not allow access of imatinib to the site, hence conferring resistance to this drug in a similar way to acquired imatinib resistance in CML (see also Chapter 37). In keeping with this, there have been early reports of its lack of efficacy in the presence of codon 816 mutations. A recent report showing that imatinib was effective in patients with mastocytosis with associated eosinophilia but without demonstrable c-*kit* mutations awaits confirmation, particularly as these cases may represent variants of chronic eosinophilic leukaemia (CEL). Novel tyrosine kinase inhibitors, which can inhibit the Asp816Va*l* mutant c-*kit in vitro*, are under investigation at present.

Prognosis

Age and disease category are the most important determinants of outcome. The most benign syndrome is paediatric mastocytoma, which disappears with time in over 50% of cases. Paediatric urticaria pigmentosa also has a good prognosis and resolves in about one-half of the cases.

In adult mastocytosis, urticaria pigmentosa is usually associated with mast cell deposits in the marrow or other tissues, making this a systemic syndrome. Indolent systemic mastocytosis carries a favourable prognosis and usually persists as a chronic low-grade disorder, although it rarely progresses to aggressive mastocytosis or mastocytosis associated with another haematological malignancy. Aggressive systemic mastocytosis can show a slowly progressive or a rapid clinical course but its overall prognosis has not been well defined in clinical studies. Mast cell leukaemia is rare but has a grave prognosis with a median survival of less than 6 months.

Clonal hypereosinophilic syndromes

Eosinophilia is aetiologically diverse, with helminthic infections being its commonest cause worldwide and atopic disease its commonest cause in the industrialized world. Paul Ehrlich was first to describe the eosinophil in 1879. Based on his and others' observations, it was realized that eosinophilia occurred in helminthic infections, tumours and allergic disorders such as asthma. A case of myeloid leukaemia with marked blood eosinophilia was described by Stillman in 1912. The term hypereosinophilic syndrome (HES) was coined by Hardy and Anderson in 1968, who gave it the definition that is still in use to date. Recently, major progress has been made in elucidating the molecular pathogenesis of clonal eosinophilia as described below.

Pathophysiology

Eosinophilia can be divided into three categories: reactive, idiopathic and clonal (Table 46.11). In reactive eosinophilia, which is by far the most common, the eosinophil count is thought to reflect release of a number of growth factors including IL-3, IL-5 and granulocyte–macrophage colony-stimulating factor (GM-CSF). A large number of diseases can result in the release of these

Table 46.11 Causes of eosinophilia.

Reactive eosinophilia	Infections	Parasitic
		Others (rarely)
	Vasculitides	Polyarteritis nodosa
		Churg–Strauss syndrome
	Connective Tissue Disorders	Rheumatoid arthritis
		Systemic sclerosis
		Systemic lupus erythematosus
	Allergic and inflammatory disorders	Asthma
		Eczema
		Bullous skin diseases
		Inflammatory bowel disease
	Drug reactions	Hypersensitivity
		L-Tryptophan (eosinophilia–myalgia syndrome)
	Immunodeficiencies	Wiskott–Aldrich Syndrome
		Job's syndrome (hyper-IgE syndrome)
	Neoplasia	Hodgkin's disease
		Non-Hodgkin's lymphoma
		Peripheral blood T-cell clones
		Some cases of acute lymphoblastic leukaemia
		Non-haematological cancers (rarely)
Clonal eosinophilia	Chronic eosinophilic leukaemia	
	Atypical chronic myeloid leukaemia (*PDGFR*β fusions)	
	8p11 Myeloproliferative syndrome (*FGFR1* fusions)	
	Chronic myeloid leukaemia (*BCR–ABL* fusion)	
	Acute myeloid leukaemia, e.g. carrying inv(16)	
	Acute lymphoblastic leukaemia (occasionally)	
Idiopathic eosinophilia	Hypereosinophilic syndrome	

cytokines, including parasitic infections, allergic diseases, vasculitides, drug reactions and malignancies.

Idiopathic eosinophilias are those in which the cause is obscure. Within this category, HES describes patients with an unexplained elevation of peripheral blood eosinophils ($> 1.5 \times 10^9$/L) for more than 6 months associated with end-organ damage.

Clonal eosinophilias are those in which the eosinophilia is part of a clonal haematological malignancy. CEL is defined as an eosinophil count $> 1.5 \times 10^9$/L, with evidence of eosinophil clonality or an increased blast account in blood or bone marrow. The distinction between this entity and HES is blurred as it relies on the availability of a clonal marker. Indeed it has been shown recently that 25–50% of cases labelled as HES in fact have a microdeletion on chromosome 4, which results in the fusion of the *FIP1L1* and *PDGFR*α genes and the generation of a constitutively active tyrosine kinase. Importantly, patients carrying this fusion respond well to the tyrosine kinase inhibitor imatinib. Some patients with HES that do not carry this fusion gene also

respond to imatinib, suggesting that in such cases other tyrosine kinases may be dysregulated.

In addition to CEL, a number of other haematological malignancies may be associated with increased numbers of clonally derived eosinophils, and in many cases, this reflects tyrosine kinase dysregulation. *PDGFR*β rearrangements (e.g. *TEL–PDGFR*β) may present as chronic myelomonocytic leukaemia (CMML) or atypical CML. The 8p11 myeloproliferative syndrome (EMS) is associated with rearrangements in the *FGFR1* gene (e.g. *ZNF198–FGFR1*) and leads to a chronic myeloproliferative disorder that frequently presents with eosinophilia and associated T-cell lymphoblastic lymphoma. CML, a consequence of the *BCR–ABL* tyrosine kinase fusion protein, may also be associated with a clonal increase in eosinophil counts (see also Chapter 37).

Eosinophilia as part of the malignant clone also occurs in patients with AML associated with inversion of chromosome 16 and the *SMMHC–CBF*β rearrangement. It has been reported

that rare cases of acute lymphoblastic leukaemia (ALL) may be associated with clonal eosinophilia but in this disease the eosinophilia is more usually secondary to growth factor release. Growth factor release is also believed to underlie the reactive eosinophilia seen in Hodgkin's disease and in cases with clonal T cells in the peripheral blood.

Sustained hypereosinophilia can lead to symptomatology and end-organ damage regardless of its aetiology, but does not always do so. The reasons for this are unclear but may lie in the heterogeneity of eosinophilia and genetic differences between individuals that affect the propensity of eosinophils and other granulocytes to inflict tissue damage.

Clinical features

Much of the tissue damage in eosinophilia is believed to be secondary to eosinophil degranulation and release of mediators such as eosinophil cationic protein and major basic protein. Eosinophil mediators act mainly locally in tissues infiltrated by eosinophils to cause tissue damage. The recent finding that a raised serum tryptase in a subset of cases with clonal eosinophilia hints at a role for other cells (mast cells) in some cases.

Patients can present with constitutional symptoms such as fatigue, muscle aches or fevers. Pruritus, angioedema, diarrhoea and cough may also be present. Many tissues can be involved, but cardiac disease is the major cause of mortality. The heart can be affected by endomyocardial fibrosis, pericarditis, myocarditis and intramural thrombus formation. Death is usually due to dilated cardiomyopathy.

Involvement of the central and peripheral nervous systems can result in mononeuritis multiplex, paraparesis, encephalopathy and even dementia. Pulmonary involvement can take the form of pulmonary infiltrates, fibrosis or pleural disease with effusions. Gastrointestinal involvement can manifest as diarrhoea, gastritis, colitis, hepatitis or the Budd–Chiari syndrome. The skin can be affected by pruritus, angioedema, papules or plaques. Rarely, other tissues such as the kidneys and bones can be involved.

Investigations

There are two aims in the investigation of eosinophilia, one is to establish its aetiology and the other to look for evidence of end-organ damage. As regards the former, given the diverse nature of the aetiologies of eosinophilia, a full history including family history, drug history and travel history can provide valuable clues. Investigations will usually aim to exclude reactive causes and will be guided by the clinical picture.

Bone marrow aspiration will reveal morphological abnormalities associated with haematological malignancies and allows cytogenetic analysis. It is also important to look for clonal T-cell receptor (TCR) gene rearrangements, the *FIPIL1–PDGFRα* and *BCR–ABL* fusion genes, together with rearrangements of the

Figure 46.13 Cardiac magnetic resonance imaging scan in a 65-year-old man with HES, showing a rim of subendocardial fibrosis (arrow).

*PDGFR*β and *FGFR1* genes. It has been reported that serum tryptase is raised in patients who carry the *FIPIL1–PDGFRα* fusion.

Investigations to assess end-organ damage will depend on the clinical presentation. However, echocardiography should be performed and repeated annually in patients with sustained eosinophilia, particularly as cardiac disease correlates poorly with the eosinophil count. If there is strong clinical suspicion of cardiac damage then cardiac magnetic resonance imaging (MRI) can be useful, as this is more sensitive in detecting early disease (Figure 46.13). If there is doubt as to the aetiology of cardiac disease, endomyocardial biopsy may demonstrate eosinophil infiltration. Serial monitoring of pulmonary function may be required if there is evidence of lung involvement.

Treatment

Treatment should be used to halt or reverse organ damage. Eosinophilia without evidence of end-organ damage does not usually require treatment. When underlying clonal or non-clonal disorders are identified they should be treated appropriately.

Patients with rearrangements of the *PDGFR*α or *PDGFR*β genes, respond well to imatinib, with normalization of eosinophil counts within weeks. A trial of imatinib is also reasonable in patients with HES who lack a clonal marker, as a proportion of these patients also respond.

For patients who do not respond to imatinib, prednisolone is the initial treatment of choice. Steroids reduce blood eosinophilia and the inflammation resulting from tissue infiltration. Cardiac disease may respond even in the absence of a significant reduction in the eosinophil count. Hydroxyurea and IFN-α may

benefit patients resistant to steroids. Cladribine and cyclosporin were also found to be of use in some cases.

Prognosis

The reported prognoses of CEL and HES are highly variable, with estimates of 3-year survival ranging from 23% to 96%. This is likely to reflect heterogeneity within these two categories of patients. In patients with HES, indicators of a poor prognosis include lack of response to steroids, a markedly elevated eosinophil count, normal immunoglobulin E levels, splenomegaly, dysplastic features and male sex. Many of these adverse prognostic indicators may turn out to be markers of clonal (versus reactive) eosinophilia.

Chronic neutrophilic leukaemia

Chronic neutrophilia is a very common entity, and is usually secondary to chronic infections, chronic inflammation or malignancy. A very small subgroup of patients with chronic neutrophilia have chronic neutrophilic leukaemia (CNL), a clonal haematological disorder (Figure 46.14). Given the absence of a specific marker for this disease, CNL, like ET, is a diagnosis of exclusion.

The first description of CNL was probably that by Tuohy in 1920. In the ensuing 75 years, a total of less than 100 cases have been reported in the literature, mostly as isolated case reports. This rarity has hampered progress in the understanding of its pathogenesis (see also Chapter 37).

Pathophysiology

Isolated mild to moderate neutrophilia is commonly seen in many clinical contexts associated with inflammation, ranging
Figure 46.14 Abundance of mature neutrophils and band forms in a blood film from a patient with chronic neutrophilic leukaemia.

from infections to tissue trauma/infarction, haemorrhage, arthritis, inflammatory bowel disease and many other ailments. Additionally, it can be seen in smokers, after vigorous exercise and in patients taking corticosteroids. In these contexts, the aetiology is usually apparent and such cases are rarely referred to a haematologist.

Marked chronic neutrophilia (neutrophils $\geq 20 \times 10^9$/L) is usually secondary to a chronic infection or an underlying malignancy. Neutrophilia is particularly common in metastatic cancer but can pre-date overt malignancy by months or years. Such leukaemoid reactions are thought to reflect the release of cytokines such as granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF) from tumour cells.

Neutrophilia is clonal in a small number of cases. These cases can be subdivided into two main groups: 'true' CNL and neutrophilic chronic myeloid leukaemia (N-CML). The two groups are only distinguishable by the presence in the latter of a rare type of *BCR–ABL* rearrangement that produces a 230-kDa fusion protein (p230). In addition, rare patients with a myelodysplastic syndrome can closely mimic CNL but exhibit dysplastic features and there are anecdotal reports of PV evolving into a disorder indistinguishable from CNL. The literature also includes reports of what was thought to be clonal chronic neutrophilia in association with plasma cell dyscrasias. However, data are accumulating that this type of neutrophilia is non-clonal and probably a result of cytokine release from clonal plasma cells.

Diagnostic features of CNL are shown in Table 46.12. N-CML usually exhibits these features, save for its association with the p230 *BCR–ABL* rearrangement.

Table 46.12 Diagnostic features of chronic neutrophilic leukaemia.

Peripheral blood leucocytosis $> 25 \times 10^9$/L
Segmented neutrophils and bands > 80% of white blood cells
Immature granulocytes < 10% of white blood cells
Myeloblasts < 1% of white blood cells
Hypercellular bone marrow biopsy
Neutrophilic granulocytes increased in percentage and number
Myeloblasts < 5% of nucleated marrow cells
Normal neutrophil maturation pattern
Hepatosplenomegaly
No identifiable cause of reactive neutrophilia
No evidence of another haematological malignancy
No Philadelphia chromosome or *BCR–ABL* fusion
No evidence of another myeloproliferative disorder (i.e. normal PCV, platelets < 600, no bone marrow fibrosis or other features of IMF)
No evidence of a myelodysplastic syndrome (i.e. no dysplasia, monocytes $< 1 \times 10^9$/L)

Modified from Vardiman *et al.* (2001).

Clinical features and treatment

A recent review of the literature identified only 33 cases that fulfilled criteria for CNL. These cases exhibited a 2:1 male–female ratio and a median age at diagnosis of 62.5 years (range 15–86 years). The median survival was 30 months, with only 28% of cases surviving to 5 years. Transformation to AML ensued in 21% (7 out of 33) and this was invariably lethal. Other causes of death included sepsis and haemorrhage.

Hb was normal and platelet counts were above 100×10^9/L in most cases. The mean leucocyte count at diagnosis was 54.3×10^9/L. Vitamin B_{12} levels were raised and neutrophil alkaline phosphatase (NAP) levels were not low in most cases. Hyperuricaemia and gout were common. Bone marrow biopsies were markedly hypercellular and showed a marked granulocytic proliferation, as did the bone marrow aspirates. Cytogenetic abnormalities were seen in about one out of three cases, with deletion of 20q being the only recurrent abnormality identified thus far. In a small number of cases, XCIP studies were used to demonstrate the clonal nature of CNL in patients lacking a cytogenetic marker.

The optimal treatment of CNL remains unclear. Oral cytoreductive agents such as hydroxyurea and busulphan can control the neutrophil count, as can IFN. The only potentially curative modality is allogeneic bone marrow transplantation and this option should be considered in younger patients.

Neutrophilic chronic myeloid leukaemia

This entity is probably even more rare than CNL, with only a handful of documented cases in the literature. The reported cases followed a more benign course than conventional CML, with a lower white cell count, lower proportion of immature granulocytes, milder anaemia, less marked splenomegaly and a lower propensity to acute transformation. Given recent advances in the treatment of bcr–abl-related diseases, it is important to consider and exclude neutrophilic chronic myeloid leukaemia (N-CML) during the investigation of chronic neutrophilia.

Normal haemostasis

Geoffrey Kemball-Cook, Edward GD Tuddenham and John H McVey

Introduction

Haemostasis is one of a number of protective processes that have evolved in order to maintain a stable physiology. It has many features in common with (and to some extent interacts with) other defence mechanisms in the body, such as the immune system and the inflammatory response. These links are most clearly seen in ancient species such as the horseshoe crab (*Limulus polyphemus*), where a primitive 'coagulation' pathway is initiated by entry of endotoxin into the haemolymph. Vestiges of this process still exist in humans and may give rise to serious clinical consequences. For example, disseminated intravascular coagulation (DIC) can be initiated by Gram-negative septicaemia (see Chapter 51). However, consequent upon the development of a high-pressure blood circulatory system, extra components have evolved and have resulted in a complex, highly integrated process in all vertebrates (Figure 47.1). Indeed, recent analysis of the haemostatic network in bony fish suggests that the network in its entirety evolved over 430 million years ago, prior to the divergence of bony fish from tetrapods.

The high blood pressure generated on the arterial side of vertebrate circulation requires a powerful, almost instantaneous but strictly localized *procoagulant* response in order to minimize blood loss from sites of vascular injury without compromising blood flow generally. Systemic *anticoagulant* and clot-dissolving components have also evolved to prevent extension of the procoagulant response beyond the vicinity of vascular injury resulting in unwanted thrombus formation in the slow, sometimes intermittent, blood flow in the veins. The resultant haemostatic system is thus a complex mosaic of activating or inhibitory feedback or feed-forward pathways, integrating its five major components (blood vessels, blood platelets, coagula-

tion factors, coagulation inhibitors and fibrinolytic elements). Furthermore, links between haemostasis and other elements of the body's overall defence response, such as the complement and kinin-generating processes and phagocytosis, must also be considered.

This chapter reviews current concepts of haemostasis in humans and is aimed at providing a background for the understanding of the haemostatic disorders described in succeeding chapters. Attempting to understand these complex events is a considerable task, even to the expert; for the relative newcomer to the subject, it may first be useful to present an overview of events that follow damage to a blood vessel, leading to effective haemostasis and subsequent restoration of vessel patency. Following this introduction, each of five main areas will be examined in relative isolation, while at the same time acknowledging points of interaction and overlap.

Overview of haemostasis

In the most simplistic terms, blood coagulation occurs when the enzyme thrombin is generated and proteolyses soluble plasma fibrinogen, forming the insoluble fibrin polymer, or clot; this provides the physical consolidation of vessel wound repair following injury. 'Haemostasis' refers more widely to the process whereby blood coagulation is initiated and terminated in a tightly regulated fashion, together with the removal (or fibrinolysis) of the clot as part of vascular remodelling; as such, haemostasis describes the global process by which vessel integrity and patency are maintained over the whole organism, for its lifetime.

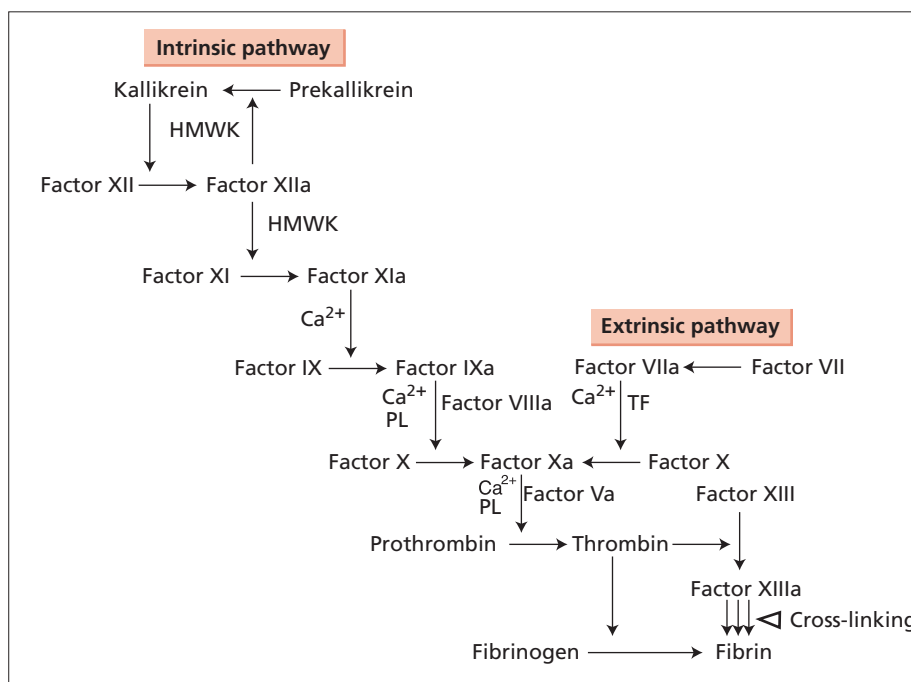
Although it is pedagogically convenient to present the subsystems of haemostasis as if they operate independently, the whole


Figure 47.2 The coagulation cascade. The traditional concept of blood coagulation with separate intrinsic and extrinsic pathways converging in the generation of FXa. HMWK, high-molecular-weight kininogen; PL, phospholipid.

haemostatic mechanism is integrated *in vivo* so that thrombin generation is localized, limited and followed by fibrinolysis and tissue remodelling, which are also localized and limited. Furthermore, thrombin generation is not a simple exponential 'cascade' as was originally envisaged, but a complex network of interactions with positive and negative feedback loops, thus the effects of varying the concentration of any component in such a system is not intuitively obvious. Figure 47.2 presents a version of the earlier 'cascade' concept for intrinsic and extrinsic pathways of thrombin generation.

Although a tremendous improvement over previous ideas, obvious deficiencies of such a scheme include:
• no explanation for the absence of a clinical bleeding tendency in deficiencies of factor (F) XII, prekallikrein or high-molecular-

weight kininogen, even though these deficiencies markedly prolong surface-activated coagulation assays for haemostasis *in vitro*;
• no explanation for why factor FVIII or FIX deficiency cause clinically severe bleeding, as the extrinsic pathway ought to bypass the need for FVIII and FIX;
• no explanation for bleeding in FXI deficiency less severe than seen with FVIII and FIX deficiency;
• no explanation for the lag phase followed by explosively rapid thrombin generation observed experimentally;
• no appreciation of the overriding importance of tissue factor (TF) in the initiation of all coagulation processes, both in normal haemostasis and pathological situations such as thrombosis;
• no appreciation of the complex role of platelets, other than as provision of a 'procoagulant surface' (see Chapter 47).

Figure 47.1 (*opposite*) The haemostasis network. The network includes elements of coagulation initiation via TF–FVIIa interaction, amplification via the FX-ase and prothrombinase complexes, feedback inhibition through specific inhibitors and clot dissolution by fibrinolysis. Module organization of proteins is indicated (see Figure 47.8) as proposed by Bork and Bairoch (www.bork.embl-heidelberg.de/modules/) and all abbreviations are given in the text. Protein names are coloured as follows: functionally active proteins, red; inactivated or inhibited proteins, blue; precursors and fibrinogen-derived components, black. Lines and arrows are coloured thus: dashed red lines, positive procoagulant feedback loops; dashed blue lines, negative feedback and inhibitory loops; solid black lines, interactions or processes. Cream boxes indicate assembly of macromolecular complexes on a cellular phospholipid surface. The process of blood coagulation is

initiated by the exposure of cells expressing TF to flowing blood. Thrombin generation is propagated by a series of positive feedback loops, leading to fibrin deposition. This process is controlled by a series of negative feedback steps: the initiation complex is inhibited by the formation of the quaternary complex TF–FVIIa–FXa–TFPI and the active proteases FIXa, FXa and thrombin are inactivated by the serpin AT. In addition, thrombin initiates a negative feedback pathway by activating PC, leading to the inhibition of FVa and FVIIIa. The generation of fibrin leads to activation of the fibrinolytic pathway through binding of tPA, which leads to plasminogen activation and fibrin degradation. This pathway is also subject to inhibition through the binding of the serpins PAI-1 and α_2-AP to tPA and plasmin respectively. All these processes, plus platelet activation occur simultaneously or with short lag times.

Table 47.1 Role of 'contact factors' in integrating body defence mechanisms.

Pathway involved	Function	Comment
Coagulation	Prevention of blood loss	Not essential for normal haemostasis
Fibrinolysis	Maintenance of vessel patency	May be important
Complement	Contribution to immune response	Not essential
Kinin generation	Pain, capillary permeability, cardiovascular effects	May be important *in vivo*
Renin–angiotensin system	Blood pressure control	No demonstrated role *in vivo*
Chemotaxis	Phagocytosis, bactericidal activity	May be important *in vivo*

Tissue factor initiates blood coagulation

A major development over the past 10 years has been the realization that exposure of blood to cells expressing TF on their surface is both necessary and sufficient to initiate blood coagulation *in vivo*. The contact system ('intrinsic' pathway, see Figure 47.2) therefore does not appear to have a physiological role in haemostasis. Table 47.1 presents some other putative roles for the 'contact factors' in body defence. TF is constitutively expressed at biological boundaries such as skin, organ surfaces, vascular adventitia and epithelial–mesenchymal surfaces, where it functions as a 'haemostatic envelope'. This ensures that following disruption of vascular integrity blood is immediately exposed to cells expressing TF, leading to the initiation of blood coagulation. The primary control of haemostasis is therefore the anatomical segregation of cells expressing functional TF from other components of the coagulation network present in blood.

Amplification of the initial stimulus

An updated concept of TF-initiated thrombin generation, including the important feedback reactions of thrombin, is shown in Figure 47.3. As stated above, it is now clear from various *in vitro* and *in vivo* experiments that the physiological initiator of blood coagulation is the exposure of the circulating zymogen FVII to membrane-bound TF. Activation of FVII to the protease FVIIa and formation of a very high affinity complex of TF with FVIIa results in the activation of factors IX (FIX) and X (FX) by the TF–FVIIa complex. In the absence of its activated cofactor FVa, FXa generates only trace amounts of thrombin from prothrombin. Although insufficient to initiate significant fibrin polymerization, thrombin formed in this 'initiation' stage of coagulation is able to back-activate FV and FVIII by limited proteolysis. In the 'amplification' phase of coagulation FVIIIa forms a complex with FIXa, the 'FX-ase' complex (FVIIIa–FIXa) and activates sufficient FXa that in complex with FVa forms the 'prothrombinase' complex (FVa–FXa), resulting in the explosive generation of thrombin that ultimately leads to generation of a fibrin clot.

A key feature of these processes is the assembly of multiprotein complexes on a phospholipid (PL) surface provided *in vivo* by cell surfaces; for procoagulant complexes such as FX-ase and prothrombinase, this surface is provided by activated platelets (see Chapter 48). Each of these complexes consist of a cofactor (TF, FVa, FVIIIa), an enzyme (FVIIa, FIXa, FXa) and a substrate that is a zymogen (FIX, FX and prothrombin) of a serine protease. The product of one reaction becomes the enzyme in the next complex. The cofactors FV and FVIII are themselves activated by limited proteolytic digestion.

Feedback inhibition of the procoagulant response

This process of 'amplification' occurs independently of the TF–FVIIa complex, which is rapidly inactivated by tissue factor pathway inhibitor (TFPI) by forming a quaternary inhibited complex (Figure 47.4). This explains the requirement for indirect activation of FX via FIXa–FVIIIa, and back-activation of FXI by thrombin, to permit further activation of FIX. Figure 47.4 also indicates the role of one of the other important inhibitors of the network, antithrombin (AT), which generally damps down thrombin generation by forming inactive complexes with FIX, FX, FXI and thrombin. The rate of inhibition by AT is substantially increased by binding glycosaminoglycans (GAGs) on the surface of endothelial cells.

Thrombin also proteolytically activates an anticoagulant pathway (Figure 47.5; protein C (PC) pathway). Thrombomodulin (TM), an endothelial cell (EC) surface receptor, plays a pivotal role in the activation of this anticoagulant pathway. TM binds thrombin and, by an allosteric mechanism, alters its substrate specificity. The procoagulant substrates of thrombin, including FV, FVIII and fibrinogen, are no longer efficiently proteolysed. The preferred substrate of the thrombin–TM complex is PC, a zymogen that is proteolysed to activated PC (APC). The activation of PC is augmented by another cellular receptor, endothelial cell protein C receptor (EPCR), which provides a direct EC binding site for PC and thus increases the apparent affinity of the thrombin–TM complex for PC. In complex with its cofactor, protein S (PS), APC rapidly inactivates the procoagulant cofac-
Figure 47.3 The haemostasis network: thrombin generation. Blood coagulation is initiated by exposure of FVII to cells expressing the integral membrane protein TF. Activation of FVII to the protease FVIIa results in the activation of FIX and FX by the TF–FVIIa complex. In the absence of its activated cofactor FVa, FXa generates only trace amounts of thrombin. Although insufficient to initiate significant fibrin polymerization, trace amounts of thrombin formed in this 'initiation' stage of coagulation are able to back-activate FV and FVIII by limited proteolysis. In the 'amplification' phase of coagulation, FVIIIa forms a complex with FIXa, activating sufficient FXa (in complex with FVa) to lead to the explosive generation of thrombin, ultimately leading to generation of a fibrin clot. The FX-ase (FVIIIa–FIXa) and prothrombinase (FVa–FXa) complexes assemble on phospholipid surfaces. Colours and symbols as in Figure 47.1.

tors FVa and FVIIIa by specific proteolysis, forming a negative-feedback loop. The PC pathway assembles on the EC surface and is most active in the microvasculature, where the relative EC surface area is highest.

Fibrinolysis

The final step in the regulation of fibrin deposition is the prevention and/or rapid removal of insoluble fibrin by the fibrinolytic system (Figure 47.6) described more fully later in the chapter. Briefly, generation of fibrin and its binding of tissue plasminogen activator (tPA) leads to an increase in the affinity of tPA for and action upon plasminogen (PLG). This results in generation of plasmin at the site of the fibrin clot, leading to generation of soluble fibrin degradation products (FDPs). The fibrinolytic sys-tem is also subject to inhibition through the action of inhibitors of tPA and plasmin, namely plasminogen activator inhibitor 1 (PAI-1) and α_2-antiplasmin (α_2-AP) respectively.

Blood vessels

Blood vessel structure

The basic structure of blood vessels can be broken down into three layers (Figure 47.7a): the intima, the media and the adventitia. It is the materials that make up these layers and the size of these layers themselves that differentiate arteries from veins, and indeed one artery or one vein from another artery or vein. The intima is the innermost layer and the surface is covered with a
Figure 47.4 The haemostasis network: inhibitors of thrombin generation. The 'initiation' of blood coagulation via generation of FIXa and FXa by TF–FVIIa is shut down by the action of TFPI, which forms a quaternary complex with TF–FVIIa–FXa. Further generation of FIXa occurs following back activation of FXI by thrombin. The serine proteases FIXa, FXa, FXI and thrombin are all inhibited by antithrombin (AT). Colours and symbols as in Figure 47.1.

single layer of ECs (the endothelium), which rest on a basement membrane of subendothelial microfibrils that are composed of collagen fibres and some elastin. The media or middle layer contains mainly circularly arranged smooth muscle cells and collagenous fibrils, and is divided from the adventitia by the external elastic lamina. The muscle cells contract and relax, whereas the elastin allows vessels to stretch and recoil. The adventitia or outermost layer is composed of collagen fibres and fibroblasts that protect the blood vessel and anchor it to surrounding structures.

The endothelium

The endothelium functions in a multitude of physiological processes including the control of cellular trafficking, the regulation of vasomotor tone and maintenance of blood fluidity. ECs possess surface receptors for a variety of physiological substances, for example thrombin and angiotensin II, which may influence vascular tone directly or indirectly through various haemostasis-

related events. Once activated, ECs express at their surface, and in some cases release into the plasma, a variety of intracellular adhesion molecules (e.g. vascular cell adhesion molecule, E-selectin, P-selectin and von Willebrand factor, vWF), which modulate leucocyte and platelet adhesion, inflammation, phagocytosis and vascular permeability.

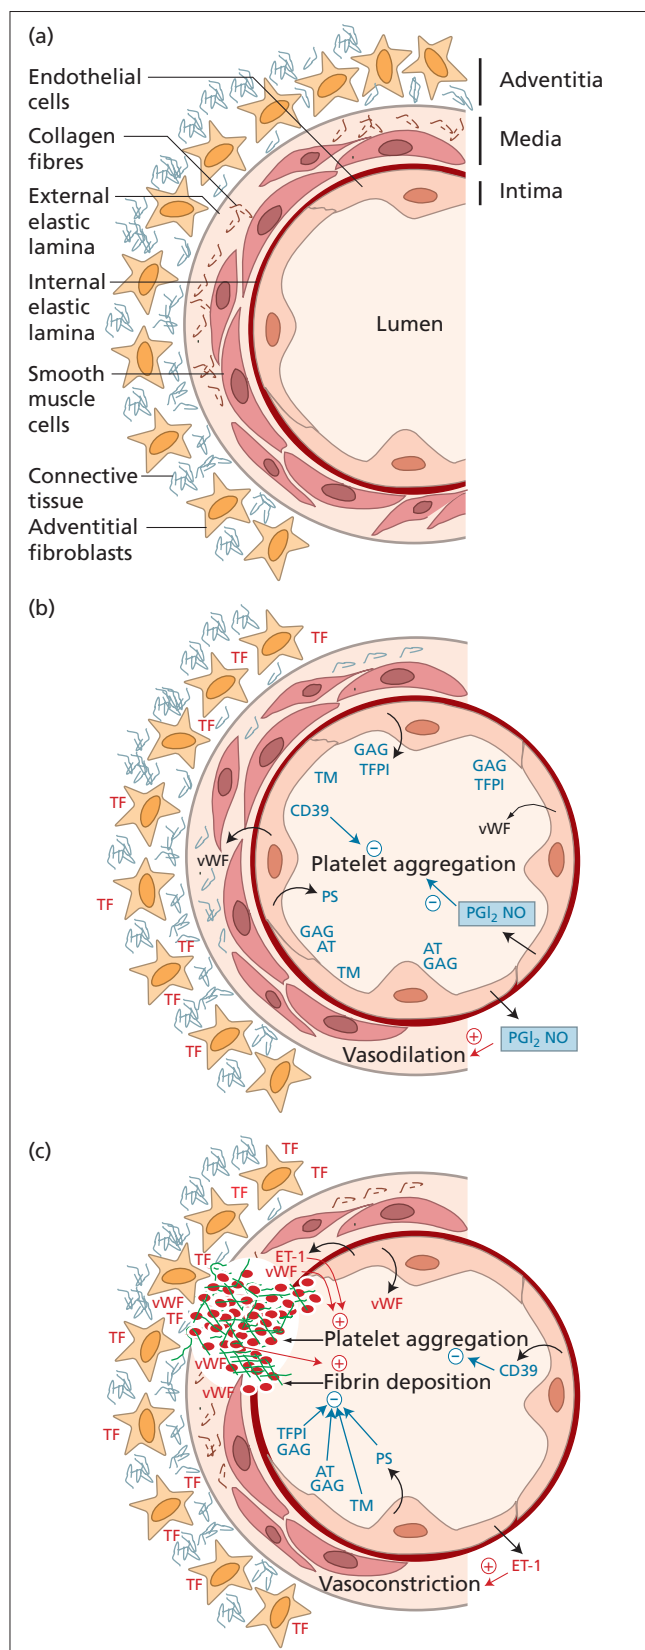
However, the endothelium should not be regarded as a simple homogeneous cell type. It would appear that EC phenotypes are differentially regulated; at any given point in time, structural and functional phenotypes may vary between segments of the vascular tree and at any given location, the endothelial phenotypes may change from one moment to the next. EC heterogeneity occurs between different organs, within the vascular loop of a given organ, and even between neighbouring ECs of a single vessel.

Endothelial cell activities affecting platelet–vessel wall interaction

Intact ECs exert a powerful inhibitory influence on haemostasis by virtue of the factors that they synthesize and release or express
Figure 47.5 The haemostasis network: protein C pathway. Thrombin bound to TM on endothelial cell surfaces activates PC bound to its receptor EPCR. APC in complex with its cofactor PS inactivates FVa and FVIIIa by further proteolytic cleavages. Colours and symbols as in Figure 47.1.
Figure 47.6 The haemostasis network: fibrinolysis. Both PLG and tPA bind to polymerized fibrin, promoting the cleavage of PLG by tPA to active plasmin, which then degrades cross-linked fibrin to soluble FDPs. Modulation of fibrinolysis is achieved by serpin inhibition: PAI-1 inactivates tPA, while α_2-AP inhibits plasmin. In addition, TAFIa removes Lys residues from fibrin, removing PLG and tPA binding sites. Colours and symbols as in Figure 47.1.

on their surface (see Figure 47.7b). Two of these, prostaglandin I_2 (PGI_2, or prostacyclin) and nitric oxide (NO), also known as endothelium-derived relaxing factor (EDRF), have powerful vasodilator activity, acting on smooth muscle cells in the vessel wall (basal-directed secretion) and hence modulating blood flow. Both substances inhibit aggregation of platelets and leucocytes (luminal-directed secretion) by raising intraplatelet levels of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) respectively (see below).

PGI_2 is the major prostaglandin synthesized by ECs, a small amount also being produced by fibroblasts and smooth muscle cells. Its action on platelets involves binding to a specific G-protein coupled receptor (PTGIR) that activates adenylate cyclase, which increases the intraplatelet cAMP concentration. This pro-motes Ca^{2+} uptake into the dense tubular system and inhibits phosphatidylinositol metabolism, both of which prevent platelet aggregation and the consequent release of storage granules containing procoagulant molecules, for example vWF and FV. The effect of PGI_2 on the vessel wall (where the target cell is the smooth muscle cell) is vasodilatation.

The precursor of PGI_2 is arachidonic acid, derived from EC membrane phospholipids by phospholipases. Arachidonic acid is first converted to prostaglandins PGG_2 and PGH_2, the so-called cyclic endoperoxides, by cyclo-oxygenase, and then to PGI_2 by prostacyclin synthetase. Thrombin and other agents (see above) that are generated at the site of injury stimulate the synthesis of PGI_2 by adjacent ECs, which counteracts the platelet-aggregating activity of the protease and thereby helps to


localize platelet plug formation. Elevation of intravascular pressure and trauma, including venepuncture, also increase PGI_2 production and may be a source of artefactually high plasma levels. PGI_2 is rather unstable and largely degrades spontaneously to 6-keto $PGF_1\alpha$, with a half-life of only a few minutes in whole blood. 6-keto $PGF_1\alpha$ is biologically inert, but in some tissues a variable proportion of PGI_2 may be enzymatically converted to other prostaglandins such as 6-keto $PGF_1\alpha$ or di-hydro di-keto $PGF_1\alpha$, which retain some platelet-inhibitory activity.

The once-held belief that PGI_2 is a circulating hormone with limited platelet–platelet interactions within the bloodstream is probably false, as plasma levels of PGI_2 are at least two orders of magnitude below that needed to inhibit platelet aggregation. Although in some settings, such as following severe trauma, it is possible that markedly raised systemic levels could occur transiently, it is more likely that PGI_2 serves mainly as a local hormone, principally concerned with vascular tone, but possibly also inhibiting the extension of the platelet plug beyond the immediate vicinity of any endothelial damage.

NO is synthesized in smooth muscle cells, macrophages and activated platelets, as well as by ECs. Its synthesis and secretion may be constitutive (when it serves as a local hormone to 'fine-tune' blood flow). Stimulated (inducible) synthesis of NO also occurs in ECs exposed to cytokines (interleukin 1, IL-1, tissue necrosis factor, TNF, or endotoxin for example), is slower but long lasting, and can have undesirable side-effects such as inflammation, cytotoxicity or prolonged hypotension. Like PGI_2, it has a very short half-life (3–5 s), being rapidly oxidized to the inactive nitrite (NO_2^-) or nitrate (NO_3^-) forms.

In addition to PGI_2 and NO, ECs also express an ecto-ADPase (CD39) on their cell surface, which rapidly metabolizes ATP and ADP that is released from activated platelets to AMP, thereby drastically reducing or abolishing platelet recruitment and aggregation.

The 21-amino-acid peptide endothelin-1 (ET-1) is the predominant isoform of the endothelin peptide family, which includes ET-2, ET-3 and ET-4. It exerts various biological effects,

Figure 47.7 (*left*) Blood vessel architecture and functions in haemostasis. (a) Anatomy of a generic blood vessel, not to scale, as layer thicknesses vary widely between arterial and venous sides, and between large and small vessels. The main three layers (intima, media and adventitia) are shown. (b) Role of the endothelium in maintaining vessel patency through general anticoagulant and anti-platelet mechanisms. In the absence of vessel damage, TF cannot contact plasma components, coagulation inhibitors are present on the endothelial surface and platelet aggregation is inhibited. (c) Localized haemostatic response to vessel injury, through initiation of coagulation by TF exposure and platelet activation/aggregation by exposure of extravascular collagen to plasma vWF. Procoagulant responses away from lesion site are damped down by anticoagulant and anti-platelet factors derived from endothelium.

including vasoconstriction and the stimulation of cell proliferation in tissues both within and outside of the cardiovascular system. In the endothelium, ET-1 is predominantly released abluminally towards the vascular smooth muscle, where it acts as a potent vasoconstrictor and mitogen for smooth muscle cells. In addition, ET-1 stimulates the production of cytokines and growth factors. Furthermore, it stimulates neutrophil adhesion and platelet aggregation and is chemotactic for macrophages.

vWF is a multimeric adhesive glycoprotein that plays an important role in primary haemostasis by promoting platelet adhesion to subendothelium at sites of vascular injury and platelet–platelet interaction under high shear-rate conditions. It is also a carrier of FVIII and this association protects FVIII from rapid proteolysis. Failure of FVIII to bind vWF, as occurs in the 'Normandy' variant of von Willebrand disease (see Chapter 49), leads to its rapid turnover and resulting FVIII deficiency. vWF is synthesized by ECs, megakaryocytes and platelets. It is secreted via constitutive and regulated pathways, the latter involving storage and release following stimulation. The constitutive secretion pathway is active only in ECs. The storage granules found in cells that synthesize vWF are the Weibel–Palade body in ECs and the α-granule in megakaryocytes and platelets.

Mature vWF is composed of identical disulphide-linked subunits, each comprising 2050-amino-acid residues and up to 22 carbohydrate chains with a mass of approximately 278 kDa of which 10–19% is carbohydrate. Two subunits joined at the C-termini form dimers that are the building blocks of larger multimers ranging in size from approximately 500 kDa to in excess of 10 000 kDa. The ultra-large vWF multimers secreted by ECs may appear as thin filaments that are several microns long or as globular molecules. Under conditions of high shear stress, these globular molecules may be unwound, especially if platelets are available to bind. These ultra-large vWF multimers can only be detected transiently in normal plasma because they are cleaved by a plasma metalloproteinase (ADAMTS 13). Deficiency of ADAMTS 13 results in accumulation of ultra-large vWF multimers in plasma, leading to enhanced shear-induced platelet aggregation; this is responsible for the microvascular thrombosis seen in patients with thrombotic thrombocytopenic purpura (TTP; see Chapter 52). The adhesion of platelets to vWF is mediated through the binding of the platelet receptor GPIbα to the A1 domain of vWF immobilized on exposed subendothelial matrices. Mutations in the genes encoding the GPIbα complex lead to the bleeding disorder Bernard–Soulier syndrome.

Thrombospondin 1 (TSP1) is an abundant constituent of the platelet α-granules of platelets and Weibel–Palade bodies of ECs. TSP1 was first identified as a thrombin-sensitive protein (TSP) that was released in response to activation of platelets by thrombin. Upon release from platelets, TSP1 binds to the platelet surface in a Ca^{2+}-dependent manner and interacts with integrins $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$, CD36 and the integrin-associated protein (IAP), integrin-bound fibrinogen and fibronectin. TSP1 activates $\alpha_{IIb}\beta_3$ through its binding to IAP. This results in spreading of platelets and aggregation.

Endothelial cell anticoagulant activities

ECs express two cellular receptors, TM and EPCR, which regulate the anticoagulant pathway initiated by thrombin (protein C pathway). TM is constitutively expressed on all ECs with the exception of the brain. EPCR is expressed strongly in the ECs of arteries and veins in heart and lung, less intensely in capillaries in the lung and skin, and not at all in the endothelium of small vessels of the liver and kidney. In addition, ECs synthesize and secrete PS, the cofactor for APC inactivation of FVa and FVIIIa.

TFPI is synthesized and secreted by ECs. TF–FVIIa activity is controlled by TFPI, which forms a quaternary inhibited complex TF–FVIIa–FXa–TFPI. The vast majority of TFPI is associated with the vascular endothelium, binding GAGs on the surface of ECs. The GAGs are also important in binding and modulating the activity of AT, which inhibits FIXa, FXa, FXIa and thrombin.

Endothelium and vessel injury

Disruption of the vessel wall following injury leads to exposure of procoagulant stimuli (see Figure 47.7c). Cells of the adventitia or epithelial cells of the surrounding tissues express TF constitutively on their surfaces. Formation of a complex between TF and FVII present in blood flowing from the injured vessel initiates coagulation, resulting in fibrin generation. Exposure of collagen within the subendothelial layers of the vessel wall leads to immobilization of plasma vWF triggering platelet adhesion, aggregation and activation. Release of the contents of platelet α-granules increases the local vWF concentration and activation of ECs results in release of Weibel–Palade bodies, further increasing the local concentration of vWF and expression of the cell adhesion molecule, P-selectin, leading to further recruitment of platelets. In addition, release of ET-1 from the endothelium stimulates platelet aggregation and vasoconstriction, limiting blood loss. The anticoagulant activities of the ECs discussed above serve to limit fibrin deposition and prevent vascular occlusion.

Endothelial cell-derived fibrinolytic factors

Three important fibrinolytic factors are detectable in the vessel wall: tissue plasminogen activator (tPA) and plasminogen activator inhibitor type 1 (PAI-1) are synthesized primarily by ECs, whereas urinary plasminogen activator (uPA, urokinase) is mainly derived from fibroblast-like cells in the kidney and gut. Unlike vWF and P-selectin, tPA and PAI-1 are not stored in the Weibel–Palade bodies and, in the resting state, synthesis and secretion are slow, resulting in low circulating levels. However, stimulated synthesis and release occur in response to a variety of stimuli.

Platelets

Platelets play a vital role both in the formation of an aggregate or primary plug that stems blood loss at the site of injury, but also by supplying a cellular surface, which is tailored to the assembly of procoagulant complexes such as FX-ase and prothrombinase. Chapter 48 gives details of platelet biogenesis and function, including their specific roles in haemostasis.

The following three sections of this chapter give an overview of the genetics, biochemistry, structure and physiology of the proteins involved in haemostasis. The first section (Coagulation factors) deals largely with the proteins that are required to generate and amplify the procoagulant stimulus, resulting in the formation of a stable fibrin clot. The following two sections (Naturally occurring inhibitors of blood coagulation, and Fibrinolysis) treat the regulatory pathways that delimit and control this powerful procoagulant response, and ultimately participate in remodelling of tissues following trauma.

Coagulation factors

Almost certainly, all the major soluble protein components of the thrombin-generating pathways, the PC pathway, the fibrinolytic pathway and their respective inhibitors have now been identified. In addition, a number of cell surface receptors relevant to these pathways have also been identified, but new receptors are still being discovered; the last word on the physiology of these systems certainly remains to be written.

Coagulation factor modules

The haemostatic proteins are generally assembled from a small number of modules or domains; indeed, the coagulation zymogens were the first family of proteins in which modular assembly was recognized (Figure 47.8). Although differing in exact amino acid sequence in different proteins, a module always adopts the same three-dimensional structure or *fold*. Here these modules will be introduced, following which the proteins themselves will be described briefly.

Gamma-carboxyglutamic acid module

The defining feature of this module is the presence of a number (9–12) of glutamic acid residues that are post-translationally modified by the addition of a carboxyl group to the γ-carbon by a vitamin K-dependent carboxylase: the gamma-carboxyglutamic acid (GLA) domain is usually N-terminal and confers affinity to negatively charged phospholipid (PL) membranes such as those of activated platelets or ECs, promoting the assembly of functional multiprotein complexes on these surfaces. Proteins containing GLA modules are commonly referred to as 'vitamin K-dependent factors' as this vitamin is a cofactor in the carboxylation reaction: they include prothrombin, FVII, FIX, FX, PC, PS and protein Z.

In the absence of Ca^{2+} ions, the module is partially disordered, but the crystal structure of several GLA-containing factors in the presence of Ca^{2+} ions reveals a fold in which the GLA residues are directed inwards towards a row of these ions; as blood contains approximately 1 mmol/L free Ca^{2+} ions it is expected that GLA modules will be in this functional form *in vivo*. The mechanism whereby the Ca^{2+} ion-dependent fold leads to the property of binding to PL probably involves the exposure of hydrophobic residues (an 'omega-loop') on the surface of the folded GLA module.

Amphipathic helix modules

These modules are also known as aromatic amino acid stacks and frequently occur immediately C-terminal to GLA modules. They consist of three turns of α-helix, one face of which has hydrophilic residues and the opposite face hydrophobic aromatic side chains. In prothrombin, the helix is folded along the top edge of the GLA module, whereas in the TF–FVIIa complex the module is stretched out so that its hydrophobic face interacts with the membrane proximal module of TF, its cellular receptor.

Epidermal growth factor-like module

These modules are widely dispersed in nature and are often involved in protein–protein interaction. The typical structure is a β-pleated sheet maintained by a characteristic 1–3, 2–4, 5–6 arrangement of three disulphide bonds. Haemostatic proteins contain one (tPA, pro-urokinase), two (FVII, FIX, FX, PC), four (PS) or six (TM) EGF modules. The N-terminal epidermal growth factor (EGF) modules of PC, FVII, FIX and FX contain a high-affinity Ca^{2+} ion binding site.

Kringle module

Found first in prothrombin (two modules) and named for the resemblance of the two-dimensional disulphide bond structure to a type of pastry, these modules also appear in fibrinolytic proteins (pro-urokinase, plasminogen and tPA) and in apolipoprotein(a). The three-dimensional fold brings into close apposition the sulphur atoms of two disulphide bonds to create a compact ellipsoidal structure that is often involved in protein–protein interaction (e.g. kringle 2 of prothrombin with FVa).

Apple module

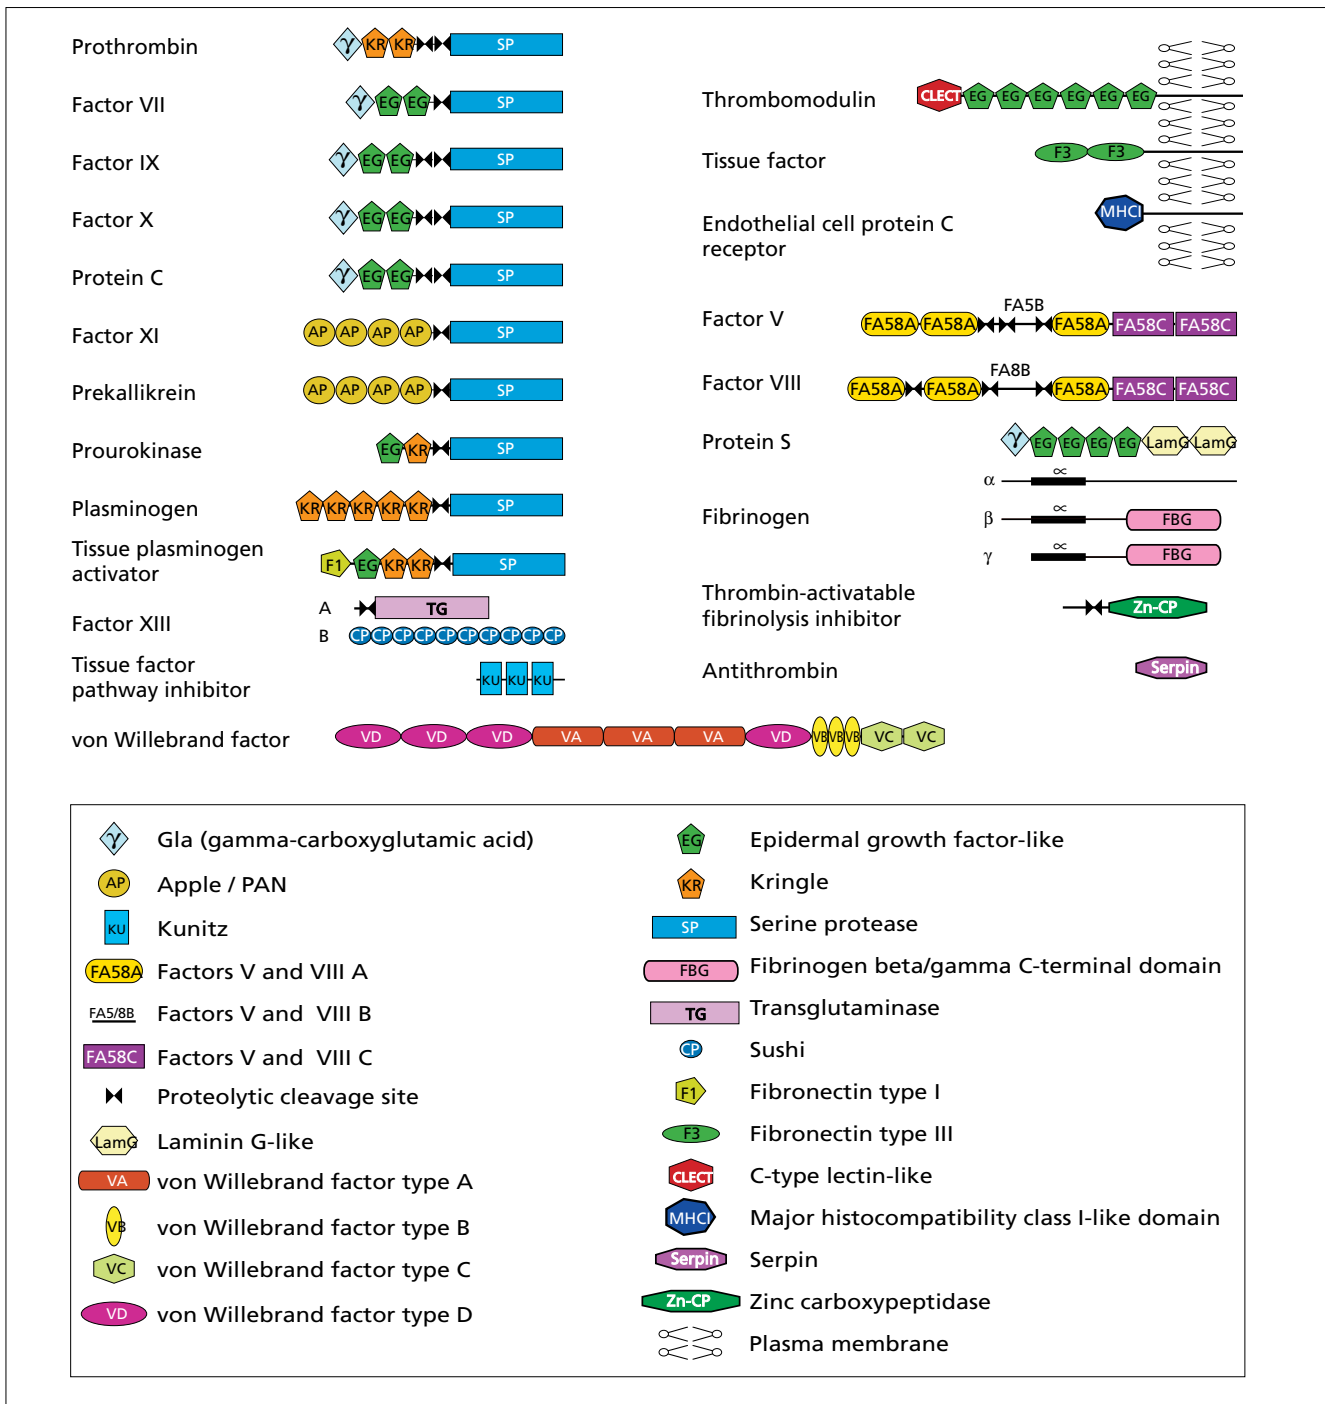
Also known as PAN modules, these are found in the haemostatic proteins only in FXI and prekallikrein (four each) and they mediate protein interactions. In FXI, binding to high-molecular-weight kininogen (HMWK) is via apple 1, FIX via apples 2 and 3 and homodimerization via apple 4. The complete three-dimensional fold is unknown although that of a submodule has been reported.


Figure 47.8 Modular organization of haemostasis proteins. Evolutionary relationship of many factors is suggested by their modular organization of proteins, represented as proposed by Bork and Bairoch (www.bork.embl-heidelberg.de/modules/).

Serine protease module

Chymotrypsin-like serine protease modules carry out many of the specific proteolytic steps in haemostasis. The core of these modules shows remarkable conservation with the structure of chymotrypsin, with three residues forming the canonical catalytic triad (His57, Asp102, Ser195; chymotrypsin numbering). All the protease modules circulate as part of a multidomain inactive zymogen, and are activated by cleavage of an interdomain connecting peptide at an Arg–Val or Arg–Ile bond. The neo-N terminus then folds into a cleft in the globular protease module

to ion-pair with an invariant Asp residue adjacent to the active site Ser, creating an oxyanion hole essential for substrate accommodation and catalytic function. These modules are always found at the C-terminus of the multidomain proteases, apart from thrombin, which consists of a single protease domain after activation of prothrombin.

Serine protease inhibitor (serpin) module

The serpins are a family of single-module proteins that have evolved to neutralize (more or less specifically) individual serine proteases, although some cross-specificity is seen. The general mechanism seems to be as follows (although in specific instances it may vary). The β-pleated sheet structure of the serpin presents a bait loop that enters the active site of its protease target; the protease cleaves the bait loop but remains covalently tethered to one end of it via its active site Ser, moves to the opposite end of the serpin molecule by a form of 'spring mechanism' and is subsequently degraded.

Glycosaminoglycans (GAGs) such as heparin or heparan sulphate accelerate the inhibition process in some serpins by converting a latent form of the serpin to an active form, through binding to a region of β-sheet strands 3 and 5, forcing the bait loop into an active conformation; this is at least a major part of the explanation for the anticoagulant action of clinical heparin administration. GAGs may also accelerate serpin inhibition of specific proteases by a 'template' mechanism, whereby both proteins bind to the same GAG chain. The detailed structure of the trimeric complex of thrombin, antithrombin and heparin has recently been determined by X-ray crystallography.

Kunitz module

Kunitz domains are found throughout nature in a large number of proteins, generally inhibitors of specific serine proteases. The canonical Kunitz inhibitor is bovine pancreatic trypsin inhibitor (BPTI), which has been closely studied. The Kunitz fold contains three disulphide bridges and structural analysis of protease inhibitor pairs shows that the general mechanism of inhibition involves insertion of a loop containing the module's Arg15 side chain (BPTI numbering) into the enzyme's serine protease module, where it occupies and disrupts the active site. Crucial for the modulation of activity of TF–FVIIa, the coagulation initiation complex, is tissue factor pathway inhibitor (TFPI), a three-Kunitz module protein found predominantly on the EC surface, tethered by affinity to cell surface GAGs.

FV and FVIII A module

Three of these (A1, A2 and A3) are each present in FV and FVIII. Each A module consists of two plastocyanin-like 'Greek key' β-barrels, which, in the blue proteins, coordinate type-I copper ions. They are involved in the multiple protein–protein interactions that permit assembly of the FX-ase and prothrombinase complexes. From the crystal structure of ceruloplasmin, it is predicted that the three modules are arranged in a triangular

structure in the two coagulation factors. The anticoagulant action of the protease activated protein C (APC) is mediated via specific cleavages in the N-terminal A1 and A2 domains of the activated cofactors.

FV and FVIII C module

Two of these (C1 and C2) are each present in FV and FVIII (and also milk fat-binding globule proteins among others). The C-terminal C2 domains of each have been implicated in PL binding, and the crystal structures of both FV C2 and FVIII C2 reveal a β-sandwich core and a possible mode of this binding, via insertion of hydrophobic amino-acid side chains into the PL bilayer, together with the close approach of positively charged Arg and Lys side-chains to negatively charged PL head groups. In FVIII, the C1 domain may have a role in vWF interaction. In addition, a recent partial structure for APC-cleaved FVa suggests that C1 may also be involved in PL binding.

FV and FVIII B sequences

Both FV and FVIII contain large heavily glycosylated sequences that have been termed 'B domains' as they lie between the A and C modules (although it is uncertain whether these fold as distinct modules). The B domains of FV and FVIII share little sequence identity with each other. They lack procoagulant function as B-domainless versions of these factors retain full activity; there is some evidence that these sequences interact with chaperone/quality-checking proteins during synthesis.

Fibronectin module types I and III

These modules are named for their appearance in the matrix protein fibronectin. An FN-I module is found in tPA and two FN-III modules in TF: the TF modules bind FVIIa in a similar manner to that in which growth hormone receptor binds its hormone ligand. The underlying fold of FN-III is a flattened β-barrel and also occurs in cytokine receptors, immunoglobulins and related proteins such as CD2 and CD4.

von Willebrand factor modules

vWF contains several types of repeated module (A, B, C and D: unrelated to A, B and C found in FV and FVIII), some of which are shared with other multimeric adhesive proteins. So far, structures have been obtained for A1 (implicated in platelet interaction) and A3 (which contains a major site for interaction with collagen fibres).

LamG module

The vitamin-K dependent PS acts as a cofactor in the APC inactivation of FVa and FVIIIa, and has two C-terminal laminin G-like modules where most other vitamin K-dependent haemostatic proteins have a serine protease module. Previously this structure was termed the steroid hormone binding-globulin domain.

MHC class I/CD1 family module

The endothelial protein C receptor (EPCR) is a transmembrane receptor whose external structure is homologous with that of the MHC class I/CD1 family: this MHC/CD1 module interacts with the GLA domain of PC.

Lectin-like module

This module is found at the N-terminus of the anticoagulant protein TM, the EC receptor responsible for binding to thrombin and altering its substrate specificity. The lectin-like module has recently been shown to be responsible for inhibition of leucocyte adhesion to activated endothelium.

Factor XIII modules

FXIII, the transglutaminase that cross-links newly formed fibrin to generate a stable clot, is a non-covalently assembled tetramer consisting of 2 FXIII A and 2 FXIII B modules. Each A module contains four domains (the enzymatic core, two β-barrels and a β-sandwich), whereas the B module consists of ten consecutive Sushi domains (also called glycoprotein-1 or CP domains).

Transmembrane and cytoplasmic modules

Transmembrane modules are hydrophobic segments of variable sequence found in the cell surface membrane-anchored proteins TF, TM, EPCR and thrombin receptors such as the protease-activated receptors (PARs), and which usually adopt an α-helical fold. Some transmembrane cellular receptors, such as TF, also have a cytoplasmic module: these may play a role in cell signalling.

Proteins of the coagulation network

Table 47.2 gives a summary of characteristics of the proteins discussed, including gene location, number of exons, molecular mass, circulating concentration, plasma half-life and presumed function.

Tissue factor

Tissue factor is unambiguously regarded as the sole initiator of coagulation in both normal and pathological coagulation. The processed mature protein is 263 amino acids in length after signal peptide cleavage. The 219-residue extracellular region consists of two FN-III modules anchored into the cell membrane by a 23-residue transmembrane sequence: the extracellular region binds tightly to FVIIa to form a highly active procoagulant complex after exposure of cell surface TF to plasma FVIIa. The 21-residue cytoplasmic module has been implicated in intracellular signalling, however transgenic experiments in mice have shown that this module is not required either for development or coagulant function, so the function of this module is still unclear.

Vascular adventitial cells, neuroglia, vascular smooth muscle and epidermal cells express TF constitutively. It therefore forms a protective envelope around blood vessels and organs, ready to initiate clotting as soon as blood leaks out of vessels. TF is also expressed by monocytes and endothelium after activation by inflammatory cytokines or by endotoxin, for example in sepsis, and on cancerous tissues. Intravascular exposure of TF by any route, but particularly after atherosclerotic plaque rupture (releasing TF-bearing monocytes), can result in thrombosis. Recent work has also focused on the novel hypothesis that functionally active TF can circulate in flowing blood on small procoagulant particles, which may also be transferred from one blood cell type to another via specific receptor-mediated interactions.

Factor VII

Plasma FVII binds to TF, for example after vessel trauma or plaque rupture, to form a complex that initiates coagulation by directly activating FX and to a lesser extent FIX. The FVII gene lies adjacent to the factor X gene, suggesting gene duplication during evolution, and close to that of protein Z. In common with other GLA module-containing proteins, a propeptide sequence encoded by exon 2 directs the GLA module, coded by exon 3, for γ-carboxylation at 10 Glu residues. The two EGF modules are encoded by exons 4 and 5. Exon 6 encodes the connecting or activation peptide, and exons 7 and 8 the serine protease module. FVII is activated by cleavage between residues Arg152 and Ile153, yielding a two-chain disulphide-linked FVIIa molecule; however, this has little catalytic activity until it is bound to TF. The half-life of FVII zymogen in plasma is 3 h and, exceptionally, the half-life of the FVIIa enzyme is 2.5 h, probably because there is no plasma inhibitor capable of effectively neutralizing free FVIIa. In recent years, recombinant FVIIa has entered clinical use as a treatment, first, for haemophiliacs with inhibitors to exogenous FVIII, and, second, for a wider range of bleeding problems and general surgical intervention.

Factor X

The gene and protein structures of FX closely resemble those of FVII. Unlike FVII, zymogen FX circulates as a two-chain, disulphide-linked heterodimer due to excision of a tribasic peptide (Arg–Lys–Arg) at residues 139–141 during synthesis. The light chain of FX therefore consists of the GLA module with 11 γ-carboxyglutamate residues, the amphipathic helix, and two EGF modules. The half-life of FX in plasma is 36 h. FX is activated by either FIXa–FVIIIa or TF–FVIIa, on PL surfaces in the presence of Ca^{2+} ions. FXa forms a PL-bound complex with FVa, which efficiently activates prothrombin (prothrombinase complex).

Factor IX

The FIX gene is located at band Xq26, about 15.2 Mbp from the FVIII gene, thus deficiencies of both factors are X-linked disorders. Deficiency of either FVIII or FIX results in clinical haemophilia (A or B respectively), as the main function of FIX is to participate in the FX-ase complex FIXa–FVIIIa. The FIX

*Factor XI circulates as a 160-kDa homodimer of two 80-kDa monomers.

†Factor XIII circulates as a 326-kDa tetramer of two A- and two B-chains.

‡Fibrinogen circulates as a 340-kDa complex of two each of A-, B- and C-chains.

promoter has been extensively studied and includes sites for liver-specific transcription factors and an androgen-responsive promoter element, which accounts for the haemophilia B Leiden phenotype (FIX deficiency which corrects spontaneously at puberty). The plasma half-life of FIX is 18 h.

The mature protein consists of 415 amino acids and the GLA module contains 12 γ-carboxylated residues. Either TF–FVIIa or FXIa cleaves FIX within the connecting peptide (between residues 145–146 and 180–181), releasing an activation peptide to achieve full activation of FIX.

Factor XI

The protein circulates as a homodimer, linked through a di-sulphide bridge located in apple module 4. Activation of FXI is by a single cleavage performed by thrombin; FXIa then activates FIX directly in free solution. FXI activation by the contact protein FXIIa was originally thought to be a relevant step in 'intrinsic' or contact-activated coagulation, but it is now considered that the feedback activation of FXI by trace thrombin provides a physiologically relevant route for generation of increased amounts of FIXa to assemble FX-ase during the amplification of the initial TF stimulus.

Factor XIII

FXIII circulates as a tetramer of two A-chains and two B-chains. The B-chains function as carrier for the A-chains, which, after activation by thrombin, function as a transglutaminase to cross-link fibrin and other proteins in the clot, resulting in a stable structure. FXIIIa contains a free sulphydryl group at the active site. Platelets also contain FXIII A-chain dimers, which are fully functional after thrombin activation.

von Willebrand factor

The vWF mRNA encodes a large propeptide essential for multi-merization and the mature protomer, totalling 2813 amino acids, which is formed of four repeating modules termed A, B, C and D. During post-translational processing, the protomers dimerize then multimerize with excision of the propeptide. vWF is synthesized in ECs (where it is stored in Weibel–Palade bodies) and in megakaryocytes, where it is stored in the α-granules of platelets. Both Weibel–Palade body and α-granule vWF are released on stimulation by various agonists, including thrombin. Plasma also contains vWF, which is released from ECs via a constitutive pathway. vWF serves two unique functions in haemostasis, as a carrier for FVIII and as the bifunctional ligand mediating platelet GPIb α adhesion to collagen.

Factor VIII

The FVIII gene spans 187 kb of the X chromosome (Xq28) and encodes a protein of 2351 amino acids. After removal of the 19-amino-acid signal sequence, a single chain of 2332 amino acids is transiently formed but is subsequently further processed prior to release as a series of heterodimers, due to variable cleavage within the B-domain sequence. Owing to internal homology, the FVIII module structure can be represented as A1–A2–B–A3–C1–C2. FVIII also has three short acidic inter-module peptides (*a1*, *a2* and *a3*) that are closely implicated in FVIII function.

FVIII is the essential cofactor for activation of FX by FIXa in the 'FX-ase' complex. It has no function until proteolysed to FVIIIa by thrombin or FXa at Arg372–Ser373 and Arg1689–Ser1690. FVIIIa is directly inactivated by APC cleavage at Arg336–Ser337 and Arg562–Ser563, however, functional activity of FVIIIa also decays rapidly by dissociation of the A2 subunit from FVIIIa. The structure and function of FVIII have recently been reviewed (Saenko *et al.*, 2002).

Factor V

The mature protein product is 2196 amino acids in length after cleavage of a 28-amino-acid signal peptide. The structure of FV, like that of FVIII, can be represented as Al–A2–B–A3–C1–C2. However, the B-domain sequences of FV and FVIII share little sequence identity with each other, although their lengths are similar and both are heavily glycosylated. FV also differs from FVIII in that it lacks the three short acidic intermodule peptides (*a1*, *a2* and *a3*) implicated in FVIII function.

FV is the cofactor for the activation of prothrombin by FXa. It has no cofactor activity until proteolysed by thrombin or FXa at Arg709–Ser710, Arg1018–Thr1019 and Arg1545–Ser1547. FVa is inactivated by APC through cleavages at Arg506–Ser507 and Arg1765–Leu1766. The initial (and rate limiting) cleavage is at Arg506. This is the site of the mutation in FV Leiden (FV Arg506 → Gln), which is resistant to APC, leading to the most common form of familial thrombophilia.

Fibrinogen

The fibrinogen gene cluster is located on chromosome 4 (q32) in the order β-α-γ, with β transcribed in the opposite direction to α and γ. The three chains of fibrinogen are disulphide cross-linked and folded together in an intricate manner. The overall structure of fibrinogen is a symmetrical dimer α2-β2-γ2. Viewed by electron microscopy, the molecule is trinodular, with the outer two globular modules (fragments D) containing the C-termini of all three chains connected to the central globular module (fragment E), which contains the N-termini of all six chains tethered together by disulphide bonds. Coiled coil regions, forming α-helical ropes, connect the lateral and central globular modules.

Polymerization of fibrinogen occurs when thrombin cleaves two short negatively charged fibrinopeptides A and B from the N-termini of the α- and β-chains respectively. This reveals new N-terminal sequences in the fragment E region (called knobs) that fit into holes in the fragment D regions. Polymerization then occurs spontaneously in a staggered half-overlap array, which can elongate indefinitely in either direction. Electron microscopy studies were and still are important in resolving

the molecular architecture of fibrillar fibrin formation, but from 1997 elegant crystal structures of parts of the fibrin(ogen) molecule were successfully produced in a number of laboratories. These structures are revealing the elegant mechanisms of fibrin polymerization.

Prothrombin

The mDNA encodes a preproleader sequence similar to that found in other vitamin K-dependent proteins, followed by a GLA module, two kringle modules, an activation peptide and a serine protease module. FXa complexed with FVa activates prothrombin zymogen to thrombin on a phospholipid surface ('prothrombinase'), upon cleavage of two peptide bonds. The first between Arg271 and Thr272 releases the protease module from the GLA and kringle modules; the second at Arg320–Ile321 generates the catalytic site of thrombin by a typical trypsin-like conformational rearrangement. Fully cleaved thrombin is termed α-thrombin, and is active in free solution against many substrates including fibrinogen, FV, FVIII, FXI (acting as a procoagulant), PC (acting in complex with TM as an anticoagulant) and a range of cellular transmembrane protease-activated receptors or PARs. Thrombin also activates thrombin-activated fibrinolytic inhibitor (TAFI) (in complex with TM), inhibiting fibrinolysis.

Naturally occurring inhibitors of blood coagulation

In common with other defence mechanisms, such as those resulting in kinin release and complement activation, the blood coagulation process can be activated very rapidly when the need arises. This involves the generation of proteolytic enzymes, such as thrombin, which are potentially lethal if their action is not limited. For example, 10 mL of plasma can generate, in theory, sufficient thrombin to clot all of the fibrinogen in the body in 30 s. That it does not normally do so is due in part to the fact that the procoagulant response is most pronounced in the vicinity of the platelet plug forming at the point of vascular injury, while, elsewhere, coagulation is inhibited by substances in plasma or on the vascular surface that exhibit anticoagulant activity.

Classification of physiological anticoagulants

Physiological anticoagulants fall into two main groups: those that inhibit the serine proteases of the coagulation cascade (both Kunitz-type and serpins), and those involved in destruction of the activated coagulation cofactors FVa and FVIIIa (components of the PC system). These inhibitors assume great physiological significance: relatively minor deficiencies (50–70% of average levels) of some of these inhibitors, such as might be found in individuals heterozygous for a genetic defect, are associated with an increased incidence of thrombosis, and homozygous

deficiencies are frequently either fatal in the first few years of life unless prophylactic replacement therapy is instituted, or are not found in nature, suggesting early fetal loss.

In addition to the specific inhibitors, there are some other inhibitory mechanisms that do not fit into either of the above categories, one of these being the detoxifying property of the liver, which plays an important role in removal of activated clotting factors, both directly and after their combination with natural inhibitors. Furthermore, the removal of free thrombin occurs as a result of its adsorption on to fibrin or on to fibrin(ogen) degradation products (FDP). The latter, which cannot themselves take part in a clot, may interfere with normal fibrin polymerization. Although less well-defined than the others, this group appears to be physiologically important, as qualitative defects of fibrinogen (dysfibrinogenaemias) that result in reduced thrombin binding may be associated with a thrombotic disorder (see Chapter 53).

Tissue factor pathway inhibitor – a Kunitz-type inhibitor

The various serpins found in blood (see below) probably play no role in the inhibition of FVIIa in the initiating TF–FVIIa complex. Instead, the action of this serine protease–cofactor complex is modulated by tissue factor pathway inhibitor (TFPI), which is largely found non-covalently associated with GAGs on the EC surface. TFPI structure comprises N- and C-terminal sequences (the latter probably responsible for interaction with GAGs), between which are found three Kunitz-type modules, K1, K2 and K3. The isolated protein has little effect on FVIIa alone, but can form a 1:1 complex with FXa, probably through specific interaction with the K2 module. This TFPI–FXa complex interacts effectively with the TF–FVIIa complex through a specific interaction between TFPI K1 and the FVIIa protease domain, forming a four-member TFPI–FXa–TF–FVIIa complex in which both proteases are inhibited.

Most TFPI in the vasculature (approximately 90%) is associated with (and thought to be synthesized by) ECs, particularly in the microcirculation, with a smaller amount (5–10%) being found in platelets and the rest in plasma. Virtually all circulating TFPI is associated with lipoproteins. Heparin therapy induces a large increase (up to 10-fold) in the plasma concentration of TFPI, suggesting that TFPI binding to ECs is mediated by surface GAGs and that this is reversed by heparin.

Disruption of the murine TFPI gene is incompatible with normal development, suggesting that a deficiency of functional TFPI might lead to clinical thrombosis. However, as the bulk of intravascular TFPI is associated with the EC surface, simple measurement of plasma TFPI levels is not a clear indicator of a deficiency state. Moderately low plasma levels can occur in DIC, septicaemia and following major surgery, possibly due to increased utilization, but heparin infusion increases plasma TFPI in such patients. Whether or not congenital deficiency

of TFPI is a risk factor for thrombosis remains uncertain: after several negative studies in this area, recently a case–control study found a relationship between low levels of TFPI and enhanced risk of deep vein thrombosis.

Serine protease inhibitors (serpins) and heparin

Human plasma contains at least seven inhibitors of serine protease coagulation factors. Apart from α2-macroglobulin, all are single-chain serpins of molecular mass 40–65 kDa. Specificity is imparted by their tertiary structure, which engenders high affinity for a defined substrate or small range of substrates. Of this group, only antithrombin (AT) and heparin cofactor II (HCII) assume haemostatic significance, acting predominantly on proteases generated late in the coagulation cascade (i.e. thrombin and FXa). A deficiency of any of the other serpins (although sometimes giving rise to a clinical disorder due to the failure of neutralization of a serine protease not involved in coagulation pathways) is asymptomatic in terms of haemostasis and will not be treated in detail below.

Several serpins contain GAG binding sites, which, particularly in the case of AT and HCII, but to a lesser extent for PAI type 1 (PAI-1) and APC inhibitor, greatly enhance the rate of interaction with (although not the affinity for) their specific protease(s). As a major source of heparin-like material is heparan sulphate on the EC surface, another possible function of the heparin binding site of these inhibitors (especially AT and HCII) might be to allow them to exert a general and constitutive anticoagulant effect on intact vessels; this may also act to prevent extension of a procoagulant response beyond an area of damaged endothelium.

Antithrombin

Antithrombin (formerly antithrombin III) is a 58-kDa serpin that is synthesized principally in the liver, with a high plasma concentration of 2.4 μmol/L. The turnover of AT *in vivo* is complex, with a rapid initial clearance ($T_{1/2}$ = 10 min) due to equilibration with EC-bound AT, a slower ($T_{1/2}$ = 3 h) clearance rate due to equilibration with the extravascular compartment, and a much slower linear phase with an overall $T_{1/2}$ of 90 h.

Disruption of the murine AT gene results in death of all embryos shortly before birth, with extensive evidence of subcutaneous haemorrhage. In humans, heterozygous AT deficiency is associated with familial thrombosis.

AT forms a stable 1:1 complex with several serine protease coagulation factors, predominantly thrombin but also to some extent FIXa, FXIa, FXIIIa and kallikrein. Initially, the serine at the active centre of the protease cleaves a peptide bond (involving Arg393) in the 'bait loop' near the C-terminus of AT: a large conformational change in the serpin ensues, with the protease still attached to the loop moving to the opposite end of the serpin. The inactivated enzyme-serpin complex is now cleared

rapidly. Complex formation is progressive and only with thrombin and FXa is it rapid enough to be of physiological significance. In purified *in vitro* systems, the $T_{1/2}$ is around 30 s for free thrombin, 90 s for FXa, and 10–25 min for the other enzymes. In each case, the inhibitor–protease complex is rapidly cleared ($T_{1/2}$ = 3 min) from the circulation by the liver.

Heparin, without altering the stoichiometry, induces a > 2000-fold increase in the rate of thrombin inactivation by AT, such that its action becomes almost instantaneous ($T_{1/2}$ < 0.01 s). The unique mechanism of this activation involves release of the 'bait loop' from partial insertion in the β-sheet core of the molecule following heparin binding to AT. Heparin also strongly enhances AT neutralization of FXa and, to a lesser extent FIXa, particularly in the presence of Ca^{2+}, but at therapeutic concentrations it is without significant effect on AT inhibition of contact factors.

Anti-angiogenic and anti-tumour activities have also been described for the cleaved serpin in mouse models. This finding provides further evidence for the inter-relationship of coagulation and angiogenic pathways.

Heparin cofactor II

This serpin (M_r 65 000) is present in plasma at a high concentration of 90 μg/mL (1.2 μmol/L). It appears to be a specific 1:1 inhibitor of thrombin and to have little or no anti-FXa activity. The rate of thrombin neutralization by HCII is increased approximately 1000-fold by heparin, although because of its lower heparin affinity it requires 5–10 times more heparin than does AT. Interaction seems to depend largely on the high anionic charge of heparin and related GAGs. Details of the molecular mechanism of HCII interaction with thrombin have recently been elucidated by X-ray crystallography.

That HCII has some physiological significance is suggested by the fact that it falls in parallel with AT in DIC. However, as AT is in a twofold molar excess over HCII, the latter cannot altogether compensate for a deficiency of AT, which, as stated above, is a well-established cause of a thrombotic tendency. Whether or not HCII deficiency leads to a similar clinical picture remains to be established, as few cases have yet been described and only occasionally has concomitant thrombotic disease been present. HCII mouse knockout animals develop normally and do not show spontaneous thrombosis; however, they show an enhanced propensity to carotid occlusion after deliberate injury to the endothelium, corrected by infusion of purified HCII, suggesting that HCII has a role in prevention of arterial thrombosis.

Heparin and heparin-like substances in plasma

Heparin belongs to the group of polysulphated mucopolysaccharides known as glycosaminoglycans (GAGs), the major commercial source being porcine intestinal mucosa. By virtue of its strong positive charge, heparin combines non-specifically with a number of cationic proteins such as albumin and reacts in a highly specific way with β-lipoproteins, fibrinogen, HCII and

AT. It also mobilizes platelet PF4 and TFPI, which are bound to GAGs on the surface of ECs, and releases lipoprotein lipase into plasma.

Unfractionated heparin (UFH) is an extremely heterogeneous polymer, being composed of between 10 and 100 saccharide units. Only about one-quarter of UFH has any anticoagulant activity *in vitro*, the remainder possibly being responsible for some of its deleterious side-effects, the most important of which is heparin-induced thrombocytopenia. In recent years, UFH has been subjected to various fractionation procedures (including cleavage by nitrous acid, heparinase and oxidizing agents), yielding a number of low-molecular-weight heparin preparations. These low-molecular-weight heparins contain 10–20 saccharide units (M_r 4–6 kDa) and are less often associated with thrombocytopenia. In addition, a minimal pentasaccharide with anticoagulant activity has been identified.

Unfractionated and low-molecular-weight heparin differ in their affinities for the plasma factors with which they interact and in the specific serine proteases that they inhibit; this, together with the dosage administered, must be taken into account when selecting laboratory tests to monitor their therapeutic effect (see Chapter 55). The major anticoagulant activity of both UFH and low-molecular-weight heparin is attributed to the pentasaccharide sequence containing at its centre a 2,3,6 (3-O-sulpho) trisulphated glucosamine group. It is this that binds to lysyl or tryptophan residues in AT in the region of the D helix, inducing the conformational change in the inhibitor. A second anticoagulant action of UFH (at least 20 saccharide units are required) involves direct binding between thrombin (but not FXa or other proteases) and a heparin sequence adjacent to the pentasaccharide. This property of UFH, which brings thrombin and AT into close proximity of each other, explains the greater thrombin-neutralizing activity of UFH compared with low-molecular-weight heparin.

There is of course no detectable heparin in normal plasma. However, endogenous heparin-like molecules (e.g. dermatan sulphate and heparan sulphate), are present on the surface of ECs and, by enhancing the action of AT and HCII, these would have antithrombotic effects. Such mechanisms seem to be of clinical importance, as recurrent thromboses have been reported in association with several dysfunctional AT molecules that inhibit thrombin normally in the absence of heparin but which do not show enhanced reactivity in its presence, presumably due to defects at the heparin binding sites. At points of vascular injury, local accumulation of activated platelets provides a source of heparin-neutralizing activity (PF4) that could overcome the anticoagulant effects of EC-bound heparinoids and permit the procoagulant response to proceed.

Protein Z and protein Z-dependent inhibitor

Protein Z (PZ) is a 62-kDa vitamin K-dependent plasma protein that serves as a cofactor for the inhibition of FXa by PZ-dependent protease inhibitor (ZPI). Although PZ was first described in the 1970s, ZPI is a recently identified 72-kDa member of the serpin superfamily.

The organization of the PZ gene and the structure of the molecule are very similar to those of coagulation factors FVII, FIX, FX and protein C; however, the PZ 'serine protease' module lacks the canonical active site His and Ser residues and therefore cannot function as a protease. PZ circulates in plasma in a complex with ZPI. Inhibition of factor Xa by ZPI in the presence of PL and Ca^{2+} ions is enhanced 1000-fold by PZ, but ZPI also inhibits FXIa in a process that does not require PZ, PL or Ca^{2+}. ZPI activity is consumed during coagulation through proteolysis mediated by FXa (with PZ) and FXIa. PZ may serve to dampen the procoagulant response *in vivo* as PZ deficiency dramatically increases the severity of the prothrombotic phenotype of FV Leiden mice. Studies to determine the potential roles of PZ and ZPI deficiency in human thrombosis are in progress.

Alpha-1-antitrypsin

This is a serpin whose primary targets are predominantly pancreatic and leucocyte elastases. In addition, it is reported to be responsible for about 70% and 35%, respectively, of the FXIa- and FXa-neutralizing activity in plasma, but it has little effect on overall thrombin inhibition and a straightforward deficiency of α_1-antitrypsin (α_1-AT) is not associated with hypercoagulability.

An abnormal molecular form of α_1-AT in which there is a Met → Ser substitution at the active centre (antitrypsin Pittsburgh) has been described, rendering it functionally identical to AT with a high affinity for thrombin. At a plasma concentration of 25 µmol/L, the variant circulates at a 10-fold higher level than AT, and gives rise to a clinical bleeding tendency. It is, however, unaffected by heparin.

C1-esterase inhibitor

The primary target of this serpin is the activated form of the first component of complement, but it also contributes in a minor way to neutralization of FXIa and plasmin. A deficiency of C1-esterase inhibitor, although of no haemostatic consequence, causes angioneurotic oedema, the characteristic lesions of which may sometimes be confused with haematomas.

α_2-Antiplasmin

This serpin is the principal inhibitor of the fibrinolytic enzyme plasmin. It also has weak activity against several coagulation proteases, especially the contact factors. However, any anticoagulant action against proteases late in the coagulation cascade (e.g. FXa) is only apparent at concentrations well in excess of those in normal plasma. Its mechanism of action and clinical importance are discussed further in the section on fibrinolysis below.

α_2-Macroglobulin

α_2-Macroglobulin (α_2-MG) (M_r 740 000) is composed of four identical chains, is not a member of the serpin superfamily

and its effects are not restricted to serine proteases. It binds to coagulation factors at a site away from the serine-active centre, the interaction involving the formation of a bond between cysteine and glutamate residues in the inhibitor and a lysyl group in the protease. Inhibition is produced by steric hindrance rather than by active site inactivation and, indeed, the proteases retain some esterolytic and amidolytic activity, particularly against small peptides, a fact that should be borne in mind when using chromogenic substrates to assay coagulation inhibitors. It is responsible for approximately 50%, 20% and 10% of the inhibition of kallikrein, thrombin and FXa respectively.

A deficiency of α_2-MG is not associated with a thrombotic tendency. It is, however, an acute phase reactant and it is possible that, when elevated under conditions of stress, or when the other major antithrombins or antiplasmins are overwhelmed, it might become a significant inhibitor of coagulation or fibrinolysis. Moreover, it has been suggested that the raised level of α_2-MG that exists in children (150–200% of adult values) may compensate for a low level of AT, and explain why thrombotic episodes do not usually occur before puberty in congenitally AT-deficient patients.

The protein C pathway – inhibition of cofactors FVa and FVIIIa

The activated forms of coagulation cofactors FV and FVIII (FVa and FVIIIa) are potent procoagulants that enormously enhance the activity of serine protease factors in the 'FX-ase' and 'prothrombinase' complexes (see above). It is not unexpected that these cofactors should be subject to a negative feedback mechanism that limits their procoagulant activity. This is achieved by a complex series of reactions collectively referred to as the 'protein C pathway'. Four key factors (Table 47.2) are now known to be involved, the interactions as shown in Figure 47.5.

Protein C

This vitamin K-dependent serine protease has an identical module composition to the procoagulant factors FVII, FIX and FX. In order to exert its anticoagulant effect, PC must first be activated to APC. This is achieved by the action of thrombin which cleaves the heavy chain, releasing a 12-residue (Gly158–Arg169) activation peptide and revealing the active site by the usual chymotrypsin-like mechanism. Thrombin activation of PC is slow in free solution but is markedly accelerated by specific EC receptors for both thrombin (TM) and PC (EPCR), which coordinate the assembly of a membrane complex for PC activation.

Once generated, APC interacts with PS bound to the phospholipid surface of activated platelets, enhancing APC's anticoagulant activity (see below) against FVa and FVIIIa. These procoagulant cofactors are inactivated by APC on the platelet surface by specific cleavage in their A domains, terminating the activity of FX-ase and prothrombinase by disrupting their binding sites for FIXa and FXa respectively; in the absence of PS,

this reaction is inefficient. It appears that APC inactivation of FVa is dominant *in vivo* compared with that of FVIIIa, as the most common form of familial thrombosis is found in individuals with FV Leiden, a mutation of Arg506 in FV, the most important APC cleavage site; however, no corresponding incidence of thrombosis has been associated with mutations at APC sites in the FVIII molecule.

PC is synthesized in the liver, and, being vitamin K dependent, is often low in the newborn. However, such deficiency is compensated for by the reduction in plasma of the vitamin K-dependent procoagulant factors (prothrombin, VII, IX and X), even though its substrates (FV and FVIII) are normal at birth (see Chapter 60). Disruption of the murine PC gene results in lethal perinatal consumptive coagulopathy, whereas in humans homozygous PC deficiency is associated with lethal purpura fulminans (in the absence of PC replacement therapy) and heterozygous individuals have a high risk of venous thrombosis. These observations underlie the crucial importance of the PC pathway for control of normal haemostasis, as well as other pathological states such as sepsis.

Thrombomodulin

Thrombomodulin (TM) is an integral transmembrane receptor found on ECs (in which it is probably synthesized) in virtually all body tissues. It appears to be absent in the brain vasculature and in hepatic sinusoids and lymph node venules. TM is essential for normal fetal development as shown by mouse knockout studies, although $TM^{+/-}$ heterozygous mice appear to be completely healthy.

The protein has an extracellular region composed of an N-terminal lectin-like or CLECT domain and six EGF modules, a transmembrane sequence and a small cytoplasmic region. TM forms a 1:1 complex with thrombin (via the protease's anion-binding exosite I and TM EGF modules 4–6), preventing binding of the protease to its various procoagulant substrates (fibrinogen, FV, FVIII, FXIII and platelet receptors involved in aggregation). TM also plays a part in binding of PC zymogen and, after formation of the TM–thrombin complex on the cell surface, there is a 20 000-fold increase in the rate of activation of PC, so that thrombin effectively becomes an anticoagulant. Binding of PC to TM is also enhanced by EPCR.

The TM–thrombin complex is short-lived, being endocytosed by ECs, where the thrombin is taken up and degraded by the lysosomes while TM recirculates to the cell membrane.

Endothelial protein C receptor

Endothelial protein C receptor (EPCR) was cloned in 1994 as a novel transmembrane receptor on ECs that was able to bind PC and promote its activation by the thrombin–TM complex. The extracellular portion of EPCR is related to the MHC class-I/CD1 proteins, however it lacks the α-3 domain found in the extracellular portion of most of the family: there is good evidence that the α-1 and -2 extracellular modules of EPCR interact with the

PC GLA module. EPCR may function by localizing the PC molecule to the EC surface, moving laterally on the cell surface to locate a thrombin–TM complex, then presenting the PC molecule optimally for thrombin cleavage to form APC.

The essential role of EPCR was demonstrated recently by targeted deletion of the murine EPCR gene, resulting in early fetal death with evidence of thrombosis at the maternal–fetal interface. Abrogation of EPCR function *in vitro* reduces the rate of PC activation by thrombin–TM, whereas blockage of EPCR action by a specific anti-EPCR monoclonal antibody in baboons given thrombin resulted in reduced APC levels amid evidence of excessive coagulopathy. Blockage of EPCR on challenge with *Escherichia coli* also led to worse outcomes in an animal model of sepsis, whereas administration of APC improved survival in experimental sepsis. Evidence supporting a role of the APC system has been provided *in vitro* by studies implicating the APC–EPCR complex in cleavage of PAR-1, leading to induction of protective genes against sepsis; however, most recently clinical trials of APC in patients with sepsis have shown no clear overall benefit.

Protein S and C4b-binding protein

Protein S is a single-chain vitamin K-dependent glycoprotein, although unlike the other vitamin K-dependent coagulation proteins it is not a serine protease, having two C-terminal LamG modules rather than a serine protease module, following an N-terminal GLA and four EGF modules rather than two. It is chiefly synthesized in the liver by ECs. About 40% of the PS in plasma is in the free form, whereas the remaining 60% is associated in a 1:1 complex with C4b-binding protein (C4bBP). Both forms bind strongly via the PS GLA module to negatively charged PLs exposed on the surface of activated platelets. Free PS (although having no strong inhibitory effect on FVa or FVIIIa itself) forms a Ca^{2+} ion-dependent complex with APC, helping to orient the APC active site above the PL surface and enhancing its anticoagulant activity against both proteins. However, C4bBP-bound PS does not enhance protein C function against FVa, suggesting a role for C4bBP in modulation of the APC pathway. Free thrombin cleaves PS N-terminal to the GLA domain, removing its ability to bind to both PL and protein C and thereby abolishing its protein C cofactor activity.

C4bBP is a large molecule containing seven α-chains (each of which binds one molecule of the C4b component of complement), and a single β-chain (to which one molecule of PS attaches). It is an acute-phase reactant, which can increase by up to fourfold in severe inflammatory states. It is likely that such raised levels would disturb the equilibrium between free and bound PS, and result in a fall in the free (biologically active) form, predisposing to a hypercoagulable state.

Many haemostatic factors change during pregnancy. Free PS falls during pregnancy (Table 47.3) and to a lesser extent in women receiving oestrogen supplements, but it is disputed whether this results from altered reactivity with C4bBP or if it contributes to hypercoagulability in pregnancy or during

Table 47.3 Haemostasis changes during pregnancy.

Platelet count	No consistent change but often falls
Platelet volume	Slight progressive increase
Platelet aggregation	Progressive enhancement
Bleeding time	Unchanged
Fibrinogen	Progressive rise up to 400% basal
Prothrombin	No consistent change
Factor V	No consistent change
Factor VII	Progressive rise up to 300% basal
Factor VIII	Progressive rise up to 200% basal
von Willebrand factor	Progressive rise up to 250% basal
Factor IX	Variable, no consistent change
Factor X	No consistent change
Factor XI	Progressive fall to 50% basal
Factor XII	No consistent change
Factor XIII	Progressive fall to 50% basal
Antithrombin	No consistent change
Heparin cofactor II	No consistent change
Tissue factor pathway inhibitor	Progressive rise
α_1-Antitrypsin	Progressive rise up to 300% basal
α_2-Macroglobulin	No consistent change
Protein C	No consistent change
Protein S	Progressive fall to 50% basal
C4b-binding protein	No consistent change
Protein C inhibitor	Progressive fall to 30% basal
Plasminogen	Progressive rise up to 300% basal
tPA	No consistent change
α_2-Antiplasmin	Progressive rise up to 300% basal
PAI-1	Progressive rise up to 300% basal
PAI-2	Progressive marked rise
TAFI	No change
FDP	Slight increase
Crosslinked FDP	Slight increase
Fibrinopeptide A	Progressive rise up to 300% basal
Euglobulin lysis time	Progressive prolongation up to 600% basal

oestrogen therapy. Total PS, like other vitamin K-dependent factors, is reduced in the newborn; levels as low as 20% of adult values can occur. However, this is compensated for by a marked reduction in C4bBP at birth (5–20% of adult levels), so that a relatively normal level of functional (free) PS is maintained.

Protein C inhibitors

As with other serine proteases, APC is subject to inhibition by serpins (the $T_{1/2}$ of APC in plasma is 15–20 min), including APC inhibitor or PCI, plasminogen activation inhibitor type-1 (PAI-1) and α_1-AT. The relative contributions of these *in vivo* is difficult to assess. PCI slowly but progressively blocks the action

of APC (and to a much lesser extent, thrombin and FXa), in each case forming a 1:1 complex: in addition PCI action is enhanced 20-fold by heparin and more weakly by other GAGs, but the physiological significance of this is uncertain. Despite the name, disruption of the murine PCI gene leads not to coagulopathy but to infertility due to lack of inhibition of another protease target of the serpin, the sperm protein acrosin.

Fibrinolysis

It is widely acknowledged that the principal functions of the fibrinolytic system are to ensure that fibrin deposition in excess of that required to prevent blood loss from damaged vessels is either prevented or rapidly removed (i.e. that a localized pro-coagulant response is achieved without compromising blood circulation generally) and, following re-establishment of haemostasis, an existing fibrin mesh is later removed as part of the process of tissue remodelling. The system of pro- and anti-fibrinolytic factors that has evolved to meet these requirements is closely coupled to that which results in fibrin clot formation. Fibrinolysis is essentially a localized, surface-bound phenomenon, with most events being catalysed by the presence of cross-linked fibrin itself, i.e. 'fibrin orchestrates its own destruction'. For this reason, the assays of fibrinolytic factors carried out in the soluble phase, in particular in systemic blood, may be misleading and should be interpreted with great caution.

Components of the fibrinolytic system

These include plasminogen (PLG) and plasmin, several endogenous (tissue or plasma-derived) or exogenous (e.g. bacterial or venom derived) PLG activators, and a number of inhibitors of plasmin or of the PLG activators. Some basic features of the endogenous factors are shown in Table 47.2, and a simplified representation of their interaction in Figure 47.6. Both endogenous and exogenous fibrinolytic factors have been used clinically to treat venous and arterial thrombosis, with varying degrees of success (see Chapter 58).

Plasminogen and plasmin

PLG is a single-chain glycoprotein zymogen of the serine protease plasmin, which carries out the enzymatic degradation of cross-linked fibrin. Besides its active site serine, plasmin contains five kringle modules, four of which have a lysine binding site, through which the molecule interacts with lysine residues in its substrates (e.g. fibrin), its activators (e.g. tissue PLG activator and urinary PLG activator) and its inhibitors (principally PLG activation inhibitor type 1). In its native form, it has a glutamic acid residue at its N-terminus and is known as Glu-PLG. Conversion of PLG to plasmin can proceed via two routes. Most PLG activators (see below) cleave the Arg561–Val562 bond to

form Glu-plasmin, a disulphide-linked two-chain molecule. The heavy chain is derived from the N-terminal region and bears the lysine binding sites, whereas the C-terminal light chain contains the serine active centre. Glu-plasmin, despite being a serine protease, is functionally ineffective as its lysine binding sites remain masked. It is converted autocatalytically to Lys-plasmin by N-terminal cleavage, chiefly between Lys76 and Lys77, which exposes the lysine binding sites and thus markedly enhances its interaction with fibrin.

Both Glu- and Lys-plasmin also attack the same Lys76–Lys77 bond in Glu-PLG to form the zymogen Lys-PLG. This binds to fibrin before activation to the protease and is thus brought into close proximity with the physiological PLG activators (which also bind to fibrin) that convert it to Lys-plasmin. As a consequence, the conversion of PLG to plasmin by tPA is enhanced by two to three orders of magnitude; this serves to localize the fibrinolytic response to the fibrin clot, where plasmin is to some extent protected from the effects of circulating antiplasmins, which (as indicated below) would otherwise neutralize plasmin extremely rapidly (< 50 ms). The fact that Lys-PLG is potentially a much more effective agent in fibrinolysis than Glu-PLG is reflected in its half-life, which is around 20 h compared with 50 h for the latter.

Action of plasmin on fibrin and fibrinogen

Plasmin can hydrolyse a variety of substrates including factors V and VIII, but its major physiological targets are fibrin and fibrinogen, which are split progressively into a heterogeneous mixture of small soluble peptides (plasmin attacks at least 50 cleavage sites in fibrinogen) known collectively as fibrin degradation products (FDPs). The first stage in the proteolysis of fibrinogen involves the removal of several small peptides (fragments A, B and C) from the C-terminus of the A α-chains, each involving cleavage after a lysine residue. This is rapidly followed by removal of the first 42 amino acids from the N-terminal end of the B β-chain (the Bβ1–42 fragment). The large residual portion, which is known as fragment X, and which still contains fibrinopeptide A, remains thrombin-clottable and will agglutinate some *Staphylococcus* spp. Assaying of the Bβ1–42 fragment released from fibrinogen by plasmin gives a sensitive index of fibrinogenolytic activity.

Asymmetrical digestion of all three pairs of chains of fibrin or fibrinogen then occurs with the release of the D fragment, in which the chains remained linked by disulphide bonds. The residue, known as fragment Y, is again attacked by plasmin, cleaving a second fragment D and leaving the disulphide-linked N-terminal ends of all six chains, which are referred to as fragment E. Fragments Y, D and E are not thrombin-clottable and do not agglutinate staphylococci. Their presence can be detected immunologically using an antibody-coated latex bead agglutination assay, which provides a simple test for most FDPs, although carefully prepared serum must be used to prevent cross-reactivity

of the antibody with fibrinogen in plasma. These assays detect both fibrin and FDPs indiscriminately.

Following thrombin generation and consequent activation of FXIII, inter- or intramolecular transamidation of the α- or γ-chains by FXIIIa occurs and then the action of plasmin yields characteristic D-dimer, D-dimer-E fragments and oligomers of fragments X and Y (collectively known as cross-linked FDP or XDP), in addition to X, Y, D and E. These XDPs can be detected very simply using monoclonal antibody-coated latex beads. Because the monoclonal antibodies to XDPs do not cross-react with fibrinogen, they can be detected directly in citrated plasma. The presence of D-dimers in blood samples can be used in a clinical algorithm that predicts the likelihood of the presence of venous thrombosis (see Chapter 55).

Furthermore, plasmin-induced cleavage of the N-terminal end of the β-chain of fibrin (the Bβ1–14 fibrinopeptide B fragment having been removed by thrombin) produces a β15–42 fragment, the detection of which indicates fibrin (as opposed to fibrinogen) degradation. Consequently, assays for the Bβ1–42 and β15–42 fragments used in combination, may be clinically useful by indicating whether fibrinogen or fibrin has been degraded, and thus whether fibrinolytic activity is primary or secondary to fibrin formation. However, clinically, FDP assays are used to detect disseminated intravascular coagulation, when mixed fibrin/fibrinogen degradation products appear in the circulation (see Chapter 51).

Plasminogen activators

Tissue plasminogen activator

Tissue plasminogen activator (tPA) is a serine protease secreted by ECs. It is not synthesized by the liver or kidney but is found in most extravascular body fluids, including saliva, milk, bile, cerebrospinal fluid and urine. Intravascular tPA is quickly cleared by the liver or inactivated by the fast-acting tPA inhibitor (see below), the half-life of tPA in plasma being approximately 2 min. The resting level of tPA in plasma is around 70 pmol/L, most of which is in an inactive complex with tPA inhibitors (see below).

Several physical and biochemical stimuli, including venous occlusion, strenuous exercise, thrombin, adrenaline and vasopressin or its analogues such as DDAVP (see Chapter 49) markedly increase the rate of tPA release, although its biological activity remains negligible until it becomes bound to fibrin, whereupon its affinity for and action upon PLG is greatly potentiated. The activity of tPA is further enhanced by plasmin itself, which cleaves tPA at Arg275–Ile276 into a two-chain molecule, whose binding sites are exposed, thus enabling it to form a complex with PLG and fibrinogen more readily. The ability of venous occlusion to stimulate tPA release from ECs forms the basis of a test of fibrinolytic activity known as the 'cuff test'.

Both single-chain tPA and the two-chain form possess very little serine protease activity until they bind to fibrin, whereupon tPA affinity for and activation of fibrin-bound PLG is increased at least 100-fold. The principal interactions involve binding between the second kringle module of tPA and lysine residues on the α- and β-chains of fibrin (and, in particular Lys157 on the α-chain of partly degraded fibrin). This association enhances the cleavage of the Arg561–Val562 bond in adjacent PLG molecules, forming active plasmin.

Urinary plasminogen activator

So called because it was first extracted from urine, urinary plasminogen activator (uPA) is synthesized chiefly by the tubules and collecting ducts in the kidney and by fibroblast-like cells in the gastrointestinal tract. It is a serine protease secreted as an inactive single-chain zymogen (pro-urokinase) that is cleaved by activators in plasma (including kallikrein and plasmin) at Lys158–Ile159 to produce active, two-chain uPA. The protease activity of uPA is associated with the heavy chain, which may dissociate from the light chain carrying the PLG binding site. The isolated heavy chains, which are also known as low-molecular-weight urokinase, are therefore poorer PLG activators than the two-chain form.

uPA cleaves the same Arg561–Val562 bond in PLG as tPA. Although uPA contains a kringle module, this does not impart high affinity for fibrin and it binds instead (via its EGF module) to its cell-associated receptor; thus it has been proposed that uPA may be preferentially involved in cellular events (such as differentiation and mitogenesis) rather than with dissolution of fibrin clots.

Exogenous plasminogen activators

These are derived from non-human sources, including animals (e.g. vampire bat saliva and some snake venoms) and certain plants and micro-organisms. The best known of these is streptokinase (SK), which is derived from some strains of β-haemolytic streptococci and which has for many years been used, with moderate success, as a fibrinolytic agent for the treatment of life-threatening thrombotic states (see Chapter 58). SK is a non-enzymatic polypeptide, which forms a stable 1:1 complex with PLG as a result of which the latter undergoes a conformational change, unmasking its serine-active centre. The 'plasmin' that is formed remains associated with SK but can convert free PLG to plasmin.

Inhibitors of fibrinolysis

The plasmin-generating potential of plasma is sufficient to degrade completely all of the fibrinogen in the body in a very short period of time. It is prevented from doing so by the PLG activator inhibitors or PAIs, most of which belong to the serpin family, and by a number of circulating inhibitors of plasmin itself (the antiplasmins).

Inhibitors of plasminogen activation

Plasminogen activator inhibitor type 1

Plasminogen activator inhibitor type 1 (PAI-1) is an important, fast-acting serpin inhibitor of tPA, uPA and, to a small extent, plasmin, which is secreted by ECs. It is also found in platelet α-granules. In plasma, it occurs in two forms: a functionally active 'free' form (that is stabilized by association with vitronectin) and as an inactive complex with tPA. Basal PAI-1 concentration in plasma is low at 0.5 nmol/L, of which at least 80% is in complex with tPA or uPA). It follows a diurnal rhythm, with an early morning peak that is around twice that in the late afternoon, and its activity is also increased by heparin. There is growing evidence that elevated levels of PAI-1 are associated with an increased incidence of venous and arterial thrombosis, and there is a suggested association between the early morning peak level of PAI-1 and a higher incidence of myocardial infarction at that time, the extent of this diurnal variation being associated with polymorphisms in the PAI-1 gene.

The three main profibrinolytic serine proteases (tPA, uPA and plasmin) all cleave the same bond (Arg346–Met347) in the reactive serpin loop of PAI-1, and are thus inhibited by formation of a 1:1 complex. PAI-1 binds non-covalently to fibrin, but, although it can then complex with and inhibit fibrin-bound tPA (with most of the complexes remaining bound to the fibrin), it does so less effectively than with free tPA. Soluble tPA–PAI-1 complexes are rapidly removed by the liver ($T_{1/2}$ = 4 min), as are uPA–PAI-1 complexes that have dissociated from fibrin.

Plasminogen activator inhibitor type 2

This serpin inhibitor of tPA is mainly produced by the placenta and may thus contribute to the inhibition of fibrinolysis which occurs during pregnancy. It is also synthesized in monocytes and epidermal cells, but is not usually found in the plasma of non-pregnant subjects. It is detectable in plasma from about the eighth week of pregnancy, rising to a peak at around 33 weeks and falling only slowly after delivery, the half-life being around 24 h. Paradoxically, levels are often low in pre-eclampsia due to placental insufficiency. The inhibitory action of plasminogen activator inhibitor type 2 (PAI-2) involves its Arg380–Thr381 residues and it is more effective against uPA than tPA, although for both the potency is at least 10-fold less than that of PAI-1.

Similarly, other protease inhibitors such as α_1-AT, C1-esterase inhibitor, α_2-AP (see below), α_2-MG and protease nexin 1 (one of a group of cell membrane-bound, heparin-potentiated serpins) also neutralize tPA, but at a rate that is probably too slow to be of physiological significance. α_2-MG is, however, thought to be the major inhibitor of the SK–PLG complex.

Inhibitors of plasmin

As they do with thrombin and tPA, a number of the broad-spectrum inhibitors contribute to neutralization of plasmin. By far the most potent plasmin inhibitor is the serpin α_2-AP, a single-chain glycoprotein synthesized by the liver, which has a half-life of about 60 h and shows considerable sequence identity with antithrombin and α1-antitrypsin. Its physiological importance is supported by the fact that a congenital deficiency (known as Miyasato disease) is associated with a clinically significant bleeding disorder due to uncontrolled fibrinolytic activity, and that levels are reduced in disseminated intravascular coagulation (DIC) and during thrombolytic therapy.

α_2-Antiplasmin

This serpin is the predominant plasmin inhibitor. It forms a stable 1:1 complex with plasmin, in which the protease is completely inactivated. The reaction appears to involve the cleavage by plasmin of a specific leucine–methionine bond in the inhibitor, exposing the reactive loop Arg364–Met365 peptide bond to the serine-active centre on the light chain of plasmin. Plasmin-modified α_2-AP can also bind to native Glu-PLG and to fibrin, the latter reaction being mediated by FXIIIa-mediated cross-linking. Thus, in addition to inactivating preformed plasmin, α_2-AP retards fibrinolysis by reducing PLG activation and by 'masking' the lysine binding sites through which plasmin(ogen) interacts with fibrin. However, these subsidiary mechanisms for inhibiting fibrinolysis are to some extent overcome by any Lys-plasmin(ogen) present, which has a higher affinity than Glu-PLG for fibrin, and is thus less susceptible to the action of α_2-AP.

In plasma (as opposed to on fibrin strands), although the concentration of PLG (~2 μmol/L) exceeds that of α_2-AP (~1 μmol/L), basal fibrinogenolytic activity is minimal because the tiny amounts of plasmin normally generated under physiological conditions are rapidly neutralized by the inhibitor. However, in certain pathological conditions (e.g. obstetric emergencies or snake bite) where extreme activation of fibrinolysis occurs, the latter may be swamped. Under these circumstances, other inhibitors, in particular α_2-MG and histidine-rich glycoprotein (HRG), may become clinically important. The action of α_2-MG on plasmin is similar to its effect on thrombin. Following the plasmin-induced cleavage of a specific arginine–leucine bond in the inhibitor, the latter forms a 1:1 complex with the light chain of plasmin. The serine-active centre of plasmin is not involved and the complex retains weak biological activity, albeit only briefly, until it is removed in the liver. HRG inhibits fibrinolysis by blocking the lysine binding sites of PLG, thus preventing its interaction with fibrinogen.

Lipoprotein A

The protein portion of lipoprotein A is termed apo(a). It is synthesized in the liver and circulates in plasma, has considerable structural homology with PLG, possessing serine protease and kringle modules. It can compete with PLG for binding sites on fibrin(ogen) or tPA, and may also increase PAI-1 expression, both actions potentially inhibiting fibrinolysis. That lipoprotein A has some clinical importance is indicated by the finding that

raised levels are associated with an increased incidence of thrombosis.

Thrombin-activated fibrinolytic inhibitor

In the presence of thrombomodulin, thrombin activates carboxypeptidase B, also called TAFI, and TAFIa in turn inhibits fibrinolysis; this provides another link between coagulation and the fibrinolytic pathway. TAFI removes the C-terminal lysine residues formed by limited plasmin proteolysis of fibrin, removing the binding-sites for PLG and tPA. Thus the fibrin cofactor function in PLG activation is reduced, downregulating fibrinolysis. Murine TAFI knockout animals have defective wound repair and data from backcrossing against heterozygous PLG-deficient mice showed that TAFI modulates both fibrinolysis and cell migration *in vivo*.

The vascular function of platelets

48

Stephen P Watson and Paul Harrison

Introduction

Platelets are small, anucleate cells that play a critical role in haemostasis and thrombosis. Platelets ordinarily circulate in the bloodstream in a quiescent state but undergo 'explosive' activation following damage to the vessel wall, leading to rapid formation of a platelet aggregate or vascular plug and occlusion of the site of damage. In simple terms, the more rapidly that platelets can achieve this, the lower the amount of blood that is lost. Platelets are therefore enriched in signalling proteins and surface receptors that enable them to achieve a rapid response, whereas major defects in platelet function or platelet number are associated with an excessive loss of blood. Significantly, disorders associated with vessel damage or a marked increase in platelet number or reactivity lead to thrombus formation in intact vessels and vascular occlusion and can cause arterial thrombotic disorders such as stroke and myocardial infarction, two of the major causes of morbidity and mortality in the Western world.

It is essential that platelets are able to achieve this interplay between quiescence and 'explosive' activation in high-pressure arteries and arterioles and in the low-pressure venous system. To achieve this interplay, platelet reactivity is strictly controlled by a series of positive feedback signals, when needed, or inhibitory signals that counter activation in intact vessels. Key factors that support rapid activation at sites of vessel injury include thrombogenic components of the subendothelial matrix, the release of positive feedback signals from the platelet, the generation of thrombin by the coagulation cascade and activation of platelet

integrins, enabling them to bind to their ligands within the bloodstream. Factors that oppose activation in the intact vasculature include the constitutive release of a gaseous transmitter, nitric oxide, from the endothelial cells that make up the vessel wall and the anti-platelet activity of the endothelial cell membrane itself.

The role of platelets in haemostasis is intimately linked to the coagulation cascade. Activated platelets provide a negatively charged lipid surface that supports the generation of thrombin, which reinforces platelet activation and other processes as discussed in the preceding chapter. The major platelet integrin $\alpha_{IIb}\beta_3$ (also known as GPIIb–IIIa) also forms a bridge between the platelet cytoskeleton and the polymerized fibrin that is generated by the coagulation cascade. Outside-in signals through $\alpha_{IIb}\beta_3$ promote 'clot retraction', which serves to strengthen the thrombus and thereby prevent embolization, even in the presence of the very high shear forces that exist within small arterioles and capillaries. Thus, the processes of platelet activation and coagulation are part of an intertwined biological programme that gives rise to the orchestrated formation of a haemostatic plug.

The role of platelets is also far wider than that of simply supporting thrombus formation. Platelet dense and α-granules are packed with a rich diversity of small molecules and proteins that play fundamental roles in other aspects of haemostasis and also in host defence. For example, platelets release agents that promote vessel constriction, vessel repair and leucocyte recruitment. In particular, there is growing recognition of the role of platelets in inflammatory responses in the vasculature. Platelets have been proposed to play a key role in the onset and

progression of vascular inflammatory disorders such as atherosclerosis and vascular infections such as endocarditis.

It is important to consider why platelets release such a diverse library of biological molecules. The cell most closely linked to platelet function in invertebrates, the haemocyte, had a far wider spectrum of actions than the platelet, supporting both inflammatory processes and aggregatory events. In higher organisms, two distinct sets of nucleated cells can be found, namely thrombocytes and leucocytes, whose primary roles are to support haemostasis and inflammatory responses respectively. Mammals, on the other hand, are the only animal to have anucleated platelets. Given this route of evolution, it is not surprising that platelets have retained many of the features of inflammatory cells, especially given that they are the first and most abundant cell that accumulates at sites of vascular infection. The challenge is to establish the significance of the non-haemostatic molecules in platelets in health and disease.

Platelets are one of the major targets for the prevention and treatment of thrombotic and, to a lesser extent, vascular inflammatory disorders. Careful attention, however, should be given to the case as to whether a patient should receive anti-platelet therapy, and the nature that this therapy should take, bearing in mind that such treatment always carries a risk, albeit usually minor, of increased bleeding. For the majority of individuals receiving the major orally active anti-platelet drugs, aspirin or clopidogrel (a $P2Y_{12}$ ADP receptor antagonist), this risk is extremely low, unless otherwise contraindicated by conditions such as peptic ulcer. But, the risk is not zero. In this context, the growing tendency of otherwise healthy passengers to take aspirin as an anti-platelet therapy in long-haul flights should be viewed with concern. The major risk in long-haul flights is venous rather than arterial thrombosis through stasis in peripheral veins. Venous thrombosis is minimally inhibited by treatment with aspirin, whereas this treatment does lead to a small increase in risk of bleeding, which exceeds the benefit. Heparin would be a far better alternative therapy, but has the drawback that it is only delivered by injection.

The decision on whether a patient should receive anti-platelet therapy is based on the net sum of risk factors for arterial thrombosis, such as age, weight, lifestyle, cholesterol, smoking and family history, and the potential of excessive bleeding. It is now accepted that individuals who are considered to be at a medium to high risk of thrombosis should receive some form of anti-platelet therapy (unless otherwise contraindicated), usually low-dose aspirin or clopidogrel, in combination with other treatments such as statins or blood pressure-lowering drugs. Stronger inhibitors of platelet function, namely blockers of the major platelet integrin, αIIbβ3, are used only in acute situations of thrombotic risk such as unstable angina or during surgical procedures such as angioplasty and stenting because of problems arising from excessive blood loss.

The aim of this short review is to describe the features of platelets that enable them to perform their physiological roles in the vasculature. More extensive information on platelets can be found in two excellent books that cover all aspects of platelet function in health and disease (Gresele et al., 2002; Michelson, 2002).

Platelet structure and organelles

Platelets have several unique features that enable them to efficiently perform their primary function, namely the rapid formation of a vascular plug following vessel injury. Platelets are extremely small and discoid in shape, with dimensions of approximately 3.0 μm by 0.5 μm, and a mean volume of 7–11 fL. This shape and small size enables the platelets to be pushed to the edge of the vessel, placing them next to the endothelial cells and in the right place to respond to vascular damage. They are present at a high level in the human circulation, usually between 150 and 400×10^9 platelets/L. This level of expression appears to represent a considerable degree of redundancy, as individuals with platelet counts as low as 10×10^9 platelets/L tend to exhibit only occasional, major spontaneous bleeds, although they are at considerable risk of bleeding during major trauma.

The discoid shape of the platelet is formed by the platelet cytoskeleton, which consists of a spectrin-based membrane skeleton; circumferential bands of single microtubule that lies beneath the plasma membrane; and a rigid actin filament network that fills the cytoplasm of the cell. The disc shape is not essential for platelet function, as murine platelets that lack $β_1$-tubulin, the major component of the microtubules, are spherical and yet undergo normal aggregation and secretion responses. Much of the rigid structure and platelet strength results from the 2 million copies of actin per platelet, of which approximately 40% are assembled into actin polymers. These polymers connect with each other and with the cyosolic tail of the membrane glycoprotein (GP) Ibα via filamin in a lattice-like structure.

A further illustration of the way that platelets have evolved to form their specialized function is the absence of a nucleus, which is consistent with their short lifespan of 10 days and their acute role in haemostasis, which does not allow sufficient time for de novo protein synthesis. In other words, when incorporated into a thrombus and having undergone activation (including secretion), the role of the platelet is simply to serve as part of a haemostatic plug. It is now recognized that stimulated platelets possess a very limited capacity for protein synthesis, as the result of residual mRNA that has been carried over from their precursor cell, the megakaryocyte. However, there is little evidence to suggest that the capacity to make new proteins is of functional relevance. Nevertheless, this does provide the opportunity to perform a limited repertoire of molecular biological approaches, although the very low levels of mRNA, its poor quality and issues concerning contamination from other cells necessitates considerable caution and care in their application and interpretation. Despite this, several groups are using genomic approaches, often in combination with proteomics, to determine the composition

of the platelet in order to gain new insights into platelet regulation. It is essential in these cases to also use other experimental approaches to confirm new findings and observations.

Platelets contain three main types of storage granules: dense, α-granules and lysosomes, each of which rapidly release their contents upon activation. α-Granules are the most numerous, with about 80 per platelet, and contain a rich diversity of proteins and membrane receptors that support many processes in haemostasis and in host defence. Dense granules contain high levels of small molecules that support platelet activation and mediate vasoconstriction. They are present at a 10-fold lower level that for α-granules, with approximately seven per platelet. Lysosomes also release their contents on activation, although the significance of this is unclear.

Platelets are particularly rich in signalling and cytoskeletal proteins. The high level of signalling proteins supports the rapid switch from quiescence to activation that occurs following damage to the vasculature. For example, it has been estimated that 0.1% of platelet protein is the tyrosine kinase Src, which is two to three orders of magnitude higher than in most other cells. The high cytoskeletal protein content is required for the dramatic change in morphology that occurs upon platelet activation and for securing the thrombus at the site of vascular damage, even in the presence of the very high shear forces. Platelets have a dense network of intracellular membranes known as the dense tubular system, which rapidly liberate their stores of the intracellular messenger Ca^{2+} in response to the generation of the second messenger, inositol 1,4,5-trisphosphate (IP3). Platelets also have a dense network of invaginations of the surface membrane known as the surface-connected canalicular system, which serves to increase the surface area of the plasma membrane and thereby provide more sites for release of intracellular granules and interactions with other surfaces. Platelets contain several mitrochondria that generate energy during their short lifespan (Figure 48.1).
Figure 48.1 Platelet ultrastructure.

Murine platelets

The uniquely small size of the platelet and absence of a nucleus restricts the application of many of the modern day molecular and cell biology technologies in the dissection of platelet regulation and function. As a consequence, genetically modified mice are being increasingly used to provide a genetic means to address protein function within the platelet, although this approach must be adopted with the very real concern of species differences both with respect to role of specific proteins and vascular rheology. The former is illustrated by the nature of the receptors for one of the major platelet agonists, thrombin. Human platelets express PAR_1 and PAR_4 receptors, whereas murine platelets express PAR_3 and PAR_4. There are also fundamental issues in rheology between human and murine vessels, as well as in platelet size and number. These are likely to have significant implications for factors such as affinities of ligand for their receptors and receptor number. Nevertheless, despite these concerns, the fundamental aspects of the processes that govern platelet activation in the mouse appear to be shared with human, and the value of murine models in analysing haemostasis and thrombosis is immense.

Platelet formation

Platelets are formed from megakaryocytes in the bone marrow. Megakaryocytes are one of the largest cells in the body, reaching up to 50 μm in diameter, and are characterized by a large nuclear content. The nucleus of the megakaryocyte undergoes a process known as endomitosis that involves nuclear replication without cellular division, giving rise to DNA ploidy values that range from 4 n to 64 n. The reason why endomitosis occurs is not fully understood, but it may simply reflect the need to increase the DNA content to enable the cell to expand its protein synthesis capacity to generate 2000–3000 platelets per megakaryocyte. In addition, it allows cell growth and differentiation to occur without interruption by nuclear and cell divisions.

The differentiation of bone marrow progenitor cells along the megakaryocyte lineage is regulated by the cytokine thrombopoietin (TPO), which was first identified in 1995. TPO regulates megakaryocytopoiesis through a single receptor, c-Mpl, which signals through the JAK–STAT family of kinases and transcription factors respectively. The circulating free level of TPO is controlled by the number of circulating platelets and bone marrow megakaryocytes and their precursors through binding to c-Mpl on their surface. This provides a simple elegant means to tightly control the circulating platelet count. TPO binds to c-Mpl, signals and is then internalized and degraded. Thus, if the platelet count decreases, the free level of TPO rises and there is an increase in megakaryocytopoiesis. TPO offers great hope as a form of treatment for patients with thrombocytopenia and is the focus of a number of ongoing clinical trials.

Recent reviews provide further information on megakaryocytopoiesis and platelet formation (Caen *et al.*, 1999; Italiano and Shivdasani, 2003). The study of Italiano and colleagues (1999) shows a remarkable time-lapse video of platelet generation from megakaryocytes *in vitro*.

Platelet function

The responses associated with platelet activation and their roles in haemostasis are discussed below.

Adhesion

The initiating event following vascular damage is platelet adhesion to exposed subendothelial matrix proteins. The platelet glycoprotein (GP) receptors which mediate adhesion are dependent on the rate of shear. Under the intermediate to high shear conditions found in arterioles, this event is strictly dependent on von Willebrand factor (vWF) and its receptor, the GPIb–IX–V complex. However, at the lower rates of shear found in the venous circulation and in the static conditions frequently used for experimental purposes, adhesion can occur directly to other subendothelial matrix proteins such as collagen and fibrinogen, although vWF also supports this event in these vessels. In both cases, adhesion is strengthened considerably through activation of platelet surface integrins, which leads to an increase in affinity for their adhesive ligands.

Adhesion applies also to recruitment of circulating platelets into the thrombus. vWF, exposed on the surface of the growing thrombus, also plays a fundamental role in this process, most notably at the high rates of shear that exist within arterioles and in diseased vessels. The platelet-bound vWF that supports these events is derived from plasma and via secretion from platelet α-granules. Adhesion to the growing thrombus is supported by binding of fibrinogen to the integrin $\alpha_{IIb}\beta_3$, a process that is more correctly termed aggregation.

Shape change and spreading

Upon activation, platelets become spherical and extend pseudopodia to enable them to attach to other platelets and to the vessel wall. The transition to a sphere increases their optical density, a process that can be readily followed in a Born aggregometer and which precedes aggregation. This increase in optical density is termed 'shape change', although this term should be used with caution unless supported by scanning electron microscopy, as an increase in density can also be brought about in other ways. Shape change is mediated by phosphorylation of myosin light chains, either as a consequence of elevation in intracellular Ca^{2+} ions, which activate myosin light chain kinase, or through inhibition of myosin light chain phosphatase, which is regulated downstream of Rho kinase.

Adhesion of platelets to a reactive surface, such as collagen or fibrinogen, is also first characterized by transition from a discoid to a more rounded form, but this is then followed by formation of filopodia, which grow from the periphery of the cell, and lamellipodia, which fill in the area between adjacent filopodia. Stress fibres can also be seen with strong agonists. As the platelet flattens and spreads, granules and organelles are squeezed into the centre of the cell, resulting in a characteristic fried egg appearance. Granules are secreted from the centre of the cell directly into the surface open canalicular system before release into the surrounding medium. These dramatic changes in morphology are brought about by a powerful severing and reassembly of the actin cytoskeleton through regulation of a number of actin regulatory proteins.

Aggregation

Aggregation is used to describe cross-linking of platelets through binding of fibrinogen, or other bivalent or multivalent ligands such as vWF to the integrin $\alpha_{IIb}\beta_3$ on adjacent cells. In resting platelets, the integrin $\alpha_{IIb}\beta_3$ exists in a low-affinity conformation that is unable to bind to vWF or fibrinogen at the concentrations found within plasma (although it is able to bind to immobilized forms of these two ligands under static or low shear conditions). Upon platelet activation, so-termed 'inside-out' signals from other receptors cause $\alpha_{IIb}\beta_3$ to undergo a conformational change that increases its affinity for fibrinogen, vWF and other RGD (arginine–glycine–aspartate)-containing ligands, including fibronectin and CD40 ligand (CD40L). In turn, binding of fibrinogen and other ligands to $\alpha_{IIb}\beta_3$ promotes 'outside-in' signals that reinforce platelet activation. Although fibrinogen is considered to be the major ligand for $\alpha_{IIb}\beta_3$, thrombus formation has been reported, albeit after a considerable delay, in mice deficient in both fibrinogen and vWF, bringing other RGD-containing ligands into consideration as potential regulators of aggregation, most notably fibronectin, which is also present in plasma.

The events that give rise to activation of αIIbβ3 remain poorly understood. The integrin can be activated through elevation of Ca^{2+} and by activation of protein kinase C, rapIb and phosphatidylinositol 3-kinase (PI3 kinase), although it is unclear whether these act through separate pathways or target a common regulatory protein. Elevation of Ca^{2+} is required for rapid activation of $\alpha_{IIb}\beta_3$ and plays an essential role in thrombus formation *in vivo*. Increasing evidence implicates the cytoskeleton-binding protein talin in the regulation of $\alpha_{IIb}\beta_3$, although the molecular basis of its action remains to be determined.

A deficiency or mutation in $\alpha_{IIb}\beta_3$ gives rise to the bleeding disorder Glanzmann's thrombasthenia. Although extremely rare, there are upwards of 300 patients who have been identified with this condition. Surprisingly, given the severity of the effect on platelet aggregation, these patients have relatively few bleeding problems, provided that they avoid unnecessary risk of

trauma and are moved to a hospitalized environment following injury.

Secretion

The three types of platelet granules contain a distinct set of contents that play varying roles in haemostasis. Platelet-dense granules contain the adenine nucleotides ADP and ATP, the amine 5-HT and Ca^{2+}. The rapid release of ADP from dense granules plays a major positive feedback role in promoting platelet activation (see below).

Platelet α-granules and their membranes contain a wide variety of proteins that support a multitude of processes during haemostasis (Table 48.1). Many of these proteins are made *de novo* in the megakaryocyte such as platelet factor 4 and vWF, whereas others are taken up from the plasma by receptor-mediated endocytosis (e.g. fibrinogen) or by fluid-phase pinocytosis.

Platelet α-granules contain the adhesive proteins fibrinogen and vWF. α-Granule release of vWF is critical for normal thrombus formation at intermediate and high rates of flow. The membrane of platelet α-granules also contains the major platelet integrin $\alpha_{IIb}\beta_3$. Resting platelets express 50 000 – 80 000 molecules of $\alpha_{IIb}\beta_3$ on their surface and this number increases to greater than 100 000 molecules following fusion of α-granules with the plasma membrane. This serves as a positive feedback signal and is also of clinical significance with respect to the action of many $\alpha_{IIb}\beta_3$ agents, which are unable to block the

Table 48.1 Platelet α-granule constituents.

Physiological role	Constituent
Angiogenesis	VEGF-A, VEGF-C
Antibodies	IgG
Coagulation cascade	FV, FVIII
Endothelial cell activation	TGF-β
Fibrinolysis	Plasminogen, PAI-1, α_2-antiplasmin
Growth factors	PDGF; FGF; HGF; IGF-1; EGF
Leucocyte recruitment	Chemokines: platelet factor 4, RANTES; β-thromboglobulin, ENA-78
Matrix breakdown	Hydrolytic enzymes
Membrane proteins	$\alpha_{IIb}\beta_3$, P-selectin
Miscellaneous	Amyloid β-protein precursor
Platelet activation	Gas6
Proteases	Protease nexin II
Thrombus formation	Fibrinogen, fibronectin, vWF
Unknown	Thrombospondin

Examples of platelet α-granule constituents and their physiological roles are shown. Several other molecules have also been reported to be present in α-granules and to be released upon activation.

integrin on α-granules until expressed on the cell surface. P-selectin is also found in α-granule membranes. P-selectin helps to stabilize the thrombus through capture of tissue factor-rich microparticles that support the coagulation cascade, and mediates leucocyte recruitment through P-selectin glycoprotein ligand-1 (PSGL-1) on the leucocyte surface. P-selectin is frequently used to monitor platelet α-granule secretion by flow cytometry using a labelled antibody.

Platelet α-granules contain a number of coagulation factors, including factor V, factor VIII, protein S and PAI-1, which play key roles in the coagulation process as discussed in the previous chapter. α-Granules also contain chemokines, such as platelet factor 4, β-thromboglobulin, ENA-78 and RANTES, which attract circulating leucocytes. They also contain platelet-derived growth factor (PDGF), which supports smooth muscle proliferation and vascular endothelial growth factor (VEGF) A and C, which support tumour angiogenesis. The role of many of the other platelet α-granule contents, such as thrombospondin-1, in thrombus formation is unclear.

Recently, a component of platelet α-granules, the vitamin K-dependent protein, Gas6, has been proposed to play a major role in supporting platelet aggregation, through activation of its surface receptors, Axl, Mer and Sky. Gas6 is of particular interest in the context of development of novel antithrombotics, as blocking antibodies prevent thrombus growth but do not have a significant effect on bleeding. The molecular basis of this action and its significance remain to be established.

Lysosomes are part of the host defence mechanism against invading organisms. They contain a variety of hydrolytic enzymes that target invading organisms and also breakdown extracellular matrix proteins. Lysosomes remove phagocytosed particulate matter and bacteria.

A deficiency in dense or α-granules is the basis of a heterogeneous group of secretory disorders that are associated with excessive bleeding. These disorders include grey platelet syndrome, which is associated with α-granule storage pool deficiency, and Hermansky–Pudlak and Chédiak–Higashi syndromes, which are associated with dense granule storage pool deficiency. The last two disorders often have characteristic pigment defects and deficiencies in lysosomes in other cells.

Phospholipase A$_2$

TxA$_2$ is one of the two major platelet positive feedback agonists. TxA$_2$ is generated *de novo* upon activation of cytosolic PLA$_2$, which liberates arachidonic acid from the 2-position of membrane phospholipids. The term *cytosolic PLA$_2$* is used to distinguish the phospholipase from the structurally distinct class of soluble PLA$_2$s, which mediate their actions through an extracellular action. Arachidonic acid is metabolized by cyclo-oxygenase (COX-1) and lipoxygenase enzymes to endoperoxides/thromboxanes and leukotrienes respectively. Endoperoxides and TxA$_2$ regulate platelets through activation of thromboxane (or TP)

receptors. Leukotrienes are not thought to play a major role in regulating platelets, with their primary actions being mediated on other vascular cells.

Cytosolic PLA$_2$ is regulated by translocation to platelet membranes founding response to elevation of cytosolic Ca^{2+}. PLA$_2$ is constitutively active and so translocation is sufficient to bring about lipid hydrolysis. In addition, the activity of PLA$_2$ is marginally increased upon phosphorylation by mitogen-activated protein kinases, although in the absence of translocation, this does not lead to activation as the lipase is unable to access its substrates.

Procoagulant activity

A critical function of platelet activation is to provide a negatively charged phospholipid surface for the assembly of two multiprotein complexes that form a vital part of the coagulation cascade, namely the tenase and prothrombinase complexes as discussed in Chapter 46. A complex of FIXa–FVIIIa on the negatively charged lipid surface converts factor X to factor Xa (tenase complex) which, in turn, forms a complex with FVa on the same surface to efficiently convert prothrombin to thrombin (prothrombinase complex). In this way, a large amount of thrombin is generated in the vicinity of the platelet surface to convert fibrinogen to fibrin and to further enhance platelet activation. The newly generated thrombin is also able to diffuse to the surface of intact endothelial cells where it binds to thrombomodulin and activates protein C, which itself is bound to the endothelial surface via endothelial cell protein C receptor (EPCR). Once generated, activated protein C (APC) interacts with phosphatidlyserine on the surface of activated platelets to prevent assembly of the tenase and prothrombinase complexes through cleavage of FVa and FVIIIa (see Chapter 46). Thus, the negatively charged platelet surface also supports the protein C pathway that serves to limit the coagulation cascade. The 'compartmentalization' of reactions to lipid surfaces in this way ensures that thrombin is generated at the place that it is required during haemostasis.

The formation of the negatively charged lipid surface on activated platelets is commonly described as aminophospholipid exposure or procoagulant activity. It is formed by the movement of phosphatidylserine from the inner to the outer leaflet of the platelet membrane. The movement of phosphatidylserine can be monitored experimentally by flow cytometry or fluorescent microscopy through the binding of annexin V, factor V or factor VIII, using either fluorescently labelled secondary antibodies or by direct labelling with a fluorescent group such as fluorescein isothiocyanate (FITC).

The molecular basis of the procoagulant response, including the identity of the enzyme (or 'flipase') that promotes the translocation of phosphatidylserine across the membrane, is not established. It is recognized, however, that the response is elicited only by powerful platelet agonists and that it requires Ca^{2+} entry

across the plasma membrane. Platelets from four patients have been reported to be unable to undergo a procoagulant response. This clinical condition has been termed Scott syndrome and is associated with significant bleeding, although, if managed, does not appear to have an effect on life expectancy.

Platelet-derived microparticles

Platelet-derived microparticles are generated during platelet activation and are usually seen together with an increase in procoagulant activity. The formation of platelet microparticles also requires Ca^{2+} entry and is readily seen in response to stimulation by Ca^{2+} ionophore but requires high agonist concentrations and favourable conditions for them to be formed upon receptor activation. The functional role of platelet-derived microparticles is unclear, although they have been proposed to play a number of critical roles in supporting thrombus formation by serving as a surface for the tenase and prothrombinase complexes. They may also play a role in promoting thrombotic disease.

The study of platelet-derived and other types of circulating microparticles is a highly active area of research. Recent evidence suggests that activated platelets and microparticles can interact with monocytes via a P selectin-dependent pathway to induce tissue factor synthesis and further release of monocyte-derived microparticles. It has been proposed that these tissue factor-positive microparticles provide a source of circulating tissue factor, which is incorporated into growing thrombi, reinforcing thrombus formation through activation of the coagulation cascade and leading to formation of fibrin. This therefore explains the ability of P-selectin and its receptor, PSGL-1, to stabilize thrombus formation.

Clot retraction

It has been known for more than two centuries that blood clots retract over a time course of minutes to hours, a process that is termed clot retraction. This event helps platelet-rich thrombi to withstand the high shear forces found in small arterioles and in other vessels. Platelets are the force-generating components of clot retraction, with the integrin $\alpha_{IIb}\beta_3$ playing a fundamental role by linking the cytoplasmic actin filaments to surface-bound fibrin polymers. In addition, the integrin generates the intracellular signals that underlie clot retraction through activation of tyrosine kinases and PI3 kinase. This cascade leads to the assembly of an intracellular complex of a number of actin-binding proteins including talin, filamin, zyxin, α-actinin, moeisin and vinculin, which interacts with the integrin tail and with actin. Once tethered in this way, platelet myosin serves as a motor to drive the process of clot retraction.

Clot retraction can be readily measured in thrombin-stimulated platelet-rich plasma by taking aliquots of the volume of plasma over time after the addition of thrombin. Thrombin rapidly generates a blood clot that fills an aggregometer tube but

which gradually reduces to almost 20% of its original volume (i.e. clot retraction) over a course of 60 min.

Late events in platelet aggregation/thrombus formation

There is increasing evidence that stabilization of the platelet plug requires delayed intracellular signals from receptors that function only when platelets make persistent contact with other platelets. This process has been termed as the 'late-events of platelet activation' or the perpetuation phase of activation. Several recently discovered platelet receptors have been implicated in these 'late-events' (as discussed in Other platelet ligands and their receptors, below).

Thrombus formation in arterioles

The molecular basis of thrombus formation *in vivo* in vascular beds at intermediate and high rates of shear is made up of a number of phases, namely tethering, adhesion, thrombus formation and thrombus stabilization (Figure 48.2). Subendothelial collagen plays a key role in this set of events through direct and indirect mechanisms. Collagen binds plasma vWF, which mediates platelet tethering at intermediate and high rates of flow because of its fast on-rate of association to platelet GPIb–IX–V. The fast off-rate of this interaction, however, and the weak nature of the signals from GPIb–IX–V (see below), means that other subendothelial proteins and soluble platelet agonists are required to generate the signals required for integrin activation and stable adhesion. Collagen is the most thrombogenic component of the subendothelial matrix, mediating activation via the immunoglobulin receptor, GPVI. Signals from GPVI lead to activation of platelet integrins, including $\alpha_{IIb}\beta_3$ and $\alpha_2\beta_1$ (also known as GPIa–IIa), which support stable adhesion. Adhesion of platelets to vWF and collagen also has the effect of reinforcing platelet activation as a result of a net increase in binding to GPVI (the so-termed, two-site, two-state model of platelet–collagen interaction). Signals from GPVI, as well as from integrins $\alpha_{IIb}\beta_3$ and $\alpha2\beta1$, stimulate platelet spreading, thereby strengthening attachment to the exposed subendothelium and increasing the surface area for thrombus growth. The intracellular signals also lead to the release of the positive feedback mediators ADP and TxA_2, which, along with GPIb–IX–V and $\alpha_{IIb}\beta_3$, help to recruit additional circulating platelets into the developing thrombus via tethering and aggregation. Signals from $\alpha_{IIb}\beta_3$ and other receptors serve to stabilize thrombus formation through processes such as clot retraction.

The glycoproteins GPIb–IX–V and $\alpha_{IIb}\beta_3$ are essential for thrombus formation, whereas other receptors can be by-passed to varying extents because of their overlapping roles. In this context, the relatively mild bleeding disorder that has been reported in genetically modified mice and human patients who are deficient in GPVI is particularly interesting, and gives rise to speculation that the subendothelium may express other adhesive proteins that are able to promote powerful platelet activation. In this context, it is interesting to speculate whether the events that underlie thrombus formation vary with the composition of the
Figure 48.2 Thrombus formation at medium and high rates of shear. Platelets are initially captured (tethered) by vWF bound to immobilized collagen. Collagen activates platelets via GPVI leading to an increase in affinity of the integrins $\alpha_{IIb}\beta_3$ and $\alpha_2\beta_1$ for vWF/fibrinogen and collagen respectively. This mediates stable adhesion and potentiates activation through further activation of GPVI and also release of ADP and TxA_2. The formation of a procoagulant surface also supports formation of thrombin. vWF and fibrinogen, in combination with ADP, TxA_2 and thrombin, mediate thrombus formation (aggregation) and stabilization (clot retraction). Platelet spreading also serves to stabilize the thrombus on the subendothelium.

subendothelial matrix. Connective tissue contains many other proteins whose role on platelets has been poorly characterized, and which may play a role in supporting thrombus formation. This is illustrated by recent reports of platelet activation by decorin, which signals via the integrin $\alpha_2\beta_1$.

Stimulatory agonists and their receptors

Platelets express surface receptors for a remarkable number and wide diversity of extracellular ligands, including adhesive ligands, amines, chemokines, cytokines, lipids, nucleotides, proteases and transmembrane proteins (Table 48.2). It is important therefore to determine which of these have significant roles in regulating haemostasis and thrombosis *in vivo*. There is a considerable redundancy between many of these stimuli and several others also induce only weak activation, questioning their functional relevance. This section focuses on those receptors and their ligands that are recognized to play important roles in platelet regulation. Many of these receptors are important targets for anti-thrombotic drugs.

ADP and ATP

ADP was first recognized as a major regulator of platelets in the early 1960s but it is only within the last few years that its importance as a positive feedback agonist has been fully established. ADP, along with ATP, is stored in dense granules and released rapidly upon platelet activation. ADP supports platelet activation through two G-protein-coupled, seven transmembrane receptors, $P2Y_1$ and $P2Y_{12}$. ATP activates the structurally distinct, $P2X_1$ receptor, which contains an intrinsic ion channel.

The $P2Y_{12}$ receptor is coupled to the G_i family of G-proteins, which, among other actions, inhibit adenylyl cyclase and activate PI3 kinase. On its own, the $P2Y_{12}$ receptor has a minimal effect on platelet activity, but it undergoes a remarkable synergy with G_q-coupled and tyrosine kinase-linked receptors to induce powerful platelet activation. Thus, the major feature of ADP's positive-feedback action is its ability to synergize with signals from other receptors, a fact that had been overlooked until the late 1990s. Significantly, the $P2Y_{12}$ receptor is unique in the context that it is the only receptor that activates the G_i family of G-proteins at sites of damage to the vasculature. The α_{2A}-adrenoceptor also activates G_i family proteins, but this is not thought to play a role in normal haemostasis, although this may be of relevance under conditions that lead to release of adrenaline. This unique role of the $P2Y_{12}$ receptor explains why it is presently considered to be the most attractive target for development of novel anti-thrombotic agents. The $P2Y_{12}$ receptor antagonist, clopidogrel, is a billion dollar-selling drug in the USA and sales are increasing rapidly. There is intense activity within the pharmaceutical sector towards development of further $P2Y_{12}$ receptor antagonists.

The $P2Y_1$ receptor is coupled to the G_q and $G_{12/13}$ families of G-proteins, which regulate PLCβ and rho kinase respectively. The $P2Y_1$ receptor is expressed at a very low level, in the order of 150 sites per platelet, and undergoes rapid desensitization during platelet preparation unless reagents such as apyrase are included used to prevent accumulation of adenine nucleotides. These two features have meant that its role has also been underestimated until the last few years. There is now a growing recognition of the role of the $P2Y_1$ receptor in the *early* events that initiate haemostasis and thrombosis through studies in $P2Y_1$-deficient mice and use of $P2Y_1$ receptor antagonists. Of particular importance is the ability of the $P2Y_1$ receptor to synergize with the $P2Y_{12}$ receptor in promoting platelet activation. The $P2Y_1$ receptor is also a potential target for novel antithrombotics, although this is unlikely to be realized because of its expression on other tissues. At later times of stimulation, the activation of G_q and $G_{12/13}$ families of G-proteins by thrombin and TxA_2 masks the role of the $P2Y_1$ receptor.

Increasing evidence suggests that the significance of the $P2X_1$ receptor has also been overlooked. As for the $P2Y_1$ receptor, it is expressed at a low level and undergoes rapid desensitization. Further, it has only recently been recognized to be a receptor for ATP, rather than for ADP. The particular significance of the $P2X_1$ receptor in mediating platelet activation is its ability to promote entry of Ca^{2+} through its intrinsic channel, a process that takes place far more rapidly than IP3-mediated Ca^{2+} release. This generates very high concentrations of Ca^{2+} close to the plasma membrane, enabling it to regulate distinct intracellular events.

TxA$_2$

TxA_2, along with ADP, is a major positive feedback mediator. TxA_2 regulates platelet activation through the G_q- and $G_{12/13}$-coupled thromboxane (TP) receptor. TxA_2 is rapidly metabolized to the inactive metabolite TxB_2, which prevents its use in functional studies, where the stable mimetic, U46619, is preferred. Additionally, TxB_2 is used to monitor activation of this pathway in platelets by radioimmunoassay. The TP receptor activates platelets through a pathway that is dependent on the $P2Y_{12}$ receptor, further emphasizing the importance of the latter in regulating platelet function.

The clinical importance of the TxA_2 pathway in platelet activation is illustrated by the antithrombotic action of aspirin, which inhibits platelet cyclo-oxygenase. The irreversible nature of aspirin, in combination with the inability of platelets to synthesize significant levels of new proteins, means that the effective therapeutic concentration of aspirin is considerably lower than that required to target cyclo-oxygenase in other cells. Large-scale clinical trials have shown that aspirin reduces the mortality of myocardial infarction by approximately 25% and the number of vascular events in individuals at risk by about one-third. The clinical effectiveness of low-dose aspirin is similar to that of the $P2Y_{12}$ receptor antagonist, clopidogrel, making it the drug of

Agonist	Receptor	Effect and physiological role
Adhesion molecules		
Collagen	GPVI	Major signalling receptor for collagen
	$\alpha_2\beta_1$	Supports adhesion by collagen
Fibrinogen	$\alpha_{IIb}\beta_3$	Aggregation, spreading and clot retraction
Fibronectin	$\alpha_5\beta_1$, $\alpha_{IIb}\beta_3$	$\alpha_5\beta_1$ mediates adhesion
Laminin	$\alpha_6\beta_1$	Adhesion
von Willebrand factor	GPIb–IX–V, $\alpha_{IIb}\beta_3$	Platelet tethering (see also fibrinogen)
Amines		
Adrenaline	α_2 and β_2	
5-HT	5-HT_{2A}	Mediates vasoconstriction
Chemokines		
SDF-1	$CXCR_4$	Maturation of megakaryocytes
MDC and TARC	CCR_4	Platelet–monocyte interactions?
RANTES	CCR_1 and CCR_3	
Cytokines		
TPO	c-Mpl	Maturation of megakaryocytes

CD40 ligand	CD40 and $\alpha_{IIb}\beta_3$	
Tyrosine kinase receptors		
Angiopoietin 1 and 2	Tie-1	
EphrinB1	EphA4 and EphB1	Late events in platelet activation?
Vitamin K-dependent		
Gas6	Sky, Axl and Mer	Supports platelet activation?

Table 48.2 Platelet agonists and their surface receptors.

Platelets express a remarkable number and variety of receptors for a wide range of ligands. For many of these receptor–ligand combinations, however, the effect on platelet activation is weak and of uncertain significance. Moreover, several of the examples shown have only been the subject of a handful of publications and require independent confirmation. Examples of these include functional roles for Gas6, insulin, PDGF, ephrins and Eph kinases and leptin. Shear forces of 1500 s^{-1} and above should also be considered to be an agonist, although the basis of this is not known.

choice unless otherwise contraindicated (e.g. peptic ulcer) on consideration of cost. Aspirin and clopidogrel are sometimes used in combination, although this carries a major risk of excessive bleeding, most notably in surgery.

Thrombin

The serine protease thrombin is the major product of the coagulation cascade (see Chapter 46). Thrombin regulates several key pathways in haemostasis, including fibrin formation, the protein C pathway and platelet activation. These diverse actions of thrombin are regulated by a series of binding proteins that target the protease to the appropriate region of the haemostatic cascade.

Thrombin activates human platelets through the proteolytic cleavage of the G-protein-coupled, seven transmembrane receptors, PAR_1 and PAR_4. Thrombin releases a short peptide from the N-terminal region of each receptor, thereby exposing a new N-terminal sequence that functions as a tethered ligand by binding to the receptor and promoting activation. Synthetic peptides corresponding to this newly exposed sequence induce receptor activation in the absence of receptor cleavage. These thrombin receptor-activating-peptides (TRAPs) are powerful tools to study the roles of PAR_1 and PAR_4 receptors. In human platelets, PAR_1 mediates rapid activation in response to low concentrations of thrombin, whereas PAR_4 is activated by higher concentrations of the protease. PAR_1 and PAR_4 receptors induce activation through G_q- and $G_{12/13}$-families of G-proteins, both of which synergize with the $P2Y_{12}$ ADP receptor.

Platelets express a third, high-affinity binding site for thrombin on the GPIbα subunit of the GPIb–IX–V. Binding of thrombin to GPIbα positions the protease in the vicinity of the PAR_1 and PAR_4 receptors, facilitating their activation. In addition, binding of thrombin to GPIbα has been proposed to generate intracellular signals through a pathway that requires cleavage of GPV. The ability of this pathway to activate platelet is controversial because it is inconsistent with reports of abolition of platelet activation by thrombin in mice deficient in PAR_4 receptors.

Collagen

Collagen is a major component of the subendothelial matrix and is recognized as one of the *initial* ligands that mediate platelet adhesion and platelet activation following damage to the vasculature. Nine forms of collagen have been described within the vessel wall, with types I and III being the predominant ones in the deeper layers of the vessel wall, whereas type VI predominate in more superficial layers. All vascular collagens bind to the receptors GPVI and $\alpha_2\beta_1$. In addition, there are reports of the presence of additional receptors for collagen on platelets, although these need to be confirmed and their role determined.

Collagen is composed of three helical chains, which interact together to form a superhelical structure that is interrupted by non-helical regions. The presence of glycine (G) at every third position is essential to form the helical structure. In addition, the amino acids proline (P) and hydroxyproline (O) make up approximately 10% of the helical backbone. Synthetic collagen peptides based on these three amino acids have been shown to bind selectively to GPVI or integrin $\alpha_2\beta_1$. Peptides that are specific to GPVI have a backbone of GPO residues, whereas peptides that bind to $\alpha_2\beta_1$ have a backbone of GPP residues interspersed with at least one or more GER motifs, usually GFOGER. The GER sequence confers binding to $\alpha_2\beta_1$, whereas GPP is unable to bind to $\alpha_2\beta_1$ (or GPVI) but is required to present GER in a helical conformation. Many snake toxins also target GPVI, such as C-type lectin, convulxin, which was instrumental in the original cloning of the receptor. Convulxin, a tetramer composed of distinct α- and β-subunits, induces powerful activation of GPVI through cross-linking.

Collagen stimulates platelet activation through the immunoglobulin receptor, GPVI, which is associated with the Fc receptor (FcR) γ-chain. The GPVI–FcR γ-chain complex signals through a tyrosine kinase-based pathway that shares many of the features used by antigen (e.g. TCR) and Fc receptors. All of these receptor complexes contain one or more immunoreceptor tyrosine-based activation motif (ITAMs) in their cytosolictails. In the case of GPVI receptor complex, the FcR γ-chain is a disulphide-linked homodimer, with each chain possessing one ITAM sequence. GPVI signals through tyrosine phosphorylation of the FcR γ-chain ITAM by the Src family kinases, Fyn and Lyn. This leads to recruitment of Syk through its SH2 domains, which bind to the ITAM phosphotyrosines. Syk regulates a downstream signalling cascade that is composed of a series of adapter proteins and effector enzymes. Adapters form an intracellular scaffold that is now recognized to be critical in the regulation of effector proteins such as PLCγ2, PI3 kinase and Tec family tyrosine kinases. A general and more detailed scheme of signalling by GPVI is shown in Figure 48.3a and b. The general mechanism of inhibition by PECAM-1 (see PECAM-1 (CD31), below) and comparison with thrombin signalling are shown in Figure 48.3a and b respectively.

GPVI can be considered to be unique among platelet glycoprotein receptors in that it is the only one that signals through an ITAM pathway at sites of damage to the vasculature. The low-affinity platelet immune receptor, FcγRIIA, also signals through this pathway but is not thought to play a role in haemostasis. GPVI synergizes with the $P2Y_{12}$ receptor to mediate platelet activation.

The primary role of the second major collagen receptor, $\alpha_2\beta_1$, is to promote platelet adhesion, although it is also able to support limited platelet activation. The physiological significance of $\alpha_2\beta_1$, in supporting thrombus formation *in vivo*, however, remains unclear because both of these roles are redundant with those of other platelet integrins, most notably $\alpha_{IIb}\beta_3$. Interestingly, polymorphisms in the α_2 subunit can lead to a three- to fivefold increase in expression. A weak correlation has been found between polymorphic forms that increase expression and thrombotic disease, most notably in younger individuals. These observations
Figure 48.3 GPVI signalling. (a) The signalling events mediated through GPVI and their regulation by PECAM-1 are shown. GPVI signalling is mediated by sequential activation of Src and Syk tyrosines. Syk regulates a number of adapter proteins that form a signalling scaffold for the regulation of effector enzymes including phospholipase (e.g. PLCγ2), kinases (e.g. a third family of tyrosine kinases, known as the Tec family which includes Btk) and GTP exchange factors (GEFs), which regulate small G-proteins. The GPVI signalling cascade is selectively inhibited by activation of another member of the superimmunoglobulin family of proteins, PECAM-1, through recruitment of the tyrosine phosphatase, SHP-2. (b) The regulation of PLCγ2 and PLCβ2 by the collagen receptor GPVI and the thrombin receptor PAR$_1$ respectively. The binding of the following domains is shown: SH3 domains bind to proline rich sequences, SH2 domains bind to phosphotyrosine groups and PH domains to the 3-phosphorylated lipid, PIP3. The following proteins are adapters: ADAP, GADS, LAT and SLP-76. Vav is a GTP exchange factor (GEF); Fyn and Lyn are Src family tyrosine kinases; Syk and Btk are members of two different families of tyrosine kinases. Signalling by GPVI and by PAR$_1$ takes place in cholesterol-rich regions of the membrane known as Gems or lipid rafts.

suggest that the integrin is a target for antithrombotics, although this is unlikely to be realized because of side-effects resulting from expression on other cells.

A handful of patients have been described with low or undetectable levels of GPVI. Surprisingly, these patients have only a mild bleeding disorder, suggesting that the role of the glycoprotein can be bypassed by other signalling receptors. The three patients that have been described with deficiency of $\alpha_2\beta_1$ also have other vascular complications that hamper the drawing of conclusions on the *in vivo* significance of the integrin.

Fibrinogen

Plasma fibrinogen is widely recognized as a major mediator of platelet aggregation and is vital for fibrin formation. Fibrinogen is composed of three, disulphide-linked chains in a symmetrical structure as discussed in Chapter 46. The two heads of fibrinogen cross-link adjacent, activated platelets by binding to the activated (or high-affinity) form of the major platelet integrin, $\alpha_{IIb}\beta_3$. Fibrinogen is the precursor of the insoluble fibrin polymer that is formed following proteolytic cleavage by thrombin.

Thus, fibrinogen plays a central role in the coagulation cascade and in platelet activation.

Studies on platelets *in vitro* have provided abundant evidence for the critical role of fibrinogen in supporting aggregation. However, several other ligands also bind to $\alpha_{IIb}\beta_3$, including the adhesive proteins vWF, fibronectin and vitronectin, and CD40L which is expressed and released from the platelet surface during activation. All of these ligands support platelet aggregation under appropriate circumstances, although their precise role in supporting haemostasis and thrombosis is unclear. Fibrinogen is also able to support platelet adhesion at low rates of shear, even in the absence of a conformational change in the integrin $\alpha_{IIb}\beta_3$. However, at higher rates of shear, it requires vWF to promote platelet tethering before it can support adhesion as discussed above.

Binding of fibrinogen and other ligands to $\alpha_{IIb}\beta_3$ is promoted by inside-out signals from various G-protein-coupled and tyrosine kinase-linked receptors as a result of a conformational change in the integrin. The binding of ligands to $\alpha_{IIb}\beta_3$, in turn, generates outside-in signals that stimulate spreading and support other responses through a synergistic interaction with the P2Y$_{12}$ ADP

receptor. Thus, $\alpha_{IIb}\beta_3$ plays a direct role in regulating platelet activity, as well as in supporting adhesion and aggregation.

Integrin $\alpha_{IIb}\beta_3$ is a major target for the acute treatment of patients with coronary artery disease undergoing procedures such as coronary angioplasty and stenting. The powerful action of the $\alpha_{IIb}\beta_3$ antagonists, however, means that excessive bleeding is a major side-effect and that therapy must be restricted to the hospitalized environment. The prototype drug in this class is the humanized antibody F(ab) fragment abciximab, which was introduced in the mid-1990s and has now been given to more than 2 million patients worldwide. Two peptide $\alpha_{IIb}\beta_3$-blocking agents, integrilin and tirofiban, are also used in the clinic. Clinical trials with orally acting active $\alpha_{IIb}\beta_3$ antagonists have been stopped, however, due to their limited efficacy and side-effects, and there now seems little prospect of this class of anti-platelet drug entering the market in this form.

von Willebrand factor

The glycoprotein vWF is made up of a series of multimers that vary in size in plasma from 0.5 to 20 million daltons, giving rise to the characteristic vWF ladder when analysed by gel chromatography. Larger multimers of vWF are more effective in mediating platelet tethering at high rates of flow. vWF is stored and released from endothelial cell Weibel–Palade bodies as an ultra-large multimer, that is greater than 20 million daltons. The released vWF is broken down into the smaller multimers by the specific metalloproteinase, ADAMTS13. Deficiencies in ADAMTS13 leads to the persistence of ultra-large vWF multimers in the circulation and a thrombotic microangiopathy, known as thrombotic thrombocytopenic purpura (TTP), which is characterized by vWF-rich platelet aggregates in skin and vital organs.

At intermediate and higher rates of shear, vWF undergoes a conformational change from a closed structure to an extended form that can reach several microns in length and which has multiple platelet and collagen binding sites. vWF can also self-associate when extended to form very large filaments on the surface of endothelial cells and on collagen. In this extended form, vWF is able to bind platelets through the GPIb–IX–V complex and thereby support thrombus formation, even at very low rates of shear when immobilized on a surface. This extended form of vWF can also be induced using the antibiotic ristocetin or the snake venom toxin botrocetin. These tools are routinely used in experimental laboratories to promote the interaction of vWF with GPIb–IX–V in the absence of shear. Ristocetin is used in clinical laboratories to promote platelet agglutination through GPIb–IX–V as a test for patients with mutations in the receptor complex, known as Bernard–Soulier syndrome (BSS).

The critical role of vWF in mediating platelet tethering during thrombus formation is discussed above. vWF's role in this process is dependent on the fast on-rate of association to the GPIbα subunit in the GPIb–IX–V complex. The stable recruitment of platelets into the thrombus, however, requires interaction with other platelet agonists or very high rates of shear (which is also able to act as an agonist) to activate platelet integrins. This dependency on multiple interactions prevents thrombus formation occurring when platelets are exposed to vWF in the absence of other stimuli, such as may occur on the surface of endothelial cells during release of the adhesive protein. The large multimeric structure enables it to interact with many other proteins involved in the coagulation cascade, including factor VIII, as discussed in Chapter 46.

GPIb–IX–V has been shown to generate weak intracellular signals that promote spreading and activation of $\alpha_{IIb}\beta_3$ through a pathway that is dependent on Src kinases and PLCγ2, but which is distinct from that used by the collagen receptor GPVI (see below). GPIb–IX–V, however, is a relatively weak stimulus and the significance of its ability to activate $\alpha_{IIb}\beta_3$ is uncertain, bearing in mind that it is unable to support stable adhesion under high shear conditions in the absence of other receptor stimuli. A full evaluation of the importance of GPIb–IX–V signalling is hampered, however, by its critical role in platelet tethering; nevertheless, the redundancy with the more powerful signals from other platelet glycoproteins suggests that its importance is likely to be relatively minor.

GPIb–IX–V binds to a number of other ligands. GPIb–IX–V binds to the integrin $\alpha_M\beta_2$ (also known as Mac-1 or CR3) on the surface of leucocytes, and this interaction, along with binding of platelet P-selectin to PSGL-1, is implicated in the attachment and transmigration of leucocytes through a mural thrombus. GPIb–IX–V also binds to P-selectin and this has been shown to support rolling of platelets with activated endothelium in low-pressure vessels, although the physiological significance of this is unclear. GPIb–IX–V binds to $\alpha_M\beta_2$ receptors in the liver and it has recently been proposed that this is responsible for the clearance of platelets that have been stored at 4°C as a result of clustering of the GPIb–IX–V complex on the platelet surface. Preliminary data suggest that modification of GPIb enables the storage of platelets at 4°C, thereby avoiding many of the lability problems that result from their storage at room temperature.

Mutations in GPIbα, GPIbβ and GPIX give rise to the bleeding disorder BSS, which is characterized by macrothrombocytopenia and fragile platelets. BSS is an extremely rare disorder, with just over 100 cases described worldwide. The reduction in platelet count and change in morphology in BSS platelets is a consequence of the pivotal role of GPIb–IX–V in platelet formation. GPIb–IX–V forms a lattice like structure on the platelet surface mediated through its interaction with the cytoskeleton via the actin-binding protein filamin. This interaction is vital for platelet generation as described in the recent reviews by Hartwig and Italiano (2003) and Italiano and Shivdasani (2003).

Other platelet ligands and their receptors

Table 48.2 lists other receptors that have been described on the platelet surface. Many of these have a minimal effect on platelet

activity, whereas others are not exposed to their endogenous ligands during normal haemostasis, although this may not be the case in thrombosis. In many of these cases, therefore, the physiological role of the receptor in regulating platelet function is negligible.

There are several reasons why platelets express receptors that do not appear to have a physiological role. Some of these receptors may regulate platelet activity in lower organisms or they may support megakaryocytopoiesis and platelet formation. The latter may explain, for example, the presence of receptors for chemokines and the cytokine thrombopoietin on platelets, which have critical roles in megakaryocytopoiesis but cause only weak potentiality of platelet activation.

Many of the receptors in Table 48.2 are activated by agonists that are released during platelet activation. The action of many of these agonists on platelets is weak, with only ADP and thromboxanes being recognized as major feedback regulators of platelet activation. However, several of these mediators play important roles in other vascular processes. For example, 5-HT mediates powerful vasoconstriction, thereby limiting blood loss.

It is of interest that platelets express low levels of the integrins $\alpha_5\beta_1$, $\alpha_6\beta_1$ and $\alpha_v\beta_3$, which support platelet adhesion to a number of subendothelial matrix proteins, including fibronectin, laminin and vitronectin respectively (see Table 48.2). The role of these integrins in supporting adhesion, however, is masked to a large extent *in vivo* by the presence of the major platelet integrin, $\alpha_{IIb}\beta_3$, and also by the presence of each other.

An emerging theme in our understanding of the events that underlie platelet activation is the role of surface proteins in 'late events' that help to stabilize the thrombus and minimize embolization. These include outside-in signals from platelet integrins as discussed above but, in addition, several recently discovered receptors on platelets have been implicated at this stage in platelet activation, including ephrins and Eph kinases, the cell adhesion molecule L1 and the α-granule membrane protein CD40L. Eph kinases are cell-surface receptor tyrosine kinases and their ligands, the ephrins and L1, are also transmembrane proteins. Potentially, both Eph kinases and ephrins can generate intracellular signals when platelets come into contact with each other. CD40L binds to its receptor CD40, which is expressed on platelets, and the integrin $\alpha_{IIb}\beta_3$. Mice deficient in CD40L have a delayed occlusion time and a reduction in thrombus stability, which is thought to be mediated through loss of the interaction with the integrin, as mice that lack CD40 do not have the same phenotype. This emerging field promises to shed new light into the mechanisms of platelet regulation and may identify new targets for development of novel antithrombotics.

Platelets express many other membrane proteins whose function is unknown. This includes CD36, which was originally thought to be a receptor for collagen and thrombospondin. CD36 is absent in 3% of the Asian population but, as these individuals do not have major haemostatic problems, it is not thought to play a major role in supporting platelet activation. Platelets also express high levels of the immunoglobulin superfamily member, JAM-1; the tetraspanin proteins, CD9 and CD63 and the integrin-associated protein, CD48. The role of these and other proteins in platelet activation is unknown.

One receptor that is worthy of special mention is the platelet low-affinity receptor, FcγRIIA. FcγRIIA stimulates powerful activation of platelets through the same signalling pathway as that used by collagen. Although FcγRIIA does not appear to be required for haemostasis, it plays a role in immunological defence against bacteria, viruses and parasites. The low affinity immune receptor also plays a critical role in a variety of immune or autoimmune and alloimmune disorders involving antibody–antigen clustering, which results in platelet activation. This is of particular relevance to heparin-induced thrombocytopenia, which is a major complication of treatment of some patients with the anticoagulant.

Inhibitory agonists and their receptors

It is essential for platelets to have powerful inhibitory mechanisms that prevent activation in intact, healthy vessels and which limit thrombus growth during haemostasis. Perhaps surprisingly, therefore, a relatively small number of pathways have been shown to mediate platelet inhibition. This is related to the antithrombotic nature of the endothelial cell surface and the presence of effective mechanisms for removal of platelet stimulatory agonists in the circulation. Additionally, platelet integrins are unable to bind to circulating adhesive proteins such as vWF, fibrinogen and fibronectin in their inactive state. The major pathways mediating platelet inhibition are discussed below. These four pathways interact in a coordinated way, together with endothelial thrombomodulin, which regulates the level of thrombin, to prevent platelet activation on the endothelial surface.

Nitric oxide

Nitric oxide (NO) is the most important inhibitor of platelet function. It is constitutively released from endothelial cells that surround the vasculature, and is made in minor levels in macrophages and in stimulated platelets. It can also be inducibly upregulated in endothelial cells. NO has a short half-life in the vasculature, in the order of 3–5 s, which means that the highest concentration of the gaseous transmitter is found in the vicinity of the endothelial cell, a key site of inhibition of platelet function.

NO mediates powerful inhibition of platelet activation and also promotes vasodilatation. These effects are mediated through direct activation of guanylate cyclase, leading to the generation of cGMP and activation of protein kinase G (PKG). The substrates for PKG in platelets include type III phosphodiesterase

(PDE), which hydrolyses cAMP, which itself is inhibitory. The inhibition of type III phosphodiesterase by cGMP leads to elevation in cAMP and activation of PKA. PKA and PKG inhibit platelet activation through a number of shared pathways, including inhibition of phosphoinositide metabolism and through Ca^{2+} extrusion. The anti-platelet function of NO is likely to contribute in part to the efficacy of cGMP-elevating drugs such as nitrites, which are used in the treatment of unstable angina.

Prostacyclin

Prostacyclin (prostaglandin I_2 or PGI_2) is the major prostaglandin synthesized by endothelial cells. It is synthesized from arachidonic acid through the sequential actions of cyclo-oxygenase and prostacyclin synthetase. Prostacyclin exerts a powerful inhibitory effect on platelets and also promotes vasodilatation through elevation of cAMP. Prostacyclin activates the Gs-coupled, seven transmembrane IP (or prostacyclin) receptor, which regulates adenylyl cyclase. cAMP inhibits platelet activation through a number of pathways, as discussed above.

The concentration of prostacyclin in the bloodstream is too low to mediate a widespread inhibition of platelet activation. Instead, the anti-platelet action of prostacyclin is thought to be of primary significance in inhibiting activation at the edge of damaged vessels, when the growing thrombus comes into contact with the endothelium. This action is facilitated by the liberation of arachidonic acid from the platelet, which is converted to prostacyclin by the endothelial cells.

Platelets express low levels of several other receptors that are coupled to Gs, most notably the adenosine A_{2A} receptor. Although the A_{2A} receptor inhibits platelet reactivity under certain experimental paradigms, it is expressed at a low level and is not considered to be a major route of inhibition.

PECAM-1 (CD31)

Recent studies have demonstrated that the transmembrane protein PECAM-1 plays an important role in inhibiting platelet function. PECAM-1 is expressed in high levels in the platelet surface membrane, with about 10 000 copies per cell. It is a member of the immunoglobulin (Ig) superfamily of surface receptors and is characterized by the presence of six extracellular Ig domains and an immunoreceptor tyrosine-based inhibition motif (ITIM) in its cytosolic tail. Increasing evidence suggests that PECAM-1 is its own ligand, and that binding to PECAM-1 molecules on other cells mediates inhibition. Cross-linking of PECAM-1 using specific antibodies or recombinant PECAM-1 selectively inhibits the activation of platelets by the collagen receptor GPVI and by FcγRIIA through the recruitment of the tyrosine phosphatase, SHP-2 (Figure 48.3). The primary role of this inhibitory action may be to prevent platelet activation on endothelial cells, which express more than 1 million copies of PECAM-1 per cell. Thus, the interaction of platelets with endo-

thelial cells generates inhibitory signals that prevent the activation of platelets by collagen and possibly also agonists.

Ecto-ADPase (CD39)

Platelets and endothelial cells express an ecto-ADPase (CD39) on their cell surface that rapidly metabolizes ATP and ADP to AMP. This prevents activation of platelets by low levels of the nucleotides in the circulation or on the endothelial surface.

Signalling pathways underlying platelet activation

The major receptor types that mediate platelet activation can be broadly divided into those that initiate activation through tyrosine kinase-linked and G-protein-dependent pathways. The former includes the major platelet adhesive ligands, namely collagen, vWF and fibrinogen, whereas, G-protein-coupled receptors are activated by 'soluble' ligands, such as thrombin, thromboxanes and ADP. These two distinct pathways undergo synergy with each other and regulate a number of closely related effector proteins, including isoforms of PLC and PI3 kinase. In addition, Ca^{2+} plays a critical role in platelet activation by both groups of receptors. Indeed, from the point of the cell, there may be little difference between activation of distinct isoforms of effector enzymes that liberate the same second messengers such as IP3, 1,2-diacylglycerol and phosphatidylinositol 3,4,5-trisphosphate (PI 3,4,5-P3). This section broadly outlines the pathways that underlie platelet activation by these two groups of receptors.

Tyrosine kinase-linked receptors

Platelets express three distinct families of surface glycoproteins that signal through Src family tyrosine kinases that lie upstream of PLCγ2 and PI3 kinase. These are the ITAM receptors, GPVI and FcγRIIA, platelet integrins, including $α_{IIb}β_3$ and $α_2β_1$, and the leucine-rich repeat protein, GPIb–IX–V. These three groups of receptors differ, however, in the mechanism and magnitude of regulation of PLCγ2. GPVI and FcγRIIA induce powerful activation of PLCγ2 through sequential activation of Src and Syk family kinases. Pivotal in their signalling cascades is phosphorylation of two tyrosines in the conserved ITAM sequence, which leads to recruitment and activation of Syk which, in turn, regulates downstream effector proteins. The major platelet integrin, $α_{IIb}β_3$, also signals via sequential activation of Src and Syk family kinases, although in contrast with the above, this pathway is ITAM independent. In addition, $α_{IIb}β_3$ induces a much lower level of activation of PLCγ2, and also activates the tyrosine kinase, focal adhesion kinase (FAK) through a pathway that is dependent on actin polymerization. The activation of Syk and PLCγ2 by $α_{IIb}β_3$ supports platelet spreading. GPIb–IX–V also

regulates Src kinases and PLCγ2 through an ITAM-independent pathway; however, GPIb–IX–V, is an extremely weak stimulus and the importance of this supporting thrombus formation *in vivo* is unclear (see above).

G-protein-coupled receptors

The major G-protein-coupled receptors that underlie platelet activation can be divided into two groups on the basis of their associated G-proteins. The largest group is coupled to the G_q and $G_{12/13}$ families of G-proteins, and includes the $P2Y_1$ ADP receptor, the PAR_1 and PAR_4 thrombin receptors and the TP thromboxane receptor. The extent to which these receptors induce platelet activation varies according to their levels of expression. Thus, for example, the $P2Y_1$ ADP receptor is present at a very low density and so is only able to stimulate aggregation through synergy with the $P2Y_{12}$ ADP receptor. The two thrombin receptors are present in higher levels and are able promote aggregation on their own, although they also undergo synergy with the $P2Y_{12}$ ADP receptor. G_q regulates PLCβ and is thought to be the primary basis of platelet activation by these receptors. $G_{12/13}$ G-proteins activate the small G-protein Rho that lies upstream of Rho kinase, which mediates shape change (see above). Activation of $G_{12/13}$ G-proteins is also able to undergo synergy with ADP to promote aggregation, although the basis of this is not established.

G_i-coupled G-proteins inhibit adenylyl cyclase and activate PI3 kinase, among other actions. The $P2Y_{12}$ ADP receptor is the major regulator of this family of G-proteins in platelets. The $P2Y_{12}$ ADP receptor undergoes marked synergy with other stimulatory receptors leading to powerful aggregation and secretion as illustrated above. The molecular basis of this synergy is mediated in part through activation of the PI3 kinase pathway, but is independent of inhibition of adenylyl cyclase.

Ca^{2+} and protein kinase C

Ca^{2+} plays a critical role in nearly all aspects of platelet activation, including aggregation and secretion. An increase in Ca^{2+} is brought about by its release from intracellular stores by the action of IP3 or by entry through the plasma membrane, either as a consequence of depletion of intracellular stores, a process known as capacitative entry, or by direct opening of membrane Ca^{2+} channels. Given the importance of Ca^{2+} in regulating platelet activity, we still know surprisingly little about the mechanisms that control Ca^{2+} entry into the cell, although it seems likely that these involve membrane TRP channels.

The majority of the actions of Ca^{2+} are dependent on the calcium-binding protein calmodulin. In addition, however, many Ca^{2+}-dependent responses also require activation of other signalling pathways, such as protein kinase C, which regulates secretion through phosphorylation of SNARE proteins and SNARE regulatory proteins. Fluorometric ratio dyes such as Fura2 or Oregon green have revolutionized the study of Ca^{2+} in platelets and have recently demonstrated the critical role of the cation in nucleating thrombus formation on immobilized ligands. Agents that block Ca^{2+} elevation and protein kinase C represent potential novel antithrombotics, but are also likely to have many other actions.

Phosphatidylinositol 3-kinase

The phosphatidylinositol 3-kinase (PI3 kinase) second-messenger pathway generates the 3-phosphorylated membrane lipids, PI 3,4,5-P3 and PI 3,4-P2. These lipid-based messengers are implicated in the regulation of over 200 proteins in the genome that contain pleckstrin homology (PH) domains. The binding of PH domains to the 3-phosphorylated lipids enables their recruitment to the plasma membrane. Examples of proteins that have PH domains are PLCβ and -γ isoforms and Tec family kinases, such as Btk, which regulate Ca^{2+} entry in platelets and phosphorylate PLCγ2. PI3 kinases isoforms are regulated by G-protein-coupled and tyrosine kinase-linked receptors. There are many potential routes through which activation of PI3 kinases can give rise to platelet activation and underlie synergy between receptors.

Platelet function testing in the clinic

Platelet-based bleeding problems

Platelet function tests are primarily utilized to aid in the diagnosis and management of patients presenting with bleeding problems rather than thrombosis. Before any platelet function test is requested a full clinical and family history is always taken to determine the underlying cause of the bleeding problem. This includes studying the pattern of bleeding, whether it is lifelong or recent, triggered by trauma (e.g. dentistry, surgery or accident), is present within other family members and associated with any medication the patient may be taking. If a platelet defect is suspected then there are now a variety of tests available that can be utilized to diagnose any underlying cause of the bleeding problem. The investigation of platelet function is often affected by the collection and processing of blood samples. Platelets are not only prone to artefactual *in vitro* activation, but also to desensitization. Most functional tests therefore have to be performed relatively quickly (e.g. < 2 h from sampling). Also normal platelet function is highly dependent upon Ca^{2+} concentration and so the choice of anticoagulant is important. Any obvious defect in platelet number should of course always be first excluded by performing a full blood count.

The bleeding time was the first *in vivo* test of platelet function and is performed by timing the arrest of bleeding from standard-sized cuts that are made within the skin of the forearm. Although the test is clinically useful and has been refined, most

clinicians consider the test to be poorly reproducible, invasive, insensitive (particularly to mild platelet defects) and time consuming. Despite these drawbacks, the test is still widely utilized as a first-line screening tool and can identify patients with severe platelet defects. In the 1960s, platelet aggregation quickly became the gold standard of platelet function testing and revolutionized our ability to identify and diagnose many platelet defects. Most aggregometers monitor the changes in light transmission that occur in a suspension of platelets that are stimulated with different concentrations of various agonists (e.g. ADP, collagen, adrenaline, ristocetin, etc.). The pattern of responses obtained enables the experienced operator to quickly diagnose whether there are defects in various platelet receptors, platelet granules and downstream signalling or metabolic pathways. These two techniques coupled with measurement of platelet adenine nucleotides remained the mainstay of platelet function testing until the late 1980s.

The introduction of flow cytometry into haematology laboratories provided an exquisite, sensitive and powerful tool for studying platelets. Flow cytometric analysis of platelets is usually performed in fresh whole blood and the technique can also be used with very small quantities of blood, even in thrombocytopenia. The major diagnostic use of this technique is to determine the copy density of platelet membrane glycoproteins and receptors. This method is therefore useful for confirming the absence of various glycoproteins or receptors in disease. Platelet function testing can also be performed and the ability of platelets to degranulate, express activation markers (e.g. P-selectin) and negatively charged phospholipid in response to agonists can all be studied.

A major limitation in the above tests is that they are performed at low shear conditions and therefore do not mimic accurately many of the important physiological processes of platelet adhesion, activation and aggregation that occur at higher shear rates *in vivo*. Given this and the problems faced with the *in vivo* bleeding time, a number of *in vitro* tests that attempt to accurately simulate platelet function have been developed. These include the PFA-100 (platelet function analyzer) and CPA (cone and plate analyzer) devices. These simulate high-shear platelet adhesion to foreign surfaces (e.g. collagen) and either monitor the drop in flow rate as an aperture is closed by platelet adhesion/aggregation or study the degree of platelet aggregation and surface coverage respectively. The PFA-100 instrument has been widely utilized for the last 6 years and provides a potential replacement of the bleeding time as a screening test, as it is more sensitive to certain platelet defects and von Willebrand disease. The CPA device has been commercialized only recently as the IMPACT device, so experience is still very limited. However, it is highly likely that these types of instruments will be increasingly utilized in the future and may prove to be useful not only as aids in diagnosing platelet defects and monitoring anti-platelet therapy, but also in predicting bleeding and thrombosis in various patient groups.

Advances in genetic testing of platelet defects coupled with the impending definition of the platelet transcriptosome should also facilitate the use of microarray technology to rapidly diagnose defects and receptor polymorphisms in both health and disease. This area, however, is still in its infancy.

There is clearly still no gold standard for platelet testing, and indeed there may never be. It is likely that a variety of approaches will always be required to confirm a platelet-based bleeding disorder and that the most important of these may remain as clinical history and the ruling out of obvious alternative explanations. It is also likely that specialist test centres will be required for the identification of rare and new platelet-based defects.

Platelets and thrombosis

It is important to consider whether patients with arterial thrombotic conditions have over-reactive platelets or whether the platelets are simply doing what they normally do within an abnormal environment. Given the link between arterial thrombosis with age and the environment, it is highly likely that the vast majority of cases fall into the latter group and that little would be gained by analysing their platelets for 'hyper-reactivity' through platelet function testing, without additional information. Individuals with a high platelet count ($> 600 \times 10^9$/L), such as that found in essential thrombocythaemia, are at increased risk of thrombosis, although many remain symptomless. An important area of research in thrombosis is the influence of inherited platelet receptor polymorphisms. These studies, although interesting, are still often limited by low sample numbers and conflicting data, most likely reflecting the complex nature of the disease, which is influenced by many factors.

Future developments

The last few years have seen remarkable advances in our understanding of the regulation and role of platelets in haemostasis and in inflammatory disorders. Many of these advances in our understanding of platelet function are the result of the impact of new technologies and experimental approaches.

The sequencing of the genome and the use of mass spectrometry in protein identification have led to attempts to map the platelet transcriptosome and proteome respectively, although these fields remain in their infancy because many modern-day molecular techniques are more difficult to apply to these anucleate cells.

An increasing emphasis is being placed by many laboratories upon the analysis of platelets from mutant mice, and many important new observations on platelet function have been made and are likely to continue to be made in this way over the coming years, many of which may stem from the unexpected observation of a platelet-based bleeding problem. Nevertheless,

this approach must be used with the caveat 'mice are not men', even although the fundamental basis of haemostasis in the two species seems to be the same. The continuing elucidation of the molecular basis of patients with novel platelet-based bleeding problems is anticipated to play a major role in our understanding of the events that govern platelet regulation, although the rarity of these patients severely hampers progress in this area.

Imaging techniques are providing remarkable new insights into the complexity and dynamics of the processes that underlie all aspects of platelet activation both *in vitro* and *in vivo*. Although these techniques are hampered by the small size of the platelet, the field is young, and many new and exciting observations are being discovered through application of this technology. This is further enhanced by its application to mouse models, which is beginning to reveal new insights into the biochemical and cytoskeletal events that underlie real time *in vivo* thrombus formation.

With all these developments and information, the student is left with a bewildering complexity and a feeling of 'where will it all end'? In considering this, it is important to recognize that, perhaps surprisingly, many of the proteins in platelets appear to have minor or negligible roles in regulating activation. The number of major proteins and pathways that play major roles in regulating platelet activation is a much smaller number.

The goal remains to develop improved antithrombotic agents that provides effective treatment without an increased risk of bleeding. Although it may never be possible to attain this goal, as we begin to understand more about the events that underlie thrombus formation, there will be increased opportunity for discovery of more rational forms of therapy. New medicines may be targeted at the very early stages of platelet activation and may be more effective in preventing thrombosis without significantly disturbing normal haemostasis.

Inherited bleeding disorders

Michael A Laffan and Christine A Lee

Introduction

The existence of lifelong bleeding disorders and their familial occurrence was noted in the medical literature as early as the sixteenth century. No doubt this was because the clinical syndrome of haemophilia is highly distinctive. Early writers were impressed by the helplessness of the physician in the face of such extreme haemophilic bleeding. A full understanding of the pathophysiology and genetics of these disorders was long delayed because of the complexities of the clotting mechanism. Advances in protein chemistry and recombinant DNA technology have now produced a comprehensive account both of normal coagulation and of the molecular genetics of haemophilia. An earlier chapter outlines the coagulation mechanism. In this chapter, the clinical features of inherited bleeding disorders will be described, together with a summary of the genetic lesions identified in the various coagulation factor deficiency states. Table 49.1 summarizes inherited bleeding disorders, their mode of inheritance, the molecular genetic basis where known and the incidence.

Advances in molecular biology have enabled more precise diagnosis and reduced the dependence on plasma-derived concentrates, at least in the economically rich countries. Direct identification of the mutation responsible for the factor deficiency in an individual kindred has now superseded the use of restriction fragment length polymorphisms (RFLPs). This can remove the uncertainty from carrier detection in many cases. The methodology for these analyses is now a crucial part of haemophilia care and will be discussed in full.

Haemophilia A

Clinical features

The majority of patients are male, but haemophilia can occur very rarely in females (see below). The severity and frequency of bleeding in X-linked factor VIII deficiency are inversely correlated with the residual factor VIII level. Table 49.2 summarizes this relationship and gives the relative frequency of categories, based on UK national data. The main load- or strain-bearing joints – ankles, knees and elbows – are most affected but any joint can be the site of bleeding. If untreated, this intracapsular bleeding causes severe swelling, pain, stiffness and inflammation, which gradually resolves over days or weeks. It is not clear why bleeding in haemophilia shows a predilection for joints, but it has been suggested recently that synthesis of tissue factor pathway inhibitor (TFPI) in synovial tissue may be at least part of the explanation.

Blood is highly irritant to the synovium and causes synovial overgrowth, with a tendency to rebleed from friable vascular tissue, thus setting up a vicious circle. It is probably through the accumulation of iron in chondrocytes that a rapid degenerative arthritis occurs, leading to an irregularity of articular contour, then thinning of the cartilage, bony overgrowth and subchondral cysts, and, finally, ankylosis (Figure 49.1). As a result of the vicious circle of bleeding and synovial hypertrophy, a particular joint tends to become the 'target joint' in an individual, whereas other joints may be relatively spared.

Muscle bleeding can be seen in any anatomical site, but it most

Table 49.1 Inherited bleeding disorders.

Disorder (synonym)	Pathophysiology	Mode of inheritance	Molecular genetics	Approximate incidence per 10^6 population[†]
Common group				
Haemophilia A (classical haemophilia)	Factor VIII deficient or defective	XL	Deletions, inversions, missense, nonsense, insertions, splicing	100
von Willebrand's disease	von Willebrand factor deficient or defective	AD or AR	Deletions, missense nonsense	AD: 100 or more* AR: 1
Haemophilia B (Christmas disease)	Factor IX deficient or defective	XL	Deletions, missense nonsense, splicing	20
Haemophilia C (PTA deficiency)	Factor XI deficient	AD or R	Missense, nonsense splicing	5% in Ashkenazi Jews, others rare
Rare group				
Factor X deficiency		AR	Deletions, missense	1
Factor V deficiency		AR	?	1
Factor VII deficiency		AR	Missense, nonsense, deletion, splicing	
Factor II (prothrombin) deficiency		AR	?, missense	1
Afibrinogenaemia		AR		
Dysfibrinogenaemia		AD	Missense	1
Factor XIII deficiency		AR	Missense, deletion	1
Factor V plus VIII deficiency		AR	Missense, nonsense, deletion, insertion	1
Hyperplasminaemia α_2-antiplasmin deficiency		AR	Missense, insertion	Very rare

XL, X-linked recessive; AD, autosomal dominant; AR, autosomal recessive.

*Recent population surveys indicate much higher incidence of mild von Willebrand's disease.

[†]Figures applicable to developed countries; incidence is lower in developing countries due to very high early mortality and low reproductive fitness of suffers.

Table 49.2 Haemophilia A*: clinical severity.

Factor VIII U/dL	Bleeding tendency	Relative incidence (% of cases)
< 2	Severe: frequent spontaneous[†] bleeding into joints, muscles and internal organs	50
2–10	Moderately severe: some 'spontaneous bleeds', bleeding after minor trauma	30
>10–30	Mild: bleeding only after significant trauma, surgery	20

*This table is also applicable to factor IX, X and II deficiences, but not to factors VII, XI, V, XIII or von Willebrand factor deficiencies (see text).

[†]'Spontaneous' bleeding refers to those episodes in which no obvious precipitating event preceded the bleed. No doubt, minor tissue damage consequent on everyday activities actually initiates bleeding.

often presents in the large load-bearing groups of the thigh, calf, posterior abdominal wall and buttocks. Local pressure effects often cause entrapment neuropathy, particularly of the femoral nerve, with iliopsoas bleeding. This causes a common symptom triad of groin pain, hip flexure and cutaneous sensory loss over the femoral nerve distribution. Bleeding into the calf, forearm or peroneal muscles can lead to ischaemic necrosis and contracture.

Figure 49.1 Radiograph of knee joint showing advanced haemophilic arthropathy. Note the loss of cartilage, eburnation, deformity subluxation, osteophytes, subchondral cysts and irregularity of joint contours.

Haematuria is less common than joint or muscle bleeding in individuals with haemophilia, but the most severely affected patients have one or two episodes per decade. These may be painless and resolve spontaneously, but, if bleeding is heavy, it can produce clot colic. Usually, no anatomical abnormality is found to account for the haematuria on radiological investigation.

Central nervous system bleeding is uncommon but can occur after a slight head injury and was formerly the most common cause of death in haemophilia A. Intestinal tract bleeding usually presents as obstruction due to intramural haemorrhage, but haematemesis and melaena also occasionally occur and should be routinely investigated, as they may be due to peptic ulcer or malignancy.

Oropharyngeal bleeding, although uncommon, is clinically dangerous, as extension through the soft tissues of the floor of the mouth can lead to respiratory obstruction. Bleeding from the tongue after laceration can be very persistent and troublesome due to fibrinolytic substances in saliva and the impossibility of immobilizing the tongue.

Surgery and open trauma invariably lead to dangerous haemorrhage in the untreated individual with haemophilia. There may be persistence of haemorrhage often after an initial short-lived period of haemostasis. Clots, if formed, are bulky and friable and break off, with renewed haemorrhage occurring intermittently over days and weeks. This is only seen today in patients who are resistant to conventional replacement therapy, and is due to the presence of inhibitors (see below) or when patients with mild or moderate haemophilia present after their first surgical or dental procedure.

Bruising is a feature of haemophilia A, but it is usually only of cosmetic significance as it remains superficial and self-limiting. Large extending ecchymoses may occasionally require treatment.

Presentation

When a woman is known to be a carrier or at high risk, the cord blood factor VIII level will establish the diagnosis in the infant. However, the haemophilia may be sporadic with no family history and, in such cases, the haemophilic condition may come to light in the neonatal period with cephalohaematoma or prolonged bleeding from the cord. In cultures where early circumcision is the rule, this will cause prolonged haemorrhage, as was noted in the Babylonian Talmud almost 2000 years ago. Quite often, the diagnosis is delayed until it is noticed that the infant has many large bruises from hand pressure when being picked up or from minor knocks on the cot. These sometimes cause diagnostic confusion and the erroneous label of 'battered baby syndrome' may be applied, with needless psychological trauma to the parents. As soon as the infant starts to crawl actively, joint bleeding will begin to appear. In other children, excessive bleeding from the eruption of primary dentition, or from lacerations, leads to the performance of diagnostic tests. Mild cases may only present in later life when severe trauma or surgery provokes unusual bleeding.

Pathophysiology

All the clinical features of haemophilia A are due directly or indirectly to lack of the clotting factor VIII. The gene for this protein cofactor is located near the tip of the long arm of the X chromosome (Xq 2.8ter), which accounts for the sex-linked pattern of inheritance. Individuals with haemophilia are unable to produce factor VIII due to various mutations (see below) at the factor VIII locus. A lack of factor VIII as a cofactor drastically slows the rate of generation of factor Xa, despite the presence of all other coagulation factors and platelets in normal amounts. Conversely, replacement by intravenous infusion of factor VIII can normalize the haemostatic mechanism of the haemophilic individual.

Laboratory diagnosis

Screening tests show a long activated partial thromboplastin time (APTT), normal prothrombin time (PT), thrombin clotting time (TCT) and bleeding time, and a normal platelet count. Specific assays show factor VIII clotting activity below 50 U/dL, with all other factors normal, and also normal von Willebrand factor (VWF) antigen and ristocetin cofactor. A test for antibodies to factor VIII should always be performed.

Treatment

Clotting factor concentrates

The discovery that factor VIIIC (FVIIIC) was concentrated in cryoprecipitate and the subsequent description of the production of antihaemophilic globulin in a closed bag system made more specific replacement therapy for people with haemophilia possible. Home treatment for the majority of patients became feasible and, with the advent of *lyophilized* concentrates prepared from the plasma from many thousands of donors, the prospect of a normal life for the severely affected haemophilic individual was brought very close. Until virucidal methods were applied to such concentrates from 1985 onwards, many individuals with haemophilia contracted hepatitis, chronic liver disease and AIDS. However, clotting factor concentrates are now virucidally treated and are very safe, particularly with the advent of recombinant clotting factor concentrates. The plasma-derived clotting factor concentrates in use at present are high-purity products with a high specific activity. They are prepared by monoclonal immunoabsorption and other techniques, which result in a pure final product of high specific activity. In the case of FVIII concentrate, this may be purified using a monoclonal antibody specific for the von Willebrand protein or a monoclonal antibody specific to FVIIIC itself. Other techniques of fractionation use chromatographic purification.

Viral infections were a major complication of replacement therapy before adequate inactivation steps were applied. There are three main virucidal methods:

1 terminal heating of the lyophilized product at 80°C (dry heating);
2 heating in solution at 60°C (pasteurization) in the presence of stabilizers or in moisture with hot vapour under high pressure;
3 adding a solvent–detergent mixture during the manufacturing process.

The risk of HIV infection in virally inactivated concentrates is very small, probably as low as 1:200 000–1:300 000. The risk of transmission of hepatitis B and C has also been dramatically reduced. However, there remains the problem of transmission of hepatitis A and parvovirus, which can break through solvent–detergent sterilization and, for this reason, many inactivation processes involve more than one virucidal method. For FIX concentrate, the process of nanofiltration has been used, which can prevent transmission of hepatitis A and parvovirus. It is probable that the fractionation processes used to produce plasma-derived concentrates also overcome the theoretical risk of prion transmission.

Recombinant factor VIII

The structure of the FVIII gene and the isolation of cDNA clones encoding the complete FVIII sequence in the *in vitro* expression of human factor VIII in tissue culture were described in 1984. As a result, it has been possible to develop a recombinant FVIII product: two full-length recombinant products, *Kogenate* (Bayer)–*Helixate* (Aventis) and *Recombinate* (Baxter), and one which is B domainless known as rVIIISQ with the trade name of *Refacto* (Wyeth).

Kogenate–Helixate was made by transfecting cDNA for FVIII into an established mammalian cell line of baby hamster kidney. The secreted protein was purified by multiple purification steps, including ion exchange chromatography and immunoaffinity chromatography with murine monoclonal antibody. The first-generation Kogenate requires albumin as a stabilizer but, more recently, this recombinant FVIII is stabilized using sucrose, avoiding the need for the addition of human albumin.

Recombinate was manufactured by introducing the human FVIII and the von Willebrand factor DNA into Chinese hamster ovary cells.

Refacto is a B domain-depleted recombinant FVIII – the domain is dispensible for the haemostatic activity of VIII. The B domain-depleted molecule is much more stable and albumin is not necessary for stabilization.

More recent formulations of recombinant FVIII are devoid of animal products such as albumin (Table 49.3).

The assay of recombinant clotting factors

In pharmacokinetic studies, it was found that the chromogenic assay produced considerably higher levels than one-stage assays. The influence of phospholipids was studied on these discrepancies. It was found that when the APTT reagent was replaced by platelets in the one-stage assays the results of the chromogenic assay and the one-stage assay were similar (Figure 49.2). Furthermore, using the basic principle of 'like *versus* like', this discrepancy between chromogenic and one-stage methods could be eliminated by using the recombinant product diluted in haemophilic plasma as a standard reference (Figure 49.2).

Treatment on demand

Since the development of replacement therapy, the goal of treatment for haemophilia patients has been the prevention of haemorrhagic episodes. Based on studies from haemophilia carriers and patients with mild haemophilia, we assume that a level of between 5% and 30% is probably adequate to overcome mild bleeds, but certainly not adequate for major surgery or trauma. We know that the severity and the frequency of haemarthrosis is

Table 49.3 Summary of recombinant products available.

	Cell line	Gene	Protein in culture medium	Murine MAbs	Human albumin as stabilizer	Viral inactivation removal	Generation
Recombinate	CHO	VIII VWF	Bovine albumin insulin, aprotinin	Yes	Yes	No	1
Helixate/kogenate	BHK	VIII	Human albumin	Yes	No	SD	2
Refacto	CHO	B domain-deleted VIII	Human albumin	Yes	No	SD	2
NovoSeven	BHK	VII	Bovine serum	Yes	No	SD	2
Benefix	CHO	IX	No	No	No	NF	3

BHK, baby hamster kidney; CHO, Chinese hamster ovary; MAbs, monoclonal antibodies; NF, nanofiltration; SD, solvent detergent.

Table 49.4 Indications and guidelines for factor replacement in haemophilia A and B.

Site of haemorrhage	Dose (U/kg body weight)			
	Optimal factor level (%)	FVIII	FIX	Duration in days
Joint	30–50	20–30	30–50	1–2
Muscle	30–50	20–30	30–40	1–2
Gastrointestinal tract	40–60	30–40	40–60	7–10
Oral mucosa	30–50	20–30	30–40	Until healing
Epistaxis	30–50	20–30	40–60	Until healing
Haematuria	30–100	25–50	70–100	Until healing
Central nervous system	60–100	50	80–100	7–10
Retroperitoneal	50–100	30–50	60–100	7–10
Trauma or surgery	50–100	30–50	60–100	Until healing

Reproduced from Escobar (2003), with permission.

directly related to the degree of deficiency of the clotting factor, but the precise plasma level needed to prevent haemarthrosis is still unknown.

Therapeutic infusion of replacement factor should be administered as early as possible and to a haemostatic level to stop haemorrhagic events. The dosing factor replacement is still based on theoretical calculations and clinical experience.

Guidelines for the treatment of haemorrhagic episodes in haemophilia are given in Table 49.4. Different levels of clotting factor have been proposed, depending on the type and severity of bleed: thus, 12–35% for major bleeding episodes, 12–17% for minor bleeding events, 40–50% for severe trauma and 30% for minor events and 10–20% for spontaneous bleeding episodes.

Formulae based on plasma volume and expected recovery give a rough guide to dosage, but, where the level is critical, as for surgery or when there is serious bleeding, it should always be checked by assay after infusion. On average, factor VIII infusion produces a plasma increment of 2 U/dL per unit infused per kilogram of body weight. From this, a simple formula can be derived as follows: dose to be infused (units) = [weight (kg) × increment needed (U/dL)]/2. Assessing the period of treatment required is a matter of clinical judgement of the individual episode or lesion.

Cover for surgery, other than very minor procedures, requires maintenance of normal factor VIII levels for approximately 1 week, followed by a period at reduced dosage during convalescence. This can be achieved either by repeated bolus injections every 8–12 h (paying particular attention to the trough levels) or by continuous infusion. It must be noted that the doses required during the immediate post-operative period may be considerably more than expected.

Prophylaxis

There is a long tradition of giving prophylaxis to young boys with haemophilia. This was begun in 1958 for boys with haemophilia A. The rationale for the prophylactic model was the observation that chronic arthropathy was seen less frequently and less severely in individuals with a FVIII level of 1–4 IU/dL.

Prophylaxis was developed at Malmö, Sweden, and based on the pharmacokinetic modelling; regular prophylactic treatment is begun at 1–1.5 years before the onset of joint bleeds.
Figure 49.2 (a) Activated partial thromboplastin time (APTT)-based one-stage assays (reproduced from Mikaelsson *et al.* (1998), with permission). (b) Platelet-based one-stage assays (reproduced from Mikaelsson *et al.* (1998), with permission). (c) FVIII recovery levels – ratio of one-stage APTT–chromogenic (reproduced from Lee *et al.* (1999), with permission).

Ideally, FVIII is administered every second day at a dose of 20–40 IU/kg. The goal is to achieve a trough level of > 1 IU/dL. There is good evidence that the Malmö model is effective in preventing haemophilic arthropathy. For the youngest cohort of
Figure 49.3 Orthopaedic joint scores for the present intensively treated. A 15-year-old group compared with a less intensively treated group at different ages, and to patients not receiving prophylaxis (historical control subjects) (UKHCDO (2003)).

boys born in 1981–90, who began prophylaxis between 1–2 years with 4000–9000 IU/kg annually, both the orthopaedic and radiological scores were zero (Figure 49.3).

The use of the peripheral vein is the most preferred approach when beginning prophylactic treatment. However, if this is not possible then the implantation of a Port-a-Cath may be necessary. Substantial experience with Port-a-Caths has been published. Although the advantages of such devices are recognized, septic complications remain a challenge. A number of studies have been published, which show an infection rate ranging from 0.2 to 3.4 infections per 1000 catheter-days.

DDAVP

The non-blood-derived alternative, DDAVP® (1-deamino-8-D-arginine vasopressin) can be used to treat mild haemophilia. This synthetic analogue of vasopressin retains the antidiuretic action of the natural hormone and also stimulates the release of tissue plasminogen activator. In practice, these effects can be used to elevate the plasma factor VIII level two- to fourfold above the baseline, presumably by its release from storage site(s). Patients are advised to restrict their fluid intake after DDAVP. This is especially important in children in whom unrestricted fluid intake may result in hyponatraemia and convulsions. DDAVP is contraindicated in elderly patients and those with vascular disease, because arterial thrombosis is a theoretical risk and has been reported following DDAVP in these circumstances.

DDAVP can correct the haemostatic defect in mild haemophilia A or von Willebrand disease (VWD) sufficiently to cover minor surgery or treat a minor bleeding episode. A typical regimen would be to give 0.3 μg/kg body weight by slow intra-

venous infusion over 20 min (or by subcutaneous injection), together with 1 g of tranexamic acid.

The effect is maximal at 30 min for an intravenous dose and 1 h following a subcutaneous dose. The factor VIII rises three-fold on average. The half-life of the endogenously released factor VIII is about 8 h and the dose can be repeated. Although tachyphylaxis occurs and the second dose may produce a rise 30% of the first, there is often no further drop with succeeding doses. It is customary to advise that no more than three infusions should be given within 48 h because the reserves will be exhausted.

Complications of therapy

Inhibitors

Antibodies to factor VIII (inhibitors) are most common in patients with severe rather than mild haemophilia and are most likely to develop during childhood, but, rarely, inhibitors may develop after years of treatment. Prospective studies have shown that in the past the incidence of inhibitors in patients with haemophilia has generally been underestimated and that virtually all inhibitors occur within 25 treatment days. Studies to determine the true incidence are fraught with difficulty owing to bias in patient selection, frequency and sensitivity of testing and previous treatment. It is impossible at present to give a definitive figure for the incidence of inhibitor development, but overall studies have reported a cumulative risk for severe haemophilia to be approximately 20% by the age of 5–8 years. There is also a genetic component and inhibitors are found six times more often in pairs of brothers than would be expected by chance. One important determinant is the genetic lesion responsible for the factor VIII deficiency. Patients with large deletions or stop codons in the light chain appear to be particularly prone to inhibitor development. Approximately 25% of patients with the common intron 22 inversion develop inhibitors. These figures apply to the high-responding inhibitors that are clinically troublesome. Close monitoring may reveal low-level and transient inhibitors in a further 20% or so of patients. As more is learned of the molecular bases for factor VIII deficiency, it should be possible, perhaps in association with human leucocyte antigen typing, to define more precisely the individual risk. Because the development of inhibitors is unpredictable, it is important to test for their emergence at clinic visits and before operations.

Antibodies to FVIII are typically time independent in their action and therefore an incubation time of 2–4 h is required to measure the effect of the antibody. The Bethesda assay is the most commonly used. An inhibitor is defined as low titre < 5 BU and high titre > 5 BU. A low-responding antibody remains at a low or moderate level, whereas in high responders, treatment with FVIII elicits a sharp anamnestic rise after 5–8 days.

Low responders can be treated repeatedly with high doses of factor VIII concentrate. However, high responders are refractory to treatment with FVIII concentrate and therefore alternative therapies have been developed.

Inhibitors – treatment of bleeding

Porcine FVIII or 'bypassing agents' may be used to treat acute haemorrhage. Plasma-derived porcine FVIII is unavailable at present and a recombinant porcine FVIII is entering clinic trial.

The most common available 'bypassing agents' are human recombinant FVIIa or plasma-derived concentrates that contain activated coagulation factors such as FEIBA and Autoplex.

Recombinant FVIIa was developed specifically as treatment for bleeding episodes in individuals with haemophilia complicated by inhibitor antibodies. Activated FVII is not proteolytically active itself and does not therefore produce systemic activation of coagulation when infused. The FVIIa complexes with tissue factor at the site of the injury and, as it is not neutralized by circulating antithrombin, infused FVIIa can reach the site of injury where it complexes with the tissue factor exposed at the site, inducing local haemostasis. The process is independent of the presence of FVIII or FIX and is not affected by inhibitors to FVIII or FIX.

Human FVIIa was cloned in the mid-1980s and was expressed in baby hamster kidney cells. The baby hamster kidney cells were capable of γ-carboxylation and the FVII is secreted in the single-chain form. The amino acid sequence has been shown to be identical to the human form.

The advantages of recombinant FVIIa include viral safety, low systemic activation of coagulation, effectiveness independent of inhibitor titre and an excellent overall safety profile allowing for home use and ease of administration. The main disadvantage is the short half-life and therefore the need for frequent administration.

The activated coagulation factors, FEIBA and Autoplex, work by activating the coagulation cascade at levels below the action of the inhibitor. Conventional factor IX concentrate (prothrombin complex concentrate) can also be used as a bypassing agent.

Treatment of inhibitors – immune tolerance

Immune tolerance regimens can be used to eradicate high-titre antibodies. It is best to allow the inhibitor to fall to a titre < 10 BU by using bypassing agents. The success is greatest in younger patients (< 7 years) and with a historic peak titre < 200 BU. At present, there is an international study comparing a dose of 50 or 200 IU/kg three times per week for 6 months. Success is defined as normalization of the FVIII recovery. The success rate using varying regimens has been reported as 70–90%.

Successful eradication of the inhibitor has also been reported with a combination regimen of cyclophosphamide, intravenous immunoglobulin, high-dose factor VIII and immunoadsorption.

Molecular genetics of haemophilia A

The factor VIII gene (Figure 49.4) spans 190-kb pairs of the X chromosome. The protein-coding regions (exons) are separated by 25 introns, some of very large size (e.g. intron 22 is over 35 kb). The processed mRNA specifies a protein of 2351 amino acids, which is synthesized in the liver, spleen and lymph nodes,
Figure 49.4 The factor VIII gene and protein. Top line, scale for gene in kilobase pairs of DNA; second line, location of exons (protein coding segments) of the factor VIII gene shown as solid bars; second to third line, corresponding domains of factor VIII gene and protein; fourth line, plasma factor VIII is heterogeneous due to cleavage at various points within the B domain during synthesis and secretion, yielding heterodimers in which the heavy chain (N-terminal segment) pairs from 740 to 1648 amino acids; fifth line, thrombin activation releases the a_2-segment from the light chain, the B domain from the heavy chain and cleaves between the A1 and A2 domains; bottom line, inactivation of factor VIIa by activated protein C is accompanied by cleavages at 336, releasing the a1-domain and 562 in the middle of the A2 domain.

and from which a 19-amino-acid N-terminal leader sequence is cleaved upon secretion. The mature plasma protein initially consists of a single chain of 2332 amino acids, but partially proteolysed derivatives are present in plasma as well. The sequence contains a triplicated region (A1, A2, A3 in Figure 49.4), whose elements are more than 30% homologous with each other and with similar regions of ceruloplasmin (the copper transport enzyme). This indicates only common ancestry, as function has diverged markedly for these two plasma proteins. A second duplicated homology region (C1, C2) bears resemblance to a lectin from the slime mould and to milk fat globule-binding protein. The third type of sequence in the protein is the heavily glycosylated B domain, which is coded entirely within exon 14, connects A2 and A3, and is removed upon thrombin activation of factor VIII. After thrombin activation, the cofactor consists of a heterotrimer: the N-terminal heavy chain corresponding to region A1, the domain isolated by cleavages at 372/373 and 740/741, which is held by a divalent cation-independent linkage

to the C-terminal light chain corresponding to part of A3 plus C1 and C2 (see Figure 49.4). The B-domain is discarded by cleavages at 740/741 and 1689/1690.

Protein C cleaves at 336/337 and 562/563, totally inactivating the cofactor. Binding to VWF is partly via the light chain, but other structure–function relationships, such as factor IXa, factor X and phospholipid binding sites, have not yet been resolved. However, quite small regions of this large protein are critical for function, as it can be totally inactivated by certain monoclonal antibodies whose binding epitopes are restricted in size. Antibodies to the B domain have no effect on function.

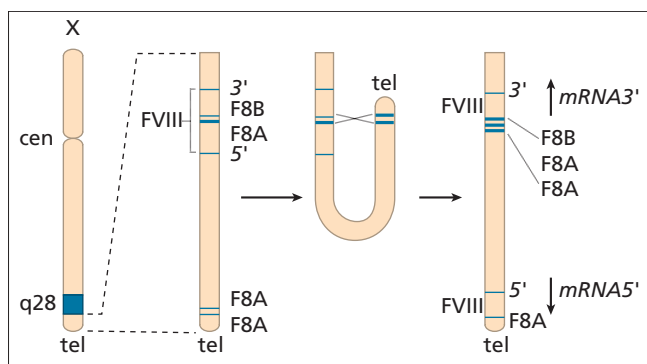
Thanks to the development of the PCR-based rapid screening and sequencing methods, the mutations in nearly all patients with haemophilia A can be identified. Consequently, a large database of mutations has accumulated. These include large deletions and missense mutations, as well as nonsense, frameshift splicing (affecting mRNA processing) and insertional mutations. Surprisingly, about one-half of all severe haemophilia is due to


Figure 49.5 How the tip flips: the mechanism of inversion through intron 22. The mutation is responsible for up to one-half of all cases of severe haemophilia A. During spermatogenesis, at meiosis the single X pairs with the Y chromosome in the homologous regions, but there is nothing to pair with most of the long arm of X. Unfortunately, the possibility of intrachromosomal pairing and crossover exists because there are three copies of a gene designated F8A, one lying within intron 22, and two in the opposite orientation situated 400 kb telomeric to the factor VIII gene. Crossover with either the distal or the proximal F8A copy divides the factor VIII gene in two, such that separately transcribed mRNAs are produced, neither of which encodes functional factor VIII.

major inversion (Figure 49.5) that occurs quite frequently during male gametogenesis (approximately 1 in 10 000 spermatozoa).

Carriers of haemophilia A have on average 50% of the normal mean level of the clotting factor (or its antigen VIII: Ag). However, owing to the wide scatter of normal values (50–150%), an individual will often be within the normal range. By measuring the level of von Willebrand factor antigen (VWF:Ag), the auto-somally coded carrier protein for factor VIII, it is possible to improve discrimination as the carriers will tend to have lower levels of VIII than VWF. Even so, there is still some overlap (about 15%) where the carriers fall into the normal ratio. This is due to the 'lyonization' effect, whereby random X inactivation can predominantly cause the X chromosome bearing the mutant allele to be inactivated. In brief, one can obtain very strong evidence for carriership by this method but never definitely rule it out.

Haemophilia A in females

True homozygous haemophilia A is rare, but well described, being due to the marriage of a carrier to an affected male, usually a cousin. Severe menstrual haemorrhage occurs but responds to factor VIII infusion. About 50% of carriers have a low enough factor VIII level to be classified as mild haemophilia, requiring precautions to cover surgery and occasionally experiencing traumatic bleeding. Due to sperm mutation in the father, especially in the prevalent inversion, a carrier can present *de novo* with no family history of haemophilia. Acquired autoantibodies

to factor VIII arise in previously normal people, sometimes in association with rheumatoid arthritis or in the puerperium. This is acquired haemophilia but has no genetic basis. Treatment resembles that described above under 'Inhibitors'. Haemophilia A has been described in a female with Turner's syndrome. Translocation through the factor VIII locus has given rise to severe haemophilia in an affected female due to exclusive inactivation of the normal X chromosome. The most usual reason for finding a low factor VIII in a female if the above has been excluded is VWD. This should usually be evident from assays of VWF and a prolonged bleeding time. Of course, VWD and haemophilia A can co-exist in the same family, which makes carrier detection difficult. Type 2N VWD (see below) may also be confused with mild haemophilia A.

Haemophilia B

Inheritance and diagnosis

Haemophilia B is an X-linked deficiency of FIX and behaves clinically like haemophilia A. FIX is responsible for the activation of FIX in the presence of activated FVIII, calcium and phospholipid. FIX is synthesized in the liver and is a vitamin K-dependent protease that is similar to prothrombin, FVII, FX and protein C. The FIX protein consists of 454 amino acids. The FIX gene is contained on the long arm of the X chromosome and contains eight exons. The complete sequence of the gene has been determined. As the FIX gene is a simple gene, it has been possible to perform detailed analysis using polymerase chain reaction (PCR)-based analysis. In this way, virtually all cases of haemophilia B genetic mutations have been established. A haemophilia database is also available on the internet at http://www.unds.ac.uk/molgen/.

It is possible to perform mutational analysis to establish carriership because the complete DNA sequence of the gene is known. Isolated factor IX deficiency is always hereditary and the clinical severity of haemophilia B shows the same relationship with the residual factor level as for factor VIII in haemophilia.

Treatment

The mainstay of treatment is factor IX concentrate. Previously intermediate-purity prothrombin complex concentrates containing all the vitamin K dependent factors were used. However, these concentrates were associated with the risk of thrombosis, particularly when used repeatedly, for example in surgery. High-purity factor IX concentrates are now available, which are produced either by monoclonal antibody or improved affinity column methods. Factor IX concentrates are prepared from the same screened plasma pools as factor VIII and undergo similar viral inactivation procedures, although for FIX concentrate the process of nanofiltration has been used, which can prevent

transmission of hepatitis A and parvovirus. Although the FIX gene was cloned in 1982, the development of recombinant FIX, Benefix, was more difficult because of the post-translational modification that is required. Clinical trials of the pharmacokinetics and treatment in previously treated and untreated patents were begun in 1995. Although the clinical effect was good, the recovery was only 72% of that observed with the monoclonal purified plasma-derived FIX.

Dosage calculation in the treatment of haemophilia B follows the same principles as set out for factor VIII deficiency, except that a higher initial dosage is required, owing to a lower recovery. Thus: dose to be infused (units) = [weight (kg) × increment needed (u/dL)]/0.9 or 0.8 for recombinant FVIII. Also, the longer half-life (18 h) means that daily infusions often suffice to maintain good levels after surgery. Severely affected patients are usually maintained on once- or twice-weekly prophylaxis to prevent spontaneous bleeds. This is practicable because of the better supply and the longer half-life of the factor.

Gene therapy

Haemophilia is an excellent model for gene therapy because the clinical manifestation is the result of a deficiency of the single gene product and only a low amount of protein is required to ameliorate symptoms. At the present time there are three gene transfer trials in patients with haemophilia A and B, and two are ongoing (Table 49.5).

The preliminary data from these phase I trials are encouraging. However, the plasma levels of FVIII or FIX attained is less than in the animal models and is certainly insufficient to free patients from treatment with clotting factor concentrates. Also, there has been a short duration of the transgene activity. Although no inhibitors have been documented, this remains a theoretical risk. Furthermore, the detection of small amounts of viral vector genome in the semen continues to raise the possibility of the risk of germline integration. Insertional mutagenesis has occurred in a phase I trial of Moloney retrovirus carrying

Table 49.5 Clinical trials of gene therapy in patients with haemophilia.

Company	Started	Type of haemophilia	Vector and method of gene transfer	Safety	Efficacy	Current status
Transkaryotic therapies	November 1998	A	Non-viral plasmid DNA/*ex vivo*, modification of autologous fibroblasts	No inhibitor	FVIII levels up to 4% transiently in 4 out of 12 subjects; reduced factor requirement	Completed and published; phase II trial starting soon
Avigen	June 1999	B	Adeno-associated virus/*in vivo*, intramuscular	No Inhibitor	FIX levels up to 1.6% transiently in 3 out of 8 subjects; reduced factor requirement	Completed and published
Chiron	June 1999	A	Replication – deficient retrovirus/*in vivo*, intravenous	No inhibitor; transient positive semen signal in one patient	FVIII levels up to 6.1% transiently in 6 out of 12 subjects or 5 more days after replacement therapy	Completed and published
GenStar	June 2001	A	'Gutted' adenovirus driven to liver-specific expression/*in vivo*, intravenous	First patient had abnormalities of transaminases thrombocytopenia and inflammatory symptoms	FVIII levels 1%	Second patient started on trial with a lower dose
Avigen	June 2001	B	Adeno-associated virus driven to liver-specific expression through hepatic artery infusion	Positive semen signals in the first three patients	No FIX levels with the low dose, data not available for mid-dose	Trial on hold

the interleukin receptor, and this has been a cause for concern for all of those involved in gene therapy.

The ethics of gene therapy for haemophilia are complex – it could be argued that for young patients with haemophilia, regular prophylactic factor infusions already deliver a near-normal life. The financing of a genetic 'cure' for haemophilia is another complicating concern. The money spent at present buys viral safety, musculoskeletal and surgical prophylaxis, inhibitor eradication and rapid treatment for acute bleeding for the haemophilia community. Gene transfer experimentation in haemophilia has played an integral role in furthering the science of gene therapy in general but it is likely to be a long time before it becomes the routine therapy for children with haemophilia.

General organization of haemophilia care

As these are relatively uncommon disorders, with many and varied effects on patients and families at all stages of life, who require care and support services across the whole field of medicine and social services, it is now accepted that this care can best be delivered comprehensively by referral centres. The staff of a major comprehensive care centre will include physicians, nurses, social workers, laboratory scientists and physiotherapists, devoting all or a substantial part of their time to haemophilia care. An orthopaedic surgeon prepared to see haemophilic patients regularly in a clinic set aside for their problems is a vital addition to this team. In the UK, there is now a national service specification produced by the Haemophilia Alliance for haemophilia and related conditions, which sets out the standards of care to be provided through the haemophilia centre network originally set up in the 1960s and early 1970s. It is recognized that not every centre can provide every facility and that there should be a fairly wide distribution according to population density, which determines numbers of patients. As defined by the national specification, the functions of a centre are to provide a 24-h emergency treatment for the haemophilic patients and their families and a full range of diagnostic tests for identifying new patients and monitoring treatment. Full records should be kept of all treatments, whether given in hospital or as home therapy. Progress should be monitored through regular follow-up, with paediatric, dental and orthopaedic referrals being organized by the centre as necessary. (Many centres are, in fact, in paediatric departments or run by paediatricians.) Genetic counselling, including carrier detection and antenatal diagnosis, must be available for families of haemophilic patients. Large centres providing all these facilities and treating at least 40 patients with severe haemophilia will be designated comprehensive care centres. It is envisaged that all patients will have access to a comprehensive care centre, either directly or via their smaller local centre. A part- or full-time social worker should be part of the team, able to review the wider problems of living that affect the haemophilic patient at school, home and work.

Centres provide access to specialized care for monitoring patients with HIV and HCV infection. Upon diagnosis, all patients are issued with a special medical card indicating laboratory test results, inhibitor status, main centre and local centre for treatment.

Caring for haemophilic patients and their families is demanding, but rewarding. Until the recent setbacks, the trend has been towards an ever-improving life expectancy and social participation, based on continuing medical progress and the skill and devotion of many professionals. It is both tragic and ironic that the main foundation upon which this progress rested (factor concentrate) has also been the route in which life-threatening infections have been introduced to about one-half of the most severely affected patients with haemophilia A. However, there are now excellent therapies for both HIV and HCV infection.

Of course, the younger generation of haemophiliacs are now treated with virus-safe concentrates and have escaped both HIV and liver disease, and lead virtually normal lives.

von Willebrand disease

Although described in 1926, our understanding of this complex and variable bleeding disorder continues to grow. The basic defect common to all variants is a deficiency of von Willebrand factor (VWF) functional activity. The abnormality may be quantitative and/or qualitative. VWF is encoded by a gene on chromosome 12, which was cloned simultaneously by several groups. The primary gene product is an extremely long protein monomer comprising 2813 amino acids. This is produced predominantly in vascular endothelial cells, but also in megakaryocytes, and undergoes a series of post-translational modifications. Dimers are formed and a very large propeptide is excised. The propeptide, previously known as von Willebrand antigen II, is detectable in plasma and it is essential for dimer formation. Dimers are then assembled into tetramers, which then further polymerize to form a series of multimers with molecular weights ranging from 1×10^6 to 20×10^6 Da.

The assembled VWF multimers may then either be released at a steady rate from the endothelial cells (constitutive pathway) or stored prior to release in the Weibel–Palade bodies of endothelial cells (regulated pathway). Platelet VWF does not contribute significantly to plasma VWF and is stored in the α-granules of platelets prior to release after platelet activation.

Rapid release of VWF from endothelial storage sites can be induced by epinephrine, histamine and vasopressin via the regulated pathway. This effect can be used to advantage by using DDAVP to treat mild forms of von Willebrand disease (VWD). Chronic elevation of VWF due to increased synthesis occurs as part of the 'acute phase' response to injury, inflammation, infection and neoplasia, and in pregnancy and hyperthyroidism. These responses are presumed to be physiological in promoting enhanced haemostasis but can reach pathological expression in being associated with an increased risk of thrombosis. These
Figure 49.6 Assembly of factor VIII–VWF complex. Factor VIII synthesized by hepatocytes as a single chain is partially proteolysed and (possibly) complexed with VWF prior to release. The von Willebrand factor is synthesized as a single-chain precursor, which dimerizes with disulphide bond formation, then multimerizes with further disulphide exchange, with concomitant loss of a large propeptide segment. The propeptide is essential for multimer formation and probably functions as an acidic disulphide isomerase.

confounding effects need to be taken into account when measuring VWF levels in attempting to diagnose VWD.

The VWF in plasma is detectable immunologically as VWF:Ag. This was formerly called factor VIII-related antigen, owing to confusion about the composition of the factor VIII–VWF complex. Although factor VIII and VWF are entirely distinct entities with separate functions (Figure 49.6), they circulate together as a complex in which VWF protects factor VIII from degradation, so that a deficiency of VWF or a reduction in its ability to bind factor VIII may also result in a low plasma level of factor VIII. Therefore, a deficiency of VWF can give rise to a dual haemostatic defect: reduced plasma levels of factor VIII (due to its shorter half-life in the absence of VWF) and a defect in primary haemostasis due to the failure in assisting platelets to adhere to the cut edges of small blood vessels (see Chapter 47). Clearly, the multistep synthesis, assembly and secretion of VWF and its multiple binding interactions provide many ways in which mutations of the VWF gene can give rise to varying types of disease. In particular, the multimeric structure is susceptible to dominant-negative effects of mutant alleles. The diagnosis of VWD is based on the recognition that for normal VWF function it must be:

1 present in adequate amounts;
2 have a normal multimeric structure;
3 have intact functional domains (binding sites).

When any of these properties is only slightly reduced, the presence or absence of a bleeding tendency may also depend on the quality and quantity of the other components, particularly platelets and collagen, with which the VWF must interact.

Clinical features

The classical picture is of an autosomal dominant, mild to moderately severe bleeding tendency. Patients suffer from bruising, epistaxes, prolonged bleeding from minor cuts, menorrhagia and excessive, but not often life-threatening, bleeding after trauma or surgery. Patients often present for investigation in the second or third decade after prolonged bleeding from dental extraction has aroused clinical suspicion. Menorrhagia, inexplicable by local or hormonal factors, can also be the presenting

symptom. An estimated 20% of women with menorrhagia have VWD. Haemarthroses do not occur in typical mild dominant VWD. Much less common is autosomal recessive (type 3) VWD, where VWF is undetectable and FVIII:C levels are usually around 1 or 2 U/dL. These patients have a bleeding tendency that clinically resembles severe haemophilia A, with haemarthroses, muscle bleeds and life-threatening haemorrhage after trauma, as well as a proneness to small vessel bleeding, which is not a feature of haemophilia A. The distribution of bleeding in VWD can be explained on the basis that VWF is required for platelet adhesion at high shear rate, which is the condition of flow found in the smallest blood vessels exposed to trauma in skin and mucous membranes.

Laboratory diagnosis

Preliminary diagnosis

After obtaining a suggestive personal history and a family history, the preliminary tests required are a full blood count and a coagulation screen. In addition, a global measure of primary haemostasis is also useful. Traditionally this was provided by the template bleeding time but this has a poor sensitivity for VWD and has largely been replaced by devices such as the PFA-100. The PFA-100 has very good sensitivity for VWD, although obviously does not distinguish it from platelet disorders and will not detect collagen abnormalities. Repeatedly normal PFA-100 results makes a platelet–VWF disorder of primary haemostasis unlikely.

The laboratory diagnosis of VWD rests on assessing both the amount of VWF present (VWF:Ag) and its functional capacity. At present, it is possible to assess three important functions:

1 *Factor VIII binding.* Assessed first by a factor VIII assay and then if reduced, by an enzyme-linked immunosorbent assay (ELISA)-based assay of VWF FVIII binding capacity.

2 *Platelet-dependent function.* The standard assessment of VWF functional activity remains the ristocetin cofactor assay (VWF:Rco). In this assay, dilutions of patient plasma are tested for their ability to promote platelet agglutination in the presence of the antibiotic ristocetin.

3 *Collagen-binding function* (VWF:CB). This recently introduced measurement is performed in an ELISA-based assay in which a well coated with collagen is used to capture VWF.

Measures of VWF:Rco and VWF:CB are both sensitive to the loss of high-molecular-weight multimers (HMWMs), but measure different binding properties of VWF. Thus they should be seen as complementary rather than alternative assays.

When there is a clear bleeding history and factor VIII, VWF:Ag, VWF:RCo are all below 30 U/dL, and the platelet count is normal, the diagnosis is easily made (Table 49.6). Unfortunately, owing to the variability of the disease and varying levels of VWF release or synthesis in individuals over time, all of these tests can give normal results on some occasions but clearly abnormal results on others. This is especially true of the milder cases of type 1 VWF (see below). It is therefore necessary to perform carefully standardized sets of assays with concordant results on at least two occasions to be sure of the diagnosis and its severity.

Secondary classification

If a deficiency suggestive of VWD is detected then further tests, in particular multimeric analysis and ristocetin-induced platelet aggregation (RIPA) are recommended to allow accurate subtyping of the VWD. The most important of these is VWF multimer size analysis, which will demonstrate the distribution of VWF polymers and the pattern of flanking bands (Figure 49.7) adjacent to the main multimer bands. Tables 49.6a and b list the main variants into which cases can be divided according to the tests described above.

Table 49.6(a) Primary classification of VWD.

Subclassification	Type of VWF deficiency	VWF protein function
Type 1	Quantitative partial deficiency	Normal
Type 2	Qualitative functional deficiency	Abnormal
Type 3	Quantitative complete deficiency	Undetectable

Table 49.6(b) Secondary classification of type 2 VWD.

Subtype	Platelet-associated function	Factor VIII binding capacity	HMW VWF multimers
2A	Decreased	Normal	Absent
2B	Increased affinity for Gplb	Normal	Usually reduced/absent
2M	Decreased	Normal	Normal and occasionally ultralarge forms
2N	Normal	Markedly reduced	Normal

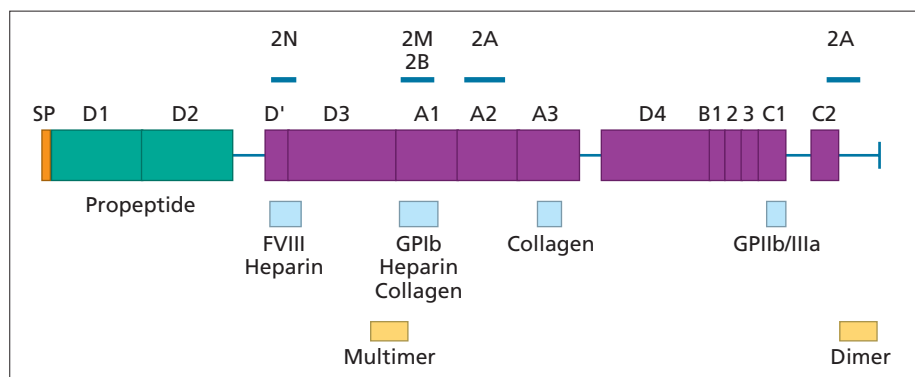
From Laffan (2004), with permission.


Figure 49.7 Distribution of mutations responsible for type 2 VWD. The domain structure of the monomer is shown and the regions in which the mutations cluster in relation to the functional domains of the molecule.

In type 1 VWD there is a simple quantitative deficiency of VWF, which is assessed as having normal functional activity. In this case, the VWF:Ag, VWF:Rco and (if measured) VWF:CB are all concordant and the multimer distribution is normal.

The characteristic of the types 2A, 2B and 2M variants is a functional deficiency of VWF activity, which is reduced to < 0.7 of the antigenic measure. In type 2A, this arises from a lack of high- and intermediate-size VWF multimers, whereas in type 2M a similar loss of platelet binding activity is seen despite the presence of normal VWF multimeric composition. Type 2A may arise from intracellular retention of large multimers or accelerated proteolysis in the circulation. In type 2B, there is excessive response to ristocetin at low concentration (0.5 mg/mL) in the patient's stirred platelet-rich plasma (RIPA). If normal washed platelets are resuspended in the patient's plasma, the phenomenon is reproduced, demonstrating that the abnormality is in the plasma. Studies with purified type 2B VWF show that it binds directly to platelets without prior activation (unlike normal VWF). This evidently results in the loss of high-molecular-weight multimers and platelets from the circulation due to *in vivo* formation of platelet aggregates. Thus routine platelet aggregation studies with a range of ristocetin dosages should be performed as part of the diagnostic work-up, as it is important to detect this variant (see below), which does not always show up in the other tests. Mutations causing types 2M and 2B affect the binding site for platelet glycoprotein Ib on VWF and are found within the A2 domain of the molecule.

The majority of patients are found to be type 1, which accounts for 75% of kindreds. Types 2A and 2B are fairly common, together amounting to about 15% of kindreds.

A fourth type 2 variant, called type 2N (for Normandy), has been described. This is characterized by a reduced affinity for factor VIII but it is normal in all other respects. Thus, laboratory investigations reveal only a reduced factor VIII level (15–35%), which is easily mistaken for mild haemophilia. A clue to the correct diagnosis may come from the family history, and confirmation requires an assay of VWF factor VIII binding capacity. Type 2A may be dominant or recessive. Type 2B is inherited

Table 49.7 Influence of ABO blood group on VWF:Ag values in volunteer blood donors.

ABO type	n	VWF:Ag geometric mean	VWF:Ag geometric mean ± 2SD
O	456	74.8	35.6–157.0
A	340	105.9	48.0–233.9
B	196	116.9	56.8–241.0
AB	109	123.3	63.8–238.2

Note the significantly lower levels in donors of blood group O compared with the non-O donors.

dominantly, whereas types 3 and 2N are recessive. Type 3 cases are more common in cultures in which intermarriage is usual, such as in the Middle East.

Problems in diagnosis of type 1 von Willebrand disease

The diagnosis of type 1 VWD implies that the patient has a significantly low level of VWF, which is responsible for an increased tendency to bleeding. It is often not easy to be certain of this conclusion for the following reasons.

1 Slightly low levels of VWF are common in the population. There are probably many reasons for this, some lying outside the VWF gene itself. For example, a major modifier of plasma VWF concentration is ABO blood group. Individuals with blood group O have VWF levels 25–30% lower than those with non-O groups (Table 49.7). This probably contributes to the observation that group O is over-represented in the VWD type 1 group, but on the other hand many people with VWF levels in the range of 30–50 IU/dL do not bleed excessively.

2 A history of minor bleeding episodes (e.g. easy bruising, epistaxes) is also very common in the population and is not a good predictor of bleeding in other circumstances such as operations. Equally, the patient may not yet have been exposed to a significant test of haemostasis.

3 As a result of the two points above, a history of (say) easy bruising and slightly low VWF levels will often be found together. This does not however mean that the patient has VWD and caution should be exercised in drawing this conclusion as it has many consequences for the patient.

4 Intercurrent events such as stress, exercise, illness and pregnancy may all elevate the VWF level, making it difficult to be certain a representative picture has been obtained.

5 The family history is often unhelpful, particularly in mild cases where penetrance is weak or variable. This is probably the result of the modifying effects alluded to in (1) above. It is now evident that in some families VWD does not segregate with the VWF gene.

6 Finally, review of many cases previously diagnosed as type 1 VWD has concluded that many are in fact better categorized as type 2M after better assessment of the VWF antigen–activity ratio.

It has been suggested recently that in recognition of the large 'grey area' between normal and VWD, low levels of VWF between 0.2 and normal should be regarded as a 'risk factor' for bleeding rather than a bleeding disease itself.

Treatment

Patients with mild or moderate VWD attend infrequently for treatment. The first-line treatment for minor bleeding after local measures have failed in type 1 VWD is DDAVP. This will produce a brisk (30 min after intravenous infusion) rise in VWF and factor VIII levels and a shortening of the bleeding time (for details of therapy, see discussion under Mild haemophilia A). DDAVP is much less effective in types 2A and 2M, presumably because the patient's released VWF is highly abnormal and still unable to promote platelet adhesion. DDAVP is generally regarded as contraindicated in 2B VWD, as the released abnormal VWF will cause circulatory platelet aggregates to form, with a further fall in the platelet count, but it has been used successfully without ill effects. A therapeutic trial may be worthwhile in type 2A as some families do respond. In 2N, the factor VIII response is of normal magnitude, but is ineffective due to its short duration, emphasizing the importance of making the correct diagnosis. DDAVP is best avoided in small children (< 2 years) as there is a risk of hyponatraemia and consequent seizures. It is also contraindicated in elderly patients or those with arterial disease as there is a risk of arterial thrombosis. DDAVP therapy is often combined with tranexamic acid. However, tranexamic acid may be effective on its own in some circumstances such as menorrhagia or as a mouthwash for oral cavity bleeding.

In patients in whom DDAVP is ineffective or contraindicated, the next line of treatment is a concentrate containing adequate amounts of functionally active VWF with preservation of the high-molecular-weight multimers. As with all concentrates, the source of plasma and viral inactivation are also im-

portant. Recombinant VWF concentrate is not yet available. Cryoprecipitate has been used in these circumstances but cannot be subjected to viral inactivation procedures and is therefore not recommended as first-line therapy. Factor concentrates will always be required for treatment of type 3. Depending on the responses obtained with DDAVP, the duration of treatment and the presence of other contraindications, they may also be required in other type 2 and type 1 variants. Factor VIII concentrates vary considerably in the amount of VWF they contain and in the extent to which this is degraded or remains in functionally active HMWMs. Those that contain significant amounts of VWF are often referred to as intermediate purity. A high-purity VWF concentrate is now available and is also capable of correcting the defect. It is important to remember that following infusion of high-purity VWF there is a delay of approximately 12 h before the level of factor VIII rises substantially and, if rapid correction is required, factor VIII concentrate should also be given. In general, none of these replacement treatments is reliable in correcting the bleeding time, but this is not necessarily a bar to effective haemostasis. This seemingly paradoxical result may be because they do not correct the deficiency of intraplatelet VWF or because the largest HMWMs are not present. In situations when concentrates fail to stop bleeding, cryoprecipitate and platelet concentrates may prove effective.

Clinical course and complications

Types 1 and 2 VWD patients lead relatively normal lives, with normal life expectancy. Menstruation is seldom a cause of severe blood loss, although menorrhagia is common. This can usually be managed satisfactorily with antifibrinolytics or by oral contraceptive oestrogen/progesterone combinations. If these are not effective then self-administration at home of DDAVP by intranasal or subcutaneous routes can be useful. In later years, some patients require hysterectomy. During pregnancy, the VWF levels rise spontaneously to the normal or low-normal range in all but the severely affected patients. Patients with severe type 3 disease have a clinical course resembling severe or moderately severe haemophilia A, including the development of joint damage. Some of the patients with type 3 disease develop antibodies to VWF, which inhibit its platelet adhesion-promoting property and cause rapid removal from the circulation of infused material. Unlike antifactor VIII antibodies, some anti-VWF antibodies may mediate anaphylactic shock.

Molecular genetics

The cloning of VWF cDNA and its gene has led to progress in identifying the underlying mutations responsible for the various phenotypes (Figure 49.8). As with the factor VIII gene, the sheer size of the DNA region involved presents some problems of localization, but these are being overcome by powerful screening methods. A database of mutations responsible for VWD has
Figure 49.8 Multimer analysis of VWF from patients with VWD and normal control subjects. Note that many cases classified at present as type 2A were previously subdivided according to the details of the abnormality of triplet pattern.

been established at http://www.shef.ac.uk/vwf/vwd.html. The rare patients who develop antibodies to VWF nearly all have large deletions of their VWF gene. Exon 28 has been found to harbour all the mutations giving rise to types 2A, 2M and 2B VWD. The molecular basis of type 1 VWD remains elusive and is rarely due to a simple heterozygote null mutation, but an increasing number of putatively causative missense mutations are being identified. As well as intragenic polymorphisms, the plasma level of VWF is modulated by many factors outside the gene and it has been shown recently that some cases of VWD do not segregate with the VWF gene at all.

Pseudo von Willebrand disease (platelet-type)

Several families have been described with a disorder closely resembling type 2B VWD, but in whom mixing experiments show the defect to be in their platelets rather than their plasma. Patients with pseudo VWD have moderately reduced levels of VWF:Ag and platelets, with an enhanced response of their platelet-rich plasma to low levels of ristocetin (0.5 mg/mL). The addition of normal cryoprecipitate to their washed platelets causes spontaneous aggregation, whereas the reverse experiment is without effect (compare with type 2B). Missense mutations in platelet membrane GPIb, such that it spontaneously binds higher multimers of VWF, have been shown to be the underlying cause of this autosomally dominant mild bleeding syndrome. Treatment has not been extensively evaluated, but it should probably be with normal platelet concentrates, rather than DDAVP or cryoprecipitate. Thus this syndrome should be excluded before diagnosing type 2B VWD.

Congenital bleeding: autosomal recessive disorders

50

Flora Peyvandi and Pier M Mannucci

Introduction

The most frequent inherited coagulation disorders are haemophilia A and B, due to the deficiency of factor VIII and IX. Haemophilia A and B are clinically indistinguishable from each other and occur in mild, moderate and severe forms (with plasma factor levels of 6–30%, 2–5% and 1% or less respectively). Inherited as X-linked traits, haemophilia A and B are prevalent in the general population of approximately 1 in 10 000 and 1 in 50 000, with no significant racial difference. Other deficiencies of coagulation factors that cause a bleeding disorder, such as afibrinogenaemia, hypoprothrombinaemia, deficiencies of factors V and combined factor V and VIII, VII, X, XI and XIII are inherited as autosomal recessive traits and are generally much rarer than the haemophilias, with are prevalent in the general population varying between 1 in 500 000 and 1 in 2 000 000 (Table 50.1). As a consequence of the rarity of these deficiencies, which are expressed clinically only in homozygotes or compound heterozygotes, the type and severity of symptoms, the underlying molecular defects and the actual management of bleeding episodes are not well established as for haemophilia A and B.

In countries where consanguineous marriages are frequent, such as Muslim countries and southern India, recessively inherited coagulation deficiencies are more frequent and together reach prevalences higher than those of haemophilia B, representing a significant clinical and social problem. Table 50.2 compares the relative frequencies of patients with clinically significant deficiencies (factor levels of 10% or less) registered in

the Islamic Republic of Iran with those registered in the UK by the Haemophilia Centre Doctors' Organisation (UKHCDO) and in Italy by the Istituto Superiore di Sanità and the Associazione Italiana Centri Emofilia (AICE). The three countries are compatible because they have compatible general populations of approximately 60 million and comprehensive registries of coagulopathies. Inherited deficiencies of fibrinogen, prothrombin, factor V, factor VII, factor V plus VIII, factor X and factor XIII are three to seven times more frequent in Iran (see Table 50.2). Only factor XI deficiency is more frequent in the UK than in Iran and Italy, probably because communities of Ashkenazi Jews, in which this deficiency is highly prevalent, are relatively small in the last two countries.

In the last few years, the number of patients with recessively inherited coagulation deficiencies has been increasing in European countries with a high rate of immigration of populations from the Middle East, India, Pakistan and North Africa. This situation underlies the importance of improved knowledge of these disorders by the general haematologist. The purpose of this chapter is to review the disorders in terms of clinical manifestations and characterization of the molecular defects. The general principles of management will also be discussed.

Fibrinogen deficiency

Fibrinogen deficiency is heterogeneous and two main phenotypes can be distinguished. In afibrinogenaemia, plasma and platelet levels of the protein are unmeasurable or very low when

Table 50.1 General features of autosomal recessively transmitted deficiency of coagulation factors.

Deficiency	Estimated prevalence*	Gene on chromosome
Fibrinogen	1:1 000 000	4
Prothrombin	1:2 000 000	11
Factor V	1:1 000 000	1
Combined factor V + VIII	1:1 000 000	18 (LMAN1), 2 (MCFD2)
Factor VII	1:500 000	13
Factor X	1:1 000 000	13
Factor XI	1:1 000 000	4
Factor XIII	1:2 000 000	6 (subunit A) and 1 (subunit B)

*Including dysfunctional proteins.

Table 50.2 Number of patients and relative frequency (in parentheses) of inherited coagulation deficiencies in Iran, Italy and UK (excluding von Willebrand disease).

Defect	Iran	Italy	UK
Fibrinogen	70 (1.5%)	10 (0.2%)	11 (0.2%)
Prothrombin	15 (0.3%)	7 (0.02%)	1 (0.02%)
Factor V	70 (1.5%)	21 (0.5%)	28 (0.6%)
Factor VII	300 (6.6%)	58 (1.3%)	62 (1.3%)
Factor V + VIII	80 (1.7%)	29 (0.7%)	18 (0.3%)
Factor VIII (haemophilia A)	3000 (65.4%)	3428 (80%)	3554 (76.8%)
Factor IX (haemophilia B)	900 (19.6%)	626 (15.0%)	762 (16.1%)
Factor X	60 (1.3%)	16 (0.4%)	25 (0.5%)
Factor XI	20 (0.4%)	60 (1.3%)	150 (3.3%)
Factor XIII	80 (1.7%)	31 (0.7%)	26 (0.5%)
All defects	4595	4286	4637

Data are obtained from the most recent adjournments of the Registries of Inherited Bleeding Disorders kept in Iran (courtesy of Dr M Lak, Iman Khomeini Hospital), Italy (Dr A Ghirardini, Istituto Superiore di Sanità) and UK (Dr P Giangrande, UK Haemophilia Centre Doctors' Organisation). Only patients with factor levels of 10% or less were evaluated.

using assays that measure clottable and immunoreactive protein, whereas in dysfibrinogenaemia low clottable fibrinogen contrasts with normal or moderately reduced fibrinogen antigen. Three separate genes clustered on chromosome 4 code for the Aα-, Bβ- and γ-chains of fibrinogen. Experimental disruption of the α-chain gene makes mice completely deficient in all the fibrinogen chains. There is no evidence of defective embryonal development but overt bleeding develops at birth in about one-third of these animals, most frequently in the peritoneal cavity, skin and joints. Ultimately, blood loss is controlled, so that most mice survive the neonatal period and reach adulthood despite recurrent bleeding episodes and failure to become pregnant.

Clinical manifestations

Whereas the majority of patients with dysfibrinogenaemia do not bleed at all, afibrinogenaemic patients have a bleeding tendency. Among severe bleeding symptoms that are dangerous for life and for the musculoskeletal function, umbilical cord and joint bleeding is relatively frequent (in 75% and 50% of patients), whereas muscle haematomas and bleeding in the gastrointestinal tract and central nervous system are less common. Milder symptoms such as epistaxis and menorrhagia are also frequent. Post-partum bleeding occurs when no prophylactic replacement therapy is given. Excessive blood loss and impaired wound healing in about one-third of the patients often accompany circumcision and other surgical manoeuvres. There is no increased prevalence of recurrent miscarriages. Central nervous system bleeding is rare.

On the whole, bleeding problems are not dramatic in patients with afibrinogenaemia, particularly if one considers that screening coagulation tests (prothrombin time, APTT) are usually incoagulable and that the bleeding time is often prolonged. The relatively mild clinical manifestations of afibrinogenaemia are consistent with those of the gene knockout mouse model, except that pregnancy failure is not apparent. Severe thrombotic episodes are perhaps explained by the intravascular formation of platelet aggregates due to the increased generation of thrombin unimpeded by fibrin formation.

Molecular defects

The three separate genes encoding Aα-fibrinogen (FGA), Bβ-fibrinogen (FBG) and γ-fibrinogen (FGG) are clustered in a region of approximately 50 kilobases (kb) on human chromosome 4. Neerman-Arbez and colleagues were the first to identify a homozygous deletion of approximately 11 kb of the FGA gene as a cause of inherited afibrinogenaemia in four members of a Swiss family. The mutation was associated with three different haplotypes and therefore probably occurred independently. Subsequently, two homozygous missense mutations were identified in the FGB gene in two families of different ethnic background (one Italian and one Iranian), both leading to a deficient secretion of the protein. Neerman-Arbez and colleagues found another mutation in the FGA gene in patients from France, Belgium and USA, which recurred in multiple discrete haplotypes, a donor splice mutation in intron 4 (IVS4+1 G → T). The relatively high number of mutations identified in the FGA gene led to the hypothesis that mutations tend to cluster in this gene, resulting in the production of no fibrinogen Aα-chain at all or of a severely truncated protein. Nonsense mutations, mutations affecting splice sites, and a 1-bp deletion were also identified in the FGG gene, whereas two missense, two splicing and two nonsense mutations were found in the FGB gene.

A missense mutation (Leu172Gln) was identified in the FGB gene, which, following *in vitro* expression, was demonstrated to cause a splicing defect rather than having an effect at the protein level. Therefore, all three fibrinogen genes are involved in causing afibrinogenaemia, confirming the importance to screen the whole fibrinogen cluster for mutations in affected patients. It is also apparent that even if mutations leading to severe truncation of fibrinogen chains are prevalent, missense mutations are not rare. Figure 50.1 shows the mutations associated with afibrinogenaemia identified so far.

Prothrombin deficiency

Even though prothrombin deficiency is reported to have a prevalence of 1 in 1 000 000, according to the number of cases described in the literature and those listed in the Iranian registry, this defect appears to be even less common (perhaps 1 in 2 000 000). Measuring plasma levels of prothrombin as functional activity or immunoreactive protein, two main phenotypes can be distinguished: hypoprothrombinaemia, characterized by concomitantly low levels of activity and antigen; and dysprothrombinaemia, characterized by the normal synthesis of a dysfunctional protein (low coagulant activity but normal or borderline antigen levels). To our knowledge no living patient with undetectable plasma prothrombin has been reported so far (see below), consistently with the demonstration that in mice complete prothrombin deficiency obtained by gene knockout is incompatible with life.

Clinical manifestations

In a series of 14 patients from Iran and Italy (11 had hypoprothrombinaemia, with levels varying between 4% and 13%, three had dysprothrombinaemia), the most frequent severe symptoms were haemarthroses and muscle haematomas, which, in a few patients, caused chronic arthropathy despite detectable levels of prothrombin in plasma. There were only two cases of gastrointestinal bleeding and one of intracranial bleeding that required prolonged hospital admission and replacement therapy. Life-endangering umbilical cord bleeding also occurred in two newborns. Epistaxis and menorrhagia were frequent but not severe. There was no case of post-partum bleeding, and dental extractions and circumcision were usually accompanied by excessive bleeding when carried out without replacement therapy.

Molecular defects

A gene of approximately 21 kb located on chromosome 11 and containing 14 exons encodes prothrombin. At the moment, 34 different mutations have been identified in prothrombin deficiency (Figure 50.2). In dysprothrombinaemia, all are missense mutations, 15 of them being homozygous and involving amino acid substitutions within the site of cleavage by factor Xa or within the serine protease domain. Even though mutations are scattered throughout the serine protease domain, many of them surround the catalytic triad, consistently with the fact that they affect the enzymatic activity of the protein. So far few functional studies have been performed to elucidate the structure–function relationship.

In a recent study, the experimental data showed that both procoagulant and anticoagulant functions are impaired in a recombinant FII-Arg67His mutant; the functional abnormalities might somewhat counterbalance each other so that ultimately the haemostatic equilibrium does not undergo drastic changes, explaining the very mild clinical phenotype associated with the case reported in the study. In total, 17 mutations have been identified in patients with hypoprothrombinaemia, six of which in the homozygous state. The majority are missense mutations, but there are also five nonsense mutations leading to stop codons, with one single and one double nucleotide deletion leading in both conditions to a premature stop codon.

Factor V deficiency

The majority of cases are phenotypically characterized by the concomitant deficiency of factor V activity and antigen (type I deficiency), but approximately one-quarter have normal antigen levels (type II deficiency), indicating the presence of a dysfunctional protein. The experimental deficiency of factor V in gene knockout mice leads to defective embryonic development and

early haemorrhagic death. However, mice expressing minimal factor V activity below the sensitivity threshold of the detection assay (< 0.1%) differ from the complete knockout mice because they survive.

Clinical manifestations

In a large series of Iranian patients, bleeding symptoms usually developed during the first 6 years of life, but only one patient bled from the umbilical stump. Epistaxis and menorrhagia were relatively frequent, even in patients with measurable factor V levels. Post-operative and oral cavity haemorrhages were common, but not fully predictable, as these symptoms also occurred with plasma levels as high as 5–10%. Haemarthroses and haematomas occurred in only one-quarter of the patients, whereas life-threatening bleeding in the gastrointestinal tract and in the central nervous system was rare. On the whole, it appears that the clinical phenotype of patients with factor V deficiency is completely different from that seen in the mouse knockout model, and that these patients are usually mildly affected. This discrepancy is likely to be explained by the relatively poor sensitivity of available factor V bioassays that do not measure those small amounts of the factor that are probably sufficient to make the deficiency compatible with life and a mild clinical phenotype.

Molecular defects

The factor V gene is on chromosome 1q23. At the moment, there is relatively little information on the molecular defects underlying severe factor V deficiency, probably because of the large size (80 kb) and complexity of the gene (25 exons). Our analysis of published data identified a total of 24 distinct mutations associated with severe factor V deficiency (Figure 50.3). Approximately one-half of the mutations (12) are located in the large exon 13, encoding the entire B domain disposed during the enzymatic activation of factor V. The remaining mutations are scattered throughout the gene and all types of lesions are represented, spanning from missense mutations that are likely to impair the secretion or accelerate the degradation of factor V, to more frequent small deletions, frameshift, nonsense and splice site mutations predicted to produce truncated proteins or no protein at all. Very few mutations are present in more than one pedigree, indicating that a founder effect is unlikely to explain most cases. Only one genetic defect associated with type II deficiency has been so far reported.

Factor VII deficiency

Factor VII deficiency is the most common autosomal recessive coagulation disorder (1 per 500 000 population). Factor VII circulates in plasma at a concentration of approximately 0.5 μg/mL (10 mmol/L). Plasma levels of factor VII coagulant activity
Figure 50.3 Mutations in the factor V gene, projected on the exons encoding the domains of the protein. Exons (rectangles) are drawn to scale, whereas introns (lines) are not to scale. *FV type II deficiency-causing mutation.

(FVII:C) and FVII antigen (FVII:Ag) are influenced by a number of genetic and environmental factors (sex, age, cholesterol and triglyceride levels). The majority of patients have concomitantly low levels of factor VII functional activity and antigen, but several cases are characterized by normal or low borderline levels of factor VII antigen, contrasting with lower levels of functional activity. Most gene knockout mice made experimentally deficient in factor VII develop normally but some suffer fatal perinatal bleeding.

Clinical manifestations

The severity of symptoms of factor VII deficiency is variable and generally reported to be poorly correlated with plasma levels. Some patients do not bleed at all after major challenges of haemostasis, and even cases of thrombosis have been described. Among our patients, life- or limb-endangering bleeding manifestations were relatively rare, the most frequent symptoms being epistaxis and menorrhagia. However, the prevalence of haemarthroses and soft-tissue bleeding was less than that found in other large series. The risk of central nervous system bleeding in infants with severe factor VII deficiency is high in some series. We could not find kindreds in which factor VII deficiency segregated with arterial or venous thromboembolism.

A lack of correlation between measured FVII:C *in vitro* and the clinical phenotype is well known and is probably due to the fact that only trace amounts of FVIIa are required to initiate coagulation *in vivo*. However empirical studies and mathematical modelling suggest that as little as 5 pmol/L (0.05% of normal FVII concentration) is sufficient to induce clot formation and none of the *in vitro* tests could differentiate between undetectable and extremely low levels of FVII:C capable of initiating coagulation *in vivo*. Previously reported data showed that increasing the FVIIa concentration does not substantially increase the amount of thrombin generated but the low concentrations of FVIIa prolong the initiation phase of the reaction.

Molecular defects

Factor VII is a zymogen for a vitamin K-dependent serine protease, synthesized primarily in the liver, which is essential for the initiation of blood coagulation. The factor VII gene is located on chromosome 13 (13q34), consists of nine exons, and spans 12 kb. It encodes a mature protein of 406 amino acids, which includes four domains: an N-terminal domain (Gla) post-translationally modified by γ-carboxylation of glutamic acid residues, two EGF-like domains (EGF1 and 2) and a C-terminal serine protease domain. The molecular basis of factor VII deficiency is more extensively characterized than those of other defects, perhaps due to the relatively high frequency of this defect and small size of the gene.

The availability of an on-line database (http://europium.csc.mrc.ac.uk) allows rapid access to the entire listing of factor VII

mutations. However, this database often lacks critical information such as clinical phenotypes and the source of the TF used in the FVII:C assay. The database currently lists 124 mutations of the factor VII gene: missense (84), nonsense (6), splice junctions (17), promoter (6), small insertions (1) and deletions (10). The reported mutations are located throughout the gene, suggesting that all domains are important in maintaining the overall structure and function of factor VII; 24 additional mutations are reported but not included in the database. The majority of individuals with mutations identified in their factor VII genes are either asymptomatic (28%) or their clinical phenotype has not been reported (39%). They usually have come to attention through preoperative screening. The genetic defects in these individuals are mainly missense mutations. The severe cases (17%) are all either homozygous or double heterozygous for mutations that disrupt expression of the protein (for example, deletions, insertions, splice junctions and promoter mutations), resulting in FVII coagulant levels typically less than 2% of normal. However, some missense mutations are also associated with a severe phenotype. Individuals with a mild/moderate clinical phenotype (16%) are homozygous or double heterozygous for missense mutations (Figure 50.4).

Combined deficiency of factor V and factor VIII

These patients have concomitantly low levels of the two coagulation factors (usually, between 5% and 20%), both as coagulant activity and antigen. For many years the molecular mechanism of the association of the two factor deficiencies, each transmitted with different patterns of inheritance (autosomal recessive for factor V, X-linked for factor VIII) and involving proteins encoded by different genes, has not been understood.

In 1998, the cause of the deficiency has been associated with mutations in the *LMAN1* gene (lectin mannose binding protein, previously referred to as *ERGIC-53*). *LMAN1* encodes a 53-kDa type 1 transmembrane protein with homology to leguminous lectin proteins. LMAN1 resides in the endoplasmic reticulum/ Golgi intermediate compartment, where, with a mannose-selective and calcium-dependent binding, it acts as a chaperone in the intracellular transport of both factor V and factor VIII. Mutations in *LMAN1* were found in approximately 70% of affected patients.

Recently, another locus correlated with the deficiency was identified in approximately 15% of affected families without any mutation in *LMAN*1. The *MCFD2* (multiple coagulation factor deficiency 2) gene encodes a 16-kDa protein. MCFD2 forms a Ca^{2+}-dependent 1:1 stechiometric complex with LMAN1 and acts as a cofactor for LMAN1, specifically recruiting correctly folded factor V and factor VIII in the endoplasmic reticulum. The presence of about 15% of affected patients in which the dis-

order is not linked to *LMAN1* or *MCFD2* mutations strongly suggests the existence of a third associated locus.

Clinical manifestations

In patients with factor V and factor VIII levels varying between 4% and 14%, symptoms were usually mild, with a predominance of epistaxis, menorrhagia and bleeding after dental extractions. More severe bleeding episodes, particularly soft-tissue bleeding, were rare. These data are broadly consistent with those previously reported in the literature, particularly in a large series of patients from Israel. It appears that the concomitant presence of two coagulation defects does not enhance the haemorrhagic tendency observed in each defect separately (see factor V deficiency). The phenotypes associated with mutations in *MCFD2* and *LMAN1* are indistinguishable and manifested only by deficiencies of plasma coagulation factor V and factor VIII, even although a selective delay in secretion of procathepsin C was observed in HeLa cells overexpressing a dominant-negative form of LMAN1.

Molecular defects

LMAN1 is encoded by a gene of approximately 29 kb located on chromosome 18 and containing 13 exons (Figure 50.5). In the original study on *LMAN1* gene, made by Nichols and colleagues, two distinct mutations were found in patients of Oriental Jewish ancestry, a splice site mutation and a single basepair insertion. In subsequent studies carried out in patients of varied ethnic origins, 16 additional distinct mutations were identified (splice site, insertions, deletion, nonsense codons). All the identified mutations are predicted to result in the synthesis of either a truncated protein product or no protein at all; 40% of this population had no detectable mutation in *LMAN1*.

MCFD2 is encoded by a gene of approximately 19 kb, located on chromosome 2 and containing four exons (Figure 50.6). Zhang and colleagues identified seven distinct mutations accounting for FV + FVIII deficiency in 9 out of 12 studied families. They found three frameshift and two splice-site mutations that were predicted to result in the complete loss of MCFD2 protein expression. Two missense mutations have been also identified. Both mutations are localized in a highly conserved region of the second EF-hand domain and eliminate the interaction with LMAN1.

Factor X deficiency

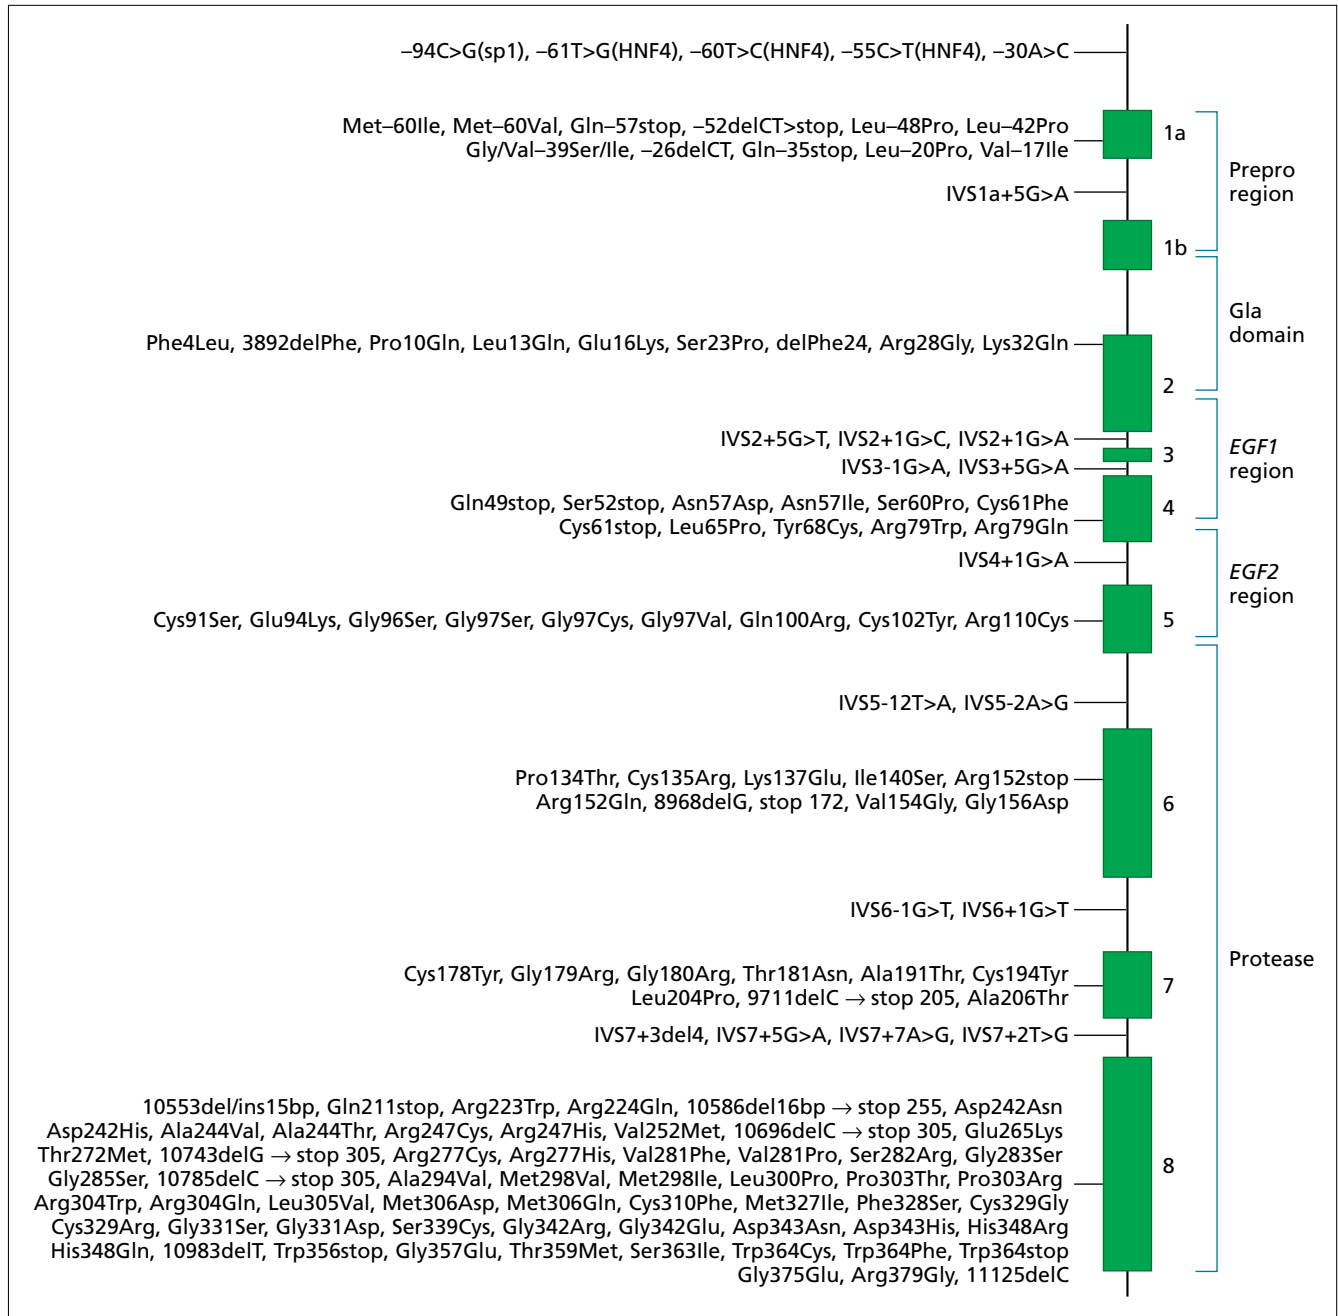
Clinical phenotypes are characterized by concomitantly low levels of coagulant activity and antigen, or by low coagulant activity contrasting with normal or low borderline antigen values. Mice rendered experimentally deficient in factor X by targeted inactivation of the factor X gene showed frequent


Figure 50.4 Mutations in the factor VII gene projected on the exons encoding the domains of the protein. Exons (rectangles) and introns (lines) are drawn to scale.

embryonic lethality. Those who survived bled to death intra-abdominally at birth and in the central nervous system within the first 3–4 weeks of life.

Clinical manifestations

Factor X deficiency is, together with factor XIII deficiency, the most severe of the rare coagulation deficiencies. Haematomas and haemarthroses occur in two-thirds of the patients. In addition, several have gastrointestinal bleeding or life-threatening bleeding from the umbilical stump. As a result of this and other bleeding symptoms occurring early in life, most patients are soon recognized to have an inherited bleeding disorder, so that a symptom such as post-operative bleeding is not frequently apparent because the great majority of patients receive replacement therapy before surgery. Hence there is reasonable consistency
Figure 50.5 Mutation in the *LMAN1* gene, projected on the exons encoding the domains of the protein. Exons (rectangles) are drawn to scale, whereas introns (lines) are not to scale.

between the severity of the clinical phenotype and that of the knockout model. That factor X deficiency appears to be one of the most severe recessively inherited coagulation deficiencies also stems from data from the UKHCDO registry, showing that the proportion of patients with this deficiency who require treatment is higher than that of the other rare coagulation deficiencies.

Molecular defects

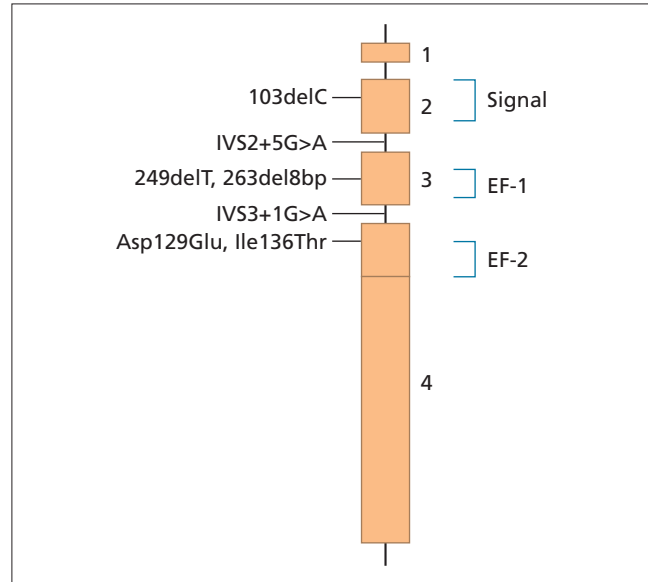
The factor X gene is on chromosome 13, has a length of 22 kb and contains eight exons. In total, 64 different mutations have been identified in patients diagnosed in the USA, Japan and Europe and in patients from Iran (Figure 50.7). The great majority of patients have missense mutations (52), mainly in exon 8, which encodes the catalytic domain. None of these mutations


Figure 50.6 Mutation in the *MCFD2* gene, projected on the exons encoding the domains of the protein. Exons (rectangles) are drawn to scale, whereas introns (lines) are not to scale.

is predicted to lead to the production of a truncated protein or no protein at all, supporting the mice knockout finding that complete absence of factor X may be incompatible with life. This viewpoint is also supported by the observation that phenotypically most of these patients have low but measurable levels of factor X coagulant activity, in association with low or normal levels of immunoreactive protein, and that only a few severe mutations have been reported (eight small or large deletions, four splice site mutations, one promoter mutation). A peculiar aspect of the spectrum of mutations underlying factor X deficiency is the complete absence of reported nonsense mutations that are expected to be present in a proportion of 1:4 with respect to other mutations and particularly to missense mutations.

Factor XI deficiency

Factor XI deficiency is characterized by a decrease of the functional activity of this plasma protein, usually accompanied by correspondingly low levels of factor XI antigen. The majority of cases reported in the literature are of Ashkenazi Jewish origin, the frequency of heterozygosity for factor XI deficiency being as high as 8% in this population. In knockout mice, the loss of the gene coding for this factor is compatible with life, with no tendency for spontaneous bleeding.

Clinical manifestations

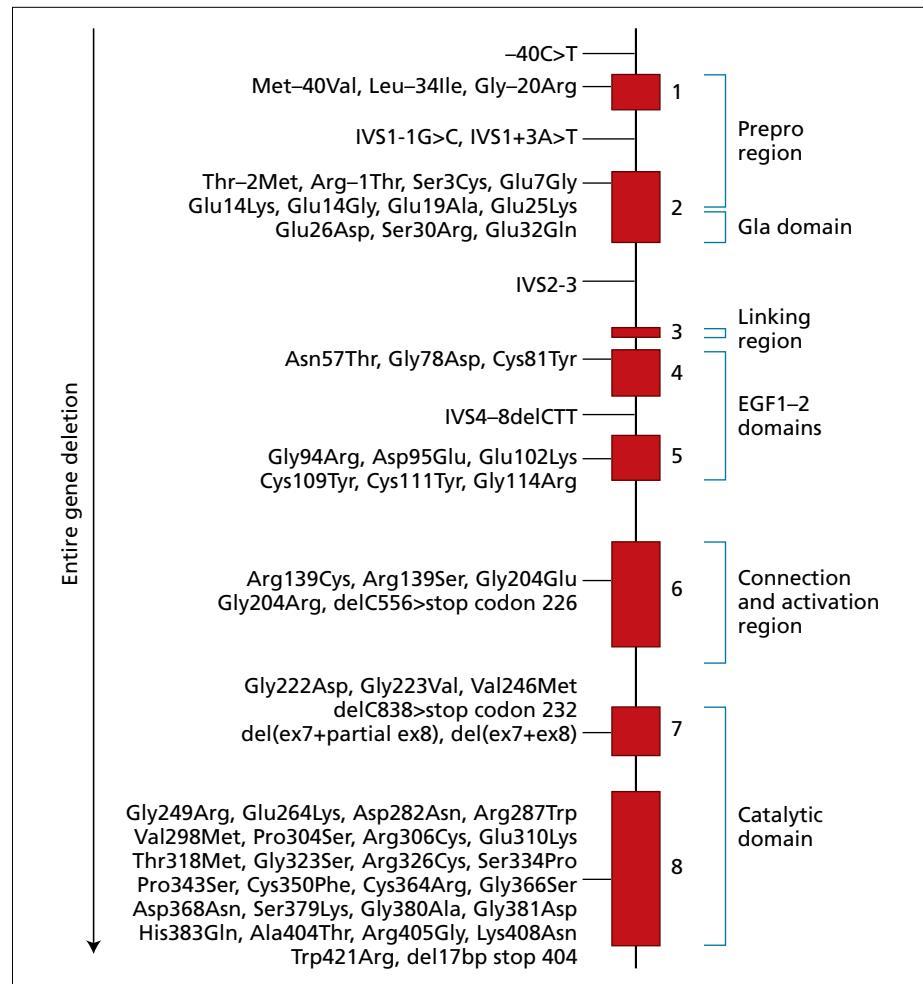
The relationship between the residual factor XI levels in plasma and the bleeding tendency is not as clear-cut as for other coagu-


Figure 50.7 Mutation in the factor X gene, projected on the exons encoding the domains of the protein. Exons (rectangles) and introns (lines) are drawn to scale.

lation factor deficiencies. Usually, patients with severe factor XI deficiency (1% or less) are mildly affected and have bleeding symptoms only after trauma or surgery. Surprisingly patients with low but detectable levels of factor XI are also mild bleeders, so that clinical phenotypes are not strikingly different in these two groups. This observation, already made for Jewish patients, was confirmed recently in a series of Iranian non-Jewish patients with severe or moderate deficiency (factor XI < 1–5%) and in patients with mild deficiency (6–30%). All patients were mild bleeders, but those symptoms that define the severity of the bleeding tendency, such as muscle haematomas and haemarthroses, showed a similar frequency in the two groups of deficient patients (approximately 25%). The most frequent symptoms were oral and post-operative bleeding, which occurred in more then 50% of patients.

The reasons for the relatively poor relation between factor XI plasma levels and tendency to bleed are still not clear. One possibility is that the APTT-based factor XI assays commonly used to measure factor activity in intrinsic coagulation do not reflect those properties of the protein that are most important for *in*

vivo haemostasis. Different degrees of the defective interactions of factor XI with blood platelets, not revealed by APTT-based assays, might be the explanation for the poor relation.

Molecular defects

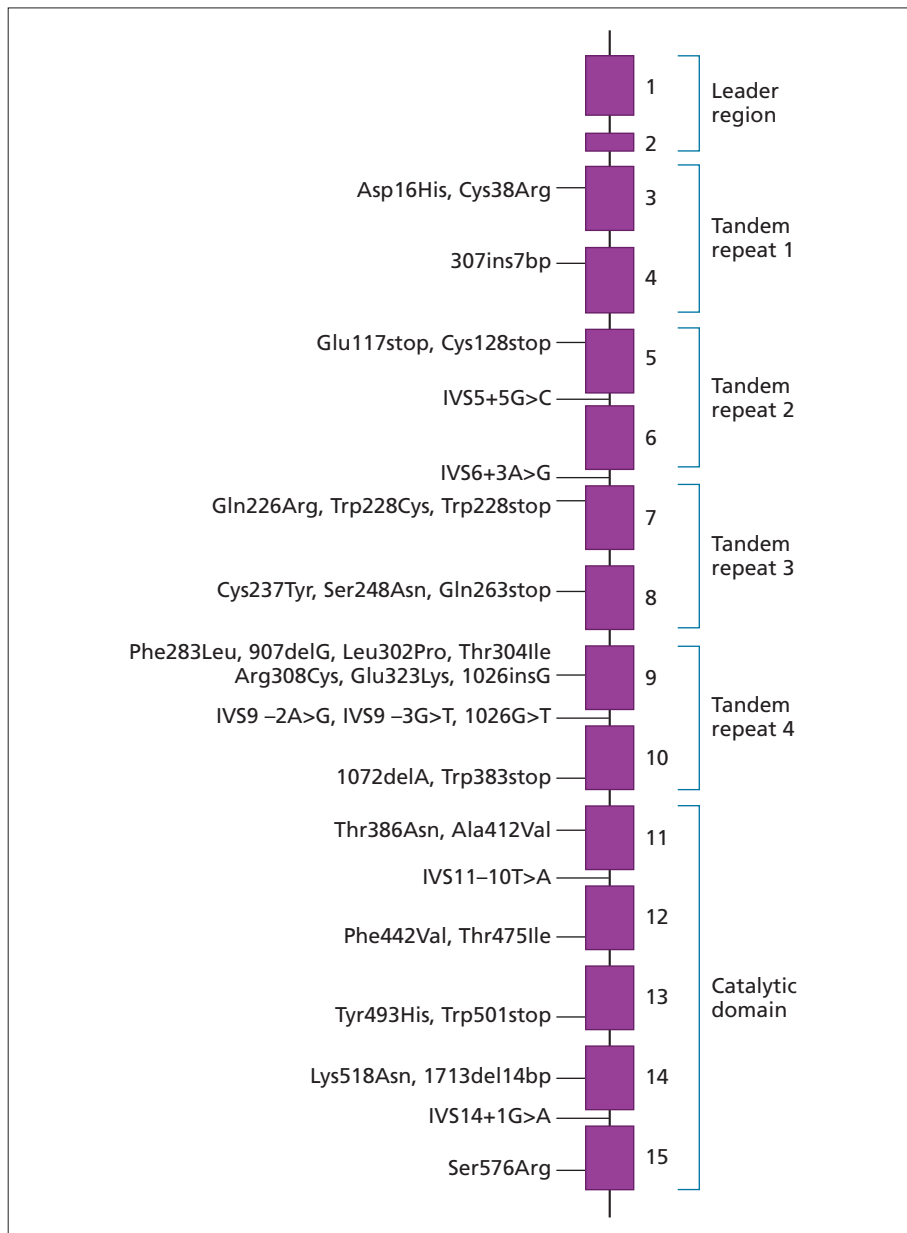
The factor XI gene is on chromosome 4 and is 23 kb in length. Altogether, 36 different gene mutations associated with factor XI deficiency have been identified so far (Figure 50.8). Two mutations are responsible for most cases of factor XI deficiency in Ashkenazi Jews, whereas mutations are more varied in non-Jews. The so-called type II Jewish mutation is a stop codon in exon 5, compatible with the observation that patients homozygous for this defect usually have undetectable levels of factor XI. The type III Jewish mutation is a missense mutation in exon 9, leading to the substitution of phenylalanine at position 283 with leucine. The mutation causes defective secretion of the protein from cells, but some factor XI is ultimately produced so that these patients have measurable levels of factor XI (at approximately 10%). Type II/III compound heterozygosity is


Figure 50.8 Mutation in the factor XI gene, projected on the exons encoding the domains of the protein. Exons (rectangles) are drawn to scale, whereas introns (lines) are not to scale.

the commonest cause of severe to moderate factor XI deficiency (< 1% to 5%) in Ashkenazi Jews. The mutations in non-Jewish patients are more numerous, and scattered throughout the gene. Some are nonsense mutations and deletions but the majority are missense mutations associated with abnormal folding and decreased secretion of the protein.

Factor XIII deficiency

Factor XIII is the last enzyme to be activated in the blood coagulation pathway and functions to cross-link α- and γ-fibrin chains, resulting in a stronger clot with an increased resistance to fibrinolysis. The plasma factor is a heterotetrameric structure consisting of two catalytic A subunits (FXIII-A) and two carrier B subunits (FXIII-B). Factor XIII deficiency is, together with prothrombin deficiency, probably one of the rarest recessively transmitted coagulation factor deficiencies (1 in 2 000 000). In inherited factor XIII deficiency, plasma levels of FXIII-A measured as functional activity or immunoreactive protein are usually unmeasurable, whereas the FXIII-B subunit is reduced but at measurable levels. No case of factor XIII deficiency with normal FXIII plasma levels measured as immunoreactive protein associated to a reduced functional activity was described, at

variance with the majority of the other clotting factors. FXIII transglutaminase activity in plasma was abolished in homozygous null mice generated by the deletion of the exon 7 of factor XIII gene. These mice were fertile, although reproduction was impaired and bleeding episodes were associated with reduced survival.

Clinical manifestations

Patients with factor XIII deficiency have a bleeding tendency that is usually severe, particularly because of the early onset of life-threatening symptoms such as umbilical cord and central nervous system bleeding. In untreated patients, umbilical cord bleeding is reported to occur in approximately 80% and central nervous system bleeding in up to 30%. These frequencies of severe symptoms are the highest among patients with inherited coagulation deficiencies, including haemophilia A and B. They usually lead to an early diagnosis, so that patients who survive are often treated prophylactically, starting early in life. This approach to treatment is rendered relatively simple and feasible by the fact that plasma levels of factor XIII of 2–5% are sufficient to prevent bleeding, and that the long *in vivo* half-life of the factor (11–14 days) makes it possible to infuse plasma cryoprecipitate or concentrates (all containing factor XIII) at intervals of 1 month or longer.

In a recent study made on the largest group of patients with severe FXIII deficiency (93 Iranians), the most frequent mucosal tract bleeding symptom was bleeding in the oral cavity (lips, tongue, gum) followed by menorrhagia and epistaxis. Gastrointestinal bleeding is not unusual. Soft tissue bleeding such as spontaneous haematoma and haemarthroses occur in a large proportion of patients; 20% of patients in the reproductive age had intraperitoneal bleeding that occurred at the time of ovulation, in some cases leading to hysterectomy and 50% of pregnant women had at least one miscarriage. On the whole, the clinical impact of factor XIII deficiencies can shift from that of a very severe disease to that of a mild one, depending on the adoption of prophylactic treatment, which, in turn, depends on the precocity of diagnosis.

Molecular defects

The XIII A and B subunits are encoded by two different genes on chromosomes 6 and 1, one of more than 200 kb in length comprising 15 exons and the other of 28 kb comprising 12 exons. According to our perusal of the literature, the molecular basis of factor XIII deficiency are 51 sequence changes in the FXIII-A gene and three in the FXIII-B gene. Overall, there are 26 missense mutations, six nonsense mutations, eight splice site defects, 10 small deletions and/or insertions and one gross deletion in the FXIII-A gene (Figure 50.9). In the FXIII-B gene, one missense mutation, one small insertion and one small deletion were identified. Mutations are scattered throughout the factor XIII

genes and there is little evidence of recurring mutations. In a few studies, the mutant proteins were expressed in cultured mammalian cell lines and it was shown that the introduction of the mutation caused destabilization of the protein structure and intracellular degradation.

Concluding remarks on symptoms

Autosomal recessively transmitted coagulation deficiencies are generally less severe than the haemophilias caused by factor VIII or IX deficiency. The only exceptions are factor X and XIII deficiencies, characterized by the early onset of life-threatening symptoms such as umbilical cord and central nervous system bleeding. Among patients with other coagulation deficiencies, only a minority have spontaneous haemarthroses and muscle haematomas.

Accordingly, permanent damage to the musculoskeletal system and the resulting handicaps are less common. Haematuria, not rare in haemophilia, is relatively frequent only in factor X deficiency but occurs very rarely or not at all in the remaining defects. Bleeding from the umbilical stump, not seen in haemophiliacs and thought to be typical of the inherited defects of fibrin formation (afibrinogenaemia and factor XIII deficiency), was also not unusual in prothrombin, factor V and factor X deficiency. A mild bleeding symptom such as epistaxis, relatively rare in haemophiliacs, was very frequent in all rare defects. In afibrinogenaemia and factor V deficiency, this mucosal-type symptom might be explained by a concomitant defect of the protein in patients' platelets, reflected by a prolonged bleeding time.

However, there is no obvious explanation for the frequency of epistaxis in defects of coagulation factors such as prothrombin, factor VII and X, not contained in platelets and not directly involved in primary haemostasis. The same considerations apply to other mucosal-type symptoms such as menorrhagia, a frequent event that often causes iron deficiency in women. There is no evidence that the coagulation defects reduce fertility in affected women, or that they cause recurrent miscarriages, with the exception of factor XIII deficiency. As expected, excessive bleeding when carried out without adopting preventive measures often follows surgical procedures. Bleeding after circumcision is often the revealing symptom in coagulation factor deficiencies. Life-endangering haemorrhages in the gastrointestinal tract and central nervous system are rare.

There are several reports of the frequent occurrence of these manifestations in patients with rare coagulation deficiencies, but report bias is likely to have emphasized their prevalence. At the moment, the observed qualitative and quantitative differences between the different defects cannot be easily explained. Animal models of gene knockout indicate that bleeding is more severe and more often lethal in mice rendered deficient in prothrombin, factor V and factor X than in those with factor VII and
Figure 50.9 Mutation in the factor XIII gene (subunit A), projected on the exons encoding the domains of the protein. Exons (rectangles) are drawn to scale, whereas introns (lines) are not to scale.

fibrinogen deficiency. Even though this pattern of varied severity of factor deficiency in mice is roughly similar to that observed in patients, it must be considered that in knockout mice the gene encoding a clotting factor is completely silenced. Accordingly, no trace of RNA or protein is produced, whereas the gene lesions found so far in humans are usually less deleterious and less likely to completely impede protein production.

Concluding remarks on molecular defects

The first remark is that in general a defect in the DNA of these patients could be identified in the actual genes encoding the different coagulation factors. Combined factor V and VIII deficiency, explained by defects located in genes encoding transport proteins, is a typical exception. Another remark is that for

each coagulation defect the mutations are multiple, and that the majority of them are 'private' mutations, unique for any given patient. The unique nature of the mutations complicates the approach to the control of these diseases through prenatal diagnosis in families with affected members, because it renders necessary the actual identification of the underlying mutation in each kindred.

The relation between genotype and phenotype is not always clear-cut. Even although 'severe' mutations predicting no protein production (stop codons, deletions, insertions, splicing abnormalities) are generally associated with severe factor deficiencies and severe clinical phenotypes, there are a number of cases with severe deficiencies and phenotypes associated with missense mutations. Usually missense mutations are associated with milder phenotypes despite unmeasurable factor levels, probably because some protein is produced in these cases, which cannot be detected with the assays available at present.

Expression of the mutations in cultured cell lines and characterization of the recombinant proteins has been useful to understand how well-defined molecular lesions lead to structural abnormalities and to functional defects of the protein. In some cases, expression studies have documented the mechanism whereby a mutant protein is synthesized normally but is not ultimately secreted in plasma from cells. In most cases, impaired folding and/or conformational changes of the mutant proteins lead to both intra- and extracellular instability, which, in turn, cause factor deficiency in plasma. Expression work is still in its infancy and needs to be expanded, mainly in cases of missense mutations that appear to be of special functional interest when projected on the available crystal structure of the coagulation factors.

Concluding remarks on treatment

Treatment of rare coagulation disorders consists in the use of the most purified blood product available that contains the missing factor. Due to the rarity of each factor deficiency, purified factor concentrates are not as widely available as they are for haemophilia A and B. Dosages and frequency of treatment depend on minimal haemostatic levels of the deficient factor, plasma half-life and type of bleeding episode. General recommendations on treatment of patients with rare coagulation disorders are summarized in Table 50.3.

Table 50.3 Treatment of recessive coagulation deficiencies.

Deficient factor	Recommended trough levels	Plasma half-life	Treatment
Fibrinogen	5–100 mg/dL	2–4 days	Cryoprecipitate (5–10 bags), solvent–detergent (SD)-treated plasma (15–30 mL/kg), fibrinogen concentrates (20–40 mg/kg)
Prothrombin	20–30%	2–3 days	SD-treated plasma (15–20 mL/kg), FIX concentrates and prothrombin complex concentrates (PCC) (20–30 U/kg)
Factor V	10–20%	36 h	SD-treated plasma (15–20 mL/kg)
Factor V + VIII	10–15%		as for Factor V
Factor VII	10–15%	4–6 h	FVII concentrates (30–40 mL/kg), PCC (20–30 U/kg) Recombinant FVIIa (15–30 μg/kg every 4–6 h)
Factor X	30–40%	20–40 h	SD-treated plasma (10–20 mL/kg), PCC (20–30 U/kg)
Factor XI	15–20%	48–72 h	SD-treated plasma (15–20 mL/kg), FXI concentrates (15–20 U/kg)
Factor XIII	2–5%	10–15 days	Cryoprecipitate (2–3 bags), SD-treated plasma (3 mL/kg), FXIII concentrates (10–20 U/kg every 5–6 weeks for prophylaxis and 50 U/kg for severe haemorrhagic events)

Table 50.4 Factor concentrates for recessive coagulation deficiencies.

Deficiency	Brand (company)	Viral inactivation	Comments
Fibrinogen	Fibrinogen HT (Benesis, Japan)	TNBP/polysorbate 80* + dry heat 80°C, 72 h	Concentrates should be used with caution in patients at risk for thrombosis
	Haemocomplettan (Aventis Bhering, Germany)	Pasteurization at 60°C, 20 h	
	Clottagen (fibrinogen) (LFB, France)	TNBP/polysorbate 80	
Prothrombin complex concentrate and Factor X	Konyne 80 (Bayer, USA)		Risk of thromboembolic complications with PCCs if FIX levels raised > 50%
	Proplex T (Baxter, USA)	Exposure to 20% ethanol + dry heat 60°C, 144 h	
	Bebulin (Baxter, USA)	Vapour heat 60°C, 10 h at 190 mbar + 80°C, 1 h at 375 mbar	
	Profilnine (Alpha, USA)	TNBP/polysorbate 80	
Prothrombin	Beriplex P/N (Aventis Bhering, Germany)	Pasteurization at 60°C, 10 h + nanofiltration	Concentrates should be used with caution in patients at risk for thrombosis
	Faktor IX HS (Aventis Bhering, Germany)	Pasteurization at 60°C, 10 h	
	Hemofactor HT (Grifols, Spain)		
	PTX-HT (CSL, Australia)		
	HT Defix (SNBTS, Scotland)	Dry heat 80°C, 72 h	
	Kaskadil (LFB, France)	TNBP/polysorbate 80	
	Faktor IX-Komplex SRK (ZLB, SRK, Switzerland)		
	Prothrombinkomplex NDS (BSD NSOB, Germany)	TNBP/polysorbate 80	
	Cofactor (CLB, Netherlands)	TNBP/polysorbate 80 + nanofiltration	
	Factor IX comp (LF Bare, Brazil)		
Factor VII	Factor VII (Baxter, Austria)	Vapor heat 60°C, 10 h at 190 mbar + 80°C, 1 h at 375 mbar	Concentrates should be used with caution in patients at risk for thrombosis
	Factor VII (BIO Products Laboratory, UK)	Dry heat 80°C, 72 h	
	Factor VII LFB (LFB, France)	TNBP/polysorbate 80	
	NovoSeven (NovoNordisk, Denmark)	Recombinant	Primarily intended for haemostasis in presence of inhibitors
Factor XI	Factor XI (BIO Products Laboratory, UK)	Dry heat 80°C, 72 h	Concentrates should be used with caution in patients at risk for thrombosis
	Hemoleven (LFB, France)	TNBP/polysorbate 80 + 15-nm nanofiltration	
Factor XIII	Factor XIII (BIO Products Laboratory, UK)		Factor XIII concentrates can be given every 21 days to affected individuals with history of spontaneous abortions
	Fibrogammin P (Aventis Bhering, Germany)	Pasteurization at 60°C, 10 h	

*Solvent/detergent.

The avoidance of transmission of blood-borne infectious agents is the primary requisite in the choice of replacement material. Solvent–detergent-treated plasma is an important source of replacement recommended in the majority of these disorders; also virus-inactivated concentrates, when commercially available, are safe but expensive, especially for developing countries. Non-virus inactivated plasma and cryoprecipitate should be avoided if possible. Of course the treatment of choice may change depending on the facilities of the country where the patient is resident. Cost is the next most important determinant.

Virally inactivated factor concentrates are available for several deficiencies (Table 50.4) and should be preferred when virally inactivated plasma is not available or repeated infusions causing fluid overload are needed, as it may occur at surgery or in cases of bleeding in the central nervous system. For a few disorders, such as factor V and combined factor V and VIII deficiency, no concentrate is available at present. In factor VII deficiency, the use of purified factor concentrates is essential, because the half-life of this factor is so short (around 6 h) that closely spaced infusions of more than two to three doses of plasma are likely to create fluid overload. In prothrombin and factor X deficiency, prothrombin complex concentrates can be used for treatment. There is no obvious need to manufacture specific factor concentrates, even though the unnecessarily high post-infusion levels of vitamin K-dependent coagulation factors might be one of the causes for thrombogenicity of these concentrates.

Prevention of rare coagulation disorders through prenatal diagnosis of the underlying mutations is feasible in couples who already have affected children. Primary prevention might be achieved by discouraging consanguineous marriages. Even although the cultural, religious and economic roots of this practice are deep in Muslim communities, consanguineous marriages are becoming much less frequent in large cities and among younger generations.

Acquired coagulation disorders and vascular bleeding

51

Michael J Nash, Hannah Cohen, Ri Liesner and Samuel J Machin

Introduction

The haemostatic process under normal circumstances is balanced so as to ensure that haemorrhage is arrested and inappropriate thrombosis is prevented. Acquired defects of the haemostatic response may occur in association with multisystem disease or pharmacological intervention. Haemostatic 'disorder' may also occur at the extremes of age and in association with pregnancy. In clinical practice, it is important that a bleeding tendency is recognized and then the defect is defined by appropriate laboratory testing so as to facilitate treatment.

Faced with a bleeding patient, it may be difficult to discern whether blood loss is due to a local factor or secondary to an underlying haemostatic defect. Continual oozing from sites of venous access along with excessive bruising at pressure areas and intramuscular injections, may be signs of actual or impending haemostatic failure. In some cases, patchy skin cyanosis or superficial gangrene may be the herald of consumptive coagulopathy prior to overt bleeding.

A list of simple laboratory tests, which should be performed first line in the bleeding patient, are shown in Table 51.1. More specialized tests may be performed to further define the cause of bleeding.

Table 51.1 Laboratory screening tests to detect haemostatic defects.

Coagulation factors
Prothrombin time (PT)
Thrombin time (TT) and reptilase time if prolonged
Activated partial thromboplastin time (APTT)
Perform 50:50 mix with normal plasma on samples with prolonged PT and APTT
Fibrinogen quantification (by Clauss method)

Platelets
Platelet count
Blood film inspection
Bleeding time – by skin template or PFA 100®

Fibrinolysis
Fibrin(ogen) degradation products including D-dimers
Euglobulin clot lysis time or fibrin plate lysis assay

Acquired consumptive coagulopathy (disseminated intravascular coagulation)

Disseminated intravascular coagulation (DIC) occurs as a result of inappropriate and excessive activation of the haemostatic system within the vascular space. The International Society on

Table 51.2 Conditions associated with overt disseminated intravascular coagulation (DIC).

Sepsis/severe infection (any organism)

Trauma (e.g. polytrauma, neurotrauma, fat embolism)

Organ destruction (e.g. severe pancreatitis)

Malignancy – solid tumours and myeloproliferative/ lymphoproliferative malignancies

Obstetric calamities (e.g. amniotic fluid embolism, abruptio placentae)

Vascular abnormalities (e.g. Kasabach–Merritt syndrome, large vascular aneurysms)

Severe hepatic failure

Severe toxic or immunological reactions (e.g. snake bites, recreational drugs, transfusion reactions, transplant rejection)

Massive blood loss with inadequate fluid replacement therapy

Thrombosis and Haemostasis (ISTH) scientific subcommittee for DIC defines the condition as 'an acquired syndrome characterized by the intravascular activation of coagulation with loss of localization arising from different causes. It can originate from and cause severe damage to the microvasculature, which, if sufficiently severe, can produce organ dysfunction.'

DIC may exist in acute and subacute or chronic forms. The chronic form is associated with malignancy, aortic aneurysm and vascular malformation. The main clinical presentation of DIC is bleeding. However, 5–10% of patients will manifest with microthrombotic lesions such as gangrene of the extremities. Thrombi may also disrupt the renal glomeruli leading to acute renal failure. The excess intravascular fibrin polymer acts as a mesh resulting in red cell fragmentation and distortion leading to intravascular haemolysis. Some of the major causes of DIC are listed in Table 51.2.

Pathogenesis

Within the circulation of a patient with DIC there is excessive thrombin formation leading to increased fibrin formation, suppression of natural anticoagulant mechanisms and a failure to remove the excess fibrin consequent upon a failure of the fibrinolytic system. An overview of the pathogenesis of acute DIC is shown in Figure 51.1.

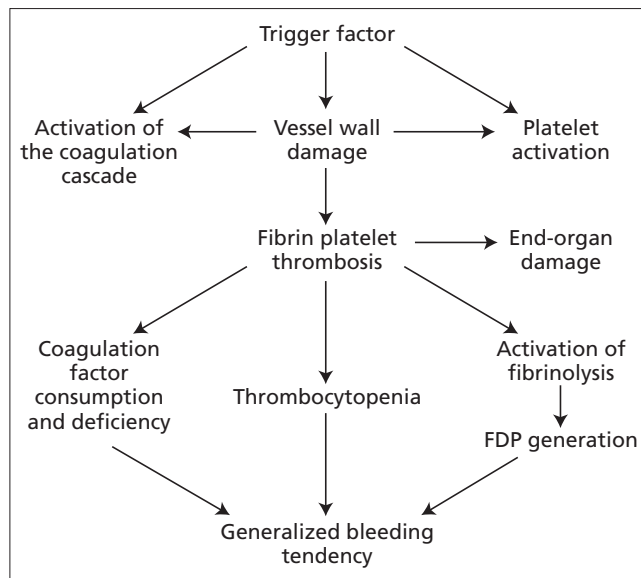
The key pathological event underlying most episodes of DIC is increased activity of tissue factor. The increased tissue factor expression occurs on activated monocytes in response to proinflammatory cytokines, along with increase in expression at the surface of vascular endothelial cells. Interleukin 1 (IL-1), endotoxin and tumour necrosis factor alpha (TNF-α) can all induce the upregulation of tissue factor mRNA by endothelial cells. In acute severe illness, another source of tissue factor may be that released into the circulation by damaged tissues.


Figure 51.1 Pathogenesis of acute disseminated intravascular coagulation.

Other mechanisms causing DIC include the release of tissue thromboplastins into the circulation following tissue damage by trauma, from malignant tissue or following a haemolytic transfusion reaction. Snake venoms can directly activate intravascular coagulation. For example, the venom of *Echis carinatus* (saw-scaled viper) can directly hydrolyse prothrombin to thrombin. The venom of *Crotalus adamanteus* (Eastern diamondback rattlesnake) can directly clot fibrinogen.

A fall in antithrombin is seen in DIC and is due to excessive thrombin production leading to the formation of thrombin–antithrombin complexes, resulting in increased consumption of antithrombin. Antithrombin levels are also reduced secondary to impaired hepatic production and due to degradation by granulocyte elastase. Levels of antithrombin may fall as low as 30% of normal in patients with severe sepsis. The activity of protein C is also impaired in DIC; lower levels of free protein S (due to increased levels of C4b-binding protein), impaired synthesis and a cytokine-mediated reduction in endothelial thrombomodulin expression (needed for the conversion of protein C to its active form) all contribute to this.

Fibrinolysis is suppressed during DIC as a result of higher levels of plasminogen activator inhibitor type 1 (PAI-1). Higher PAI-1 levels are associated with a higher mortality in meningococcal sepsis. Individuals with genetic polymorphisms leading to increased levels of PAI-1 have been shown to have a worse outcome in severe sepsis.

Despite the systemic reduction in fibrinolysis associated with DIC, tissue plasminogen activator still binds to plasminogen incorporated within fibrin clots. There it acts on plasminogen to form plasmin, which, within the confines of the clot is protected from α_2-plasmin inhibitor. If enough plasmin is generated

to exceed the neutralization potential of α_2-plasmin inhibitor then free plasmin will circulate, which can cleave circulating fibrinogen monomer as well as polymerized fibrin. The progressive degradation of fibrinogen leads to the formation of core fragments D and E (via fragment X and Y). The degradation of factor XIII cross-linked fibrin results in the formation of antigenically distinct cross-linked D-dimers. These circulating fibrin/fibrinogen degradation products (FDPs) can worsen any bleeding diathesis by binding to and inhibiting the action of thrombin and by reducing platelet function by non-specifically binding to the platelet membrane.

Continued, uncoordinated, excessive activation of the coagulation system results in the liver being unable to compensate for coagulation factor consumption. This particularly affects levels of factors V, VIII, XIII and fibrinogen. The bone marrow megakaryocytes are similarly unable to compensate the progressive consumptive thrombocytopenia. Thus a syndrome develops characterized by coagulation factor deficiency, thrombocytopenia, impaired platelet function and the inhibitory action of raised FDPs.

Clinical features and clinical associations

The patient with severe acute DIC may manifest with mucosal oozing, gastrointestinal blood loss and bleeding from surgical incisions or sites of venous access. The deposition of thrombi in the microcirculation can lead to multiple organ failure. Renal failure associated with DIC may occur secondary to hypovolaemia and also fibrin deposition in the renal vasculature.

Although Gram-positive organisms can cause DIC, Gram-negative bacteria are particularly associated with the syndrome. Viral haemorrhagic fevers may be associated with a DIC-like process; here, the mechanism is less clear than that in bacterial sepsis but may relate to viral infection of endothelial cells and cytokine release. Patients with liver disease may develop DIC after the placement of a peritoneo-venous shunt. This is due to the ascitic fluid containing thrombin activity and monocytes which express tissue factor. Severe trauma victims, notably those with necrotic cerebral lesions, may develop DIC. Here, one mechanism is the release of tissue factor into the circulation from damaged tissue. In addition, severe trauma victims have been shown to have a systemic cytokine response similar to that seen in sepsis and similar mechanisms may contribute to DIC in trauma to those seen in infection.

DIC may complicate some obstetric emergencies. Amniotic fluid may directly activate coagulation in the case of amniotic fluid embolism. Leakage of thromboplastin-like materials from the placenta contribute to the DIC seen with some cases of placental abruption.

In some patients, a syndrome of subacute or chronic DIC develops. The diagnosis of this state may be difficult as a degree of compensation by virtue of increased hepatic clotting factor synthesis may occur, rendering some of the laboratory clotting tests normal. Patients with malignancy, particularly those with mucin-secreting adenocarcinomas, may develop chronic DIC. The mechanism here is likely to relate to tissue factor expression on tumour cells and monocyte activation. Some tumour cells also express cancer procoagulant, a cysteine protease that can directly activate factor X. The retained dead fetus syndrome is another cause of chronic consumptive coagulopathy; here, spontaneous bleeding is uncommon but the patient is at increased risk of post-partum haemorrhage.

Individuals with localized abnormalities of the vasculature such as an aortic aneurysm or giant cavernous haemangioma may also develop a chronic consumptive coagulopathy. This may lead to bleeding; however, because fibrin deposition is localized to the abnormality, end organ damage is infrequent. Localized consumption in the kidneys is characterized by the presence of FDPs in the urine, with only very mild elevation in the blood. This may occur in the context of hyperacute renal allograft rejection and proliferative glomerulonephritis.

Diagnosis

In acute DIC it is essential to demonstrate abnormal laboratory results quickly so that appropriate management can be instituted. Ideally, these should be available within 30 min of sample receipt at the laboratory. The ISTH scientific subcommittee for DIC has recently published a proposed scoring system for use in the diagnosis of 'overt' and 'non-overt' DIC (Tables 51.3 and 51.4). With both scoring systems, it is suggested that reassessment of scoring is performed daily. Notably, a diagnosis of 'overt DIC' under this classification can only be made in the presence of an underlying condition known to be associated with overt DIC (Table 51.2). From these guidelines it can be seen that the first-line tests for a diagnosis of DIC are a full blood count, a coagulation screen (prothrombin time, PT; activated partial thromboplastin time, APTT; and thrombin time, TT),

Table 51.3 Diagnostic algorithm for the diagnosis of overt DIC.

Does the patient have an underlying disorder known to be associated with overt DIC? (*If yes, proceed; if no, do not use this algorithm*)

Order global coagulation tests (platelet count, PT, fibrinogen, soluble fibrin monomers (SFM) or fibrin degradation products (FDP))

Score coagulation test results

    Platelet count ($> 100 = 0; < 100 = 1, < 50 = 2$)

    Elevated FDP or SFM (*no increase = 0; moderate increase = 2; strong increase = 3*)

    Prolonged PT (by < 3 s $= 0; > 3$ but < 6 s $= 1; > 6$ s $= 2$)

    Fibrinogen level (> 1 g/L $= 0; < 1$g/L $= 1$)

Score ≥ 5 compatible with overt DIC; score < 5 suggestive (not affirmative) of non-overt DIC; repeat tests in 1–2 days.

1 Risk assessment. Does the patient have an underlying disorder known to be associated with DIC?	Yes = 2; no = 0
2 Major criteria	
(a) Platelet count	$> 100 \times 10^9 = 0$; $< 100 \times 10^9 = 1$; rising = –1; stable = 0, falling = 1
(b) PT prolongation	< 3 s = 0; > 3 s = 1; falling = –1; stable = 0; rising = 1
(c) FDPs	Normal = 0; raised = 1; falling = –1, stable = 0, rising = 1
3 Specific criteria	
(a) Antithrombin	Normal = –1; low = 1
(b) Protein C	Normal = –1; low = 1
(c) TAT complexes	Normal = –1; low = 1
4 Calculate score	

Table 51.4 Template scoring system for non-overt DIC.

TAT, thrombin–antithrombin.

fibrinogen quantification (by Clauss method) and measurement of fibrin/fibrinogen degradation products (D-dimers).

In some cases of DIC, fibrinogen may remain within the normal range. This finding can be explained by fibrinogen synthesis being increased as part of an acute phase response. Likewise, the fibrinogen level is normally raised in pregnancy, whereas in a patient with liver disease it may be chronically reduced. Serial coagulation tests are particularly useful in the diagnosis of DIC. A progressive decrease in the platelet count and increasing prolongation of the clotting times is seen.

The ISTH scoring system for non-overt DIC suggests that assays to detect a fall in protein C and antithrombin along with a rise in thrombin–antithrombin (TAT) complexes are included in the extended laboratory assessment of DIC. However, access to some of these tests may be limited in some centres. Other more specialized investigations include the detection of raised levels of prothrombin fragments 1 and 2 and fibrinopeptide A (cleaved from the N-terminal of fibrinogen by thrombin). Fibronectin may be non-specifically cross-linked to fibrin by factor XIII and indeed its plasma levels may fall in DIC and correlate with elevated FDPs.

Patients with chronic liver disease may exhibit a state of systemic hyperfibrinolysis. This occurs due to increased levels of plasminogen activators secondary to decreased hepatic clearance and lower circulating levels of PAI-1 and α_2-plasmin inhibitor. This state can be difficult to distinguish from DIC and may present with haemorrhage. The main distinguishing laboratory tests are the presence of a shortened euglobulin clot lysis time (usually normal in DIC) and a normal platelet count (usually reduced in DIC). In both situations, fibrinogen levels are low, FDPs are elevated and screening coagulation tests are prolonged. Treatment for hyperfibrinolysis may include the administration of antifibrinolytic drugs. The two states (DIC and hyperfibrinolysis) may both exist in the same patient. In the absence of demonstrable hyperfibrinolysis, antifibrinolytic drugs should be avoided in patients with DIC.

The serum of some patients with sepsis contains a calcium-dependent complex of C-reactive protein (CRP) and very low-density lipoprotein (VLDL). This complex results in the transmission waveform during clot formation in the APTT assay changing to an abnormal biphasic waveform pattern, which can be monitored by certain automated coagulometers. Recently, this pattern of waveform has been shown to correlate with a high risk of adverse outcome and may be useful in risk stratification of patients with sepsis in the intensive therapy unit setting. The presence of a normal waveform has a high negative predictive value in excluding sepsis.

Management

Underpinning any management strategy in a patient with DIC must be a resolve to treat and cure the underlying disorder. All the other aspects of management of DIC, although they may be life saving in the acute situation, can only be viewed as supportive. In the case of DIC related to obstetric complications, delivery or evacuation of the uterine contents may be life saving. The patient may require support with fluid replacement to ensure optimal end organ perfusion pressure and treatment with antibacterial agents to treat infection leading to sepsis. The management of patients presenting with predominantly haemorrhagic manifestations of DIC differs from that of patients with thrombotic problems.

In patients who are bleeding or are in need of acute surgical intervention replacement of clotting factors in the form of fresh-frozen plasma (FFP) (12–15 mL/kg) and cryoprecipitate is indicated. Cryoprecipitate may be indicated for low (< 1 g/L)

fibrinogen levels. Cryoprecipitate also contains von Willebrand factor (vWF) and factor XIII. Therapy should aim to maintain a PT/APTT ratio of 1.5 or less and a fibrinogen of greater than 1 g/L. Bleeding patients may also require platelet transfusion to maintain levels greater than 50×10^9/L. The response of the patient's platelet count and clotting times to treatment should be regularly monitored. The administration of prothrombin complex concentrate is unwise in view of its thrombogenicity in this context, as this may enhance fibrin deposition. Prophylactic plasma infusion is not advocated in the non-bleeding patient. This is not only wasteful, but may expose the patient to an unnecessary risk of transfusion-related complications, such as infection.

The administration of heparin to interfere with the cycle of continued thrombin activation has been used in management of DIC, particularly in patients with thrombotic manifestations such as dermal ischaemia. Usually, a low dose of unfractionated heparin (300–500 units/h) is employed. Care needs to be taken as these patients are at risk of bleeding. The use of heparin in the treatment of DIC is controversial and in septic patients its use would usually be reserved for those with thrombosis and/or a failure of platelet and clotting parameters to improve despite aggressive transfusion.

There are, however, some instances where heparin may be particularly useful. The syndrome of retained dead fetus is a case in point, where heparin therapy may result in a normalization of fibrinogen levels. Localized consumption secondary to aortic aneurysm may also respond to heparin therapy. The efficacy of therapy with heparin can be monitored by analysis of serial platelet counts, FDP (D-dimer) quantification and fibrinogen levels. The APTT may already be abnormal in patients with DIC and one may seek to measure the pharmacological effects of heparin by measurement of the anti-Xa activity of the patient's plasma. Heparin therapy is unwise in cases of DIC secondary to placental abruption, sepsis, severe liver disease and major trauma.

Infusion of an antithrombin concentrate has been shown to be beneficial in some patients with DIC. The rationale for this is to neutralize the excess thrombin formed by the DIC process. Antithrombin may be of particular use in patients with DIC secondary to sepsis. However, the role of antithrombin in treating DIC needs further investigation at the level of randomized controlled trials. The use of activated protein C in sepsis is discussed later in this chapter.

Coagulopathy associated with severe sepsis

A particularly severe coagulopathy may occur in patients with severe sepsis. This is particularly marked in the approximately 10% of patients who develop fulminant disease when systemically infected by *Neisseria meningitidis*. This organism is carried in the nasopharynx; however, in a proportion of individuals, it breeches the mucosal barrier. In some, the organism then produces a severe clinical state characterized by vasomotor collapse, multiple organ failure, rapidly enlarging skin and mucosal purpura (purpura fulminans) and arterial thrombi, leading to gangrene and end organ damage. Why some individuals are more susceptible than others to developing this severe state is unclear at present.

An outline of the events that lead to disturbance of the clotting mechanism is shown in Figure 51.2. A massive cytokine response is seen following cells of the immune system being stimulated by bacterial lipopolysaccharide. TNF-α and IL-1α stimulate increased tissue factor expression at the surface of endothelial cells and monocytes. In addition, the natural anticoagulant function of protein C is relatively reduced. This comes about by several mechanisms including a reduction in thrombomodulin expression by endothelial cells, an increase in C4b binding protein (which binds to and lowers free protein S levels) and an increase in levels of α_1-antitrypsin (which inhibits the serine protease action of protein C).

The importance of this reduction of activity of activated protein C (APC) in severe sepsis has been made greater following the discovery that as well as possessing an anticoagulant function, APC also has anti-inflammatory properties that may limit the excessive activation of inflammatory cascades seen in severe sepsis. The anti-inflammatory activity of APC has been demonstrated in experiments in which baboons are infused with a large dose of *Escherichia coli*. In those baboons concurrently given APC, survival and the degree of septic shock that ensues on infusion are improved. APC may act by dampening the response to inflammatory cytokines; it may also interfere with the CD14-dependent activation of monocytes by endotoxin. APC has now undergone a phase III trial in the Recombinant Human APC Worldwide Evaluation in Severe Sepsis (PROWESS) study. In this placebo-controlled trial, APC was shown to reduce the relative risk of death in patients with severe sepsis by 19.4%. In this study, APC in the form of drotrecogin alpha was administered at a dose of 24 µg per kilogram of body weight per hour, for a total duration of 96 h. However, there was an increased risk of bleeding complications in the APC-treated arm.

In 2001, APC received a licence from the Food and Drugs Administration for use in severe sepsis. The treatment has maximum clinical benefit if used in patients with severe sepsis with an APACHE II score of 25 or more and in those with a reasonable life expectancy if they survive the septic episode. A summary of the actions of protein C in this context is shown in Figure 51.2. Further targeting of subgroups who will benefit most from activated protein C infusion may be possible following the recent development of an enzyme capture assay employing a monoclonal antibody with high specificity for activated protein C.

Haemostatic defects in acute promyelocytic leukaemia

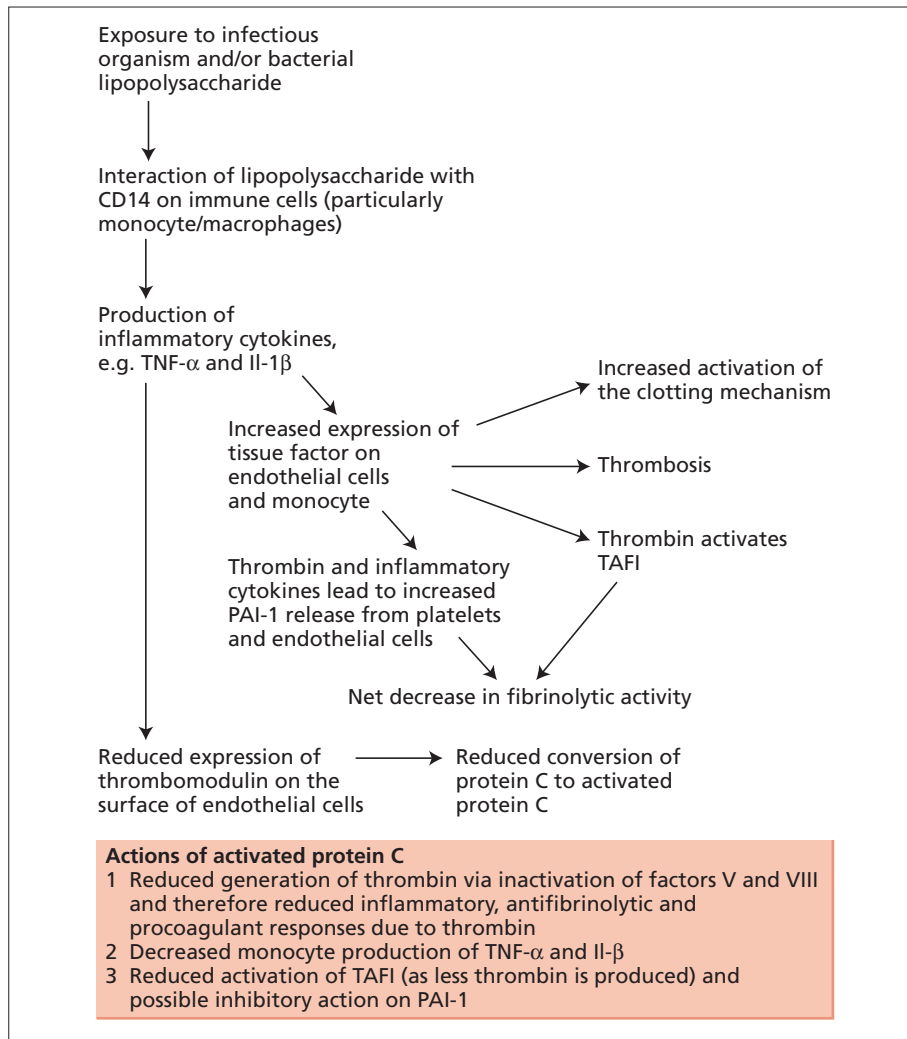
Acute promyelocytic leukaemia (APML) is characterized by a clonal expansion of immature promyelocytes with a characteristic


Figure 51.2 Mechanism of the coagulation disturbance seen in severe sepsis and the actions of activated protein C.

balanced chromosomal translocation between chromosomes 15 and 17: t(15;17)(q22–24;q12–21). The condition is responsive to treatment with all-*trans*-retinoic acid (ATRA) which causes differentiation of the leukaemic cells. APML is also associated with a bleeding diathesis, which, in some cases, can be fatal. It now appears that the APML cells are themselves causal in the coagulopathy seen in this condition. Patients with APML at presentation may have prolongation of the PT, APTT and TT, along with increased levels of FDPs. APML cells have been shown to stimulate more thrombin generation than other leukaemic cell lines in thrombin generation assays, this in part may be due to high expressed levels of tissue factor. In addition, APML cells may increase tissue factor expression on endothelial cells through expression of IL-1β. The increased tissue factor is further augmented by the presence of increased surface expression of phosphatidyl serine at the surface of APML cells.

The cells in APML also have been demonstrated to express high levels of annexin II. This protein acts as a coreceptor for plasminogen and tissue plasminogen activator. This results in excessive plasmin formation, which is sufficient to exceed the capacity of circulating α_2-plasmin inhibitor. This unopposed excessive fibrinolytic potential of the plasma results in a bleeding diathesis. Expression of annexin II mRNA has been demonstrated to fall following exposure of APML cells to ATRA. Indeed, treatment with ATRA has been shown to reduce the duration of the haemorrhagic phase of APML.

Coagulopathy in the patient with massive blood loss

The conventional definition of massive blood loss is that of one blood volume in a 24-h period. (Normal blood volume is approximately 5 L, i.e. about 7% of an adult's ideal body mass.) The development of a coagulopathy in patients with massive blood loss is multifactorial. Clotting factor deficiency is unlikely to occur until 80% of the patient's blood volume has been replaced. In the acute situation, the infusion of colloid or crystalloid

may result in dilution of coagulation factors and platelets. In addition, some colloid preparations may impede coagulation directly (see later in chapter). These inhibitory actions of colloids are usually of little clinical consequence, provided that the patient has normal renal function and the volume of colloid infused in 24 h is not in excess of 1.5 L.

As discussed earlier, trauma itself and some of the obstetric emergencies associated with massive blood loss may precipitate DIC, which will further consume already depleted coagulation factors. Patients with prolonged hypoxia or hypovolaemia and those with cerebral trauma are at high risk of developing DIC. Metabolic acidosis developing as a consequence of tissue hypoperfusion may also upset the coagulation mechanism. Hypothermia, which may manifest in patients with massive blood loss, may also worsen any coagulopathy present. Many trauma patients will reach the emergency department with a core temperature of less than 36°C. Many factors may predispose to hypothermia in trauma victims, including a prolonged extraction time from the accident scene, spinal cord injury, alcohol ingestion and the administration of cold intravenous fluids. The prewarming of fluids before transfusion into the patient will help to prevent this.

Management of patients with massive blood loss often requires the coordination and cooperation of individuals from many specialties. Local guidelines should be in place to optimize treatment. The use of formulaic replacement strategies with blood components is no longer regarded as optimal, as it may lead to the unnecessary transfusion of patients with exposure to the infectious and non-infectious risks of blood products or inadequate replacement. It is recommended that frequent checks are made of the patient's haemostasis tests to ensure that treatment is tailored to the patients needs. Some flexibility is needed, however, and it may be necessary to pre-empt the

need for blood components, especially platelets. This should be reflected in local protocols.

When managing these patients, one should transfuse platelet concentrate with the aim of maintaining a platelet count of at least 50×10^9/L in all patients and of $80-100 \times 10^9$/L in patients with central nervous system injury or polytrauma. The APTT and PT should be maintained such that they are less than 1.5 times that of the normal control time. FFP should be infused to achieve this and should be requested initially in volumes to infuse 12–15 mL of FFP per kilogram of patient body mass. Cryoprecipitate should be administered to maintain a plasma fibrinogen of at least 1 g/L. Cryoprecipitate is usually initially administered at a dose of 1.5 packs per 10 kg of patient body mass.

Recently, reports relating to the use of rVIIa in patients with massive blood loss have appeared in the literature. The doses used in these studies have ranged from 60 to 212 µg/kg. Large-scale studies relating to the use of rVIIa are needed to clarify dose, efficacy and potential thrombotic side-effects of this compound.

Near-patient testing of clotting parameters

The use of thromboelastography (TEG®) in the near-patient testing of coagulation parameters in patients undergoing liver transplantation and cardiopulmonary bypass (CBP) is now well established. The method involves the measuring of torque exerted on a pin placed in a rotating cup that contains a small volume of whole blood. As the blood clots, the rotational force from the cup is transmitted to the pin and then recorded by means of an electrical transducer. A typical TEG® trace, along with some of the parameters measured on it, is shown in Figure 51.3. Further study is needed; however, the TEG® may also have a role in
Figure 51.3 A typical TEG® trace. Hyperfibrinolysis is associated with a shortened *r* time and reduced MA and A_{60}; increased coagulation is indicated by a shortened *r* time and an increase in the MA.

Parameters measured on the TEG® trace

r time = time from reaction starting to amplitude reaching 2 mm
k time = time for amplitude to increase from 2 to 20 mm
MA = maximum amplitude
A_{60} = amplitude 60 minutes after MA
Whole blood clot lysis index = (A_{60}/MA) x 100%

screening for patients with a hypercoagulable state, assessing the effect of drugs on the fibrinolytic system and in screening for patients at high risk of surgical bleeding.

The Platelet Function Analyser (PFA 100®) measures the time for whole blood in a capillary device under simulated high shear stress conditions to occlude a coated membrane, the so-called *closure time*. The system employs a disposable membrane containing platelet agonists. At present, membranes containing collagen and epinephrine or collagen and ADP are used. The test is sensitive to defects relating to platelet function and some quantitative and qualitative abnormalities of vWF.

Cardiopulmonary bypass

Cardiopulmonary bypass (CPB) surgery is frequently associated with laboratory abnormalities of coagulation. However the operation is now routine and only rarely associated with excessive peri- or post-operative bleeding that is related to specific haemostatic defects. Bleeding is more common in patients needing reoperation or undergoing more complex procedures such as heart and lung transplants. Patients are routinely heparinized to prevent thrombosis within the oxygenator and bypass circuit.

The control of heparin therapy is performed in theatre by means of an activated clotting time test. (At an activated clotting time of 400–600 s, clots do not spontaneously form in the oxygenator.) Heparinization is reversed at the end of the procedure by means of a slow infusion of protamine sulphate. (Approximately 1 mg of protamine neutralizes 100 units of heparin.) Excess protamine may cause clinical bleeding by producing a consumptive coagulopathy. Following initial neutralization with protamine, the reappearance of active heparin in the blood may occur 2–6 h later. This is due to the return to the circulation of sequestered extravascular heparin and its release from heparin–protamine complexes. Thrombocytopenia of some degree occurs in all patients on CPB, due to platelet damage in the pump and oxygenator system. Platelet function usually corrects itself by 3 h post-operatively. Severe post-operative thrombocytopenia of less than 50×10^9/L and more persistent platelet functional defects occur in those patients undergoing prolonged complicated procedures.

The use of aprotinin in high-risk patients, particularly those undergoing repeat cardiac surgery has been shown to reduce bleeding. Shorter operative times are seen as a result of reduced generalized oozing from operative sites. Aprotinin is a broad-spectrum Kunitz-type protease inhibitor with actions against plasmin, kallikrein and trypsin. At the doses used in CPB, aprotinin will limit contact activation by inhibiting kallikrein and fibrinolysis by plasmin inhibition. The use of aprotinin is probably best limited to patients with a high risk of haemorrhagic complications, as it may increase thrombotic risk in patients in whom coronary artery patency is paramount. Analysis of the TEG® trace in patients during CPB has been found to be of use in guiding the administration of plasma and antifibrinolytics.

Patients found to be bleeding excessively post-operatively should be examined to ensure that one of the chest drains is not filling more than the other, indicating a specific bleeding vessel. A FBC and coagulation screen is useful, and it is usual practice to give platelet concentrate transfusion irrespective of the count, in view of the acquired platelet functional deficit associated with CPB. FFP should be given to correct prolonged clotting times and aprotinin may be necessary if there is a suggestion of fibrinolytic bleeding.

Haemostatic disturbance in hepatic disease

All the coagulation factors, with the exception of vWF, are synthesized in the liver along with antithrombin, protein C, protein S, α_2-plasmin inhibitor and plasminogen. The liver is also involved in the clearance of activated clotting factors from the circulation. Hepatic disease may therefore have profound effects on haemostasis.

Acute hepatitis

Patients with acute hepatitis may display a mild thrombocytopenia ($100–150 \times 10^9$/L). The mechanism for this may be immune or be due to concurrent hypersplenism. Thrombocytopenia may also be manifest in relation to DIC. Platelet function may also be impaired in acute hepatitis, although in the absence of severe thrombocytopenia this is unlikely to be of clinical significance. In acute liver disease, hepatic biosynthesis of clotting factors is impaired and this may be reflected in a prolongation of screening tests of coagulation. The prothrombin time and factor V levels are the most sensitive test to hepatic biosynthetic dysfunction. The plasma fibrinogen may be raised in acute hepatic disturbance as part of an acute phase response. A low fibrinogen level is associated with a poor prognosis in this context. Rather than being due to DIC, a pattern of reduced fibrinogen and increased FDPs seen in acute liver disease may be due to hyperfibrinolysis. Features distinguishing this state from one of DIC are discussed in the section on management of DIC.

Chronic liver disease

In chronic liver disease thrombocytopenia is frequently noted. In patients with cirrhosis, this is frequently related to hypersplenism, secondary to portal hypertension. One must be mindful, however, of the possibility that dietary problems, such as folate deficiency and the direct toxic effect of ethanol on megakaryocyte function, may also contribute to thrombocytopenia in a patient who takes excess alcohol. Platelets may manifest functional disturbance in chronic liver disease, although the

mechanism of this is unclear. Coagulation factor synthesis is affected by chronic liver pathology. With respect to the vitamin K-dependent factors, factor IX synthesis is usually less reduced than that of factors II, VII and X. Low factor V levels may correlate better than reduced vitamin K dependent factors with the level of hepatic dysfunction. Cholestatic liver disease will impair absorption of fat-soluble vitamins including vitamin K and will lead to reduced levels of vitamin K-dependent clotting factors.

Most patients with stable chronic liver disease have a normal or increased fibrinogen level. Some patients may develop dysfibrinogenaemia; this is thought to be because of increased sialic acid content of the fibrinogen. This causes slowing of the polymerization of fibrin following the release of fibrinopeptides A and B by thrombin. When finally formed, the clot is unstable. Dysfibrinogenaemia is reflected by a prolonged thrombin time with a more normal fibrinogen antigen level compared with that determined functionally by the Clauss assay.

Reduced hepatic clearance of activated clotting factors and lower synthesis of natural anticoagulants may predispose individuals with hepatic disease to developing DIC. This may occur following Gram-negative infection or in association with the insertion of a peritoneo-venous shunt. Ascitic fluid should be discarded at the time of shunt insertion to prevent this complication. Cirrhosis is associated with increased fibrinolysis; this is caused by increased levels of plasminogen activators (particularly tissue plasminogen activator), without an equivalent rise in plasminogen activator inhibitors such as PAI 1.

The management of a bleeding patient with hepatic dysfunction will in terms of specifics of management depend on the site of bleeding (e.g. from varices or from a biopsy site). Clotting function should be assessed by means of the PT, APTT, TT, fibrinogen levels and D-dimer levels. Vitamin K should be administered intravenously (slow i.v., 10 mg daily for 3 days) to aid biosynthesis of vitamin K-dependent factors. FFP contains coagulation factors and anticoagulants and is therefore appropriate to correct the bleeding diathesis if one is present. Large volumes of FFP may however be required and this may present a management problem in patients with hepatic disease who are at risk of fluid overload. Fibrinogen may be supplemented by transfusion of cryoprecipitate. Platelet transfusion may be necessary but platelet recovery may be reduced in the context of hepatic disease, however, because of hypersplenism. In patients with evidence of increased fibrinolysis, antifibrinolytic drugs such as tranexamic acid (1 g t.d.s.) should be considered.

Liver transplantation

The changes in the balance of haemostasis seen during liver transplantation are both complex and multifactorial. As discussed in the previous sections, patients with chronic and acute liver failure reacquiring transplantation are likely to have preoperative coagulopathy to some extent. Traditionally, the process of liver transplant is split into three stages: stage I, the pre-

anhepatic stage, which ends with the occlusion of the recipient's hepatic blood flow; stage II, the anhepatic phase, which ends with the reperfusion of the donor liver; and stage III, the reperfusion and neohepatic period.

A reduction in activity of clotting factors may be seen in stage I, especially if large blood losses necessitate transfusion and possible dilution of clotting factors. Release of heparin from the transplanted liver may also impair coagulation. Hyperfibrinolysis is seen in a significant number of liver transplant patients, often during stage II, with a recovery in stage III. Plasma levels of tissue plasminogen activator (tPA) are seen to rise in stage II and fall again late in stage III; levels of PAI-1 follow a reciprocal pattern. The mechanism of the increase in tPA levels is most likely to be due to lack of hepatic clearance. The platelet count usually falls during the procedure, reaching a nadir during the reperfusion phase. This fall is more profound if the transplanted organ is severely damaged and may be due to sequestration of platelets in the transplanted liver.

There is little evidence that one can predict the transfusion needs of a patient by examining their preoperative coagulation results. Correction of the profound coagulation abnormalities seen in fulminant hepatic failure is wise preoperatively. However, the correction of a mild coagulopathy in a patient with chronic liver disease prior to the operation is less likely to be of benefit.

During surgery, the aim is to tailor blood components administered to prevent the development of intractable coagulopathy but, at the same time, ensure that the patient does not receive unnecessary blood components. Near-patient tests of haemostasis such as the thromboelastograph (TEG®) are often used in theatre to complement the tests performed in the coagulation laboratory. The TEG® can monitor both the overall clotting and fibrinolytic potential of whole blood. Many laboratory tests correlate well with their TEG® equivalent; for example, a low fibrinogen is associated with reduced maximal amplitude of the TEG® trace, whereas thrombocytopenia is characterized by a prolonged reaction time and lower maximal amplitude values. Many departments use algorithms based on clotting and TEG® results to guide FFP, red cells, cryoprecipitate and platelet transfusion during the procedure. Aprotinin can be administered to counteract the increase in fibrinolysis observed.

Haemostatic disturbance in renal disease

Patients with chronic renal impairment may clinically express a bleeding diathesis with epistaxis, menorrhagia and gastrointestinal bleeding. Bleeding from the upper gastrointestinal tract may be secondary to angiodysplasia. Occasionally, haemorrhagic pericarditis and intracranial haemorrhage is seen. The main defect seen in association with renal disease is impairment of platelet function and the platelet vessel wall interaction. This will manifest with an increased bleeding time.

The pathogenesis of the haemostatic disturbance seen in renal disease is multifactorial. Increased levels of platelet inhibitory prostacyclin (PGI_2) are released by the vascular endothelium. The platelets of patients with renal impairment may exhibit multiple functional disturbances, including defective *in vitro* aggregation in response to ADP, adrenaline, collagen and thrombin. The platelets of those with renal disturbance also exhibit reduced expression of procoagulant anionic phospholipids at their surface in response to activation and also have impaired clot retraction. The disturbance of platelet function in uraemia may relate to the accumulation of platelet toxic materials in the plasma; candidate molecules include guanidosuccinic acid, which is a product of ammonia metabolism, and phenolic acids. Some of the disturbance of platelet function may relate to increased nitric oxide levels. Global screening tests of coagulation are usually normal in renal disease, although an increase in factor VIII and fibrinogen may be observed. Fibrinolysis is often impaired in renal disease.

1-Deamino-D-arginine vasopressin (DDAVP) has been shown to effectively reduce the bleeding time in patients with renal impairment (at a dose of 0.3–0.4 µg/kg i.v.). As in the treatment of mild von Willebrand disease with this compound, tachyphylaxis may occur because of depletion of endothelial stores of vWF. The bleeding time may also be partly corrected by the treatment of the anaemia frequently associated with chronic renal disease (particularly if the packed cell volume has fallen to less than 20%). This correction is now often achieved via the regular administration of recombinant erythropoietin. Dialysis itself may also improve the bleeding diathesis of renal disease; patients at high risk of bleeding during dialysis may have this risk reduced by reducing the heparin dose used during dialysis or replacing it with prostacyclin. Conjugated oestrogens have also been shown to reduce the bleeding time of uraemic patients.

Renal disease may also be complicated by thromboembolic phenomena. These are occasionally related to vascular access points for dialysis. Nephrotic syndrome with antithrombin deficiency is associated with renal vein thrombosis, especially when caused by membranous glomerulonephritis. Patients with this condition should therefore be considered for thromboprophylaxis. Renal allograft failure may occur secondary to thrombosis; the incidence of this complication may be reduced by preoperative thrombophilia screening and appropriate additional thromboprophylaxis.

Haemostatic changes associated with alcohol consumption

Moderate alcohol consumption appears to have beneficial effects on the individual with respect to rates of cardiovascular disease. The mechanism for this effect is not entirely clear and although some of it may relate to changes in lipid metabolism, the effects of alcohol on haemostasis may also play a role. At low levels, alcohol has been shown to increase the fibrinolytic potential of endothelial cells, for example by increasing levels of the urokinase receptor. In addition, lower levels of lipoprotein (a) in moderate drinkers may increase the activity of plasmin (lipoprotein (a) contains sequences homologous to the kringle domains of plasmin and can compete with the protein for its binding sites). Moderate alcohol consumption is also associated with a reduction in the response of platelets to agonists *in vitro*. Some of this effect is mediated by a reduction in the activity of phospholipase A_2 and a concurrent fall in thromboxane synthesis. The Framingham study showed that mild to moderate alcohol intake was associated with lower levels of fibrinogen, vWF, VII and plasma viscosity. However, higher levels of intake were associated with a reduced fibrinolytic potential.

When the blood ethanol concentration becomes greater than 0.2 g/dL, this generally inhibits platelet aggregation in a dose-dependent fashion and prolongs the skin bleeding time. As well as ethanol, there are specific additional platelet inhibitors in red wine and grape juice. These flavonoids inhibit thromboxane A_2 production by blocking phospholipase A_2 and cyclo-oxygenase activity and increase the inhibitory effects of platelet cyclic AMP by inhibiting cyclic AMP phosphodiesterase. It is now widely accepted that the cardioprotective effects of red wine are due, in part, to the antioxidant platelet inhibitory properties associated with flavonoids rather than specifically with any ethanol effect. Thus, regularly drinking small amounts of red wine would seem by several large epidemiological studies to reduce the incidence of arterial thrombotic cardiovascular disease, particularly myocardial infarction and thrombotic stroke.

Regular heavy drinking damages the synthetic capacity of the liver hepatocytes, so that in patients with advanced liver disease and cirrhosis, there is a hypocoagulable state due to deficiency of the vitamin K-dependent clotting factors and factor V. There is also evidence that changes in lipid metabolism related to alcohol consumption may also alter the synthesis and activation state of several clotting factors, particularly factor VII. However, light to moderate alcohol use may be protective, as it lowers the levels of fibrinogen, factor VII and vWF towards the lower end of the overall normal range.

Overall fibrinolytic potential tends to be lower with increasing alcohol consumption. In particular, inhibitor PAI-1 levels are consistently higher as alcohol consumption increases and levels decrease after abstinence from alcohol. The effects on PAI-1 are linked to fasting and post glucose insulin concentrations as these decrease with increasing alcohol consumption and it is well known that high PAI-1 levels are associated with late-onset diabetes and obesity. Fibrinolytic potential shows a marked circadian rhythm, with the lowest activity being in the morning. Heavy binge drinking is associated with a further fall in fibrinolytic potential at this time of the day, and correlates with high PAI-1 and tPA antigen levels but a low tPA activity.

In any individual, the effect of alcohol and its various constituents on haemostasis is extremely variable and any clinical

event, including beneficial effects and bleeding or thrombotic events, is usually multifactorial. Overall, the peak protective effect is seen at a 20 g per day intake of alcohol (approximately) but there is a definite increased risk of adverse events in individuals who have an intake of greater than 90 g per day, particularly if associated with episodic binge drinking. Binge drinkers have an increased risk of developing both spontaneous bleeding and thrombotic events.

Haemostasis in the newborn

The haemostatic system, like many other parts of the body undergoes rapid and dynamic changes during the first few days and weeks of life and there is a 'physiological' deficiency of many pro- and anticoagulant proteins in the neonatal period, which is even more profound in premature infants. Only coagulation factors V, VIII, fibrinogen and platelets have levels in the adult range in the newborn. The majority of those that are low at birth reach adult values by 6 months. Interpretation of coagulation tests in premature and term neonates must take these physiological differences into account and remember that what is 'normal' in this age group may differ from results found in healthy adults and appropriate age-adjusted normal ranges should always be applied. The results of screening tests of coagulation in premature and newborn infants are shown in Table 51.5.

Most infants will never undergo a screen of haemostatic function. Those in whom testing is indicated include infants with haemorrhage, including intraventricular or intracranial haemorrhage, significant bleeding from the umbilical cord or delayed cord separation, a family history of a severe inherited bleeding disorder, conditions predisposing to DIC and maternal history of anticonvulsant ingestion. In addition, many neonates admitted to neonatal intensive care centres will undergo coagulation screening. Sampling difficulties are frequent in samples taken from this population; platelet clumping occurs commonly and may produce an erroneously low result for the platelet count

and, if micro-techniques are not available in the local laboratory, it can be difficult to obtain a good free-flowing sample for accurate assessment of coagulation status. Assessment of platelet function with formal platelet aggregation is extremely difficult owing to the large volumes of blood required, but flow cytometry can be used to check for deficiencies in platelet glycoproteins. Although rare, factor XIII deficiency may result in bleeding diathesis without causing abnormality of any routine coagulation tests and its presence must be specifically sought in this circumstance (for example by the urea clot lysis time or FXIII assay).

Acquired haemostatic disorders are much more likely to cause bleeding symptoms in the neonatal period than inherited conditions. Vitamin K deficiency is covered in the next section. DIC can occur secondary to many of the causes seen in adults; however, there are also conditions that are more specific to the age of the patient, such as necrotizing enterocolitis, amniotic fluid aspiration, meconium aspiration and birth asphyxia. Neonatal DIC may also be caused by maternal illness such as placental abruption and severe pre-eclampsia. Because of the changes in coagulation, which occur normally in this age group, diagnosis of DIC may be difficult. Along with the 'usual' tests for DIC, assays of individual factors (V and VIII) may be useful in diagnosis.

Vitamin K

Vitamin K is a fat-soluble vitamin essential for the post-translational modification of factors II, VII, IX and X and proteins C and S. Vitamin K is an essential cofactor in the gamma carboxylation of glutamic acid residues on these proteins, which occurs in the endoplasmic reticulum (Figure 51.4). During this process, the reduced form of vitamin K (quinol) is metabolized

Table 51.5 Haemostasis screening tests and factor assays in premature and term infants compared with the adult normal range (note that ranges will vary between laboratories).

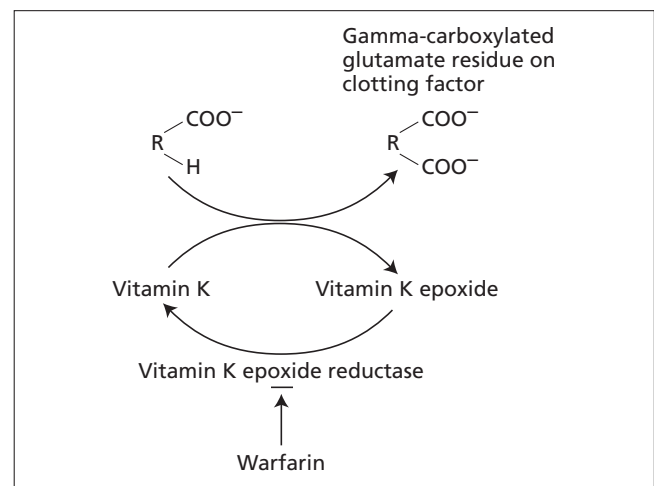
	Premature infant	Term infant	Normal adult
PT (s)	16–20	14–17	12–14
TT (s)	15–24	14–18	12–14
APTT (s)	50–65	40–50	30–40
Factor IX (%)	15–20	20–40	50–200
Factor VII (%)	20–60	35–70	50–200
Antithrombin (%)	25–35	45–75	80–120


Figure 51.4 The mechanism of action of warfarin.

to vitamin K epoxide, which is then reduced again to quinol form. This modification, which results in two negative charges at the end of glutamate residues, allows interaction with divalent cations, specifically calcium, and allows the proteins to undergo conformational change in its presence.

Plants produce vitamin K_1, whereas vitamin K_2 is synthesized by micro-organisms. Vitamin K is absorbed in the proximal small intestine in the presence of bile. The liver stores vitamin K, however only a small amount is stored and without intake deficiency can ensue in a few days. Serum vitamin K levels can be quantified by high-pressure liquid chromatography techniques (normal adult fasting levels 150–800 pg/mL). When vitamin K levels are low or when its action is antagonized (for example by warfarin), inactive precursors of II, VII, IX and X are released without gamma carboxylated glutamate residues (so-called PIVKAs). Vitamin K deficiency is characterized by prolongation of the prothrombin time and activated partial thromboplasin time (reflecting reduced levels of vitamin K-dependent factors). The prothrombin time is relatively insensitive to early vitamin K deficiency; however, this may be detected by immunoassays for PIVKAs, which are not present in the plasma of vitamin K-replete subjects. Because the half-life of protein C (6–7 h) is less than that of the procoagulant vitamin K-dependent factors, early vitamin K deficiency or antagonism is manifest by a prothrombotic tendency. This may manifest as skin necrosis secondary to dermal capillary thrombosis.

Haemorrhagic disease of the newborn

The newborn infant is prone to vitamin K deficiency. There is a relatively poor exchange of vitamin K across the placenta (although a therapeutic dose of vitamin K given maternally may reach the unborn child in significant quantities). Moreover, PIVKAs are found in the plasma of neonates. This deficiency, if anything, intensifies during the first few days of life if supplemental vitamin K is not administered. The neonatal liver stores predominantly K_1, which has a more rapid turnover, compared with K_2, which is the dominant storage vitamin K in the adult liver. The newborn also lacks the gut flora to produce vitamin K and if receiving breast milk, its main/only source of food contains very little (< 5 μg/L compared with 50 μg/L for formula milk). This deficiency of vitamin K may lead to bleeding manifestations as part of the syndrome of haemorrhagic disease of the newborn (HDN). HDN may present with intracranial haemorrhage, gastrointestinal bleeding and bleeding from other sites.

HDN is said to occur in three forms.

1 *Early HDN*. This occurs following maternal ingestion of compounds that can interfere with vitamin K metabolism, notably phenytoin and barbiturate and manifests in the first 24 h of life. It may also be seen after taking rifampicin or warfarin. This form may be prevented by the maternal administration of vitamin K before delivery.

2 *Classic HDN*. This may have an incidence of 0.4–0.7 per 100 births when prophylactic vitamin K is not administered, it may appear at any time in the first month of life.

3 *Late HDN*. This form occurs at 2–12 weeks. It manifests in breast-fed infants who did not receive vitamin K at birth and in those with cholestatic liver pathology such as biliary atresia. Other conditions associated with late HDN include cystic fibrosis, alpha 1-antitrypsin deficiency and coeliac disease.

HDN may be prevented by the administration of vitamin K to infants just after birth. This may take the form of an intramuscular injection or oral administration. There has been some recent controversy over the route of administration. Fears that vitamin K can result in haemolytic anaemia are mainly a result of very large doses of vitamin K in its water-soluble form, which were given in the past. More seriously, concern was raised in the 1990s that the intramuscular administration of vitamin K could predispose to childhood cancers. More recent epidemiological studies performed in the light of the initial report have, in the main, concluded that there is no significant risk associated with intramuscular vitamin K. Explanations offered for the initial findings have included that the studies showing a link, may have intrinsic bias as a result of 'high-risk' newborns being selected for intramuscular vitamin K because of other conditions which may themselves have provided an increased risk of childhood cancer.

Disadvantages of the oral route for vitamin K include problems such as occult regurgitation and compliance issues, as further oral doses must be given between days 3 and 5 and days 21 and 28. In addition, there is some evidence that intramuscular vitamin K produces more sustained and predictable vitamin K bioavailability and that oral vitamin K may not fully prevent late HDN. If given orally, health-care provision must ensure follow-up of infants is adequate to ensure that the later doses of vitamin K are administered.

Vitamin K deficiency

Adults require a minimum daily intake of vitamin K of 0.1–0.5 μg/kg. The absorption of this fat-soluble vitamin is dependent on the presence of bile salts in the upper small intestine. Therefore, cholestatic disease may lead to vitamin K deficiency, as can coeliac disease and significant small bowel resection, which may also lead to malabsorption. Subclinical vitamin K deficiency (with a normal prothrombin time but reduced serum vitamin K and the presence of PIVKAs in the plasma) may be seen in association with inflammatory bowel disease, cystic fibrosis and intestinal fistulae. Patients with generalized poor nutrition or malabsorption may also be deficient in vitamin C and folic acid, which will accentuate any bleeding tendency. Individuals requiring total parenteral nutrition will need vitamin K supplements. This may be provided in a fat-soluble vitamin mixture, such as Vitlipid, given weekly.

Broad-spectrum antibiotics may produce a vitamin K-deficient state in those receiving them. The mechanism for this is not

clear, but may be due to suppression of K_2 production by the large bowel gut flora. However whether significant vitamin K absorption occurs in the large bowel is a matter of debate. Some cephalosporin antibiotics are weak inhibitors of the vitamin K epoxide reductase enzyme and may lead to bleeding in patients with poor vitamin K stores.

Pharmacological manipulation of vitamin K

Coumarin class anticoagulant drugs such as warfarin exert their action by inhibiting the cyclical interconversion of vitamin K and its epoxide derivative essential for the formation of active forms of factors II, VII, IX and X (Figure 51.4). Coumarins inhibit vitamin K epoxide reductase and also possibly vitamin K reductase. Warfarin also interferes with the carboxylation of Gla proteins, which are synthesized in bone. This second effect may explain some of the teratogenic actions of warfarin.

When warfarin is first administered there is a delay in prolongation of the prothrombin time owing to the time taken for normally gamma carboxylated factors to be replaced by their non-gamma-carboxylated counterparts. The half-life of factor VII is relatively short (4–6 h) and thus early in therapy a prolongation may be seen in the prothrombin time due to this alone. However, the full anticoagulant potential of warfarin is not achieved until the other vitamin K-dependent factors have been reduced to 10–20% of their normal biological activity. The main anticoagulant effect of warfarin is likely in fact to reside in its lowering of prothrombin levels. Moreover, the half-life of protein C is also relatively short, therefore early in warfarin therapy one may have the situation of a relatively procoagulant state because of reduced natural anticoagulant function and as yet no real pharmacological anticoagulant function. This situation can rarely manifest as so-called warfarin induced skin necrosis especially in individuals with inherited or acquired deficiency of protein C or S. The aforementioned underpin the rationale for overlapping heparin therapy with warfarin therapy for at least 5 days in patients with an acute thrombosis or at high risk of thrombosis until the international normalized ratio (INR) is stable and within the desired therapeutic range.

Many drugs and other compounds administered to individuals may affect the pharmacokinetics of warfarin (Table 51.6). Significantly, warfarin as administered is a mixture of R and S isomers. The S isomer is five times more potent than the R form, thus drugs which affect the metabolism of the S form will have a much greater effect than those acting on the R form. Warfarin has a half-life of 47 h; 99% of circulating warfarin is bound to albumin and it is metabolized in the liver to compounds with little anticoagulant activity. The cytochrome P450 system is responsible for the metabolism of warfarin.

The major complication of warfarin therapy is over anticoagulation leading to bleeding. The risk of bleeding increases significantly with INR values greater than 5. However, even within the therapeutic range, bleeds do occur. The annual risk of

Table 51.6 Examples of drugs that interfere with oral anticoagulation control.

Mechanism	Drugs
Reduced coumarin binding to albumin	Phenylbutazone Sulphonamides
Reduced coumarin metabolism	Cimetidine Allopurinol Tricyclic antidepressants Metronidazole Sulphonamides
Alteration of hepatic receptor for drug	Thyroxine Quinidine
Induction of hepatic microsomal metabolism of coumarin	Barbiturates Rifampicin
Enhanced synthesis of clotting factors	Oral contraceptives Stanazol

Note: Drugs which interfere with platelet function may increase the bleeding risk with warfarin.

bleeding is approximately 0.3% for an INR of 2, 1% for an INR of 3, and 3% for an INR of 4. Recommendations as to the management of a patient who is over anticoagulated and/or bleeding need to take measure not only of the risk of haemorrhage, but also of the potential risk of viral transmission if plasma-based products (FFP or prothrombin complex concentrate) are infused and the risk of removing full anticoagulation from a patient at potential risk of a thrombotic event. Oral vitamin K is nearly as bioavailable as intravenous vitamin K. The management guidelines of the British Committee for Standards in Haematology for treating over-anticoagulation are shown in Table 51.7. Following a dose of vitamin K intravenously, effective hepatic synthesis of gamma-carboxylated factors does not begin for 6 h and is not maximal until 24–36 h.

Non-thrombotic vascular purpuras

A variety of general medical disorders may lead to widespread purpura. The challenge with respect to these problems is to distinguish them from thrombocytopenia and functional platelet disorders.

Simple easy bruising

Purpuric lesions are frequently encountered in normal individuals, usually women. Single or multiple bruises appear spontaneously, usually on the arms or legs and rapidly resolve without

Table 51.7 Management of bleeding in patients with excessive anticoagulation.

Clinical situation	Action
3 < INR < 6 (target 2.5)	Reduce warfarin dose or stop
4 < INR < 6 (target 3.5)	Restart when INR < 5
No bleeding	
6 < INR < 8	Stop warfarin
No bleeding or minor bleeding	Restart when INR < 5
INR > 8	Stop warfarin
No bleeding or minor bleeding	Restart warfarin when INR < 5
	If other risk factors for bleeding, give 0.5–2.5 mg of vitamin K orally
Major bleeding	Stop warfarin
	Give prothrombin complex concentrate*
	50 units/kg or fresh-frozen plasma (FFP)
	15 mL/kg
	Give 5 mg of vitamin K i.v.

*Factors II, VII, IX and X or factors II, IX and X with factor VII concentrate.

any specific treatment. Those patients who consult a medical practitioner may be exceedingly anxious or concerned regarding the cosmetics of the problem. No abnormalities are found in coagulation or platelet numerical or functional tests, and the patient can be reassured.

Senile purpura

This condition is seen frequently in the elderly population, usually in areas exposed to repeated low-level trauma such as the hands and forearms. The purpura is caused by atrophy of the subcutaneous tissue, with progressive loss of collagen and elastin fibres in the skin, leading to inadequate support to the subcutaneous blood vessels. Mild shearing forces can then lead to rupture and subcutaneous extravasation and spread of blood. Although there are no abnormalities in the haemostatic screening tests, a prolonged skin bleeding time may be observed in this condition. The lesions may retain their dark colour for several weeks. There is no specific therapy.

Hereditary haemorrhagic telangiectasia (HHT; Osler–Rendu–Weber syndrome)

This is a rare autosomal dominant condition. It is caused by mutations in the genes of endoglin (HHT1) and ALK-1 (*HHT2*).

Endothelial cells express both of these proteins, both of which are involved with signalling by the *transforming* growth factor beta superfamily. It is believed that abnormal blood vessels develop in HHT as a result of aberration in this signalling pathway. The condition presents with telangiectasia of the mucous membranes of the nose, mouth, gastrointestinal tract, vagina and skin. The lesions appear individually and in small groups. They blanche on pressure and bleed easily following minor trauma. This tendency to bleed increases with age.

Patients with HHT may also develop pulmonary and cerebral arteriovenous malformations (AVMs). Pulmonary AVM may enlarge in pregnancy leading to bleeding. At present, there is debate as to whether asymptomatic patients should be screened for cerebral AVMs. The most common presentations of this condition are recurrent epistaxis or gastrointestinal bleeding from multiple sites, which may eventually lead to iron deficiency. The standard coagulation tests are normal. Repeated intestinal bleeding may need treatment with therapeutic endoscopy and local cautery. Oral oestrogen therapy may reduce bleeding. The mechanism of action of oestrogen is to convert columnar epithelium to stratified squamous epithelium, which offers more protection against bleeding.

Giant cavernous haemangioma

In this condition, thin walled venous abnormalities appear on the skin in the first months of life. They may gradually enlarge until puberty. Although they do not cause a primary haemostatic abnormality, they may occasionally precipitate chronic activation of the coagulation system leading to laboratory features of chronic DIC. Spontaneous regression of the lesions may occur with age. The combination of giant haemangioma and thrombocytopenia with consumptive coagulopathy was first described by Kasabach and Merritt in 1940. Treatment for this condition may include corticosteroids, antifibrinolytic agents, cryosurgery, laser treatment and radiotherapy. Antiangiogenic agents are being investigated at present to see if they have a role in this condition's treatment.

Hereditary connective tissue disorders

Ehlers–Danlos syndrome, pseudoxanthoma elasticum, osteogenesis imperfecta and Marfan's syndrome can all present or be associated with recurrent bruising or skin purpura.

In Ehlers–Danlos syndrome, patients may have specific platelet functional abnormalities, but these may only be apparent in *in vitro* studies if a collagen preparation from the patient is used. The condition is associated with a defect in type III collagen, which leads to recurrent stretching of the skin with recurrent haematomas, causing thin atrophic skin with paper-like scars. Excessive bleeding or its prevention in the peri-operative setting may be achieved by infusion of platelet concentrates.

Metabolic causes of purpura

Severe scurvy or vitamin C deficiency typically presents with bleeding from multiple sites, including the gums, gastrointestinal tract, joints and brain. Perifollicular skin bleeding may also be seen. In this condition, the skin bleeding time may be prolonged but platelet function tests are usually normal. The diagnosis is made by observing reduced leucocyte vitamin C levels; the condition responds to vitamin C supplements.

Amyloidosis can cause skin purpura. Amyloid fibrils may infiltrate the walls of small blood vessels and also may cause functional platelet disturbance by binding to the platelet membrane. Lesions are often found in the periorbital region and may be distributed in linear streaks. Amyloid splenomegaly may lead to thrombocytopenia. Factor X may bind amyloid deposits, resulting in reduced levels of this factor in the plasma.

Long-term administration of corticosteriods may lead to atrophy of collagen fibres, which support blood vessels in the skin. This causes widespread purpura and bruises, usually on the extensor surfaces of the limbs. A similar finding is seen in Cushing's syndrome.

Allergic purpura

Allergic vasculitic purpura is caused by infiltration and inflammation of the blood vessel wall in response to a variety of agents, including chemicals, toxins and infections.

The most common example of this is Henoch–Schönlein purpura (HSP), which may involve the skin, joints, gastrointestinal tract, kidneys, heart and central nervous system. It is often preceded by β-haemolytic *Streptococcus* infection producing a rising anti-streptolysin O titre. Histologically, the condition is characterized by a leucocytoclastic vasculitis with IgA-predominant deposits affecting capillaries, venules and arterioles. Outbreaks of HSP may be seen in children in whom fever is followed by a purpuric rash, which is classically raised and affects the legs, thighs and buttocks. The patient may also develop nephritis (with proteinuria), arthritis and abdominal pain. The most serious complications of HSP are central nervous system bleeding, acute intussusception and renal failure. The condition is usually self-limiting, but may respond to steroid therapy.

A range of drugs have been reported to cause vascular purpura via an allergic mechanism. Examples include aspirin, sulphonamides and β-lactams. Skin testing with the offending drug may cause localized petechiae.

Psychogenic purpura

Bizarre bleeding and purpuric problems have been associated with psychological disturbance. These include self-induced bleeding, hysterical bleeding, religious stigmata and auto-erythrocyte sensitization.

Acquired inhibitors of coagulation

Specific coagulation factor inhibitors

Acquired haemophilia occurs as a result of the production of autoantibody activity directed against a coagulation factor, resulting in a decrease in the factor's function. The incidence of acquired inhibitor development is reported to be between one and four per million per year. The condition most frequently presents in the elderly and has an equal sex distribution. It may also be associated with autoimmune disease, lymphoproliferative disease (including chronic lymphatic leukaemia) and is also seen in the post-partum period. Associated autoimmune disorders include systemic lupus erythematosus (SLE), rheumatoid arthritis and graft-versus-host disease following allogeneic bone marrow transplant. Post-partum-associated acquired haemophilia usually occurs in primiparous women within 3 months of delivery, although in some patients an inhibitor may develop during pregnancy. Acquired haemophilia is also associated with solid tumours, including prostate and lung cancer. Some drugs, for example β-lactams and diphenylhydantoin, have been associated with the development of acquired inhibitors. Notably, in approximately 50% of patients with an acquired inhibitor, no clinical association may be found. By far the most common clotting factor against which acquired inhibitors develop is factor VIII; acquired inhibitors to all of the other coagulation factors (including factor XIII) have been described but are much less common.

Acquired inhibitors usually present with bleeding. Frequently, this manifests as extensive bruising or bleeding into muscles. Occasionally compartment syndrome may ensue in the presence of an extensive muscle haematoma. The condition may also present with haematuria, melena or haemoptysis. In contrast with inherited haemophilia, haemarthroses are rare as presentations of an acquired inhibitor. Acquired inhibitors may also present with bleeding following catheterization of the bladder or the insertion of an intravenous line.

The diagnosis of an acquired inhibitor is usually first made by noting the prolongation of the relevant clotting test (e.g. the APTT with a factor VIII inhibitor). This prolongation will fail to correct by more than 50% of the difference between the test and normal control plasma clotting time on incubation of the patient's and normal plasma in a 50:50 mix. It is important that the 50:50 mix is performed on a sample incubated for 1 h at 37°C with similarly incubated normal plasma as a control (to compensate for labile factor loss on incubation). Failure to perform a prolonged incubation may result in some inhibitors being missed in the laboratory because of their time-dependent nature. A specific factor assay will reveal reduced activity of the factor to which the inhibitor is directed. The Bethesda assay will quantify the inhibitor. The Nijmegen modification of this assay is now used as the original version of the Bethesda method may

produce false-positive results due to loss of factor VIII activity consequent on pH shift and reduced protein concentration. The temporal kinetics of an acquired inhibitor are often complex and non-linear with a rapid inactivation phase, in contrast with the linear kinetics seen in the inhibitors that develop in the context of the treatment of inherited haemophilia. The Bethesda assay may also be used to determine whether the inhibitor has activity against porcine factor VIII. This may be important in deciding how to treat the patient.

The treatment of acquired coagulation factor inhibitors needs to address both the definitive treatment of the pathological antibody activity and, if present, the management of bleeding. Bleeding manifestations in acquired haemophilia may be very severe and necessitate prompt definitive treatment, including fluid resuscitation. Patients with acquired inhibitors to factor VIII are usually resistant to infusion of human factor VIII. In patients with a low level inhibitor in whom some residual factor VIII activity is still demonstrable, DDAVP may be considered for the management of non-life-threatening bleeds. Prothrombin complex concentrate containing IXa and VIIa (also to a lesser extent Xa, XIa and thrombin) may also be used for non-serious bleeds. Porcine VIII may be given by infusion to treat severe acquired VIII inhibitors, although close monitoring is required owing to unpredictable pharmacokinetics in this context. The main adverse effects of administration of porcine VIII are allergic reactions and thrombocytopenia (which is usually mild). Recombinant VIIa may resolve severe bleeding also in this context. Most responses to rVIIa will occur in 8–24 h, and if no change in condition is seen in this time, alternative therapy must be considered. An important side-effect to consider with rVIIa, especially in the older population is that of thrombosis, which may include coronary thrombosis leading to myocardial infarction. (The United Kingdom Haemophilia Centre Doctors' Organisation (UKHCDO) recommends that severe bleeding should be treated with porcine factor VIII or rVIIa in the first instance.)

Agents that have been used with some success as part of an immunosuppressive regime to treat acquired inhibitors include corticosteriods, cyclophosphamide, azathioprine, cyclosporin A and rituximab. A reduction of a patient's inhibitor titre may be achieved in an emergency by the use of immunoabsorption with a protein A column if one is available. In women of childbearing age or those who are pregnant the most appropriate treatment may be intravenous immunoglobulin, which may work by an anti-idiotype mechanism. The guidelines of the UKHCDO recommend that unless contraindicated, immunosuppressive therapy should commence as soon as an acquired inhibitor is diagnosed. First line, the UKHCDO recommends a combination of prednisolone and cyclophosphamide. Secondary therapy is recommended if there is no response within 2–4 weeks.

Rarely, individuals may develop autoantibodies directed against epitopes on platelet glycoproteins or vWF, resulting in a bleeding tendency secondary to impaired platelet function.

Autoimmune 'versions' of Bernard–Soulier syndrome (glycoprotein Ib) and Glanzmann's disease (glycoprotein IIb/IIIa) may be seen depending on the target glycoprotein of the autoantibody. Autoantibodies directed against protein S, which were associated with infection and led to skin necrosis, have been described.

Lupus anticoagulants

Lupus anticoagulant (LA) activity is seen in some patients with primary and secondary antiphospholipid syndrome. These antibodies possess the paradoxical effect of prolonging clotting times (usually the APTT but sometimes the PT) *in vitro*, while being associated with thrombosis *in vivo*. Their 'anticoagulant' effect *in vitro* may relate to an ability via interaction with β_2-glycoprotein I to occupy limited negatively charged phospholipid binding sites, which are, required for coagulation factor interactions in the APTT and PT assays. The mechanism of the thrombophilia associated with LA *in vivo* is as yet unclear. It may however relate to the antibody causing endothelial cellular activation with an upregulation of tissue factor expression or by virtue of the LA disrupting the interaction of β2-glycoprotein I with anticoagulant factors such as protein C. In rare cases, LA may be associated with bleeding; this may occur via the immune thrombocytopenia associated with the antiphospholipid syndrome and by some rare forms of LA that can inhibit prothrombin *in vivo*.

LA activity may cause prolongation of the APTT, which is not corrected on 50:50 mix with normal plasma. The dilute Russel's viper venom time (DRVVT) will be prolonged and fail to correct with 50:50 mixing with normal plasma. However, the DRVVT will correct on addition of a high concentration of negatively charged phospholipid (e.g. freeze–thawed platelets) to the assay (presumably because extra phospholipid binding sites are made available by this addition).

Other acquired bleeding diatheses

Drug therapy

The bleeding tendency induced by exposure to coumarin class drugs and non-steroidal anti-inflammatory drugs (which inhibit platelet cyclo-oxygenase) are well described. Other drugs however may have effects on the haemostatic system distinct from their primary therapeutic role. Colloids, which are often used during fluid resuscitation, may impair coagulation. Of compounds in this class, hydroxyethyl starch is that most frequently associated with bleeding. This may relate to a reduction of the half-life of vWF, which may become complexed to the starch molecules. Dextrans may impede coagulation by causing binding to platelet membranes and causing steric hindrance of receptor function as well as reducing the plasma levels of vWF.

Gelatins may interfere with fibronectin function, this may decrease the opsonization of foreign material, delay early wound healing and the cross-linkage of fibrin by factor XIII.

Along with the reduction in vitamin K levels associated with the use of β-lactam antibiotics (discussed earlier), they may also have an anti-platelet effect. Binding of penicillin to platelet membranes may reduce the platelets' response to agonists.

Paraproteinaemia

Non-specific stoichiometric effects, which inhibit platelet function and the polymerization of fibrin, may occur in patients with high circulating immunoglobulin levels. In addition, antibodies with specific activity against factor VIII and vWF may be seen in patients with paraproteins. Antibodies with LA-like activity have also been described in this context. Patients with paraproteinaemia may develop AL amyloidosis. This may lead to impaired haemostasis by infiltrating and weakening small blood vessel walls and by binding to and reducing the plasma levels of factor X.

Hypothermia

The coagulation factors (with the exception of fibrinogen and vWF) are all enzymes or co-factors in enzymatic reactions. They have an optimal functional temperature of 37°C. Hypothermia may therefore impair the function of the clotting factors, resulting in a bleeding tendency. Hypothermia must not be overlooked as a cause of excessive bleeding in the trauma patient, when, unless warmed fluids are used, the patient's core temperature may fall as large volumes of fluid are transfused. The clotting times may appear normal in a hypothermic patient as the sample is warmed to 37°C for laboratory analysis. Hypothermia may also lead to thrombocytopenia secondary to platelet pooling in the liver and spleen.

Thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome (congenital and acquired)

52

Pier M Mannucci and Flora Peyvandi

Historical introduction

A brief historical sketch of the progress of knowledge is useful to frame these complex syndromes, which are difficult to diagnose. Thrombotic thrombocytopenic purpura (TTP) was first described in 1924 by Moschowitz in a previously healthy 16-year-old girl who died after an acute illness presenting with a pentad of signs and symptoms (anaemia, thrombocytopenia, fever, hemiparesis and haematuria). Post-mortem examination showed widespread thrombi in the terminal circulation of several organs, composed mainly of platelets. Over the next three decades, other cases were described, mainly, but not exclusively, in young or adult women. Some of these cases occurred in isolation (idiopathic), others in association with diseases or conditions (Table 52.1). It was understood that anaemia was due to massive intravascular haemolysis, in turn due to fragmentation (schistocytosis) of red

Table 52.1 Conditions and diseases associated with TTP.

Pregnancy and post partum
Infections (particularly HIV)
Drugs (quinine and quinidine, ticlopidine, clopidogrel,
   cyclosporin, interferon-α, statins)
Chemotherapy (mitomycin, cisplatin, gemcitabine)
Allogeneic bone marrow transplantation
Connective tissue disorders (lupus erythematosus and
   scleroderma)
Cardiac surgery

cells that were forced by blood flow to pass through partially occluded vessels in the terminal circulation, and that thrombocytopenia was caused by consumption of platelets due to their widespread deposition in microvascular thrombi.

Thirty-one years after Moschowitz, the paediatric nephrologist Gasser described a syndrome that was called *haemolytic uraemic syndrome* (HUS) and, in common with TTP, had microangiopathic haemolytic anaemia, consumption thrombocytopenia and microvascular thrombosis, but differed because it occurred in very young children, with absent or minimal neurological symptoms but severe signs of renal damage. Subsequently, when larger series of patients with HUS and TTP were examined, it became apparent that a neat distinction between the two syndromes was often difficult. Although thrombocytopenia, microangiopathic haemolytic anaemia and ischaemic symptoms due to widespread formation of thrombi in the terminal circulation of several organs were consistent features, age and the prevalence of neurological over renal symptoms could not clearly differentiate TTP from HUS and vice versa. There were, for instance, recurrent forms, which, in the same individual, presented sometimes with prevalent neurological symptoms (TTP) and on other occasions with renal symptoms (HUS). The term *thrombotic microangiopathies* (TMAs) was then proposed, meant to emphasize the common pathology of the two syndromes, with no implication on the prevalence of neurological or renal symptoms.

In the early 1980s, a major breakthrough in understanding the pathogenesis of TMAs strengthened the idea of the unitarian terminology. Even though it had been postulated for a long time that massive thrombus formation in the terminal circulation was due to the presence of 'toxic' substance(s) aggregating

Figure 52.1 Domain structure of ADAMTS-13. Pro, propreptide; TSP1, thrombospondin 1; CUB, *c*omplement components C1r/c1s, *u*rinary epidermal growth factor *b*one morphogenetic protein-1.

Figure 52.2 Interaction between vWF and ADAMTS-13 in plasma. vWF is secreted from endothelial cells as ultralarge multimers that anchor to endothelial cell surfaces and are also released into the circulation. ADAMTS-13 cleaves a Try–Met bond in the A2 domain of vWF, severing the ultralarge multimers. Failure of cleavage leads to the persistence in plasma and on endothelial cells of ultralarge multimers, which tend to aggregate platelet, especially in conditions of high shear forces.
platelets intravascularly, the putative aggregating agent had remained elusive. In 1982, Moake and others demonstrated, first in TTP and subsequently also in HUS, that the plasma of these patients contained highly thrombogenic forms of the multimeric glycoprotein von Willebrand factor (vWF), a major adhesive protein contained in endothelial cells, platelets and plasma. Abnormal vWF multimers of particularly high molecular weight (ultralarge) bind more avidly to platelet glycoproteins Ib and IIb/IIIa and aggregate platelets in conditions of high shear stress in the terminal circulation. Accordingly, it was postulated that ultralarge vWF was the 'toxic' aggregating agent involved in the formation of occlusive thrombi both in TTP and HUS.

It remained to be explained why such ultralarge multimers, normally absent in the circulation, were present in patients' plasma. The deficiency or dysfunction of one or more enzymes disposing them physiologically was postulated but it was not until the late 1990s that Furlan and Tsai and their associates independently showed that the link between ultralarge vWF multimers and TTP was a metal ion-dependent plasma metalloproteinase of 190 kDa called ADAMTS-13, a disintegrin and

metalloprotease with thrombospondin 1 repeats (Figure 52.1). The only known physiological function of this protease, present mainly in plasma, is to regulate the size of vWF by cleaving ultralarge multimers as soon as they are secreted from endothelial cells into plasma (Figure 52.2), thereby avoiding their circulation in plasma, platelet aggregation and thrombus formation. Most importantly, both the investigators made the intriguing observation that ADAMTS-13 was deficient in patients with TTP but measurable in normal amounts in those with HUS. This observation challenged the unitarian theory of TTP and HUS as different clinical manifestations of the same pathological process, and generated the paradigm that TTP is due to low levels of the vWF-cleaving protease, that is not involved in the pathogenesis of HUS.

As often in clinical medicine, the paradigm did not sustain the subsequent progress of knowledge. Not all the cases of thrombotic microangiopathy diagnosed as TTP owing to the prevalence of fluctuating neurological symptoms have low or undetectable levels of ADAMTS-13. On the other hand, even if most cases diagnosed as HUS for the prevalence of renal

symptoms have normal levels of ADAMTS-13 (particularly the cases typically occurring in association with bloody diarrhoea), there are unequivocal cases of HUS, particularly the forms called atypical or diarrhoea-negative, characterized by low or undetectable protease levels. With this as historical background, the author has decided to keep the description of TTP separate from that of HUS in this chapter.

Thrombotic thrombocytopenic purpura

TTP is a rare disease, with an estimated incidence of 2–10 cases per million per year in all racial groups. Recently, greater awareness and perhaps improved diagnostic facilities give the impression that incidence is increasing. Even though both sexes may be affected, the syndrome is definitely more frequent in women (two-thirds of the cases), as usually happens for diseases with an immunological basis (see below). Cases with a genetic basis, usually but not exclusively occurring in infants or young children, are very rare (1 in 1 million or less) and represent a small proportion of all TTP (approximately 5%). Mortality was very high (80–90%) until plasma exchange therapy was introduced, and is still unacceptably high (10–20%), despite the dramatic improvement due to the adoption of this therapeutic measure. Owing to the variability of presenting symptoms and of the associated comorbid conditions (Table 52.1), cases of TTP may be seen initially by a variety of physicians other than haematologists and pathologists, such as neurologists, nephrologists, oncologists and gynaecologists, and sometimes this makes it difficult to get a prompt recognition of the syndrome, an essential requisite for optimal management.

Pathology and pathogenesis

As mentioned above, the pathological basis of TTP is the widespread formation in the microcirculation of platelet thrombi, associated with relatively little endothelial cell injury and fibrin formation but with abundant vWF. Microthrombi are in several organs (mainly brain, kidney, myocardium, lung and pancreas), whereas grossly detectable thrombi, arterial or venous, are lacking. The present pathogenetic model implies that endothelial cells, activated by varied and often unidentified triggering agents, secrete large amounts of ultralarge uncleaved vWF, which aggregates platelets directly in conditions of high fluid shear stress and leads to massive intravascular platelet aggregation, ischaemic organ damage, consumptive thrombocytopenia and schistocytic anaemia. Two main mechanisms cause ADAMTS-13 deficiency in TTP: mutations on chromosome 9q34 in the gene that encodes the protease and the acquired occurrence of inactivating autoantibodies.

However, several observations fail to fit perfectly with this relatively straightforward pathogenetic mechanism. Only a minority of patients with bona fide TTP, as diagnosed with clinical

criteria (thrombocytopenia, anaemia and fluctuating neurological symptoms), have severe ADAMTS-13 deficiency. This may be explained by the incapacity of the functional assays available at present to reveal some types of deficiencies of ADAMTS-13 activity, and/or by the deficiency of vWF cleaving proteases other than ADAMTS-13. Ultralarge vWF multimers, pivotal players in the presently accepted model of TTP, are not constantly detected in patient plasma. In some instances, there is an imbalance between their release into plasma from endothelial cells and excessive binding to platelets, so that even defects of large multimers may be present in plasma. It is unclear why patients with sustained ADAMTS-13 deficiency, genetic or immunomediated, develop clinical symptoms and signs only sporadically. Still unknown factors that trigger excessive endothelial cell activation may be necessary for the full clinical spectrum of the syndrome to be manifested.

In summary, the prevailing paradigm holds that TTP is often the consequence of the defective processing of highly thrombogenic ultralarge multimers of vWF, which are secreted in excess by endothelial cells and not disposed of adequately owing to a congenital or immune-mediated dysfunction of ADAMTS-13 (Figure 52.2). There are data suggesting other possible mechanisms of disease that do not involve vWF and its cleaving processes (Table 52.2).

Clinical and laboratory findings

TTP occurs frequently, unheralded, in previously healthy individuals (acute idiopathic), but also in association with physiological or pathological conditions (Table 52.1). The presence of thrombocytopenia and haemolytic anaemia, common to all thrombotic microangiopathies, is essential for the diagnosis of TTP. Like HUS, TTP is a clinical diagnosis and biopsies are not necessary. Platelet count is often very low in the acute phase, with values of 20×10^9/L or less and petechiae are frequently seen. Signs of microangiopathic haemolytic anaemia (with haematocrits of usually less than 20%) are the presence of schistocytes on peripheral blood smears, reticulocytosis, increased indirect bilirubin, low or unmeasurable haptoglobin and negative direct Coombs' test. High serum lactate dehydrogenase

(LDH), usually in excess of 1000 U/L, is a sensitive, albeit non-specific, sign of red cell destruction and necrosis of other tissues due to microthrombotic end-organ ischaemia. Neurological symptoms (coma, stroke, seizures or focal signs such as motor deficits, diplopia and aphasia) typically fluctuate in presentation and severity, due to the sustained formation and dissolution of thrombi in the cerebral microcirculation. Other symptoms or signs such as headache, blurred vision, ataxia or mental status changes are less typical and are of difficult reproducible documentation. Even though only a minority of patients with TTP have elevated serum creatinine levels (> 1.5 mg/dL), signs of renal involvement such as microscopic haematuria and proteinuria are frequent. High fever is not constant in TTP, despite the inclusion of this symptom in the original description. There is no or little alteration of coagulation and fibrinolysis.

Differential diagnosis

Typical cases of HUS are distinguished from TTP by the occurrence of diarrhoeal prodromes and of more severe and persistent symptoms of renal impairment (see below). It is much more difficult to distinguish cases of TTP from atypical HUS, except for the paradigmatic prevalence of neurological symptoms in the former and of renal failure in the latter. Other issues of differential diagnosis are with conditions that present themselves as thrombotic microangiopathies, all characterized by thrombocytopenia and microangiopathic haemolytic anaemia (Table 52.3).

DIC can be distinguished by markedly increased levels of fibrin degradation products (FDPs) and D-dimer and, in decompensated cases, by the presence of hypofibrinogenaemia, prolonged prothrombin and activated partial thromboplastin times. Issues of differential diagnosis are also with such other thrombotic microangiopathies as pre-eclampsia and eclampsia, because pregnancy is one of the most frequent clinical associations of TTP. Hypertension is less frequent if renal damage is not severe and the degrees of anaemia and thrombocytopenia are more severe in TTP.

Coagulation and fibrinolysis tests are usually abnormal in pre-eclampsia or eclampsia, albeit less markedly than in DIC. Abnormally high serum transaminases differentiate TTP from the so-called HELLP (haemolysis, elevated, liver enzymes and low platelets) syndrome of pregnancy. Sometimes connective tissue disorders such as systemic lupus erythematosus and severe scleroderma present with widespread microvascular thrombosis, haemolytic anaemia, thrombocytopenia and fluctuating neurological symptoms. This situation may also occur in severe cases with the so-called catastrophic antiphospholipid antibody syndrome. These conditions may be distinguished from TTP because symptoms and signs are usually less severe, and laboratory tests such as antinuclear and anticardiolipin antibodies and the lupus-like anticoagulant give positive results.

The Evans syndrome, due to the concomitant presence of anti-platelet and anti-erythrocyte antibodies, is distinguished by a positive Coombs' test, the lack of schistocytes and the usual absence of end-organ ischaemic symptoms. Severe ischaemic manifestations due to platelet thrombi are frequent features of heparin-induced thrombocytopenia, but TTP can be distinguished not only by lack of exposure to this drug but also by the absence of haemolysis and schistocytosis. Disseminated malignancy is sometime associated with thrombocytopenia and microangiopathic haemolytic anaemia. Until further investigations permit to exclude or confirm the presence of metastatic cancer, it is not easy to distinguish TTP from this type of TMA.

What is the help of ADAMTS-13 testing in the differential diagnosis between the forementioned TMAs and TTP? In none of the former ADAMTS-13 is activity undetectable in plasma. So a complete deficiency of the protease clearly directs towards TTP or atypical HUS. Normal or reduced but detectable plasma levels of the protease do not help in the differential diagnosis, because they may be found albeit rarely in TTP, in typical HUS, in other TMAs and in several other unrelated conditions (Table 52.4).

Table 52.6 Steps in the treatment of TTP.

Clinical diagnosis (based upon severe thrombocytopenia, presence
    of schistocytes, high serum LDH, fluctuating neurological
    symptoms)
Plasma infusion (30 mL/kg) until plasma exchange can be started
Daily plasma exchanges (3–6 L per day) until platelets are higher
    than 150×10^9/L for at least 3 days and LDH is normal
Adjuvant treatments: prednisone, 1–2 mg/kg per day
Red cell transfusion as needed (avoid platelet transfusion)

Natural history (Table 52.5)

In approximately two-thirds of the cases, TTP occurs only once
(acute sporadic TTP). There are, however, cases that tend to
relapse early, after brief periods of apparent remission of the
acute episode. Usually, but not always, relapses are associated
with the persistence of anti-ADAMTS-13 autoantibodies. How-
ever, the most typical chronic recurrent forms of TTP are those
that manifest themselves cyclically, mainly, but not exclusively,
during childhood. They usually have a genetic basis, even
although familial segregation is not always apparent, because
ADAMTS-13 gene defects are transmitted as autosomal re-
cessive traits and only one child in the sibship may be affected.
In inherited TTP, ADAMTS-13 plasma levels are usually consist-
ently below the limit of sensitivity of assays available at present
and are reduced to half of the normal levels in their asymptom-
atic parents. It is not understood why ADAMTS-13-deficient
patients remain asymptomatic for some time (usually from 3
weeks to 3 months) and then, at intervals that are often quite
regular, thrombocytopenia and schistocytic anaemia herald the
appearance of new symptoms of end-organ ischaemia.

Treatment

The modern management of TTP started with the serendipitous
observations that plasma infusion improved the clinical course
of TTP. Plasma exchange was subsequently found to be equally
or more effective than plasma infusion. In 1991, the results of
a prospective randomized clinical trial definitely confirmed the
greater efficacy of plasma exchange over infusion, the clinical
response rate being 78% in the former compared with 49% in
the latter (mortality rates of 22% and 37% respectively). Only
recently, after the discovery of the role of vWF and its protease
ADAMTS-13 in the pathogenesis of TTP, these empirical treat-
ments have found a rationale. Plasma exchange may help by
removing anti-ADAMTS-13 autoantibodies, the most frequent
mechanism of acute sporadic TTP. Plasma exchange also helps
to replace the deficient protease, infusion alone being prob-
ably sufficient in congenitally deficient cases with no associated
autoantibody. Nevertheless, the efficacy of plasma therapies is
still not fully explained, because exchange and/or infusion are
definitely efficacious even in cases with normal plasma levels of

ADAMTS-13 and no detectable autoantibody. A scheme sum-
marizing the steps to be followed in the treatment of acute TTP
is shown in Table 52.6.

Plasma therapy

Treatment with plasma should be initiated as soon as a clinical
diagnosis is suspected for the presence of schistocytic anaemia,
severe thrombocytopenia and high serum LDH. There is as yet
no evidence that ADAMTS-13 and autoantibody testing are
necessary to start therapy, because as forementioned there are
unequivocal cases of TTP with normal or borderline levels of the
protease. Moreover, the available assays are time consuming,
poorly standardized and results are not always specific for TTP.

Critically ill TTP patients are often first admitted to hospitals
with no facilities for plasma exchange; in such circumstances,
daily infusion of large amounts of fresh-frozen plasma (FFP)
(30 mL/kg) should be started promptly, taking measures to
avoid volume overload (Table 52.6). Patients are optimally assisted
in intensive care units, where renal failure, coma, seizures and
such severe side-effects of plasma exchange as congestive heart
failure and catheter-related bleeding, thrombosis and infections
can be optimally managed. At least one plasma volume should
be exchanged daily until platelets are 150×10^9/L or more for at
least 3 days, LDH is normal and schistocytes are no longer pre-
sent on blood films (Table 52.6).

Treatment should be continued following this schedule for at
least 10 days, whether or not early signs of clinical and laboratory
improvement are observed. Daily exchanges for up to 1 month
are sometimes necessary to achieve remission of TTP. It is not
established whether discontinuation of plasma therapy should
be abrupt or progressive. Cryoprecipitate-depleted plasma can
be used instead of FFP if this fraction is available and con-
venient, but there is no evidence that this vWF-poor plasma is
more effective than whole plasma. Plasma treated with virus
inactivation methods (for instance, solvent/detergent) should
be preferred because it decreases the risk of infections associ-
ated with patients' exposure to plasma from a large number of
donors.

In *chronic recurrent TTP*, prophylactic plasma infusions
(30 mL/kg) are often administered at regular intervals. It is has

been suggested that trough plasma levels of 10% ADAMTS-13 are sufficient to avoid recurrence. A more conservative approach is to monitor platelet count and serum LDH at intervals of 5–10 days and to start plasma therapy as soon as these measurements begin to become abnormal. There is as yet no definite evidence that patients with congenital ADAMTS-13 deficiency develop alloantibodies, nor that an anamnestic response invariably occurs in patients with autoantibodies after they are treated with plasma.

Other therapies

Before the advent of plasma therapy, many other modalities of treatment have been attempted to control the dramatic course of TTP. Their generally poor efficacy is apparent from the fact that only with the advent of plasma therapy has mortality dropped dramatically. Hence, these treatments should be generally attempted only when plasma therapy at full doses and for at least a fortnight gave no or minimal benefit (refractory TTP) (Table 52.7).

There is little or no theoretical or practical role for the use of anti-platelet agents, because these drugs (including aspirin) fail to inhibit shear stress-induced platelet aggregation, the prevailing pathogenic mechanism of thrombus formation in TTP. Inhibitors of glycoproteins Ib and IIb–IIIa, by blocking binding of ultralarge vWF multimers to platelets, should perhaps be considered in the prevention or early management of chronic recurrent TTP, but not in full-blown TTP, because they may increase the risk of thrombocytopenic bleeding. The immune pathogenesis of TTP may be tackled using immunomodulating agents such as corticosteroids, cyclophosphamide, azathioprine, intravenous immunoglobulins and immunoadsorption on staphylococcal protein A (Table 52.7). Splenectomy has also been attempted.

In general, it is difficult to recommend the most useful among these agents or procedures. Considering that autoantibodies are a frequent pathogenetic mechanism, large doses of prednisone (1–2 mg/kg) are often prescribed in addition to plasma exchange during the acute phase of TTP, tapering off this treatment when remission is obtained (Table 52.6). The same treatment may be

Table 52.7 Suggested immunological treatments of refractory, antibody-mediated TTP.

Prednisone (1–2 mg/kg for at least 15 days, then tapering the drug off over 45 days)
Vincristine (2 mg on day 1, then 1 mg on days 3, 6 and 9)
Cyclophosphamide or azathioprine (100–200 mg per day)
Intravenous immunoglobulins
Immunoadsorption on staphylococcal protein A
Splenectomy
Anti-CD20 (rituximab)

considered in the chronic recurrent variant of TTP due to the persistence of autoantibodies. Efficacy of corticosteroids is not unequivocally demonstrated, and the adverse effects of prolonged intake of large doses are severe. Splenectomy is an alternative option in patients with chronic recurrent forms during remission, but carries a high risk of death in severely ill patients with acute TTP. Another recent attempt to suppress the production of anti-ADAMTS-13 autoantibodies is based upon a monoclonal antibody directed against CD20 antigen (rituximab). This therapy may be considered in chronic recurrent forms refractory to other immunomodulating agents.

A new, obviously promising approach is replacement therapy with ADAMTS-13 concentrates. A recombinant preparation has been shown to improve the defective proteolysis of vWF *in vitro*, but clinical trials with this product have not yet started. Another pharmaceutical company is considering the clinical evaluation of a humanized monoclonal antibody directed against platelet glycoprotein Ib to prevent the occurrence of relapse in chronic recurrent forms. This treatment is meant to inhibit the binding of ultralarge vWF multimers and thereby avoid intravascular platelet aggregation in the microcirculation.

Haemolytic uraemic syndrome

The typical form of HUS called diarrhoea-related HUS (or D(+) HUS) is acquired and occurs acutely and sporadically after gastrointestinal infections with toxin-producing bacteria, particularly in infants and young children but sometimes also in elderly individuals. There are two atypical forms of HUS. One is familial, has a sporadic or chronic recurrent course and is due to the inherited deficiency of complement factor H. It occurs mainly in infants or young children but at least one-third of cases also occur in adults. Another atypical form of HUS occurs at all ages in association with situations commonly seen also in association with TTP (Table 52.8).

Diarrhoea-related haemolytic uraemic syndrome

This acute syndrome almost always occurs as a single, sporadic episode, heralded 2 days to 2 weeks before by bloody diarrhoea.

Table 52.8 Variants of HUS.

Typical
Exotoxin-producing bacteria (*E. coli* 0157:H7, *S. dysenteriae*)

Atypical
Inherited (complement factor H deficiency) or acquired (association with post partum, drugs, bone marrow transplantation, chemotherapy) (see also Table 52.1)

Oligoanuria, jaundice, petechial haemorrhages, anaemia with schistocytosis and LDH increases are present but usually less marked than in TTP. Serum creatinine and urea are definitely more abnormal than in TTP. Signs of compensated DIC, with high plasma levels of D-dimer, are another distinctive feature. Neurological involvement is uncommon but seizures and coma may occur in association with severe uraemia and hypertension.

Aetiology

The most common bacterial agent that causes the prodromal gastrointestinal infection is *Escherichia coli* type 0157:H7 or, less frequently, *Shigella dysenteriae* serotype I. These and other more rarely involved infectious agents produce similar forms of exotoxins called verotoxin, shiga toxin and shiga-like toxins. These toxins, after absorption from the gastrointestinal tract into the blood, have in common the property to bind to the glycosphingolipid membrane receptor globotriaosyl ceramide (Gb_3) that is particularly dense in the glomerular capillary endothelial cells of infants, young children and elderly individuals. The toxin–receptor complex is endocytosed and thereby causes cytolysis and extensive endothelial swelling and desquamation, which in turn engenders massive thrombus formation in the renal microvasculature.

Pathology and pathogenesis

The pathology of diarrhoea-related HUS is characterized by more extensive endothelial injury and less vWF deposition in thrombi than in TTP. The behaviour of plasma vWF is also different, because ultralarge, highly thrombogenic multimers are detectable less frequently during the acute phase of the disease. This phenomenon is thought to be due to the fact that vWF multimers leaking in excess into plasma from damaged endothelial cells bind avidly to glycoprotein Ib on the platelet membrane and are thereby removed from plasma, particularly the multimers of larger size. There is quasi unanimity of views that ADAMTS-13 is normal in the plasma of patients with this variant of HUS (Table 52.9).

Table 52.9 Clinical applications of ADAMTS-13 testing in TTP and HUS.

Stage	ADAMTS-13 deficiency (< 10%)	Diagnostic implications
Acute phase	Yes	TTP/atypical HUS
	No	Typical HUS/TTP cannot be excluded
Remission	Yes	Risk of relapse

ADAMTS-13 levels are usually normal or only mildly reduced in the TMAs listed in Table 52.2.

Natural history

In the great majority of cases, diarrhoea-related HUS is self-limiting, with much less tendency to early or late relapses than TTP. The acute episode is often accompanied by such severe renal failure that temporary haemodialysis is frequently required. Residual renal dysfunction is common after the acute episode and renal failure requiring maintenance dialysis or kidney transplantation occurs in approximately one-third of the patients.

Treatment

During the diarrhoeal prodrome antimotility agents are contraindicated, because they favour the permanence of the bacterial toxins in the gastrointestinal lumen and their passage into blood. The role of antibiotics is controversial, with a strong indication only for patients with evidence or suspicion of sepsis or *S. dysenteriae* infection. Plasma exchange is usually not recommended in patients with typical HUS, whereas it is indicated in the atypical forms (see below), emphasizing again the similarities between this variant of HUS and TTP. A possible forthcoming approach to the prevention of toxin-induced HUS is vaccination of children who live in endemic areas.

Familial haemolytic uraemic syndrome

Autosomal recessive and dominant forms of familial HUS without diarrhoeal prodromes account for about 5–10% of all cases (Table 52.8). This variant is associated with a markedly severe impairment of renal function and with a high mortality rate (approximately one-third of the cases). Approximately one-half of the patients who survived acute disease require maintenance haemodialysis. In total, 30–40% of patients with familial HUS have a deficiency or dysfunction of complement factor H, which results in excessive C3 activation, membrane deposition of this complement fraction and renal cell injury. A recessively transmitted variant of familial HUS is very rare and is associated with very low levels of factor H in plasma and with the early onset of HUS in childhood. Dominantly transmitted variants are usually due to missense mutations in the gene encoding factor H, entailing the production of normal amounts of a dysfunctional protein. Dominantly transmitted HUS is usually less severe than the recessive form, and affects late infancy or adulthood. Low serum C3 levels may be a simple and widely available method to diagnose affected patients and to detect family members at risk.

Treatment of familial HUS is based on the replacement of factor H with FFP, associated with transient haemodialysis in the attempt to control oligoanuria and uraemia. Unfortunately, chronic renal failure is frequent and kidney transplantation fails to cure the syndrome, because the persisting plasmatic deficiency of factor H maintains the conditions that lead to damage of the kidney allograft. The severity of the disease warrants gene transfer as a therapeutic approach, but lack of animal models

and of suitable vectors of the transgene have hindered this approach so far.

Atypical (non-diarrhoea related) haemolytic uraemic syndrome

This form can only be distinguished from TTP by the absence of neurological symptoms and the predominance of renal symptoms. Atypical HUS is often associated with the post-partum period or with the intake of several drugs (Table 52.8). Individuals who have been treated for various illnesses by marrow transplantation make up a relatively large subgroup. Plasma therapy, using the same protocol recommended for TTP, is the treatment of choice.

Concluding remarks

In the last few years, TTP and HUS, known for several decades to clinicians and pathologists for their dire consequences, have witnessed spectacular improvements in terms of understanding pathogenesis, developing new diagnostic criteria, and decreasing mortality and morbidity. The pivotal role of vWF and of its major proteolytic enzyme in inducing microvascular platelet thrombi is evident, even though not all the variants of TTP, and particularly of HUS, fit into this disease mechanism. Other proteins disposing ultralarge highly thrombogenic forms of vWF may be involved, platelet thrombospondin 1 being at the moment the main candidate. The development of laboratory methods that measure ADAMTS-13 in plasma has allowed to demonstrate that several cases of TTP have very low levels of this protease. On the other hand, severe ADAMTS-13 deficiency is not found in all patients who have the appropriate clinical criteria for TTP diagnosis (Table 52.9). The trigger(s) of full-blown TTP or HUS need to be elucidated, because patients with constitutionally low levels of ADAMTS-13 or factor H remain without disease expression for long periods of time. It also remains to be seen which and how many cases respond to replacement therapy with protease concentrates, plasma derived or made with recombinant DNA technologies. Meanwhile, the clinician confronted with the difficult treatment of these seriously ill patients should be cognizant that plasma therapy, mainly as plasma exchange plasmapheresis, remains the treatment of choice for all patients with clinically diagnosed TTP and the related syndrome called atypical HUS. Diarrhoea-related HUS is now well characterized from an aetiological standpoint, so that it can be recognized and properly treated by paediatricians. A major problem remains the prevention of inherited HUS associated with factor H deficiency, because the long-term consequences of this scourge are dire. A suitable screening test is not yet available, even though there are theoretical possibility of a DNA-based approach, because most mutations are located in the gene exon encoding the most C-terminal short consensus repeat involved in binding factor H

to complement C3b and to sialic acid molecules on host cells, thereby protecting host cells from excessive C3 activation.

Inherited thrombophilia

53

Isobel D Walker

Introduction

In the mid-nineteenth century, the German pathologist Virchow postulated that thrombosis was due to alteration in blood flow (stasis or turbulence), changes in the vessel wall and changes in the composition of the blood (hypercoagulability). Thrombi are composed of fibrin strands and enmeshed blood cells, the relative composition differing between venous and arterial thrombi. Arterial thrombi arise in the setting of high flow and high shear forces in regions where the blood flow is disturbed and in vessels where the wall is damaged. Vessel wall injury leads to platelet activation, which plays a major role in the pathogenesis of arterial thrombi. Venous thrombosis, on the other hand, usually occurs where the degree of vessel wall damage is modest or minimal but where blood flow is abnormally slow and there is local activation of coagulation. Arterial thrombi are composed largely of platelet aggregates and a relatively minor amount of fibrin. Venous thrombi are composed mainly of red blood cells trapped in an extensive fibrin mesh, with relatively few platelets.

Imbalance between the anticoagulant and procoagulant activities of plasma in which the procoagulant activities predominate result in hypercoagulability and increased thrombotic risk. Hypercoagulability may be acquired and temporary (e.g. following surgery or trauma or during pregnancy) or it may be the result of an inherited change in one or more components of haemostasis. Much interest has focused on the role that underlying hypercoagulable states, in particular inherited life-long hypercoagulability, may play in the pathogenesis of venous or arterial thromboembolic disease.

Heritable risk factors for venous thromboembolism: thrombophilia

There is no internationally accepted definition of thrombophilia. In Europe, the term is used to describe disorders of haemostasis that appear to predispose to venous thrombosis. This laboratory-based definition is widely applied but has a number of disadvantages. First, it has become evident that many individuals – in fact the majority – who carry thrombophilic defects remain asymptomatic. Second, although the number of thrombophilic defects continues to increase, detailed laboratory investigation still fails to detect any abnormality in at least one-half of the patients who present with venous thromboembolism – including many who appear clinically thrombophilic.

In North America, the term thrombophilic has been used to describe individuals who developed venous thrombosis either spontaneously or of a severity apparently out of proportion to any identifiable stimulus, patients who have recurrent events and patients who have had a first event at a young age. This definition may be more clinically useful. A definition that encompasses both the laboratory and clinical aspects is lacking but clinicians investigating and managing patients considered to be at increased venous thrombotic risk should remain aware of that clinical history and laboratory findings are each relevant.

The heritable abnormalities that have been associated with an increased risk of venous thrombosis include those due to reduction in anticoagulant function – deficiency of the natural anticoagulants antithrombin, protein C or protein S, and those that are associated with increased procoagulant activity, factor V Leiden (FV Leiden) and the G20210A prothrombin

polymorphism (FII G20210A). The natural anticoagulant deficiencies are the result of a large number of gene defects. FV Leiden and the FII G20210A polymorphism are the results of single nucleotide polymorphisms. There are also a number of other abnormalities, for example elevated levels of clotting factor VIII (FVIII) and hyperhomocysteinaemia, which appear to have a mixed genetic and environmental origin (Table 53.1).

Natural anticoagulant and coagulation factor defects

Thrombin is the main effector enzyme of the coagulation system. It is produced by the activation of prothrombin by the prothrombinase complex, which comprises a phospholipid-bound complex of activated factor X (FXa) and its cofactor activated factor V (FVa). Factor V is activated by FXa (on the phospholipid surface) and thrombin (in solution and on the surface). Factor X is activated by tenase, a complex of activated factor IX (FIXa) and activated factor VIII (FVIIIa) on the platelet surface. Natural anticoagulant mechanisms regulate thrombin activity and function by direct inhibition of formed thrombin by antithrombin and by downregulating thrombin production via the inhibition of FVa and FVIIIa by the protein C–protein S system.

Antithrombin deficiency

Antithrombin (previously called antithrombin III) is synthesized in the liver. It is a glycoprotein member of the family of serine protease inhibitors. Its inhibitory effect is not confined to thrombin; antithrombin also inhibits the activated clotting factors IXa, Xa, XIa, XIIa and tissue factor-bound FVIIa. Free enzymes are preferentially inhibited, those that are part of the prothrombinase or tenase complexes being less accessible for inhibition. The rate of complex formation between antithrombin and activated clotting factors is markedly accelerated by heparin and by proteoglycans on the vascular endothelium.

Heritable antithrombin deficiency subtypes

Two major phenotypes of heritable antithrombin deficiency are recognized. Type I is characterized by a quantitative reduction of qualitatively normal antithrombin. Type II deficiency is due to the production of a qualitatively abnormal antithrombin protein. In both types of antithrombin deficiency, antithrombin activity is reduced to a variable extent. In type I deficiency, antithrombin antigen levels are reduced concordantly with the functional reduction. In type II deficiency, antithrombin antigen levels are discordantly higher than the functional levels and may be close to normal.

Understanding of the basis of familial antithrombin deficiency has been facilitated by advances made in molecular biology and in the functional characterization of this inhibitory glycoprotein. The antithrombin molecule possesses two important functional regions – a heparin-binding domain and a thrombin-binding domain. Type II antithrombin deficiency is subclassified according to the site of the molecular defect: (i) reactive site (RS), abnormalities residing in the reactive (thrombin-binding) site; (ii) heparin binding site (HBS), abnormalities residing in the heparin binding site; and (iii) pleiotropic effect (PE), abnormalities residing in both reactive and heparin binding sites.

Many mutations associated with antithrombin deficiency have been described, but identification of the specific mutation in particular patients is neither practical nor necessary for clinical purposes. Phenotypic distinction between the subtypes of antithrombin deficiency is, however, of clinical relevance as the incidence of thrombosis is higher in association with type I deficiency and type II deficiency when the mutation affects the reactive site than in type II deficiency when the mutation affects the heparin binding site. Type II HBS variants, although associated with a lower risk of thrombosis than type II RS defects, may increase the attributable risk of an additional thrombophilic defect, such as the FV Leiden mutation. Heritable antithrombin deficiency is uncommon, and type II deficiency is more prevalent than type I deficiency. The prevalences of heterozygous type I and type II mutations are approximately 0.02% and 0.15% respectively (Table 53.2).

Antithrombin assays

As antithrombin antigen levels may be normal or near normal in type II deficiency, immunological assays may fail to identify patients with these variants. Only functional assays measuring heparin cofactor activity will detect both type I and type II deficiencies. When reduced activity is demonstrated and an inherited deficiency postulated, comparison of the result of the functional heparin cofactor assay with the result of an immunological assay allows phenotypic classification into type I or type II deficiency. Commercially available antithrombin activity assays are robust and reliable, and usually use a chromogenic substrate. Most utilize a long incubation period and some have heparin in the dilution buffer. As a short incubation (of 30 s or

Table 53.2 Prevalences of heritable thrombophilias.

	General population	History of venous thrombosis	
		Unselected (%)	Selected (%)

*Type I antithrombin deficiency.

less) with a low concentration of heparin is required to detect type II HBS variants, laboratories using commercial antithrombin activity assays may fail to detect these defects. Crossed immuno-electrophoresis with heparin may be used to detect type II HBS variants in those centres that require identification of these defects.

Age- and sex-related variations in antithrombin activity and antigen levels are minor and the reference ranges in healthy populations are narrow. Antithrombin levels are slightly lower in premenopausal females than in males or older women.

Acquired antithrombin deficiency

Normal pregnancy is associated with a slight decrease in antithrombin activity. Use of a combined oral contraceptive pill is also associated with a slight reduction in antithrombin activity. Acquired antithrombin deficiency occurs as a result of decreased synthesis in severe liver disease or during treatment with L-asparaginase. Increased consumption of antithrombin occurs in patients with disseminated intravascular coagulation or with a current massive thrombosis, and in nephrotic syndrome and in inflammatory bowel disease, increased loss may cause an acquired deficiency. Decreased antithrombin activity has also been noted in patients on heparin treatment.

Protein C deficiency

Protein C is a member of the family of vitamin K-dependent glycoproteins. It is synthesized in the liver and, prior to activation by thrombin to activated protein C (APC), it circulates as a two-chain zymogen. The activation process is enhanced approximately 1000-fold when thrombin is bound to thrombomodulin on the endothelial surface of blood vessels. This binding blocks the ability of thrombin to catalyse fibrin formation, factor XIII activation, platelet activation and feedback activation of coagulation cofactors. In some blood vessels, protein C activation is further augmented by the binding of protein C to a transmembrane protein, endothelial cell protein C receptor (EPCR). Once APC is generated, it binds to protein S on the surface of activated cells and this complex then inactivates FVa and FVIIIa.

Factor V (FV) has both procoagulant and anticoagulant functions. FV and FVa both bind to phospholipid and APC is able to cleave not only procoagulant FVa but also FV. The consequence of cleavage of FV is the formation of anticoagulant FV, which functions in synergy with protein S as a cofactor for APC in the degradation of FVIIIa. The anticoagulant activity of FV may be particularly important in the regulation of tenase by APC and protein S. *In vivo*, intact factor VIII (FVIII) is bound to von Willebrand factor and prevented from interacting with phospholipid surfaces. Therefore, only FVIIIa and not intact FVIII is cleaved by APC. By degrading the activated clotting factors Va and VIIIa, APC downregulates thrombin generation.

Activated protein C reduces platelet prothrombinase activity by degrading platelet-bound FVa at the receptor for FXa. It also plays a major role in the modulation of leucocyte function and reduction of the inflammatory response in septicaemia.

Heritable protein C deficiency subtypes

Familial protein C deficiency, like antithrombin deficiency, can be classified into two types on the basis of phenotypic analysis employing functional and immunological assays. In contrast with antithrombin deficiency, type I protein C deficiency is more common than type II deficiency. Type II protein C deficiency may result in defective activation by thrombin–thrombomodulin, decreased binding to phospholipids or poor interaction with cofactors or substrates. Unlike antithrombin deficiency, when the underlying genetic variant and associated phenotype predicts the degree of thrombotic risk, there is no clinical advantage in phenotypic subclassification of protein C deficiency, as no difference in the thrombotic risk of type I and type II protein C abnormalities has been identified. The prevalence of heritable protein C deficiency in the general population is approximately 0.2% (Table 53.2).

Protein C assays

In clinical practice, the diagnosis of protein C deficiency is based on a functional assay (either amidolytic or clotting). Most commercially available functional assays of protein C employ the specific activator Protac, which is derived from snake venom. Alternatively, protein C may be activated by thrombin or thrombin–thrombomodulin complex. Chromogenic assays are simple to perform and will detect all type I defects and the

majority of type II defects. In the presence of FV Leiden, misleadingly low protein C activity levels may be recorded when a clotting method is used. Clotting methods may also underestimate protein C activity in patients with elevated levels of plasma FVIII or hyperlipidaemia. Protein C activity results measured by clotting assay are unreliable in the presence of a lupus inhibitor. Comparison of the result of an immunological assay with the result of a functional assay allows phenotypic classification into type I or type II deficiency but there is no clinical justification for this extra investigation.

The diagnosis of protein C deficiency is problematic because of the wide overlap in protein C activity between heterozygous carriers and unaffected individuals. Variation in protein C activity levels with age and between the sexes is explained by blood lipid levels. Both activity and antigen levels of protein C remain unchanged during pregnancy.

Acquired protein C deficiency
Acquired protein C deficiency is noted in patients using vitamin K antagonists (oral anticoagulants) and in patients with vitamin K deficiency, disseminated intravascular coagulation, liver disease or rarely a mutation in the γ-glutamylcarboxylase gene.

Protein S deficiency
Protein S, another vitamin K-dependent glycoprotein is produced by the liver, endothelial cells, megakaryocytes and the testicular Leydig cells. Approximately 60% circulates bound to the β-chain of C4b-binding protein and is inactive. The remaining 40%, designated free protein S, is uncomplexed and is the active moiety. The bioavailability of protein S is closely linked to the concentration of C4b-binding protein, which acts as an important regulator of the APC–protein S inhibitory pathway. Free protein S increases the affinity of APC for negatively charged phospholipid surfaces on platelets or the endothelium, enhancing complex formation of APC with FVa and FVIIIa. In addition, protein S has an independent anticoagulant effect on the free form of FIXa–FVIIIa–phospholipid complex (tenase) and the FVa–FXa–phospholipid complex (prothrombinase).

Heritable protein S deficiency subtypes
Three types of protein S deficiency have been described in accord with the classification of antithrombin and protein C deficiencies. Type I protein S deficiency is a quantitative defect caused by genetic variation, which results in reduced production of structurally normal protein. In type I protein S deficiency, both total and free protein S antigen levels are reduced, as is protein S activity. Type II protein S deficiency (also sometimes called type IIb protein S deficiency) has been characterized as a qualitative (functional) defect but it has become evident that some individuals with inherited or acquired APC resistance have been incorrectly diagnosed as having type II protein S deficiency. In type II protein S deficiency, both total and free antigen levels

are normal (or near normal) but protein S activity is reduced. In type III deficiency (which has also been called type IIa deficiency), the total protein S antigen level is normal but there is a reduction in free protein S antigen and in protein S activity. It has been suggested that type I and type III protein S deficiency may be phenotypic variants of the same genetic disorder.

The prevalence of protein S deficiency in the general population is not firmly established. In two case–control studies, reduced free protein S antigen was found in around 3% of patients with venous thromboembolism and in 1.3–2.1% of the control subjects, suggesting that protein S deficiency is prevalent and a mild risk factor for venous thrombosis. This conclusion may however be flawed if the prevalence of familial protein S deficiency is, as demonstrated in a survey of blood donors in the West of Scotland, only around 0.03–0.13%.

Protein S assays
A number of techniques are available for the measurement of total protein S antigen including enzyme-linked immunosorbent assays (ELISAs) and radioimmunoassays. The majority of commercially available kits and reagents employ ELISA methods. It is important to establish that the method chosen for measuring total immunoreactive protein S is not influenced by the concentration of C4b-binding protein.

All protein S deficiency subtypes have reduced levels of free protein S antigen. In the most widely used method, separation of free protein S from C4b-binding protein-bound protein S is achieved by precipitation with polyethylene glycol followed by centrifugation. Results are expressed relative to a plasma pool, which has been calibrated against the current international standard and may be expressed either as a proportion of the total protein S content or, preferably, against the free protein S content. More recently, assays using monoclonal antibodies for distinct epitopes of free protein S have been developed and allow direct measurement of free protein S antigen in citrated plasma without the requirement for a precipitation stage.

Functional protein S assays based on cofactor activity have been developed. Ideally, the assays should reflect only free protein S activity but as separation of free protein S from C4b-binding protein-bound protein S is not always performed, this is not always guaranteed. Although functional assays detect all types of protein S deficiency, some are non-specific and have been shown to be sensitive to both the inherited APC resistance that is associated with FV Leiden and the acquired APC resistance observed in some patients with antiphospholipid antibodies. When a functional protein S assay is used in clinical practice as an initial screening test for protein S deficiency, it is prudent to carry out further investigation of samples with low functional protein S assay results, using an immunoreactive assay of free protein S. Protein S levels are higher in males than in females, and different reference ranges are required for males and females.

Acquired protein S deficiency

Protein S levels fall progressively during normal pregnancy and are reduced in women using oestrogen-containing oral contraceptives or hormone replacement therapy. There is a significant risk of overdiagnosis of protein S deficiency in women. Acquired protein S deficiency is seen in patients on vitamin K antagonists and also in some patients with disseminated intravascular coagulation, liver disease or antiphospholipids.

Activated protein C resistance and factor V Leiden

Factor V circulates in plasma as an inactive profactor. Activation by thrombin results in the formation of a two-chain molecule: FVa, which as part of the phospholipid bound prothrombinase complex, acts as a cofactor of FXa in the conversion of prothrombin to thrombin. This process is limited by the inactivation of FVa by selective proteolytic cleavage of its heavy chain by APC at positions Arg306, Arg506 and Arg679.

Activated protein C resistance is defined as an impaired plasma anticoagulant response to APC added *in vitro*. This phenomenon has been observed in the plasma of about 5% of the general population and over 20% of unselected consecutive patients under the age of 70 years with a first venous thrombosis and no underlying malignancy. In 1993, Dahlback and co-workers reported that increased APC resistance cosegregated with thrombosis in families with familial venous thromboembolism. The following year it was reported that the majority of patients with familial APC resistance had the same point mutation in the gene for FV, a guanine to adenine transition at nucleotide position 1691 in exon 10 of the FV gene, the FV Leiden mutation. This mutation causes a substitution of glutamine for arginine at position 506, one of the major sites at which APC cleaves factor Va. Mutant FV Leiden has normal procoagulant activity but substitution of glutamine for arginine at position 506 results in slower inactivation of FVa by APC. Additionally, because normally the anticoagulant activity of FV is stimulated by the arginine 506 cleavage, the FV Leiden mutation affects FVIIIa degradation.

The FV Leiden mutation is much more common than any other heritable thrombophilia in white populations, with a reported prevalence of between 2% and 15% (Table 53.2). It is more prevalent in individuals of northern European extraction than in those from southern Europe. Factor V Leiden is not found in the indigenous populations of Asia, America, Australia and Africa. In northern Europe, the prevalence of homozygosity for FV Leiden has been estimated at 1 in 2500. It has been suggested that carriage of the FV Leiden mutation may have a species benefit in so far as it may be associated with a reduced blood loss *intra partum*.

Activated protein C sensitivity ratios and factor V Leiden detection

The most widely used system to detect increased APC resistance employs the activated partial thromboplastin time (APTT).

Samples are tested with and without an added fixed concentration of APC and the resultant clotting times are expressed as a ratio; the APTT result in seconds of the sample plus APC divided by the APTT result in seconds of the sample without added APC – the so-called APC sensitivity ratio (APC/SR). In the test performed in this manner, the greater the APC resistance the lower the APC/SR. In the pre-analytical handling of samples for APC resistance testing, care must be taken to avoid platelet contamination and activation. Because methodological variability has been reported with APTT-based tests for the detection of APC resistance, it has been suggested that the results are 'normalized' by dividing the result of the patient's APC/SR by the APC/SR of a pooled normal plasma. If 'normalization' is employed, care must be taken to exclude from the normal plasma pool any individual who carries the FV Leiden mutation, as even a single affected donation is sufficient to affect the APC/SR of a pool.

The APC resistance test performed as described above is abnormal, not only in individuals with the FV Leiden mutation but also in subjects which acquired APC resistance (due to elevated FVIII levels or the presence of antiphospholipids) and in individuals who have a prolonged baseline APTT (due to clotting factor deficiencies or anticoagulant therapy). It is therefore not specific for FV Leiden. Modification of the test by predilution of the test plasma in FV-deficient plasma increases the sensitivity and specificity of the APTT-based APC/SR as a screen for FV Leiden. With this modification, the test is almost 100% specific and sensitive for the FV Leiden mutation and can be used reliably if genetic analysis is not available. If available, the presence of the FV Leiden mutation may be confirmed by amplification of the nucleotide region close to the exon–intron boundary in exon 5 of the FV gene from either genomic DNA or from mRNA followed by a mutation detection step.

Acquired activated protein C resistance

Resistance to activated protein C may be acquired in patients with increased plasma levels of FVIII or with antiphospholipids. Activated protein C resistance increases with age and in women using oestrogen-containing contraceptive pills or hormone replacement therapy. The increase in APC resistance is greater in women using combined oral contraceptives containing third-generation progestogens than in women using compounds containing second-generation progestogens. Activated protein C resistance increases from early pregnancy and the APC/SR performed as described above remains below that seen in non-pregnant women throughout pregnancy.

There is evidence that APC resistance determined with the original unmodified test correlates with increased venous thrombosis risk, irrespective of whether or not FV Leiden is present and there is an inverse relationship between the degree of the response to APC and thrombosis risk. The specificity of the modified APC/SR test means that individuals who have increased APC resistance for reasons other than the possession

of the FV Leiden mutation will be overlooked if the original unmodified APC/SR test is not performed.

Heritable activated protein C resistance not due to factor V Leiden

Two rare mutations that result in amino acid substitutions at the 306 cleavage site on FVa have been described – 306 arginine to threonine (FV Cambridge) and 306 arginine to glycine (FV Hong Kong). In addition, a specific FV gene haplotype (HR2) that contains a histidine to arginine substitution at position 1299 has been shown to be more prevalent in individuals with an APC/SR beneath the 15th percentile than in those with higher ratios or in normal control subjects. It has a prevalence of 8–10% in the general population. In families that carry the FV Leiden mutation, the HR2 haplotype is found more frequently in family members with venous thromboembolism than in those without. Coinheritance of the HR2 haplotype with FV Leiden confers a three- to fourfold increase in the relative risk of venous thromboembolism compared with FV Leiden alone.

Prothrombin G20210A mutation

A single nucleotide change of guanine to adenine at position 20210 in the 3′-untranslated region of the prothrombin gene (FII G20210A) is associated with elevated plasma prothrombin levels and an increased risk of venous thrombosis. The prevalence of the FII G20210A polymorphism is between 1% and 4% in northern European populations (Table 53.2). Higher prevalences have been reported in southern Europe, where FII G20210A is the most prevalent heritable thrombophilic defect.

The mechanism whereby FII G20210A affects the prothrombin level has not been clearly established. No specific phenotypic test for the presence of the variant 20210A allele has been described and diagnosis depends on DNA-based procedures. The 20210A transition is not associated with the introduction or loss of a specific restriction enzyme recognition site and detection methods have been devised that do not require the use of restriction enzyme digestion of the amplified polymerase chain reaction (PCR) product.

Dysfibrinogenaemia

Over 250 cases of heritable dysfibrinogenaemia have been reported. The majority are asymptomatic and found coincidentally but, in about 20%, there is an increased tendency to arteriovenous thromboembolism. Dysfibrinogenaemia has been found in only 0.8% of patients with a history of venous thromboembolism but a high incidence of post-partum thrombosis and an increased risk of pregnancy loss have been reported in women with thrombophilic fibrinogen variants. Several mechanisms to explain the thrombotic tendency have been proposed, including defective binding of thrombin to the abnormal fibrin with consequent elevated plasma thrombin levels and impaired stimulatory function of the abnormal fibrin in fibrinolysis mediated by tissue plasminogen activator (tPA). In some, there is a low fibrinogen functional level. The diagnosis of dysfibrinogenaemia is established when there is discordance between functional and immunological assay results – the functional activity of fibrinogen being significantly lower than the immunological assay result in patients who have a prolonged thrombin time.

Combined thrombophilias

Because of the high prevalence of FV Leiden and the FII G20210A mutation in many populations, individuals and families with more than one heritable thrombophilic condition are encountered. The prevalence of thrombosis is often higher in family members with combinations of thrombophilic abnormalities.

Mixed aetiology thrombophilia

Elevated FVIII Levels

Higher risks of venous and arterial thrombosis have been described in individuals with non-O blood groups and it has been assumed that the excess risk is due to the higher levels of von Willebrand factor and FVIII found in these people. An elevated plasma concentration of FVIII (greater than 1500 IU/L), but not of von Willebrand factor, is an independent risk factor for venous thromboembolism. Although analysis within families has revealed cosegregation of elevated FVIII levels and venous thrombosis, no specific genetic abnormality has been identified to date.

Homocysteine and methylene tetrahydrofolate reductase

Plasma homocysteine levels are increased in individuals with reduced levels of folate, cobalamin or pyridoxine due to dietary deficiency, drugs or underlying disease (see Chapter 5).

Hyperhomocysteinaemia may be caused by genetic abnormalities affecting the trans-sulphuration or remethylation pathways of homocysteine metabolism. The severe inherited abnormalities of homocysteine metabolism (homozygous cystathionine beta-synthase deficiency and homozygous deficiency of methylene tetrahydrofolate reductase) result in congenital homocysteinuria. Classically, patients suffer severe mental retardation, seizures, skeletal deformity, ectopia lentis, premature vascular disease associated with severe atherosclerosis, and venous thromboembolism. Around one-half of the affected patients present with venous or arterial thrombosis before the age of 30 years. Individuals who are heterozygous for the cystathionine beta-synthase deficiency have moderately elevated levels of plasma homocysteine.

A common mutation in the gene encoding methylene tetrahydrofolate reductase (MTHFR) has been described. A cytidine residue at position 677 in the gene is replaced by thymidine resulting in the substitution of valine for alanine at nucleotide 677 in the enzyme. The resultant variant is thermolabile and, in its homozygous form, is associated with an approximately 50%

reduction of the enzyme activity. It occurs in white people and East Asians but has not been shown in Africans. In its homozygous form, the prevalence of this mutation in the general population is 5–15%. In the presence of folate deficiency, homozygosity for this mutation results in elevated plasma homocysteine levels.

Increased levels of FIX or FXI

In addition to those abnormalities described above, which have been shown in individual patients to be associated with venous thrombosis, there are a number of other abnormalities such as elevated levels of clotting factors IX or XI (above the 90th percentile for the general population), which have been shown in epidemiological studies to be associated with increased venous thrombotic risk. As in the case of elevated FVIII levels, this appears not to be the result of an acute phase reaction and to date no genetic explanation has been identified.

The 'thrombophilia screen'

Clinical assessment

The initial assessment must commence with a carefully taken personal and family history and a carefully performed clinical examination (Table 53.3). Patients should be asked specifically if they have a personal history of venous thromboembolism or a family history of venous thrombosis. Ideally, these events should have been objectively confirmed but because less emphasis was placed on the requirement to confirm a clinical diagnosis of deep vein thrombosis or pulmonary embolism in the past, a degree of pragmatism is necessary. Thus, if a venous thrombosis has not been confirmed by objective testing, it would seem reasonable to accept the clinical diagnosis if the history is plausible and if it resulted in the patient being given anticoagulant treatment. Additional risk factors including advancing age, a past history of venous thrombosis, immobility, trauma, surgery, hormone use, pregnancy, post-partum state and obesity should be clearly documented.

Laboratory tests

When laboratory testing is indicated, it should include assays and tests for heritable defects – deficiency of antithrombin, protein C or protein S, FV Leiden and the FII G20210A polymor-

phism, and also testing for antiphospholipids, the most common acquired cause of thrombophilia (Table 53.4). A full blood count, platelet count, APTT, prothrombin time and thrombin clotting time should be incorporated in the initial screening. Liver function tests and measurement of urea and electrolytes are also helpful. The full blood count and platelet count are useful indicators of general health and will identify myeloproliferative conditions that increase thrombotic risk. The APTT may identify some individuals with antiphospholipids, but formal testing for the presence of lupus inhibitors and measurement of anticardiolipins should be included. The thrombin clotting time will allow identification of dysfibrinogenaemia and heparin contamination. The prothrombin time is useful in the interpretation of low protein C or protein S results.

Functional assays should be used to determine antithrombin and protein C levels. Chromogenic assays of protein C activity are less subject to interference than are clotting assays and are preferable for clinical purposes. If a protein S activity assay is used in the initial screen, low results should be confirmed with an immunoreactive assay of free protein S. The modified APC/SR test (predilution of the test sample in FV-deficient plasma) as opposed to the original APC/SR test, may be used as a phenotypic test for the FV Leiden mutation. PCR-based testing for FII G20210A is required as there is no screening test. Laboratories must establish their own reference ranges for the assays and tests which they use. Rigorous internal quality assurance and participation in accredited external quality assessment schemes are mandatory.

Factor VIII and homocysteine assays may be considered as 'second line' tests and fibrinogen assays are indicated in patients with prolonged thrombin times.

Interpretation of laboratory results

There are significant problems in the accurate diagnosis and classification of deficiencies of the natural anticoagulants – antithrombin, protein C and protein S. Thus diagnostic uncertainty

is commonly encountered and both over- and underdiagnosis of thrombophilia occur as a result. When laboratory investigation for heritable thrombophilia is pursued, it is essential that facilities are in place for the provision of informed and detailed advice, based on a clear appreciation of the limitations of laboratory tests.

Some tests for heritable thrombophilia (e.g. assays of antithrombin, protein C and protein S) are affected by the acute post-thrombotic state and by anticoagulant use. As finding a thrombophilic abnormality seldom influences the management of an acute thrombotic event, there is little point in striving to obtain samples for tests for heritable thrombophilia when the patients present with an acute thrombotic event. Testing is usually best delayed until at least 1 month after completion of a course of anticoagulation. If possible, testing should be avoided during intercurrent illness, pregnancy, use of combined oral contraceptive pills or hormone replacement therapy. If this is not possible then it is essential that the individual interpreting the screen is aware of the presence and potential influence of these various factors on the components of the test results.

Clinical presentation of heritable thrombophilia

Patients with heritable thrombophilia typically present with thrombosis in the deep veins of the legs, pulmonary embolism or both. Less frequently, they present with superficial vein thrombosis or thrombosis at an unusual site such as mesenteric vessels or cerebral vessels. In more than one-half of the thrombotic events, an acquired precipitant such as surgery, pregnancy or oral contraceptive use can be identified. In most patients, the first event occurs before the age of 50 years. It is unusual for the first presentation to occur in childhood. Patients with natural anticoagulant deficiencies are likely to present with clinical manifestations in early adulthood, but patients with the less severe FV Leiden or FII G20210A mutations may not present until later in adulthood. Asymptomatic but affected relatives of patients with thrombophilia who have had venous thrombosis are at increased risk of venous thrombosis compared with the general population.

Deep vein thrombosis and pulmonary embolism

Antithrombin deficiency has been reported in between 0.5% and 1% of unselected patients presenting with venous thrombosis and around 4% of selected patients with a family history of venous thrombosis (Table 53.2). The annual incidence of venous thrombotic events in patients with familial antithrombin deficiency is estimated to be 0.87–1.6%. Family and prospective studies suggest that antithrombin deficiency – type I deficiency or type II RS deficiency – is a more severe disorder than deficiencies of protein C or protein S. Around 50% of individuals heterozygous for these antithrombin defects develop venous thrombosis and present with major venous thrombo-

embolism at a younger age than those with other thrombophilic abnormalities. Although pulmonary embolism associated with antithrombin deficiency may be fatal, there is a lack of evidence to suggest that antithrombin deficiency reduces the normal lifespan. Homozygous antithrombin deficiency is probably incompatible with life unless it is a type II defect involving the heparin binding site, in which case the clinical presentation is likely to be indistinguishable from heterozygous type I deficiency.

Protein C deficiency is found in around 3% of unselected patients with venous thromboembolism and between 5% and 6% of those with a family history of venous thrombosis (Table 53.2). Venous thrombotic events occur in around 0.5–1.65% of heterozygotes per year. Heterozygous protein C deficiency does not appear to be associated with excess mortality. Classically, homozygous protein C deficiency manifests as purpura fulminans as a result of thrombosis in small vessels and subsequent necrosis of the skin and subcutaneous tissues. This usually occurs during the neonatal period or in the first few years of life – depending on the level of protein C activity.

There is evidence that there is a substantial difference in the risk associated with protein S deficiency in thrombophilic families and in unselected consecutive patients. This suggests that the effect on families is the result of interaction of protein S deficiency with other defects. About 0.43–0.73% of protein S heterozygotes have a venous thromboembolic event per year. The clinical manifestations of protein S deficiency are similar to those of protein C deficiency, with patients suffering from an increased risk of venous thromboembolism as well as an increased risk of superficial thrombophlebitis. Homozygous protein S deficiency, like homozygous protein C deficiency, may present soon after birth with purpura fulminans or massive venous thrombosis.

Compared with individuals with a natural anticoagulant deficiency, the incidence of venous thrombotic events associated with the more prevalent thrombophilias – heterozygosity for FV Leiden and heterozygosity for the FII G20210A polymorphism – are associated with a lesser risk of venous thrombosis, the annual incidence being 0.25–0.45% and 0.55% respectively. FV Leiden is found in around 20–50% of unselected patients presenting with a first episode of venous thromboembolism and in more than one-half of probands from selected families with familial thrombophilia (Table 53.2). Heterozygous carriers are reported to have a three- to eightfold increased risk of venous thrombosis. Homozygous FV Leiden is reported to increase the risk of venous thrombosis approximately 30- to 140-fold, and these patients experience their first event at a young age. In northern Europe, about 4% of patients who have a venous thrombosis under the age of 45 years are homozygous for FV Leiden.

It has been claimed that deep vein thrombosis associated with the FV Leiden mutation is more stable and adherent to the vessel wall than deep vein thrombosis occurring in the absence of this mutation. This is presumed to be due to enhanced local thrombin generation intensifying the local inflammatory process and

impairing the profibrinolytic response to APC. It has been demonstrated that deep vein thrombosis occurring in the presence of the FV Leiden mutation is less likely to extend into the ileofemoral veins than a deep vein thrombosis occurring in the absence of this mutation, and patients with FV Leiden have a reduced risk of developing symptomatic or fatal pulmonary embolism when compared with other patients with deep vein thrombosis. Coinheritance of factor V Leiden with other heritable thrombophilias increases the risk of venous thrombosis.

Of unselected patients presenting with a first thrombosis, 6% have been found to have the FII G20210A polymorphism (see Table 53.2) and the evidence suggests that carriers have a three- to fivefold increased risk of venous thrombosis. Just under 20% of patients presenting with a first venous thrombosis belong to families with a history of familial venous thrombosis and have the FII G20210A polymorphism. The clinical manifestations in heterozygotes are similar to those seen in FV Leiden heterozygotes but it has been suggested that individuals homozygous for the FII G20210A polymorphism have a lesser risk of venous thrombosis than individuals homozygous for FV Leiden. Although the G20210A transition of the prothrombin gene appears to be a mild risk factor for venous thromboembolism, it may contribute to the incidence of thromboembolic disease in patients with other prothrombotic abnormalities, such as FV Leiden.

There is a dose–response relationship between FVIII level and risk of thrombosis – subjects with FVIII concentrations greater than 1500 IU/L having a four- to fivefold increased risk. This finding appears to be independent of the blood group and is not the result of an acute phase reaction. In unselected patients with venous thrombosis, there is a 25% prevalence of FVIII levels above 1500 IU/L. Elevated FVIII levels are not in themselves sufficient to cause thrombosis but will interact with other predisposing factors.

Case–control studies have demonstrated an approximately 2.5-fold increased risk of venous thrombosis in individuals with homocysteine levels exceeding 18.5 μmol/L and a three- to fourfold risk associated with levels exceeding 20 μmol/L. The data relating the C677T MTHFR mutation to venous thrombosis risk are conflicting; some studies have shown no association, whereas others have suggested a possible increased risk of venous thrombosis in homozygotes who have other venous thrombosis risk factors.

Site of venous thrombosis

The pathogenesis of venous thrombosis of the lower limbs, where the major mechanism is hypercoagulability, may be different from that of thrombosis in upper limb veins. Upper limb veins lack valve pockets. Thus local accumulation of activated clotting factors is less likely in upper limb veins unless the patient has a predisposing anatomic abnormality causing venous compression. Some workers have suggested that the prevalences of deficiencies of natural anticoagulants and of increased APC resistance in patients with primary upper limb venous thrombosis are significantly lower than the prevalences in patients with lower limb thrombosis. However, this suggestion is controversial and others have claimed that hypercoagulability is as frequent in patients with upper limb venous thrombosis as in those with lower limb events.

Recurrent venous thrombosis

Patients with a history of venous thrombosis are at increased risk of recurrence irrespective of whether or not they have an identifiable thrombophilia. The risk of recurrent venous thrombosis after stopping oral anticoagulant therapy in subjects heterozygous for FV Leiden has been compared with that in subjects with no detectable thrombophilia. A higher recurrence rate in FV Leiden heterozygotes has been suggested in some studies but, in the majority of prospective studies, the thrombosis recurrence rate was not increased in FV Leiden heterozygotes, although homozygotes may be at increased risk. There is also evidence suggesting the risk of recurrent venous thromboembolism is not increased in heterozygous FII G20210A carriers.

Because deficiency of the natural anticoagulants antithrombin, protein C or protein S is relatively uncommon, there are a lack of reliable data on the risk of recurrent venous thromboembolism in affected individuals. Some studies have suggested that recurrent venous thrombosis after discontinuation of warfarin therapy is high in patients with antithrombin or protein S deficiency but other studies have failed to corroborate this finding and have suggested that the recurrence rate may be similar to that in unselected patients with venous thrombosis.

Oral contraceptive use and hormone replacement therapy

Combined oral contraceptives cause slight increases in some procoagulant factors and reduce the levels of some natural anticoagulants – in particular antithrombin and protein S. These effects are more marked with third-generation pills (containing desogestrel or gestodene) than with second-generation pills (containing levonorgestrel). Compared with women not using combined oral contraceptives, plasma from combined oral contraceptive-using women has significantly increased APC resistance, and women who use third-generation pills have significantly greater APC resistance than women using second-generation preparations.

There is evidence that the risk of venous thrombosis is increased in women with thrombophilia when they use combined oral contraceptives. The Leiden Thrombophilia Study reported that the relative risk of venous thromboembolism for FV Leiden heterozygotes using combined oral contraceptives is 34.7 – significantly higher than expected if the relative risks associated with combined oral contraceptive use and with heterozygosity for FV Leiden were simply additive. This risk has been confirmed in other studies and shown to be even greater for FV Leiden homozygotes. The interaction between combined oral

	General population (%)	Pregnancy VTE population (%)	Estimated risk
Antithrombin deficiency – type I	0.02	8.0	1 in 2.8 (36%)
Antithrombin deficiency – type II	0.15	4.0	1 in 42 (2.4%)
Protein C deficiency	0.20%	2.0	1 in 113 (0.9%)
Protein S deficiency	?	0.0	?
Factor V Leiden	3.0	8.0	1 in 437 (0.2%)
Prothrombin G20210A	2.0	9.0	1 in 232 (0.4%)

Table 53.5 Thrombophilia and risk of pregnancy-associated venous thromboembolism.

From McColl *et al.* (1997, 2000), with permission.

contraceptive use and FV Leiden is greater for pills containing third-generation progestogens. The FII G20210A mutation has also been shown to increase the risk of venous thromboembolism in combined oral contraceptive users.

Because of the relative rarity of inherited deficiencies of natural anticoagulants, there is little information about the risk of venous thrombosis in women with these defects using contraceptive pills. One study noted a significant increase in the risk of venous thromboembolism in combined oral contraceptive users with antithrombin deficiency compared with non-pill using antithrombin deficient women but this study was too small to reveal any significant difference between combined oral contraceptive users and non-users with either protein C or S deficiency.

Hormone replacement therapy also exposes women to exogenous oestrogen and, in women who still have their uterus, progestogen may be added to reduce the risk of endometrial cancer. Early studies suggested that hormone replacement therapy did not significantly increase the risk of venous thromboembolism. More recently, however, clear evidence linking hormone replacement therapy and venous thrombosis has been published. For women using hormone replacement, the evidence is consistent in demonstrating a relative risk of venous thromboembolism that is 2–4 times that of non-users. The changes in haemostasis associated with hormone replacement therapy are similar in type and direction to those associated with combined oral contraceptive use but lesser in magnitude. There are as yet few published studies examining venous thrombosis risk in women with thrombophilia using hormone replacement. In one study, the relative risk of thrombosis showed significant associations with certain thrombophilic markers, including increased APC resistance, low antithrombin and low protein C. For hormone replacement users with abnormalities of haemostasis, the relative risks of venous thromboembolism were around 3.5–4.0 times the risk in non-hormone users with the same defect(s).

Pregnancy

Early studies suggested that in the absence of anticoagulant prophylaxis about 40% of pregnancies in antithrombin-deficient women may be complicated by venous thromboembolism. These studies were retrospective reports of events occurring in women who were already known to have antithrombin deficiency diagnosed, because either they personally or other family members had a history of venous thrombosis. They are therefore biased – the risk of thrombosis may have been overestimated. However, a study of 50 unselected, consecutive Glasgow women with a history of pregnancy-associated venous thromboembolism revealed that for type I antithrombin-deficient women, the risk of developing venous thrombosis associated with pregnancy is almost 40% – even in otherwise asymptomatic kindred (Table 53.5). In this study, the risk of pregnancy-associated venous thrombosis for women with type II defects was much lower, being about 2.5%.

The incidence of pregnancy-associated venous thromboembolism in women with protein C or S deficiency appears to be considerably less than that for antithrombin-deficient women. In the Glasgow study, only one protein C-deficient patient was found, suggesting a risk of only 1:113 (less than 1%) (see Table 53.5). No patients with protein S deficiency were found. The risk of pregnancy venous thrombosis was less than 1 in 350 (about 0.3%) for FV Leiden or FII G20210A heterozygotes (see Table 53.5) and the majority had additional acquired thrombosis risk factor. Other studies have confirmed that the risk of pregnancy-associated venous thromboembolism in heterozygous carriers of FV Leiden or FII G20210A is approximately five- to 10-fold that in non-carriers. The risk is significantly greater in homozygotes and in women doubly heterozygous for FV Leiden and FII G20210A.

Homocysteine levels fall during normal pregnancy. Folic acid supplements further lower homocysteine concentrations. The contribution of homocysteine levels to the risk of pregnancy-associated venous thrombosis is unclear but the C677T MTHFR mutation is not associated with an increased risk of pregnancy-associated thrombosis.

Venous thromboembolism is a rare but well documented complication of pharmacological ovarian stimulation in assisted conception protocols. Cases of venous thrombosis in women with heritable thrombophilias undergoing ovarian stimulation have been reported but, at present, the magnitude of the risk conferred

by prothrombotic mutations in these women is unknown. There is evidence that thrombophilia may increase the risk of fetal loss and other vascular complications of pregnancy such as intra-uterine growth restriction or pre-eclampsia. The data, however, remain controversial and further studies are necessary.

Case finding – who should be tested?

The high prevalences of FV Leiden and the prothrombin G20201A polymorphism have prompted a broad application of thrombophilia testing – not always appropriately. Thrombophilia screening has become commonplace in patients with a history of venous thrombosis. Detection of a heritable prothrombotic state may lead to screening of family members in an attempt to identify asymptomatic relatives who may be at increased risk of venous thromboembolism.

Clinicians tend to overestimate the risk of thrombosis associated with thrombophilias and to underestimate the risks associated with anticoagulation. Frequently, this has led to the belief that prophylactic anticoagulation is a safer option than clinical surveillance. As evidence about the risk of venous thrombosis associated with thrombophilias accumulates, it is becoming clear that for many patients this is not the case. Furthermore, there is often a lack of recognition that failure to identify a defect in an individual is not proof that no defect exists, only that the particular defects for which tests have been performed are probably not present. The patient with 'negative' test results may well have as yet unidentifiable prothrombotic abnormalities, which increase his or her risk of thrombosis. Reassuring patients with normal test results may constitute false reassurance, which may present a real risk for the patient if negative laboratory results lead to ignoring or underestimating the clinical history.

There is no evidence that the detection of a heritable thrombophilic defect is helpful in guiding clinical decision-making, in relation to either the choice of anticoagulant or to the intensity or duration of anticoagulant therapy to treat a venous thrombotic event. Although heparin resistance and thrombus progression are theoretical risks in antithrombin deficiency, retrospective data suggest that these are infrequent problems in clinical practice. In theory, warfarin-induced skin necrosis may complicate the introduction of coumarin therapy in subjects deficient in protein C or S if there is underanticoagulation with heparin when the oral agent is introduced, but, in practice, this is rarely a problem.

The management of deep vein thrombosis or pulmonary embolism in patients with heritable thrombophilia is in general no different from the management of venous thrombosis in any other patient. A target international normalized ratio (INR) of 2.5 is generally deemed to be appropriate for the management of a first acute venous thromboembolism. On standard anticoagulant therapy, major haemorrhage occurs at a rate of around 1% per year of treatment and one-quarter of these bleeds are fatal. For the patient without an identifiable thrombophilia, who has

had a first venous thrombotic event, the benefits of long-term treatment (more than 6 months) have not yet been shown to outweigh the risks. The risk of recurrence is not significantly increased in patients with the most prevalent defects (FV Leiden and the FII G20210A polymorphism). For these patients, therefore, management as for non-thrombophilic patients seems appropriate. Patients who have defects such as type I antithrombin deficiency or combinations of thrombophilias seem to be at additional risk of venous thromboembolism. The risk of recurrent events in such subjects is not known and they may merit a longer duration of anticoagulation.

Thrombophilia screening may be useful in decisions on the usefulness of primary prophylaxis in the presence of temporary risk factors in asymptomatic relatives in symptomatic families with identifiable thrombophilic defects. Identification of a thrombophilic defect may suggest prophylactic anticoagulation during surgery for relatives who are younger than the usual age at which prophylaxis is usually considered or prophylaxis to prevent pregnancy-associated thrombosis.

The increased risk of venous thrombosis associated with combined oral contraceptive use in patients with heritable thrombophilias has led to the suggestion that women should be screened for these defects (or at least the most prevalent defects) prior to prescription of a combined contraceptive pill. However, it has been estimated that if screening of the women was adopted and if advice to avoid oral contraceptives was given to all women carrying the FV Leiden mutation then more than 2 million women would need to be tested to prevent a single death from oral contraceptive-related pulmonary embolism each year – assuming that 1% of all venous thromboembolic events would be fatal. A greater number of non-fatal thromboses may be avoided but, as the combined pill is the most efficient form of contraception, it could be anticipated that additional pregnancies with their associated thrombotic risk would occur and negate any benefit.

Similarly routine screening of pregnant women for thrombophilic defects is not justifiable and may cause more harm than good, as finding a defect may precipitate unnecessary intervention with antithrombotics. In the UK and Europe, many clinicians recommend screening of women who have already suffered a thrombotic event, and many would advocate in addition screening personally asymptomatic women who give a family history of proven venous thromboembolism. Thrombophilia screening of these selected women may provide information useful in the assessment of the individual patient's overall venous thrombotic risk, in making decisions about their requirement for anticoagulation and the timing of its introduction. Antithrombotic prophylaxis may be considered post partum in asymptomatic carriers of the milder defects such as FV Leiden or the FII G20210A polymorphism, and should perhaps be offered to carriers of the more severe abnormalities such as antithrombin deficiency throughout pregnancy and the puerperium.

Thrombophilia testing is rarely indicated in children as it is unlikely to influence their management. Genetic testing should

be avoided in minors except in the very rare circumstance when the result is required to determine treatment.

Heritable abnormalities of haemostasis and arterial thrombosis

Arterial thrombotic diseases arise from two related processes – atherosclerosis and thrombosis. Atherosclerosis is a disease of the vessel wall, which results from chronic changes in vessel wall cellular phenotypes, occurring over a period of many years. Environmental risk factors for arterial disease including cigarette smoking, diet, abnormalities of lipid metabolism, elevated blood pressure and abnormalities of glucose metabolism are well established. Clinical symptoms are usually precipitated by thrombosis – an acute process thought to be triggered by tissue factor interaction with FVIIa, and almost certainly influenced by haemostatic factors such as fibrinogen, fibrinolytic factors and platelet reactivity. At present, there is considerable interest in the potential role of genetic changes in these and other components of haemostasis in the clinical expression of arterial thrombotic disease.

Coagulation abnormalities

Fibrinogen

Fibrinogen has been extensively studied in relation to arterial disease and elevated fibrinogen levels are consistently associated with myocardial infarction, stroke and peripheral arterial disease in prospective studies. An approximately twofold increased risk of myocardial infarction has been associated with elevated fibrinogen levels (> 3.4 mg/mL) compared with individuals with levels below this limit. A number of mechanisms to explain this association of increased fibrinogen with arterial disease has been postulated including increased viscosity, increased coagulation, increased availability for platelet adhesion and aggregation. However, it has also been suggested that elevated fibrinogen levels noted in patients with arterial disease may be effect rather than cause.

A number of polymorphisms in the three genes that code for fibrinogen polypeptide chains have been studied, including the BcII, Arg448Lys, −148C/T and −455G/A polymorphisms in the β-chain gene. In most studies, the −455G/A polymorphism was examined, and in most of them an influence of the polymorphism on the level of fibrinogen was observed either in patient or control plasma samples. Most studies confirm an association between the phenotype (elevated fibrinogen level) and disease, but only in one study have fully consistent associations between genotype, phenotype and myocardial infarction been reported. Other studies have failed to find an association between the genotype and coronary heart disease. Thus it would appear that if there is a causative relationship between fibrinogen genotype, plasma level and disease then it is very small.

Factor VII gene polymorphisms

Plasma factor VII (FVII) activity has been shown by some authors to be associated with an increased risk of myocardial infarction but others have failed to confirm this finding. A number of polymorphisms of the gene encoding FVII have been described, including an insertion of a decanucleotide at position 323 and a substitution of glutamine for arginine at position 353, which is associated with a 20–25% reduction in the plasma concentration of FVII. Some studies have reported that the risk of myocardial infarction is lower in patients with the 353 arginine allele than in patients with the glutamine allele. Others, however, although confirming that FVII levels are lower in patients with the arginine allele, did not find a difference in the genotype frequency between patients with myocardial infarction and control subjects. No link between FVII polymorphisms and stroke has been reported and there is no evidence of an association with venous thrombosis. Thus, as with fibrinogen, if there is an effect of the FVII polymorphism on disease it is small.

Heritable thrombophilias

Although a few case reports have suggested a possible link between inherited deficiency of antithrombin, protein C or S and a risk of arterial thrombosis, there is no convincing evidence. Endothelial cell protein C receptor (EPCR) is found predominantly on the endothelium of large vessels and may be important in enhancing protein C activation in these vessels. It has been suggested that the presence of high levels of EPCR on arterial vessels may help to explain why inherited protein C deficiency appears not to constitute a significant risk of arterial thrombosis.

The roles of FV Leiden and the FII G20210A polymorphisms in arterial disease have been the subject of a large number of reports with inconsistent outcomes. The majority have been negative but some studies have reported positive associations, particularly when highly selected patient populations have been studied and when the interaction of these polymorphisms with environmental factors has been evaluated. In a prospective study, the prevalences of FV Leiden heterozygosity in men who had a myocardial infarction and in men who suffered a stroke were similar to that in male control subjects who had no vascular events but, in another large case–control study of men with myocardial infarction, a small increase in the risk of myocardial infarction was associated with both FV Leiden and the FII G20210A polymorphism. The risk associated with these polymorphisms is amplified in the presence of other coronary heart disease risk factors such as smoking and metabolic risk factors.

In a study of young women with a history of myocardial infarction, compared with non-smoking non-carriers, young women carriers of FV Leiden or the FII G20210A polymorphism who smoked had a significantly increased risk of myocardial infarction. On balance, it would appear that FV Leiden and the

FII G20210A polymorphism increase slightly the risk of arterial thrombosis in young patients who have other additional risk factors for arterial thrombosis.

Although the phenotype (hyperhomocysteinaemia) is associated with an increased risk of arterial thrombotic disease, the results of studies investigating a link between the C677T MTHFR mutation and myocardial infarction have produced conflicting results. The consensus, however, would appear to be that the mutation does not constitute a significant risk factor for myocardial infarction or stroke.

Fibrinolytic system abnormalities

Plasminogen activator inhibitor-1

Plasminogen activator inhibitor-1 (PAI-1) is the major inhibitor of tissue plasminogen activator (tPA). There is evidence that increased PAI-1 levels are associated with atherosclerotic progression and myocardial infarction risk, but it remains to be proven that PAI-1 is an independent risk factor for cardiovascular disease. A single gene on the long arm of chromosome 7 encodes PAI-1. Several polymorphisms in this gene have been described including a *Hind* III site at the 3′-region of the gene, a CA dinucleotide repeat in intron 3, and a single nucleotide insertion/deletion (4G/5G) – 675 basepairs (bps) upstream from the start of the transcription site. The 4G allele is associated with higher PAI-1 levels than the 5G allele, particularly in patients with elevated triglyceride levels.

Following an early report that the 4G allele might be associated with myocardial infarction support for an association between this allele and coronary heart disease has been obtained. However, there are reports from several well designed studies that PAI-1 polymorphisms have not been found to be associated with myocardial infarction or coronary artery disease and there are no studies that confirm a consistent association between genotype, phenotype and disease. Collectively, the results of the various studies do not appear to support an important role for PAI-1 genotypes in ischaemic heart disease but in a prospective study of 12239 women followed up for 18 years, the 4G/4G homozygotes had a reduced risk of cerebrovascular mortality compared with 5G/5G homozygotes.

Tissue plasminogen activator

An increased risk of myocardial infarction has been found in individuals with elevated levels of tissue plasminogen activator (tPA). The polymorphism that has been studied most in respect of cardiovascular disease is the Alu-repeat insertion/deletion (I/D) polymorphism within the intron between exons 8 and 9. However, to date, a relationship between this polymorphism and elevated tPA levels has not been established, and no association has been found in patients selected for a family history of cardiovascular disease.

Neither tPA nor PAI-1 levels has been found to be associated with increased venous thrombotic risk.

Platelet membrane glycoprotein abnormalities

Glycoprotein IIb/IIIa

Glycoprotein (Gp) IIb/IIIa, a member of the integrin family, plays a key role in platelet aggregation and activation. It is the primary receptor for fibrinogen and also binds von Willebrand factor fibronectin and vitronectin. The genes encoding glycoproteins IIb and IIIa lie close to each other on chromosome 17.

The PLA1/PLA2 polymorphism results in a substitution of proline for leucine at position 33 in the GpIIIa ($\gamma3$) subunit of the GpIIb/IIIa. Around 25% of white persons carry the PLA2 allele and 2% are PLA2 homozygotes. The HPA-3a/3b GpIIb polymorphism results in substitution of serine for isoleucine at position 843.

Most studies have failed to find an association between the PLA1/PLA2 polymorphism and myocardial infarction, but some have reported a weak positive association in young patients. An increased risk of coronary stent thrombosis in PLA2 patients has been reported but other studies have not confirmed this finding. There is no evidence that the PLA2 allele increases the risk of stroke or venous thrombosis. The clinical relevance of the GpIIb polymorphism HPA-3 remains unclear but it appears not to increase the risk of stroke.

Glycoprotein Ia/IIa

This collagen receptor consists of an α_2- and a γ_1-polypeptide and is expressed at low density on the platelet surface. Two linked silent dimorphisms, 807 cytosine to thymine (Phe224) and 873 guanine to adenine (Thr246) within GpIa gene have been described. An association between the receptor density and these polymorphisms has been reported; individuals homozygous for the 807C/873G allele having low receptor density and individuals homozygous for the 807T/873A allele high receptor density and thus enhanced platelet binding to collagen. An increased risk of myocardial infarction in patients with the homozygous 807T/873A genotype has been described but other studies have not confirmed this link. The 807T/873A allele has been found to be associated with stroke in young patients.

Glycoprotein 1b/IX/V

This complex is a combination of four glycoprotein chains: GpIbα, GpIbβ, GpIX and GpV. Interest has centred on a polymorphism of the GpIbα with four polymorphic forms A, B, C and D and a cytosine-to-thymine change at position 3550, which results in a Thr145Met substitution, the latter part of the HPA-2 alloantigen system.

The C/B genotype has been associated with increased risk and stroke. A few studies found associations between Thr145Met and coronary artery disease but other studies have been negative with respect to myocardial infarction or ischaemic heart disease. Similar results have been found in studies of cerebrovascular

disease – some suggesting a positive association and others reporting no association. No association between these polymorphisms and venous thrombosis has been found.

Other candidate genetic risk factors for thrombosis

It is likely that there are yet unidentified heritable abnormalities of haemostasis associated with an increased risk of thrombosis. Some additional candidates such as heparin cofactor II deficiency and deficiencies of histidine-rich glycoprotein have been studied. However, none has been demonstrated conclusively to contribute to heritable thrombophilia.

Thrombomodulin and endothelial cell protein C receptor

Thrombomodulin is a receptor for thrombin on the endothelial cell surface of most blood vessels. Thrombin-bound thrombomodulin activates protein C to form APC, which inhibits thrombin generation by degrading FVa and FVIIIa. On binding to thrombomodulin, thrombin loses its procoagulant properties (fibrinogen clotting, platelet activation and the activation of FV and FVIII). Thus, thrombomodulin plays a key role in the conversion of thrombin from a procoagulant to an anticoagulant.

Identifying individuals with a thrombomodulin deficiency phenotype is problematic. Leucocyte proteases cleave off a large extracellular portion of thrombomodulin generating soluble thrombomodulin (sTM), which is composed of a variety of molecular species. The physiological function of sTM is unclear. A large prospective study of ischaemic heart disease and atherosclerosis in the community (ARIC Study), however, found an inverse relationship between sTM levels and the risk of ischaemic heart disease.

The thrombomodulin gene is located on chromosome 20. Three polymorphisms in the gene: Ala455Val and Ala25Thr in the coding region and –33 G/A in the vicinity of the promoter have been described but no association of these polymorphisms with thrombotic disease has been consistently reported.

Endothelial cell protein C receptor

The endothelial cell protein C receptor (EPCR) presents protein C to the thrombin–thrombomodulin complex on the surface of endothelial cells and results in increased activation of protein C. A 23-bp insertion in the gene for EPCR, prevalent in Italians, has been shown to be weakly associated with myocardial infarction.

Protein C inhibitor

Protein C inhibitor (PCI), also known as plasminogen activator inhibitor-3, is a serine proteinase inhibitor that inhibits enzymes in blood coagulation, fibrinolysis and fertility. By virtue of inhibiting thrombin, FXa and FXIa, it has an anticoagulant effect; by inhibiting APC and thrombin–thrombomodulin (preventing activation of protein C), it has an anti-anticoagulant effect; by inhibiting tissue type and urokinase type plasminogen activators it has and antifibrinolytic activity and by inhibiting thrombin–thrombomodulin activation of thrombin-activatable fibrinolysis inhibitor (TAFI), it has anti-antifibrinolytic activity. Most of the inhibitory functions are enhanced in the presence of heparin or other glycosaminoglycans. Despite all of these identified activities, the physiological role of PCI is unknown and although and association between high PCI levels and increased venous thrombosis risk has been postulated, this awaits confirmation.

Tissue factor pathway inhibitor

The principal inhibitor of the FVII-tissue factor pathway is the tissue factor pathway inhibitor (TFPI), which binds and inhibits FXa thereafter forming a larger quaternary complex with FVIIa, tissue factor and calcium. A single nucleotide substitution in exon 7 (536 cytidine to thiamine) leading to a proline to leucine exchange at position 151 has been described. It has been suggested that this mutation is more prevalent in patients with venous thrombosis than in control subjects but other studies have failed to confirm this finding. No increased risk of stroke has been found in carriers of the TFPI C536T mutation.

Protein Z deficiency

Protein Z (PZ) is a vitamin K-dependent plasma protein that acts as a cofactor for the inhibition of FXa by protein Z-dependent protease inhibitor (ZPI). Protein Z-dependent protease inhibitor is a member of the serpin family of proteinase inhibitors. Protein Z circulates in plasma in complex with ZPI. Inhibition of FXa by ZPI in the presence of phospholipids and calcium is enhanced approximately 1000-fold by PZ. Protein Z, like protein S, does not in itself have proteolytic activity.

Warfarin therapy reduces both PZ antigen levels and the degree of gamma carboxylation much more than the other vitamin K-dependent factors. *In vitro* and *in vivo* studies suggest that PZ is important in dampening coagulation. Based on data from murine gene deletion modules it has been suggested that PZ deficiency may be a modest thrombotic risk factor in humans. It has been suggested that concomitant PZ deficiency may reduce the age of onset and increase the risk of venous thrombosis in patients with FV Leiden.

Plasminogen

Case reports have suggested that hypoplasminogenaemia and dysplasminogenaemia may be associated with venous thromboembolism but this association has not been confirmed in case–control studies.

Factor XII

Although *in vivo* FXII seems to be of minimal importance for blood coagulation, it may play a role in the fibrinolytic system by enhancing the release of tPA. It has been suggested that FXII may be a risk factor for venous thromboembolism but this has not been confirmed.

Factor XIII – a protective mutation

The main function of factor XIII (FXIII) is the formation of stable cross-linked fibrin and deficiency of FXIII is associated with severe bleeding. A number of polymorphisms in the FXIII gene have been described, especially in the A subunit; there, the $G \rightarrow A$ transition in exon 2 causes a valine to leucine change at position 34, which has been most extensively investigated. *In vitro* studies have shown that FXIII containing 34Leu is activated more rapidly by thrombin, with a twofold increase in catalytic efficiency. As a result, the structure of the fibrin is altered and fibrin formed in the presence of this mutation has reduced mass–length ratio and porosity.

The FXIII Val341Leu polymorphism is significantly less common in patients with coronary heart disease than in control subjects. A protective effect of this transition for venous thromboembolism has also been demonstrated.

Acquired venous thrombosis

54

Beverley J Hunt and Michael Greaves

Introduction

Deep vein thrombosis is common, principally affecting the lower limbs. In many populations the annual incidence is around 1 per 1000 of the population. However, the disorder is highly age dependent. For example, it is exceptional in childhood; in young adults the incidence is of the order of 1 per 10 000 of the population each year, and it may reach 1% per year in the very elderly. The incidence of pulmonary embolism is lower, possibly around 1 per 3000 of the population annually, although subclinical pulmonary embolism occurs frequently in subjects with lower limb proximal deep vein thrombosis. In patients who die in hospital, there is evidence of pulmonary embolism in up to 20% of cases and in many it contributes to the cause of death. Clinically apparent pulmonary embolism occurs rarely when deep vein thrombosis is confined to calf veins but, if untreated, calf vein thrombosis propagates to proximal veins in around 20% of cases, with an accompanying risk of significant pulmonary embolism. In occasional cases, pulmonary embolism presents without identifiable deep vein thrombosis.

Deep vein thrombosis is important because of the associated acute morbidity and risk of fatal pulmonary embolism, and also because of the potential long-term sequelae. These are a high risk of recurrent thrombosis and of development of chronic post-phlebitic symptoms. The risk of recurrence after a first episode of apparently unprovoked proximal deep vein thrombosis of a lower limb is around 25% during the 5 years after discontinuation of oral anticoagulant therapy. However, the risk is considerably lower when the first event is precipitated by a transient risk factor, such as a surgical procedure. When the first episode affects the deep veins, the symptoms of recurrence are most commonly those of deep vein thrombosis also. Similarly, recur-

rence after a first episode of pulmonary embolism is typically with pulmonary symptoms.

Chronic post-phlebitic symptoms in the leg range from minor itching and swelling to intractable ulceration. Some degree of post-phlebitic syndrome is present in around 30% of sufferers of previous lower limb deep vein thrombosis. It is most frequent and severe after recurrent thrombosis and uncommon after deep vein thrombosis confined to the calf vessels.

Vessels other than the deep veins of the limbs may be affected by thrombosis, including superficial limb veins, the intracranial venous sinuses and visceral veins. The pathogenesis of superficial thrombophlebitis may differ from that of deep vein thrombosis. Thrombosis of retinal veins appears also to have a different pathogenesis and natural history.

As described in the preceding chapter, venous thromboembolic episodes result from the interaction of multiple risk factors. These may be gene–environment interactions or multiple environmental or acquired risk factors (Table 54.1). In this chapter, the acquired conditions that predispose to venous thromboembolism are considered, although in most cases it is likely that the individual genotype influences the likelihood of thrombosis in particular circumstances.

Pregnancy and venous thromboembolism

Around 1 in 1000 pregnancies is complicated by deep vein thrombosis or pulmonary embolism. Massive pulmonary embolism is the leading cause of pregnancy-related death in the UK. Although the post-partum phase has been considered to be the time of highest risk, overall at least as many episodes of venous thromboembolism (VTE) occur ante partum, including some in

Table 54.1 Causal factors in acquired venous thromboembolism.

Inevitable/environmental	Iatrogenic	Disease related
Increasing age	Post-operative/immobilization	Antiphospholipid syndrome
Pregnancy and post partum	In-dwelling venous devices	Cancer, including: myeloproliferative diseases, acute promyelocytic leukaemia
Immobility, e.g. long-haul travel	Pharmacological:	Inflammatory states
Dehydration	• Oestrogen related: combined oral contraceptive, hormone replacement therapy, tamoxifen	Other haematological disease: paroxysmal nocturnal haemoglobinuria, thrombotic thrombocytopenic purpura, sickle cell disease
	• Chemotherapy, heparin, haemostatic treatments	Intravenous drug abuse

the first trimester. There are notable clinical features in pregnancy-related deep vein thrombosis: around 90% of thromboses affect the deep veins of the left lower limb and the vast majority of cases involve the iliofemoral veins from the time of presentation; thrombosis restricted to the deep veins of the calf is uncommon in pregnancy. The left-sided predominance most likely relates to the anatomical relationship between the iliac artery and vein on that side. Many of the women develop post-phlebitic syndrome.

The pathogenesis of pregnancy-related VTE is multifactorial, as in other situations. Unique features include the raised intra-abdominal pressure and vascular compression caused by the gravid uterus, suppressed systemic fibrinolytic capacity and the progressive increase in plasma concentrations of clotting factors from around 10 weeks' gestation, including factor VIII and fibrinogen. Tissue trauma from delivery contributes to the pathogenesis of post-partum VTE and operative delivery increases the risk further.

Although the heritable thrombophilic conditions that are identifiable at present contribute to the risk of pregnancy-related VTE, in around 70% of cases no hereditary thrombophilia can be identified and in 25% there is also no obvious risk factor other than otherwise normal pregnancy.

Immobility as a risk factor for venous thromboembolism

It is likely that venous stasis is a significant pathogenetic factor in VTE. It probably contributes to post-operative thrombosis and is a factor in deep vein thrombosis in paralysed limbs and that associated with splinting, for example in a plaster cast.

There has been considerable interest in the relationship between VTE and the physically cramped conditions encountered during travel, especially long-haul aeroplane journeys. The term *economy class syndrome* has been coined to encompass the occurrence of VTE during and after air travel. Although the true level of risk has not been established, observational data indicate that the incidence of death from pulmonary embolism induced by

air travel is less than one in a million journeys. The duration of the flight is a factor, with some evidence that VTE risks begin to increase progressively with flight time of greater than 4 or 5 h. The elderly appear to be at greater risk. The contribution of the particular environmental conditions within a pressurized cabin, including hypobaric hypoxia and a dry atmosphere, to hypercoagulability is now the subject of investigation. At present it is reasonable to assume that any form of long-distance motorized travel carries a low but increased risk of VTE and to recommend simple precautionary measures such as maintenance of hydration and calf exercises and ambulation in order to maintain venous flow in the lower limbs.

Iatrogenic venous thromboembolism

Venous thromboembolism is common in hospitalized subjects, despite the widespread adoption of physical and pharmacological methods of thromboprophylaxis. As indicated above, immobility is probably a significant contributory factor. In post-operative patients, the procoagulant responses to tissue trauma, such as increased fibrinogen and factor VIII concentrations in plasma and reactive thrombocytosis, may also play a part. The highest prevalence of VTE occurs in major orthopaedic surgery to the lower limb. In hip replacement and knee replacement surgery, subclinical deep vein thrombosis is detectable by imaging in up to 50% of cases, although there is some evidence that clinically significant VTE may be becoming less common owing to improvements in surgical techniques and materials, as well as wider use of thromboprophylaxis.

Indwelling venous devices, such as Hickman catheters, are a significant cause of deep venous thrombosis, which may progress to complete occlusion of the superior vena cava, for example. Up to 60% of patients with central venous catheters (CVCs) will develop a complication secondary to the device, thrombosis being one of the most common. Thrombosis associated with a CVC may involve the catheter tip, the length of the catheter, the catheterized vessel in the upper limb, the central vasculature of the neck/mediastinum or a combination of these. A higher

incidence of thrombosis is seen in catheters with a larger external diameter and those with a tip positioned distal to the superior vena cava. Other factors that predispose to a higher rate of catheter-related thrombosis include catheter infection, infusion of sclerosing chemotherapeutic agents, extrinsic vessel compression and a previous history of venous thromboembolism.

Patients with CVC-related thrombosis may present with swelling and or pain of the arm, neck or face. Some may present with symptoms suggestive of a pulmonary embolism or with catheter malfunction. Many of the symptoms are non-specific and for this reason, objective testing is needed. Contrast venography remains the reference standard for diagnosis of CVC-related thrombosis but this is invasive and may be painful. Ultrasonography is the most accurate non-invasive test with a sensitivity and specificity of 93% and 95% respectively. Treatment of central venous catheter-related thrombosis remains poorly studied. There are several treatment options available: anticoagulation alone, systemic thrombolysis, low-dose local thrombolysis and catheter removal or any combination of the above. Systemic thrombolysis may cause bleeding and should be avoided. There is some evidence that low-dose warfarin and low-molecular-weight heparin reduce the incidence of thrombosis in adults with cancer and indwelling venous catheters. Almost all episodes of VTE in neonates are provoked by indwelling vascular devices.

Iatrogenic VTE may be due to pharmaceuticals and VTE associated with use of the *combined oral contraceptive* is of particular importance because it affects healthy women in a young age group. The overall relative risk of VTE in a pill user is around four- to fivefold higher than in a non-pill user, although this is influenced greatly by the presence of some heritable thrombophilias as described in the previous chapter. The risk is also increased by obesity and older age. Fortunately, the absolute risk remains acceptable because of the low background prevalence of thrombosis in women of child-bearing age. It is around 10 to 20 episodes per 100 000 exposed woman-years. Oestrogen-containing preparations induce a state of reduced sensitivity to activated protein C, and this appears to be more marked with the third-generation contraceptives than second-generation preparations. (Most preparations in use at present contain an equivalent dose of oestrogen, usually 30–35 μg of ethinyloestradiol. However, the progestagen content varies. In so-called second-generation oral contraceptives, this is levonorgestrel, whereas in third-generation products it is desogestrel, gestodene or norgestimate.) There is convincing epidemiological evidence that the third-generation pills carry a greater risk of clinical VTE also, although this has been disputed. Progestagen-only oral contraceptives appear to carry a lower risk of VTE such that their use can be considered in women in whom the combined oral contraceptive is deemed to be contraindicated.

Hormone replacement therapy (HRT) use is also associated with VTE. In this case, the absolute risk is higher due to the greater background prevalence of VTE in older women. Observational data indicate a very high rate of VTE in women with a previous history of venous thrombosis who embark subsequently upon HRT. Such is the level of risk that HRT is contraindicated in such women. If there are overwhelming indications for HRT (usually disabling menopausal symptoms), some clinicians consider warfarin thromboprophylaxis alongside HRT in high-risk situations. Also, the procoagulant changes induced by transdermal preparations appear to be less marked, suggesting that they may be less likely to provoke VTE than oral formulations.

Use of *chemotherapeutic agents* and adjunctive therapies in malignancy has been linked to VTE. Notable examples are asparaginase in acute lymphoblastic leukaemia, thalidomide in myeloma and tamoxifen in breast cancer. Tamoxifen blocks oestrogen receptors but has weak oestrogenic activity and this may underlie the association with VTE. Asparaginase inhibits protein synthesis and markedly reduced plasma concentrations of antithrombin may be one mechanism of the prothrombotic state associated with its use. The pathogenesis of thrombosis associated with thalidomide has not been elucidated. It appears to be associated particularly with use of the agent in myeloma, rather than other indications.

Heparin-induced thrombocytopenia is an important diagnosis because failure to recognize the syndrome carries a high risk of death from associated venous or arterial thrombosis. It is due to development of antibodies to a complex of heparin and platelet factor 4, which induce intravascular platelet activation and consumption. Typically, the platelet count begins to fall between 5 and 10 days after first exposure to heparin. In subjects with recent exposure, it may occur earlier and, very occasionally, the thrombocytopenia develops after heparin has been discontinued. The condition may complicate heparin administered at any dose, including that used as peri-operative thromboprophylaxis and even when very low doses are used to maintain the patency of intravascular cannulae. Heparin-induced thrombocytopenia is around 10-fold less common with low-molecular-weight preparations than with unfractionated heparin, and has not been reported with the synthetic pentasaccharide, fondaparinux. In contrast with other drug-related immune thrombocytopenias, the degree of thrombocytopenia is rarely severe and bleeding is not a feature. There may be systemic symptoms including fever and a local reaction at the heparin injection site, such as erythema or even skin necrosis after subcutaneous administration. Because of the platelet activation there is often new thrombosis, and this may manifest before the platelet count reaches thrombocytopenic levels.

When heparin has been administered to treat arterial disease, the new thrombosis is most commonly arterial, and in treatment of deep vein thrombosis there is usually extension of the presenting thrombus, often with pulmonary embolism. Thrombotic stroke, myocardial infarction, visceral ischaemia and disseminated intravascular coagulation have all been reported.

Confirmatory laboratory tests are not entirely satisfactory. Immunoassays for heparin/platelet factor 4 are sensitive but lack

specificity because a significant proportion of subjects treated with heparin have positive antibody tests but neither thrombocytopenia nor thrombosis. In contrast, bioassays that rely on activation of normal platelets in the presence of test plasma and a low concentration of heparin are specific, but high sensitivity is difficult to achieve. Sensitivity is improved by use of platelet serotonin secretion as an end-point and employment of donor platelets of proven sensitivity. Specificity is achieved by the demonstration of a positive result with a low heparin concentration, which is absent in the presence of a high concentration. Because of the limitations of these confirmatory tests monitoring of the platelet count and a high index of clinical suspicion are essential whenever heparin is administered.

When there is a noteworthy fall in the platelet count that cannot be accounted for in any other way then heparin, in all forms, must be discontinued. An alternative anticoagulant must be administered immediately as the risk of thrombosis persists for several days after heparin withdrawal. Warfarin given alone is contraindicated as massive thrombosis has been described in this situation, most likely due to the rapid fall in protein C caused by warfarin against a background severe prothrombotic state. Aspirin is insufficient. The antibody may cross-react with low-molecular-weight heparins and they should be avoided. Danaparoid is a mix of anticoagulant glycosaminoglycans, predominantly heparan sulphate and dextran sulphate. There is a significant risk of cross reactivity with the HIT antibody *in vivo*, which may not be predicted by *in vitro* testing, and for this reason its use is no longer recommended.

The anticoagulant of choice is lepirudin, and warfarin can be introduced once an adequate anticoagulant effect with the thrombin inhibitor has been established. The pathogenetic antibodies tend to become immeasurable in the ensuing few months

but further exposure to heparin after this time should be avoided if possible.

Haemostatic treatments may induce thrombosis, most notably prothrombin complex concentrates. They should not be used to reverse the coagulopathy in severe liver impairment as major thrombosis has been reported, with disseminated intravascular coagulation and death in some cases. This is probably due to impaired clearance of activated clotting factors in liver failure.

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is an important thrombophilic condition because it is of high prevalence and is associated with considerable morbidity and mortality.

The essential features are arterial or venous thrombosis or recurrent pregnancy loss or placental dysfunction occurring in a subject in whom laboratory tests for antiphospholipid antibody (aPL) are positive. Diagnostic criteria have been established (Table 54.2) in order to standardize diagnosis for the purpose of clinical studies.

Limb deep vein thrombosis, pulmonary embolism and ischaemic stroke are the principal thrombotic manifestations, but any vessel may be involved. A characteristic of antiphospholipid syndrome in an individual patient is the tendency to cause recurrent problems in the same vascular bed. APS is not always a 'full house' syndrome, in that women can have severe thrombotic events without pregnancy complications and those with pregnancy complications most commonly have no other manifestation. In addition to thrombosis and pregnancy failure, additional clinical and laboratory features are variably present in APS. These include mild thrombocytopenia and an unusual

Table 54.2 Diagnostic criteria in antiphospholipid syndrome.

Clinical criteria*	Laboratory criteria*
Thrombosis	
Arterial, venous or microvascular thrombosis in any tissue or organ	IgG and/or IgM aCL antibodies at moderate or high concentration[†]
	Lupus anticoagulant
Pregnancy complications	
Unexplained death of morphologically normal fetus at or beyond 10 weeks' gestation	
Three or more unexplained consecutive miscarriages before 10 weeks	
One or more premature births of a morphologically normal fetus before 34 weeks' gestation due to pre-eclampsia, eclampsia or severe placental insufficiency	

*There must be at least one clinical and at least one laboratory criterion present. The laboratory test must be consistently positive on at least two occasions 6 weeks apart, as transient antibodies may occur, for example in infection. Such antibodies are not usually associated with clinical events.

[†]There is no consensus on the definition of moderate/high concentration. In general, values of IgG aCL of > 30 or 40 GPL units are considered to be moderate-titre antibodies. The significance of low-titre antibodies is less clear.

dermatological feature – livedo reticularis. Cardiac valvular abnormalities occur in up to 30% of patients. Usually the mitral or aortic valves are affected and have mild thickening or incompetence. However, haemodynamic changes as a consequence of valvular damage are rare. Exceptionally, the syndrome may manifest as widespread microvascular occlusion, with multiorgan failure, so-called 'catastrophic APS'.

APS may occur with another chronic systemic autoimmune disease, usually systemic lupus erythematosus (SLE), when the term *secondary antiphospholipid syndrome* is used. In primary APS, there is no evidence for another relevant underlying condition.

Antiphospholipid antibodies

Antiphospholipid antibodies (aPLs) are a family of antibodies reactive with proteins, which are themselves complexed with negatively charged phospholipid. For example, many aPLs require β_2-glycoprotein I (β_2-GPI), a phospholipid-binding plasma protein with weak anticoagulant activity, for binding to acidic phospholipids such as phosphatidyl serine and cardiolipin. The relationships between β_2-GPI, phospholipid and autoantibody are disputed. One possibility is that cryptic epitopes are exposed on β_2-GPI when it binds to phospholipid (Figure 54.1a). It is more probable that binding to phospholipid allows the clustering of antigenic sites and facilitates bivalent antibody interaction of what are essentially low-affinity antibodies (Figure 54.1b). The plastic of an enzyme-linked immunosorbent assay (ELISA) plate can substitute for negatively charged phospholipid in this reaction and this has allowed the development of new, possibly more specific assays for aPL, which employ purified β_2-GPI. Other proteins share this property of binding to phospholipid in a manner that promotes interaction with aPL. These include the coagulation factor prothrombin, the anticoagulant protein C and its cofactor protein S, and annexin V (previously known as placental anticoagulant protein).

The lupus anticoagulant (LA) is an *in vitro* phenomenon in which the antiphospholipid antibody slows down clot formation, thereby lengthening the clotting time. This is probably due to impairment of the assembly of the components of prothrombinase on phospholipid caused by interference by the antibody (Figure 54.1c).

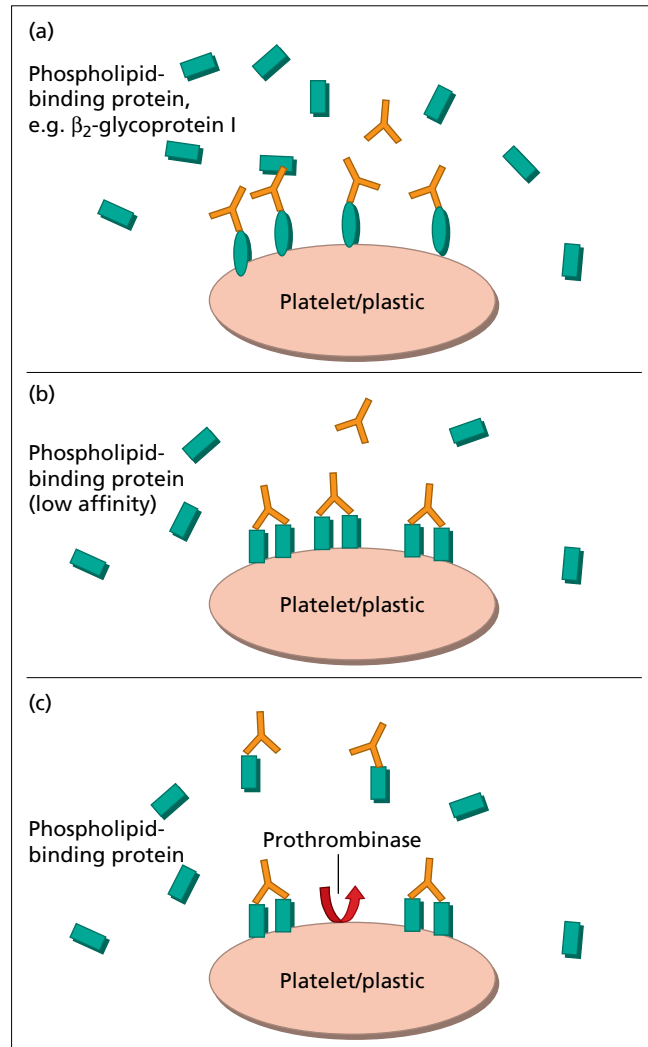
LA is due to antibodies reactive to β_2-GPI phospholipid or to prothrombin/phospholipid. The β_2-GPI-dependent antibodies also bind in anticardiolipin (aCL) assays, as the glycoprotein is present in test serum and often in assay reagents. LA due to prothrombin-reactive antibodies may be negative in aCL assays. Therefore, some subjects with APS have LA and aCL and some LA only. Others have aCL without LA, due to the presence of non-β2 GPI and non-prothrombin-dependent antibody or possibly to relative insensitivity of the coagulation assays for LA. Because aPLs are so heterogeneous, a comprehensive laboratory approach is essential for their reliable detection. In most


Figure 54.1 aPL binding. (a) Exposure of cryptic epitopes; (b) antigen clustering and bivalent binding; (c) explanation for the LA phenomenon.

laboratories, ELISAs employing cardiolipin and coagulation-based assays for LA remain the principal diagnostic tools. β_2-GPI ELISA may offer improved specificity but the practical value of this assay has not yet been established and it is not included in the standardized diagnostic criteria. The pathogenicity of immunoglobulin A (IgA) aCL antibodies is disputed and, again, their detection is not utilized in diagnosis.

Pathogenetic mechanisms in antiphospholipid syndrome

The pathogenesis of pregnancy failure and thrombosis in APS is not fully understood. Whether antibodies to β_2-GPI/phospholipid are causal is unproven. It is unlikely that a single mechanism accounts for the multiple clinical manifestations.

Important candidate mechanisms for thrombosis are antibody-induced concentration of prothrombin on phospholipid surface *in vivo* resulting in enhanced thrombin generation, interference with the activated protein C anticoagulant pathway and increased monocyte and endothelial tissue factor expression. Increased platelet activation and inhibition of fibrinolysis by aPLs have also been proposed. Also, antibodies reactive with cellular antigens, including some on platelets and vascular endothelial cells, frequently co-exist with antiphospholipid antibodies. Endothelial antibodies activate endothelial cells *in vitro*. It is also possible that, in some situations, antiphospholipid antibodies may represent an epiphenomenon in thrombotic disease due to another pathological process.

Whether aPLs have a pathogenetic role in pregnancy failure is unproven, although some animal studies support this view. Placental dysfunction is the hallmark of second- and third-trimester complications of intrauterine fetal death, intrauterine growth restriction, pre-eclampsia and placental abruption. The aetiology of the placental dysfunction has been related to placental infarction and an acute atherosis in the maternal spiral arteries; however, these are not universal features. One interesting hypothesis for the cause of placental insufficiency is displacement of annexin V from trophoblast by aPLs, with resultant acceleration of thrombin generation on the exposed negatively charged phospholipid. First-trimester loss has been related to *in vitro* inhibition of trophoblast proliferation by antiphospholipid antibodies.

Laboratory diagnosis of antiphospholipid antibodies

In the diagnosis of APS it is essential to consider that aPLs are not specific to APS. In addition to transient antibodies which may, for example, be triggered by intercurrent infection some chronic infections are associated with aPLs, such as syphilis and hepatitis C. aPLs may also be detected incidentally in healthy subjects and they occur in relation to use of some drugs, particularly chlorpromazine. These drug-induced and infection-related antibodies do not appear usually to be associated with the clinical thrombotic manifestations of APS. In some cases they appear to be neither β_2-GPI nor prothrombin dependent.

The diagnosis of APS relies on the demonstration of the presence of either LA by coagulation tests, or aPL by solid-phase immunoassays. The latter typically employ cardiolipin as antigen (aCL assays). Reliance on just one type of assay may lead to false-negative aPL assessments.

Coagulation assays (lupus anticoagulant tests)

The LA assay is a double misnomer for it is neither a test for lupus nor an *in vivo* anticoagulant. LA tests are indirect assays that rely upon the slowing of the clotting time of plasma through interaction of the autoantibody with phospholipid. The tests most frequently employed in LA testing are the activated partial thromboplastin time (APTT), the dilute Russell's viper venom time (DRVVT) and the kaolin clotting time (KCT).

Platelet activation causes exposure of negatively charged phospholipid at the cell surface and therefore contamination of test plasma with platelets must be minimized, as these will limit the sensitivity of tests, particularly when plasma must be stored frozen prior to testing. Platelet depletion may be achieved in various ways, most commonly by careful double centrifugation.

None of the above coagulation assays is specific for LA. Specificity and sensitivity are reagent dependent also. For example, some partial thromboplastin reagents are insensitive to LA. If the same reagent is employed in LA testing as in the routine laboratory screening APTT sensitivity to LA must be assured. Factors that lengthen or shorten clotting times (other than aPL) potentially interfere in LA tests. Examples are anticoagulant drugs and clotting factor deficiencies and inhibitors, which lengthen clotting times and increased clotting factor levels, especially factor VIII, which shortens the time to clotting in some assays, potentially masking the presence of LA.

To reduce the risks of false interpretation, in addition to prolongation of clotting time in a phospholipid-dependent coagulation test, the criteria for LA positivity also include:
• evidence of an inhibitor demonstrated by mixing studies;
• confirmation of the phospholipid-dependent nature of the inhibitor.

In principle, the laboratory tests should employ a detection or screening stage (prolongation of the clotting time) and a confirmation stage (failure of correction of the prolongation when normal plasma is added, to exclude factor deficiency as the cause of the prolongation, and demonstration that the prolongation is phospholipid dependent, for example by showing that addition of excess phospholipid corrects the clotting time). To achieve this, and because no LA test consistently shows 100% specificity and sensitivity, more than one test system should be used for detection of LA. The prothrombin time and thrombin time should be performed also as they are not usually affected by the presence of LA and the results assist in the interpretation of LA tests, for example when there is undisclosed anticoagulant therapy.

The APTT is employed commonly as the initial screening test for LA. Its specificity for inhibitor detection is improved by inclusion of a mixing study with platelet-free normal pooled plasma. When prolongation of the APTT is due to coagulation factor deficiency, the clotting time corrects when the test is repeated on an equal mixture of patient and normal plasma, whereas the prolongation above normal may persist with LA, consistent with its inhibitory activity. Correction in a mixing study does not exclude LA however as a weak antibody is of course diluted out by addition of normal plasma and this may be sufficient to abolish its effect. Very occasionally LA causes enhancement of the prolongation of the APPT when normal plasma is added. This phenomenon has been called the *lupus cofactor effect* but is the exception rather than the rule. Inhibitors

to clotting factors, usually factor VIII, are associated with bleeding rather than thrombosis, but also cause prolongation of the clotting times, which may not be corrected by addition of normal plasma. Factor VIII inhibitors are time dependent, typically and unlike LA. A normal APTT is insufficient to exclude LA and additional tests must be performed.

The DRVVT involves neither the clotting factors of the intrinsic system, unlike the APTT, nor factor VII, unlike the prothrombin time. Any inhibition of the coagulant active phospholipid in the test by LA results in a prolonged DRVVT. However, as is the case with all LA tests, it is not specific. Deficiencies of clotting factors, for example factors II and X due to warfarin therapy, will also prolong the DRVVT. The specificity of the test is improved by repeating it in the presence of a high concentration of phospholipid, which should result in partial or complete correction of the prolonged clotting time if it is due to LA. This phospholipid is conveniently provided as platelet membranes in which negatively charged phospholipid is exposed by freezing and thawing. In the presence of LA, the ratio of test–normal plasma clotting time is often > 1.2, and corrects to < 1.2, or at least partially, in the platelet neutralization procedure. As with all coagulation tests, because of variations in reagents and techniques, it is essential that laboratories derive local normal ranges using a large number of plasma samples from healthy volunteers.

In the KCT, no additional phospholipid is employed. The test therefore resembles the APTT in that it involves the intrinsic and common pathways of coagulation but the sensitivity to LA is enhanced because the small amount of phospholipid present is only that derived from residual platelets in the test sample and plasma lipids. The test is affected by clotting factor deficiencies and anticoagulants, but specificity can be improved by use of normal plasma mixing at more than one ratio to test plasma. LA is identified when the KCT fails to correct even after relatively large proportions of normal plasma are added, whereas in factor deficiency the KCT is corrected with small amounts of normal plasma.

Alternative tests for LA may be employed but are not in general use. They include the tissue thromboplastin inhibition test and clotting tests which use venoms other than Russell's viper venom; examples are Taipan and Textarin venoms.

Solid-phase assays (for anticardiolipin and β₂-GPI antibodies)

Solid-phase assays for aPL, such as the aCL ELISA allow rapid processing of numerous serum samples and the results are not affected by factor deficiency or the use of anticoagulants. The introduction of international standards allows the calculation of aCL results in IgG or IgM antiphospholipid units (GPLU and MPLU respectively) related to a given concentration of affinity-purified aCL immunoglobulin. Despite this, there remains a lack of precision, and comparability between laboratories using different assays is not ensured.

The detection of aCL allows the diagnosis of APS in a subject with an appropriate clinical history, even when LA is absent. However, the aCL assay is neither a substitute for the LA test, nor does it confirm that LA is present, as different antibodies may be responsible for the two activities. Furthermore, the clinical significance of low-titre aCL is doubtful. Thus, in cases where the aCL titre is less than 20 GPL units and tests for LA are negative, a diagnosis of APS may not be conclusive. Under these circumstances, it is particularly important to consider other causes of thrombosis or miscarriage.

Specific assays for β₂-GPI antibodies have been developed and several commercial kits are available. β₂-GPI antibody assays may show higher precision and better correlation with the thromboembolic complications in APS and SLE than assays for aCL, and are less likely to show transient positive results in association with infection. Antiprothrombin antibodies generally exhibit poor specificity for venous thrombosis and recurrent fetal loss, and may be found in patients with infection. Neither assay is included in the diagnostic criteria for APS at present.

The prevalence of aPL in subjects with thrombosis varies with selection criteria for testing. Because the risk of recurrent thrombosis appears to be great, aPL should be sought in subjects with arterial, venous or microvascular thrombosis where no other cause is apparent. Examples are younger subjects with ischaemic stroke in the absence of cardiovascular disease and subjects with unprovoked venous thromboembolism.

The prevalence of persistent aPL among women with recurrent miscarriage is around 15%. In women with recurrent miscarriage due to APS the prospective fetal loss rate may be as high as 90%. In contrast, the prevalence of positive tests for aPL in unselected women of child-bearing age is around 3% and they are not sensitive predictors of poor pregnancy outcome in women with no history of pregnancy complications. Because miscarriage is a common phenomenon, screening for aPL is not indicated after a single event. Maternal aPL may be downregulated during pregnancy; tests are best performed preconceptually when possible. A small proportion of women with aPL also have anti-Ro antibodies. Their detection is important as it is associated with a 2% risk of complete heart block in the fetus and a 5% chance of neonatal lupus.

Management of antiphospholipid syndrome

Thrombosis
There is a wide variability in severity of prothrombotic states between individuals with APS. Epidemiological studies suggest that LA and high-titre aCL antibodies are associated with a greater risk of thrombosis than moderate or low-titre aCL alone, but these studies are difficult to extrapolate to individual patients.

The management of patients with antiphospholipid antibodies and previous thrombosis remains contentious. Retrospective observational studies suggest that these patients should remain on indefinite oral anticoagulation maintaining an international

normalized ratio (INR) of 3–4. However a recent prospective randomized study indicates that a lower target INR of 2–3 is effective in preventing recurrent thrombosis in the majority of patients with previous venous thrombosis. There is less certainty in arterial thrombosis, for example there is a significant subpopulation of APS patients with small vessel cerebral thromboses, some evident as lacunar infarcts on magnetic resonance imaging, who appear to require a target INR of 3–4 to prevent recurrent cerebral thrombosis.

Immunosuppressive therapy is not generally indicated in primary APS. An exception may be catastrophic APS when combination treatment with antithrombotics, corticosteroids and other immunomodulatory therapies is administered as a potentially life-saving emergency measure.

Pregnancy

The management of recurrent fetal loss is based on the use of anticoagulation with empirical doses of heparin, usually low-molecular-weight heparin in the UK, in combination with low-dose aspirin. Initial studies indicated that this approach increases the chances of a successful outcome of a healthy live birth from 30% to 70–80%, although this has been challenged recently. Heparin use carries a small risk of osteoporosis and increased bleeding and is inconvenient. Some clinicians believe that combination antithrombotic therapy as a first line should be reserved for women with a previous history of fetal death, and those with recurrent miscarriage should be given supportive care as a first line and aspirin or aspirin/heparin should be reserved for those with further pregnancy failure. Intravenous immunoglobulin therapy has not been formally assessed for this clinical indication. Corticosteroids are associated with frequent maternal morbidity from hypertension, glucose intolerance and premature labour and should not be used.

Thromboprophylaxis for those with a previous history of thrombosis is based again on use of low-molecular-weight heparin, although there is neither consensus on dosing nor the need to monitor therapy.

Venous thromboembolism and cancer

Cancer is a major risk factor for venous thromboembolism. Venous thromboembolism is the major cause of morbidity and mortality after the cancer itself in patients with malignancy. It is estimated that almost 15% of cancer patients will have a thromboembolic event. Post-mortem studies have shown that thromboembolism is common in patients who died of cancer. Of all oncology patients, palliative care inpatients have the highest risk of venous thromboembolism, with a deep vein thrombosis prevalence as high as 52%, with 33% of these having bilateral deep vein thromboses. Cancer patients have a high risk of venous thromboembolism after surgery and some forms of chemotherapy may also increase that risk, the most recently

Table 54.3 Risk factors for thrombosis in cancer patients.

Stasis
Immobility
Extrinsic pressure, e.g. oedematous limbs

Vessel wall/endothelial perturbation
Cytokine release from tumours
Local tumour infiltration
Central venous catheter

Hypercoagulability
Dehydration
Cytokine-related prothrombotic changes
Tissue factor/cancer procoagulant expression on tumour cells
Disseminated intravascular coagulation
Increased platelet activation

described being thalidomide. The risk of thrombosis varies with the type of cancer, with ovarian, brain and pancreatic cancers having the highest rates. Lymphomas and leukaemia account for a significant proportion of thromboses as do colonic and lung cancers.

Venous thromboembolism is a common complication of advanced malignancy and this has been recognized since Trousseau's original descriptions of migratory thrombophlebitis associated with adenocarcinoma in 1865. In Trousseau's syndrome, unlike the more common, lower limb solitary, deep vein thromboses, the phlebitis is recurrent and migratory, and it affects both the superficial and deep vein systems. Unusual sites such as arms, neck, as well as superficial veins of the thorax and abdomen may be involved. Typically such a patient has an occult tumour, usually adenocarcinoma, although up to 10% may have an acute leukaemia. In Trousseau's syndrome, conventional anticoagulation often fails to prevent recurrent thromboses.

Prothrombotic changes associated with malignancies

In Table 54.3 the components of Virchow's triad are used to illustrate the features that lead to oncology patients having such a high risk of thrombosis. There are specific abnormalities that are unique to cancer patients: these are tumour procoagulants. Tumour procoagulants are surface molecules on cancer cells that activate coagulation. The two principal tumour cell procoagulants are tissue factor and cancer procoagulant. The latter directly activates factor X in the absence of factor VII. The increasing number of tumour procoagulants that have been described are listed on the International Society for Thrombosis and Haemostasis registry. The APS has been reported in malignancy also, particularly in association with myeloma and immunosecretory disorders.

Difficulties in management

Cancer patients with thrombosis are at particularly high risk of recurrent thrombotic events. Cohort and population-based studies have shown that the risk of recurrence after stopping anticoagulation in patients with cancer is approximately double that of non-cancer patients. Treatment with anticoagulation in cancer patients is often unsuccessful, due to the high risk of recurrent venous thromboembolism and major bleeding. Unfortunately, these risks are associated with oral anticoagulation intensities within the usual therapeutic range. The risks are greatest during the first few weeks of anticoagulation treatment and increase with cancer extent. Several studies have demonstrated significant increases in rates of bleeding, as high as 20% amongst cancer patients receiving oral anticoagulation. Within the palliative care setting, in patients with far more advanced disease, the bleeding incidence was higher, even with strict monitoring of anticoagulation. Oral anticoagulation in cancer patients is complicated further due to anorexia, vomiting, liver disease and drug interactions. Moreover, there may be frequent interruption to treatment due to thrombocytopenia and the need for invasive procedures, and venous access is often difficult in these patients, especially if they have had previous chemotherapy through peripheral veins.

The decision to use oral anticoagulation in this group of patients should not be undertaken lightly and safe treatment requires intensive monitoring of the INR and the burden of repeated blood tests. Disillusionment with the use of oral anticoagulation in cancer patients has led to trials assessing low-molecular-weight heparins. The CLOT trial randomized over 650 cancer patients with symptomatic proximal deep vein thromboses and/or pulmonary embolism to treatment doses of dalteparin for 5–7 days and then randomization to either oral anticoagulation maintaining a target INR of 2.5 or dalteparin. In the dalteparin arm, full-treatment dose was given for 1 month and then reduced to 75–80% of this dose. After 6 months there was a significantly reduced rate of recurrent VTE in the dalteparin group of 8.8% compared with 17.4% rate with oral anticoagulation. Bleeding was also significantly reduced. A similar reduction in VTE was found in patients with cancer who entered the LITE study, in which treatment-dose tinzaparin was compared with oral anticoagulation after VTE.

Thrombotic risk in polycythaemia rubra vera and essential (primary) thrombocythaemia

Polycythaemia vera (PV) patients, if left untreated, have a median survival of 18 months, with the majority dying of vascular occlusion. The occlusive lesions may involve the larger vessels or the microvasculature. In PV, large vessel events involve arteries and veins equally, whereas in essential thrombocythaemia (ET) arteries are more commonly involved. A high proportion of thromboses occur in the cerebral circulation, although widely distributed arterial and venous system and splanchnic vessel thromboses have been well documented. Hepatic vein and portal vein thromboses are more commonly associated with PV than ET. Indeed it has been reported that some patients with apparently idiopathic hepatic or portal vein thrombosis have subclinical myeloproliferative disease based on the finding of erythropoietin-independent erythroid colony growth in marrow culture. In PV, there is good evidence that the incidence of vascular occlusion is positively related to the packed cell volume level, with the lowest incidence in patients with good control of haematocrit. The role of thrombocytosis in risk of thrombosis in PV is disputed. The risk of thrombosis in PV also increases with advancing age and a past history of thrombosis.

ET is often diagnosed in the subclinical phase but a number of studies suggest that overall survival is determined principally by occurrence of thrombosis. In a study of 100 patients by Cortelazzo and colleagues a rate of thrombosis of 1.7% per patient-year was found in those aged less than 40 years, 6.3% per patient-year in those aged 40–60 years, and 15.1% in those aged greater than 60 years.

The pathogenesis of thrombosis in essential thrombocythaemia is poorly understood. Elevated platelet counts are implicated, with platelet counts greater than 600×10^9/L being associated with increased incidence of vascular occlusion. Although treatment to reduce abnormal counts will reduce the frequency of events, a proportion will still experience thrombosis. In addition, some patients with essential thrombocythaemia will remain thrombosis-free with no treatment to reduce their platelet count. As a consequence, thrombosis risk-adjusted treatment strategies have evolved.

The microvascular events and vasomotor manifestations of both PV and ET almost certainly relate to quantitative and qualitative changes in platelets, as they are not seen in other forms of polycythaemia or thrombocytosis. It is possible that similar small vessel occlusive and vasomotor changes seen in the feet and hands may also occur in other parts of the body. Erythromelalgia, a syndrome consisting of painful, burning red extremities with normal peripheral pulses is the characteristic vasomotor disturbance. Physical findings may be absent or there may be warmth, duskiness and mottled erythema of the involved areas. Livedo reticularis is occasionally found. In the digital vessels, usually of the toes, but occasionally the fingers, the development of thrombosis can lead to digital ischaemia and gangrene. In relation to the cerebral circulation, a range of symptoms and signs involving transient cerebral ischaemia, transient monocular blindness, migraine, headaches and seizures are seen. Both the cerebrovascular complications and erythromelalgia of myeloproliferative disease may respond promptly to low-dose aspirin and/or platelet cytoreduction.

Conventional risk factors for cardiovascular disease are implicated in the pathogenesis of thrombosis in ET, including hypertension, smoking, hypercholesterolaemia and diabetes. The presence of monoclonal haemopoiesis may be a significant

risk factor and a significant number of individuals with ET have been found to have antiphospholipid antibodies.

Acute promyelocytic leukaemia

In comparison with the severe haemorrhages present in the majority of cases of acute promyelocytic leukaemia (APL), acute arterial thrombosis is a rare presenting feature. Thrombosis is associated with the microgranular variant of APL, which accounts for 25% of all cases, characterized by a paucity of myeloid granules and a lobulated monocytoid nucleus. The cells stain positive with Sudan black and myeloperoxidase, and there is a high incidence of CD34+. Vascular occlusion is more common when a high white cell count ($> 150 \times 10^9$/L) predisposes to leucostasis. It is thought that the leukaemic cells release procoagulants, causing a disseminated intravascular coagulation. It is important to recognize this variant of APL, as the use of all-*trans*-retinoic acid (ATRA) may increase the risk of thrombosis owing to a further increase in peripheral white cell count exacerbating leucostasis.

Inflammation and thrombosis

Systemic inflammation is a potent prothrombotic stimulus. Also, some physiological anticoagulants also have an anti-inflammatory effect.

Inflammatory mechanisms upregulate procoagulant factors, downregulate physiological anticoagulants, inhibit fibrinolytic activity and increase platelet reactivity (Table 54.4). Inflammatory mediators promote coagulation by causing endothelial cell activation and thus increasing expression of tissue factor. Endotoxin, tumour necrosis factor and interferon-1α induce tissue factor expression primarily on monocytes/macrophages, and probably in atherosclerotic plaques as well. Thrombin, although a key element in coagulation, also has cytokine-like

Table 54.4 Effects of inflammation of haemostasis.

Platelet reactivity
Increased levels of fibrinogen and other coagulation proteins

Decreased
Thrombomodulin expression
Endothelial cell protein C receptor
Half-life of activated protein C
Protein Z
Fibrinolytic activity due to increased PAI-1
Endothelial glycosaminoglycans

activities, as it augments leucocyte adhesion and can activate endothelium, leucocytes and platelets. Activation of these cells by thrombin increases the expression of negatively charged phospholipids such as phosphatidylserine on the surface of the cells to promote surface procoagulant activity.

Interleukin 6 and its family of molecules mediate the acute-phase response. This increases liver synthesis of plasma proteins including fibrinogen and other coagulation proteins, thus priming the blood coagulation system for action. Interleukin 6 also increases platelet reactivity. Plasma levels of the recently discovered vitamin K-dependent anticoagulant protein Z, which acts by inhibiting factor Xa, fall during inflammation, thus protein Z appears to be a negative acute-phase protein.

Of all the physiological anticoagulant pathways, the protein C pathway appears to be the most influenced by inflammation. Thrombomodulin and the endothelial cell protein C receptor (EPCR) are both downregulated by inflammatory cytokines such as tumour necrosis factor alpha (TNF-α). There is both inhibition of the promoter and of the thrombomodulin gene as well as active pinocytosis to remove existing surface molecules, whereas neutrophil elastase readily cleaves thrombomodulin from the endothelial cell surface. Moreover, thrombomodulin is very sensitive to oxidation of an exposed methionine by oxidants produced by leucocytes. These observations have led to studies demonstrating apparent therapeutic value of activated protein C in subjects with multiorgan failure due to severe sepsis.

Endothelial cell activation occurs in inflammation. This causes downregulation of fibrinolytic activation by increased production of plasminogen activator inhibitor-1. There may also be cleavage of the glycosaminoglycans from the surface of the endothelium, so that there is loss of heparan sulphate and other molecules that activate antithrombin.

As a consequence of these changes, conditions that provoke an inflammatory response are associated with increased risk of venous thrombosis. Such chronic states include inflammatory bowel disease, Behcet's disease, systemic tuberculosis, SLE and diabetes. Atherosclerosis can be considered a chronic inflammatory state and has been associated recently with an increased incidence of venous thrombosis. The association between inflammation and thrombosis emphasizes the need for thromboprophylaxis in such patients when they are immobilized in hospital.

Haematological prothrombotic states

Paroxysmal nocturnal haemoglobinuria
(see Chapter 11)

Venous thrombosis occurs in up to 40% of patients with paroxysmal nocturnal haemoglobinuria (PNH) and represents a significant cause of morbidity and mortality. Thrombosis most commonly occurs in the hepatic veins, the portal veins and sagittal sinus. Hepatic vein thrombosis leading to the Budd–Chiari

syndrome is the commonest site and affects 15–25% of patients with PNH. Presentation is with pain in the right upper quadrant, jaundice and abdominal distension due to hepatomegaly and ascites. Thrombosis in the abdominal veins results in persistent abdominal pain, and symptoms and signs of intestinal obstruction may occur if infarction of the bowels ensues. Thrombosis of the splenic vein leads to splenomegaly and, occasionally, splenic rupture can occur. Portal vein thrombosis produces ascites and the later development of oesophageal varices.

Sagittal sinus thrombosis is the most frequent neurological complication. Symptoms include severe headache. There may be focal or non-focal neurological signs.

Occasional painful, discoloured skin lesions occur when the dermal veins are affected. These lesions rarely ulcerate. Occasionally, skin lesions can resemble purpura fulminans; these can affect large areas of skin, with necrosis and demarcation.

Pregnancy in PNH is associated with an increased risk of fetal loss (40%) from thrombosis and haemorrhage.

The pathogenesis of thrombosis in PNH remains uncertain. Platelets are capable of compensating for the decreased expression of decay accelerating factor (CD55) due to the presence of factor H, a similar protein that is present within alpha granules. In PNH there is also a deficiency of membrane inhibitor of reactive lysis (MIRL: CD59). In the absence of CD59, platelet lysis is minimized by the release from the cell surface of excess membrane attack complex by exovesiculation. The externalized phospholipid serine on the microvesicles released into the circulation acts as the binding site for prothrombinase complexes. It is likely that the release of procoagulant microvesicles contributes to the increased risk of venous thrombosis. Increased platelet activation and an increased sensitivity to aggregation by thrombin have also been described. Fibrinolysis is also affected in PNH. Urokinase-type plasminogen activator receptor is also a GPI-bound protein that is absent from PNH cells. It binds urokinase to the cell surface and converts plasminogen to plasmin.

Thrombotic thrombocytopenic purpura
(see Chapter 52)

Sickle cell disease
In sickle cell disease, the pathophysiology involves microvascular and macrovascular occlusion with sickled cells. There is also considerable clinical and post-mortem evidence of cerebral, pulmonary and placental thrombosis, suggesting a prothrombotic tendency in these patients. Additional evidence for a prothrombotic state is enhanced thrombin generation as shown by increased levels of prothrombin fragment 1 + 2 and thrombin–antithrombin in patients with sickle cell disease in their steady state when compared with age-matched control subjects.

There is also evidence that sickled erythrocytes adhere more readily to vascular endothelium and strongly accelerate coagulation due to abnormal exteriorization of procoagulant anionic membrane phospholipids. Comparison of the coagulation and fibrinolytic pathways in sickle cell patients with ethnically matched control subjects has shown increased levels of von Willebrand factor during sickling, but it is not clear whether this is specific or part of the acute-phase reaction. Low levels of protein C, protein S, and heparin cofactor II are well described. The aetiology of the reduction of these physiological anticoagulants is unclear. It may relate to impaired liver function from repeated hepatic sickling, whereas increased consumption has also been proposed as a cause. Low heparin cofactor II levels are also found in other chronic haemolytic anaemias such as thalassaemia intermedia, suggesting chronic haemolysis may also lead to increased consumption of this protein. Nephrotic syndrome, often found in association with sickle nephropathy, leads to low antithrombin levels and a prothrombotic state.

Management of venous thromboembolism

55

Sam Schulman

Diagnosis of venous thromboembolism

The diagnosis of deep vein thrombosis (DVT) or pulmonary embolism (PE) relies on the use of objective diagnostic methods. Symptoms and clinical signs alone are not useful for verification of suspected DVT or PE, as several studies have demonstrated a similar prevalence among patients with and without these conditions, when subsequently investigated with objective methods.

Electrocardiography may show ST–T abnormalities that are unspecific and, although the classical but rare signs of right ventricle overload are seen in massive pulmonary embolism with unstable haemodynamics, the main role of this test is to exclude other conditions, such as acute myocardial infarction. Arterial blood gases and transthoracic echocardiography have too low sensitivity. However, the risk factors for venous thromboembolism (VTE), clinical symptoms and signs with the highest predictive value can be assigned points that are added to obtain a 'clinical score' (Tables 55.1 and 55.2) that can be used as the first step in a diagnostic strategy to reduce costs and the requirement for invasive diagnostic procedures. The clinical scores on their own are not sufficient for confirmation or exclusion of the diagnosis.

The next step, if such a strategy is employed, is the measurement of fibrin D-dimers, which are split products of fibrin, degraded by plasmin, where the D-fragments of two fibrin molecules still are covalently bound and often also in complex with the E-fragment. Several methods can be used, such as enzyme-linked immunosorbent assay (ELISA), whole-blood agglutination of erythrocytes, latex agglutination or immunofiltration. ELISA methods have the best sensitivity, whereas the others are semiquantitative or qualitative methods.

Table 55.1 Clinical scores used for predicting the probability of DVT prior to further testing (from Anderson *et al.*, 2003).

Risk factors, symptoms or signs	Points
Active cancer (treatment ongoing or terminated within 6 months or palliative care)	1
Paralysis, paresis, recent plaster cast on the leg	1
Recent confinement to bed of more than 3 days or major surgery within 12 weeks	1
Localized tenderness along the deep venous system	1
Swelling of the entire leg	1
Calf circumference > 3 cm larger than the asymptomatic leg (measured 10 cm below the tibial tubercle)	1
Pitting oedema (more on the symptomatic side)	1
Collateral flow in superficial veins (not varicose veins)	1
Previous DVT	1
Alternative diagnosis as or more likely than DVT	–2

In the case of symptoms from both legs, the leg with the most pronounced symptoms is used.
> 2 points = high probability; 1–2 points = medium probability; < 1 point = low probability.

There are also quantitative automated latex methods. The manual latex methods have lower sensitivity and negative predictive value for exclusion of DVT or PE. Each hospital should provide information on sensitivity and specificity of the test chosen for D-dimers. In general, a negative result is useful for the exclusion of venous thromboembolism, when the clinical score indicates low clinical probability. A positive result cannot be used for confirmation of the diagnosis, owing to a low specificity. For this reason, D-dimer is not a useful test for pregnant

Table 55.2 Clinical scores used for predicting the probability of PE prior to further testing (from Wells, 2001).

Risk factors, symptoms or signs	Points
Signs of deep vein thrombosis (swelling, tenderness)	3
Heart rate > 100	1.5
Immobilization > 2 days or recent surgery (< 4 weeks)	1.5
Previous objectively verified deep vein thrombosis	1.5
Haemoptysis	1
Cancer	1
Pulmonary embolism as or more likely than other diagnoses	3

> 6 points = high probability; 2–6 points = medium probability; < 2 points = low probability.

or hospitalized patients, the elderly or those with concomitant severe illness.

Whenever the clinical probability is high and/or the D-dimer test is positive, verification using diagnostic imaging techniques is necessary. These include phlebography and ultrasonography for DVT and perfusion–ventilation lung scanning, spiral (helical) computerized tomography (CT) and pulmonary angiography for PE. A novel possibility is magnetic resonance tomography of the lungs, which can be combined with examination of the legs and, due to the low risk for the fetus, it is especially advantageous for diagnosis during pregnancy.

Various diagnostic strategies for DVT and PE have been constructed, in which the aim is to confirm or exclude the diagnosis in the majority of the patients with the least expensive, preferably also non-invasive, method. For the minority of patients for whom uncertainty remains, the investigation is stepped up to more complex methods. The strategies may not be applicable to all clinical settings, due to limited availability of equipment or staff. The cost-effectiveness of a strategy may also be quite different in a clinical study and in routine at a hospital with a large turnover of physicians.

Objective diagnosis with imaging techniques

For objective verification of DVT, phlebography is the 'golden standard', but the diagnostic accuracy is dependent on a high quality of the examination. The veins and possible thrombi have to be well visualized. The correct interpretation of the phlebogram depends on the experience of the radiologist, as artefacts may be difficult to differ from thrombi. A non-ionic contrast medium with low osmolarity should be used to minimize side-effects and the risk that the phlebography causes endothelial damage and the development of a post-phlebographic DVT. Caution is still needed with regard to renal failure.

Ultrasonography of the leg veins is non-invasive and has no contraindications. It is progressively replacing phlebography

as the method of choice. The simplest variant is compression ultrasonography, where a cross-section of the vein is compressed with the transducer. A non-compressible vein is diagnostic for a DVT. The pelvic veins are not accessible for this method and recurrent thrombosis is difficult to discern. The most sophisticated variant of the technique is colour Doppler (colour duplex), which can determinate the flow in several venous segments simultaneously. Provided that the veins of the calf are visualized, this technique has the same diagnostic accuracy as phlebography, but in general the sensitivity is higher for proximal than for distal DVT. Low clinical probability in combination with a negative ultrasonographic examination, including the common and superficial femoral veins, the popliteal vein and the trifurcation in the proximal part of the calf is sufficient for exclusion of DVT. However, with medium clinical probability, a negative ultrasonographic examination should be repeated within 1 week and, if still negative at that point, a DVT is satisfactorily excluded. Presentation with high clinical probability and a negative ultrasonography requires further investigation with phlebography.

Objective verification of suspected PE has typically been obtained with perfusion–ventilation lung scanning, following a normal chest radiograph. Perfusion scanning with technetium-99m (^{99m}Tc) albumin macroaggregates is a sensitive but not very specific method. The specificity is improved by adding ventilation scanning, usually with xenon-133 (^{133}Xe) aerosol or ^{99m}Tc-labelled carbon particles (technegas), considering a *V/Q* mismatch (negative ventilation and positive perfusion scan) indicative of pulmonary embolism. However, an embolus may cause bronchospasm and thereby a ventilation defect and, more importantly, a *V/Q* mismatch may occur with several other conditions, including tumours, pneumonia, atelectasis, chronic obstructive pulmonary disease and others, and it does not differ between old and new emboli. The interpretation of lung scans is difficult, especially with a picture with low or intermediate probability for PE.

Therefore, other methods should be preferred for concurrent cardiopulmonary disease. Treatment can safely be withheld if the perfusion scan is negative or with a low probability scan in combination with low clinical probability. A high probability lung scan, which should require perfusion defects corresponding to at least two segments, together with high clinical probability has a positive predictive value of more than 90%. For other combinations there is a need to proceed with other diagnostic methods.

Spiral CT of the lungs has rapidly gained popularity. The inter-observer agreement is good and the number of inconclusive examinations is definitely lower than with lung scanning. With multislice technique and a slice thickness of 2 mm, adequate assessment of 93% of the segmental arteries and of 62% of the subsegmental arteries is achieved. Although the diagnostic accuracy for subsegmental PE is low with spiral CT, follow-up studies have shown that it was safe to withhold treatment on presentation of

a negative examination. For critically ill patients or those with limited cardiopulmonary function, this may not be true. The positive predictive value of spiral CT with injection of contrast is at least as high as that of a high-probability lung scan.

In the situation with high clinical probability for PE and a negative perfusion lung scan or a negative spiral CT, one possibility is to investigate the presence of thrombi in the lower extremities with bilateral ultrasonography or otherwise to proceed with pulmonary angiography. The latter is rarely used, perhaps due to fear for serious or lethal complications. With contrast medium of low osmolarity, pulmonary angiography was not associated with any mortality and only 0.4% of serious complications in four studies with more than 3000 patients altogether. Although pulmonary angiography is considered the 'golden standard' for diagnosis of PE, there are both false-positive and false-negative results, and the inter-observer variability is poor when the PE is located in subsegmental arteries. Nevertheless, the method appears to exclude with great certainty PE that requires therapy.

Investigation for concomitant cancer

The prevalence of cancer is approximately 20% in many cohort studies of patients with VTE, and in many of those patients the malignancy is still occult at the time of diagnosis of VTE. It is therefore often discussed whether these patients routinely should be screened for cancer with radiological, endoscopic and biochemical examinations, but so far there is no evidence that such a strategy decreases the mortality and morbidity in cancer. Instead, directed examinations should be performed when suspicion is raised by clinical signs or symptoms, as identified on a thorough medical history and clinical examinations. In addition, investigation for cancer should be considered in patients with bilateral DVT, concomitant deep and superficial vein thrombosis at separate locations or recurrent VTE despite anticoagulant treatment within the therapeutic range of laboratory monitoring.

Therapeutic agents

All agents discussed below have in common the obvious side-effect of bleeding complications, which will be described in association with the different treatment options.

Thrombolytic therapy

Streptokinase and tissue plasminogen activator (tPA) are widely available fibrinolytic agents. Streptokinase, a glycoprotein purified in 1947 from the supernatant of β-haemolytic streptococci, cleaves, when in complex with plasminogen, other plasminogen molecules to plasmin. This indirect action results in complex pharmacokinetic characteristics. Furthermore, streptokinase is

immunogenic, which may cause allergic reactions as well as a reduced or eliminated response on repeated use or after a recent infection with streptococci. tPA is an autologous glycoprotein, produced commercially with recombinant DNA technique, and it has a direct enzymatic effect on plasminogen, strongly enhanced by the presence of fibrin. The half-life of both agents is short, and for the treatment of VTE an initial bolus dose is usually followed by continuous intravenous infusion, although other regimens have been tested with tPA. The recombinant form of tPA that is used for the treatment of PE is alteplase, with a half-life of 5 min, whereas variants with longer half-life, for example reteplase, are mainly used for myocardial infarction, although some studies with the latter agent for PE have been published.

Anticoagulant therapy

Glycosaminoglycans

The anticoagulant effect of heparin was first described in 1916 by Jay McLean. It is produced from animal sources, usually from porcine intestinal mucosa, and heparin actually consists of a wide range of glycosaminoglycan chains with molecular weights from 3000 to 30 000 Da. It is an indirect inhibitor of the serine proteases in the coagulation cascade, acting as a cofactor for antithrombin, which, after binding to heparin, changes its conformation, whereby the inhibiting capacity increases by several orders of magnitude. Heparin is administered as a bolus injection intravenously, followed by continuous infusion or by subcutaneous injections. It has a half-life of 1–2 h in the circulation. Allergic reactions occur rarely and long-term treatment for months causes osteoporosis. Moreover, heparin induces an elevation of liver transaminases, which is harmless, and a reduction of the platelet count which may be very mild or pronounced and sometimes combined with serious venous and arterial thrombotic complications [heparin-induced thrombocytopenia (HIT), type II]. The mechanism for this is that the patient has developed antibodies, usually immunoglobulin G (IgG), against complexes of heparin and platelet factor 4. These immune complexes bind to Fc receptors on platelets and endothelial cells. The platelets become activated, release more platelet factor 4, aggregate and platelets are consumed. After neutralization by all heparin present, the excess of platelet factor 4 binds to endothelial heparan sulphate, which also may generate antibody formation and endothelial injury by immune complexes. Thrombosis formation or disseminated intravascular coagulation may then follow.

Unfractionated heparin (UFH) is the source for low-molecular-weight heparin (LMWH), which is obtained by fragmentation or depolymerization of the former. LMWH still consists of a mixture of glycosaminoglycan chains, but with molecular weights of between 3000 and 7000 Da. LMWH has the same principal mode of action as UFH, but the inhibition of thrombin is reduced compared to the inhibition of factor Xa, as the former effect

requires longer polysaccharide chains for binding to thrombin as well as to antithrombin in order to bring the two molecules together. The bioavailability after subcutaneous injection is better than for UFH and the effect is more predictable, due to less binding to platelet factor 4 and other plasma proteins. The half-life is also longer (3–5 h), so that subcutaneous injection once daily is usually sufficient. Intravenous administration of LMWH is rarely used.

Treatment with heparin requires daily monitoring with activated partial thromboplastin time (APTT), whereas with LMWH monitoring is rarely needed, with the main exceptions being renal failure and long-term prophylaxis during pregnancy, when the inhibition of activated factor X (anti-Xa) is measured. Some side-effects, such as heparin-induced thrombocytopenia and osteoporosis, are less common with LMWH than with UFH. Although there are differences such as in molecular range, sulphation, ratio of factor Xa to thrombin inhibition and pharmacokinetic characteristics between different LMWHs, there is no evidence for a clinically important difference between them.

The shortest sequence of heparin with affinity to antithrombin and an anticoagulant effect is a pentasaccharide which, as opposed to UFH and LMWH, is produced synthetically and at the same time slightly modified compared with the native counterpart in order to obtain the desired pharmacokinetic characteristics. The pentasaccharide fondaparinux has a half-life of 17 h and is given subcutaneously once daily. It is presently used for prophylaxis in association with orthopaedic surgery and it has a similar effect and safety as UFH and LMWH for the treatment of PE and DVT respectively.

Danaparoid is a heparinoid, consisting of the glycosaminoglycans heparan sulphate, dermatan sulphate and chondroitin sulphate but without any heparin present. Accordingly, it has a low cross-reactivity with antibodies induced by heparin and it is therefore mainly used in patients with HIT. It is administered intravenously or subcutaneously and has an effect that is similar with UFH in the prevention and treatment of VTE; with the dose of 2000 units every 12 h it has even a slightly better therapeutic effect than UFH.

Vitamin K antagonists

Vitamin K antagonists have been given to humans since 1942 for prevention or treatment of VTE. These are the original oral anticoagulants but, after 60 years, some alternatives are on the way. There are two groups of vitamin K antagonists, the more commonly used coumarin derivatives and the indanediones, and their availability varies between countries. These agents exert their effect via inhibition of the enzymes vitamin K epoxide reductase and vitamin K reductase, which are required for the regeneration of KH_2 from vitamin K epoxide. The latter is generated when the vitamin K-dependent coagulation factors (factors II, VII, IX and X – as well as the inhibitors protein C and protein S) undergo post-translational modification with γ-carboxylation of approximately 10 glutamic acid residues in the N-terminal Gla domain.

During treatment with vitamin K antagonists, typically three of these residues remain in the non-carboxylated stage, which reduces the ability of these coagulation factors to bind calcium and to localize the coagulation process to phospholipid surfaces. The vitamin K antagonists are bound to plasma proteins, mainly albumin, 98–99%. The metabolism occurs in the liver with the cytochrome P450 enzymatic system. Interactions with other drugs or food may occur at many levels (Table 55.3), and constitute a major disadvantage of vitamin K antagonists. The treatment therefore requires regular monitoring with the prothrombin time (PT). With the widely adopted use of a standardized calibrations system, international normalized ratio (INR), the reliability of

Table 55.3 Mechanisms for drug interactions with vitamin K antagonists with typical examples of such drugs.

Enhancement of vitamin K pathway	Vitamin K, lipid emulsions
Reduced endogenous synthesis of vitamin K	Induced by antibiotics
Accelerated catabolism of coagulation factors	Thyroid hormone, androgens
Decreased synthesis of coagulation factors	Clofibrate
Decreased warfarin absorption due to binding	Cholestyramine
Increased absorption of warfarin	Acarbose
Inhibition of cyclic interconversion of vitamin K	Second-/third-generation cephalosporins
Inhibition of cytochrome P450 (CYP3A4)	Clarithromycin
Inhibition of cytochrome P4502C9 – S-enantiomer	Sulphinpyrazone
Stereoselective inhibition of hydroxylation – R-enantiomer	Cimetidine
Non-stereoselective clearance	Amiodarone
Induction of hepatic enzymes	Barbiturates, rifampicin
Displacement of protein binding	Etoposide
Potentiation of the warfarin receptor effect	Clofibrate
Anti-platelet effect	Acetylsalicylic acid

comparisons of treatment intensities at different laboratories has been improved. The INR from an individual sample is calculated with the formula: $INR = (PT_{patient}/PT_{control})^{ISI}$.

Rare side-effects of vitamin K antagonists are skin necrosis, purple toe syndrome, rash and toxic hepatitis, whereas the adverse effect of warfarin on bone mineral density is debated. Skin necrosis occurs in approximately 1 out of 5000 patients and is due to an imbalance between mildly depressed vitamin K-dependent coagulation factors and a more pronounced reduction of protein C and protein S early after initiation of treatment, resulting in a hypercoagulable state with thrombus formation in small veins and venules in the dermis and subcutaneous fat. The purple toe syndrome is a very painful, burning dark-blue discoloration of the toes and sides of the feet, probably due to cholesterol embolization from atherosclerotic plaques, which have become friable owing to reduced fibrin deposition or haemorrhage into the plaques several weeks after initiation of anticoagulation. Skin rashes may be papular, vesicular or urticarial and often very itchy. Vitamin K antagonists also have a teratogenic effect, with skeletal malformations, optic atrophy and mental impairment, occurring in a few per cent of babies of exposed mothers.

To date, direct thrombin inhibitors have had a very limited use in VTE. Lepirudin is a recombinant derivative of hirudin, which is produced by the saliva of the leech (*Hirudo medicinalis*). It selectively, irreversibly and directly inhibits thrombin without involving antithrombin, and the administration is via the intravenous route. Owing to the complete absence of cross-reactivity against antibodies induced by heparin, it is used with HIT.

Novel anticoagulant drugs

A large number of new fibrinolytic and anticoagulant drugs have been developed but a majority of these did not reach beyond the preclinical studies. Some novel anticoagulant drugs are at the time of writing at the stage of advanced clinical trials and are briefly described below.

The nematode anticoagulant protein c2 (NAPc2), identified in a haematophagous hookworm (*Ancylostoma caninum*), binds stoichiometrically to factor X or Xa, and the complex interacts with and inhibits the membrane-bound tissue factor–factor VIIa complex, whereby the coagulation cascade is slowed down already at the initiation stage. It is now produced by recombinant DNA technique (rNAPc2) and is administered subcutaneously or intravenously. The elimination half-life is more than 50 h.

Modifications of the pentasaccharide have yielded a variant with high affinity to antithrombin and a half-life of 130 h, suitable for subcutaneous injections once weekly. Idraparinux is intended for long-term anticoagulant therapy and at a dose of 2.5 mg it appears as effective and possibly safer than warfarin. Monitoring does not seem necessary but renal failure requires modification of the dose.

Small oligopeptides or peptidomimetic substances with a direct and reversible inhibitory effect on thrombin have a potential for being orally available. Melagatran and its prodrug ximelagatran have a similar anticoagulant effect to LMWH and warfarin. Ximelagatran may cause less bleeding complications during long-term treatment, due to absence of interactions with food or other drugs. Ximelagatran is administered orally and melagatran subcutaneously and the half-life is 3–5 h, requiring dosing twice daily. No monitoring of coagulation parameters is required. Elimination of the drug depends on renal function.

Initial treatment of venous thromboembolism

Before treatment is initiated, blood samples should be obtained for baseline assessment of the risk of bleeding and for comparison in the subsequent monitoring of therapy. The analyses should include haemoglobin, platelet count, APTT and PT. In addition, with anticipated treatment with LMWH, serum creatinine and with thrombolytic therapy, plasma fibrinogen, blood group and cross-match should also be performed. It may also be desirable to secure samples for analysis of markers of thrombophilia before onset of therapy (see Chapter 53).

Thrombolytic therapy

The most serious consequence of VTE is fatal PE, which occurs in 1–3% after surgery in elderly patients with cancer or undergoing arthroplastic surgery of the lower limb, but also in medical patients, again more commonly in association with metastasizing cancer. Many of these patients die before a diagnosis of PE has been made. On presentation of massive pulmonary embolism with unstable haemodynamics, the mortality is very high but with rapid lysis of the emboli the prognosis improves dramatically. In the case of PE with right ventricle failure, although without shock, the benefit of thrombolytic therapy is more difficult to assess, but there is no significant reduction of the mortality. Thus, despite a more rapid removal of the thrombotic material from the arterial tree of the lungs with thrombolytic treatment than with heparin, there is in the majority of patients no major benefit of the former. In view of the doubling of the risk of major haemorrhage (heparin 5%, streptokinase or tPA 11%), thrombolytic therapy should be reserved for the most serious cases.

A number of contraindications have to be taken into account, so that the risk of bleeding complications can be minimized (Table 55.4). The by far most frequently used thrombolytic regimen in randomized trials on PE is tPA 100 mg over 2 h, with 10 mg given as an initial bolus dose and the remainder in continuous infusion. If an infusion with heparin already has been started, it may be continued or stopped during the treatment with tPA. Several other regimens have been studied, such as rapid infusion over 15 min, as a 2-min intravenous bolus injection or as a local infusion in the pulmonary artery, but there is no evidence for an improved risk–benefit ratio. For patients with

Table 55.4 Contraindications to thrombolytic therapy.

Absolute contraindications
Active internal bleeding
Known haemostatic disorder
Cerebrovascular accident, craniocerebral trauma or neurosurgery
  within 6 months
Active intracranial process

Relative contraindications
Major surgery, biopsy, puncture of non-compressible vessels,
  vaginal delivery, external heart massage or major trauma within
  7 days
Vascular or eye surgery within 3 weeks
Gastrointestinal bleeding, acute pancreatitis or pericarditis within
  3 months
Uncontrolled hypertension (diastolic ≥ 110 mm mercury)
Age > 80 years
Diabetic retinopathy

In addition, caution should be observed during the first trimester of pregnancy, the first 20 h of menstruation, bacterial endocarditis and in the case of abnormal screening tests for haemostasis. Patients with previous treatment with streptokinase within 3–4 months are unlikely to respond to repeated treatment due to antibody formation. The adherence to these precautions and contraindications should be more strict for the treatment of DVT than of massive PE.

cardiac arrest and high clinical probability for massive PE, a bolus dose of 50 mg alteplase intravenously can be given during the resuscitation.

In a life-threatening situation caused by massive PE and circulatory collapse, it is reasonable to disregard the relative contraindications to thrombolytic therapy (Table 55.4). In the presence of absolute contraindications or if the condition of the patient deteriorates despite thrombolytic therapy, there is a possibility to fragment the emboli via a right heart catheter or to perform surgical embolectomy, provided that equipment and expertise are available.

In patients with DVT there are, in addition to the risk of pulmonary embolism, also long-term sequelae to take into account. Destruction of the venous valves results in chronic venous insufficiency (see The post-thrombotic syndrome, below). Thrombolytic therapy yields better and faster re-opening of the veins after DVT, which saves the venous valves. A few studies with long-term follow-up have also demonstrated a reduction of the incidence of post-thrombotic syndrome to approximately 43% in these patients. The patient population recruited for studies on thrombolytic therapy for DVT has been very selective, with exclusion in case of increased risk of bleeding and usually only with patients with a short duration of symptoms included. Still, thrombolytic therapy for DVT is associated with a higher risk

of major haemorrhage than with heparin and this difference is more pronounced than in PE (3–4 times increase versus a doubling) due to the longer duration of treatment. The risk of haemorrhage increases with age and seems to be low for patients under 40 years of age.

The majority of studies on DVT were performed with streptokinase, usually given with a bolus dose of 250 000 IU as intravenous bolus to neutralize the antibodies from any previous infections with streptococci, followed by continuous infusion with 100 000 IU per hour for several days. Heparin is discontinued 30 min before the thrombolytic therapy and restarted 2–4 h after its discontinuation. Regional or local infusion of fibrinolytic agents has not proved to be more effective, bleeding complications are still prevalent and the procedure is relatively labour intensive. Antipyretics such as paracetamol may be given against febrile reactions, and steroids against more pronounced allergic reactions, but prophylaxis with the latter does not provide any additional benefit.

With major haemorrhage, the infusion of tPA should be stopped and blood losses replaced. For patients with streptokinase therapy, the situation is more complex. Owing to the indirect pharmacokinetics, a paradoxical effect may occur if the infusion of streptokinase is slowed or stopped. More plasminogen will then become available for transformation to plasmin by already circulating streptokinase–plasminogen complexes. It is therefore vital to reduce the proteolytic potential, which can be done with aprotinin. Conventional inhibitors of fibrinolysis, such as tranexamic acid, are not effective, as they only counteract plasminogen conversion to plasmin but do not inhibit already formed plasmin. With very low levels of fibrinogen and major haemorrhage, treatment with fibrinogen concentrate or, if unavailable, with plasma or cryoprecipitate is also indicated.

During treatment of DVT with streptokinase, the plasma fibrinogen level should be monitored every 12–24 h. If the level is not reduced at all, it is unlikely that a thrombolytic effect is achieved. The target is approximately 0.2–1.0 g/L, but levels higher than 0.2 g/L do not exclude the risk of haemorrhage, and therapeutic levels do not provide a guarantee for removal of the thrombotic mass.

In summary, thrombolytic therapy should be limited to patients with massive PE and unstable haemodynamics or young patients with extensive DVT and onset of symptoms within 1 week, and perhaps to any patient with massive DVT causing phlegmasia coerulea or alba dolens.

Venous thrombectomy

With only one randomized trial, based on 58 patients, there are insufficient data to evaluate the long-term benefit of surgical removal of the thrombus. The procedure is often combined with formation of an arteriovenous fistula to improve the flow, but there is not enough evidence to show that this increases the patency rate of the vein. Bleedings occur, transfusions are often

required and a fatal outcome has been reported in up to 14%. This mortality rate is at least partly related to fact that several of the patients were seriously ill. The benefit of the treatment is that relief of symptoms is immediate, and it may be considered in the rare cases when loss of the limb is imminent.

Interruption of vena cava

Caval interruption can be achieved by insertion of a temporary or permanent filter and provides a short-term tool to prevent pulmonary embolism by reducing the risk during the first 12 days from 4.8% to 1.1%. It should be considered when VTE has been diagnosed and anticoagulant therapy is contraindicated because of a very high risk of bleeding (e.g. ongoing or very recent intracranial or gastrointestinal haemorrhage), or when there is progressive DVT or recurrent PE despite adequate anticoagulant therapy, as verified by APTT, anti-factor Xa levels or PT (e.g. in patients with cancer).

It should be taken into account that in a large randomized trial, no benefit from caval filters was seen regarding mortality or long-term reduction in the risk of PE and, after 2 years, there was an increased risk of recurrent thrombosis.

Anticoagulant therapy

The objective of anticoagulant therapy in the acute phase is to prevent further progression of the DVT as well as (further) embolization to the lungs. It is not sufficient to start treatment with vitamin K antagonists alone, due to the delay of about 5 days until they provide full anticoagulant effect. An initial intravenous bolus dose of UFH, 80 IU per kilogram body weight should be given as soon as PE is clinically suspected, as it may take several hours to establish the diagnosis objectively, and the patient may deteriorate in the meantime. Depending on the possibility for surveillance while the patient is referred to other departments for diagnostic imaging, an intravenous infusion with UFH may be started immediately after the bolus dose or when the patient returns but, in that case, additional bolus doses will be necessary if more than 4 h elapse. When the diagnosis has been confirmed, treatment is continued with intravenous infusion of UFH, 500 IU/kg per day and continued until treatment with vitamin K antagonist, started simultaneously, has become effective (see below).

Randomized trials have shown that adjustments of the bolus dose and the maintenance infusion dose with UFH according to body weight is more effective than a standardized dose. The treatment with UFH is targeted at an APTT of 2–3 times the upper limit of normal, which is measured 4 h after starting the infusion and then once daily. With APTT below the target range, another bolus dose is given and the infusion rate is increased. Conversely, with APTT above the treatment range, the infusion may be halted for 30 min and should be restarted at a reduced rate.

Failure to reach the therapeutic APTT range is associated with a poor antithrombotic effect, whereas a possible association between long APTT results and bleeding complications is less evident. Occasionally, there may be difficulties to reach a therapeutic APTT with congenital deficiency of antithrombin, although treatment with UFH is effective in the majority of those patients. If the APTT is not prolonged despite increased doses of UFH, and especially if there is a clinical deterioration, the antithrombin level should be measured and, if there is a deficiency, substitution with antithrombin concentrate should be considered. More often a therapeutic APTT is not achieved despite normal antithrombin levels, but there is no evidence of clinical progression. This condition is believed to be caused by high levels of acute-phase proteins, such as factor VIII or histidine-rich glycoprotein, which counteract the prolongation of APTT but apparently not the antithrombotic effect of heparin. Measurement of anti-factor Xa in those patients often demonstrates therapeutic levels and should be taken into account so that undue increment of the dose of heparin is avoided.

If the baseline APTT is prolonged, the reason may be presence of a LA (mildly to moderately prolonged APTT) or congenital deficiency of factor XII (severely prolonged APTT for homozygous patients). The association between these conditions and VTE is strong or probable, respectively, and monitoring of treatment with UFH is almost impossible. The alternatives are treatment with UFH, monitored with anti-factor Xa, or treatment with LMWH, which does not require monitoring.

For patients with suspected PE, mild symptoms and stable haemodynamics treatment can alternatively be started with a maintenance dose of LMWH subcutaneously, which is then continued once or twice daily until treatment with vitamin K antagonists, initiated simultaneously, becomes effective (see below). A few randomized trials have demonstrated that this treatment is as effective as with UFH for submassive PE. Treatment with LMWH does not require monitoring unless the patient suffers from renal failure (see below). It is thus possible to give this treatment on an outpatient basis, but the safety has so far not been demonstrated for patients with PE in a randomized trial.

Treatment for DVT with LMWH is as effective as with UFH, but it does not require monitoring and can be undertaken safely without or with only 1–2 days of hospitalization. Randomized trials have demonstrated equal effect and safety with LMWH injected once or twice daily. For hospitalized patients, LMWH is associated with a lower incidence of haemorrhage than treatment with UFH. In the case of very ill patients or a high risk of bleeding, it still may be preferable to treat with UFH, infused intravenously, in view of the shorter half-life if the treatment has to be discontinued abruptly and the more convincing neutralizing effect of protamin sulphate.

It has been shown in several meta-analyses that initial treatment with LMWH instead of UFH is associated with a reduced mortality during 3 months of follow-up. This is entirely due to an increased survival in the subgroup of patients with concomitant

cancer disease, and it is not generated by a reduced incidence of fatal pulmonary embolism or haemorrhage.

Although the dose of LMWH is adjusted according to body weight, this is a matter of debate regarding obese patients. A few pharmacokinetic or treatment studies have provided conflicting data regarding whether the dose should be increased linearly or 'capped'. Patients with renal failure were also excluded from all large trials. With mild to moderate renal failure (serum creatinine 200–400 μmol/L), it is recommended to check the anti-factor Xa level after 2–3 days at the time of peak concentration and if it is above 1 IU/mL to reduce the dose. For patients with severe renal failure UFH is preferred.

Patients with VTE should be mobilized early, preferably within 1 day, unless thrombolytic therapy is given. The risk of new pulmonary emboli is not increased with this regimen, whereas pain and swelling of the leg diminishes more rapidly than if the patients are immobilized for 1 week. The patients should wear compression stockings as soon as they are out of bed (see The post-thrombotic syndrome, below).

Secondary prophylaxis

If the initial anticoagulant treatment with UFH or LMWH is not followed by a period of secondary prophylaxis, the absolute increase in the risk of recurrence over 90 days is 29%. Secondary prophylaxis is usually given with vitamin K antagonists, mostly with warfarin. In some European countries, phenprocoumon or acenocoumarol is prescribed predominantly. Phenprocoumon has a half-life of 160 h compared with 20–55 h for warfarin, which may cause difficulties when the drug has to be eliminated quickly in case of an overdose or haemorrhage. Acenocoumarol has a half-life of only 11 h, and this does not result in a requirement for dosing twice daily. Comparative studies with warfarin and acenocoumarol have demonstrated a similar effect and safety profile.

The treatment with a vitamin K antagonist should be started concomitantly with the initial anticoagulant therapy, but the first dose can reasonably be withheld until the diagnosis of PE or DVT is established. Early initiation of the secondary prophylaxis allows for a shorter treatment period with UFH or LMWH and reduces the risk of development of heparin-induced thrombocytopenia. The optimal intensity of anticoagulation with vitamin K antagonists is at an INR of 2.0–3.0, at least during the first 6 months after an episode of VTE. Although previously debated, it has now been shown in several clinical trials that patients with the phospholipid antibody syndrome do not require more intensive anticoagulation. It may take 3–10 days to reach this target range and the maintenance dose varies from 1 to 20 mg per day. The time to reach the therapeutic range and to find the individual maintenance dose is shortened with a higher initial dosing (15 mg of warfarin daily versus lower doses or with 10 mg warfarin versus 5 mg) and by using a nomogram or computer software for the dose adjustments. Although the higher induction dose of 15 mg is not less safe than lower doses, it should be avoided in patients with a high risk of bleeding and not used in patients with a deficiency of protein C or S due to the increased risk of warfarin-induced skin necrosis.

The initial treatment with UFH or LMWH may be discontinued when the vitamin K antagonist has been given for at least 5 days and an INR of at least 2.0 has been achieved for two consecutive days. The secondary prophylaxis with vitamin K antagonists is then continued for a duration that sometimes can be decided very shortly after the diagnosis of VTE, but often requires reassessment due to the results of evaluation for thrombophilia or other investigations that may favour a longer treatment period. Conversely, bleeding complications or poor compliance may prompt a shortening of the planned treatment period. In order to improve the quality of anticoagulant therapy with vitamin K antagonists it is crucial that the patient is followed properly as an outpatient.

The treatment is monitored with analyses of the prothrombin time (PT) at least once monthly and, with results outside the therapeutic range, the dose is adjusted more frequently. The dose adjustments become more precise with less PT results outside the therapeutic range if decisions supports, such as nomograms, algorithms or computer software are used. It matters less which medical staff (specialist physicians, general practitioners, nurses, pharmacists) are in charge of the dose adjustments, as long as they are well trained and follow a large number of patients regularly. For well-motivated patients, it may be an advantage in terms of less clinical complications to perform self-testing with capillary blood sampling, using a 'point-of-care' instrument and to be in charge of the dose adjustments. This requires some training and visits at an anticoagulant clinic a few times per year for comparison of the results with those obtained at the laboratory and rehearsal of the instructions.

All patients who receive a prescription for vitamin K antagonists should be informed about the risk of bleeding and whom to contact whenever such symptoms occur. They should be informed about the risk of using analgesic or antiphlogistic drugs, i.e. acetylsalicylic acid and non-steroid anti-inflammatory drugs, which impair the platelet function, and about the alternatives that can be used; although paracetamol interacts with warfarin, this is not clinically significant, as demonstrated in a randomized study. They should know that a vast number of drugs interact with vitamin K antagonists so that the possibility of an interaction should be questioned for each new drug prescribed. Furthermore, several herbal medicines, including St John's wort, ginseng and garlic reduce the concentration of warfarin in blood, and gingko in combination with warfarin has been reported to cause bleeding. Finally, balanced information should be given about the effect of large amounts (250 g daily on more than a single occasion) of dark green vegetables, which contain considerable amounts of vitamin K and therefore may neutralize the anticoagulant effect, but stressing that a regular

intake of moderate amounts of vegetables is recommended. Proper delivery of this information requires that the physician is familiar with all these aspects and can present it to the patient so that it is easy to understand, but in addition printed information should be provided.

Duration of secondary prophylaxis

The optimal duration of secondary prophylaxis is difficult to pinpoint owing to the large number of factors that affect the risk of recurrence. The decision is often a compromise between avoidance of haemorrhagic complications and recurrent VTE. Meta-analyses of randomized trials have shown that a longer duration reduces the risk of recurrence, but with treatment for more than 6–12 months there appears to be a significant increase in the risk of bleeding. Factors associated with a higher risk of recurrence are shown in Table 55.5. The order of importance of these risk factors is not clear, but most guidelines have primarily been based on the nature of the triggering risk factor and sometimes also on the anatomic extension of the VTE. For the majority of patients a treatment of at least 6 months is recommended at present. Shorter treatment is indicated for patients with a distal DVT and temporary (removable) risk factor, such as trauma, surgery or oral contraceptives (6 weeks) or for patients with a high risk of bleeding (3 months). For those with a very high risk of bleeding (actual or very recent intracranial or gastrointestinal haemorrhage), insertion of a vena cava filter may be considered (see above).

In randomized trials on the duration of secondary prophylaxis, there has typically been an annual incidence of 2–4% of major haemorrhage. Attempts have been made to reduce this risk. One option is to reduce the intensity of anticoagulant therapy, and several studies on treatment with vitamin K antagonists targeted at an INR of less than 2.0 have shown a favourable risk–benefit profile. Large, randomized trials on low-intensity warfarin therapy in the extension of secondary prophylaxis after at least 3–6 months of treatment, targeted at the usual INR of 2.0–3.0, have shown that a prophylactic antithrombotic effect is obtained, but perhaps less than with full intensity. In these trials, the annual incidence of major haemorrhage was only 0.9–1.0% and, although the reason may be a selection bias, it appears that for the extension of treatment beyond 6–12 months, low-intensity vitamin K antagonist therapy is an alternative that allows for less frequent monitoring of the PT. It should be realized that secondary prophylaxis targeted at an INR of 1.5–2.0 was not tested in patients with active cancer, for whom even standard vitamin K antagonist therapy often is insufficient (see Treatment of patients with cancer, below). Similarly, in patients with a high risk of recurrence due to severe thrombophilic abnormalities, low-intensity vitamin K antagonist therapy is not recommended, for example in patients with LA, phospholipid antibodies or deficiency of antithrombin.

With the availability of low-intensity anticoagulation, prolongation of the secondary prophylaxis for many years may appear reasonable in a majority of the patients. A decision in favour of such a prolongation should be weighed against the cost and burden for the patient of monitoring the treatment, effects on the quality of life in view of restrictions regarding diet and carefulness with many other concomitant medications and, finally, the fact that about 1% of the patients annually will have a major haemorrhage. Suggestions for appropriate periods of secondary prophylaxis in patients with different risk factors alone or in combination are given in Table 55.6.

A decision to prolong the duration of anticoagulation should not be made without providing an annual follow-up by a specialist in order to reassess the treatment with respect to patient compliance, complications and new scientific data. It has not

Higher risk	Lower risk
Triggering risk factor not identified	Triggering risk factor removable or
Proximal DVT and/or PE	permanent
Presence of cancer	Distal DVT
Thrombophilic defects	*Thrombophilic defects*
Deficiency of antithrombin, protein C or protein S; homozygosity for factor V Leiden or for prothrombin G20210A (?); presence of cardiolipin antibodies or lupus anticoagulant; elevated factor VIII or homocysteine; combined defects	Heterozygosity for factor V Leiden, heterozygosity for prothrombin G20210A
Follow-up of the thrombotic disease	
Persistent elevation of D-dimers	Normalized level of D-dimers
Remaining thrombus on ultrasound examination	Normalized ultrasonogram

Table 55.5 Factors associated with a higher risk of recurrence of venous thromboembolism.

Table 55.6 Suggested duration of secondary prophylaxis in relation to presence of risk factors (from Schulman, 2003).

Condition	Duration
Thrombophilic defects not identified or unknown	
First event, distal DVT, provoked by temporary risk factor	6 weeks
First event, distal DVT with idiopathic or permanent risk factor; or any proximal DVT or pulmonary embolism	6 months or longer
As above with increased risk of bleeding	3 months
Single life-threatening event	12 months or longer
First event, active cancer	Until cancer resolved
Second event, contralateral DVT	As after the first event
Second event, ipsilateral or pulmonary embolism	12 months or longer
Third event or more	Indefinitely
*Thrombophilic defects identified**	
Deficiency of antithrombin	Indefinitely
Deficiency of protein C or protein S	12 months or longer
Homozygous form of thrombophilic defect	Indefinitely[†]
Double heterozygous for thrombophilic defects	Indefinitely
Antiphospholipid syndrome	Years
Hyperhomocysteinaemia	As without[‡]
Elevated factor VIII activity (above 2.3 IU/mL)	6 months or longer
Factor V Leiden mutation, heterozygous	As without the defect
Prothrombin polymorphism, heterozygous	As without the defect
Life-threatening event and any defect	Indefinitely

*Independent of the event being provoked by a temporary or permanent risk factor, whenever the thrombophilic defect is permanent.

[†]Possibly excluding the homozygous form of the prothrombin polymorphism.

[‡]Tentatively with B vitamins thereafter.

been shown convincingly that the risk of recurrence is higher after the second episode of VTE than after the first. However, recurrent DVT in the ipsilateral leg causes additional damage to the venous valves and increases the risk of the post-thrombotic syndrome significantly, which explains the different strategy from when the recurrence is in the contralateral leg. Patients with PE have a higher risk of recurrent symptomatic PE than do patients with initial DVT, and an extension of the secondary prophylaxis may thus be justified after recurrent PE. Patients with LA or cardiolipin antibodies do not only have a high risk of recurrence after cessation of anticoagulation, but also they have an increased incidence of fatal arterial and venous thromboembolic events, and therefore anticoagulation should be extended, although there are no data to show for how long. An elevated level of factor VIII above the 90th percentile (> 2.36 IU/mL) is associated with an increased risk of recurrence.

Treatment with the beta-blocker propranolol has not been effective in reducing that level and extension of the anticoagulant therapy may be considered. For patients with hyperhomocysteinaemia, it has been demonstrated that B-vitamins (folic acid, cobalamin and pyridoxin) reduce the level of homocysteine, in most cases to within the normal range. This has

also been associated with a reduced risk of arterial restenosis, whereas the effect on recurrent venous thromboembolic events has so far not been demonstrated convincingly, but that would require studies with many thousands of patients. As this treatment is harmless and may be beneficial for several disorders in populations without food fortification with such vitamins, it seems reasonable to prescribe this combination to patients with VTE and hyperhomocysteinaemia rather than to extend the anticoagulant therapy.

Cessation of the treatment with vitamin K antagonists is often associated with an increment of prothrombin fragment 1 + 2 and of D-dimers, independent of whether it is done abruptly or gradually. There are insufficient data on clinical complications to support one of the modes of cessation more than the other.

Management in the case of bleeding or surgery

Excessive anticoagulation may be identified as an isolated prolonged PT (INR above 4.0) or in combination with bleeding. Although elimination of one dose of the vitamin K antagonist followed by a reduction of the maintenance dose may suffice in

most cases, the addition of 1 mg of vitamin K_1 orally reduces the risk of bleeding. The reason for excessive anticoagulation should be investigated and may reveal an interaction with other drugs or irregular dosing.

For minor bleeding in combination with an INR above 4.0, a similar strategy is applicable. In the case of major or life-threatening bleeding, reversal with vitamin K_1 is too slow, as only a weak effect is noticed after 2 h and the full effect occurs after 12–24 h. Substitution with the vitamin K-dependent coagulation factors is necessary, but the volumes of plasma required are invariably so large (typically 2–3 L to reduce the INR from 4.0 to 1.5 in a patient with body weight of 80 kg) that there is a substantial risk of volume overload. Prothrombin complex concentrate carries no risk of volume overload and has undergone viral inactivation to eliminate the risk of transmission of HIV or hepatitis B or C. A few cases with thromboembolic complications in association with the use of prothrombin complex concentrate have been reported, but the risk appears small as no complications were observed in prospective cohorts. The target should be an INR of 1.0 in the case of life-threatening haemorrhage in a patient who has had VTE many months previously and an INR of 1.5 when there is still an appreciable risk of recurrent VTE.

In patients with bleeding at INR levels within or below the therapeutic range, cancer should be suspected and investigations of the source are indicated.

For minor surgery, such as tooth extractions or dermatological surgery, anticoagulant therapy can be maintained within the therapeutic range. Randomized trials have shown an excellent prophylactic effect against bleeding complications (from 40% to 5% or from 21% to 0%) after tooth extractions if the patients were prescribed mouth rinses with the fibrinolytic inhibitor tranexamic acid every 6 h. For major surgery, the INR has to be reduced to 1.5, either by complete interruption or by reduction of the vitamin K antagonist. Substitution with LMWH or UFH is given post-operatively until therapeutic INR has been regained and for patients with VTE within 2–3 months or with major thrombophilic defects also preoperatively.

Secondary prophylaxis with low-molecular-weight heparin

Secondary prophylaxis with UFH has been compared with vitamin K antagonists in a few studies. Whereas the efficacy of a fixed dose of UFH was questionable, a dose regimen with UFH twice daily subcutaneously, adjusted to prolong the APTT 1.5 times the normal value at 6 h after an injection, was as effective as vitamin K antagonists. This regimen never gained any popularity due to the requirement for two doses and adjustments. A meta-analysis of studies on secondary prophylaxis, comparing LMWHs with vitamin K antagonists, has shown that they are equally effective and safe. LMWH, injected once daily subcutaneously, may be the drug of choice for patients with a very short treatment duration ($\leq$ 6 weeks), with pronounced difficulties to

achieve stable INR values or when monitoring of the vitamin K antagonist is problematic owing to geographic inaccessibility, frequent travelling or rare cases with a false prolongation of the PT by a LA. The dose of LMWH should be approximately 50% of the initial treatment dose and monitoring with anti-factor Xa is not required unless there is an impairment of the renal function. The risk of long-term anticoagulation with LMWH regarding osteoporosis is minimal and heparin-induced thrombocytopenia is very rare.

Treatment of patients with cancer

In cohorts of unselected patients with VTE, the prevalence of cancer is about 20%. Even occult cancer may increase the risk of thrombosis for several years until it becomes clinically manifest. The diagnosis and treatment of patients with VTE and known cancer differs somewhat from what has been described above. The diagnosis of DVT with ultrasonography or phlebography may become false-positive due to obstruction of the iliac vein by a pelvic tumour mass or metastases, and computerized tomography may therefore be the diagnostic method of choice. Compression of a pulmonary artery by a tumour mass or tumour emboli may simulate perfusion defects by PE, both on lung scanning and pulmonary angiography. Measurement of D-dimers is not of any value in these patients, who typically have elevated levels even in the absence of VTE.

The initial treatment should preferably be given with LMWH in view of the survival benefit in patients with cancer over the following 3 months in comparison with those treated with UFH (15% and 22% mortality, respectively, in a meta-analysis). Although patients with cancer have massive thromboembolism more frequently than those without cancer, thrombolytic therapy is very hazardous, as the risk of bleeding is aggravated by necrosis in highly vascularized tumour tissue, erosion of normal tissues and thrombocytopenia due to bone marrow invasion by tumour or aplasia after chemotherapy. In some of these patients, the risk of bleeding is so pronounced that in the case of pulmonary embolism or massive DVT there is an indication for inferior vena cava filter.

Long-term anticoagulation in patients with cancer has traditionally been considered as cumbersome. There is an absolute increase of the annual risk of recurrence despite vitamin K antagonists by 14–18 percentage points compared with patients without cancer and concomitantly an absolute increase of major bleeding of 7–11 percentage points. For the secondary prophylaxis, LMWH may be a better alternative than vitamin K antagonists in the majority of patients with cancer. The advantages and drawbacks are summarized in Table 55.7. The dose should be 75% of the initial treatment dose. There are now indications from several trials that long-term LMWH may prolong the survival in patients with cancer and VTE, and perhaps also in those without VTE. This does probably not apply to terminally

Table 55.7 Advantages of LMWH or vitamin K antagonists in the secondary prophylaxis for patients with VTE and cancer.

For LMWH	*For vitamin K antagonists*
No interactions with chemotherapy, analgesics or other drugs	Oral administration
No monitoring in most patients	Inexpensive drug
Subcutaneous administration is advantageous in the case of emesis	Can be used with renal failure
Simple adjustment for biopsy, surgery	

ill patients but rather to those with an expected survival of at least 1 year. However, many questions remain to be answered, including the mechanism for this effect, whether the effect is confined to certain types of cancer, the minimum treatment period required and the optimal dose of LMWH. The secondary prophylaxis should continue as long as active cancer is present unless the severity of bleeding complications precludes the treatment.

Venous thromboembolism in pregnancy

The incidence of VTE in association with pregnancy is 0.5–1.0 per 1000 with 1–2 fatal cases of PE in 100 000 pregnancies. The DVT occurs predominantly (70–95%) in the left leg and is often isolated to the iliac or iliofemoral vein. This may generate a clinical picture that is slightly different from the one generally seen in DVT. The only symptoms may be abdominal cramps, sciatic back pain or fever. Objective diagnosis is even more important in the pregnant patient, as failure to treat an undiagnosed VTE as well as treatment of a false-positive diagnosis may cause harm to both the mother and the baby.

The diagnosis of DVT is more difficult in pregnancy as the pressure from the uterus on the pelvic veins may simulate the effect of thrombosis on ultrasonography and plethysmography, particularly in the third trimester. These examinations are more accurate if performed with the patient resting on her side. Plethysmography has been evaluated in several studies in pregnancy, and with repeated negative exams a DVT can be excluded. Ultrasonography is now more widely available, but diagnosis of a distal DVT may be difficult. The radiation dose from phlebography, perfusion–ventilation lung scanning, spiral CT or pulmonary angiography is so small that the possible risk for the child of future malignancy caused by radiation or hypothyroidism due to free iodine is substantially less than the risk of missing the diagnosis. Any of these examinations should therefore be performed if they are considered to be important for the diagnosis, but obviously with all available precautions, such as reduction of the dose of isotopes, ample administration of fluids to the patient with frequent emptying of the bladder or avoidance of direct radiation to the pelvis by limiting the field to below the groins. Magnetic resonance tomography is not know to cause any harm to the fetus and, if available, may be a

useful diagnostic tool for the pregnant patient with suspected VTE. D-dimers are not helpful in these patients, who often have increased levels during a normal pregnancy and especially in the case of a twin pregnancy.

Thrombolytic therapy may be used for massive DVT or PE, but the risk of bleeding is particularly high if this is used shortly before or during the delivery or the puerperium. Thrombectomy for iliac or iliofemoral DVT can be performed safely in pregnant patients, but there are no controlled studies to show that this gives any better short-term or long-term results than anticoagulant therapy. Although there are substantial data, including a few randomized trials regarding the use of LMWHs as prophylaxis during pregnancy, there is only limited experience from these drugs in the treatment of established DVT or PE and, in most countries, UFH is still considered the standard therapy for this indication. However, as data from case series on various LMWHs continue to accumulate, this modality will probably gain popularity owing to the ease of administration. If UFH is chosen, it is started as a bolus dose followed by continuous intravenous infusion to prolong the APTT at 1.5–2 times the upper limit of normal. After 1 week, the treatment is switched to 3 weeks of subcutaneous injections with UFH twice daily at the same total daily dose as on the last day of infusion. Thereafter, the patient may receive secondary prophylaxis with LMWH (see below).

An alternative is to switch to LMWH after the first week, aiming at anti-factor Xa levels of 0.6–1.0 IU/mL at peak concentration 3 h after injection, also given for 3 weeks. Finally, treatment with LMWH may be started immediately when the diagnosis is made, but monitoring with anti-factor Xa is necessary, as the requirement for any form of heparin is increased during pregnancy. Some continue with the treatment dose until the end of pregnancy, but usually secondary prophylaxis is carried on with a slightly lower dose of LMWH twice daily, targeted at anti-factor Xa levels of 0.1–0.2 IU/mL immediately before the next dose. Vitamin K antagonists should not be used owing to an increased risk of fetal haemorrhage, teratogenic effects, mental retardation, opticus atrophy and late neurological impairment. UFH and LMWH do not pass the placenta.

At the time of delivery, blood samples are taken on admission for platelet count, APTT and PT to evaluate the risk of bleeding, and the dose of LMWH is halved. Epidural or spinal anaesthesia should be avoided for higher doses of LMWH, but if the dose is

5000 anti-Xa units, the procedure can be performed 12 h after the previous dose of LMWH and must not be followed by a new dose until at least 2 h have elapsed. With a dose of only 2500 units, a lag time of 6 h is sufficient. Removal of the catheter is also performed at least 12 h or 6 h, respectively, after the previous dose. Post partum, the prophylaxis is continued with initially the same dose of LMWH as during the last part of the pregnancy, for at least 6 weeks and with a total duration that is at least as long as would have been chosen for a non-pregnant patient with the same risk factors, except for the pregnancy. Monitoring with anti-factor Xa is still necessary owing to decreasing requirements for LMWH post partum. Alternatively, vitamin K antagonists can be given after the delivery, and LMWH is then stopped when the INR is within 2.0–3.0 for at least 2 days and after a minimum of 5 days. Neither LMWH nor vitamin K antagonists pass over to breast milk in any amounts that can have an effect on the baby.

Women with congenital deficiency of antithrombin require higher doses of heparin. Substitution with antithrombin concentrate should be considered in association with delivery to allow for a safe reduction of the dose of LMWH, and thereby to reduce bleeding.

The post-thrombotic syndrome

Thrombi that do not undergo thrombolysis or are not removed rapidly will destroy venous valves in the process where they are incorporated into the venous wall and transformed into fibrous tissue. Venous return of blood becomes impaired, accompanied with increased venous pressure. Permeation of fluid to the extravascular space causes oedema and creates a perivascular barrier to plasma proteins, which reduces the transport of nutrients to the tissues and results in skin atrophy and in the most severe cases venous ulcers. This process takes between 1 and 5 years, sometimes even longer, and is seen in up to 75% of the patients. The tools available to reduce the risk of developing the post-thrombotic syndrome are:
• thrombolytic therapy, which has a limited use due to the risk of haemorrhage; and
• graduated compression stockings.

With the use of such stockings for 2 years after an episode of DVT, the incidence of post-thrombotic syndrome was reduced from 70% to 31%. It is not known if treatment for 1 year would suffice for the same effect or if it should be even longer in some patients. Knee-high stockings are sufficient for the vast majority of patients; they should be of compression class II (20–30 mmHg), fitted individually and they should be worn whenever the patient is not recumbent.

Congenital platelet disorders

56

Maurizio Margaglione

Introduction

In haemostasis, a sequence of local events culminates in spontaneous arrest of bleeding from a traumatized blood vessel. The normal haemostatic mechanisms are sufficient to seal up the interruption of vascular continuity. Three closely linked biological systems are involved: blood vessels, coagulation proteins and platelets. Platelets, which normally circulate in the bloodstream for about 7–10 days, are anucleate cells that derive megakaryocytes from the cytoplasm of the giant bone marrow. They normally do not interact with endothelial cells or other blood cells but, when the vessel wall is disrupted, they adhere to exposed subendothelial components, then become activated, amplify and propagate platelet activation by secreting from platelet organelles adenosine diphosphate (ADP) and other active substances, and finally aggregate each other.

Platelets are important in arresting bleeding from damaged blood vessels by plugging the rupture in the vessel wall and providing a surface that promotes blood coagulation. In addition, platelets play an important role in maintaining the integrity of blood vessel wall. Strictly related clinical findings of abnormalities of these two platelet functions are a prolonged skin bleeding time and a history of easy and spontaneous bruising. Abnormal bleeding due to deficiencies of platelets shows characteristic clinical features distinct from those seen in disorders of plasma coagulation factors (Table 56.1). The occurrence of superficial bleedings in patients presenting with platelet disorders and deeper bleeding in those with coagulation disorders is a clinically useful point, but it must be remembered that activities of platelets and coagulation factors are closely related.

Bleeding associated with platelet abnormalities manifests as haemorrhages from small vessels. Petechiae usually develop on the skin and the visible mucosal membranes, but they may be distributed throughout the body, including internal organs. Characteristically, bleeding resulting from platelet diseases is immediate and transient, tends to stop promptly with local pressure and not to recur when the pressure is removed. The occurrence of haemorrhages in infancy or childhood clearly suggests the presence of a congenital deficiency of platelets. However, the disease may be clinically silent and the patient may enter adult life before characteristic bleeding occurs.

Table 56.1 Main specific clinical differences between diseases of coagulation factors and platelet disorders.

Findings	Disorders of coagulation	Platelets/vessels
Onset of bleeding	Delayed after trauma	Spontaneous or immediately after trauma
Mucosal bleeding	Rare	Common
Petechiae	Rare	Characteristics
Deep haematomas	Characteristics	Rare
Ecchymoses	Large and solitary	Small and multiple
Haemarthrosis	Characteristics	Rare
Bleeding from superficial cuts and scratches	Minimal	Persistent, often profuse
Sex of patient	80–90% male	Equal

Table 56.2 Classification of congenital platelet disorders.

Thrombocytopenia
Non-inherited thrombocytopenia
    Drugs and chemical agents
    Isoimmune thrombocytopenia
    Infiltration of bone marrow
    Infections
    Other causes
Inherited thrombocytopenias
    Thrombocytopenias with reduced platelet size
    Thrombocytopenias with normal platelet size
    Thrombocytopenias with increased platelet size

Thrombocytopathies
    Disorders of platelet adhesion functions
    Disorders of platelet signalling transduction functions
    Disorders of platelet aggregation functions

The family history may be of great importance providing a characteristic pattern of inheritance, but it should be remembered that a negative family history does not exclude an inherited platelet abnormality, i.e. the family history is usually negative in autosomal recessive traits. A comprehensive medical history and a careful clinical examination of the patient presenting with a haemorrhagic disorder is crucial for the correct diagnosis. Then, laboratory tests, chosen on the basis of clinical information previously obtained, will lead to a precise characterization and will define the severity of the platelet abnormality.

Congenital defects of platelets may give rise to bleeding syndromes of varying severity and are difficult to classify because of the rarity of many forms, the extreme heterogeneity, and also of the incomplete knowledge about a series of diseases. In the classification presented in Table 56.2, platelet congenital disorders are divided in two main groups: thrombocytopenias and thrombocytopathies. Then, each group is further divided according to specific criteria based on functional and biochemical defects. Such a classification has to be considered as tentative, as in many disorders multiple distinct pathogenetic factors may play a major role and some platelet disorders are put together for convenience of classification rather than on the basis of knowledge of their pathophysiology.

Thrombocytopenia

Thrombocytopenia, defined as a subnormal number of platelets in the circulating blood, usually below 100 000/mL, is the most frequent cause of severe bleeding and, except for chronic thrombocytopenia, the risk for haemorrhages is inversely proportional to the platelet count, spontaneous bleeding occurring frequently when the platelet count is below 20 000/mL. As a rule, there is an inverse relationship between platelet count and skin bleeding time. When automated methods are used, 'artifactual thrombocytopenia' or pseudothrombocytopenia can be observed. Several different mechanisms falsely lower platelet counts. This condition may occur in patients with a wide panel of clinical disorders. Non-technical factors inducing pseudothrombocytopenia include paraproteinaemias, platelet cold agglutinins, giant platelets, previous contact of platelets with foreign surfaces (i.e. dialysis membrane), lipaemia and EDTA-induced platelet clumping. The possibility of a pseudo-thrombocytopenia has to be ruled out through careful manual counting of a well-prepared blood film before concluding that a patient has true thrombocytopenia.

Congenital non-inherited thrombocytopenia

Congenital thrombocytopenia not to be ascribed to inherited causes may be the result of a series of pathogenetic mechanisms. Thrombocytopenia may be attributable to deficient platelet production or enhanced destruction of circulating platelets.

Drugs and chemical agents

The maternal use of drugs and chemical agents has become an increasingly common cause of thrombocytopenia. They may exert their effect suppressing platelet production, damaging platelets directly, or provoking the formation of platelet antibodies. Maternal ingestion of ethanol, thiazides, chlorpropamide, tolbutamide, oestrogens, steroids and other drugs may selectively suppress thrombopoiesis. Drugs such as alkylating agents, antimetabolites or cytotoxic chemotherapeutic agents capable of crossing the placenta may lead to severe thrombocytopenia in newborns as the result of a predictable suppression of the bone marrow; the maternal ingestion of quinine, quinidine, hydralazine or selected antibiotics known to induce immune-mediated thrombocytopenia may induce congenital immune-mediated thrombocytopenia. In these newborns, thrombocytopenia usually remits rapidly and only rarely severe and fatal haemorrhages occur.

Isoimmune thrombocytopenia

Immunological thrombocytopenia may also result from the placental transfer of platelet antibodies formed as the results of active immunization of the mother by fetal platelet isoantigens, if the fetus has inherited a paternal platelet-specific antigen that induces immunoglobulin (IgG) antibody formation. Transplacental passage of the maternal antibody (usually an IgG) may induce a severe thrombocytopenia in the fetus. This usually occurs when the mother has PlA1-negative platelets and the fetus carries PlA1-positive platelets. Newborns may show petechiae and purpura, or more severe bleeding at the time of birth, or may appear normal at the delivery and then manifest severe bleeding within the first week after birth. In this case,

thrombocytopenia usually remits within 1 month, but severe and fatal intracranial haemorrhage may occur.

Infiltration of bone marrow

Congenital thrombocytopenia caused by bone marrow infiltration is extremely rare, being limited to cases of disseminated reticuloendotheliosis and congenital leukaemia. Thrombocytopenia with or without associated myeloid and erythroid depression occurs in children with numerous infiltrative disorders including lymphoma, solid tumors, myelofibrosis, Gaucher's disease, Niemann–Pick disease and the mucopolysaccharidoses.

Infections

Thrombocytopenia, usually mild but sometimes very severe, is commonly seen in infected newborns and several mechanisms are probably responsible. In fact, an impaired platelet production as a result of invasion of megakaryocytes, the destruction of circulating platelets and the formation of antigen–antibody complexes may explain many instances of thrombocytopenia associated with viral infections. Maternal infection with toxoplasma, cytomegalovirus, rubella, herpesviruses or hepatitis varicella, as well as recent maternal vaccinations (rubella), may induce congenital thrombocytopenia.

Other causes

Occasionally, children born to women with chronic idiopathic thrombocytopenic purpura manifest congenital thrombocytopenia. It is likely that autoantibodies causing the disease in the mother cross the placenta and bind to fetal platelets, causing their destruction. Other causes of congenital thrombocytopenia due to increased platelet consumption or destruction include preeclampsia, lupus erythematosus or other autoimmune diseases, especially if the woman has a lupus anticoagulant or anticardiolipin antibodies. Finally, a moderate to severe thrombocytopenia has been observed, associated with giant cavernous haemangioma, first described by Kasabach and Merritt, in which the consumption of platelets occurs primarily within the tumour. Thrombocytopenia is often found associated with coagulation abnormalities typical of disseminated intravascular coagulation and the severity tends to parallel the size of the vascular tumour.

Inherited thrombocytopenias

Several inherited diseases may occasionally present with thrombocytopenia, which is an accompanying sign as the result of a generalized bone marrow failure (e.g. Fanconi's anaemia) or metabolic diseases (e.g. Gaucher's disease). These diseases and other complex clinical syndromes (e.g. Noonan's syndrome) will not be discussed in this review. Inherited thrombocytopenias are very rare. In addition, in some diseases both a constitutional thrombocytopenia and a thrombocytopathy (e.g. Bernard–Soulier syndrome, Wiskott–Aldrich, etc.) are observed. These diseases will be discussed in the appropriate section according to the most prominent defect. As proposed by the Italian Working Group, both platelet size and the presence (syndromic) or the absence (non-syndromic) of other clinical features, different from those deriving from platelet abnormalities, are helpful criteria to classify inherited thrombocytopenias.

Inherited thrombocytopenias with reduced platelet size

The *Wiskott–Aldrich syndrome* (WAS) is a rare (1:250 000) X-linked recessive disorder characterized by eczema, susceptibility to infections associated with defects in cellular and humoral immunity, and thrombocytopenia with reduced platelet size. The gene responsible for WAS maps to Xp11.1 and codes for a protein, WASp, expressed only in haemopoietic-derived cells and involved in the transduction of the signals from the receptor to the actin cytoskeleton. Intermittent bleeding, recurrent bacterial and viral infections, and progressive eczema occur during the first months of life. Death at an early age commonly results from intracranial haemorrhage, infection or lymphoreticular malignancy. A number of kindreds have been reported in whom *X-linked thrombocytopenia* (XLT) occurred alone or in association with partial manifestations of WAS. Also XLT is caused by mutation within the *WAS* gene. Patients with XLT mainly suffer from an isolated bleeding tendency.

Inherited thrombocytopenias with normal platelet size

Congenital deficiency of megakaryocytes is a rare form of thrombocytopenic purpura in the newborn and may occur with skeletal, renal or cardiac malformations. Isolated congenital *amegakaryocytic thrombocytopenia* (CAMT) is an autosomal recessive syndrome leading to bone marrow aplasia later in childhood. This disorder is associated with abnormalities in the expression or function of the thrombopoietin receptor, c-mpl, and a series of mutations in the *c-mpl* gene have been identified. Usually, associated skeletal anomalies are present. Bilateral agenesis of the radius is the most commonly associated abnormality [*thrombocytopenia with absent radius* (TAR) *syndrome*]. TAR syndrome is an autosomal recessive disease characterized by severe, even fatal, haemorrhagic manifestations. Although abnormalities in the thrombopoietin–c-*mpl* signalling pathway have been suggested, no mutations have been found in genes coding for these proteins. In some infants, the ulna and humerus may also be absent and other skeletal abnormalities may occur. In addition, a proximal radioulnar synostosis, syndactyly and other skeletal abnormalities are reported in association with an autosomal dominant congenital amegakaryocytic thrombocytopenia in patients carrying heterozygous mutations of the *HOXA11* gene. Less commonly, patients manifest cardiac and other minor defects. *Schulman–Upshaw syndrome*, which is caused by mutations in the *ADAMTS13* gene, is characterized by thrombotic thrombocytopenic purpura with neonatal onset (congenital microangiopathic haemolytic anaemia), thrombocytopenia and frequent relapses, and response to fresh plasma infusion.

Inherited thrombocytopenias with increased platelet size

Thrombocytopenias with increased platelet size are characterized by the presence of an increased volume and a reduced number of the platelets, megathrombocytopenia, and are the commonest inherited forms of thrombocytopenias. Among them, a series of diseases have been characterized at the molecular level, whereas other clinical entities still wait for the identification of the molecular defect. Giant platelets and moderate thrombocytopenia are most frequently found in certain populations of Mediterranean extraction and also may be associated with other inherited or congenital syndromes, such as *May–Hegglin* anomaly, Bernard–Soulier syndrome, stomatocytosis, etc. The May–Hegglin anomaly is a rare autosomal dominant disease characterized by giant platelets and basophilic inclusions (Döhle's bodies) within granulocytes. Large Döhle's bodies are seen in peripheral and in bone marrow granulocytes, and most patients show mild neutropenia but no significant susceptibility to infection. About 50% of patients have significant thrombocytopenia deriving from an ineffective thrombopoiesis, but the occurrence of a life-threatening haemorrhage is rare. The platelets in patients suffering from May–Hegglin anomaly show not only a greatly, more than twice, increased volume, but also most of them display bizarre morphology and hypergranularity. Strictly related to the May–Hegglin anomaly are a group of other autosomal dominant diseases, known as Sebastian, Fechtner and Epstein syndromes. The main characteristic is the presence in almost all patients of giant platelets with thrombocytopenia. In addition, patients may develop sensorineural hearing loss, cataract and glomerulonephritis, and most of them display Döhle's bodies. The exact classification of patients according to the presence or the absence of the above-mentioned clinical signs is shown in Table 56.3. Recently, the molecular basis of these syndromes has been elucidated. All of these clinical entities are caused by mutations that occur within a gene (*MYH9*) located on the long arm of the chromosome 22 (22q12–13). This gene encodes for the heavy chain of non-muscle myosin IIA (NMMHC-IIA), a protein involved in motor activity of cytoskeleton. *Grey platelet syndrome* (GPS) is a rare disorder inherited as an autosomal dominant trait, although one example of recessive transmission has been shown, and is characterized by large platelets with a selective deficiency in the number and content of α-granule content. For this reason, platelets are either markedly hypogranular or agranular and display a deficiency of α-granule proteins, such as fibrinogen, von Willebrand factor (vWF), thrombospondin, β-thromboglobulin and platelet factor 4. Thrombocytopenia is usually pronounced and severe bleedings may occur. *Mediterranean macrothrombocytopenia* is usually an asymptomatic disorder with moderate isolated thrombocytopenia and large platelets inherited as an autosomal dominant trait. The condition is characterized by mild or no clinical manifestations and normal bone marrow megakaryocytosis, platelet survival, and *in vitro* platelet functions. Recently, in a series of patients suffering from Mediterranean macrothrombocytopenia, a reduction of the content of the GPIb–IX platelet receptor has been shown and in some of them heterozygous mutations within the *GPIbα* or *Ibβ* genes have been described. Therefore, in these patients, Mediterranean macrothrombocytopenia may be classified as a heterozygous form of the Bernard–Soulier syndrome (see below). On the other hand, the remaining patients having *Mediterranean macrothrombocytopenia* do not show a reduction of the content of the GPIb–IX platelet receptor and the pathogenesis of this form remains to be clarified. A thrombocytopenia resulting from enhanced platelet destruction may be present in *type IIB von Willebrand disease*. Patients suffering from this syndrome show a qualitative abnormality of plasma vWF such that vWF binds inappropriately to circulating platelets. The molecular bases are mutations within the vWF gene, usually the exon 28, which give rise to an increased reactivity of vWF with the platelet receptor GPIb–IX. Clearance of the resulting vWF–platelet complexes leads to thrombocytopenia and the selective loss of the largest vWF multimers from plasma. In general, the degree of thrombocytopenia is moderate and bleedings are of variable severity. The type IIB von Willebrand disease has to be distinguished from the rare pseudo-von Willebrand disease (or *platelet-type von Willebrand* disease). The defect in this autosomal dominant condition results from mutations in gene encoding for the GPIb-α subunit of the platelet receptor GPIb–IX. The few mutations identified give rise to a gain of function of the platelet receptor and increase the affinity for the vWF. As a consequence, spontaneous binding of platelets to vWF occurs with shortened platelet survival and related thrombocytopenia. Reasons why most patients suffering from platelet-type von Willebrand disease show variable enlarged

platelets remain unclear. Other very uncommon causes of macrothrombocytopenia are the *Jacobsen* and the *Paris–Troussau* syndromes. Both are syndromic diseases inherited as autosomal dominant traits and characterized by chromosomal deletion encompassing the same region of the chromosome 11 (11q23.3–11q24.2). In addition, isolated kindreds have been described with distinct forms of giant platelets and a reduced platelet count, such as the *Montreal platelet* syndrome, a platelet disorder characterized by a spontaneous *in vitro* platelet aggregation, the pathogenesis of which is unclear.

Thrombocytopathies

Platelets have a complex ultrastructure comprising a multitude of molecules and the malfunctioning of any of these may give rise to a specific disease (Figure 56.1). Platelets participate in haemostasis by adhering to exposed elements of the subendothelial matrix. Then, they spread on the subendothelial surface, becoming activated, release the content of their storage organelles and aggregate each other. Abnormalities in any of these phases of platelet functions, adhesion, activation and secretion, and aggregation may give rise to congenital disorders of platelets. Patients suffering from one of these diseases usually show a bleeding diathesis, with a prolonged bleeding time and a normal platelet count.

Disorders of platelet adhesion functions

The adhesion of platelets to the injured blood vessel wall is possible through the interaction of platelet receptors with elements of the subendothelium, collagen, fibronectin and blood components that adhere to the subendothelium, such as vWF (Figure 56.2). A series of receptors have been identified on the

platelet surface and they interact with one or more of these elements. The most important receptors are the GPIb–IX and the $\alpha_2\beta_1$ (previously known as GPIa–IIa). The $\alpha_2\beta_1$ is one of receptors on the platelet surface that binds collagen and is a member of the integrin β_1 subfamily. Different receptors for the collagen are the GPIV and GPVI. Binding of molecules to these receptors leads to the subsequent binding to other receptors, which serves to reinforce adhesion and to generate intracellular signals, such as calcium mobilization and protein phosphorylation.

The *Bernard–Soulier syndrome* (BSS) is a bleeding disorder characterized by giant platelets in the blood smear, mild or moderate thrombocytopenia, and prolongation of the skin bleeding time disproportionate to the thrombocytopenia. BSS is a recessively inherited autosomal disorder and consanguinity is common in reported kindreds. Based on reported data, the frequency of the BSS has been estimated to be approximately one case in 1 million people. Bleedings may be severe and fatal haemorrhages may occur. Cutaneous haemorrhages and muscular/visceral bleedings are common. Epistaxis and menorrhagia may be difficult to control. Haemarthrosis has also been reported. Platelet counts range from as low as 20 000/mL to near normal and, on the peripheral blood film, over 80% of the platelets are usually larger (more than 2.5 mm, to as much as 8.0 mm, in diameter). The number of bone marrow megakaryocytes is usually normal.

Patients presenting with BSS show an absent platelet agglutination in response to ristocetin (in the presence of human vWF) and normal aggregation, ATP secretion and thromboxane (TX) B_2 formation in response to a variety of aggregating agents, and delayed response to thrombin. Biochemical and cellular factors contributing to these abnormalities have been clarified in a series of studies. Because of the defective binding with vWF, platelets in BSS do not agglutinate in response to ristocetin and
Figure 56.1 The complex structure of platelets. Abnormalities of any platelet complex can lead to an alteration of a specific function.
Figure 56.2 Platelets circulate in the bloodstream and do not interact with endothelial cells (a), unless the vessel wall is damaged (b). Adhesion of platelets to injured blood vessel wall (c) and spreading on it (d) is possible through the interaction of platelet receptors with their ligands and vWF collagen.

have substantial reduction in their ability to adhere to sites of vascular injury where subendothelial vWF becomes exposed. As a consequence, plug formation, the primary haemostatic response, is impaired in BSS and increased and prolonged bleeding occurs. Variable levels of the glycoprotein (GP)Ib–IX–V complex have been detected on the platelet surface of patients with BSS, some patients with BSS exhibiting nearly normal GPIb–IX–V amounts (variant type of the BSS). Despite the difference in glycoprotein content, clinical bleeding problems and platelet functional and morphological abnormalities of these patients were indistinguishable from the classical BBS phenotype.

The GPIb–IX–V receptor complex provides the principal site for mediating the interaction of platelets with the adhesive vWF. The entire cDNA sequences encoding the protein chains comprising this receptor have been obtained, allowing for studies on the molecular basis of the syndrome. This complex consists of four proteins: the disulphide-linked α-(135 kDa) and β-chains (25 kDa) of GPIb, and the non-covalently associated subunits GPIX (22 kDa) and GPV (82 kDa). All of them share structural and functional features, suggesting a common evolutionary origin. Different transcripts encode the four polypeptidic chains and, with the exception of that of the GPIbβ, genes show continuous (intron-depleted) open reading frames. In addition, each element contains one or more homologous 24-amino-acid leucine-rich glycoprotein repeats. The genetic heterogeneity in the glycoprotein content of BSS patients shows that multiple molecular abnormalities may lead to a similar clinical disorder, and implies that BSS may be the result of defects within the subunits that hamper the coordinate expression of the complex on the platelet membrane. In this respect, BSS would resemble abnormalities of other multi-subunit complexes, in which a defect in a single subunit prevents the assembly and the surface expression of the complex.

In addition to quantitative and qualitative abnormalities of the GPIbα gene, the recognized BSS phenotype has also been documented in patients with detrimental mutations within platelet GPIX and GPIbβ genes. Very few patients with a defect of one of the platelet receptors for collagen have been described. These patients showed mild bleeding disorders and a selective impairment, at a variable extent, in collagen response, adhesion to subendothelial surfaces and collagen-induced platelet aggregation. Platelets have two major receptors for collagen, the $\alpha_2\beta_1$ integrin, with a major role in adhesion of platelets to subendothelial surfaces, and the GPVI, mainly involved in platelet activation. Thus, it is conceivable that collagen binding to platelets occurs through a multistep mechanism involving first the attachment of platelets to exposed collagen of the subendothelium in flowing blood by means of the $\alpha_2\beta_1$ receptor and then platelet activation through a second receptor, GPVI.

Disorders of platelet signalling transduction functions

Platelets that adhere to the subendothelial surface become activated and begin the production or release of several intracellular messengers, which modulate a series of platelet responses, such as calcium mobilization, protein phosphorylation, and production of arachidonic acid. Activated platelets also release substances stored in their granules, some of which act in the recruitment of additional platelets and lead to the formation of the primary haemostatic plug (Figure 56.3). Several signalling mechanisms are involved in events that govern platelet responses starting from platelet adhesion to blood vessel wall injury and leading to secretion and aggregation. Evidence has become available that specific abnormalities in platelet signalling mechanisms may be the basis of platelet dysfunction. With the term of
Figure 56.3 Platelets after adhering to the subendothelial (a) surface become activated, release intracellular messengers (b) and aggregate with each other leading to the formation of the primary haemostatic plug (c).

platelet signalling, disorders may be grouped as a heterogeneous group of abnormalities in platelet secretion and signal transduction. Congenital defects of platelet signalling mechanisms are put together for convenience of classification rather than on the basis of knowledge in the pathophysiology of specific diseases. Patients suffering from these kinds of defects represent the vast majority of subjects presenting with inherited thrombocytopathies.

Platelet activation by means of binding to receptors gives rise to hydrolysis of phosphoinositide by phospholipase C, leading to the formation of inositol triphosphate, which, in turn, functions as a messenger to release calcium from intracellular stores. In addition, hydrolysis of phosphoinositide leads to the formation of diacylglycerol, which activates protein kinase C. The activation of the protein kinase C is thought to play a major role in platelet secretion and in the activation of the $\alpha_{IIb}\beta_3$ complex. In several patients, defects in phospholipase C activation, calcium mobilization and protein phosphorylation have been suggested on the basis of platelet-impaired functions, despite the presence of normal granule stores and normal thromboxane A_2.

Following stimulation, platelet phospholipase A_2 mobilizes the arachidonic acid from the phospholipid pool. Then, the arachidonic acid is metabolized by cyclo-oxygenase and thromboxane synthase to form thromboxane A_2, a strong platelet-

aggregating agent that is necessary for a secretion response. A defect in arachidonic acid mobilization and thromboxane A_2 production has been identified in some patients. Few patients with an impaired liberation of arachidonic acid have been described. Individuals with this defect showed an abnormal aggregation and secretion in response to a series of stimulating factors but a normal production of thromboxane A_2 in response to arachidonic acid. Several patients have been reported with a deficiency of cyclo-oxygenase and showing a slightly prolonged bleeding time and impaired platelet aggregation. In addition, few patients have been described with a defect in thromboxane A_2 formation presenting with a variable bleeding diathesis.

Disorders of platelet aggregation functions

Platelet aggregation may be defined as the interaction of activated platelets with one another and occurs after adhesion of platelets to the injured blood vessel wall. A series of factors are capable of inducing platelet aggregation and may be classified as primary and secondary platelet-aggregating agents. Primary aggregating substances are those factors, such as ADP, adrenaline and thrombin, which are able to directly induce platelet aggregation independently of their ability to release the ADP contained within platelets or to induce the production of prostaglandins. Secondary aggregating factors are substances that induce aggregation of platelets through their ability to provoke the release reaction of ADP or the synthesis of prostaglandins. According to this, disorders due to an impairment of platelet aggregation may be classified into defects of primary aggregation: Glanzmann's thrombasthenia; selective impairment of platelet receptors (ADP, adrenaline); and defects of secondary aggregation: storage pool disease and selective impairment of platelet receptors (thromboxane, collagen). *In vitro*, a series of substances are used to challenge platelets and the manner in which they respond to these stimuli may be helpful to identify specific thrombocytopathies (Table 56.4).

Glanzmann's thrombasthenia (GT) is a bleeding diathesis marked by prolonged bleeding time, normal platelet count and absence of platelet aggregation in response to platelet agonists such as ADP, collagen, arachidonic acid and thrombin. Platelet agglutination induced by ristocetin and vWF is normal. This congenital bleeding disorder is associated with an impaired or absent clot retraction. GT is one of the less common of the congenital bleeding disorders and is transmitted as an autosomal recessive trait, and consanguinity has been reported in affected kindreds. The clinical features are those usually expected with platelet dysfunction: easy and spontaneous bruising, mucosal membrane bleeding, subcutaneous haematomas, and petechiae. Rarely, patients suffer from intra-articular bleeding with resultant haemarthroses. Fatal haemorrhages have been reported. Quantitative or qualitative (variant GT forms) abnormalities of the platelet $\alpha_{II}b\beta_3$ integrin (also known as the glycoprotein complex IIb–IIIa) have been shown to be responsible for this

Table 56.4 Platelet response to aggregating agents in different thrombocytopathies.

Disorder	ADP	Adrenaline	Collagen	Arachidonic acid	Ristocetin

Thromboxane receptor defect	Impaired	Impaired	Impaired	Impaired	Present

disorder. Mutations within the genes that code for $\alpha IIb\beta_3$ subunits have been described in GT patients. As other integrins, α_{IIb}- and β_3-subunits are prominent integral components of the platelet membrane that form heterodimers containing specific sites for platelet–platelet cohesion. The $\alpha_{IIb}\beta_3$ integrin serves as platelet receptor for fibrinogen, fibronectin, vitronectin and vWF. In addition, the $\alpha_{IIb}\beta_3$ integrin modulates to some extent calcium influx, cytoplasmic alkalinization, tyrosine kinase phosphorylation and clot retraction. Clinical heterogeneity of GT has been stressed on the basis of platelet function testing or using crossed immunoelectrophoresis, Western blot, flow cytometry and fibrinogen binding. Type I Glanzmann's thrombasthenia is characterized by the lack of surface-detectable $\alpha_{IIb}\beta_3$ complex and a profound defect of platelet aggregation and clot retraction. At variance with the type I, platelets of patients suffering from type II Glanzmann's thrombasthenia have detectable, but markedly reduced, amounts of the $\alpha_{IIb}\beta_3$ receptor on their surface, usually from 10% up to 20% of normal values. Platelets show sufficient amounts of receptors to allow for microaggregate formation, although there is still a profound defect in the ability to form large aggregates. The clot retraction is only moderately impaired. In addition, a series of patients with a variant form have been described, who presented near normal levels of the $\alpha_{IIb}\beta_3$ complex, which is dysfunctional in that platelets, when activated, can neither aggregate nor bind fibrinogen. An extreme variability in the clinical symptoms is present, even among patients with similar degrees of platelet abnormality and prolongation of the bleeding time. In general, no aggregation abnormalities are detected in heterozygotes, but a decreased amount of the $\alpha_{IIb}\beta_3$ integrin has been reported, platelet content being approximately one-half of the normal amount.

Defects of platelet ADP receptors have been characterized in few patients and all suffered from a bleeding diathesis. On the platelet surface, different types of ADP receptors have been identified, two G-protein coupled receptors, $P2Y_1$ and $P2Y_{12}$, and a ligand gated ion channel one, $P2X_1$. The P2Y1 receptor is responsible for the shape change of platelets and transient platelet aggregation, giving rise to centralization of platelet granules and formation of filopodia, whereas the $P2Y_{12}$ receptor is involved in the amplification of the response and in the stabilization of platelet aggregates through the full activation of the $\alpha_{IIb}\beta_3$ integrin. The $P2X_1$ receptor has been suggested to be involved in platelet shape change. The $P2Y_{12}$ receptor defect is inherited as an autosomal recessive trait and all patients so far identified were born from consanguineous parents. In these patients, a blunted platelet aggregation in response to ADP, with a retained shape change, has been reported. Only one patient has been briefly reported with a defect of the $P2Y_1$ receptor. This patient showed an impaired platelet aggregation in response to ADP and other agonists. Finally, a selective impairment of ADP aggregation associated with a dominant negative mutation in the $P2X_1$ gene has been identified in a patient who presented with a severe bleeding disorder.

The *selective impairment of adrenaline receptors*, α_2-adrenergic receptors (α_2-AR), has been associated with bleeding. A number of individuals with an impaired aggregation response to adrenaline and a congenital defect of platelet α_2-AR receptors have been described and some of them presented a history of easy bruising. Secondary aggregation disorders are more frequent than primary aggregation disorders and the most common in this category are the *storage pool deficiency* (SPD) syndromes. SPD syndromes may be classified in a system that takes into account the content of both dense and α-granules (Figure 56.4). The term δ-SPD identifies patients who show low platelet content of dense granules only. Patients with deficiency of both types of granules are designated as $\alpha\delta$-SPD. Finally, patients presenting with reduced or absent platelet content of α-granules but normal levels of dense granules (α-SPD) are designated as patients with grey platelet syndrome. The disorder is heterogeneous and the term SPD includes a group of disorders having as their common feature a diminution in secretable substances stored in platelet granules.
Figure 56.4 In platelets, granules are the storage site for substances that are important for the haemostatic process. The α-granules contain proteins involved in adhesion (fibronectin, vWF) cell–cell interaction (P-selectin), and in promoting the coagulation (FV, PF4), whereas the content of dense granules is important to recruit additional platelets (ADP, serotonin).

A storage pool disease is found as an associated defect in most of the patients carrying other rare syndromes, such as the Wiskott–Aldrich syndrome and the thrombocytopenia with absent radius syndrome. However, the majority of patients presenting with a SPD have no associated diseases and are otherwise normal. The clinical features of this type of secondary aggregation disorder are those expected with a platelet function defect and consist of easy and spontaneous bruising, mucocutaneous haemorrhages, haematuria and epistaxis. Patients with δ-SPD or αδ-SPD usually have absent ADP and adrenaline-induced secondary aggregation waves, although the primary waves are present. Patients with δ-SPD may present a severe or partial granule deficiency. Collagen-induced aggregation is absent or markedly reduced, whereas ristocetin-induced agglutination is normal. In several kindreds, the disorder appeared to be inherited as an autosomal dominant trait. However, in other families the type of inheritance could not be determined. In the absence of other congenital abnormalities or an associated α-granule deficiency, SPD is inherited as an autosomal dominant trait.

The other forms of dense-SPD coincident with other congenital abnormalities, such as TAR, are usually inherited as autosomal recessive traits, or X-linked, as in the case of WAS. An SPD is usually present in *Hermansky–Pudlak syndrome* and in *Chédiak–Higashi* syndrome. Hermansky–Pudlak syndrome (HPS) is a rare autosomal recessive inherited disorder characterized by the presence of oculocutaneous albinism, absence of platelet-dense granules, and infiltration of ceroid pigmented reticuloendothelial cells in the lung and in the colon, leading to pulmonary fibrosis and inflammatory bowel disease. HPS shows genetic heterogeneity, and mutations within two genes have

been identified in patients with this disease, the *HPS1* gene, mapped on the chromosome 10q23.1–23.3, and the *ADTB3A*, on the chromosome 5q11–14. However, it is conceivable that different additional genes may be involved in the pathogenesis of the HPS.

In Chédiak–Higashi syndrome (CHS), a variable degree of oculocutaneous albinism and a poor resistance to respiratory and cutaneous infection are usually found. The infections are generally fatal during infancy or in early childhood, but patients may also die of a chronic lymphohistiocytic infiltration, known as *the accelerated phase*, during the second or third decades of life. CHS is extremely rare and is inherited as an autosomal recessive trait. Unlike HPS, the CHS does not seem to display locus heterogeneity and the only gene proved to cause CHS, *LYST*, is located on chromosome 1q42.1–42.2. Both in HPS and in CHS there are findings typical of an SPD, bleeding of mucosae, epistaxis and spontaneous soft-tissue bruising. On the other hand, in *Quebec platelet disorder*, a rare autosomal dominant bleeding disease associated with abnormal proteolysis of α-granule proteins, patients show a severe deficiency of platelet multimerin, a factor V binding protein contained within α-granules, and a severe impaired aggregation in response to adrenaline. Several patients have been described with a *selective impairment of the thromboxane A$_2$ receptor*, a mild bleeding disorder and a defective platelet aggregation in response to several agents but not thrombin. Autosomal dominant inheritance has been suggested in some cases.

Therapy

As a rule, in the vast majority of congenital platelet disorders there is no specific treatment. In congenital thrombocytopenias due to maternal use of drugs or chemical agents, recovery of thrombocytopenia needs from a few days to some weeks, such as in the case of thiazide drugs. In surviving thrombocytopenic newborns who are infected with rubella or cytomegalovirus, platelet levels return to normal, but several months may be required. In newborns with isoimmune congenital thrombocytopenia, usually the recovery is uneventful and platelets return to normal values in 14–21 days. Only severe cases need to be treated with washed maternal platelets, corticosteroids or exchange transfusions. In general, principal treatments in patients with congenital platelet diseases are general measures aiming at avoiding bleeding and the use of supportive therapeutic approaches for controlling haemorrhages. However, as types and severity of bleeding vary in different patients, therapeutic approaches have to be individualized.

General measures

Education of patients is of great importance. Patients and their parents have to be instructed to avoid trauma. Regular dental

care may be helpful to prevent gingival bleeding. Drugs that impair platelet functions, such as acetylsalicylic acid-containing medications, should be avoided. In women, the use of oral contraceptives can be applied to prevent menorrhagia. Local measures, such as the application of firm pressure in the case of epistaxis, will usually suffice in the event of mild bleeding.

Drugs

Desmopressin (1-desamino-8-D-arginine vasopressin or DDAVP) is a mainstay of the therapy of patients with congenital platelet defects. Depending on platelet defect, administration of DDAVP may shorten the bleeding time. Intravenous, subcutaneous or intranasal administration of DDAVP increases factor VIII and vWF transiently by releasing them from storage sites, and its use has been suggested to be of value in some patients presenting with congenital platelet defects, as BSS, May–Hegglin anomaly, GPS, SPD and Glanzmann's thrombasthenia. In general, the response to DDAVP varies among patients but it is constant in each patient; a test dose may be of value to identify those patients who will benefit from this treatment to prevent or control future bleedings.

The use of recombinant activated factor VII (rFVIIa) has been proved to be helpful in the treatment of bleeding in haemophilic patients with inhibitors. Recently, administration of rFVIIa has been used to stop bleeding in patients with congenital platelet disorders, such as BSS and Glanzmann's thrombasthenia. In addition, this drug has been used to treat thromboasthenics to avoid bleeding during surgical procedures. However, adverse reactions, such as vein thromboembolism and arterial ischaemia, have been described. Thus, the role of rFVIIa remains promising but deserves to be carefully defined.

Platelet transfusions

Platelet transfusions, using platelets from HLA-matched donors when available, are used to control severe haemorrhage in thrombocytopenic patients or in individuals with thrombocytopathies. As the risk of post-traumatic as well as of spontaneous bleeding increases as the platelet count falls, spontaneous haemorrhage becomes common as platelet count drops below 20 000/mL and is extremely likely at counts below 5000/mL. Extensive clinical experience has shown that control of bleeding is possible on achievement of an adequate elevation in the circulating platelet counts. However, the co-existence of platelet dysfunctions has to be taken into account to correctly calculate the dosage of platelets required. Platelet transfusions are effective in controlling bleeding but may be responsible for transmission of infectious diseases, febrile reactions or development of alloimmunization. In patients carrying thrombocytopathies, platelet transfusions should be employed only for the treatment of severe bleeding because of the risk of alloimmunization. The occurrence of platelet alloimmunization is more frequent in

patients lacking a membrane glycoprotein, such as BSS and Glanzmann's thrombasthenia. Alloantibodies develop because they recognize lacking proteins as foreign in transfused proteins and, in turn, induce refractoriness to platelet transfusions.

Other measures

Splenectomy has generally no effect in congenital thrombocytopathies and in thrombocytopenias but has proven to be effective in patients with WAS. Allogenic bone marrow transplantation may provide, in theory, an effective cure for inherited disorders involving platelet count or functions restoring a normal megakaryocytopoiesis. Transplants have been successfully performed with complete correction in patients with WAS and severe Glanzmann's thrombasthenia. However, risks of such a drastic procedure still overcome those related to bleeding tendency and, therefore, rarely required in patients suffering from congenital platelet disorders.

Conclusions

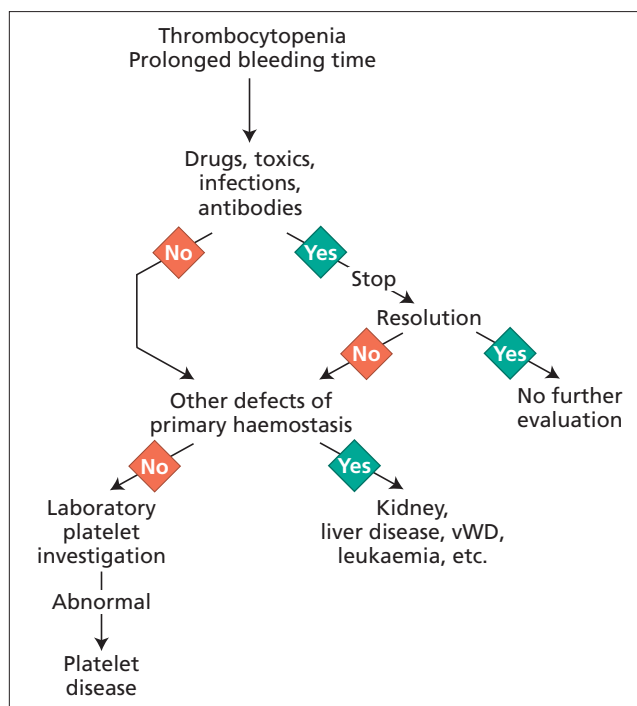
Over the last few years, a series of improvements to better understand pathogenesis of congenital platelet disorders have been achieved. In several congenital platelet diseases, the gene responsible has been identified and several patients have been characterized at molecular level (Table 56.5). This information


Figure 56.5 Algorithm for the initial screening of patients with congenital platelet disorders.

Table 56.5 Genes involved in congenital platelet disorders.

Disorder	Gene	Locus
Wiskott–Aldrich syndrome	WAS	Xp11.23–p11.22

Thromboxane receptor defect	$TXBA_2$	19p13.3

has allowed for a more accurate comprehension of congenital thrombocytopenias and thrombocytopathies. Careful collection of personal and family clinical data, physical examination and appropriate laboratory testing work-up are of value for the evaluation of a patient presenting with bleeding due to congenital platelet disorders (Figure 56.5). Using this approach, in several instances it is possible to correctly identify the platelet defect. However, despite recent advances in knowledge, in most of the patients with a congenital bleeding disorder and impairment of platelet functions the underlying molecular mechanisms are still unknown. In the future, one of the challenges will be to ameliorate our understanding of congenital platelet disorders in order to obtain powerful tools for prevention, diagnosis and therapy of bleeding. On the other hand, alternative treatments, such as gene therapy, may offer, in theory, a cure for diseases such as congenital platelet disorders. Hopefully, improvements in such approaches will provide a curative treatment for the majority of patients suffering from severe congenital platelet disorders.

Immune thrombocytopenic purpura: pathophysiology in patients with persistent problems

57

April Chiu, Wayne Tam, Doug Cines and James B Bussel

Introduction

Immune thrombocytopenic purpura (ITP) is a 'simple' auto-antibody-mediated disease, which, nonetheless, has a complex pathophysiology and clinical course. Although ITP is known to be caused by (auto) anti-platelet antibodies, the aetiology of the autoimmune disease remains mysterious. Numerous immunological studies have not yet clarified why certain people create anti-platelet antibodies and develop ITP, whereas the great majority do not. Among patients who develop ITP, certain patients have more benign courses, whereas others develop refractory life-threatening bleeding. Clearly, ITP is heterogeneous but the factors that underlie this heterogeneity are not well understood.

New studies have re-evaluated the role of splenectomy. Novel treatments have been tested in ITP at an increasing rate. The most exciting ones include rituximab (anti-CD20), anti-CD40 ligand (anti-CD154), thrombopoietin mimetics and autologous bone marrow transplantation. Other treatments are also being evaluated and the appropriate ordering of standard treatments is being revised.

Clinical presentation

ITP is an autoimmune disorder in which platelet sensitization by autoantibodies takes place, leading to destruction of opsonized platelets, primarily by the mononuclear phagocytic system. The clinical presentation differs somewhat between pediatric and adult patient populations. ITP in children is commonly associated with a preceding viral infection, and often follows an acute course in which the initially severe thrombocytopenia develops 'overnight' (based upon the sudden occurrence of symptoms), but often resolves spontaneously within 1–2 months.

On the other hand, ITP in adults usually occurs without an obvious inciting event and typically progresses to chronic disease associated with moderate to severe bleeding. Some adults with ITP have an acute presentation resembling that of children, whereas in some series approximately 50% are asymptomatic and diagnosed with low counts on a routine visit to a physician that is not directly connected with bleeding signs or symptoms. Regardless of the type of presentation, otherwise classical ITP in adults occasionally occurs as a so-called secondary event. This means that it presents in association with other conditions, such as lymphoproliferative disorders, especially chronic lymphocytic leukaemia or Hodgkin's disease, common variable immunodeficiency, HIV or other infection, or systemic autoimmune disorders such as autoimmune haemolytic anaemia (Evans' syndrome) or systemic lupus erythematosus.

Whether primary or secondary, patients with platelet counts persistently less than 10 000–20 000/µL are susceptible to intracranial haemorrhage and other major bleeding, although fortunately the incidence of serious haemorrhage is rare. The risk of a major bleeding episode is related to a number of factors, most of which have not been defined, but patients with persistently low counts are the ones at highest risk. Treatment plans for patients with ITP take into account the patient's age, disease severity and anticipated clinical course. In this report, the pathology and

pathophysiology of ITP and the treatment modalities available at present for patients with ITP will be discussed.

Pathophysiological features

Platelet antibodies

As clearly demonstrated many years ago, initially by plasma infusion studies by Harrington, later Shulman and subsequently by McMillan and colleagues, the thrombocytopenia in ITP is mediated by anti-platelet antibodies (at least in the great majority of cases). The spleen plays a crucial role in the pathogenesis of ITP, in that it is not only a major site of platelet destruction, but also possibly the site where platelet sensitization is initiated and therefore also a major source of anti-platelet antibody production. In most instances, the anti-platelet antibodies are autoantibodies directed against the platelet-specific glycoproteins (GP). Studies by van Leuwen *et al.* demonstrated that eluates from platelets of 32 of 42 patients with ITP would bind to normal platelets but not to thrombasthenic platelets deficient in glycoprotein (GP) IIb–IIIa. In other cases, the antibodies may be generated against viral protein antigens that are cross-reactive against platelet antigens, as is the case for HIV infection. More recent studies have identified multiple targets of anti-platelet antibodies, i.e. to GPIIb–IIIa, Ib–IX and Ia–IIa and patients have antibodies to several of these targets. This is suggestive of epitope and/or determinant spreading and may be a result of platelet destruction with perhaps only one or none of these antibodies responsible for initiating the destruction. Finally it is uncertain how often ITP may be the result not of antibodies but rather of T cells directed against platelets and/or megakaryocytes.

CD5[+] B cells have been implicated in the pathogenesis of many human autoimmune diseases and Mizutani and colleagues observed that B cells bearing the CD5 antigen are markedly increased in peripheral blood and spleen in ITP patients. However, a recent study by Hou and colleagues noted that the increase of splenic CD5[+] B cells in ITP patients was not statistically significant. Moreover, both CD5[+] and CD5[−] B cells from four out of eight ITP patients produced immunoglobulin (IgG) autoantibodies against both GPIIb–IIIa and GPIb.

Several reports have suggested that anti-platelet antibodies in some cases of ITP are clonally derived based on immunoglobulin light-chain restriction, either by using flow cytometric analysis or by DNA analysis for immunoglobulin heavy- and light-chain rearrangement. In one study, 10 out of 11 ITP patients had a clonal B cell population. However, whether these B cells are involved in autoantibody production was not shown.

More recently, Roark and colleagues demonstrated that at least some anti-platelet autoantibodies result from rearrangements of a single Ig heavy-chain variable region gene, V_H3–30. Interestingly, V_H3–30 has been found to be expanded or pathogenetic-

ally involved in several other disorders seemingly unrelated to but known to be associated with ITP, for example autoimmune haemolytic anaemia, systemic lupus erythematosus (SLE), chronic lymphocytic leukaemia (CLL), common variable immunodeficiency (CVID) and HIV infection. These authors concluded that the autoantibodies directed against platelets arise from clonal expansion of B cells upon encountering the diverse platelet antigens, which lead to Ig gene rearrangements using specific combination of heavy- and light-chain gene products.

Fc receptors

Antibody-coated platelets are rapidly cleared from the circulation via Fc receptors of macrophages in the splenic cords and elsewhere, which bind to the Fc portions of the IgG molecules. Studies of intravenous immunoglobulin (IVIg) showed that 'FcR blockade' was an important mechanism of steroid and especially IVIg effect in patients with ITP. There are a number of Fc receptors that have different properties and cell distributions. Several recent studies of the FcR system may have important clinical implications if confirmed and/or extended to humans. Two studies in mice have suggested that the ability of IVIg to slow the clearance of opsonized platelets is mediated by upregulation of FcRIIb, the inhibitory FcR, whereas anti-D appears to act by blocking FcRIIA. This is compatible with previous studies of FcR in patients, i.e. the use of a monoclonal anti-FcRIII antibody, because certain patients responded to it but not to IVIg and vice versa.

A technical issue preventing definitive study of this potential mechanism in humans has been the inability to distinguish FcRIIa from FcRIIb by monoclonal antibodies. Simultaneously, there has been a focus on polymorphisms of FcR, i.e. FcRIIa and FcRIIIa, suggesting that they may be involved in response to treatment with intravenous anti-D and rituximab respectively. The role of these FcRs in the course of ITP itself, as estimated by the frequency of the polymorphisms, is less clear. Several studies of these polymorphisms do not reach the same conclusions, i.e. that one form is increased in children who develop chronic disease or is increased in patients with ITP compared with normal control subjects. Similarly, past studies of HLA have been largely inconclusive outside of more inbred (Japanese) populations.

Pathology

Grossly, the spleen is typically of normal size or only mildly enlarged, usually weighing less than 200 g. The histological appearance is highly variable, ranging from completely normal to showing varying degrees of hyperplasia of malpighian corpuscles with germinal centre formation (Table 57.1). Frequently, plasmacytosis is also seen in the red pulp and marginal zones. Platelets in varying degrees of degeneration can usually be demonstrated trapped in the cords of Billroth, imparting a

Table 57.1 Inherited thrombocytopenias.

WAS/XLT: small platelets, poor platelet function

VWIIB: platelet clumping on smear, varying platelet counts exacerbated by pregnancy and other stresses

May–Hegglin: large platelets, Döhle-like bodies in neutrophils (other forms of MYH9 syndromes may have hearing loss, cataracts, and renal disease)

Bernard–Soulier syndrome: epistaxis, very large platelets

Congenital amegakaryocytic thrombocytopenia: no characteristic anomalies; *c-mpl* mutation in most patients, may progress to aplastic anaemia, diagnosis usually before the age of 2 years

granular or 'dirty' appearance. Platelet sequestration and phagocytosis can be demonstrated clearly using touch preparations and electron microscopy. Another characteristic finding is collections of foamy histiocytes in the red pulp as well as in the marginal zone. These collections of histiocytes, detected in 23–67% of splenectomy specimens are the result of platelet phagocytosis and contain partially degraded membrane-derived phospholipids and diverse platelet antigens, for example CD41. The white pulp in such patients treated with steroids shows diminished to absent germinal center formation.

Bone marrow

Bone marrow biopsies from patients with ITP show normal to increased numbers of megakaryocytes diffusely dispersed throughout the marrow space. The mean ploidy (endomitotic index) of ITP megakaryocytes is more variable than the megakaryocytes from normal individuals. In patients whose ITP arises in the context of HIV infection, both pyknotic and dyspoietic megakaryocytes may be seen including the so-called 'naked' megakaryocyte nuclei, which are devoid of cytoplasm. The aetiology of the 'naked' megakaryocytes is unknown.

Platelet lifespan

The increased number of megakaryocytes in the marrow and the evidence of platelet destruction in the spleen as well as the studies demonstrating platelet antibodies lead to the assumption that platelets were synthesized at an increased rate. The presumption was that the antibodies resulted in a very increased rate of platelet destruction. This was supported by numerous studies of allogeneic platelets labelled by [59]Cr, all of which demonstrated very short platelet lifespans. The ability of ^{111}In to label autologous platelets resulted in several studies demonstrating that platelet lifespans were surprisingly long, implying that platelet turnover (both destruction and production) was much less than had been assumed. More recently, antibodies that impair megakaryocyte development *in vitro* have been iden-

tified, consistent with the finding of partially impaired platelet production in a substantial subset of patients with ITP.

Overall, it is unclear how many patients with ITP, and which ones, are not making platelets well. Specifically, it is not known whether the patients who are particularly difficult to treat are the ones with the most reduced platelet production. It is believed that virtually all licensed treatments slow platelet destruction. It is also possible that some of these treatments increase effective marrow platelet production.

Multiple studies of ITP have shown that thrombopoietin (Tpo) levels in patients are essentially the same as those measured in normal individuals. This is in contrast to the 10–20-fold increase in Tpo levels seen in amegakaryocytic states. This suggests that thrombopoietin may be a clinically effective treatment of ITP because platelet production could be further augmented; the first study of a thrombopoietin mimetic agent has confirmed that this appears to be a useful approach.

Diagnosis

Is a bone marrow examination required?

Until recently, bone marrow examination was routinely performed in both children and adults who were suspected of having ITP, to exclude the diagnosis of leukaemia or other clonal or infiltrative processes. Bone marrows were also performed to exclude hypoplastic or aplastic states. Several studies support the infrequency with which leukaemia is diagnosed in a healthy child with isolated thrombocytopenia and an otherwise typical presentation (normal haemoglobin, white count, smear and normal physical examination except for signs of haemorrhage). A retrospective analysis of several thousand patients entered in paediatric leukaemia studies identified no patients who presented with isolated thrombocytopenia in the absence of hepatosplenomegaly or adenopathy.

In another study, none of over 100 children who met the 'ASH Guidelines definition' of ITP and in whom a bone marrow was performed had the diagnosis changed to leukaemia; only one child was diagnosed with aplastic anaemia. In contrast, seven incidences of aplastic anaemia and seven of leukaemia were seen in > 100 children with thrombocytopenia in the context of other abnormalities of the complete blood count or the examination. Similar but less extensive experience in adults has led to several practice guidelines that recommend that bone marrow examination may be reserved for patients who are unresponsive to therapy, those over 60 years of age or those in whom splenectomy is considered. In the more elderly, the exclusion of myelodysplastic syndrome (MDS) presenting with isolated thrombocytopenia becomes an important consideration. In one retrospective study of 1539 cases of MDS, 1% of patients presented with isolated thrombocytopenia. Several of these patients

were misdiagnosed as having ITP, all of whom were 50 years of age or older and lacked significant splenomegaly.

Therefore, in children and adults, a presumptive diagnosis of ITP can generally be made without a bone marrow examination in a patient with isolated thrombocytopenia without an underlying disorder, and with a normal physical examination.

Is platelet antibody testing required?

Studies of ITP have failed to demonstrate any form of available testing that is both sensitive and specific in distinguishing patients with ITP from those with other types of thrombocytopenia. Thus, the clinical utility of measuring serum or platelet-eluate immunoglobulin is unproven in the diagnosis or treatment of ITP or in predicting its clinical course. Consequently, the diagnosis of ITP remains clinical and is one of exclusion. Probably the most specific test to confirm the diagnosis of autoimmune thrombocytopenia (primary or secondary) is response to IVIg or anti-D, especially if dramatic and repeated.

Differential diagnosis in children and adults

The diagnosis of ITP should be considered in all patients who are otherwise well but present with petechiae, bleeding or bruising. If a complete blood count (CBC) reveals an isolated thrombocytopenia, with a normal haemoglobin, white blood cell count, peripheral blood smear and a physical examination notable only for bleeding, they are likely to have ITP. As indicated above, too many patients with causes of thrombocytopenia other than ITP have positive platelet antibody tests for these to be included in the decision-making process. Secondary causes of ITP should be considered when circumstances warrant. For example, SLE should be considered in the setting of a butterfly rash and signs or symptoms of arthritis and common variable immunodeficiency (CVID, hypogammaglobulinaemia) if there are recurrent infections, especially pneumonia. In the absence of such signs or symptoms, routine serological and other testing for these conditions is not indicated (see discussion of the utility of bone marrow examination and platelet antibody testing above).

The most common alternative diagnosis in the paediatric population is familial thrombocytopenia (see Table 57.1). These conditions are discussed in Chapter 58 on p. 950. Important considerations concerning the diagnosis of ITP include: (i) Bernard Soulier syndrome and the MYH9 group have 'too large' platelets on smears; (ii) Wiskott–Aldrich exists in the X-linked thrombocytopenia form in which the immune deficiency is minimized but the platelets are still small; (iii) platelet clumping on a smear should create suspicion of von Willebrand type IIB; and (iv) in the authors' experience, if two or more first degree relatives in a family have 'ITP', an inherited thrombocytopenia is more likely than are two cases of ITP (Table 57.2).

In adults, the differential diagnosis also includes familial thrombocytopenias but more common secondary causes include

Table 57.2 Features consistent with non-immune thrombocytopenia.

All syndromes
Family history
Lack of response to standard ITP therapy, i.e. steroids, IVIg, i.v. anti-D, splenectomy
Platelet appearance on smear (too large, too small or clumping)
Clinical suspicion that platelet function is more impaired than expected for ITP at that platelet count
Persistent, consistent thrombocytopenia without much variability in the platelet count

HIV infection, lymphoproliferative disorders such as CLL, SLE and hepatitis B or C. Less commonly, patients may have CVI, sarcoidosis or Gaucher's disease. Hypothyroidism, i.e. Hashimoto disease, is common in women and is more commonly found in women with ITP than in age- and sex-matched control subjects. Its prognostic significance for ITP is uncertain. Recently, an association between ITP and the presence of *Helicobacter pylori* has been established in some series, but not in others. The reason for this discrepancy has not been resolved, and no consensus has been reached as to the role of testing for and treatment of *H. pylori* in patients with ITP. Similarly, the role of hepatitis C in the aetiology and persistence of ITP is unclear.

Management of acute immune thrombocytopenic purpura

The initial treatment of children presenting with acute ITP remains a topic of considerable debate, with both strong proponents and opponents of treatment. Randomized controlled trials demonstrate that the platelet count can be bought into the 'safe' level more rapidly in children treated with corticosteroids, IVIg or 'high-dose' i.v. anti-D than in those in whom a watchful waiting approach is taken, and acute intracranial haemorrhage rarely occurs at platelet counts above 10 000/μL. On the other hand, over 70–80% of cases of ITP in children will resolve spontaneously, with haemostatic platelet counts often attained within weeks, and the risk of acute intracranial haemorrhage is exceedingly low (0.1–1.0%).

There is no formal evidence that the incidence of this rare event is lessened by treatment and therapy is often inconvenient, expensive, and, in the case of high-dose corticosteroids, often accompanied by adverse effects, i.e. in mood and behaviour. There are also considerable inaccuracies in the enumeration of platelets when the count falls below 10 000/μL. Treatment is certainly indicated for the unusual situation in which a child presents with serious bleeding or even with signs of bleeding beyond petechiae and ecchymoses, i.e. wet purpura, those with co-existent bleeding risks like head trauma and perhaps for

those at high risk of trauma due to behavioural or other disturbances. In some areas, inaccessibility to medical care becomes a factor as well.

On the other hand, all would agree that pauci-symptomatic children with platelet counts above 20 000/μL can be observed in all but the most unusual circumstances. Differing opinions concern whether therapy is required in any or all children who present with otherwise typical, but profound thrombocytopenia (<10–20 000/μL) without extensive petechiae and ecchymoses, haematuria or haematochezia, or 'wet' purpura. Our opinion is that it is safer to treat these children. However, we recognize that other experts may prefer observation in this setting. There is a clear need for larger and longer observational studies to determine whether there are subsets of children (e.g. adolescents) who appear to be at greater risk for bleeding soon after presentation. Clearly, the prognosis of ITP in association with autoimmune haemolytic anaemia (AIHA), HIV or other associated disorders typically requires treatment, one closer to the one generally employed in the management of adults.

The treatment of adults with acute ITP differs from the treatment of children in several important respects. In adults, ITP rarely remits spontaneously within days to weeks and co-morbid risks for bleeding are far more common than in children. Moreover, a greater percentage of adults than children (30%) fail to respond to the typical initial forms of therapy, necessitating the introduction of alternative modes of therapy. Nevertheless, the same issues of when to treat the asymptomatic adult and whether the platelet count is a useful surrogate marker of morbidity occur commonly, often because of failure or intolerance of standard treatment. As the natural history of adult ITP, the incidence of haemorrhage and the adverse effects of therapy have been somewhat clarified over the past several years, the 'threshold' platelet for treating adults with ITP has fallen, with most experienced haematologists choosing not to treat the average-risk patient whose platelet count exceeds 30 000/μL.

Paediatrics

Patients receiving treatment generally initially receive one of the following: prednisolone at 1–4 mg/kg per day; i.v. Ig at 400–1000 mg/kg; i.v. steroids such as methylprednisolone at 5–30 mg/kg; and i.v. anti-D at 75 μg/kg. If prednisolone is used and there is a response, it is rapidly tapered (1–4 weeks). The i.v. medications are followed with initially weekly counts and are repeated as needed for a platelet count < 20 000/μL. If a treatment is administered and symptoms continue or worsen then a combination of the three i.v. treatments indicated above (MP, IgG and anti-D) should be administered together to avoid a potentially significant risk of intracranial haemorrhage (ICH). Vincristine can be added (0.03 mg/kg up to 1–1.5 mg) if there is no response or if there is great concern regarding the risk of bleeding.

Adults

Treatment in adults is generally initiated with prednisolone in a dose of 1–2 mg/kg per day and the drug is continued until the platelet count exceeds 50 000/μL or the patient fails to respond by 3–4 weeks. Those with more clinically severe presentations and those intolerant of corticosteroids are generally treated with IVIg of 1 g/kg per day for 2 days or i.v. anti-D (if Rh$^+$) at a dose of 75 μg/kg per day with similar outcomes. Recently, a one-armed study of adults treated with high-dose dexamethasone (10 mg per day for 4 days per month) showed an initial response of > 75% with durable remissions in 40–50%. This long-term outcome is similar to what has been seen in patients treated with anti-D and is only somewhat higher than the 10–30% reported long-term outcome in patients initially treated with corticosteroids in traditional doses. It may be no different from the outcome in those who did not require therapy at all. In emergent situations, patients should be treated with platelet transfusions for ongoing bleeding or headache or head trauma, and also with high doses of methylprednisolone (1 g per day for 1–3 days), i.v. anti-D, IVIg as above, with or without vincristine 1–1.5 mg i.v. push. When these agents are combined together in groups of three, or using all four together at the same time, they may be remarkably effective even in refractory patients. Furthermore, these treatments may serve to protect transfused platelets allowing them to achieve greater haemostatic efficacy. In all patients, general measures to reduce the risk of bleeding should be taken, including control of hypertension, cessation of drugs that interfere with platelet function, hormonal treatment of severe menorrhagia, etc.

Therapy with corticosteroids is generally associated with moderate toxicity including (acutely) mood alteration, difficulty sleeping, hypertension, gastritis and hyperglycaemia. This necessitates dose reduction as soon as practicable, which is usually accompanied by a fall in the platelet count, although not to pre-treatment levels in all patients. Common side-effects associated with IVIg include headaches and fever–chill reactions, in addition to its high cost and the inconvenience of long-term (4- to 6-hour) i.v. administration, especially if it is needed repetitively. Therefore, IVIg treatment is discontinued once a haemostatic platelet count has been obtained and reliance is placed on corticosteroids thereafter. Anti-D is generally better tolerated and it is administered more rapidly than IVIg (in minutes); rare cases of intravascular haemolysis have been reported and very occasionally there is significant extravascular haemolysis i.e. 2–4 g/dL decrease in haemoglobin.

Steroids are believed to impair destruction of platelets by inhibiting the interaction of the IgG-coated platelets with the Fc receptors of splenic macrophages. Over the longer term, steroids may also suppress anti-platelet autoantibody production. IVIg works acutely by reducing the rate of phagocytosis of opsonized platelets. Recent work suggests that the mechanism of this effect in mice is mediated by upregulation of the inhibitory FcRgIIIb

receptor and also that saturation of FcRn may accelerate clearance of auto-anti-platelet antibody. In contrast, anti-D in ITP appears to inhibit clearance of opsonized platelets by FcRIIa and FcRIIIa, although changes in cytokine expression and reactive oxygen species appear to be involved in the longer responses.

Management of chronic immune thrombocytopenic purpura

Paediatrics

Management of chronic ITP in children (> 6 months duration) usually involves repeated administration of one of three agents: steroids, IVIg or i.v. anti-D. The goal is to give the child time to improve spontaneously. Splenectomy is deferred until at least 1 year from diagnosis in a child > 5 years of age, unless there are very special circumstances; these are most common in adolescents in whom maintenance treatment is problematic either because of poor response or poor compliance. Long-term 'high-dose' steroids are to be avoided. Splenectomy is avoided if at all possible in a child < 5 years of age even if this requires maintenance therapy for a number of years. Azathioprin at 2 mg/kg is an option; it seems to have little toxicity and is typically given at bedtime to avoid any nausea. Danazol is avoided until after puberty because of the adverse effects on growth (reduction of final height). Rituximab is increasingly used, despite few data in children, because of its potential for lasting responses and apparently little toxicity. Children who fail to respond to splenectomy are fortunately very rare and treatment should be guided by the experience in adults.

Adults

There is little consensus on the appropriate duration of therapy with any of these agents, either with respect to attempting to induce a more durable remission or with respect to defining failure. Patients who fail to respond or who show poor response to single-agent therapy may show synergistic effects with combined therapy. This approach also permits the dose of each individual agent to be reduced with attendant lessening of their generally non-overlapping side-effects. Occasional patients can be maintained on low daily or alternative-day doses of prednisolone, but most cannot at a dose low enough to be feasible. Multiple modalities have been introduced as alternatives to corticosteroids or as adjunctive therapy to permit a lower and more tolerable dose to be employed.

Approximately 10–20% of adults with ITP are truly refractory to initial management and remain symptomatic or with platelet counts below 20 000/µL; a similar percentage will maintain platelet counts over 50 000/µL even when therapy is discontinued and they will require no additional treatment. A very few of these individuals will require additional treatment because

the antibody has induced a qualitative bleeding disorder. The majority of adults respond to one or a combination of these agents to a greater or lesser extent, but require persistent treatment, often with unpleasant or unsafe side-effects, to maintain their platelet count in the range of 20 000–50 000/µL; it is this population where the decision to proceed with splenectomy must be entertained. This decision is predicated on severity of thrombocytopenia and bleeding, side-effects of treatment, fitness for surgery, patient lifestyle (compliance with treatment, risk of trauma) and patient preference. A bone marrow evaluation should be made (if not recently performed) in all individuals with a suboptimal response to ITP-directed therapy, especially before splenectomy. Evolution to overt MDS or marrow aplasia is sometimes evident on repeat examination.

There is no generally available method to predict response to splenectomy, although finding a predominantly hepatic clearance of radiolabelled platelets may augur poorly. In general, approximately 85% of young adults and a somewhat lower proportion of older adults will have an initial haemostatic response to splenectomy, in which about two-thirds of the initial group will be durable. Responses to laparascopic and open surgical splenectomies appear similar, as do the complication rates, including the need for later accessory splenectomy; the laparoscopic procedure facilitates post-operative recovery (in experienced hands) (see Chapter 23).

There is a low risk of anaesthetic complications in appropriately chosen patients and the risk of post-operative bleeding is sufficiently low, even at very low platelet counts, such that prophylactic platelet transfusions should generally not be employed. The major risk of splenectomy is that of the overwhelming sepsis syndrome, which approximates 1% over a lifetime in all patients who are undergoing splenectomy. Patients should be immunized preoperatively and re-immunized at appropriate intervals post-operatively with polyvalent pneumococcal vaccine, *Haemophilus influenzae* flu vaccine and, in susceptible populations (military, immunosuppressed), with meningococcal vaccine. All patients who have undergone splenectomy should receive immediate medical care that includes prompt introduction of appropriate i.v. antibiotics at the first sign of a systemic febrile illness until a suitable diagnosis is established. Travel to regions where malaria, babesia and other organisms are cleared in the spleen requires special consideration.

Management of refractory immune thrombocytopenic purpura

If a patient is 'refractory', i.e. undergoes and does not respond to splenectomy, it is important to do a careful re-evaluation of the diagnosis including possibly a bone marrow examination and/or other testing. The most consistent use of the term refractory ITP involves the patient who has undergone but not responded to splenectomy. This is considered to be a more serious disease,

especially when patients have platelet counts persistently below 20 000 μL and bleeding symptoms. As a result of this persistent, severe thrombocytopenia, these patients have a high rate of serious bleeding, including, but not limited to, intracranial haemorrhage. No matter what treatments are attempted, their ITP typically persists. Morbidity and mortality rates are increased fourfold compared with the general population. Azathioprin, danazol and oral cyclophosphamide, each have at best a 30% response rate in truly refractory patients. In addition, these patients may not respond to IVIg, and anti-D works substantially less well after splenectomy. Note that we are specifically not delaying with treatments that have not yet been published in peer-reviewed literature.

If there is an urgent need to increase the platelet count then combination treatment (as discussed above) can be used. Treatments that may be highly effective at increasing the platelet count in difficult patients involve combinations of IVIg, i.v. methylprednisolone, and either or both i.v. anti-D and vincristine. In 35 patients, 24 adults and 11 children, approximately three-quarters responded with an acute platelet increase to these combinations despite the patients being completely refractory to IVIg and/or steroids given individually. Even if this combination is highly effective, its effects will be short-lived, i.e. 1–3 weeks, and it is important to anticipate that a more lasting treatment effect will be needed (see below).

Therefore, agents are used in combination; this approach has not been adequately pursued. In order not to use two immunosuppressive agents, we combine danazol with azathioprin. The advantages of these agents are that they have relatively low toxicity and have extensive usage in ITP. The disadvantage is that neither is a very potent agent and therefore they may not work in certain circumstances. There are a number of studies using cyclophosphamide alone, either orally or, especially, intravenously. This latter usage follows the treatment of nephritis in SLE, when it is given at a dose of 500–1000 mg/m^2 once every 4 weeks. In more extensive usage, cyclophosphamide has been combined with steroids, vincristine and other agents. The best documented combination ITP chemotherapy with patients was published in 1993 by Macmillan and Figueroa. A recent letter confirmed that although the protocol was effective in only one-half of the very difficult patients in whom it was tried, apparently almost all of the patients who responded had a durable effect. Some have advocated a hormonal approach combining provera, danazol and possibly other related agents.

A number of very small trials had been performed with other agents with inconclusive results. Experimental therapies to some extent share this characteristic. In the case of rituximab, there are now more than five publications in ITP including a recent study of 57 patients. In this study, there is approximately a 50% response rate with the major advantage being durability; one-third achieved a lasting response of > 1 year's duration at the time of data analysis. As in other studies, i.e. of anti-CD40 ligand, patients whose duration of ITP is > 15 years are poorer responders. In the studies cited, non-splenectomized patients do as well as splenectomized patients but, surprisingly, not better. The treatment of non-splenectomized patients usually reflects treatment of patients who are earlier in their disease and more susceptible to curative effects. In these cases, its advantage may be the ability to create a lasting response so that no treatment is required for at least 6–12 months, if not indefinitely. It does not appear that rituximab is as effective in the '*worst*' patients who have failed splenectomy and multiple therapies.

Anti-CD40 ligand has also been effective in some refractory patients, however it is no longer in clinical trial.

Other agents include mycophenolate mofetil and cyclosporine. Both have had limited efficacy in difficult patients; these agents may be more promising when used as part of combination treatment rather than singly.

Thrombopoietin (Tpo) and Tpo mimetics have been effective in a small number of patients treated to date. This is consistent with the known physiology, i.e. relatively low levels despite severe thrombocytopenia in ITP. Furthermore, in refractory patients especially, it is suspected that there is a lack of accelerated platelet production. Even in the studies that demonstrated accelerated or even normal platelet production in ITP, the overall rate of increase has only been two- or threefold, suggesting that it could be further increased. Given the treatments that had been described earlier, which block opsonized platelet destruction, the addition of Tpo might substantially increase the platelet count in those patients capable of producing platelets. As it would appear that the hard-core group that is the most difficult to treat may be those who are not making platelets, Tpo might be especially useful. An abstract reporting on a thrombopoietic peptide drug has confirmed substantial short-term efficacy of this approach in refractory patients. Further trials are in progress.

Finally, bone marrow transplantation has been attempted in up to 16 patients in one series at the National Institutes of Health. The complications are not surprising but are daunting. These include sepsis in many of the patients, considerable amounts of IVIg and platelet transfusions required for line insertions, and the use of high-dose cyclophosphamide. However, at least two of the responders are in stable remission more than 24 months following transplant and approximately one-half of the patients with Evans' syndrome responded. Therefore, one can be guardedly optimistic about the results.

In summary, there are a number of novel therapies being explored in refractory ITP. There is increasing knowledge of pathophysiology, including a very recent study suggesting that cytotoxic T cells may be important in certain patients. As biological treatments are being developed for and explored in B-cell lymphomas, at this moment the number of novel treatments that could be tested has outstripped the ability to do the studies. The possibility of combination treatments, which clearly will be superior to single agents as discussed above, is staggering and should be the next era of exploration.

Atherothrombosis, thrombolysis and anti-platelets

58

Lucinda KM Summers, Stephen P Marso and Peter J Grant

Introduction

The term atherothrombosis describes the formation of thrombus on atheromatous plaques within the high-pressure arterial circulation. Atherothrombosis is the pathological process underlying the development of cardiovascular disease (CVD), a systemic condition. Coronary heart disease (CHD), peripheral vascular disease (PVD) and cerebrovascular disease are all manifestations of CVD, the commonest cause of death in the Western world. This spectrum of diseases includes type 2 diabetes.

Epidemiology

Mortality rates from CVD in Western countries increased steadily during the last century until the 1960s and 1970s, when they began to decline substantially. However, CVD mortality continues to increase in Eastern Europe and in certain subgroups of people in the rest of Europe and the USA. There is also evidence that the incidence of CVD in the USA has not declined, rather that it is the case fatality rate that has declined. This has resulted in an increased prevalence of CVD, with associated increased disability and health-care costs.

Geographical and ethnic variations

There are considerable geographical and ethnic variations in the incidence of CVD. In Europe, the risk of myocardial infarction (MI) increases from south to north and from east to west. These variations are only partly explained by different preventative practices. In the USA, black people have the highest rates of CHD. Non-Hispanic white people also have relatively high CHD mor-

tality rates, whereas Hispanics, Native Americans and Asians have lower rates. Stroke mortality rates are also strikingly higher in black people, whereas Hispanics and Native Americans have the lowest stroke rates. On the other hand, in the UK South Asians have increased rates of CHD compared with other ethnic groups. These variations in the incidence of CVD are partly explained by the prevalence of insulin resistance and diabetes in different ethnic groups. However, most of the variability remains to be explained.

Aetiology and pathophysiology

The inflammatory process in the arterial wall

For some years, it has been proposed that atherosclerosis is a chronic inflammatory process. In the arterial wall, the endothelial inflammatory response is mediated by macrophages (derived from circulating monocytes) and specific subtypes of T lymphocytes. These T lymphocytes recognize antigens expressed by activated macrophages and, in response, generate cytokines that amplify the inflammatory process. If this inflammatory response does not remove or neutralize the offending agents, the process continues, with eventual thickening of the arterial wall as outlined below. Circulating inflammatory markers, for example C-reactive protein, fibrinogen and cytokines, increase in concentration when this inflammatory process is extensive and continues for a long period of time.

Endothelial dysfunction

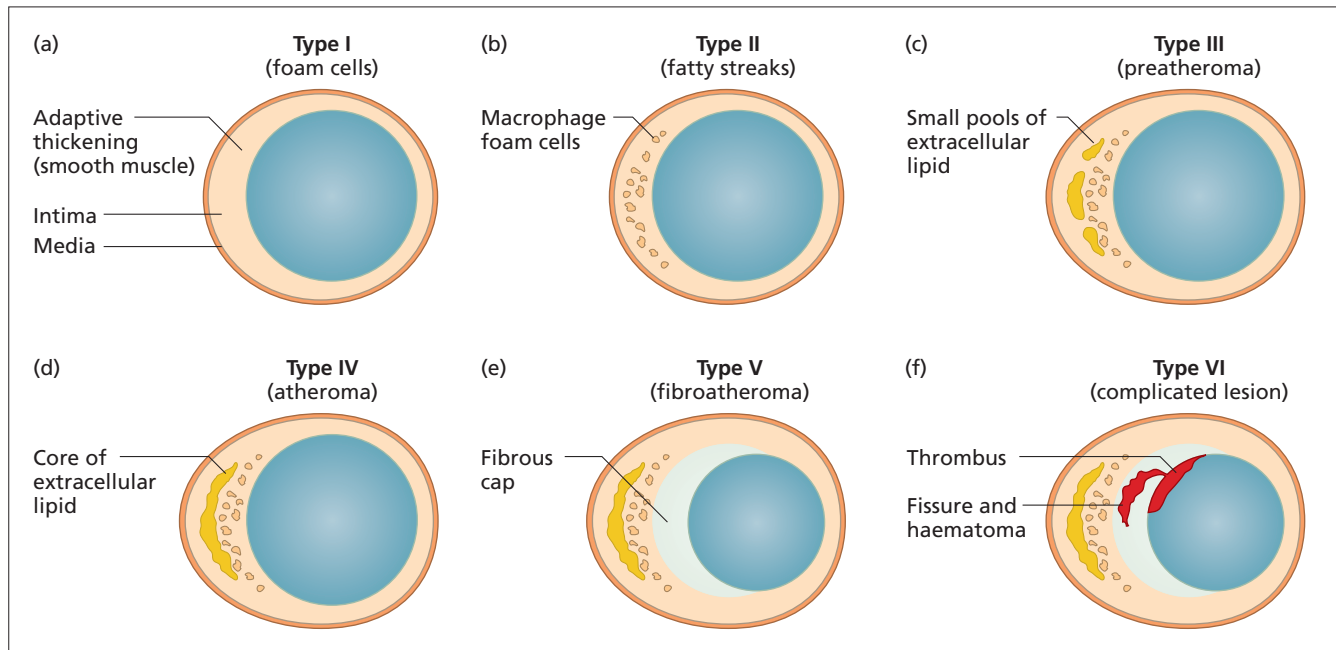
Endothelial denudation has been proposed as the initial step in the development of atherosclerosis, as part of 'the


Figure 58.1 (a–f) Cross-sections of the proximal left anterior descending coronary artery, showing the development of an atheromatous lesion (adapted from *Atherosclerosis and Coronary Artery Disease*, V Fuster, R Ross, EJ Topol, Vol. 1, 1996, Lippincott Williams and Wilkins, Philidelphia).

response-to-injury hypothesis'. More recently, it has been suggested that endothelial dysfunction, rather than denudation, leads to the development of atherosclerotic lesions. Whichever mechanism is responsible, there is a resultant increase in the permeability of the arterial wall to blood constituents, including low-density lipoproteins (LDL). Platelets and monocytes adhere to areas of damage on the arterial wall and release growth factors which, in turn, promote the migration and proliferation of intimal smooth muscle cells.

Endothelial dysfunction is associated with impaired endothelium-dependent relaxation, resulting from perturbations in the synthesis, release or action of vasoactive substances produced by endothelial cells, including nitric oxide, endothelins and prostacyclin. Endothelial function is impaired in dyslipidaemia, type 2 diabetes, type 1 diabetes, hypertension and obesity.

Formation of atheroma

The formation of atheroma is a very slow process and the atherosclerotic lesion is classified histologically into six types. Figure 58.1 shows the process by which an atheromatous lesion develops, and Figure 58.2 shows a post-mortem section of a coronary artery occluded by atheroma.

Type 1 (Figure 58.1a)
'Foam cells' form at sites prone to the development of atherosclerotic lesions. Such sites exist from birth, owing to the varying
Figure 58.2 Post-mortem section of a left anterior descending coronary artery occluded by atheroma (courtesy of Dr L Davidson).

intima media thickness in different sections of the arteries. At arterial bifurcations, the arterial wall tends to be thickened in a focal and eccentric (crescent-like) manner, whereas, in other arteries, for example main coronary branches, diffuse thickening is seen. Foam cells can be visualized within the arterial wall intima using lipophilic stains, such as Sudan III and IV. They consist of macrophages and, to a lesser extent, smooth muscle cells containing small intracellular lipid collections. Multiple layers of foam cells eventually form fatty streaks.

Type II (Figure 58.1b)

Fatty streaks, the earliest manifestations of atheromatous disease detectable on gross pathological examination, can be found in the aorta and coronary arteries of children as young as 2 years old. They are especially prevalent in those with a genetic predisposition to CVD; a family history of CVD or features of the insulin-resistant syndrome. There is a slow progression to intermediate and then advanced lesions, with formation of a fibrous cap that seals off the lesion from the lumen. Within the lesion, there is a collection of debris containing accumulated leucocytes and lipid. This core may become necrotic, whereas the lesion itself continues to expand as leucocytes continue to adhere and enter. The internal necrosis can result in lipid leaking out of the foam cell.

Type III (Figure 58.1c)

Eventually, there is a massive accumulation of extracellular lipid, disrupting the continuity of the intima smooth muscle cells. This stage is known as 'pre-atheroma', as although these lesions are associated with marked thickening of the arterial wall, there is no interference with blood flow. To a certain extent, there is compensatory gradual dilatation of the arterial wall, ensuring that the lumen is unaffected. This process is known as remodelling and it has been estimated that functionally important lumen stenosis may be delayed until the atherosclerotic plaque occupies up to 40% of the internal elastic lamina area.

Type IV (Figure 58.1d)

'Atheroma' is derived from the coalescence of extracellular lipid, resulting from macrophage necrosis, to form a large lipid core. This lipid centre contains a few isolated smooth muscle cells with macrophages in the periphery of the lipid material. Atheroma is not usually present before puberty.

Type V (Figure 58.1e)

A more advanced lesion, 'fibroatheroma', is covered on the luminal side by a fibrous cap formed by smooth muscle cells within a dense extracellular matrix. This matrix contains collagen and capillaries. In regions where new blood vessels are forming within the lesion, microscopic haemorrhages are sometimes seen. Some type V lesions are largely calcified (type Vb), whereas others are made up chiefly of fibrous connective tissue and contain little or no lipid or calcium (type Vc). Type V lesions are usually detected in the third decade.

Type VI (Figure 58.1f)

The 'complicated lesion' is an unstable lesion, which can be complicated by erosion or rupture of the fibrous cap, intraplaque haemorrhage or formation of superficial thrombus. Such lesions may significantly impair blood flow and produce clinical symptoms and signs of ischaemia: angina, MI, transient ischaemic attacks, stroke, intermittent claudication and PVD.

Thrombotic occlusion

It was originally believed that occlusive lesions in coronary arteries begin with fatty streaks in the arterial wall, gradually developing into stenotic coronary artery lesions that are composed largely of lipids. However, stenoses of less than 50% were found to be responsible for MIs in several studies. These lesions would previously have been termed 'non-severe' compared with 'severe' lesions causing greater than 70% stenosis. As a result of these findings, it is now thought that complete occlusion occurs as a result of the frequent rupture of minimally stenotic lipid-rich plaques in the coronary artery wall with resultant thrombosis playing a major role in coronary artery occlusion. The coagulation and fibrinolysis systems involved in regulating these processes are discussed in detail in Chapter 46.

When a plaque in an arterial wall ruptures, collagen and other constituents of the vessel wall are exposed to blood, leading to platelet adherence. Tissue factor (cell surface protein) is released simultaneously from damaged cells. Tissue factor activates the intrinsic and extrinsic coagulation systems, leading to thrombin generation. Thrombin, in turn, activates platelets and cleaves fibrinogen to form soluble fibrin. Platelet activation and the activation of coagulation factors VIII, V and XI by thrombin further increase thrombin generation, thereby amplifying the coagulation process. The crucial final step of the coagulation cascade, the production of insoluble fibrin (Figure 58.3), resistant to physical and chemical insults, is achieved by covalent cross-linking of the fibrin(ogen) γ- and α-chains mediated by factor XIIIa, a proglutaminase. Thus, a fibrin clot is formed on the surface of the ruptured plaque in the wall of the affected artery.
Figure 58.3 Fibrin clot in the absence of platelets, visualized using scanning electron microscopy (courtesy of Dr A Atwa).

At the same time, plasmin is degrading the fibrin that is being formed. Tissue plasminogen activator (tPA) and urinary-type plasminogen activator (uPA) regulate the conversion of plasminogen to plasmin. Plasminogen, plasmin and tPA bind to cross-linked fibrin and these reactions can then occur without interference from plasminogen activator inhibitor-1 (PAI-1), the major inhibitor of fibrinolysis. Activation of fibrin-bound plasminogen by tPA is increased by the polymerization of fibrin. The resultant fibrin degradation reveals new binding sites for plasminogen, increasing the rate of fibrinolysis. In the circulation, tPA and uPA are rapidly inactivated by PAI-1, which is present in excess. This ensures that fibrinolysis is localized to the site of thrombus formation and systemic fibrino(geno)lysis does not occur. PAI-1 is released on the platelet surface when platelets are stimulated by thrombin, preventing immediate clot lysis. Endothelial cells exposed to thrombin also synthesize PAI-1, causing a rapid local increase in PAI-1 concentration. The relative activities of the coagulation and fibrinolytic systems regulate fibrin clot formation and lysis and its effect on blood flow through the affected artery.

Risk factors for atherothrombosis

The major risk factors for atherothrombosis are shown in Table 58.1. Many of these risk factors are found in association in insulin-resistant individuals and the effects of insulin resistance (IR) on endothelial function, formation of atheroma and effects on the coagulation system are discussed.

Insulin resistance and diabetes

Insulin resistance (IR) has been defined as a state (of a cell, tissue, system or body) in which greater than normal amounts of insulin are required to elicit a quantitatively normal response. IR is said to be present when the ability of insulin to stimulate the uptake and disposal of glucose is impaired. It is common in obesity and type 2 diabetes, but can also manifest as impaired fasting glucose or impaired glucose tolerance. The diagnostic criteria for these conditions are given in Table 58.2. It has been estimated that approximately 25% of the apparently healthy population have IR similar to that of type 2 diabetes. IR combined

Table 58.1 Risk factors for atherothrombosis.

Non-modifiable	Modifiable	'Emerging'/putative
Age	Smoking	Homocysteine
Male gender/oestrogen deficiency	Diabetes	Fibrinogen
Family history	Hypertension	Factor VII
	Diet/exercise	vWF
	'Atherogenic' lipid profile*	Factor XIIa
		Factor XIII
		tPA
		PAI-1
		C-reactive protein

*Small dense LDL, cholesterol-depleted HDL, excess chylomicron remnants and IDL.
PAI-1, plasminogen activator inhibitor-1; tPA, tissue plasminogen activator; vWF, von Willebrand factor.

Table 58.2 Diagnostic criteria for type 2 diabetes, impaired glucose tolerance and impaired fasting glucose.

Condition	Criteria
Type 2 diabetes	*With symptoms of diabetes*: random venous plasma glucose ≥ 11.1 mmol/L *or* fasting plasma glucose ≥ 7.0 mmol/L *Without symptoms of diabetes*: two plasma glucose results in the diabetic range on different days *or* 2-h plasma glucose concentration ≥ 11.1 mmol/L 2 h after 75-g oral glucose tolerance test
Impaired glucose tolerance	Fasting plasma glucose > 7.0 mmol/L and ≥ 7.8 mmol/l but < 11.1 mmol/L 2 h after 75-g oral glucose tolerance test
Impaired fasting glucose	Fasting plasma glucose ≥ 6.1 mmol/L but < 7.0 mmol/L; oral glucose tolerance test recommended to confirm diagnosis

with compensatory hyperinsulinaemia predisposes an individual to the development of a cluster of abnormalities, including glucose intolerance, increased plasma triglyceride concentrations, decreased high-density lipoprotein (HDL)–cholesterol, smaller denser LDL particles, hypertension, hyperuricaemia and increased PAI-1 concentrations. It has become apparent over the last decade that this group of metabolic abnormalities ('syndrome X' or the 'insulin resistance syndrome') is a major risk factor for CHD.

Patients with IR make up a large proportion of patients presenting with an acute MI. In a recent study of patients with acute MI who were not previously diagnosed with diabetes, up to 40% and 25% were found to have impaired glucose tolerance and type 2 diabetes respectively. Both type 1 and type 2 diabetes are associated with greater progression of CHD and a higher CHD-related mortality rate. Cardiovascular disease is responsible for about 70% of deaths in diabetic patients and, in the UK, a large proportion of the inpatient budget spent on diabetes relates to the management of cardiovascular disease. The management of cardiovascular risk factors in patients with IR and diabetes, therefore, represents a major challenge.

CHD was the major cause of death in men with diabetes in the Multiple Risk Factor Intervention Trial (MRFIT) and was responsible for approximately 40% of deaths over a 16-year period. The risk of death from CHD in diabetic men was three times greater than that in non-diabetic men, even after adjustment for risk factors such as cigarette smoking, age, race, income, systolic blood pressure and cholesterol concentration. Cigarette smoking, systolic blood pressure and cholesterol concentration were predictors of coronary artery disease (CAD) mortality for all participants, but the absolute risk of death from CAD increased more steeply with each risk factor for men with diabetes. These findings underline the importance of risk factor clustering in the pathogenesis of MI and the increased vascular risk in diabetic patients. Approximately 85% of people with type 2 diabetes are insulin resistant and these individuals tend to have this cluster of atherothrombotic risk factors. It is important, therefore, to have an understanding of the complexity of vascular risk and the implications for its prevention and management, rather than a purely glucocentric view of the pathogenesis of macrovascular disease in diabetes. Atherothrombotic risk factors that cluster together to form the insulin resistant syndrome, including changes to platelets, coagulation and fibrinolytic pathways, are discussed.

Coagulation and platelets

Over the past 20 years increased concentrations of various coagulation factors, including fibrinogen, factor VII and von Willebrand factor (vWF), as well as the antifibrinolytic protein, PAI-1, have been linked with CHD. Increased concentrations of tPA are associated with increased risk of MI, although this seems counterintuitive. Factor XIIa concentrations are also related to previous MI and the extent of coronary atheroma on angiogram.

Fibrinogen, factor VII, von Willebrand factor (vWF) and PAI-1 are associated with IR. *In vitro* studies show that insulin, very low-density lipoprotein (VLDL)-triglyceride and non-esterified fatty acids synergistically increase PAI-1 expression by human hepatoma cells There is also evidence of a genotype-specific interaction, with triglyceride regulating PAI-1 concentrations. Therefore, the combination of increased concentrations of fibrinogen, factor VII, factor XII and PAI-1 interacting with factors such as smoking, increased body mass and physical inactivity leads to a cluster of pro-atherothrombotic factors.

Platelets are essential for effective haemostasis and their structure and function are discussed in detail in Chapter 47. In patients with type 2 diabetes, platelets adhere to the vascular endothelium and aggregate more easily than in people without diabetes. In health, prostacyclin and nitric oxide combine to prevent the adherence of platelets to the normal endothelium, as well as preventing platelet aggregation. At physiological concentrations, insulin shows anti-aggregatory properties (effects mediated by prostacyclin and nitric oxide). Insulin increases endothelial production of nitric oxide and prostacyclin and increases platelet sensitivity to prostacyclin. The major defect in platelet function in type 2 diabetes is a loss of sensitivity to prostacyclin and nitric oxide, which may be due to changes in the activity and expression of G-proteins. Lean diabetic subjects have normal insulin anti-aggregatory responses, although this is not true of obese diabetic subjects. This implies that loss of sensitivity to nitric oxide in platelets is another feature of IR.

vWF, a glycoprotein (GP) constituent of the factor VIII complex, is found in increased concentrations in the plasma of type 2 diabetic patients. It is released by endothelium and causes platelet clumping by binding to platelet GPIb–IX and IIb–IIIa. GPIb is a receptor for vWF, as well as acting as a substrate for thrombin, whereas GPIIb–IIIa is a receptor for fibrinogen and other adhesive proteins involved in platelet aggregation. Diabetic patients have increased numbers of GPIb and GPIIb–IIIa complexes on the surface of their platelets and this may explain the increased platelet adherence seen in type 2 diabetes.

Insulin

In vitro, insulin has effects on smooth muscle proliferation, lipid metabolism, and hepatic PAI-1 synthesis and secretion, whereas insulin has been shown *in vivo* to have effects on renal sodium handling, nitric oxide expression and blood flow. Hyperinsulinaemia can be expected, therefore, to have major effects on the processes involved in atherothrombosis.

Insulin dilates isolated rat skeletal muscle arterioles in an endothelium-dependent manner, mediated by nitric oxide. *In vivo*, insulin-mediated vasodilatation is also dependent on endothelium-derived nitric oxide and it is therefore likely that insulin-mediated vasodilatation of skeletal muscle vasculature occurs due to increased nitric oxide synthesis and release. There is resistance to the effect of insulin on enhancement of endothelium-dependent

vasodilatation and resultant endothelial dysfunction in obese and insulin-resistant human subjects. Endothelium-dependent relaxation is decreased and there is a generalized loss of vascular compliance. In patients with type 2 diabetes associated with a combined hyperlipidaemia, this may partly reflect insudation of plasma lipids into the arterial wall.

Hyperglycaemia

Hyperglycaemia leads to the accelerated formation of advanced glycation end-products (AGEs), which cross-link vascular proteins, causing thickening and leakage of the vasculature. This results from AGE forming irreversible abnormal deposits in the subintimal layers of blood vessels, interfering with cellular interactions and generating toxic reactive oxygen species. The receptor for AGE (RAGE) is expressed by vascular endothelial and smooth muscle cells, macrophages, monocytes, cardiac myocytes, neuronal and mesangial cells and mediates some of these effects; vascular endothelial dysfunction can be induced by injection of AGE in animal studies, and RAGE antibodies or the truncated domain, soluble RAGE, reverse this effect. The AGE–RAGE interaction in the endothelium leads to upregulation of procoagulant and adhesive proteins, including PAI-1, tissue factor and vascular cell adhesion molecule-1 (VCAM-1).

VCAM-1 is expressed on the endothelium in atherosclerotic plaques and causes increased monocyte adhesion. Chemotaxis at sites of AGE accumulation recruits monocytes expressing RAGE, where they infiltrate the subendothelium to form foam cells. Animal studies show that RAGE expression is upregulated in the aorta and heart of diabetic as compared with non-diabetic rats. This has also been shown in arterial atherosclerotic tissue from diabetic subjects.

There are other RAGE ligands apart from AGE, including extracellular-newly identified RAGE binding protein (EN-RAGE). EN-RAGE is one of the S100 proteins. Other members of this family are found in atherosclerotic plaques and have chemo-attractant effects on mononuclear phagocytes. EN-RAGE interacts with RAGE to induce tumour necrosis factor a, VCAM-1 and interleukin 1 expression on endothelial cells, mononuclear phagocytes and lymphocytes. There are known to be several polymorphisms in the RAGE gene and one of these, a Gly82Ser polymorphism, affects a residue within the AGE binding site. Variants of the RAGE gene affect the cytokine cascade, causing inflammation, and this may lead to the development of vascular disease.

Dyslipidaemia

Dyslipidaemia is a major risk factor for CVD. Patients with primary hypercholesterolaemia have greatly increased LDL cholesterol and develop extensive atherosclerosis early in life, leading to death before the age of 30 years without treatment. LDL is thought to be important in the pathogenesis of athero-thrombosis, with endothelial dysfunction allowing LDL to enter the arterial wall, become progressively oxidized and initiating the inflammatory response. Macrophages phagocytose LDL via scavenger receptors on their surfaces and start the process of atheroma formation.

Hypertriglyceridaemia is also associated with a high risk of CVD, especially CHD, in prospective and epidemiological studies. Postprandial hypertriglyceridaemia may be particularly important due to the generation of an 'atherogenic lipid profile' consisting of small, dense LDL, increased concentrations of remnant particles and lipid-depleted HDL.

Hypertension

Hypertension is a major cardiovascular risk factor. Lowering blood pressure decreases the risk of CVD. The formation of hydrogen peroxide and free radicals is increased in patients with hypertension, which inactivates basal endothelial nitric oxide production in canine basilar arteries and increases monocyte adhesion *in vitro*. Hypertensive patients frequently have increased plasma concentrations of angiotensin II, the main product of the renin–angiotensin system and a potent vasoconstrictor. Angiotensin II stimulates smooth muscle cell proliferation and increases protein synthesis, eventually leading to smooth muscle hypertrophy.

Hyperhomocysteinaemia

An increased concentration of the sulphur-containing amino acid homocysteine in plasma is associated with thrombosis. The pathogenetic mechanisms underlying this have not been well defined, although there are claims for prothrombotic effects on coagulation and its inhibitors, fibrinolysis, platelets and vascular endothelium. Whatever the mechanisms, hyperhomocysteinaemia is a risk factor for CVD, CAD, PVD and deep vein thrombosis (DVT). Elevated levels result from genetic or nutritional disturbance of the trans-sulphuration or remethylation pathways for homocysteine metabolism (Figure 58.4). It is of note that the coenzymes for the three enzymes involved are dependent on adequate levels of vitamin B_6, cobalamin and folate. Deficiency of any of these vitamins can cause hyperhomocysteinaemia. The commonest genetic cause of hyperhomocysteinaemia is inheritance of the thermolabile variant of 5,10-methylene tetrahydrofolate reductase, which is polymorphic in European populations. It has been reported to be present in excess in subjects with CAD and PVD. Heterozygosity for cystathione synthase deficiency may also be a risk factor for early-onset cardiovascular disease; homozygosity for cystathione synthase deficiency gives rise to the rare condition of homocystinuria in which Marfan-like features are accompanied by a severe generalized thrombotic tendency affecting both arterial and venous circulations.

As folate supplementation reduces plasma homocysteine concentrations, there is considerable research activity directed towards using this simple therapy to reduce cardiovascular risk. However, to date no clear reduction in arterial thrombotic event rates have been reported.

Figure 58.4 Homocysteine metabolic pathways. In the methylation pathway, homocysteine acquires a methyl group either from betaine or from 5-methyltetrahydrofolate. In the trans-sulphination pathway homocysteine condenses with serine to form cystathione in a reaction catalysed by CBS.

CBS: cystathione beta synthase; MTHFR: methylene tetrahydrofolate reductase; SAM: S-adenosyl methionine; PLP: pyridoxal 5′ phosphate; FAD: flavine adenine dinucleotide. B_{12} = methylcobalamin. Adapted from D'Angelo and Selhub (1997).

Genetic and environmental influences

Heritability studies

The relative contributions of environmental and genetic factors to the development of risk factors for CAD have been estimated in several studies. In the San Antonio Family Heart Study, heritabilities of fasting glucose and insulin concentrations were estimated as 18% and 35% respectively. A large twin study recently showed that genetic factors were responsible for between 41% and 75% of the variation in fibrinogen, factor VII, vWF, factor XIII A-subunit, factor XIII B-subunit and PAI-1 concentrations and 82% of the variation in factor XIII activity. Other family studies have estimated similar heritability for fibrinogen and a small twin study has found that up to 30% of the genetic variance of vWF can be attributed to the effect of blood group, those with blood group O having the lowest concentrations of vWF.

Genotype association studies

It is most unlikely that a single genetic polymorphism responsible for CAD will be identified. The results of studies detailed in the following section have been disappointing because most were too small to detect interactions between genetic polymorphisms and environmental changes. Although relationships between the gene and the protein and between the protein and the disease are found, frequently there is no relationship between the gene and the disease. This is explained by the fact that it is the quantitative contribution of heritability to the phenotype that determines the link between the gene and the disease. Larger studies are needed to investigate the links between genetic polymorphisms and acquired environmental risk factors.

Fibrinogen

There are conflicting findings about the effect of polymorphisms on fibrinogen concentration, with one study showing that the effect is negligible, and another that polymorphisms of the β-fibrinogen gene were associated with an increased concentration. The latter study and several others have described associations between various polymorphisms and CAD, although two large studies showing an association between genotype and fibrinogen concentration failed to find a relationship between genotype and disease. In a small study in people with type 2 diabetes, there was a higher prevalence of the G allele of the −455 G–A polymorphism in those with CAD. These conflicting findings are partly due to the fact that fibrinogen concentrations vary widely in populations because it is an acute-phase reactant.

Plasminogen activator inhibitor-1

Some studies report a negligible effect of PAI-1 genotype on PAI-1 concentrations, and it has been suggested that features of IR were the major determinant. However, homozygotes for the

commonest polymorphism, a single basepair in the promoter region (4G/5G), have been described as having plasma PAI-1 concentrations that are increased by 25% compared with those who are homozygous for the 5G allele. There is evidence, from a study of subjects with type 2 diabetes, of a genotype-specific interaction with triglyceride. At a given concentration of triglyceride, subjects with the 4G/4G genotype had increased PAI-1 concentrations compared with those with the 5G/5G genotype. There is a VLDL response element in the promoter region of the PAI-1 gene adjacent to the 4G/5G site, which might explain these findings. VLDL causes HepG2 cells to release more PAI-1 antigen and activity, and insulin augments this effect.

von Willebrand factor

Only about 20% of the variability in concentration of vWF is accounted for by polymorphisms in the 3′-region. One study in people with type 1 diabetes and proliferative retinopathy has found an association between the Thr789Ala polymorphism and CAD.

Factor VII

Factor VII concentrations are related to two sites on the factor VII gene that are in linkage disequilibrium, a single base change at position R353Q in exon 8 and a promoter decanucleotide repeat. No relationship has been found between particular genotypes or FVII:C concentrations and the extent of atheroma, although certain factor VII genotypes may have a protective effect against MI. Dietary fat intake has been found to influence factor VII concentrations and there is a relationship with triglyceride concentrations.

Factor XIII

The effect of genetic polymorphisms on factor XIII and its role in fibrin clot formation is reviewed in Ariens *et al.* (2002). A common polymorphism, Val34Leu, in the factor XIII A-subunit has attracted interest as a potential risk factor for atherothrombosis. It has little effect on factor XIII concentration but accelerates factor XIII activation by thrombin, altering the structure of cross-linked fibrin. Because of this effect, the polymorphism may explain the high heritability of factor XIII activity. The factor XIII B-subunit merely acts as a carrier of the A-subunit. It has a lower heritability, and it has been estimated from a twin study that about 25% of the variance is explained by a common environmental influence.

Clinical features

Coronary heart disease

The clinical manifestations of CHD are angina, acute coronary syndromes (ACS), myocardial infarction (MI), heart failure and dysrhythmias.

Figure 58.5 Coronary angiogram showing stenosis of the left anterior descending coronary artery (courtesy of Dr A Catto).

Angina and myocardial infarction may be painless, especially in people with diabetes. However, most patients complain of central, dull, crushing chest pain that may radiate to the jaw or down the left arm. This pain is often associated with shortness of breath. The patient with acute MI usually has more severe symptoms and feels sweaty and nauseated, often vomiting. Anginal symptoms are usually brought on by exercise and subside with rest. The typical electrocardiogram (ECG) changes of an acute MI are S–T segment elevation, followed within hours by T-wave inversion and then Q-wave formation. Intracellular enzymes are released into the circulation; the most commonly measured enzyme, creatine kinase (CK-MB), increases in concentration within hours and decreases again within 24–48 h. Troponin, a myofibrillar cardiac protein, also increases in concentration after a few hours and is increased for several days. About 25% of people who have an acute MI die before reaching hospital. Most of these will have suffered a dysrhythmia, commonly ventricular fibrillation, and death will have occurred instantaneously or within the first hour.

In a patient with anginal symptoms, exercise testing or ambulatory monitoring may show ischaemic electrocardiographic changes. In the absence of obvious angina, myocardial isotope perfusion scanning can be used to identify reversible cardiac ischaemia. Coronary angiography reveals the presence of stenosis in the coronary arteries (Figure 58.5) and decisions can then be made on appropriate management, either with bypass surgery, coronary artery angioplasty or stenting, or with drug therapy. The drug treatments for those diagnosed as having an acute S–T segment elevation MI (STEMI) or ACS is discussed later in this chapter.

Heart failure can occur in the absence of overt CHD, particularly in diabetes, but is usually secondary to atherosclerosis. Left ventricular failure presents with shortness of breath on exercise, orthopnoea and paroxysmal dyspnoea, whereas right-sided failure presents with peripheral oedema.

Figure 58.6 The ischaemic right foot of a diabetic man with peripheral vascular disease. The first toe and distal second phalanx are gangrenous (courtesy of Dr C Amery).

Peripheral vascular disease

PVD often presents as intermittent claudication; patients complain of pain in the back of the calf on walking, which is relieved by rest. Pedal pulses will usually be absent or diminished on the affected side and Doppler ultrasound can be used to confirm the diagnosis. Angiography is used to locate stenosis and determine whether management should be interventional (arterial bypass, angioplasty or stenting) or with drug therapy. Severe PVD, often in people with diabetes or smokers, can lead to ischaemia and amputation of digits or lower limbs (Figure 58.6).

Cerebrovascular disease

Cerebrovascular disease is manifested by transient ischaemic attacks, stroke and multi-infarct dementia. A stroke characteristically presents with the abrupt onset of hemiplegia, dysphasia,
Figure 58.7 Computerized tomographic scan showing a recent extensive right frontotemporal infarct (courtesy of Dr A Catto).

sensory impairments, visual field defects or cerebellar dysfunction. The symptoms and signs depend on the artery occluded and the region of brain that consequently infarcts. Transient ischaemic attacks present in the same manner but resolution occurs within 24 h, often lasting only a few minutes or 1–2 h at the most. Computerized tomography scanning of the head will reveal an area of infarction (Figure 58.7) in a patient with a stroke, but may be normal in a patient with a transient ischaemic attack. In some units, acute ischaemic stroke is treated with immediate thrombolysis, but, at the time of writing, this is not standard practice throughout the UK. Aspirin is usually started once the diagnosis is confirmed. If subsequent investigations reveal carotid arterial stenosis, endarterectomy may be performed once the patient has recovered from the acute event.

Management of cardiovascular disease

Table 58.3 lists the factors that should be assessed in all patients, especially those with existing CVD. In the UK, patients with no evidence of CVD should be assessed using the Joint British Societies Coronary Risk Prediction Chart (British Cardiac Society, British Hyperlipidaemia Association, British Hypertension Society, endorsed by the British Diabetic Association 1998). Once a risk assessment has been performed, appropriate therapy can be commenced. Standard primary and secondary preventative drug treatments are presented in Table 58.4.

Anti-platelet drugs and fibrinolytic treatment

Ischaemic coronary syndromes have been previously classified as either unstable angina (UA), non-Q wave MI or Q-wave MI. The recent change in nomenclature to STEMI or ACS, defined as either UA or non-ST segment elevation MI (NSTEMI), has been a direct result of facilitating early diagnosis and risk stratification, and underscores the importance of rapid classification. At present, 1.83 million persons are admitted annually to US hospitals with an ischaemic coronary syndrome. Of these patients, 1.42 million are classified as having an ACS and 0.41 million are classified as STEMI. In addition to being a prevalent clinical entity, patients with an ACS or STEMI are at considerable risk for in-hospital mortality or a non-fatal MI within the first year of hospital discharge. This section focuses on the numerous classes of agents used to manage persons with ischaemic heart disease as well as other vascular syndromes.

A primary goal of therapy for patients with ACS NSTEMI is rapid diagnosis and risk-stratification as well as implementation of an appropriate medical and revascularization strategy. As seen in Figure 58.8, patients (defined by clinical presentation) and the therapeutic interventions they undergo have an associated risk. According to the recent American College of Cardiology Foundation and American Heart Association (ACC/AHA) 2002 Guidelines, it is imperative that a 12-lead ECG be obtained

Cardiovascular risk factors	Action
Smoking	Discuss willingness to stop smoking Refer to smoking cessation clinic Nicotine replacement therapy Amfebutamone (bupropion)
Weight/diet	Discuss current diet and willingness to change Refer to dietitian Orlistat Sibutramine Surgery, e.g. gastric bypass
Exercise	Discuss current exercise regimen Refer to local lifestyle clinic/gym/swimming pool
Lipid profile	Consider HMG CoA reductase inhibitor in inherited dyslipidaemias or if chol. $\geq$ 5 mmol/L*
Renal function	ACE inhibitor for patients with diabetes and microalbuminuria or proteinuria Consider HMG CoA reductase inhibitor and aspirin
Blood pressure	Treat if BP $\geq$ 160/100 or if > 140/90 with estimated 10-year risk of CHD $\geq$ 15%, CVD or diabetes[†] Aim for clinic BP $\leq$ 140/85 in non-diabetic patient BP $\leq$ 140/80 in diabetic patient or lower if microalbuminuria or proteinuria present Consider HMG CoA reductase inhibitor if systolic BP > 160 mmHg with/without diastolic > 100 mmHg
Glycaemic control	All patients with CVD should be screened for diabetes In those with diabetes, aim for HbA_{1c} < 6.5–7.5% Consider HMG CoA reductase inhibitor and aspirin

and definitively interpreted within 10 min of the clinical presentation. This is particularly important in patients presenting with STEMI, as rapid coronary revascularization has been shown to be associated with a marked improvement in cardiovascular survival. In addition to patient history, physical examination, ECG and biochemical markers (CK-MB and cardiac troponins) are commonly used to further stratify patients with both ACS and NSTEMI. Utilization of cardiac troponins increases the sensitivity for measuring myonecrosis such that many clinicians utilize the terms 'micro-infarction' or 'minor myocardial damage' to identify the clinical setting of an elevated cardiac troponin with a

normal CK-MB and further risk-stratify patients. Biomarkers used less commonly at present include myoglobin and lactate dehydrogenase.

Immediately following diagnosis and risk assessment, an effective medical management strategy must be instituted in order to affect not only short-term survival and ischaemic events, but also to prevent long-term sequelae from ischaemic heart disease. Although anti-ischaemic agents are commonly employed early in the course of care for patients with acute ischaemic syndromes, the mainstay of early therapy for patients with ACS and STEMI are antithrombotic agents. For the course of this discussion,

Table 58.4 Primary and secondary prevention for CVD.

Treatment	Indication	Current Evidence (2003)
Lifestyle changes	General population	Regular exercise ↓ obesity, diabetes and subsequent CVD
	Obese	Weight loss of 10 kg ↓ mortality, angina, BP, lipids, ↓ HbA$_{1c}$ in diabetes
	Impaired glucose tolerance	Weight loss and exercise delay onset of type 2 diabetes
	Smokers	Smoking cessation ↓ risk of CVD
	Post MI	'Mediterranean diet' ↓ CHD in people with a previous MI; n-3 PUFA supplements immediately post-MI ↓ death, non-fatal MI and stroke
HMG CoA reductase inhibitors	CHD risk of ≥ 30% over 10 years	Pravastatin and lovastatin ↓ CHD risk in people with hypercholesterolaemia; atorvastatin ↓ CHD risk in hypertensives with at least three other risk factors for CVD
	CVD or diabetes (chol. ≥ 4 mmol/L)[7]	Pravastatin ↓ CHD, stroke and mortality post MI or in people with angina; simvastatin ↓ CHD, stroke and mortality post MI, in people with angina, with CVD or diabetes
ACE inhibitors	CVD or diabetes and one risk factor for CVD	Ramipril ↓ incidence of stroke, MI and death from CVD
	Post MI	Early treatment with captopril or lisinopril ↓ mortality especially with previous MI or heart failure (enalapril within 24 h of acute MI did not improve survival)
	Post stroke	Perindopril ↓ risk of further stroke or any CVD events
β-Blockers	Heart failure	Bisoprolol ↓ survival in patients with stable heart failure
Metformin	Type 2 diabetes, BMI > 25 kg/m^2	Metformin ↓ all-cause mortality and incidence of stroke
Insulin	Diabetes and acute MI	Intensive treatment with insulin and glucose infusions followed by intensive subcutaneous insulin regimens ↓ long-term mortality

BMI, body mass index; BP, blood pressure; CHD, coronary heart disease; chol., cholesterol; CVD, cardiovascular disease; HMG CoA reductase, 3-hydroxy-3-methylglutaryl coenzyme A; MI, myocardial infarction; PUFA, polyunsaturated fatty acids.

these agents can be divided into four broad categories: (i) oral anti-platelets (aspirin and thienopyridines); (ii) anticoagulants (heparins, warfarin and direct thrombin inhibitors); (iii) intravenous anti-platelet agents; and (iv) fibrinolytic agents. Other vascular indications for these agents will also be discussed.

Oral anti-platelet therapy

Aspirin and thienopyridines (ticlopidine and clopidogrel) are two oral anti-platelet agents commonly utilized for the prevention of and treatment for ischaemic heart disease and cerebrovascular disease.

Aspirin

Aspirin irreversibly inhibits cyclo-oxygenase-1 within platelets, thus preventing the formation of thromboxane A$_2$, resulting in decreased platelet aggregation. Although numerous studies have shown that aspirin has a robust impact on reduction of adverse cardiovascular events, it is a relatively weak anti-platelet agent. It has also been suggested that aspirin may have important anti-inflammatory effects resulting in additional anti-ischaemic

properties. Four prospective randomized controlled trials have established the efficacy of aspirin in the setting of ACS patients. Pooled analysis from these four trials covered 2448 patients and demonstrated a significant reduction in the 30-day death or non-fatal MI rate for those patients randomized to aspirin therapy (6.4% versus 12.5%, $P = 0.0005$). Given the ease of administration, cost, and prompt bioavailability of a chewed aspirin, it is always indicated for people with suspected ACS or STEMI.

Numerous other studies on aspirin have demonstrated a significant reduction in vascular-related death, stroke and MI. Among a primary prevention cohort, there was a significant reduction in non-fatal MI but at the cost of increased stroke rates. Further, there is a significant reduction in the prevalence of deep venous thrombosis (DVT) and pulmonary embolism (PE) in postsurgical and high-risk medical patients.

Although data for aspirin use are unequivocal, several important issues remain. First, although frequently four 'baby' aspirin are chewed (rather than swallowed) by the patient in the accident and emergency department in order to decrease the time to onset of action, this strategy has never been studied in a prospective fashion. Second, the optimal dose of aspirin remains unknown. Trials of secondary prevention for stroke, MI, and death have not shown an added benefit for aspirin in doses either > 80 or 160 mg per day but have shown an increased tendency towards bleeding. As a direct result of the 2nd International Study of Infarct Survival (ISIS-2), either 160 mg or 325 mg are initially prescribed to suspected ACS patients who are not already receiving aspirin. Subsequent aspirin doses are often administered in the range of 75–325 mg per day (ISIS-2).

Limited data exist for the long-term efficacy of aspirin administration for patients following ACS. Secondary prevention studies have demonstrated benefit through the first two years of aspirin administration and a trend for benefit in the third year. At present, it is recommended that patients receive aspirin therapy indefinitely unless side-effects emerge. Contraindications for aspirin administration are listed in Table 58.5. Side-effects commonly seen with aspirin therapy are mainly gastrointestinal and include dyspepsia and nausea. Rarely, acute gout can be precipitated due to impaired urate excretion. It has been suggested that there is an adverse interaction with angiotensin-converting enzyme (ACE) inhibitors and aspirin therapy. It has been postu-

lated that aspirin inhibits ACE inhibitor-induced prostaglandin synthesis, reducing its vasodilatory effects. However, this biochemical interaction does not appear to have an adverse effect on either drug in clinical practice.

Thienopyridines

Thienopyridines are commonly prescribed for patients presenting with ACS, following percutaneous coronary intervention (PCI) in patients with STEMI and for the secondary prevention of stroke, non-fatal MI and acute limb events. Both ticlopidine and clopidogrel are thienopyridine derivatives, pro-drugs and selective antagonists of adenosine diphosphate-induced platelet aggregation. Historically, ticlopidine was used for the secondary prevention of stroke, MI and subacute intracoronary stent thrombosis. There are limited data regarding the efficacy of ticlopidine in patients with ACS. A small, randomized controlled trial demonstrated a reduction in the rate of fatal and non-fatal MI at a 6-month follow-up.

At present, adverse effects of ticlopidine limit its use in clinical practice to patients who are intolerant of clopidogrel. The most worrying potential side-effects are severe neutropenia and thrombotic thrombocytopenic purpura (TTP). Severe neutropenia occurs in less than 1% of patients who are treated with ticlopidine, and life-threatening TTP is also extremely rare. However, patients receiving ticlopidine therapy for more than 2 weeks require a full blood count, including a differential white cell count every 2 weeks for the first few months of therapy. If it occurs, neutropenia usually resolves within 1–2 weeks following drug cessation. It does not appear that clopidogrel is associated with an increased risk of TTP relative to the general population. Thus, the use of ticlopidine has generally been supplanted with clopidogrel as the preferred thienopyridine. The initial indication for ticlopidine among patients with ischaemic heart disease was for the prevention of subacute thrombosis following placement of an intracoronary stent. It appears that clopidogrel is a reasonable alternative anti-platelet strategy for this indication.

The largest body of clinical evidence for the utilization of clopidogrel in patients with ACS originates from the Clopidogrel and Unstable angina to prevent Recurrent Events (CURE) trial. In this trial, 12 562 patients were randomized, within 24 h of presenting with an ACS, either to clopidogrel plus aspirin or aspirin alone. There was a 12-month rate of cardiovascular death, non-fatal MI or stroke of 9.3% for patients randomized to clopidogrel, compared with 11.5% for patients randomized to placebo (relative risk = 0.80, $P < 0.001$). Further, there was a consistent benefit across many subgroups of patients presenting with ACS, including those undergoing PCI. Given the results of CURE, clopidogrel is routinely used in many centres across the world in patients presenting with an ACS. It is recommended that clopidogrel is not administered until coronary anatomy has been defined and a revascularization strategy determined. If the patient is to be managed medically or undergo PCI, a loading dose of 300 mg of clopidogrel orally can be administered

following coronary angiography or on the catheter laboratory table respectively.

However, universal utilization of clopidogrel in ACS patients has not occurred for two major reasons. First, CURE demonstrated increased bleeding in patients randomized to clopidogrel (placebo: 2.7%, clopidogrel: 3.7%; $P = 0.003$). The greatest risk for severe bleeding was seen in patients who underwent coronary artery bypass grafting (CABG) in the setting of ACS. Clopidogrel was often administered to patients prior to coronary angiography and therefore prior to any revascularization procedure. The peri-operative bleeding rates approached 10% if clopidogrel was not stopped 5 days prior to CABG. For this reason, some hesitation exists among the medical community for widely adopting early use of clopidogrel before determining whether or not CABG is warranted. Therefore, many physicians refrain from administering clopidogrel until after coronary angiography in the setting of ACS. Second, cost has been a major limitation for the widespread use of clopidogrel both in the UK and the USA.

Anticoagulants

Intravenous anticoagulation remains the mainstay for medical management of patients presenting with both ACS and STEMI. Intravenous anticoagulation has been utilized for nearly three decades to improve both short-term mortality and reduce recurrent ischaemic events. Historically, the sole agent available for management of patients with acute ischaemic syndromes has been unfractionated heparin (UFH).

Unfractionated heparin

Unfractionated heparin (UFH) is a heterogeneous mixture of heparin with molecular weights ranging from 5000 to 30 000 Da, it is highly bound and has a complex effect on the coagulation mechanism. Primarily, the major effect of heparin is interaction with antithrombin-III (AT-III), inhibiting thrombin generation. However, heparin is also a relatively weak inhibitor of factor Xa and the dose–response relationship is rather difficult to predict because of the variable strength from each heparin preparation. Additionally, there is variable binding of heparin to plasma proteins, endothelial cells and circulating macrophages, making the dose response less than predictable. The indications for heparin therapy are numerous and include treatment for pulmonary embolism, venous thrombosis, unstable angina (UA), non-ST segment elevation MI (NSTEMI), S–T segment elevation MI (STEMI) and acute peripheral arterial occlusion. It is also used for prevention of venous thromboembolism in high-risk cohorts (postsurgery and high-risk medical patients), prevention of thrombosis in extracorporeal systems (such as those used in haemodialysis or cardiovascular surgery involving mechanical prosthetic valves) and in patients with hypercoagulable syndromes.

The studies evaluating heparin efficacy in ACS patients were performed in a previous era of cardiology management strategies and were largely underpowered. Pooled data from four studies allowed comparison of 999 patients being treated with UFH plus aspirin compared with aspirin alone. Data from these trials demonstrated a reduction in 30-day death and non-fatal MI rates for UFH-treated patients (2.6% versus 5.5%, $P = 0.018$). This has resulted in the widespread use of UFH in ACS and STEMI patients. The UFH dosing recommendations at present for patients with ACS are a bolus infusion equal to 60–70 U/kg (maximum of 5000 U) intravenously followed by a continuous infusion of 12–13 U/kg/h (not to exceed 1000 U/h).

Low-molecular-weight heparins

Low-molecular-weight heparins (LMWHs) have emerged as a potential alternative to UFH as a result of its aforementioned limitations. There are numerous features of LMWHs that make them potentially superior agents compared with UFH. In a similar fashion to UFH, LMWHs inhibit platelet thrombus formation primarily through their effects on AT-III. In general, LMWHs have a mean molecular weight of 5000 Da, have a more potent anti-Xa:IIa effect, are less plasma protein bound, have a longer half-life (2–4 h versus 1 h for UFH), are significantly more bioavailable (> 90% compared with 30% for UFH), have a more predictable dose–response and undergo less neutralization by platelet factor IV and protamine. There is also a weaker inhibitory effect on platelet function and a less common association with heparin-induced thrombocytopenia. It is thought too that rebound ischaemia occurs less commonly with LMWHs than with UFH.

LMWHs, including dalteparin, nadroparin and enoxaparin, have been evaluated in numerous clinical settings in ACS patients. The two enoxaparin trials enrolled over 7000 patients and demonstrated a significant, 20% relative risk reduction in the composite endpoint of 14-day death, non-fatal MI or urgent revascularization. As a result, enoxaparin is now commonly utilized as an early and preferred anticoagulant in patients presenting with ACS. Additionally, economic analysis suggested a cost saving for those patients randomized to enoxaparin. Enoxaparin has also been shown effective in the setting of STEMI when coupled with a fibrinolytic agent.

Small, randomized, controlled trials have evaluated the combination of LMWH and GPIIb/IIIa inhibitors in the medical management of ACS patients. It appears that the rates of major bleeding, with the combination of LMWHs and GPIIb–IIIa inhibitors for these randomized controlled trials, remains relatively low at 0.3–1.8%. Additionally, there did not appear to be an additional risk of bleeding at the time of PCI.

Non-cardiac indications for heparin

Numerous other indications exist for the use of intravenous UFH. These include the treatment of venous thromboembolic disease. Intravenous or subcutaneous UFH is often used as prophylaxis for DVT and PE. Various clinical trials have shown that 5000 U subcutaneously every 8–12 h results in a 67% relative risk reduction for the formation of venous thrombosis

and fatal PE. UFH is also used for the treatment of DVT and PE. Recommended dosing regimens for these include 5000 U intravenous bolus followed by a continuous intravenous infusion adjusted to maintain the activated partial thromboplastin time (APTT) in the therapeutic range. LMWHs have also been extensively studied for the prophylaxis and treatment of DVT and PE. A meta-analysis comparing LMWHs with UFH following elective hip surgery demonstrated a marked superiority of LMWHs for the prevention of proximal venous thrombosis and a reduction in major bleeding.

Complications of heparin therapy

Two complications of heparin therapy must be noted. First, heparin-induced thrombocytopenia (HIT) is not uncommon. It is mediated by the formation of an antibody to a neo-antigen on platelet factor IV (a platelet granule protein) that is exposed when it binds to heparin. This is an IgG-immune mediated process and results in paradoxical thrombosis as well as an unexplained decrease in the platelet count to less than 50%. It is diagnosed on the basis of both clinical and laboratory results. The platelet-activating properties of HIT serum or plasma in the presence of heparin can be measured with an activation assay. Antigen assays also exist for detecting antibodies, which recognize platelet factor IV bound to heparin. Treatment for HIT-associated thrombosis includes the use of danaparoid, lepirudin or argatroban. Warfarin therapy may also be utilized for long-term anticoagulation for limb gangrene in patients with HIT. It should be noted that both UFH and LMWHs can cause HIT, however, low-molecular weight preparations theoretically should lead to fewer occurrences of HIT.

A second potential side-effect of heparin treatment is heparin-induced osteoporosis. This most commonly occurs in pregnant women in whom systemic anticoagulation is indicated. Significant reduction in bone density has been documented in patients receiving heparin for 1 month or more. Small studies suggest that LMWHs may carry a lower risk of osteoporosis compared with UFH.

Warfarin is an oral anticoagulant that is commonly employed in numerous clinical settings. It is a racemic mixture of two optically active isomers, is highly bioavailable, is rapidly absorbed in the gastrointestinal tract, reaches peak blood concentrations 60–90 min after oral administration and has a half-life of 36–42 h. Warfarin is highly plasma protein bound, and the dose–response relationship is complex, unpredictable and determined by both genetic and environmental factors. Warfarin is a vitamin K antagonist and, thus, its anticoagulation effects are a result of inhibiting vitamin K-dependent coagulation factors including factors II, VII, IX and X. The variability in the anticoagulant response is described in detail elsewhere. In addition to numerous environmental factors, there are innumerable drug and food interactions with warfarin.

Warfarin has both antithrombotic and anticoagulant effects. Thus, it is indicated in numerous clinical settings. Warfarin therapy is frequently monitored by measuring the prothrombin time (PT). The PT is dependent on a response to reductions in the vitamin K-dependent procoagulant clotting factors (II, VII, IX and X) and is performed by adding both thromboplastin and calcium to citrated plasma. Thromboplastin is a phospholipid–protein extract that varies in its responsiveness to the anticoagulant effects and, thus, results in varying PT results. As a result of the varying anticoagulant effects of thromboplastin, PT results were non-standardized. Therefore, in 1977, the World Health Organization designated a reference preparation for human brain thromboplastin, allowing for a calibration model to be widely adopted in 1982, known as the international normalized ratio (INR). This is calculated using the following equation: INR = (patient PT/mean normal PT)^{ISI}, where ISI is the International Sensitivity Index for the thromboplastin used to perform the PT measurement at any given laboratory. Table 58.6 gives the suggested INR for the various indications for warfarin therapy.

Warfarin is effective in the prevention of venous thromboembolism following hip surgery and major gynaecological surgery. The INR is usually maintained between 2.0 and 3.0. For the treatment of a DVT, the duration of therapy is dependent on numerous clinical factors; however, it is indicated for no less than 3 months in patients with proximal DVT and no less than 6 months in those with PE. Indefinite oral anticoagulation therapy should be considered in patients with more than one episode of idiopathic DVT or PE, thrombosis related to malignancy, DVT associated with factor V Leiden genotype, antiphospholipid antibody syndrome or deficiencies in either protein C, AT-III or protein S.

There are mixed data with respect to the use of warfarin in primary prevention of ischaemic coronary events. Although the thrombosis prevention trial demonstrated effectiveness of the combination of low-intensity warfarin plus aspirin, both the Coumadin Aspirin Reinfarction Study (CARS) and the Stroke Prevention in Atrial Fibrillation III (SPAF-3) randomized clinical trial have shown no efficacy using warfarin in the prevention of primary ischaemic heart disease events. Warfarin administration following acute MI is controversial and clinical practice varies widely. Based on present literature, some physicians believe that it is reasonable to anticoagulate a person following a recent moderate to large anterior wall MI for a period of approximately 6 weeks to prevent further embolic events. However, there are a paucity of clinical data to support this or, indeed, the routine use of warfarin following acute MI. Warfarin is typically used in preventing thromboembolic events in patients with mechanical prosthetic heart valves. In fact, based on recent findings, it is common to treat patients with mechanical prosthetic heart valves with both warfarin and low-dose aspirin.

Based on recent guidelines, it is commonly thought that the newer bioprosthetic heart valves will require a lower INR. Additionally, warfarin is utilized frequently in patients with chronic or paroxysmal atrial fibrillation. Numerous studies have demonstrated the efficacy of this strategy. Pooled analysis of five large-scale clinical trials demonstrated a 69% reduction in ischaemic

Table 58.6 Recommended INR for different clinical indication.

Indications	Valve position	European Society for Cardiology (1995)	British Society for Haematology	AHA/ACC (1998)
Mechanical prosthetic valves				
First generation (Starr–Edwards, Björk–Shiley standard)		3.0–4.5	3.5	2.5–3.5*
Second generation	Aortic	2.5–3.0	3.5	2.0–3.0
(St Jude, Medtronic Hall)	Mitral	3.0–3.5	3.5	2.5–3.5
Third generation (Sorin Bicarbon	Aortic	2.5–3.0	3.5	2.0–3.0
bileaflet valve)	Mitral	2.5–3.0	3.5	2.5–3.5
Bioprosthestic valves in sinus rhythm	Aortic	2.5–3.0	No anticoagulation	2.0–3.0
(anticoagulation for first 3 months only)	Mitral	3.0–2.5	2.5	2.0–3.0
Bioprostheses in atrial fibrillation	Aortic	3.0–4.5	2.5	2.0–3.0
	Mitral	3.0–4.5		2.5–3.5

*INR = 2.0–3.0 in some centres.

In some centres, aspirin 80–100 mg per day is used for bioprosthetic valves in the aortic position, rather than warfarin.

An INR of 2.0–3.0 is recommended for prophylaxis or treatment of deep venous thrombosis or pulmonary embolus, and treatment of patients with thrombosis associated with antiphospholipid syndrome.

ACC, American College of Cardiology Foundation; AHA, American Heart Association; INR, International Normalized Ratio.

strokes for those patients with atrial fibrillation treated with warfarin. The recommended anticoagulation regimen for patients with atrial fibrillation is given in Table 58.7.

Direct thrombin inhibitors

Thrombin is thought to play a key role in the process of thrombus formation in patients with ACS. It plays a deterministic role

Table 58.7 Recommended antithrombotic therapy for patients with atrial fibrillation (Fuster *et al.*, 2001).

Clinical features	Recommended therapy
Age < 60 years, with structurally normal heart	Aspirin/no therapy
Age ≤ 60 years, with heart disease, low risk	Aspirin
Age ≥ 60 years, with diabetes or CHD	Warfarin
Age ≥ 75 years, high-risk features	Warfarin
Mitral stenosis, prosthetic heart valve, prithromboembolism, atrial thrombus on TOE	Warfarin (INR 2.5–3.5)

Note: The recommended aspirin dose varies around the world,
High-risk factors = congestive heart failure, left ventricular ejection fraction < 35% or history of hypertension.
CHD, coronary heart disease; TOE, transoesophageal echocardiogram.

in the conversion of fibrinogen to fibrin, activation of platelets and recruiting additional platelets to the site of thrombus formation. As a result, agents that directly inhibit thrombin activity have been developed and studied extensively among patients with ACS and STEMI. Direct thrombin inhibitors are able to inhibit both circulating and tissue-bound thrombin and, thus, were thought to have theoretical benefit over both UFH and LMWHs. Additionally, direct thrombin inhibitors are not heavily protein bound, not inactivated by heparinases, have a predictable biological response and are potent *ex vivo* inhibitors of thrombus formation.

Although there was initial enthusiasm for direct thrombin inhibitors in preventing mortality and recurrent ischaemic events among patients presenting with IHD, trials performed to date have been disappointing. Several agents were developed and studied in various clinical settings, including argatroban, bivalirudin, efagatran and inogatran. Although bivalirudin has been extensively studied in various clinical settings, the prototype direct thrombin inhibitor is hirudin, as it is a potent near-irreversible inhibitor of thrombin. Its half-life is approximately 60 min and is renally excreted. Bivalirudin is a synthesized 20-amino-acid polypeptide, which forms a bivalent complex with thrombin, with a half-life of 20–25 min and is non-renally excreted.

Four large-scale randomized controlled trials have studied the efficacy of direct thrombin inhibitors in patients with ACS. None of these trials demonstrated a superiority of the direct thrombin inhibitor compared with heparin alone. Pooled

analysis of these trials suggests that hirudin is superior to heparin for the prevention of death or non-fatal MI at the time of completion of the study drug infusion, but there appeared to be a diminished benefit of direct thrombin inhibitors at 30 days. Direct thrombin inhibitors have also been extensively investigated in STEMI patients. Pooled analysis from the STEMI trials included over nearly 10 000 patients and demonstrated no additional benefit in either the incidence of or non-fatal MI rate for those patients treated with a direct thrombin inhibitor compared with UFH.

Bivalirudin is being extensively evaluated in elective PCI patients in the REPLACE II trial. (Additional studies of bivalirudin are being planned at the moment for the management of ACS patients.) At present, direct thrombin inhibitors are the anticoagulant of choice among persons with a history of HIT. Furthermore, as additional data emerge with bivalirudin in the setting of elective PCI and ACS, this agent may become more readily used in clinical practice.

Intravenous anti-platelet agents

Glycoprotein IIb–IIIa inhibitors
The use of oral GPIIb–IIIa antagonists has not been shown to be beneficial among patients with CHD. In fact, a pooled analysis from four large-scale randomized clinical trials using Xemilofiban evaluated the efficacy of oral GPIIb–IIIa antagonists in over 33 000 patients and demonstrated an approximate 37% increase in mortality for those patients randomized to an oral GPIIb–IIIa inhibitor.

The development of intravenous anti-platelet agents, such as GPIIb–IIIa inhibitors, has resulted in a significant reduction in mortality and non-fatal ischaemic events among patients with CHD. There are three commercially available intravenous GPIIb–IIIa inhibitors: abciximab, eptifibatide and tirofiban. Abciximab is a monoclonal antibody directed against the GP receptor. Eptifibatide is a synthetic cyclic heptapeptide GPIIb–IIIa antagonist and tirofiban is a non-peptide antagonist. Each of these agents has been extensively studied in both the ACS and the elective PCI setting.

The clinical effectiveness of GPIIb–IIIa inhibitors was initially shown in elective PCI patients. Following this, several studies investigated the efficacy among ACS patients. These agents were often started prior to the determination of coronary anatomy. In total, there have been five large-scale prospective randomized controlled clinical trials evaluating the efficacy of GPIIb–IIIa inhibitors in patients with ACS. In total, these trials have randomized over 26 000 patients presenting with ACS. Pooled analysis of these trials, which investigated the efficacy of tirofiban, eptifibatide, abciximab and lamifiban, have demonstrated a modest 12% relative risk reduction in death or non-fatal MI at 30 days. The point estimates for all trials, with the exception of the GUSTO IV-ACS (effect of GPIIb–IIIa receptor blocker abciximab on outcome in patients with acute coronary

syndromes without early revascularization) randomized trial, which used abciximab, demonstrated a significant reduction in the primary endpoint of death and non-fatal MI at 30 days. The GUSTO IV-ACS trial failed to demonstrate a benefit of abciximab in the setting of an ACS. In clinical practice, eptifibatide and tirofiban, which were investigated in the PURSUIT and PRISM trials respectively, are usually used in the initial management of patients with ACS.

Although these trials demonstrated a modest reduction in endpoints overall, several subgroups have been shown to have increased benefit from the early use of intravenous GPIIb–IIIa inhibitors. For example, patients with diabetes have been shown in a multitude of studies to be at heightened risk for both short- and long-term adverse cardiovascular events. The addition of GPIIb–IIIa inhibitors to the medical regimen of patients with diabetes presenting with ACS have dramatically improved the outcomes of this high-risk group of patients. Pooled data from the ACS trials mentioned previously have demonstrated a significant reduction in 30-day mortality for those diabetic patients treated with an intravenous GPIIb–IIIA inhibitor. Additionally, patients undergoing early PCI in the setting of an ACS were shown to be at high risk. The addition of intravenous GPIIb–IIIa inhibitor prior to PCI in patients with ACS has dramatically improved the safety profile of PCI in this setting.

Additional high-risk groups of patients are those with increased cardiac troponin concentrations and those undergoing CABG in the setting of ACS. There are two major limitations for the use of intravenous GPIIb–IIIa inhibitors; first, the added cost of delivering care, and second, a modest increase in the risk of bleeding during the time of PCI. Bleeding complications have diminished over time as a result of decreasing the peri-PCI heparin dose and early removal of the intra-atrial sheath. At present, all patients presenting with suspected or confirmed ACS should be considered candidates to receive intravenous GPIIb–IIIa inhibitors. These agents are administered within the first several hours of hospital admission and continued for 48–72 h, often until angiography and PCI has been performed.

It should be noted that there is a risk of thrombocytopenia with these agents, most commonly seen with abciximab. Clinical experience with other monoclonal antibodies has shown that a potential immune response exists to the non-human regions of these molecules. The administration of abciximab has been shown to induce human antichimeric antibodies (HACA) in approximately 6% of patients in the trials performed to date. Development of HACA could, in theory, induce an immediate thrombocytopenia, allergic reactions, and/or decreased effectiveness with repeat abciximab administration. A registry of re-administration has reported data on 500 patients demonstrating similar rates of thrombocytopenia and no evidence of reduced safety or efficacy with abciximab re-administration, even in the presence of HACA. The incidence of mild thrombocytopenia

($< 100\,000$ cells/mm^3) is approximately 5% and severe thrombocytopenia ($< 50\,000$ cells/mm^3) is approximately 1–2%. As in all cases of thrombocytopenia, other causes should be excluded. As patients with ACS are often on a multitude of medications, other agents may play a role in the cause of thrombocytopenia. The primary treatment of thrombocytopenia in the setting of GPIIb–IIIa inhibitor treatment is generally supportive. Abciximab should be discontinued and platelet transfusions may be required. It is recommended that platelet counts should be followed closely with the administration of abciximab. Platelet transfusion should be considered for platelet counts $\leq 50\,000$ cells/mm^3 in patients with active bleeding, vascular access complications or requiring further invasive procedures such as CABG.

Fibrinolytic agents

Coronary atherosclerotic disease is the underlying mechanism for acute MI. As discussed above, it is commonly believed that a rupture in the fibrous cap overlying the atheromatous lesion is the impetus for plaque rupture and subsequent atherothrombosis. If occlusive thrombus forms, patients uniformly develop acute STEMI on the presenting ECG unless there is prompt collateralization from other arterial beds, or if there is spontaneous thrombus resolution. Occlusive thrombus consists of a white (platelet-rich) and red (fibrin- and erythrocyte-rich) clot. The prognosis for patients with STEMI has been improving over the years, such that in-hospital and out-of-hospital mortality has been decreasing since the early 1970s. This is due to a multitude of reasons. The main change in medical care for patients with STEMI has been the recognition that prompt restoration of epicardial coronary blood flow is requisite. There are essentially two strategies to achieve this. The initial reperfusion strategy is the administration of an intravenous fibrinolytic agent. More recently, an aggressive catheter-based reperfusion strategy has been further refined and investigated extensively in the clinical literature.

In general, fibrinolytic agents are plasminogen activators that facilitate the conversion of plasminogen to plasmin. Plasmin is a potent fibrinolytic moiety that acts on cross-linked fibrinogen, promoting fibrinolysis. Furthermore, plasmin interacts with platelets and results in decreased platelet adhesion and disaggregation. Numerous agents have been developed to re-establish arterial flow in the setting of occlusive atherothrombosis formation in the setting of STEMI.

The first-generation agents included drugs such as streptokinase, anistreplase, and two-chain urokinase-type plasminogen activator (tcu-PA). The first-generation fibrinolytic agents were rather fibrin non-specific, they induced systemic coagulation changes and resulted in normal coronary flow rates of only 30% (in the setting of STEMI) with remarkable antigenicity and risk of hypotension. The prototype for the first-generation fibrinolytic agents was streptokinase (Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardio, GISSI, 1986).

Streptokinase was associated with a significant and durable reduction in in-hospital mortality in the setting of STEMI. This trial revolutionized the care of patients with STEMI. The prototypic second-generation fibrinolytic agent developed was recombinant tissue-type plasminogen activator (tPA), synthetically engineered to resemble intrinsic tPA. Recombinant tPA (alteplase) was more fibrin specific and was shown to be superior with respect to short-term mortality when compared with streptokinase in a large-scale clinical trial (The GUSTO Investigators, 1993).

The concept of the 'open artery hypothesis', following an acute MI, emerged following data from the early thrombolytic trials. For example, within the GUSTO trial (The GUSTO Investigators, 1993), the streptokinase group achieved a 31% 90-minute normal coronary artery flow rate, whereas this was achieved in 54% of the tPA cohort. This translated into an absolute 1% reduction in 30-day mortality. This observation led investigators to conclude that prompt and complete epicardial coronary blood flow would be associated with an improvement in short-term mortality rates. Third-generation fibrinolytic agents were, therefore, evaluated on the basis of initial coronary artery flow rates and numerous third-generation fibrinolytic agents were then developed. The primary limitations of second-generation fibrinolytics included a complex infusion regimen, a risk of intracranial haemorrhage of approximately 1%, only 50% achievement of normal coronary artery flow rates at 90 min, significant re-occlusion and re-infarction, and a 30-day mortality rate of approximately 6–7%. The third-generation fibrinolytic agent, reteplase (r-PA), was compared with an accelerated alteplase (tPA) regimen in the GUSTO III trial. Although there was a modest improvement in the 90-minute normal coronary artery flow rates for the r-PA group, the mortality rate was identical for both fibrinolytic agents. During the 1990s, numerous other fibrinolytic agents were investigated in various randomized controlled trials. In each of these trials, there was no significant reduction in mortality for the studied fibrinolytic agents. Thus, the third-generation fibrinolytic agents have failed to demonstrate a marked improvement in mortality in the setting of STEMI. The approved agents are shown in Table 58.8.

Nonetheless, numerous third-generation fibrinolytic agents have been developed and are undergoing investigation. These various fibrinolytic agents are depicted in Table 58.8. Other novel fibrinolytic agents include staphylokinase. Staphylokinase, although highly fibrin-specific, is associated with the development of antibodies. Therefore, staphylokinase has been modified using site-directed recombinant amino acid substitution, termed *PEGylated Sak STAR*. This has resulted in an improved half-life. Another fibrinolytic agent, monteplase, is a variation of tPA with an amino acid substitution in the epidermal growth factor domain, resulting in a longer half-life of 23 min. Pamiteplase is a mutation of tPA with a kringle-1 deletion and a point mutation in the protease cleavage site of tPA, resulting in a prolonged half-life of 30–47 min.

Table 58.8 First-, second- and third-generation fibrinolytic agents.

Fibrinolytic agent	Plasma half-life (min)	Dose	Fibrin specificity	Modification
First generation SK (streptokinase)	23	1.5 MU/16 min	0	NA
Second generation tPA (alteplase)	4	15-mg bolus 15 mg/30 min, 35 mg/h	++	NA
Third generation r-PA (reteplase)	15	Bolus 10 U + 10 U 30 min apart	+	Deletion of the finger, EGF and kringle-1 domains from tPA
TNK-tPA (tenecteplase)	20	0.5-mg/kg bolus	+++	Three-point mutations in threonine and asparagines of tPA Substitution in the kringle-1 domain improves half-life Asparagine and lysine–histidine–arginine–arginine substitution improves fibrin binding and PAI-1 resistance
n-PA (lanoteplase)	37 min	120-k/U/kg bolus or 20-mg bolus	+	Deletion of the finger and EGF domain; modification of kringle-1 glycosylation points
R-CSU-PA (Saruplase)	9 min	60 mg/h	+	Pro-urokinase polypeptide Pro-drug, converted into tcu-PA

EGF, epidermal growth factor; PAI-1, plasminogen activator inhibitor-1; tcu-PA, two-chain urokinase-type plasminogen activator.

Facilitated fibrinolysis

Fibrinolytic therapies used at present fail to achieve optimal reperfusion in many patients. LMWHs and platelet GPIIb–IIIa inhibitors have shown the potential to improve pharmacological reperfusion therapy. Thus, a strategy of adding a GPIIb–IIIa inhibitor to the regimen of heparin, plus a fibrinolytic agent, has been investigated in the ASSENT III and GUSTO trials. In ASSENT III, there was a significant decrease in adverse events in patients randomized to UFH and abciximab when compared with UFH. The rates of death, MI or recurrent ischaemia were 11.4% for enoxaparin patients, 11.1% for abciximab patients and 15.4% for UFH patients ($P = 0.0001$). However, patients receiving abciximab experienced a significant increase in major bleeding, transfusions and a higher rate of thrombocytopenia. The concept of facilitated fibrinolysis was further studied in the GUSTO V trial. Patients were randomized to full-dose fibrinolytic therapy or half-dose with abciximab. At 30 days, the combination of reteplase and abciximab did not result in a significant reduction in all-cause mortality. Furthermore, there was an absolute 1% increase in intracranial haemorrhage. In summary, similarly to the recent outcomes for the third-generation fibrinolytics, a combination of a reduced dose of a fibrinolytic agent with a GPIIb–IIIa inhibitor failed to be superior to standard fibrinolytic therapy. Whether the strategy of facilitated fibrinolysis coupled with a catheter-based reperfusion strategy will be advantageous remains unknown, but is being investigated in ongoing trials.

Summary

Atherothrombosis is the pathological process underlying the development of CVD, a systemic disease and the commonest cause of death in the Western world. A chronic inflammatory process, triggered by endothelial dysfunction, leads to the formation of atheromatous plaques in the arterial wall. These plaques eventually rupture causing thrombosis to occur on their surfaces. The degree of thrombosis, and therefore the impact on the blood flow through the affected artery, depends on the balance of activities of thrombotic, antithrombotic and fibrinolytic factors. Certain conditions, such as IR and diabetes, dyslipidaemias and hypertension predispose individuals to atherothrombosis by their effects on endothelial function, formation of atheroma and the coagulation system. Lifestyle factors too, such as smoking, diet and physical inactivity predispose to atherothrombosis. It can also be assumed that acquired environmental risk factors and their interactions with genetic polymorphisms increase an individual's risk of developing atherothrombosis. CVD manifests itself as CHD, PVD and cerebrovascular disease. There are now considerable data on both primary and secondary prevention

measures for CVD. The challenge for the future is to investigate the complex interactions between genotypes and environmental factors with large-scale studies, with the aim of developing genotype-specific therapies.

Haematological aspects of systemic disease

59

Atul B Mehta and A Victor Hoffbrand

Anaemia of chronic disease

The anaemia of chronic disease (ACD) is a common normochromic or mildly hypochromic anaemia, occurring in patients with a systemic disease (Table 59.1). It is characterized by a reduced serum iron and iron binding capacity, and normal or raised serum ferritin with adequate iron stores (Table 59.2).

Table 59.1 Conditions associated with anaemia of chronic disorders.

Chronic infections
Especially osteomyelitis, bacterial endocarditis, tuberculosis, abscesses, bronchiectasis, chronic urinary tract infections

Other chronic inflammatory disorders
Rheumatoid arthritis, juvenile rheumatoid arthritis, polymyalgia rheumatica, systemic lupus erythematosus, scleroderma, inflammatory bowel diseases, thrombophlebitis

Malignant diseases
Carcinoma (especially metastatic or associated with infection), lymphoma, myeloma

Others
Congestive heart failure, ischaemic heart disease, AIDS

It is not due to marrow replacement by tumour, bleeding, haemolysis or haematinic deficiency, although these often complicate it.

Pathogenesis

A mild decrease in red cell lifespan occurs in ACD, but it is at a level that could be compensated by a normal bone marrow. The major cause of ACD is a disturbance of erythropoiesis due to a reduced sensitivity to physiological erythropoietic stimuli and reduced iron utilization. The interaction of a number of cytokines (including interleukin 1 (IL-1), IL-6, tumour necrosis factor (TNF) and transforming growth factor beta, with accessory marrow stromal cells and with the erythroid progenitors themselves) is probably responsible.

Relative lack of erythropoietin

The plasma erythropoietin (Epo) level in ACD remains inversely correlated with the haemoglobin level but compared with patients with other types of anaemia and normal renal function, it is inappropriately low. The plasma levels of TNF-α, IL-1 (IL-1α and IL-1β) and IL-6 are raised. Tumour necrosis factor and IL-1 have been shown in experimental systems to reduce Epo production by cultured hepatoma cells. In addition, IL-1α inhibits Epo production by isolated serum-free perfused kidneys.

Haemoglobin	Not less than 9 g/dL	
Mean corpuscular volume	Normal or mildly reduced (usually 77–82 fL)	
Mean corpuscular haemoglobin	Usually normal; occasionally reduced	
Serum iron	Reduced	
Total iron binding capacity (transferrin)	Reduced	
Transferring saturation	Mildly reduced	
Serum ferritin	Normal or increased	
Serum and urine hepcidin	Raised	
C-reactive protein	Usually raised	
Erythrocyte sedimentation rate	Usually raised	

Table 59.2 Haematological features of anaemia of chronic disease.

Inhibition of erythropoiesis

Both TNF and IL-1 inhibit erythropoiesis *in vitro* and it is likely that TNF increases apoptosis of bone marrow erythroid cells. Anaemia is observed in humans treated with TNF and in animals receiving either cytokine. The effect of IL-1 is probably mediated by interferon-γ (IFN-γ) secreted by T lymphocytes, whereas the TNF action is probably mediated by IFN-γ produced by marrow stromal cells. IL-6 and TGF-β may also have roles as mediators of ACD through inhibition of erythropoiesis.

Iron metabolism

A characteristic in ACD is the presence of a low serum iron with adequate reticuloendothelial iron stores, but with a reduction of iron granules in marrow erythroblasts. A fall in serum transferrin and a rise in serum ferritin occur as part of the acute-phase response. The fall in serum iron can occur as early as 24 h after the onset of a systemic illness, and will persist during the course of a prolonged illness. The fall in serum iron results from an impaired flow of iron from cells (including intestinal mucosal cells, hepatocytes and macrophages) to plasma. This is due to increased secretion by hepatocytes of hepcidin (see p. 32) in response to inflammation. Hepcidin inhibits release of iron from macrophages and iron absorption. Inflammation can cause a 100-fold increase in urinary hepcidin excretion. Microbial products may act on Kupffer cells to secrete IL-6, which then stimulates hepcidin secretion from hepatocytes. Low serum iron inhibits proliferation of micro-organisms. Hepcidin secretion is also increased in iron overload. This seems unlikely to be due to a direct effect on hepatocytes. It is possible that iron in Kupffer cells or sinusoidal cells, like infection, stimulates production of cytokines, which act on hepatocytes.

In clinical specimens, there is a significant positive correlation between serum and urinary hepcidin and serum ferritin levels. The cytokines TNF, IL-1 and IFN-γ have all been shown to cause reduced serum iron and increased serum ferritin concentrations. The fall in serum iron is probably mainly, if not entirely, due to hepcidin. Anaemia usually reduces hepcidin secretion. In ACD, this effect is clearly abrogated by the effect of inflammation or malignancy increasing its secretion. Increased lactoferrin, occurring in response to inflammation and mediated by cytokines, competes with transferrin for iron and forms a complex, which is taken up by macrophages in the liver and spleen. Increased intracellular apoferritin synthesis occurs in response to inflammation and malignancy and this too will bind iron. Both of these mechanisms reduce the amount of iron available for binding to serum transferrin.

Treatment

The severity of the anaemia correlates with the activity and severity of the underlying chronic disease. Successful therapy of this leads to a reduction in the levels of the mediator cytokines, increased Epo production and reduced inhibition of erythropoiesis. Correction of the anaemia may take weeks or months. Pharmacological doses of recombinant Epo have been used successfully to improve anaemia in patients with rheumatoid arthritis, cancer and myeloma. This observation suggests that inadequate Epo production and its reduced action are more important than disturbed iron metabolism in the pathogenesis of ACD. It further suggests that the suppressive action of various cytokines can be overcome by use of pharmacological doses of Epo. Iron therapy should be reserved for patients who have genuine iron deficiency.

Malignancy

Anaemia

Anaemia is the most frequent haematological abnormality in cancer patients and may be due to many causes (Table 59.3). The anaemia of chronic disorders (see above) will affect almost all cancer patients at some stage of their illness. The degree of anaemia reflects the extent of the malignancy and may be worsened by the myelotoxic effects of chemotherapy. Plasma Epo levels tend to be inappropriately low and therapy with recombinant Epo can reduce transfusion requirements by improving the haemoglobin level in cancer patients who are undergoing chemotherapy.

Table 59.3 Causes of anaemia in cancer patients.

Type of anaemia	Associations
Anaemia of chronic disease	All neoplasms
Blood loss	Gastrointestinal neoplasms, gynaecological neoplasms
Haemolysis – immune	Ovarian carcinoma, lymphoma others
Haemolysis – non-immune fragmentation syndrome	Mucin-secreting adenocarcinomas
Haemolysis – secondary to drugs	Mitomycin, cyclosporin, cisplatinum
Pure red cell aplasia	Thymoma
Megaloblastic	Chemotherapy, folate deficiency, cobalamin deficiency, (gastric carcinoma)
Leucoerythroblastic	Metastatic disease in bone marrow
Marrow hypoplasia	Chemotherapy/radiotherapy
Myelodysplasia	Chemotherapy/radiotherapy

Haemolysis

Warm antibody autoimmune haemolytic anaemia (AIHA) is most frequently found in association with the following malignant diseases: chronic lymphocytic leukaemia, Hodgkin's disease and non-Hodgkin's lymphoma. However, it has also been reported in association with solid tumours (e.g. carcinoma of the ovary). Cold-antibody AIHA is less common, but occurs in association with monoclonal cold agglutinins in chronic cold agglutinin disease, Waldenstrom's macroglobulinaemia and myeloma.

Microangiopathic haemolytic anaemia (MAHA) with intravascular haemolysis may occur in association with disseminated carcinoma. An abrupt onset of anaemia and thrombocytopenia often occurs, with a leucoerythroblastic blood picture, reticulocytosis and red cell fragmentation. Renal failure may occur as a complication. Mucin-secreting adenocarcinomas (especially gastric), breast cancer and lung cancer are the most common underlying malignancies; in about one-third of patients with MAHA, it is the presenting feature of the tumour. Abnormal blood vessels may be within the tumour itself (or within metastatic tumour thrombi, especially in the lungs) or fibrin deposition may occur at other sites because of disseminated intravascular coagulation (DIC). Widely disseminated disease with bone marrow infiltration is almost always present and the outlook is poor. A syndrome resembling MAHA and the idiopathic haemolytic–uraemic syndrome has been reported with a number of chemotherapeutic agents and following allogeneic bone marrow transplantation. Principal among these is mitomycin, whereas cisplatin, carboplatin, bleomycin and cyclosporin have also been reported. Immune complex deposition has been implicated in the pathogenesis.

Red cell aplasia

Acquired pure red cell aplasia is associated with a thymoma in approximately 50% of patients, although it complicates only approximately 5% of thymomas. Antibodies to erythroid precursors have been demonstrated in some patients, and removal of the thymoma (which is usually benign) leads to resolution of the anaemia in about one-half of those affected. Immunosuppressive therapy with cyclophosphamide, cyclosporin, steroids or plasma exchange may be helpful in patients who relapse. Red cell aplasia may also occur in a minority of patients with chronic lymphocytic leukaemia (CLL) or non-Hodgkin's lymphoma and with large granular lymphocytic (LGL) leukaemia and as part of general marrow aplasia due to chemotherapy or radiotherapy.

Leucoerythroblastic anaemia

The blood film (Figure 59.1) shows the presence of erythroblasts and granulocyte precursors (e.g. myelocytes and myeloblasts). It is seen in primary myelofibrosis but is also frequent when there is marrow infiltration by tumour. This disturbs the marrow microvasculature and allows early release of the precursors. Marrow infiltration is most commonly observed in breast (Figure 59.2), prostate and haematological malignancies, but also in tumours of lung, thyroid, kidney and gastrointestinal tract
Figure 59.1 Nucleated red cells and an immature myeloid precursor in the peripheral blood film of a patient with a leucoerythroblastic anaemia.
Figure 59.2 Bone marrow aspirate showing infiltration by metastatic breast carcinoma.

and melanoma. It can also occur as a reflection of active bone marrow response to peripheral consumption (acute haemolysis, DIC, septicaemia, hypersplenism) or of extramedullary haemopoiesis (e.g. myelofibrosis or megaloblastic anaemia).

Other causes

Megaloblastic and dyserythropoietic anaemias are most commonly due to chemotherapy-induced disturbance of DNA synthesis within the bone marrow. Folate deficiency may also occur in patients with a poor diet and widespread disease. Cobalamin (vitamin B_{12}) deficiency due to underlying pernicious anaemia may complicate cancer of the stomach. Both chemotherapy and non-ionizing radiotherapy may lead to the development of myelodysplasia (MDS), which may progress to acute myeloid leukaemia (AML). Alkylating agents, especially melphalan and chlorambucil, nitrosoureas and epipodophyllotoxins in particular have been implicated, and there is evidence of a synergistic effect of these agents with small, chronic doses of radiotherapy. The principal categories of patients affected are those who have received therapy for a haematological malignancy, but patients treated for non-haematological malignancies (especially ovarian and gastrointestinal carcinoma) are also susceptible. The median latency prior to onset of MDS is 2–3 years and AML usually supervenes 6 months to 2 years later.

Treatment

Erythropoietin is effective in reversing anaemia in a proportion of patients with malignant disease, e.g. myeloma, lymphoproliferative disorders, myelodysplasia and carcinomas. It is recommended if the haemoglobin is less than 10 g/dL or symptomatic patients with haemoglobin of 10–12 g/dL. Dosage is 10 000 IU three times per week or 30 000 IU as a single weekly dose. The dose could be increased if there is no response (< 1 g/dL rise in 4 weeks).

Patients who are most likely to respond are those who have low pre-treatment Epo levels (< 100 mU/mL), well-preserved marrow function and normal/low levels of serum ferritin (< 400 ng/mL). A number of studies have demonstrated that Epo therapy can lead to a reduced need for blood transfusion, better quality of life for patients and possibly improved overall outcome of anti-cancer therapy.

Polycythaemia

This is a rare complication of non-haematological malignancy. It usually arises through elaboration by tumour cells of Epo and Epo-like peptides. The tumours most commonly associated are renal cell carcinoma and hepatoma; others include uterine myoma, androgen-secreting ovarian tumours, phaeochromocytoma and cerebellar haemangioblastoma. Non-malignant conditions affecting these organs (e.g. renal cysts, viral hepatitis) may also rarely be associated.

White cells (Table 59.4)

Granulocytosis

Granulocytosis is a frequent manifestation of non-haematological malignancies. In part, the response is due to inflammation

Table 59.4 White cell changes in malignancy.

Neutrophils increased	Most, especially renal Hodgkin's disease
Neutrophils decreased	Bone marrow infiltration Hypersplenism Treatment induced Chemotherapy/radiotherapy Large granular lymphocytic leukaemia
Basophils increased	Myeloproliferative disorders
Eosinophils increased	Hodgkin's disease T-cell lymphomas, Metastatic adenocarcinoma Other tumours (e.g. lung) Drug allergy Opportunistic infection
Monocytes increased	Carcinoma Hodgkin's disease
Monocytes decreased	Treatment induced
Lymphocytes increased	Lymphoid malignancies Post splenectomy Opportunistic infection
Lymphocytes decreased	Treatment induced Radiotherapy/chemotherapy Lymphoma Opportunistic infection

    and S
Direct activation of coagulation by tumour cells: factor VII, factor X
Indirect activation: through trypsin release, through mucin
    secretion, via monocytes, through endothelial damage
Increased platelet aggregability and adhesiveness
Thrombocytosis

induced by the tumour. Interaction of tumour cells with host T lymphocytes and mononuclear phagocytic cells leads to the production of a range of cytokines, which induce white cell proliferation and differentiation. Tumour cells may also secrete specific agents that directly stimulate reactive proliferation. Cancer patients frequently have opportunistic infections, may bleed and are typically on a range of medications, all of which may influence the level of the white cell count.

Granulocytopenia

This is most frequently due to chemotherapy or radiotherapy but may also occur with widespread marrow infiltration, for example by lymphoma or due to LGL leukaemia.

Platelets

Thrombocytopenia (Table 59.5)

This may arise through decreased production or accelerated peripheral destruction and/or hypersplenism. The former may result from extensive marrow infiltration or be secondary to chemotherapy or radiotherapy. Hypersplenism is usually due to splenic infiltration by a haematological malignancy (e.g. lymphoma, CLL) but is rarely due to obstruction of the splenic or portal vein by hepatic and pancreatic malignancies. Increased destruction occurs with DIC. Immune thrombocytopenia may occur in association with haematological malignancy (CLL, lymphoma, MDS) and rarely may complicate solid tumours (e.g. breast, lung, ovary).

Thrombocytosis

A raised platelet count is frequently seen as a reactive phenomenon in patients with malignancy but is usually $< 1000 \times 10^9$/L and is rarely of clinical significance.

Platelet function abnormalities

Impaired platelet function leading to excessive bleeding is primarily seen in myeloproliferative disorders (e.g. essential thrombocythaemia) and MDS. Paraproteins, especially immunoglobulin M (IgM) in Waldenstrom's macroglobulinaemia and IgG in myeloma, are frequent causes of impaired platelet aggregation

and adhesion. Increased platelet aggregation occurs in cancer patients when tumour cells release adenosine diphosphate (ADP), prostaglandins or thrombin. Increased platelet adhesiveness has also been reported, but is probably secondary to other coagulation changes.

Coagulation (Table 59.6)

A wide range of coagulation changes can occur in patients with malignant disease and can predispose to either haemorrhage or thrombosis. The distinction between activation of the coagulation part of the haemostatic pathway (DIC), which leads physiologically to activation of fibrinolysis (secondary fibrinolysis), and primary or direct activation of fibrinolysis may be difficult, and in some ways academic, in view of the intimate and dynamic relationship that exists between the coagulation and fibrinolytic pathways. These patients may also have other general medical problems, including infection; they may have undergone surgery, chemotherapy or radiotherapy and will typically be on a range of medications. All of these factors may contribute to coagulation changes.

Disseminated intravascular coagulation

Chronic or compensated disseminated intravascular coagulation (DIC) is probably underdiagnosed in cancer patients. It occurs particularly in those with gastrointestinal, lung, pancreatic and breast neoplasms. Thrombosis, including migratory thrombophlebitis (Trousseau's syndrome) and non-bacterial thrombotic endocarditis, is a more frequent manifestation of DIC than haemorrhage. Acute or uncompensated DIC, in contrast, is uncommon with solid tumours but occurs frequently

Heparin-like anticoagulants – dysproteinaemias

with acute promyelocytic leukaemia (APL, FAB M3) and is associated with excessive bleeding. The triggering event in APL is likely to be release from the malignant promyelocytes of procoagulants and proteases, which may directly activate both coagulation and fibrinolysis. Tumour cells may activate coagulation by release of tissue factor (TF), which activates factor VII. Direct activation of factor X through the action of a cancer procoagulant has been reported in lung, kidney, colon and breast cancer. The sialic acid moiety of secreted mucin can directly activate factor X, whereas the systemic release of trypsin in pancreatic tumours can also activate coagulation. Tumour cells may also activate the monocyte–macrophage system to produce procoagulant materials including TF and factor X activators.

Primary fibrinolysis

This is less common as a cause of increased bleeding than DIC, but can occur, for example, in patients with prostatic cancer who undergo surgery. The release of proteases from leukaemic cells in both APL and monocytic leukaemia has been reported to induce fibrinolysis. Platelet counts tend to be higher than those seen in DIC, and fibrinogen levels are low, with raised fibrin degradation products (FDPs).

Acquired circulating anticoagulants (Table 59.7)

The most frequent is an acquired von Willebrand syndrome (both type 1 and type 11 disease) in patients with a paraprotein or a B-lymphoid malignancy. A number of different mechanisms may operate. The paraprotein may be directed against an epitope within the factor VIII–von Willebrand factor (vWF) molecule and inactivate it, or reduce its plasma half-life. Alternatively, immune complexes may form which bind non-specifically to factor VIII–vWF and accelerate its clearance, or the malignant lymphoid cells may actually absorb factor VIII–vWF onto their surface. Paraproteins may also interfere with cross-linking of fibrin.

Treatment-induced bleeding disorders

Thrombocytopenia and MAHA may occur as a result of therapy (see below). Cancer patients with poor nutrition or who are on long-term antibiotics may develop vitamin K deficiency. L-Asparaginase induces defective hepatic protein synthesis and can lead not only to impaired production of coagulation factors but also to low levels of antithrombin (AT), plasminogen and proteins S and C, and so give rise to thrombosis, most seriously of the cerebral veins. Mithramycin, which is used in the treatment of malignant hypercalcaemia, causes thrombocytopenia as well as platelet function defects, coagulation factor deficiencies and increased fibrinolytic activity.

Connective tissue disorders (Table 59.8)

Anaemia

Anaemia of chronic disease (see above) is the most common haematological abnormality seen in patients with rheumatoid arthritis (RA). Iron deficiency may co-exist, particularly in patients taking non-steroidal anti-inflammatory agents. Folate deficiency may occur with severe disease and poor dietary intake. Warm-type AIHA with IgG and complement on the red cell surface is most frequently seen in systemic lupus erythematosus (SLE), although it can occur in the other connective tissue disorders (CTD), notably RA and mixed CTD. Sideroblastic anaemia has been reported in both SLE and RA, but MDS must be excluded. Pure red cell aplasia and dyserythropoietic anaemia with ineffective erythropoiesis are rare complications of SLE. Haemolysis can also occur as part of thrombotic thrombocytopenic purpura (TTP), complicating SLE.

White cells

The inflammatory process in CTD can lead to a neutrophilia. Neutropenia is a feature of Felty's syndrome, which is associated with splenomegaly in patients with RA. The pathogenesis is multifactorial and involves increased margination of neutrophils, sequestration of neutrophils within the enlarged spleen, immune complex-mediated and humoral inhibition of granulopoiesis in the marrow. Antibodies to mature neutrophils have also been reported in SLE. Lymphopenia occurs in both SLE and RA, and may be a measure of disease activity. Eosinophilia may be seen in SLE, RA, polyarteritis nodosa and Churg–Strauss syndrome. The pathogenesis is unknown, but presumably involves release of cytokines by T lymphocytes. Functional defects in polymorph and lymphocyte function have been reported in SLE and RA.

Platelets

Immune thrombocytopenia is a common manifestation of SLE and also occurs in mixed CTD, scleroderma, RA and dermato-

Amyloidosis

myositis. Autoantibodies to platelets may also impair platelet function. TTP is an association of SLE. Thrombocytosis is a nonspecific reaction to inflammation and tissue damage in CTD.

Coagulation

A wide diversity of coagulation changes may occur in patients with CTD. In part, this may be due to liver and renal disease or to drug therapy. DIC has been reported in SLE patients who have high levels of circulating immune complexes and resulting angiopathy. The lupus anticoagulant (see Chapter 55) occurs as a complication in about 10% of patients with SLE and is associated with a thrombotic tendency, thrombocytopenia, recurrent miscarriages and pulmonary hypertension. Specific coagulation factor inhibitors encountered in patients with CTD (especially SLE) include antibodies to vWF and to factors VIII, VII and fibrinogen.

Other changes

Rheumatoid arthritis is a relatively common cause of amyloidosis. An increased incidence of haematological malignancies (principally Hodgkin's and non-Hodgkin's lymphomas and B-lymphoproliferative disorders, including paraproteinaemias) has been noted in SLE, RA and, particularly, in Sjögren's syndrome. A wide range of haematological abnormalities also results from immunosuppressive therapy in these patients.

Renal disease (Table 59.9)

Anaemia

This is the most important haematological abnormality and its management has been revolutionized by the availability of recombinant human erythropoietin (rEPO). Patients with acute or chronic renal failure develop a normochromic, normocytic anaemia, with the presence of ecchinocytes (burr cells) in the blood film. The reticulocyte count is normal or slightly low, and the bone marrow shows normoblastic erythropoiesis without the erythroid hyperplasia expected at that level of anaemia. Patients who have undergone nephrectomy tend to be more severely anaemic than patients with polycystic disease. Reduced Epo levels occur in renal failure and this is the dominant cause of anaemia.

An increase in serum creatinine above 133 μmol/L is associated with the loss of the normal inverse linear relation between plasma Epo and haemoglobin concentration, but there is no direct correlation between reduction in glomerular filtration rate and impairment of renal Epo production. Circulating inhibitors of erythropoiesis have also been demonstrated. Chronic ambulatory peritoneal dialysis is more effective than haemodialysis in removing these inhibitors but, as rEPO can overcome these inhibitors, they are not of great clinical significance. Red cell survival is diminished in renal failure, but this is also a minor factor. Iron deficiency can arise through blood loss (exacerbated by haemodialysis). Folate deficiency arises in dialysed patients but is now prevented by prophylactic folic acid therapy. Renal failure is associated with elevated 2,3-DPG levels and a right shift of the haemoglobin oxygen dissociation curve.

Recombinant Epo therapy can fully correct anaemia in renal failure. It can be administered intravenously, subcutaneously or intraperitoneally. The subcutaneous route is effective at lower doses, and it is usual to commence 5–75 units/kg per week, given in two or three divided doses. Anaemia is corrected up to a level of 10–12 g/dL at a rate of 1 g/dL per month. Subclinical iron deficiency and impaired mobilization of storage iron are often present, so concomitant iron therapy is usually required. An impaired response to rEPO should prompt a suspicion of iron, cobalamin or folate deficiency, haemolysis, infection, occult

↓Fibrinolysis

malignancy, aluminium toxicity and hyperparathyroidism. Hypertension occurs in about one-third of rEPO-treated patients and is dose dependent; the risk of thrombosis of an arteriovenous fistula is also increased. In acute renal failure, anaemia is commonly due to the drug or condition causing the renal failure, e.g. haemolysis due to sepsis or TTP.

Polycythaemia

Secondary and inappropriate polycythaemia may result from either ectopic Epo production by renal tumours or regional renal hypoxia (in benign disease and following renal transplantation), which disturbs physiological Epo homeostasis. Up to 5% of patients with renal cell carcinoma have paraneoplastic polycythaemia.

Haemostatic abnormalities

Abnormal platelet function is probably due to the accumulation of toxic metabolites (e.g. guanidinosuccinic and phenolic acids). DDAVP (1-deamino-8-D-arginine vasopressin) therapy, which leads to the appearance of large multimers of vWF, can shorten the bleeding time in anaemic patients. Dysfibrinogenaemia has been reported rarely, whereas FDPs are often elevated and may prolong the thrombin time. Hypercoagulopathy with a predisposition to thrombosis can also occur, especially after rEPO therapy. Haemodialysis with heparin anticoagulation can cause platelet activation. Fibrinolytic activity, AT and protein C are all reduced in renal failure, and factors V, VII, VIIIc and X are increased. Thrombosis (particularly of the renal vein) is a particular feature of the nephrotic syndrome. Platelet hyperaggregability with increased plasma β-thromboglobulin is described and hypoalbuminaemia may enhance the synthesis of prostaglandins involved in platelet activation.

Endocrine disease (Table 59.10)

Both hyper- and hypothyroidism are associated with mild anaemia, which is usually normochromic and normocytic, but may be macrocytic in hypothyroidism. A raised mean corpuscular volume (MCV) can occur without anaemia in hypothyroidism, and low MCV has been described in thyrotoxicosis. Thyroid hormones stimulate erythropoiesis, and tissue oxygen demands are increased in hyperthyroidism, whereas, in hypothyroidism, oxygen utilization is reduced. However, plasma volume is also increased and part of the anaemia in hypothyroidism is dilutional, and/or due to defective iron utilization. Co-existent deficiencies of iron (due to menorrhagia or achlorhydria), folate and cobalamin must be excluded.

There is an increased incidence of pernicious anaemia in patients with hypothyroidism, hypoadrenalism and hypoparathyroidism. Antithyroid drugs (carbimazole, methimazole and propylthiouracil) can cause aplastic anaemia or agranulocytosis. Anaemia in patients with diabetes mellitus is usually due to complications of diabetes, although hyperglycaemia itself may lead to shortened red cell lifespan and decreased erythrocyte deformability. Polycythaemia (usually pseudo) can also occur with endocrine diseases. In anterior pituitary disease, androgen deficiency, adrenal insufficiency, a normochromic, normocytic anaemia is common. Changes in leucocyte number and function are rarely of clinical significance, although many have been reported. Chemotaxis, phagocytosis and intracellular killing may all be disturbed in diabetes mellitus. Coagulation changes may contribute to a mild bleeding diathesis in hypothyroidism and to the thrombotic predisposition in diabetes mellitus.

Cushing's syndrome	↑Factors II, IV, IX, XI, XII

Liver disease (Table 59.11)

Liver disease causes a greater range of haematological change than does disease in any other organ, with the exception of the bone marrow. The liver is an important source of Epo in the fetus, and serves as a haemopoietic organ *in utero*; extramedullary haemopoiesis occurs within the adult liver only in pathological states (e.g. myelofibrosis, severe haemolysis or megaloblastic anaemia).

Anaemia

Anaemia occurs in up to 75% of patients with chronic liver disease. Portal hypertension often results in splenomegaly, which may cause haemodilution and pooling of red cells. Haemorrhage is a frequent complication, often due to oesophageal varices and the red cell lifespan is shortened even in uncomplicated liver

Table 59.11 Haematological changes in liver disease.

disease. Ferrokinetic studies suggest that the bone marrow response to anaemia is suboptimal, and many of the mechanisms that operate in the anaemia of chronic disease (see above) may be relevant. Macrocytosis occurs in approximately two-thirds of patients and erythropoiesis is macronormoblastic, indicating abnormal marrow function. Macrocytosis is particularly frequent in alcoholics, in whom reversible sideroblastic change may also occur. Target cells occur as the surface area of the cell increases, due to increased membrane lipid content without an increase in volume. Ecchinocytosis is fairly common because of binding of the red cell membrane by abnormal high-density lipoproteins. In contrast, true acanthocytes are uncommon in uncomplicated liver disease, although they are a characteristic finding in 'spur-cell anaemia' (non-immune haemolytic anaemia in patients with alcoholic cirrhosis). Zieve's syndrome of haemolytic anaemia with hypertriglyceridaemia in patients with alcoholic liver disease is also rare. Haemolysis due to the direct toxicity of copper ions on red cells is characteristically an early presentation of Wilson's disease. Intracorpuscular changes are rare in liver disease. However, abnormal pyruvate kinase activity has been demonstrated in Zieve's syndrome, and reduction of hepatocyte glucose-6-phosphate dehydrogenase (G6PD) levels in G6PD-deficient individuals, and in neonates, may exacerbate and prolong hyperbilirubinaemia with haemolysis. Viral hepatitis, including hepatitis A, B and C but most frequently hepatitis viruses yet to be fully characterized, may lead to a transient and mild pancytopenia or to severe aplastic anaemia.

Platelets and haemostasis

These are discussed in Chapter 30.

Liver transplantation

Orthotopic liver transplantation (OLT) is increasingly used for end-stage liver disease. Thrombocytopenia is frequently present prior to transplantation. The count tends to fall post-operatively despite platelet transfusions and this may be due to platelet sequestration in the transplanted liver. Immune thrombocytopenia has also been reported post OLT. Antibody mediated haemolysis occurs in recipients of ABO-incompatible grafts, but the engrafted liver can also produce mild haemolysis due to antirecipient ABO antibody. This is a form of humoral graft-versus-host disease (GvHD), but T cell-mediated GvHD has also been reported post OLT. Although aplastic anaemia is a rare complication of viral hepatitis, there are reports that it may occur in as many as 30% of patients transplanted for fulminant non-A, non-B viral hepatitis.

Infections (Tables 59.12 and 59.13)

Infection may produce a tremendous variety of haematological

Table 59.12 Haematological changes in viral infection.

Red cells
Anaemia
Autoimmune
  Measles
  Epstein–Barr virus (EBV)
  Hepatitis
  Cytomegalovirus (CMV)
  Human immunodeficiency virus (HIV)
  Others including herpesviruses, varicella, influenza
Non-immune
  Microangiopathic haemolytic anaemia
Reduced red cell production
  Marrow hypoplasia
  EBV (especially in X-linked lymphoproliferative syndrome)
  Hepatitis viruses
  HIV
  CMV (especially post renal or bone marrow transplantation)
  Others (rare) include togaviruses epidemic haemorrhagic
    fevers, dengue
Red cell aplasia
  B19 parvovirus, especially with haemolytic anaemia

White cells
Neutrophilia
  Especially HIV, influenza, hepatitis, rubella, adenoviruses, measles,
    mumps, CMV and EBV as part of nearly all viral infections
Neutropenia
  Aplasia (see above)
  Complicating myalgic encephalitis
  (?Enteroviruses, EBV)
Lymphocytosis
  Wide variety, especially early in course of infection
Malignant transformation
  HTLV-1
  EBV
  HIV

Platelets
Thrombocytosis (e.g. Kawasaki)
Thrombocytopenia
  Often history of viral prodromal in childhood immune
    thrombocytopenic purpura
  Autoimmune: EBV, hepatitis, rubella, CMV, HIV
  ↓Production: aplasia (see above), measles, dengue, CMV, others
  ↑Consumption: disseminated intravascular coagulation
    (DIC)/haemolytic uraemic syndrome (HUS) (see below)

Coagulation changes
  DIC, especially varicella, vaccinia, rubella, arbovirus with/
    without microangiopathy, epidemic haemorrhagic fevers
  Haemolytic–uraemic syndrome: Coxsackievirus, mumps,
    echoviruses
  Haemophagocytosis
  Herpesviruses, adenoviruses, cytomegalovirus

Table 59.13 Haematological changes in bacterial/fungal/protozoal infections.

Anaemia
Anaemia of chronic disorder
Haemolytic
    Immune: mycoplasma, malaria, syphilis (PCH), listeriosis
    Non-immune: *Clostridium perfringens* (toxin related)
    Bartonella bacilliformis (Oroya fever)
    Malaria, trypanosomiasis with microangiopathy/disseminated
        intravascular coagulation (DIC), septicaemia
    Haemolytic–uraemic syndrome: verotoxin-producing
        Escherichia coli and Streptococcus pneumoniae
Dilutional
    Splenomegaly (e.g. malaria, schistosomiasis)
Blood loss
    Helicobacter pylori
    Ancylostoma

White cells
Neutrophilia
    Virtually any bacterial/fungal infection
Neutropenia
    Salmonella, *Rickettsia*, brucellosis, pertussis, disseminated
        tuberculosis (TB)
    Overwhelming septicaemia
Neutrophil function defects
    Rare (e.g. *Bacteroides*, endocarditis)
Lymphocytosis
    Whooping cough (*Bordetella pertussis*), *Rickettsia*
Lymphopenia
    TB, acute bacterial infections, brucellosis
Eosinophilia
    Aspergillosis, coccidioidomycosis, *Chlamydia*, streptococcal
        infections, *Ancylostoma*
Eosinopenia
    Common in acute bacteroides infections
Monocytosis
    Subacute/chronic infections (e.g. disseminated TB listeriosis)
Pancytopenia
    Bone marrow suppression (e.g. disseminated TB, listeriosis)
    Haemophagocytosis: septicaemia
    Peripheral destruction (e.g. DIC)

changes. Many of these are covered in other sections of this book.

Viruses

Anaemia

Haemolytic anaemia due to red cell autoantibody production, usually of the warm type, may occur, although cold-antibody syndromes have been reported in measles, influenza, infectious mononucleosis and mumps. Paroxysmal cold haemoglobinuria is rare and occurs in children due to Donath–Landsteiner IgG, anti-P antibodies. Non-immune MAHA may be associated with TTP or DIC, which may be the result of viral infections.

Anaemia due to transient red cell aplasia is seen with B19 parvovirus infection in patients with haemolytic anaemias ('aplastic crisis'). This virus may also cause erythema variegetum, or fifth disease, in children. It invades and destroys red cell progenitors and the aplasia is terminated when neutralizing IgM and IgG antibodies develop. If the virus attacks pregnant women, it may cross the placenta and cause spontaneous abortion or hydrops fetalis. Intravenous Ig therapy has been used for severe cases (e.g. in pregnancy, HIV infection and post bone marrow transplantation).

Anaemia occurs with pancytopenia in virus-associated bone marrow aplasia, for example with hepatitis viruses. The presence of viruses, either within lymphocytes or on their cell surface, may lead to production of a range of cytokines (including TNF, IFN-α and IFN-γ), which inhibit haemopoietic cell proliferation *in vitro* and *in vivo*. This may cause a substantial reduction in erythropoiesis and is presumably the mechanism underlying neutropenia and lymphopenia in viral infections. In infectious mononucleosis and other viral infections such as viral hepatitis, the virus infects B lymphocytes and the characteristic activated lymphocytes seen on the blood film are a reactive population of T cells.

Platelets

Thrombocytopenia may occur due to multiple mechanisms. Children with idiopathic thrombocytopenic purpura frequently give a history of a preceding viral illness, and autoantibody production is well described in infectious mononucleosis, rubella and cytomegalovirus infections. Reduction of bone marrow thrombopoiesis is frequently subclinical, but it is particularly important in virus-associated aplasia and dengue fever. Thrombocytosis can also occur in response to viral infections.

Bacterial, fungal and protozoal infections

Anaemia

Anaemia of chronic disease can occur in acute infections, overwhelming septicaemia and chronic or suppurative infection. Haemolytic anaemia is less common, but can occur through both immune (e.g. cold antibodies with anti-I specificity in mycoplasma infection) and non-immune mechanisms. Direct red cell invasion frequently results in severe haemolysis in infections caused by *Bartonella baciliformis*, with elements of intravascular haemolysis (due to increased red cell fragility) and extravascular haemolysis. *Clostridium perfringens* produces an alpha toxin (a lecithinase) and a theta toxin, and *Staphylococcus aureus* an alpha toxin, which act as haemolysins to cause severe intravascular haemolysis. DIC and MAHA can occur in any

severe bacterial, fungal or protozoal infection. The haemolytic–uraemic syndrome has been associated with a range of bacterial infections, including *Salmonella*, *Shigella* and *Campylobacter* spp., but most frequently with verotoxin-producing strains of *Escherichia coli*.

White cells

Neutrophilia is the most common manifestation. Circulating neutrophils constitute less than 5% of the total body pool, and the neutrophil response shows great individual variation, with no clear relationship to the severity of the infection. The term *leukaemoid reaction* is used to describe marked leucocytosis ($> 50 \times 10^9$/L), with circulating immature forms occurring in patients with non-leukaemic conditions, typically severe infection or haemolysis or with generalized malignancy. Such reactions are more common in children. Features that distinguish such a reactive leucocytosis from CML include the presence of toxic granulation, elevated leucocyte alkaline phosphatase, Döhle bodies, and the lack of twin peaks of neutrophils and myelocytes in the differential count. Neutropenia can also occur with virtually any bacterial infection, although it has been most frequently noted with *Salmonella*, *Rickettsia* and *Brucella*. Defects of neutrophil function may also occur.

Platelets

Thrombocytosis is frequent in patients with chronic infections, and during the convalescent phase of acute infections. Thrombocytopenia also occurs during severe bacterial or fungal infection, particularly where there is bloodstream invasion or in intensive care patients. Certain rickettsial infections (e.g. Rocky Mountain spotted fever) are almost always associated with thrombocytopenia. Accelerated platelet destruction is the most frequent mechanism and can arise through DIC or microangiopathy with platelet attachment to damaged endothelium. Immune destruction can also occur and circulating immune complexes may lead to thrombocytopenia. Decreased platelet production is a less common mechanism, but may occur (e.g. in disseminated tuberculosis). The inflammatory and procoagulant responses to infections are clearly related. TNF-α, IL1α and IL-6 may activate coagulation and inhibit fibrinolysis, whereas thrombin may stimulate inflammatory pathways. In severe infection, the end result may be endovascular injury, DIC, multiorgan failure and death.

Haemostasis

DIC occurs frequently and may dominate the clinical picture in certain infections (e.g. bacterial meningitis). The acute-phase response that accompanies severe infection can lead to a rise in a range of coagulation factors, which may contribute to thrombotic manifestations. Suppurative thrombophlebitis, particularly in association with in-dwelling catheters, can occur in relation to both Gram-positive and -negative infections. In patients with systemic inflammation and organ failure due to acute infection, plasma protein C levels are reduced, and recombinant human activated protein C given as an intravenous infusion over 96 h reduces the death rate but may be associated with increased risk of bleeding. Activated protein C promotes fibrinolysis and inhibits thrombosis and inflammation and reduces circulating levels of D-dimers and IL-6.

Malaria

Anaemia is the most prominent haematological manifestation of malarial infection. It is most marked with *Plasmodium falciparum*, which invades erythrocytes of all ages (*P. vivax* and *P. ovale* invade only reticulocytes, *P. malariae* only mature cells) and can give parasitaemia levels as high as 50%. Cellular disruption and haemoglobin digestion lead directly to haemolysis. Parasitized cells have an increased osmotic facility and lose deformability; they thereby become sequestered and destroyed within the spleen, which often becomes massively enlarged. Non-parasitized cells may then become sequestered within the spleen and a raised plasma volume contributes to the anaemia. In addition, malarial antigens may attach to non-parasitized red cells to give rise to a positive direct antiglobulin test and haemolysis via a complement-mediated immune response. Acute intravascular haemolysis with haemoglobinuria, often leading to renal failure ('black water fever'), occurs rarely in *P. falciparum* infection.

An inadequate bone marrow response to anaemia is seen with relative reticulocytopenia at times of active infection, with some recovery after effective therapy. TNF levels are typically elevated and ACD occurs. Leucocyte numbers may be slightly increased or normal, but leucopenia as a result of splenomegaly and impaired marrow function is characteristic. Eosinophilia is variable. Thrombocytopenia is seen in nearly 70% of *P. falciparum* infections and has multifactorial aetiology. Autoimmune mechanisms may operate as for red cells, splenic sequestration is a contributory factor, DIC (either acute as in blackwater fever, or low grade and chronic) is common, and ADP release from damaged red cells may lead to platelet activation and consumption.

Haemophagocytic syndrome (Table 59.14; see also Chapters 8 and 12)

This may occur in association with a wide range of systemic illness. It is particularly common in patients who are immunosuppressed or who are acutely ill (e.g. septicaemic). Occasionally, patients may have haemophagocytosis as a presenting feature of lymphoma. Pancytopenia is usual, although cytopenias affecting an individual cell lineage also occur, and coagulopathy due to associated DIC is frequently present. Abnormal liver function commonly co-exists. The bone marrow (Figure 59.3) shows the presence of increased numbers of histiocytes displaying haemophagocytosis. Myelofibrosis and/or marrow hypocellu-

larity are present in a minority of cases. The underlying mechanisms are poorly understood. Treatment should be directed at the underlying disease process and possible infection treated after appropriate cultures have been taken. The condition is usually of brief duration until recovery or, sometimes, death occurs.

Haematological aspects of pregnancy
(Table 59.15)

Pregnancy poses a major physiological challenge to the human body and a number of haematological changes accompany it.

Anaemia

Maternal plasma volume increases by approximately 50% during the first and second trimesters of pregnancy, whereas the corres-

ponding increase in red cell mass is only 20–30%. A dilutional anaemia results, so that the lower limit of normal haemoglobin concentration is approximately 10.5 g/dL between 16 and 40 weeks of pregnancy. The increase in maternal red cell mass, transfer of iron to the fetus (which takes place largely in the third trimester), and blood loss during labour, together impose a requirement of about 800 mg of iron, so that iron deficiency frequently arises in mothers with normal or reduced iron stores. Folic acid requirements are also raised during pregnancy (increased folate breakdown due to increased nucleic acid synthesis in mother and fetus) and routine supplementation is advised even during early pregnancy to prevent megaloblastic anaemia and neural tube defects in the fetus. A physiological rise in MCV of 5–10 fL occurs during normal pregnancy with pre-existing aplasia. AIHA occurring during pregnancy is typically severe and refractory to therapy.

White cells

A mild neutrophil leucocytosis with a left shift and occasional Döhle bodies occur during normal pregnancy.

Platelets

The normal range for the platelet count ($140-400 \times 10^9$/L) does not alter during pregnancy; thrombocytopenia occurring during pregnancy requires evaluation. Gestational thrombocytopenia complicates 8–10% of pregnancies and is characterized by mild thrombocytopenia occurring for the first time during pregnancy (platelets $80-150 \times 10^9$/L) and is usually not associated with neonatal thrombocytopenia or significant bleeding in the mother. Maternal immune thrombocytopenic purpura may antedate or present during pregnancy: it is often associated with increased levels of platelet associated IgG, although this is a nonspecific finding and the presence of serum platelet autoantibodies to platelet glycoproteins (GP)IIb-IIa or GPIb-IX is more specific. The management of immune thrombocytopenic purpura is discussed in Chapter 57. Thrombocytopenia is regularly seen in pre-eclampsia. The mechanism is unknown, but increased aggregation is suggested, as low-dose aspirin therapy may reduce platelet consumption. TTP may occur at any time during pregnancy but typically it is before 24 weeks; the use of fresh-frozen plasma and plasma exchange has been shown to improve fetal outcome. The haemolytic uraemic syndrome typically occurs within 48 h of delivery in an otherwise normal pregnancy.

The potentially fatal syndrome of haemolysis, elevated liver enzymes and low platelets (HELLP) occurs in up to 10% of pregnancies complicated by eclampsia. The existence of coagulation abnormalities with red cell fragmentation suggests that microangiopathy, DIC and endothelial damage all have a role in its pathogenesis. Fetal and maternal outcomes are characteristically poor.

Basophilic stippling, crenated red cells and large platelets are characteristic peripheral blood findings in acute fatty liver of pregnancy.

Coagulation changes

Normal pregnancy is associated with a range of alterations to haemostatic components (see Table 59.15), which combine to give an increased risk of haemorrhage, thrombosis and DIC, occurring in up to 40% of patients with abruptio placentae, leading to haemorrhage and shock. Amniotic fluid embolism typically occurs during the course of a difficult delivery in a multiparous woman and rapidly leads to a picture of chronic low-grade DIC, with onset over a period of 1–2 weeks. Venous stasis resulting from the gravid uterus combines with the coagulation changes to make pregnancy a hypercoagulable state; operative delivery imposes an additional risk.

Haematological aspects of tropical diseases

60

Imelda Bates and Ivy Ekem

Introduction

For the purposes of this chapter, 'tropical diseases' refers to infectious diseases occurring predominantly in tropical areas. The chapter has been divided into two sections, covering tropical diseases in which organisms can be visualized in the blood or bone marrow and those that cause secondary haematological abnormalities.

Net international migration contributed to 88% of the population growth in Europe in 1990–95 and travelling migrants are responsible for a major component of imported tropical infections. These rapid increases in worldwide travel mean that haematologists need to know about the tropical diseases that can cause haematological disturbances. They also need to be able to take a relevant travel history from patients and to be aware of ethnic variations in reference ranges to avoid wasting resources on unnecessary investigations and to reduce undue anxiety for the patient.

Ethnic variations in reference ranges

The white blood count and relative and absolute neutrophil counts are lower in black people, Yemenite Jews, Palestinians and Saudi Arabians than in white people. After the age of 1 year,

Africans have lower counts than West Indians or black Americans (Table 60.1). This is due to the non-white populations having a greater number of neutrophils in the storage pool. Stimulation of a neutrophil response in these ethnic groups leads to rises in the neutrophil count to the same level as white populations irrespective of the baseline level. Indian, Chinese and South-East Asian populations have the same white blood count and neutrophil counts as white northern Europeans. There is a suggestion that black races may have lower platelet counts than white races. It is not clear whether there are true ethnic variations in eosinophil counts but counts of up to 2×10^9/L have been described in healthy blood donors in Africa.

Tropical diseases with organisms in peripheral blood or bone marrow

Malaria

Epidemiology and biology

Four species of mosquito cause human malaria disease, *Plasmodium falciparum*, *P. vivax*, *P. ovale* and *P. malariae*. *P. falciparum* is by far the most dangerous and responsible for almost all the mortality and morbidity. Malaria is the single most important disease hazard facing travellers, with 8 in 1000 travellers from developed countries becoming infected annually. More than

Table 60.1 Automated WBC and neutrophil counts in adults: 95% ranges.

	Male WBC ($\times 10^9$/L)	Neutrophil count ($\times 10^9$/L)	Female WBC ($\times 10^9$/L)	Neutrophil count ($\times 10^9$/L)
Caucasian	3.7–9.5	1.7–6.1	3.9–11.1	1.7–7.5
Afro-Caribbean	3.1–9.4	1.2–5.6	3.2–10.6	1.3–7.1
African	2.8–7.2	0.9–4.2	3.0–7.4	1.3–3.7

10 000 cases of malaria are imported into Europe each year. In 2001, 2069 cases of malaria were reported in the UK, 1576 of which were due to *P. falciparum*, and there were nine deaths. The malaria rates are highest in immigrants who visit their countries of origin, and account for one-third of all reports. Over 80% of *P. falciparum* infections in the UK are acquired in sub-Saharan Africa; 85% of *P. vivax* infections are acquired in South Asia, especially India and Pakistan. Over one-half of the patients returning to the UK with malaria did not take malaria chemoprophylaxis.

Malaria is transmitted by the bite of an infected female anopheline mosquito. The infecting agent is the sporozoite and thousands of these spindle-shaped cells may be injected by a single bite. Infrequently, transmission may also occur through blood transfusion, bone marrow transplants and transplacentally (0.5% of all UK cases). There have also been reports of malaria transmission in aircraft or near airports in temperate zones due to infected mosquitoes being brought to non-malarious areas.

Within a few hours of an infected bite, the sporozoites enter the hepatocytes, where they divide (Figure 60.1). Rupture of the hepatocyte releases the parasites into the blood and they attach to red cell membranes using specific receptors. They feed on stroma inside the red cell and the digestion of haemoglobin produces the characteristic brown pigment (haemozoin). This accumulates in cells as the parasites mature. Asexual replication of the malaria ring forms (trophozoites) takes place in the red cells, giving rise to erythrocyte schizonts. Once the trophozoites are mature, they are released into the circulation to re-infect other red cells. The periodicity of this release varies with the species and is responsible for the classical cyclical nature of malaria fevers. Relapses, which are characteristic of infection with *P. vivax* and *P. ovale*, are due to activation of dormant hypnozoite stages in the liver.

A few of the trophozoites will develop into male and female banana-shaped gametocytes and are taken up by a mosquito in the course of having a blood meal. Inside the mosquito's stomach, they undergo sexual reproduction and sporozoites migrate to the salivary glands, ready to infect another host when the mosquito bites.

Unlike the schizonts of *P. vivax*, *P. ovale* and *P. malariae*, those of *P. falciparum* are commonly seen in the peripheral blood
Figure 60.1 Life cycle of the malarial parasite.

Table 60.2 Features of *P. falciparum* malaria infection.

Target organ	Clinical features	Potential common misdiagnosis
Gastrointestinal	Diarrhoea, vomiting	Traveller's diarrhoea
Respiratory	Cough, pulmonary oedema	Pneumonia, cardiac failure
Neurological	Delirium, coma, convulsions, focal neurological signs	Encephalitis, meningoencephalitis
Renal	Oliguria, haemoglobinuria	Nephritis
Hepatic	Jaundice, hypoglycaemia	Hepatitis
Haematological	Anaemia, splenomegaly	Viral infection, lymphoma

of the human host. This is because *P. falciparum*-infected cells have surface cytoadherence molecules that enable them to be sequestered in the deep tissues. *P. falciparum* schizonts therefore only appear in the blood in very severe infections or in splenectomized patients. Sequestration is responsible for some of the severe clinical consequences of *P. falciparum* malaria such as cerebral malaria.

Clinical features

The time between the infected bite and the appearance of clinical symptoms and parasites in the peripheral blood varies between species. It is 7–30 days (mean 10 days) in *P. falciparum* but can be months, or even years, with other species, particularly *P. vivax* and *P. ovale*, because of their hypnozoite stage. The dormancy time of hypnozoites varies with different strains. When they become activated they reinvade the blood resulting in a clinical relapse.

Maximal immunity to malaria takes around 10 years to develop and is lost over the course of 1–5 years if the individual leaves a malarious area and is no longer exposed to infections. This is often not appreciated by, for example, students or immigrants from malaria-endemic countries, who may be more prone to severe attacks of malaria when they return home after a prolonged period in a non-malarious area. They will rapidly regain their immunity on re-exposure to infection.

All four malaria species produce factors that cause release of tissue cytokines, especially from leucocytes. These produce fever and contribute to anaemia through marrow suppression. Splenomegaly is a feature of acute malaria and mild jaundice may also occur secondary to haemolysis. All malaria species, but particularly *P. falciparum*, are associated with an increased risk of abortion in pregnancy. Other clinical features vary with different species.

Plasmodium falciparum

P. falciparum is the only species associated with complicated and severe disease. Death may occur after a single exposure to malaria, particularly in those who have no immunity such as non-immune travellers or young children in endemic countries. Despite this, the majority of infections cause a self-limited febrile illness. Recurrent fevers and other symptoms of malaria may be due to either recrudescence of blood forms that persist between attacks or to re-infection with a new strain or species. Recurrent attacks with different strains leads to the development of clinical, but not necessarily parasitological, immunity. Parasites may therefore be detected in a high proportion of adults in endemic areas who are clinically asymptomatic.

In addition to fever with rigors and hot and cold phases, *P. falciparum* infection commonly presents with diarrhoea and cough (Table 60.2). Serious complications include severe anaemia, cerebral involvement and failure of major organs such as kidneys and liver.

During pregnancy, immunity to malaria is reduced and parasite density increases. Even if parasites cannot be visualized in the peripheral blood they may be sequestered in the placenta and compromise fetal development. *P. falciparum* is therefore an important cause of low birth weight in neonates and anaemia in pregnant women. Both of these factors have a detrimental effect on the later development of the infant.

Plasmodium malariae

The incubation period of *P. malariae* may be several weeks. It is associated with recurrent fever, anaemia and enlargement of the liver and spleen. Without treatment, recrudescences may occur with decreasing severity over many years. Clinical symptoms of malaria have been reported up to 30 years after the initial infection.

Plasmodium vivax and *Plasmodium ovale*

These species cause a similar clinical picture with bouts of fever occurring periodically up to 5 years after the initial infection. These are relapses rather than recrudescences and are due to re-invasion of red cells by hypnozoites. The trigger for these parasites to re-activate after dormancy is unknown.

Haematological abnormalities

Normochromic, normocytic anaemia is a common manifestation of malaria, particularly in children, but the degree and rapidity of onset are very variable. The haemoglobin may fall by up to 2 g/dL each day. In malaria-endemic regions, chronic anaemia due to nutritional deficiencies, intestinal helminths, HIV and haemoglobinopathies may be compounded by the effects of malaria. In chronically anaemic patients, the oxygen dissociation curve is shifted to the right and this makes them

better able to tolerate further falls in haemoglobin. The clinical effects of anaemia in malaria are therefore due to a combination of the degree and rate of fall of haemoglobin.

The anaemia that accompanies malaria has multiple aetiologies. Red cells containing parasites are removed from the circulation by the reticuloendothelial system. There is also accelerated destruction of non-parasitized cells, which is the major reason why the haemoglobin falls rapidly in severe malarial anaemia. Both parasitized and non-parasitized red cells lose deformability and the high shear rates in the spleen enhance their removal by the spleen. In the acute phase of the disease there is suppression of the reticulocyte response. Erythropoietin levels are usually elevated, although occasionally they are less than those anticipated for the degree of anaemia.

Unusual complications of malaria that can exacerbate the anaemia are hyper-reactive malarial splenomegaly and 'blackwater fever'. Massive splenomegaly as a result of a disordered immune complex production in response to malaria (hyperreactive malarial splenomegaly) may be associated with anaemia and other features of hypersplenism (see later). Severe intravascular haemolysis with haemoglobinuria ('blackwater fever') can lead to acute renal failure. The mechanism is unknown but it has been associated with antimalarial drugs, particularly quinine, and may also be more common in individuals with glucose-6-phosphate dehydrogenase deficiency.

Case fatality rates of children with severe anaemia in Africa are 9–18% and mortality rises steeply at haemoglobin concentrations of less than 4 g/dL. Severe malarial anaemia is accompanied by hypovolaemia and therefore requires urgent fluid volume replacement and blood transfusion. The risk of transfusion-transmitted infections in poorer countries makes it increasingly important to prevent and adequately treat the milder forms of anaemia. There is now good evidence to show that antimalarial prophylaxis and insecticide-treated bed nets are both valuable in reducing anaemia in children in endemic countries.

The white cell count in malaria is usually normal but it may be raised in severe disease. Other white cell changes that have been described in malaria include a leucoerythroblastic response, monocytosis, eosinopenia and a reactive eosinophilia during the recovery phase. Neutrophil activation, indicated by raised leucocyte elastase levels, may be apparent in severe malaria. Mild thrombocytopenia with counts down to 100×10^9/L is common in malaria infection. It is due to increased splenic clearance and is associated with increased platelet turnover and raised thrombopoietin levels. Pancytopenia without hyper-reactive malarial splenomegaly has also been described in malaria infection.

The bone marrow of patients with acute malaria due to any of the four human species shows prominent dyserythropoiesis. This may persist for weeks after the acute infection and is caused by intramedullary cytokines produced by the infection. Erythrophagocytosis and macrophages containing malaria pigment are frequently seen in marrow samples from malaria patients.

In malaria, the coagulation cascade is accelerated, the degree of acceleration being proportional to the severity of disease. Fibrinogen levels are often increased and there is rapid fibrinogen turnover with consumption of antithrombin III and factor XIII, and increased fibrin degradation products (FDPs). The trigger for this activation is uncertain but there is evidence that it may be a combination of procoagulant cytokines and parasitized erythrocytes, which can directly activate coagulation pathways. Disseminated intravascular coagulation has been shown to be unimportant in the pathogenesis of severe malaria and significant bleeding is unusual, even though the prothrombin and partial thromboplastin times may be prolonged.

Haematological indicators of a poor prognosis in severe malaria include:
- leucocytosis $> 12 \times 10^9$/L;
- severe anaemia (PCV < 15%);
- platelets $< 50 \times 10^9$/L;
- prolonged prothrombin time > 3 s;
- prolonged partial thromboplastin time;
- fibrinogen < 200 mg/dL;
- hyperparasitaemia > 100 000/μL (high mortality > 500 000/μL);
- > 20% of parasites are pigment-containing trophozoites and schizonts;
- > 5% of neutrophils contain visible malaria pigment.

Genetic haematological protection mechanisms
P. vivax needs Duffy blood group antigen as a receptor to enter red cells. This is lacking in individuals belonging to certain black races and explains why they have a natural resistance to infection with this organism. The protective effect of haemoglobin AS against the life-threatening complications of malaria is well recognized. It provides 10 times the level of protection against severe disease of haemoglobin AA. Evidence is accumulating that a similar but less marked protection is associated with G6PD deficiency, α thalassaemia trait and other common erythrocyte polymorphisms.

Diagnosis
Microscopy
Direct visualization of parasites by light microscopy using a combination of thick and thin blood films is the gold standard diagnostic technique for malaria (Table 60.3 and Figure 60.2). A Romanowsky stain (e.g. Field's, Giemsa's, Leishman's) pH 7.2 is used so that the parasite cytoplasm stains blue and the nuclear chromatin red. A thick blood film should be used as the first screening tool as it allows larger volumes of blood to be examined than the thin film. However, the parasites appear distorted due to the process of lysing the red cells so this method cannot be used for parasite morphology and speciation. A thin blood film allows visualization of undistorted parasites and of the size and shape of the red cells but it has low sensitivity because of the small amount of blood that can be examined.

Table 60.3 Differential diagnosis of human plasmodium/babesia species in stained thin blood films.

	Species				
	P. falciparum	P. malariae	P. vivax	P. ovale	Babesia sp.
Appearance of infected red blood cells (size and shape)	Both normal	Normal shape; size normal or smaller	1.5–2 times larger than normal; shape normal or oval	As for P. vivax, but some have irregular frayed edges	Both normal
Schüffner's dots (eosinophilic stippling)	None (but occasionally comma-like red dots present = Maurer's dots)	None	Present in all stages, except early ring form	As for P. vivax	None
Red cells with multiple parasites/cell	Common	Rare	Occasional	As for P. vivax	Common
Stages present in peripheral blood	Rings and gametocytes; occasionally schizonts	All stages	All stages	As for P. vivax	Only rings and rare pear-shaped forms ('Maltese cross'); no gametocytes
Ring form (young trophozoite)	Delicate, small ring; scanty cytoplasm; sometimes at the edge of red cell ('accolé form')	Ring one-third of the diameter of cell; heavy chromatin dot; vacuole sometimes 'filled in'	Ring one-third to one-half of the diameter of cell; heavy chromatin dot	As for P. vivax	Resembles ring of P. falciparum; look for pear-shaped structure
Schizont	Occasionally in peripheral blood, 16–30 merozoites	6–12 merozoites in rosette; coarse pigment clump in centre	12–24 merozoites in rosette filling entire RBC; central pigment	8–12 merozoites in rosette	No schizont
Gametocyte	'Crescent' or 'sausage' shape are characteristic	Round or oval; dark coarse pigment	Round or oval	Round or oval (smaller than P. vivax)	No gametocyte
Main criteria	Delicate ring forms and crescent-shaped gametocytes are the main forms in the bloodstream; multiple infection common; normal RBC shape/size; level of infection may be high	Red cell normal or slightly smaller; trophozoites compact and intensely strained; band-form suggestive; no Schüffner's dots; coarse and dark pigment	Large pale RBC; presence of Schüffner's dots in cytoplasm of RBC; round gametocytes; large amoeboid trophozoite with pale pigment	Oval RBC with fimbriated edges characteristic but not always present; generally like P. vivax	Ring forms very similar to P. falciparum; presence of group of 2–4 pear-shaped bodies ('Maltese cross') is characteristic; absence of gametocytes

(a)

(b)

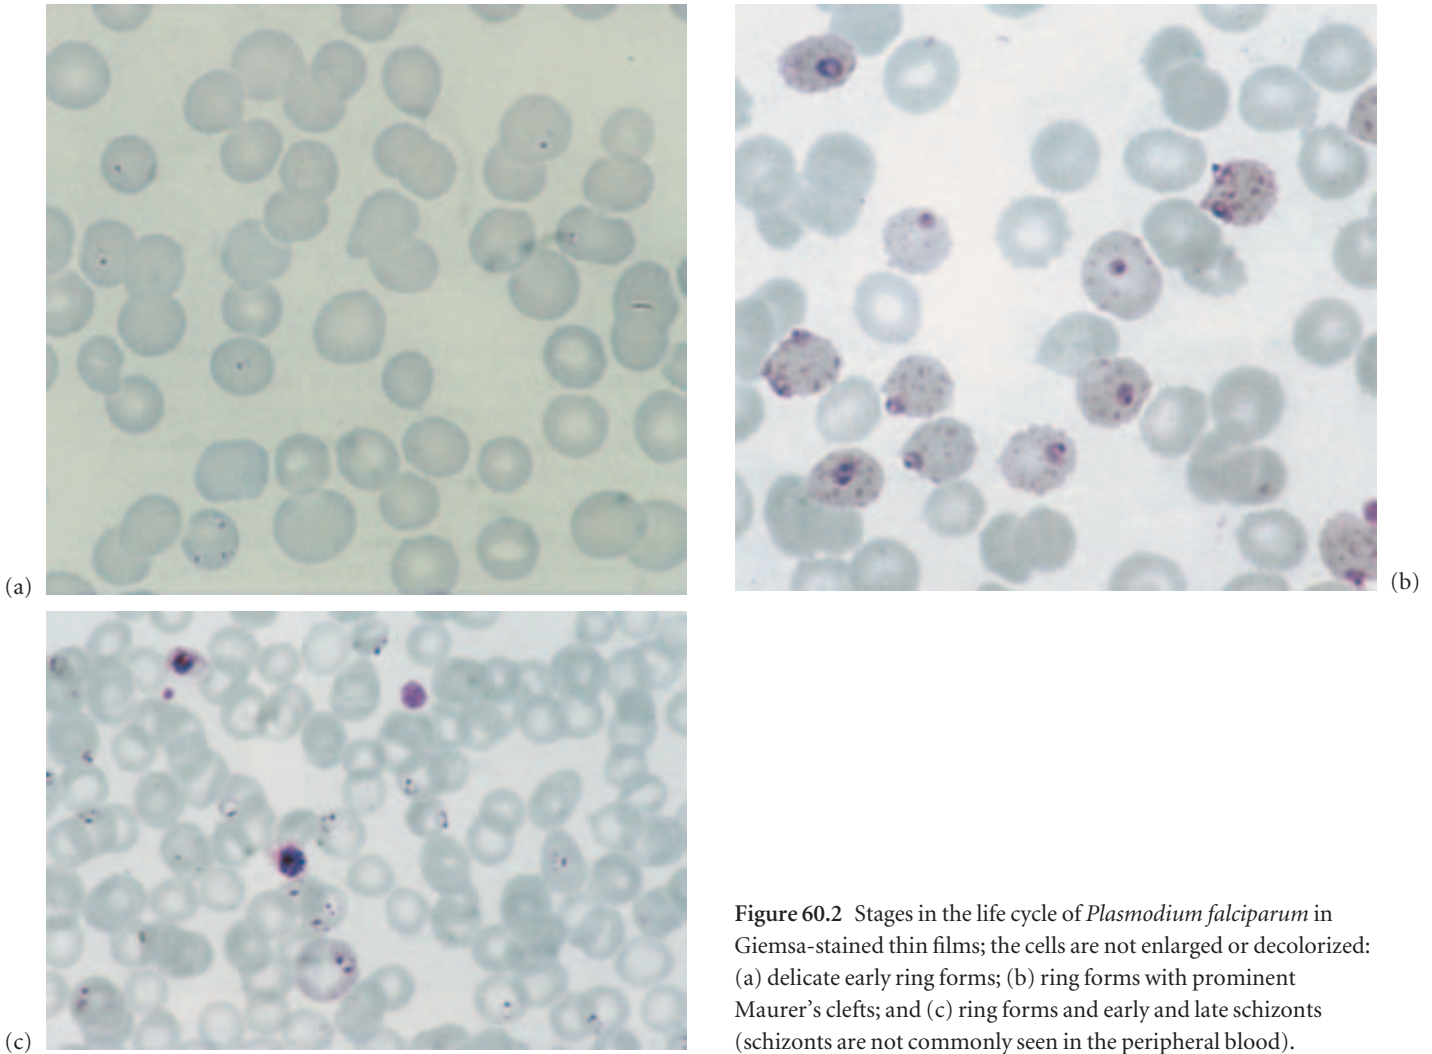
(c)


Figure 60.2 Stages in the life cycle of *Plasmodium falciparum* in Giemsa-stained thin films; the cells are not enlarged or decolorized: (a) delicate early ring forms; (b) ring forms with prominent Maurer's clefts; and (c) ring forms and early and late schizonts (schizonts are not commonly seen in the peripheral blood).

Disadvantages of basing a diagnosis of malaria on blood film examination include the following points:

• A negative film does not exclude malaria – at least three films taken during episodes of fever should be examined and even if these are negative it does not entirely exclude the diagnosis especially in the presence of antimalarial drugs.

• A positive film does not prove that symptoms are due to malaria – asymptomatic parasitaemia is common in adults from endemic areas.

• Parasites, particularly *P. falciparum* gametocytes, may be washed off the slide during staining; bulk staining of slides may result in transfer of parasites between slides.

• Parasite density does not necessarily correlate with disease severity although a heavy parasitaemia (> 5% of red cells infected) indicates a poor prognosis.

Malaria pigment may persist in phagocytic cells for several weeks after an acute attack and may be helpful in retrospective diagnosis of malaria. Automated haematology analysers may produce an abnormal pattern on the white cell differential count histogram. Debris below the white cell threshold may be due to malaria parasites and manual examination of blood films is indicated if this pattern is flagged up by the machine.

Antibody detection

As malarial antibodies can remain in the blood after the eradication of parasites, their detection is not useful for diagnosis in the acute attack. The main uses of malarial antibody detection are for excluding malaria as a cause of chronically recurrent fever between febrile attacks, population surveys and as a screening test for blood transfusion purposes.

Antigen detection

These tests are based on detection of the malaria antigen 'histidine-rich protein 2' (HRP2) or parasite enzyme lactate dehydrogenase (pLDH). They have been incorporated into im- munochromatographic antigen-capture kits for rapid diagnosis.

The sensitivity of these dipstick strip tests approaches that of thick film microscopy (i.e. 0.002% parasitaemia equivalent to 100–200 parasites/µL of blood). HRP2 protein may remain positive for 14 days after successful treatment and false-positives due to rheumatoid factor have been reported. pLDH is only produced by viable parasites so it becomes negative 2–3 days after successful treatment. None of these kits are able to provide quantitative information about parasitaemia but some are able to distinguish between *P. falciparum* and other species.

Potential uses of malaria antigen detection tests include:
- confirmation of malaria diagnosis on a blood film;
- detection of *P. Falciparum* when the microscopist is inexperienced (e.g. on-call or emergency situations);
- determination of species when there is a possibility of mixed infection;
- monitoring response to treatment.

DNA-based methods
DNA hybridization and polymerase chain reaction (PCR) have both been used for malaria diagnosis predominantly in a research context.

Haematological implications of treatment for malaria

Chloroquine has been the first-line treatment for malaria in many countries for decades and is generally well tolerated. However, widespread parasite resistance is now seriously restricting its use and it is being replaced with newer drugs, some of which have haematological side-effects.

Amodiaquine has a similar mode of action to chloroquine but causes agranulocytosis in 1 in 2000 patients. Its use is therefore restricted to treatment and it is not recommended for prophylaxis.

Quinine is rarely associated with immune thrombocytopenia and severe intravascular haemolysis ('blackwater fever'). Blackwater fever has also been described with other antimalarial drugs and the underlying pathophysiology is not completely understood.

Pyrimethamine is used together with a long-acting sulphonamide, such as sulphadoxine (e.g. Fansidar). It is a dihydrofolate reductase inhibitor and this explains why pyrimethamine may induce megaloblastic anaemia, neutropenia or thrombocytopenia in patients with pre-existing folate deficiency. The sulpha component of these combinations may rarely cause blood dyscrasias and methaemoglobinaemia.

Dapsone, used as part of a fixed combination with proguanil or chlorproguanil, may be associated with haemolytic anaemia, methaemoglobinaemia and eosinophilia.

Primaquine is active against the hypnozoites of *P. vivax* and the gametocytes of *P. falciparum*. It causes oxidant haemolysis in patients with glucose-6-phosphate dehydrogenase deficiency and, rarely, methaemoglobinaemia.

Mefloquine, *halofantrine*, *proguanil*, *lumefantrine* and *artemisinin-related compounds* do not commonly cause significant haematological side-effects. Some antibacterial drugs, such as *doxycycline*, *trimethoprim* and *sulphonamides* have also been used for their antimalarial effect and may be associated with haematological side-effects.

Babesiosis

Epidemiology and biology
Babesiosis is not a tropical disease but is briefly described here as it can be confused with malaria. It has been predominantly reported from the USA, particularly coastal regions, and Europe. It is primarily a disease of animals and rarely infects humans. It is due to a protozoan parasite transmitted by a tick bite. *Babesia bovis*, *B. microti* and *B. divergens* are responsible for the majority of human infections. There is geographical variation in the *Babesia* species responsible for disease in humans. Most of the cases reported from Europe have been due to *B. divergens* and occurred in patients who were asplenic, whereas in north America almost all the cases have been due to *B. microti*.

Following the bite, the organisms penetrate red cells, where they take on an oval, round or pear shape and multiply by budding. The erythrocytic ring forms of *B. microti* and *B. divergens* may be confused with malaria *P. falciparum* rings, but they do not produce pigment or cause alterations in the red cell morphology. A minority of organisms take on a folded shape and are thought to be gametocytes.

Clinical features
The incubation period varies from 1–4 weeks, and the severity and progression of the clinical features vary with the infecting species. Most patients have no recollection of a tick bite. The disease presents with fever, prostration, mild hepatosplenomegaly and haemolytic anaemia with jaundice and haemoglobinuria. Severe complications including acute tubular necrosis, respiratory distress and DIC, and a fulminant, fatal course has been described in splenectomized patients. *B. microti* usually produces a subclinical infection. Although babesiosis has a worse prognosis in patients who have been splenectomized or who are immunosuppressed, co-infected with HIV or elderly, it can occur in the presence of an intact spleen.

Haematological abnormalities
The anaemia may be mild to moderately severe and is due to parasite-induced abnormalities in the red cell membrane. Haemolytic anaemia, which may last for several weeks, is a prominent feature of babesiosis, particularly in splenectomized individuals. Although the haemolysis is due to complement or antibody coating of the red cells, the direct antiglobulin test is usually negative. Haptoglobin levels are reduced and the reticulocyte count is increased. The presence of parasitaemia needs to be interpreted with caution as parasites may persist for months after the resolution of symptoms and the level of parasitaemia does not parallel the severity of disease (Table 60.3).

Babesia parasites may be confused with Pappenheimer bodies in splenectomized patients with active haemolysis. Thrombocytopenia may occur in severe cases. Total white cell counts are usually normal or low.

Haematological implications of treatment for babesiosis

There have been no randomized controlled trials to determine optimal treatment for babesiosis. Treatment recommended at present includes the use of clindamycin and quinine, with exchange blood transfusion for those who are critically ill with high parasitaemias. Atovaquone and azithromycin have also been used successfully.

Filariasis

Epidemiology and biology

There are two groups of human filarias: those that occur in the blood (lymphatic filariasis) and those that occur in the skin (onchocerciasis). Only lymphatic filariasis will be considered in this chapter, as it is associated with detectable organisms in the peripheral blood.

Two species of filarial worms cause lymphatic filariasis in humans and are relevant for haematologists, *Wuchereria bancrofti* and *Brugia malayi*. They have different geographical distributions with *W. bancrofti* being the most widespread. More than 90% of infections due to *W. bancrofti* are found in Asia, although it also occurs in Africa, America and the Pacific Islands. Filariasis due to *B. malayi* occurs in China, Indo-China, Thailand, Malaysia, Indonesia, the Philippines and south-west India (Figure 60.3).

The worms are 4 (male) to 10 cm (female) long and can live for over 10 years in the lymphatics. Microfilariae, which are 250–300 μm long, are produced by the female worm and released into the blood after 3–8 months, where they may live for up to 1 year. Microfilariae densities can reach 10 000/mL but are usually much lower. They exhibit daily periodicity in the blood and this timing is designed to match the biting habits of their mosquito vector. This maximizes their chances of being taken up during the blood meal of culicine or anopheline mosquitoes. The microfilariae develop but do not multiply in the mosquito and pass into the proboscis, ready to be injected into another human.

Clinical presentation

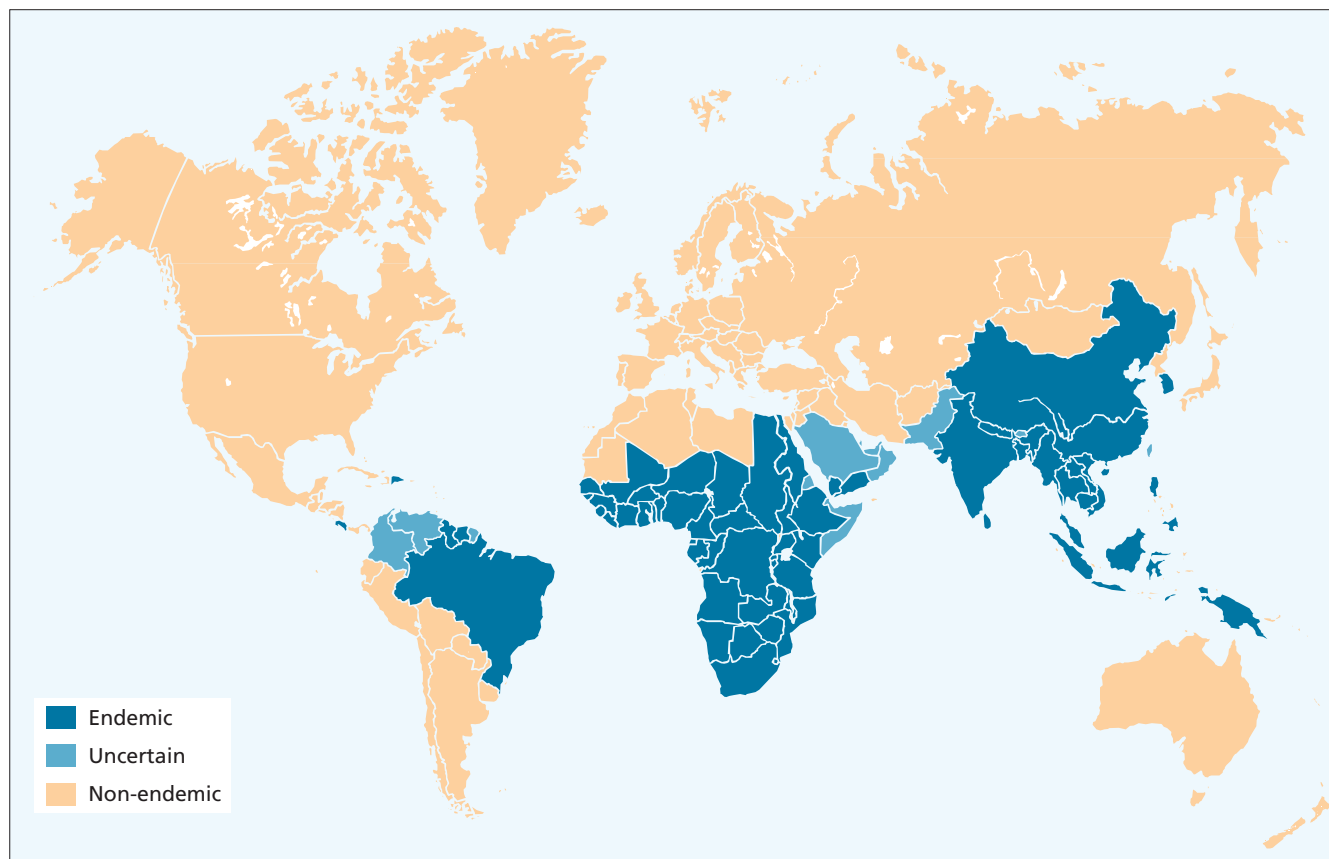
There is a wide variation in the presenting features of lymphatic filariasis, which may occur 6 months or more after the infective bite. The symptoms and signs are due to lymphangitis. There


Figure 60.3 Global distribution of lymphatic filariasis.

are recurrent bouts of fever with heat, redness and pain over lymphatic vessels. In fair-skinned people, the lymphangitis can be seen to spread distally (i.e. the opposite direction to septic lymphangitis). In *W. bancrofti* these repeated episodes of inflammation eventually result in the typical chronic picture of filariasis, including hydrocele, lymphoedema and elephantiasis, chyluria and tropical pulmonary eosinophilia. The clinical picture in *B. malayi* infection is similar but it does not cause hydrocele or chylous urine.

Other filariae with blood-inhabiting larvae

Loa loa: This occurs in the rain forest belt of Central Africa, especially West Africa. The adult worms migrate through the subcutaneous tissues, including the conjunctiva, and occasionally can be seen passing across the eye.

Mansonella perstans: This is a non-pathogenic and common infection of people in Africa. These organisms may therefore co-exist in the blood with *W. bancrofti* but can be distinguished by their smaller size and absence of a sheath.

Mansonella ozzardi: This is also probably non-pathogenic and occurs in the West Indies and South America.

Haematological abnormalities

Eosinophilia is the major and most frequent haematological abnormality produced by lymphatic filariasis. The development of tropical pulmonary eosinophilia is an unusual complication of filariasis. This is an immunological hyper-responsiveness to microfilaria in the lungs and is more common in males than females. Although microfilariae are absent from the blood in this syndrome, they may be seen in lung biopsies and adult worms can be visualized in lymphatics on ultrasound. There is an extreme eosinophilia with eosinophil counts of greater than 10×10^9/L; the level of eosinophilia is not related to the severity of symptoms. In tropical pulmonary eosinophilia, diethylcarbamazine treatment reduces the eosinophil count and produces resolution of symptoms. This rapid response to treatment distinguishes filariasis from other causes of marked eosinophilia, such as helminths that affect the lungs (*Ascaris*, *Strongyloides*, *Schistosoma* subsp. *trichinosis*) and *Toxocara*.

Diagnosis of filariasis

The adult worms residing in the lymphatics are inaccessible, so diagnosis is based on finding microfilariae in the peripheral blood. The level of filaraemia is inversely related to the clinical signs because much of the damage is due to immunological responses to the microfilariae rather than to the organisms themselves. Furthermore the presence of microfilariae does not necessarily mean that they are causing clinical problems and conversely a lack of microfilariae in the blood does not exclude a diagnosis of filariasis. The peripheral blood findings must therefore be assessed in the context of the clinical picture.

Figure 60.4 Microfilaria of *Wuchereria bancrofti*.

To optimize the chances of finding scanty microfilariae in the blood, the sample should be taken at the appropriate time for the expected peak concentration of microfilariae (i.e. around midnight or midday for nocturnally and diurnally periodic forms respectively). There are many techniques for demonstrating microfilariae in the laboratory. The simplest method is a wet preparation of fresh blood. Microfilariae will survive in venous blood collected into EDTA for 2 days at room temperature. Motile microfilariae can be seen on a slide under low power and can be counted in a counting chamber. Numbers of microfilariae may be low, so concentration techniques are often required. Sensitivity can be increased by passing the whole blood sample through a 3-μm Nuclepore filter membrane and then staining the microfilariae trapped in the filter.

For species identification, thick and thin blood films should be stained with Giemsa or haematoxylin and the microfilariae differentiated according to the pattern of their sheaths, nuclei distribution and size (Figure 60.4). The edges of the film should be examined carefully as microfilariae tend to be concentrated at the periphery and are easily missed if the microscopist goes straight onto high power in the centre of the film.

Detection of circulating antigen by enzyme-linked immunosorbent assay (ELISA) or ICT has replaced microscopy for the diagnosis of bancroftian, but not brugian, filariasis. An antigen immunochromatography card test is available for the detection of *W. bancrofti*, which does not react with other filariae and is highly sensitive (100%) and specific (92%). Filarial DNA can be detected by PCR, and ultrasound can help to identify adult worms within the lymphatic system. Serological tests are not very helpful in the diagnosis as most individuals from endemic areas have antibodies to crude filarial antigens and there is cross-reactivity with other filariae and nematodes.

Haematological implications of treatment for filariasis

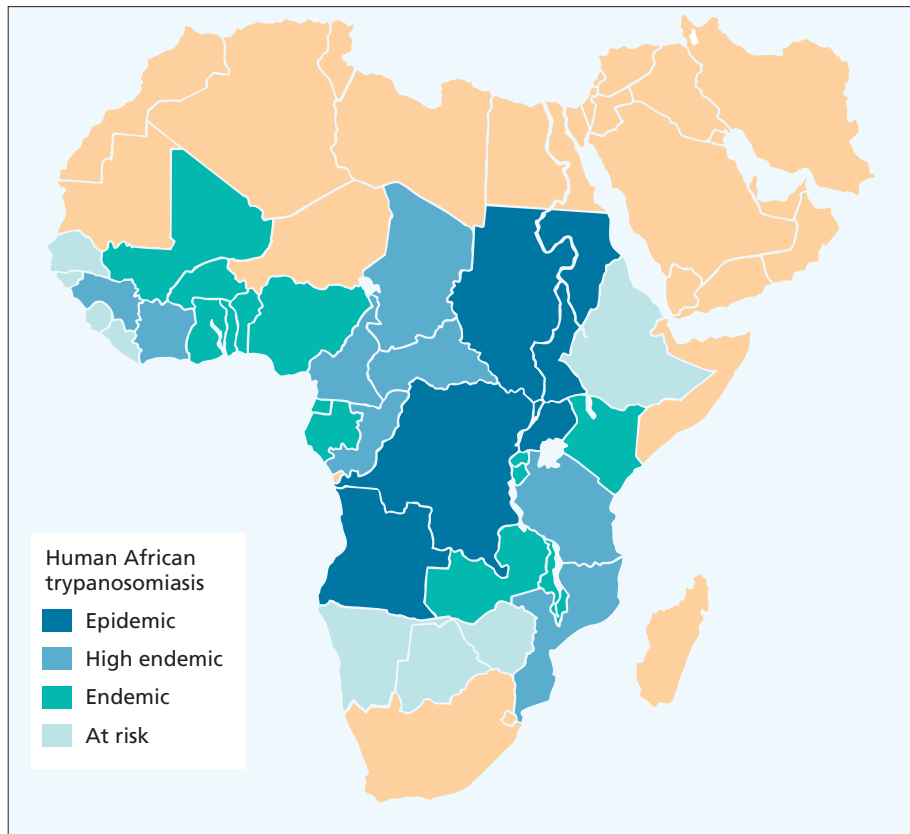
Oral diethylcarbamazine is the drug of choice in all forms of lymphatic filariasis, including subclinical infection. Alternative


Fig. 60.5 Geographical distribution of African trypanosomiasis.

treatments include combinations of albendazole and ivermectin. None of these drugs has common, serious haematological side-effects.

African trypanosomiasis (sleeping sickness)

Epidemiology and biology

African sleeping sickness is caused by the haemoflagellate protozoa *Trypanosoma brucei gambiense* in West and Central Africa, and *T. brucei rhodesiense* in Eastern Africa (Figure 60.5). These parasites are fusiform in shape, 12–35 μm long and morphologically indistinguishable from each other. The disease is transmitted by the bite of the tsetse fly, which is only found in Africa. The trypanosomes multiply by fission in the vicinity of the infected bite and are then disseminated by the bloodstream. Congenital transmission has also been described. The distribution of African sleeping sickness is determined by the ecological limits of the tsetse fly vector and lies in the region between Senegal and Somalia in the north and the Kalahari and Namibian deserts in the south. There have been recent surges of the disease in Congo, Angola, Sudan and Uganda, and there is relentless spread of the disease in Central Africa.

Clinical features

The bite of a tsetse fly is very painful and causes a small indur-

ated lesion that may persist for some days. The local multiplication of the trypanosomes may cause a marked inflammatory reaction (a chancre) that regresses after 2–3 weeks. Entry of the trypanosomes into the bloodstream is associated with fever, which tends to be less marked in West African trypanosomiasis than in the East African variety. East African trypanosomiasis is primarily a disease of cattle and it only enters human hosts by accident. It is therefore less well tolerated than West African sleeping sickness, having a more aggressive course and intense symptoms.

The early stages of sleeping sickness can be associated with prominent lymphadenopathy, particularly of the posterior cervical nodes, and mild splenomegaly. These features may be suggestive of infectious mononucleosis, tuberculous lymphadenitis or a lymphoproliferative disorder. Severe anaemia, haemorrhages and petechiae may occur at this stage.

Both types of African sleeping sickness cause a protracted febrile illness, which, despite the name, are not always associated with drowsiness. Death is inevitable if the disease is left untreated. As the disease progresses parasitaemia decreases, trypanosomes invade the CNS and neurological disturbances due to inflammatory chronic meningoencephalitis supervene. In West African trypanosomiasis, the disease runs its course over several years but in East African trypanosomiasis infection, CNS involvement may occur within weeks.

Table 60.4 Drugs for African trypanosomiasis.

	Haemolymphatic stage		Encephalitic stage	
	First line	Second line	First line	Second line
West African (*T. brucei gambiense*)	Pentamidine	Eflornithine or melarsoprol	Suramin	Melarsoprol
East African (*T. brucei rhodesiense*)	Suramin	Melarsoprol	Melarsoprol	Melarsoprol plus nifurtimox

Haematological abnormalities

The aetiology of the anaemia in sleeping sickness is multi-factorial but primarily due to phagocytic removal of immune complex-coated red cells from the circulation. Trypanosomes liberate haemolytic factors that contribute to this process, and increases in plasma volume cause a dilutional anaemia. There is a failure to incorporate iron into red cell precursors and the resulting dyserythropoiesis means that the bone marrow is unable to compensate for the fall in haemoglobin. There may be a moderate leucocytosis with increased monocytes, lymphocytes and plasma cells. Mott morular cells have also been described in sleeping sickness. The bone marrow is hypercellular, with areas of gelatinous degeneration.

As the disease advances, a bleeding tendency may develop due to thrombocytopenia, vascular injury and coagulopathy with increased fibrinolysis. Platelet dysfunction has also been described and is manifest as clumping and abnormal aggregation responses. DIC with raised FDPs may occur in the later stages. Although some of these complex haematological changes can be linked to the non-specific polyclonal activation of B cells, overall the mechanisms underlying these are not well understood.

Diagnosis of sleeping sickness

Wet preparations of fluid aspirated from the chancre of lymph nodes may reveal live, motile organisms (Figure 60.6). This technique is more likely to be productive in the case of infection with *T. brucei rhodesiense* than *T. brucei gambiense*. The organisms are fragile so care must be taken not to damage them when making the smears. Trypanosomes can be seen on stained thin blood films but the number of trypanosomes in the circulation can vary considerably and is often low, so concentration techniques are usually required.

Quantitative buffy coat (QBC) method is the technique of choice for diagnosis of African trypanosomiasis. This involves concentrating the trypanosomes at the plasma–platelet interface in a special microhaematocrit tube using differential centrifugation. Parasites are identified by labelling with the fluorescent marker, acridine orange.

The highly specific and sensitive serological agglutination test (CATT) may be used in conjunction with a direct visualization microscopic method. If these tests are positive then CSF examination is mandatory to determine the stage of the illness.

(a)
(b)

Fig. 60.6 Microfilariae of *W. bancrofti* in thick film: (a) microfilaria showing the negative impression of the sheath (×365); (b) tail of the microfilaria showing that the nuclei do not extend into the tail (×912).

Haematological implications of treatment for African trypanosomiasis (Table 60.4)

Pentamidine and *suramin* are the drugs of choice for the early stages of West and East African trypanosomiasis respectively. They have a cure rate of around 90% but are only able to achieve modest CSF concentrations so they cannot be used for later stages of the disease. The most common haematological side-effects of pentamidine are leucopenia, thrombocytopenia and

anaemia. Suramin has serious side-effects, including haemolytic anaemia and bone marrow toxicity.

Melarsoprol, an arsenic-based compound, has been the drug of choice for late-stage sleeping sickness but is highly toxic, with a mortality of 4–12%. Its main adverse effect is a fatal encephalopathic syndrome and haematological toxicity is not a particular problem.

Eflornithine is expensive but is of benefit in late-stage sleeping sickness, particularly West African disease; 25–50% of patients treated with this drug exhibit bone marrow toxicity with anaemia, leucopenia and thrombocytopenia.

American trypanosomiasis (Chagas disease)

Epidemiology and biology
Chagas disease is due to a haemoflagellate protozoa, *T. cruzi*, which is transmitted by triatomine bugs that infest poor quality housing. It can also be transmitted through blood transfusions and congenitally. It is restricted to a region in the Americas between Argentina and the southern states of the USA.

Clinical features
The incubation period is usually a couple of weeks but may be up to several months if transmission was through blood transfusion. In the acute phase, swelling at the site of entry of the organism, a chagoma, may be accompanied by fever, mild hepatosplenomegaly and local or generalized lymphadenopathy. The trypanosomes multiply intracellularly in muscle tissue, particularly the heart, colon and oesophagus. Once infection has occurred, and if no treatment is given, the organisms will be present for life. The chronic phase of the disease is associated with heart disease in 30% of infected individuals, which is manifest as arrhythmias and megacardia. A small proportion of individuals also have clinical involvement of the gastrointestinal tract and other hollow organs, with loss of peristalsis and organomegaly with organ failure. Asymptomatic infection is common and poses a problem for blood transfusion services in endemic areas, so some countries have now introduced routine screening of blood for American trypanosomiasis.

Diagnosis of Chagas disease
Although similar methods to those used for African trypanosomiasis can be helpful for diagnosis, serological tests are more commonly used as the primary diagnostic tool. They are based on enzyme immunoassay (EIA) or immunofluorescent antibody test (IFAT) and have good sensitivity. PCR may also be useful but is not in routine use.

Haematological implications of treatment for American trypanosomiasis
Benznidazole is recommended for acute and congenital *T. cruzi* infection. Major haematological side-effects are not common with this drug, although agranulocytosis has been reported.

Leishmaniasis

Epidemiology and biology
Visceral and cutaneous leishmaniases are caused by protozoan flagellates that are transmitted through the infective bite of a phlebotomine sandfly. Following an infected bite, parasites spread from the inoculation site to the mononuclear phagocytic system. Only the visceral form ('kala-azar') is associated with organisms in haemopoietic tissues and will be considered in this chapter. Visceral leishmaniasis is due to the species *Leishmania donovani* and *L. infantum* and is found in 47 countries throughout the world, with extension limits from 45° north to 32° south; 90% of cases are in Bangladesh, India, Nepal, Sudan and Brazil (Figure 60.7). The number of cases of visceral leishmaniasis, particularly round the Mediterranean basin in southern Europe, has been increasing over the last 10–15 years in association with HIV-related immunosuppression.

Clinical features
The clinical expression of leishmaniasis depends on both the genotypic potential of the parasite and the immunological response of the patient. Incubation period varies from days to years but is generally 2–6 months. Onset can be sudden with high fever, or gradual with intermittent fever. Diarrhoea, joint pains, weight loss and bleeding gums occur in the acute phase. This is followed by progressive muscle wasting, protuberant abdomen, fever, weight loss, anaemia and hepatosplenomegaly. The splenomegaly appears early and the spleen increases in size in relation to the duration of the disease, so that eventually it may reach into the left hyopchondrium. In immunocompromised patients, such as transplant recipients and those with advanced HIV disease, kala-azar behaves like an opportunistic infection.

Haematological abnormalities
Normochromic, normocytic anaemia is a frequent and clinically significant feature of visceral leishmaniasis and haemoglobin levels of 7–10 g/dL are common. The massive splenic enlargement is associated with hypersplenism and consequent anaemia, leucopenia and thrombocytopenia. Liver dysfunction with jaundice, ascites and deranged coagulation may occur in the late stages and has a poor prognosis. The bleeding tendency may be exacerbated by thrombocytopenia and result in clinical haemorrhages. A high degree of suspicion for a diagnosis of leishmaniasis needs to be maintained by haematologists in all patients with unexplained splenomegaly, pancytopenia or fever.

Diagnosis of leishmaniasis
Definitive diagnosis is based on detection of the parasites, or their DNA, in smears of bone marrow or splenic aspirate samples. Fluid aspirated from lymph nodes can also yield parasites if lymphadenopathy is present. Splenic aspirate has a higher diagnostic yield than bone marrow. It has been suggested that the intercostal route for splenic aspiration is safer and causes less

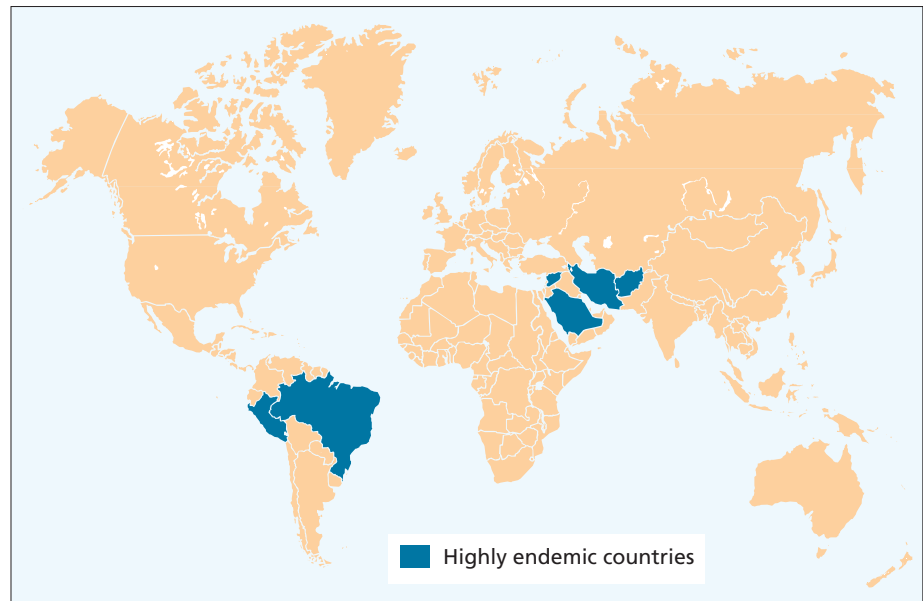
Highly endemic countries


Fig. 60.7 Geographical distribution of cutaneous leishmaniasis.

discomfort than the abdominal approach, providing that the prothrombin time and platelet count are adequate.

In haematological practice, leishmania are usually encountered as intracellular amastigotes in mononuclear cells in the bone marrow, but can also be seen extracellularly (Figure 60.8). They are 2–6 μm in diameter and contain a nucleus lying close to the rod-shaped kinetoplast, and an internal flagellum. Using a Romanowsky stain, the nucleus and kinetoplast stain purple and can be clearly distinguished. Amastigotes can be seen in both bone marrow aspirates and in trephine-impression smears. They are rarely seen in peripheral blood and then only in buffy coat preparations.

Direct microscopic visualization is less sensitive then molecular diagnosis, particularly when there is co-infection with
Fig. 60.8 Bone marrow aspirate of leishmaniasis, showing a macrophage containing numerous organisms, which, in addition to a nucleus, have a small paranuclear kinetoplast, giving them a characteristic 'double-dot' appearance (MCG ×940).

HIV. Under these circumstances, PCR can be very useful for diagnosis and speciation. It can be performed on lesion aspirate, marrow, blood and biopsy material. The indirect fluorescent antibody tests ELISA and DAT (direct antiglobulin test) are useful for detecting antibodies to visceral leishmaniasis, but results may be inconclusive in immunosuppressed patients.

Haematological implications of treatment for leishmaniasis
For the last 80 years, the treatment of leishmaniasis has been based on pentavalent antimony drugs, although their mode of action is still unclear. Resistance levels to antimonals in India, particularly in Bihar, where 90% of India's cases of leishmaniasis occur, are high so other options such as amphotericin B, paromomycin and miltefosine need to be considered. HIV co-infected patients do not respond well to antimonials so amphotericin is the drug of choice. Side-effects can be reduced by using the liposomal preparation. Even after successful treatment, immunocompromised patients may require prophylaxis to prevent relapses.

Sodium stibogluconate is the most commonly used antimonial. It can be associated with worsening anaemia, although its most serious detrimental effects are on cardiac function.

Amphotericin B can produce haematological side-effects but its most serious toxicity is related to renal, cardiac, neurological and hepatic dysfunction.

Non-specific haematological abnormalities associated with tropical diseases

Hypersplenism

Hypersplenism is a syndrome characterized by splenomegaly and cytopenias. Tropical infections associated with massive

Fig. 60.9 Patient with massive splenomegaly due to hyper-reactive malaria splenomegaly.

splenomegaly include hyper-reactive malarial splenomegaly, visceral leishmaniasis, schistosomiasis and trypanosomiasis (Figure 60.9). The anaemia, leucopenia and thrombocytopenia in hypersplenism are due to a combination of sequestration and haemodilution. The degree of expansion of plasma volume is proportional to the size of the spleen, and can be improved by splenectomy. The thrombocytopenia and neutropenia are rarely severe enough to cause clinical problems. Most of the thrombocytopenia is due to pooling in the spleen which, when massively enlarged, can hold up to 90% of the platelet mass. Neutropenia is the result of increased marginalization of granulocytes. In the case of tropical infections, treatment of the underlying disorder generally leads to regression of the splenomegaly with resolution of the haematological abnormalities.

Tropical diseases associated with changes in the full blood count

Anaemia
Anaemia of chronic disease is a common and non-specific finding in many types of tropical infections. Some infections are responsible for specific types of anaemia. For example, hookworm infection contributes to iron deficiency anaemia and megaloblastic anaemia secondary to parasite consumption of vitamin B_{12} is a feature of infection with the tapeworm *Diphyllobothrium latum*. Intra-erythrocytic parasites, such as those that cause malaria and babesiosis, may be directly responsible for intravascular haemolysis.

White cell abnormalities
Severe infections particularly due to bacteria may cause a neutrophilia and a leukaemoid reaction with myeloid precursors in the peripheral blood and circulating neutrophils, with toxic

granulation, vacuolation and Döhle body formation. Lymphocytosis with neutropenia, splenomegaly, nose bleeds, rash and neurological complications is a feature of rickettsial diseases (e.g. typhus, Q fever). These are small (0.3–1 μm diameter) intracellular parasites. They have a worldwide distribution and can infect rodents. Some, such as trench fever, may persist for many years and are transmissible in blood transfusions. The absence of neutrophilia in the presence of marked fever is a particular feature of typhoid. Lymphocytosis or monocytosis may also be present in typhoid and other clinical features include hepatosplenomegaly and, in severe disease, haemorrhage from ileal ulcers exacerbated by DIC. Helminths and other predominantly tropical organisms that invade tissues may be associated with a significant eosinophilia ($> 0.5 \times 10^9$/L). Such diseases include loiasis, lymphatic filariasis, schistosomiasis, trichinosis, toxocariasis, strongyloidiasis, hydatid disease, oriental liver flukes and guinea worm.

Tropical infections with fever and haemorrhage

Relapsing fever
Relapsing fevers are borne by either lice or ticks. Louse-borne relapsing fever is endemic in the horn of Africa and Rwanda. Tick-borne relapsing fever has a wider distribution through Africa, the Mediterranean basin and the Middle East. They have a relapsing course and severe disease is characterized by fever with jaundice, neutrophilia, thrombocytopenia and DIC. There is a marked bleeding tendency, with petechial haemorrhage and epistaxis. Spiral organisms (*Borrelia* spp.) can be seen in the blood. Relapsing fevers respond well to tetracycline but this must be given with care as it can generate a severe, life-threatening Jarisch–Herxheimer reaction.

Viral haemorrhagic fevers
These are caused by dengue virus, several arenaviruses and hantaviruses and yellow fever virus. Viruses that are likely to cause haemorrhagic fever can be classified according to their reservoir hosts and their primary means of transmission. They are divided into:
• rodent-associated viruses (e.g. Lassa fever, hantaviruses);
• arthropod-borne viruses (e.g. dengue, yellow fever and Chikungunya viruses);
• unknown vectors or hosts (e.g. Marburg, Ebola).
  They often occur in epidemics, have human-to-human transmission and may only be suspected if a relevant travel history is elicited from the patient. Dengue and yellow fever are becoming increasingly important imported infections.

Dengue
The four types of dengue virus belong to a group of flaviviruses and are transmitted by the *Aedes* mosquitoes. Dengue is endemic

in tropical areas of Asia, Africa, South America and the Caribbean and is particularly virulent in South-East Asia, including Thailand and Vietnam. There has been a resurgence of the disease over the last decade as a result of urbanization, poverty, the demise of *Aedes* eradication programmes and increasing travel.

Primary infection occurs in young children and is usually asymptomatic. Older children and adults develop acute fever, headache and myalgia ('breakbone fever'). Leucopenia may accompany this stage of the illness. Severe complications may arise in those who have had previous dengue infection. These include hypotensive shock with marked thrombocytopenia, producing spontaneous bleeding, including epistaxis and gastrointestinal haemorrhage. There is also neutropenia and bone marrow hypoplasia with abnormal megakaryocytopoiesis.

Arenavirus infections: Lassa fever, Ebola virus and Marburg virus

These are endemic in equatorial Africa and are important because they produce potentially fatal infection and have the ability to spread from person to person.

The rat is the main vector of Lassa fever. Only about 10% of infected individuals become ill and only 1–2% of these develop fatal disease. The clinical features of these three haemorrhagic fevers are similar. They are characterized by headache, fever and oesophagitis. Spontaneous bleeding occurs in 25% of hospitalized patients and is thought to be due to abnormal platelet function. Case reports have suggested that heparin may be helpful in controlling the bleeding problems.

Yellow fever

Yellow fever virus is transmitted by *Aedes* mosquitoes and exists throughout equatorial Africa, and northern and central south America. It has a propensity to invade hepatocytes, causing hepatocellular dysfunction and jaundice. Fever, myalgia and back pain may be followed by jaundice, bleeding and renal failure in the most severe cases. Thrombocytopenia, prolonged prothrombin and partial thromboplastin times and DIC are responsible for the bleeding tendency.

Neonatal haematology

Irene AG Roberts

61

Developmental haemopoiesis

Haemopoiesis begins in the yolk sac in the third week of gestation and moves sequentially to the aorta–gonad–mesonephros (AGM) by 5 weeks' gestation, the liver by 6–8 weeks and the bone marrow around the eleventh week of gestation. The AGM involutes early in the first trimester and the liver is the principal site of haemopoiesis until the end of the third trimester. The predominant lineage during fetal life is erythropoiesis but platelets and all types of leucocyte found in adult blood are also seen in the fetus from as early as 4–5 weeks' gestation.

There are a number of differences between erythropoiesis in the neonate and the adult: red cell morphology is distinctive with large numbers of crenated red cells, particularly in preterm neonates (Figure 61.1); red cell lifespan is reduced (35–50 days in preterm infants; 60–70 days in term infants), susceptibility to oxidant-induced injury is increased because of differences in the glycolytic and pentose phosphate pathways; the erythropoietin response to anaemia is blunted, and specific embryonic and fetal globin chains are synthesized (Table 61.1). The first globin chain produced is ε-globin, followed by α- and γ-globin chains. Haemoglobin F (HbF–$\alpha_2\gamma_2$) is produced from 4–5 weeks' gestation and is the predominant haemoglobin until after birth. Adult haemoglobin (HbA–$\alpha_2\beta_2$) is produced from 6–8 weeks' gestation, but remains at low levels until after birth. In term babies, the average HbF at birth is 70–80%, the HbA is 25–30%, there are small amounts of HbA2 and sometimes a trace of Hb Barts (γ_4).

Immediately after birth, rates of haemoglobin synthesis and red blood cell production fall in response to the sudden increase in tissue oxygenation at birth. In term babies, the haemoglobin reaches a mean of 13–14 g/dL at 4 weeks and 9.5–11 g/dL at 7–9 weeks of age. Studies of well preterm infants show a steeper fall in haemoglobin, reaching a mean of 6.5–9 g/dL at 4–8 weeks of
Figure 61.1 Typical erythrocyte morphology in a preterm neonate. Crenated red cells are a normal feature of the blood film of preterm neonates during the first few weeks of life. This film is from a neonate born at 26 weeks' gestation and shows the number of crenated cells present in neonates under 28 weeks' gestation. The numbers of these cells is inversely proportional to gestational age at birth.

age. The reticulocyte count falls after birth as erythropoiesis is suppressed and increases to normal values at 6–8 weeks of age. The blood volume at birth varies with gestational age and the timing of clamping of the cord. In term infants, the average blood volume is 80 mL/kg and in preterm infants 106 mL/kg (range of 85–143 mL/kg). Term and preterm babies have adequate stores of iron, folic acid and vitamin B_{12} at birth. However, stores of both iron and folic acid are lower in preterm infants and are depleted more quickly, leading to deficiency after 2–4 months if the recommended daily intakes are not maintained.

Table 61.1 Composition of haemoglobins in the human embryo, fetus and neonate.

Haemoglobin	Globin chains α-Globin gene cluster	β-Globin gene cluster*	Gestation
Embryonic			
Hb Gower 1	ξ_2	ϵ_2	From 3–4 weeks
Hb Gower 2	α_2	ϵ_2	
Hb Portland	ξ_2	γ_2	From 4 weeks
Fetal			
HbF	α_2	γ_2	From 4 weeks
Adult			
HbA	α_2	β_2	From 6–8 weeks
HbA2	α_2	δ_2	From 30 weeks

*The α-globin gene cluster is situated on chromosome 16 and the β-globin gene cluster on chromosome 11. Note that fetuses and neonates with α-thalassaemia major, who are unable to synthesize α-globin chains, will have Hb Portland as well as Hb Barts (β4), detectable by haemoglobin electrophoresis or HPLC.

Neonatal anaemia

Definition and pathophysiology

Any neonate with a haemoglobin of less than 14 g/dL at birth should be considered anaemic and may require investigation (Figure 61.2). However, it is important to be aware that the haemoglobin concentration is affected by the site of sampling (it is up to 4 g/dL lower in venous than in heel-prick samples in the first few days of life) and the timing of the clamping of the cord (around 3 g/dL higher after late clamping). The clinical significance of neonatal anaemia depends on whether the baby is able to maintain adequate tissue oxygenation. This in turn depends on the position of the haemoglobin–oxygen dissociation curve, which is principally determined by the concentrations of HbF and of 2,3-diphosphoglycerate (2,3-DPG); a high HbF and low 2,3-DPG both shift the curve to the left, i.e. the affinity of haemoglobin for oxygen is increased and less oxygen is released to the tissues. This is the situation just after birth and may be more of a problem for very preterm babies as their HbF levels are greater than 90%. Over the first few months of life, 2,3-DPG levels rise and HbF levels fall so that the haemoglobin–oxygen dissociation curve gradually shifts to the right, the oxygen affinity of haemoglobin falls and oxygen delivery to the tissues increases, ameliorating the effects of the falling haemoglobin.

Causes of neonatal anaemia

Anaemia may be caused by (i) reduced red cell production; (ii) increased red cell destruction (haemolysis); or (iii) blood loss (Table 61.2).

Table 61.2 Common causes of neonatal anaemia.

Reduced red cell production
Diamond–Blackfan anaemia
Congenital viral infections, e.g. parvovirus, cytomegalovirus
Congenital dyserythropoietic anaemia
Pearson's syndrome

Increased red cell destruction (haemolysis)
Alloimmune: haemolytic disease of the newborn (Rh, ABO, Kell, other)
Red cell membrane disorders, e.g. hereditary spherocytosis
Red cell enzyme deficiencies, e.g. pyruvate kinase deficiency
Some haemoglobinopathies, e.g. α-thalassaemia major, HbH disease

Blood loss
Occult haemorrhage before or around birth, e.g. twin–twin, feto-maternal
Internal haemorrhage, e.g. intracranial, cephalhaematoma
Iatrogenic, due to frequent blood sampling

Anaemia of prematurity
Impaired red cell production plus reduced red cell lifespan

Neonatal anaemia due to reduced red cell production

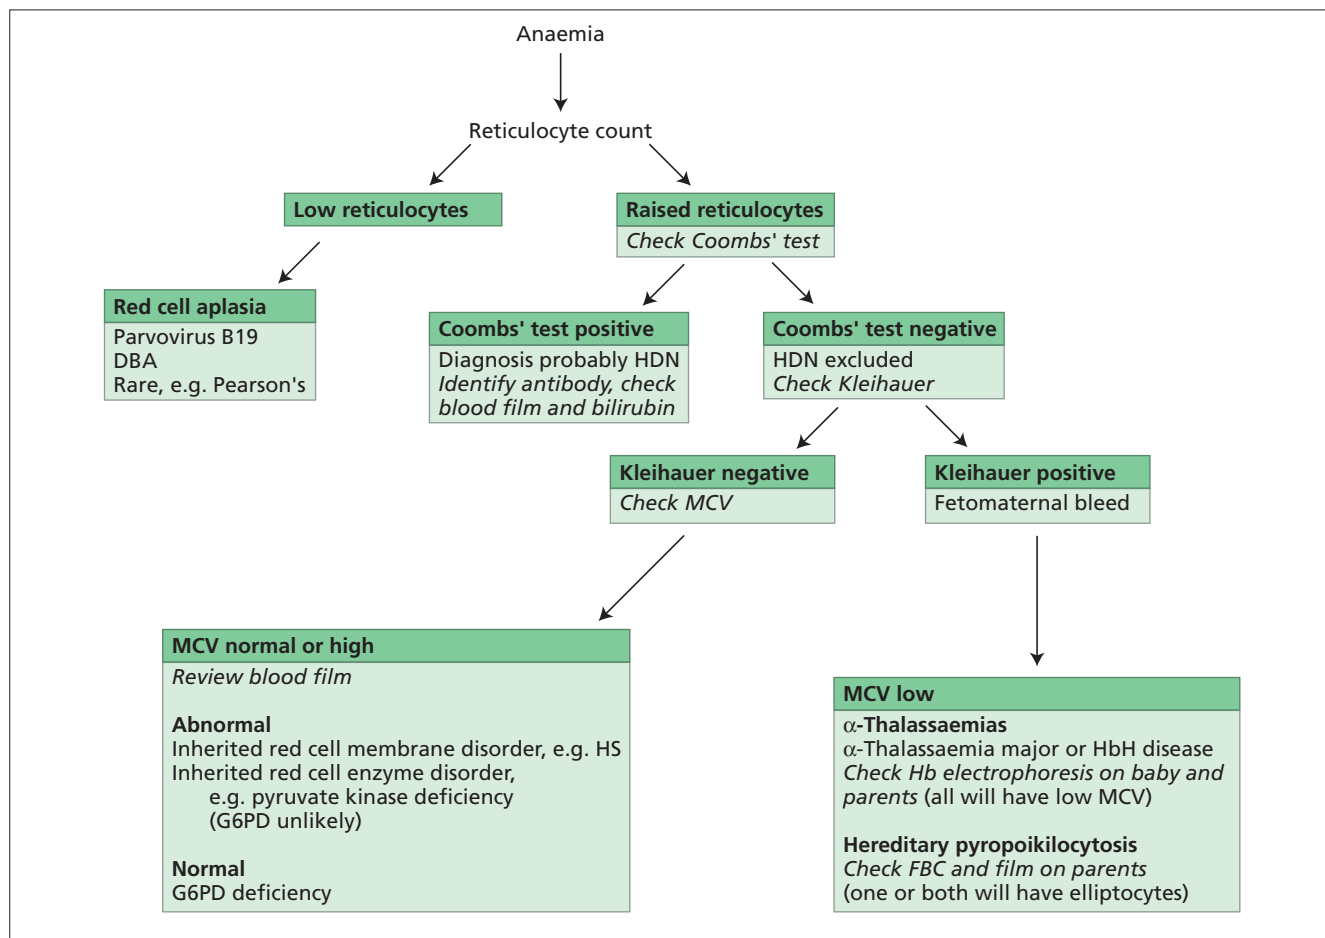
The main diagnostic clues to reduced red cell production are the combination of a low reticulocyte count ($< 20 \times 10^9$/L) with a negative direct antiglobulin test (Coombs' test). The most common causes are congenital parvovirus infection and genetic red cell aplasias, particularly Diamond–Blackfan anaemia (DBA).


Figure 61.2 A diagnostic algorithm for neonatal anaemia. The most useful screening tests for investigating unexplained neonatal anaemia are the reticulocyte (retic) count, the Coombs' test and the MCV of the red blood cells. DBA, Diamond–Blackfan anaemia; G6PD, glucose-6-phosphate dehydrogenase; HDN, haemolytic disease of the newborn; HS, hereditary spherocytosis.

Parvovirus B19 and fetal/neonatal anaemia

Maternal infection with parvovirus B19 can cause severe fetal anaemia and in 9% of cases leads to intrauterine death. The baby has marked reticulocytopenia ($< 10 \times 10^9$/L) and thrombocytopenia may also occur. The diagnosis is made by maternal serology and demonstration of B19 DNA in the fetus or neonate by dot-blot hybridization or polymerase chain reaction (PCR) of peripheral blood (bone marrow aspiration for morphology and parvovirus B19 PCR may be necessary in difficult cases). Severe cases require intrauterine transfusion but have a good long-term outcome if they survive to delivery.

Genetic red cell aplasia

Apart from DBA, the genetic causes of congenital red cell aplasia are extremely rare. They include congenital dyserythropoietic anaemia (CDA) and Pearson's syndrome; the other inherited bone marrow failure syndromes, such as Fanconi anaemia, are almost never present at birth. DBA, which occurs in five to seven babies per million live births, has a clear family history in 20% of cases (autosomal dominant or recessive) and appears to be sporadic in the remaining 80%. It usually presents as increasing anaemia over the first few weeks or months of life but more severe cases manifest as second trimester anaemia or hydrops fetalis. Around 40% of infants have associated congenital anomalies, particularly craniofacial dysmorphism, neck anomalies and thumb malformations similar to those seen in Fanconi anaemia. The blood film shows normochromic red cells with an absence of polychromasia and nucleated red cells despite severe anaemia (Figure 61.3); there is a severe reticulocytopenia and absent erythroid precursors on the bone marrow aspirate. These features are diagnostic of DBA if parvovirus infection is excluded. Raised red cell levels of adenosine deaminase (ADA) in the patient and/or parents may be useful to confirm the diagnosis, although normal red cell ADA levels
Figure 61.3 Blood film from a neonate with Diamond–Blackfan anaemia. This baby presented with fetal anaemia at 20 weeks' gestation and received intrauterine transfusion. At birth, the baby had normochromic anaemia and the blood film showed a complete absence of polychromasia and nucleated red cells, despite a haemoglobin of 7 g/dL.

Figure 61.4 Pearson's syndrome. Bone marrow aspirate from a neonate with Pearson's syndrome, showing typical vacuolation of erythroblasts and a dysplastic megakaryocyte.

do not exclude DBA. Around 25% of cases have mutations of the ribosomal protein (RP) S19 gene on chromosome 19. In the neonatal period, the only treatment of DBA is red cell transfusion.

Other genetic causes of congenital red cell aplasia, CDA and Pearson's syndrome, can be distinguished from DBA by marrow morphology. In Pearson's syndrome, which is caused by mutations in mitochondrial DNA and presents with normochromic anaemia, neutropenia, thrombocytopenia and failure to thrive in the first few weeks of life, there is highly characteristic vacuolation of early erythroid cells on the marrow aspirate (Figure 61.4). Unfortunately, the prognosis for children with Pearson's syndrome is very poor, with few surviving beyond the second year of life.

Neonatal anaemia due to increased red cell destruction (haemolysis)

The main diagnostic clues suggesting a haemolytic anaemia are: increased numbers of reticulocytes and/or circulating nucleated red blood cells (Figure 61.5), unconjugated hyperbilirubinaemia, a positive Coombs' test (if immune) and characteristic changes in the morphology of the red cells on a blood film (e.g. hereditary spherocytosis; Figure 61.5). The main cause of immune haemolytic anaemia is haemolytic disease of the newborn. The main causes of non-immune neonatal haemolysis are: red cell membrane disorders, red cell enzymopathies and, occasionally, haemoglobinopathies (Table 61.2).

Immune haemolysis, including haemolytic disease of the newborn

The principal alloantibodies causing haemolytic disease of the newborn are those against rhesus antigens (anti-D, anti-c and anti-E), anti-Kell, anti-Kidd (J^k), anti-Duffy (F^y) and antibodies

Figure 61.5 Haemolytic disease of the newborn. (a) Blood film from a neonate with ABO haemolytic disease of the newborn due to anti-A showing very large numbers of spherocytes, polychromasia and no nucleated red cells. (b) Blood film from a baby with rhesus haemolytic disease of the newborn due to anti-D showing polychromasia and large numbers of nucleated red cells but relatively few spherocytes.

(a)

(b)
of the MNS blood group system, including anti-U. Anti-D is the most frequent alloantibody causing significant haemolytic anaemia affecting 1 in 1200 pregnancies. Anti-Kell antibodies are less common but can cause severe fetal and neonatal anaemia as they inhibit erythropoiesis as well as causing haemolysis. Most babies with haemolytic disease of the newborn present with jaundice and/or anaemia; in severe cases there is hepatosplenomegaly and/or skin deposits due to extramedullary haemopoiesis. ABO haemolytic disease occurs only in offspring of women of blood group O and is confined to the 1% of such women that have high-titre IgG antibodies. Haemolysis due to anti-A is more common (1 in 150 births) than anti-B. In contrast with anti-rhesus antibodies, both anti-A and anti-B usually cause hyperbilirubinaemia without significant anaemia; however, hydrops has occasionally been described. The blood film in ABO haemolytic disease characteristically shows very large numbers of spherocytes with little or no increase in nucleated red cells (see Figure 61.5a); this contrasts with rhesus haemolytic disease of the newborn, in which there are few spherocytes and large numbers of circulating nucleated red cells (see Figure 61.5b).

Management of haemolytic disease of the newborn

All neonates at risk should have cord blood taken for measurement of haemoglobin, bilirubin and a Coombs' test and should remain in hospital until hyperbilirubinaemia and/or anaemia have been properly managed. Rhesus-alloimmunized infants with haemolysis should receive phototherapy from birth, as the bilirubin can rise steeply; this prevents the need for exchange transfusion in some infants. In haemolytic disease due to anti-Kell, anaemia is usually more prominent than jaundice and minimal phototherapy may be necessary despite severe anaemia. ABO haemolytic disease of the newborn usually just requires phototherapy as anaemia is uncommon. The indications for exchange transfusion in haemolytic disease of the newborn are:

1 severe anaemia: haemoglobin < 10 g/dL at birth and/or;
2 severe or rapidly increasing hyperbilirubinaemia.

The British Committee for Standards in Haematology (BCSH) recently published guidelines for neonatal exchange transfusion. Affected neonates may also develop 'late' anaemia at a few weeks of age, requiring 'top-up' transfusion; irradiated blood must be used for infants previously receiving intrauterine transfusion to prevent the risk of transfusion-associated-graft-versus-host disease (TA-GvHD). Recombinant erythropoietin sometimes prevents the need for 'top-up' transfusion for late anaemia but is not effective when haemolysis is brisk. Folic acid (500 μg/kg per day) should be given to all babies with haemolysis until they reach 3 months of age.

Neonatal haemolytic anaemia due to red cell membrane disorders

In neonates, these disorders present with jaundice and moderate anaemia (usually due to hereditary spherocytosis), as an incidental finding on routine blood films in the absence of jaundice or anaemia (usually hereditary elliptocytosis), or, occasionally, as severe, transfusion-dependent haemolytic anaemia with a characteristic low mean corpuscular volume (MCV) of 50–60 fL (usually due to hereditary pyropoikilocytosis, HPP). The main clues are a family history and an abnormal blood film, as red cell membrane disorders can nearly always be recognized by the characteristic shape of the red cells (Figure 61.6a). Identification of the exact type of membrane abnormality may require specialized investigations. The osmotic fragility test is of limited value in neonates and recent data suggest that the dye binding test is more useful. If the clinical phenotype is severe and family history or family studies are unhelpful, red cell membrane electrophoresis is indicated to clarify the diagnosis (on pre-transfusion blood samples to minimize diagnostic confusion due to transfused cells).

Hereditary spherocytosis occurs in 1 in 5000 live births to parents of northern European extraction. It is usually autosomal dominant and caused by mutations in spectrin, ankyrin, protein 4.1 or protein 3. The blood film shows spherocytes and is identical to that of ABO haemolytic disease (see Figure 61.6b).
(a)   (b)

Figure 61.6 Red cell membrane disorders. (a) Blood film from a baby with hereditary pyropoikilocytosis, showing microspherocytes, red cell fragments and polychromasia. (b) Blood film from a neonate with hereditary spherocytosis, showing large numbers of spherocytes and polychromasia.

Neonatal anaemia due to hereditary spherocytosis is usually moderate (7–10 g/dL); it is not uncommon for affected neonates to require one or two transfusions during the neonatal period before a transfusion-free plateau haemoglobin of 8–10 g/dL is achieved after a few months. *Hereditary elliptocytosis*, which is caused by different mutations in the genes for spectrin, ankyrin or protein 4.1, usually has no clinical manifestations in the neonate apart from elliptocytes on the blood film. However, neonates who are homozygous or compound heterozygotes for hereditary elliptocytosis mutations have severe haemolytic anaemia; the most common form is HPP. *HPP* causes severe, transfusion-dependent haemolytic anaemia. The diagnosis is easily made from the low MCV and blood films of the baby (which show bizarre fragmented red cells and microspherocytes; Figure 61.6a), and both parents (one or both of which usually have elliptocytosis). Red cell transfusion is necessary until the child is old enough to undergo splenectomy, to which there is an excellent response.

Neonatal haemolysis due to red cell enzymopathies

The commonest red cell enzymopathies presenting in the neonatal period are glucose-6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase deficiency. *G6PD deficiency* has a high prevalence in individuals from Central Africa (20%) and the Mediterranean (10%). In neonates, G6PD deficiency nearly always presents with jaundice within the first few days of life; the vast majority of affected neonates are boys, as the G6PD gene is on the X chromosome. The jaundice is often severe, whereas anaemia is extremely rare and the blood film is completely normal. The diagnosis is made by assaying G6PD on a peripheral blood sample. The pathogenesis of the jaundice is unclear as most babies with G6PD deficiency have no evidence of haemolysis. Management of neonatal G6PD deficiency requires close monitoring of the bilirubin to prevent kernicterus, particularly when interactions with other risk factors for neonatal hyperbilirubinaemia are present, such as Gilbert's syndrome or hereditary spherocytosis, and also the counselling of the babies' parents regarding which medicines, chemicals and foods may precipitate haemolysis. For the vast majority of patients there is no chronic haemolysis and no anaemia and therefore folic acid supplements are not indicated.

Pyruvate kinase (PK) deficiency is the second most common red cell enzymopathy in neonates. It is autosomal recessive and clinically heterogeneous varying from anaemia severe enough to cause hydrops fetalis to a mild unconjugated hyperbilirubinaemia. In severe cases, the jaundice has a rapid onset within 24 h of birth and exchange transfusion may be required. The diagnosis is made by measuring pre-transfusion red cell PK activity; in mild cases the PK activity may be relatively modestly reduced making the diagnosis difficult and it is often useful to assay levels in the parents for confirmation. The blood film is sometimes distinctive but more often shows non-specific changes of non-spherocytic haemolysis. Management in the neonatal period depends on the severity of the jaundice and anaemia; some, but not all, children are transfusion dependent and folic acid supplements should be given to prevent deficiency due to chronic haemolysis. The other red cell enzymopathies are rare. The most important in the neonatal period is *triosephosphate isomerase deficiency*, as one-third of patients present with neonatal haemolytic anaemia, often many months before the devastating neurological features of this disorder become apparent.

Neonatal haemolysis due to haemoglobinopathies

The only haemoglobinopathy that presents typically in the neonatal period is α-thalassaemia major, as all 4 α-globin genes are deleted. Occasional non-thalassaemic, structural α- and γ-globin gene mutations, which are clinically completely silent in adults and children, cause transient neonatal haemolytic anaemia in the neonate because they are unstable (e.g. Hb Hasharon, Hb Poole), whereas the major β-globin haemoglobinopathies (sickle cell disease and β-thalassaemia major) rarely manifest clinically in neonates.

α-Thalassaemia major predominantly affects families of South-East Asian, Mediterranean or Middle Eastern origin, and presents with second-trimester fetal anaemia or hydrops fetalis, which is fatal within hours of delivery. The only long-term survivors of α-thalassaemia major are those who have received intrauterine transfusions followed by regular post-natal transfusions and/or a bone marrow transplant. There is also a high incidence of hypospadias and limb defects in survivors and others have severe neurological problems. If intrauterine transfusions are delayed until anaemia is severe, neonatal pulmonary hypoplasia is a cause of early mortality. The diagnosis of α-thalassaemia major should be suspected in any case of severe fetal anaemia that presents in the second trimester, and any case of hydrops fetalis with severe anaemia in which the parents come from high-prevalence areas, particularly South-East Asia. Checking the blood counts of the parents will immediately identify whether they are at risk of having a child with α-thalassaemia major – both parents will have hypochromic, microcytic red cell indices (MCV usually < 74 fL and mean corpuscular haemoglobin (MCH) usually < 24 pg). The diagnosis of α-thalassaemia major is confirmed by haemoglobin electrophoresis or HPLC (which shows Hb Barts, Hb Portland and sometimes HbH; HbF and HbA are absent); the blood film shows hypochromic, microcytic red cells with vast numbers of circulating nucleated red cells (Figure 61.7).

Neonatal anaemia due to blood loss

Blood loss as a cause of neonatal anaemia may be very obvious, e.g. a cephalhaematoma or rupture of the cord, or be concealed and easy to miss unless specifically sought (e.g. feto-maternal bleeds). Usually, the most serious blood loss occurs prior to delivery and important causes of this are twin–twin transfusion and feto-maternal blood loss. *Twin–twin transfusion* occurs in monochorionic twins with monochorial placentas. If the
Figure 61.7 α-Thalassaemia major. Blood film from a neonate with α-thalassaemia major, born at 28 weeks' gestation, showing severe hypochromia, microcytosis, target cells, polychromasia and nucleated red cells.

bleeding is chronic, there may be a marked difference in birth-weight between twins: the donor twin is smaller, pale, lethargic and may have overt cardiac failure; the recipient twin may be plethoric, with hyperviscosity and hyperbilirubinaemia and may rarely have a haemoglobin as high as 30 g/dL.

Feto-maternal haemorrhage occurs spontaneously or secondary to trauma usually in the third trimester. Most episodes involve very small quantities of blood (0.5 mL or less) but acute loss of > 20% of the blood volume may cause intrauterine death, circulatory shock or hydrops. Diagnostic clues are anaemia at birth in an otherwise well baby with no or minimal jaundice. The most useful diagnostic tests are a Coombs' test to exclude immune haemolysis, a reticulocyte count to exclude red cell aplasia, a Kleihauer test on maternal blood to quantify the number of HbF-containing fetal red cells in the maternal circulation and a blood film (Figure 61.8). Blood loss around the time of delivery is usually due to obstetric complications (e.g. placenta praevia, placental abruption); in these circumstances, the babies are often extremely ill, with circulatory shock, anaemia worsening rapidly after birth, large numbers of circulating nucleated red cells and disseminated intravascular coagulation (DIC).

Anaemia of prematurity

The normal fall in haemoglobin in preterm neonates has been termed 'physiological anaemia of prematurity', as it does not appear to be associated with any abnormalities in the baby. The pathogenesis is not fully elucidated but contributory factors include the reduced red cell lifespan of fetal erythrocytes, the relatively low erythropoietin concentration, the rapid growth rate and iatrogenic blood loss. Routine supplementation of preterm neonates with folic acid and iron means that nutritional deficiency rarely plays a role. The diagnosis is usually straightforward – a well preterm baby with a slowly falling haemoglobin, unremarkable blood film showing normochromic/normocytic red cells, slightly low reticulocytes (20×10^9/L) and no nucleated red cells.

Management of anaemia of prematurity and the role of erythropoietin

The severity of anaemia of prematurity and thereby the need for red cell transfusion can be reduced by: (i) limiting iatrogenic blood loss by appropriate use of blood tests; (ii) administering iron and folate supplements to all preterm infants (iron 3 mg/kg per day from 4–6 weeks of age or iron-fortified formula with 0.5–0.9 mg/dL of iron and folic acid 50 μg daily or 500 μg once weekly); and (iii) judicious use of erythropoietin. The many controlled trials of recombinant erythropoietin for prevention of neonatal anaemia have been reviewed extensively. Erythropoietin reduces the number of transfusions in relatively well infants with low transfusion requirements, but not in sick preterm infants who have a need for frequent phlebotomy and multiple transfusions. The main roles for recombinant erythropoietin in

Twin–twin transfusion
Delayed clamping of the cord
Endocrine disorders: thyrotoxicosis, congenital adrenal hyperplasia

neonates are in ameliorating the anaemia in infants who have received intrauterine transfusions for alloantibody-mediated anaemia and in preterm babies of Jehovah's Witnesses. The usual dose is 300 μg/kg of epoietin-β by subcutaneous injection three times per week, starting in the first week of life, together with oral iron supplements.

Indications for red cell transfusion in neonatal anaemia

The BCSH recently revised their guidelines for transfusion of fetuses, neonates and older children; the guidelines contain recommendations about the products and indications for red cell transfusion in neonates. These are consensus guidelines and need to be adapted for use in each individual Neonatal Intensive Care Unit, depending on the case mix of babies, as adherence to strict neonatal transfusion guidelines reduces both the number of transfusions and donor exposure.

A simple diagnostic approach to neonatal anaemia

Red cell disorders associated with neonatal or fetal anaemia present in three main ways: with a low haemoglobin, with jaundice due to haemolysis or with hydrops. A diagnostic algorithm to help identify which of these causes is most likely, which can be excluded and what further investigations are most appropriate is shown in Figure 61.2.

Neonatal polycythaemia

For both term and preterm infants, polycythaemia can be defined as a central venous haematocrit of greater than 0.65, as there is an exponential rise in blood viscosity above this level. However, even at haematocrits greater than 0.70, only a minority of neonates have clinical signs of hyperviscosity, such as lethargy, hypotonia, hyperbilirubinaemia and hypoglycaemia. Causes of polycythaemia are shown in Table 61.3. Treatment is controversial and is not necessary in infants with very minor symptoms (e.g. borderline hypoglycaemia or poor peripheral perfusion). Infants with neurological signs and a haematocrit greater than 0.65 should have a partial exchange transfusion (using a crystalloid solution such as normal saline) to reduce the haematocrit to 0.55.

White cell disorders

Normal values

In the neonate, normal values for leucocytes, in particular for neutrophils, are affected by a number of factors including gestational age, post-natal age, antenatal history, perinatal history and ethnic origin. Neutrophil counts in healthy babies increase for the first 12 h then fall to a nadir at 4 days of age. The neutrophil count is higher in capillary samples and after vigorous crying; it is lower in neonates of African origin. Healthy preterm babies often have circulating myeloblasts and lymphoblasts, although these usually form less than 5% of the white cell differential count.

Neutropenia

A pragmatic approach is to consider a neutrophil count at birth of less than 2×10^9/L as abnormal and worth monitoring, and a neutrophil count during the first month of life of less than 0.7×10^9/L as significant enough to merit further investigation.

Causes of neutropenia

The commonest cause of neutropenia at birth in preterm neonates is reduced neutrophil production, secondary to intrauterine growth restriction or maternal hypertension. Most affected neonates also have thrombocytopenia and increased erythropoiesis (polycythaemia and/or increased circulating nucleated red cells), secondary to fetal tissue hypoxia. The neutropenia resolves spontaneously usually within a few days of birth. The commonest cause of neutropenia in term infants is bacterial or viral infection. Other important causes of neutropenia are alloimmune neutropenia and congenital neutropenia due to failure of neutrophil production (e.g. Kostmann's syndrome), both of which predispose to severe neonatal infection.

Alloimmune neutropenia is the neutrophil equivalent of haemolytic disease of the newborn and alloimmune thrombocytopenia, and may affect 3% of all deliveries. It occurs when fetal neutrophils express paternally derived neutrophil-specific antigens absent on maternal neutrophils and against which the mother produces immunoglobulin G (IgG) neutrophil alloantibodies. The causative antibodies are usually anti-NA1 or -NA2. It presents in the first few days of life with fever and infections of the respiratory tract, urinary tract and skin, particularly due to *Staphylococcus aureus*, and the mainstay of treatment is antibiotics. The diagnosis is made by demonstrating antineutrophil antibodies in the mother and baby, which react against paternal, but not maternal, neutrophil antigens. The neutropenia is self limiting, usually resolving within 1–2 months.

Congenital and inherited neonatal neutropenias should be sought when the neutropenia is prolonged, if there is a relevant family history or consanguinity or if the baby has typical dysmorphic
Figure 61.9 Transient leukaemia in a neonate with Down's syndrome. Leucoerythoblastic blood film showing increased numbers of blast cells, which spontaneously returned to normal by 2 months of age.

features (e.g. thumb/radial abnormalities in Fanconi's anaemia). Kostmann's syndrome (severe congenital neutropenia) is the most likely cause in the neonatal period. Infants usually present with severe infections and a marked neutropenia ($< 0.2 \times 10^9$/L), often with a compensatory monocytosis. The diagnosis is made by the severity of the neutropenia, the bone marrow appearance ('arrest' of differentiation at the myelocyte/promyelocyte stage) and the absence of antineutrophil antibodies. The inheritance of Kostmann's syndrome can be autosomal recessive or dominant; recently, several cases of Kostmann's syndrome have been found to be due to mutations in the neutrophil elastase gene.

Congenital leukaemias

The most common types are acute monoblastic leukaemia and acute megakaryoblastic leukaemia; acute megakaryoblastic leukaemia is particularly common in babies with Down's syndrome. The babies present with signs of anaemia, thrombocytopenia and/or skin lesions caused by leukaemic infiltration. The blood film and bone marrow aspirate show large numbers of primitive blast cells. The prognosis is extremely poor; few are cured by chemotherapy and bone marrow transplantation may be the best option. Around 10% of neonates with Down's syndrome have a transient megakaryoblastic leukaemia also known as transient abnormal myelopoiesis (TAM) or transient myeloproliferative disorder (TMD), characterized by leucocytosis and circulating blast cells (Figure 61.9). Most cases spontaneously resolve within 2–3 months and no treatment is indicated, but around 10% evolve to acute megakaryoblastic leukaemia. Mutations in GATA-1 have been reported recently, both in TAM and in the megakaryoblastic leukaemia associated with Down's syndrome.

Haemostasis and thrombosis in the newborn

Bleeding and thrombotic problems are relatively common in neonates, particularly in those who are preterm and/or sick, and the number of genetic and acquired causes of thrombophilia that can be identified in neonates and their families is rising.

Developmental haemostasis

Coagulation proteins are present at measurable levels from the tenth week of gestation and gradually rise during fetal life. They do not cross the placenta, or do so in very small amounts, and therefore need to be independently synthesized by the fetus. 'Normal values' in the neonate vary not only with gestational but also with post-natal age. Data for babies at less than 30 weeks' gestation derive from fetoscopy samples: levels of the vitamin K-dependent factors (II, VII, IX and X) and of factors XI and XII are all low (< 40% of adult values) and remain so during the first month of life. By contrast, even in preterm babies (> 30 weeks), levels of Factor V, Factor XIII and fibrinogen are normal at birth and levels of factor VIII and von Willebrand factor (vWF) are normal or increased. Platelet counts at birth in term and preterm neonates are within the normal adult range. Many studies have found impaired function of neonatal platelets *in vitro* in term and preterm infants; the most consistent abnormalities are reduced aggregation in response to adrenaline, ADP and thrombin. Their significance in clinical practice is unclear as the bleeding time is normal in term and preterm infants (≤ 135 s).

Screening tests for bleeding disorders

Nearly all significant bleeding disorders in neonates can be identified using simple screening tests; exceptions are factor XIII deficiency and platelet function disorders. It is often helpful to test both parents for coagulation abnormalities to help identify inherited disorders as there is considerable overlap between the deficiency states and the lower limit of normal. The most useful screening tests in neonates are: the prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin time (TT), fibrinogen and platelet count. Bleeding times are generally unhelpful in neonates and investigation of platelet function abnormalities is often deferred until a few months of age when platelet aggregometry and PFA-100™ become practical.

Inherited coagulation disorders

The commonest inherited disorders presenting in the neonatal period are factor VIII deficiency (haemophilia A), which has a frequency of 1 in 5000 male births and factor IX deficiency (haemophilia B), which occurs in 1 in 30 000 male births.

Factor VIII deficiency

Almost 40% of patients with inherited factor VIII deficiency present in the neonatal period. The clinical signs include intracranial haemorrhage, cephalohaematomas and bleeding post circumcision or from venous or arterial puncture sites. As in adults, the diagnosis is made by finding an isolated prolonged APTT and reduced factor VIII clotting activity. Acute management of the bleeding neonate with haemophilia requires intravenous administration of recombinant factor VIII (50–100 units (u)/kg intravenously, twice daily) to achieve factor VIII levels of 1.0 u/mL. As the half-life of factor VIII is shorter than in adults, more frequent dosing or a continuous factor VIII infusion may be required. For neonates with intracranial bleeding treatment with factor VIII should continue for at least 2 weeks. Fibrin glue may be useful in circumcision-associated bleeds. For patients diagnosed prenatally, vaginal delivery is safe provided that no difficulties are anticipated and vacuum extraction is avoided. The role of prophylactic factor VIII administration to haemophiliac newborns following difficult delivery to reduce the risk of intracranial bleeding (1–4%) is controversial, but it seems reasonable to recommend prophylactic factor VIII for a newborn haemophiliac when a previous sibling has had a major intracranial bleed.

Factor IX deficiency

This is clinically indistinguishable from Factor VIII deficiency. As factor IX levels are also low in liver disease and vitamin K deficiency, it is important to recheck factor IX levels at 6 weeks and 6 months of age if the diagnosis is in doubt. Neonates with bleeding are treated with recombinant factor IX concentrate (100 u/kg intravenously, once daily, monitored to achieve a factor IX level of 1.0 IU/mL).

von Willebrand disease in neonates

The two forms of von Willebrand disease (vWD) that can present in neonates are type 2b vWD, which presents with thrombocytopenia and bleeding is uncommon, and type 3 vWD, which has a clinical phenotype similar to haemophilia, as levels of both vWF and factor VIII are low. Type 3 vWD is autosomal recessive. The diagnosis is made by measuring vWF, factor VIII and the pattern of vWF multimers. At present, type 3 vWD is treated with intermediate purity FVIII (Haemate-P is the most commonly used product).

Factor XIII deficiency

This rare, autosomal recessive disorder usually presents with delayed bleeding from the umbilical cord during the first 3 weeks of life. The diagnosis is made by measuring clot solubility in 5 M urea solution as a screening test followed by a specific factor XIII assay; molecular tests for the common mutations are also available. The routine diagnostic coagulation screen is normal. Bleeding is treated with FXIII concentrate; cryoprecipitate (10 mL/kg) can also be used.

Acquired disorders of coagulation

Causes of acquired coagulopathy in neonates include vitamin K deficiency, DIC, liver disease, metabolic disorders, extracorporeal membrane oxygenation and giant haemangioendotheliomas (Kasabach–Merritt syndrome).

Vitamin K deficiency

Levels of vitamin K-dependent procoagulant factors (factors II, VII, IX and X), protein C and protein S are low at birth because of poor placental transfer of vitamin K, low vitamin K stores at birth, low vitamin K in breast milk and the lack of bacterial vitamin K synthesis in the sterile neonatal gut. Vitamin K deficiency can lead to 'haemorrhagic disease of the newborn' (also known as vitamin K deficiency bleeding, VKDB). Early VDKB presents in the first 24 h of life with severe gastrointestinal and intracranial haemorrhage. It is usually due to maternal medication that interferes with vitamin K, e.g. anticonvulsants (phenobarbitone, phenytoin), antituberculous therapy and oral anticoagulants. Classical VDKB presents at 2–7 days in 0.25–1.7% of babies who have not received prophylactic vitamin K at birth, especially if breast fed or with poor oral intake. Late VKDB occurs between 2 and 8 weeks after birth and presents with sudden intracranial haemorrhage in an otherwise well, breast-fed term baby or in babies with liver disease.

The diagnosis of VKDB is usually made by an isolated prolonged PT, which corrects following vitamin K administration. If doubt remains, assays of the inactive form of factor II (decarboxyprothrombin; PIVKA II) can be used to confirm the diagnosis. Treatment of VKDB is vitamin K (1 mg) intravenously or subcutaneously with fresh-frozen plasma only in severe haemorrhage. Classic and late VKDB can be prevented by a single intramuscular dose of vitamin K or, slightly less effectively, by repeated oral doses of vitamin K over the first 6 weeks of life. Some studies, but not others, suggest a link between intramuscular vitamin K at birth and later childhood malignancies (see reviews). In healthy babies, the choice of which route of administration is increasingly being left to parents.

Disseminated intravascular coagulation

The main triggers of DIC in neonates are severe hypoxia and/or acidosis and sepsis. It occurs in sick neonates and presents with generalized bleeding, including pulmonary haemorrhage and oozing from venepuncture sites. The usual pattern of coagulation abnormalities in neonatal DIC is prolongation of the PT, APTT and TT, together with low platelets and fibrinogen. D-Dimers are increased but are not specific and can be found in healthy neonates with no evidence of coagulopathy. The most important aspect of management of DIC is treatment of the underlying cause. Blood product replacement is indicated for clinical bleeding aiming to maintain the platelet count above 30×10^9/L and the fibrinogen greater than 1 g/L.

Table 61.4 Causes of neonatal thrombocytopenia.

Early (< 72 h)
Placental insufficiency (PET, IUGR, diabetes)
Neonatal alloimmune thrombocytopenia
Birth asphyxia
Perinatal infection (group B *Streptococcus*, *Escherichia coli*, *Listeria*)
Congenital infection (CMV, toxoplasmosis, rubella)
Maternal autoimmune (ITP, SLE)
Severe rhesus HDN
Thrombosis (renal vein, aortic)
Aneuploidy (trisomy 21, 18, 13)
Congenital/inherited (TAR, Wiskott–Aldrich)

Late (> 72 h)
Late-onset sepsis and necrotizing enterocolitis
Congenital infection (CMV, toxoplasmosis, rubella)
Maternal autoimmune (ITP, SLE)
Congenital/inherited (TAR, Wiskott–Aldrich)

CMV, cytomegalovirus; HDN, haemolytic disease of the newborn; ITP, idiopathic thrombocytopenic purpura; IUGR, intrauterine growth restriction; PET, pre-eclampsia; SLE, systemic lupus erythematosis; TAR, thrombocytopenia with absent radii.

Neonatal thrombocytopenia

Thrombocytopenia occurs in 1–5% of all neonates and up to 50% of neonates who are preterm and sick. It usually presents in one of two clinical patterns: early thrombocytopenia (within 72 h of birth) and late thrombocytopenia (after 72 h of life) (Table 61.4). The most frequent causes of early thrombocytopenia in preterm infants are intrauterine growth restriction and maternal hypertension or diabetes; the most frequent causes in term infants are neonatal alloimmune thrombocytopenia (NAITP) and thrombocytopenia secondary to maternal immune thrombocytopenic purpura (ITP). The most common causes of late thrombocytopenia are sepsis and necrotizing enterocolitis.

Neonatal alloimmune thrombocytopenia

This is the platelet equivalent of haemolytic disease of the newborn and affects around 1 in 1000 pregnancies. It is frequently severe (platelet count $< 30 \times 10^9$/L) and occurs in the first pregnancy in almost 50% of cases. Thrombocytopenia results from transplacental passage of maternal platelet-specific antibodies to human platelet antigens (HPA), which the mother lacks but which the fetus inherits from the father. In 80% of cases, these are anti-HPA-1a antibodies and in 10–15% anti-HPA-5b; occasional cases are due to anti-HPA-3a. HLA DRB3*0101-positive women are 140 times more likely to make anti-HPA-1a than HLA DRB3*0101-negative women. Intracranial haemorrhage occurs in 10% of cases, with long-term neurodevelopmental sequelae in 20% of survivors.

The diagnosis is made by demonstrating platelet antigen incompatibility between mother and baby and anti-HPA antibodies in the mother. Transfusion with HPA-compatible platelets is recommended for neonates with platelets $< 30 \times 10^9$/L and/or those with bleeding. Intravenous IgG (total dose 2 g/kg, over 2–5 days) may be useful if thrombocytopenia is prolonged. Pre-natal management of NAITP is controversial. The options are an invasive approach using fetal blood sampling plus fetal transfusion with HPA-compatible platelets if thrombocytopenia is detected, or a non-invasive approach relying on maternal intravenous IgG therapy.

Neonatal autoimmune thrombocytopenia

This is secondary to transplacental passage of maternal platelet autoantibodies in maternal ITP and systemic lupus erythematosus (SLE), which affects 1–5 in 10 000 pregnancies. Around 10% of infants develop thrombocytopenia, which is severe in less than 1%. In babies with severe thrombocytopenia, intravenous IgG is usually effective.

Indications for platelet transfusion

A number of countries have published consensus guidelines to help decide the indications for platelet transfusion in term and preterm neonates. In general, platelet transfusion is not considered necessary in well babies if the platelet count is above $20–30 \times 10^9$/L. Most groups agree that the threshold for transfusing sick babies, particularly preterm babies in the first few weeks of life, should be higher ($30–50 \times 10^9$/L).

Neonatal thrombosis: physiology and developmental aspects

Neonates have an increased risk of thrombosis (2.4 per 1000 hospital admissions) compared with older infants and children. This is largely due to the physiologically low levels of many of the inhibitors of coagulation and the frequent use of in-dwelling vascular catheters. Concentrations of antithrombin, heparin cofactor II and protein C are decreased at birth; protein S levels are also low but overall protein S activity is normal as it exists mainly in its free active form due to the virtual absence of its binding protein (c4b-BP) in neonates. Levels of plasminogen at birth are only 50% of adult values so neonates have a reduced ability to generate plasmin in response to fibrinolytic agents.

Screening tests for thrombophilia in neonates

The only inherited deficiencies for which there is a proven role in neonatal thrombosis are deficiencies in proteins C and S, which cause purpura fulminans. Factor V Leiden and the prothrombin 202010A promoter mutation (prothrombin[20210A]) have not yet been reported to cause neonatal thrombotic problems in isolation. Recent guidelines from the Haemostasis and Thrombosis Task Force of the BCSH state that congenital thrombophilia should be considered and screened for in any child with:

- clinically significant thrombosis, including spontaneous thrombotic events, unanticipated or extensive venous thrombosis, ischaemic skin lesions or purpura fulminans; and
- a positive family history of neonatal purpura fulminans.

The screening tests that should be performed in all suspected cases of thrombophilia are:
- protein C activity;
- protein S;
- antithrombin;
- factor V Leiden;
- prothrombin[20210A].

In addition, babies with thrombosis who are born to mothers with SLE and/or antiphospholipid syndrome should be tested for lupus anticoagulant, as antiphospholipid antibodies may cross the placenta and are a rare cause of neonatal thrombosis in such babies. The relevance of serum liporotein a and the MTHFR genotype to neonatal management is unclear at present.

Inherited thrombotic disorders in neonates

Proteins C and S deficiency

Protein C deficiency occurs in 1 in 160 000–360 000 births. Affected babies usually present with purpura fulminans within hours or days of birth, in which there is DIC and rapidly progressive, life-threatening, haemorrhagic necrosis due to dermal vessel thrombosis or with cerebral, renal vein or ophthalmic thrombosis. The diagnosis of protein C deficiency is made by the clinical picture and undetectable levels of protein C (< 0.01 u/mL) in the patient, together with heterozygote levels in the parents. Protein C deficient heterozygotes rarely present as neonates and have low protein C levels, which may overlap with the lower limit of normal in the first few months of life, delaying diagnosis until 6 months or later. The treatment is with protein C concentrate (40 u/kg, aiming to maintain a plasma level of > 0.25 u/mL). Protein S deficiency presents with identical features; levels of protein S are undetectable (< 0.01 u/mL) and the treatment is with fresh-frozen plasma (10–20 mL/kg) to maintain a plasma protein S of > 0.25 u/mL.

Antithrombin deficiency

Homozygous antithrombin deficiency usually presents later in childhood but neonatal deep venous thrombosis and inferior vena caval thrombosis have been reported. Heterozygous antithrombin deficiency is more common (1 in 2000–5000 births); it usually presents in the second decade of life but neonatal presentation with aortic thrombosis, myocardial infarction and cerebral dural sinus thrombosis may occur.

Acquired thrombotic problems in neonates

The most common risk factors for neonatal thrombosis are an intravascular catheter and shock, secondary to sepsis, hypoxaemia or hypovolaemia. Thrombosis particularly affects the renal veins, the aorta, aortic arch or cerebral vessels. Catheter-related thrombosis causes more than 80% of venous thromboses and more than 90% of arterial thromboses. The diagnosis is made by Doppler ultrasound or contrast angiography. Treatment of catheter-related thrombosis depends on the severity and extent of thrombosis. The first step is prompt removal where possible. If signs progress despite catheter removal, unfractionated heparin or low-molecular-weight heparin (LMWH) should be started using a dosing regime adapted for neonates. Thrombolytic therapy with urokinase or tissue plasminogen activator (tPA) has been used successfully for catheter-related thrombosis in neonates, but experience in preterm neonates is very limited. It is important to maintain the fibrinogen at levels less than 1 g/L and the platelet count greater than 50×10^9/L in neonates receiving thrombolytic therapy and heparin (starting dose 28 IU/kg/h) is often given to maintain vessel patency after thrombolytic therapy, although there is no evidence that this is beneficial.

Laboratory practice

S Mitchell Lewis

62

Introduction

The practice of haematology is diverse, encompassing clinical medicine, laboratory technology, blood transfusion, aspects of histopathology, DNA analysis and genetics. The medically qualified haematologist has been concerned traditionally with both the diagnostic laboratory and clinical management of patients with blood diseases. Management of patients with haematological disorders has become increasingly arduous, requiring the haematologist to acquire unique clinical skills; conversely, major developments in laboratory practice require a high level of technical expertise, especially in handling automated instruments and information technology. It is essential that the medical haematologist becomes conversant with modern laboratory practice as he or she has an important role in maintaining the link between laboratory and clinic, ensuring that the laboratory serves clinicians from all specialties authoritatively and reliably, guiding diagnosis and management of patients as well as the needs of health surveillance for the community in general. This chapter describes the aspects of laboratory practice that are especially important towards these goals.

Good laboratory practice ensures that reliable results of clinically relevant laboratory tests are received by the clinician in good time, that the laboratory functions efficiently and economically, and that there is adequate protection of the health and well-being of the staff. It is essential to avoid faults that may lead to misdiagnosis and patient mismanagement, unnecessary over-investigation, delay in treatment while awaiting the laboratory report and, ultimately, loss of credibility of the laboratory service. The rules that govern the laboratory are no different to those established by industry for good manufacturing practice; they highlight the fact that good management is as important as technical skill if the objectives are to be attained.

The following aspects of laboratory function will be discussed:
• *quality assurance* – various procedures that are directly concerned with test reliability;
• *clinical reliability* – use of appropriate test methods or analytical systems, test interpretation, relevant reference ranges, specimen collection and sampling;
• *staff* – health and safety control, professional education and training opportunities, clinical and technical audit, involvement in management with delegated responsibilities, and confidence in the management;
• *organization and management* – strategic planning, budget control, computer applications, record-keeping, application of up-to-date methods and adherence to mandatory regulations.

Quality assurance

For reliable test results it is important to ensure *precision* (i.e. reproducibility within agreed limits when an analysis is performed repeatedly on the same specimen), *accuracy* (i.e. truth), *standardization* and *harmonization* (i.e. comparability of results between laboratories). Different procedures are used in respect of quantitative, semi-quantitative and qualitative tests. Precision in quantitative tests, expressed as coefficient of variation of the measurements ($CV\%$), is relatively easy to achieve. Accuracy is more problematic for most haematology tests, as there are few internationally established reference standards, and standardization is usually based on calibration by arbitrary standard preparations or by using standardized methods. But the most important criterion is *harmonization* to ensure comparability of measurements between laboratories, for the benefit of both the individual patient, who may be seen at different times in different clinics, and for collaborative studies, such as therapeutic trials, which may be undertaken at different centres.

There are five components in a quality assurance programme:
- standardization and instrument calibration;
- internal quality control (IQC);
- statistical control with patient data;
- correlation assessment;
- external quality assessment (EQA).

Standardization

Most modern analysers are arbitrary comparators rather than absolute measurement devices. To perform reliably they must be calibrated; thus correct measurements on test samples depend on the accuracy of the value that has been assigned to the calibrator.

Generally, calibrators are provided by the instrument manufacturers or are available from commercial companies; their reliability depends on the efforts made by the manufacturers to establish their true value. Control preparations (see below) also have assigned values, but these are only approximations, and controls should not be used as calibrators. Wherever possible, calibrators should be directly traceable to an international (primary) standard with exactly defined physical or chemical measurement.

Where no reference standards are available, harmonization depends on adherence to written standards and practice guidelines such as those published by WHO and the International Council for Standardization in Haematology (ICSH), which are listed on their websites (p. 1018). Similar documents have been published by various national authorities, taking account of specific situations. Thus, in the UK this is undertaken by the British Committee for Standards in Haematology (BCSH). In the USA, a wide range of practice guidelines have been published by the National Committee for Clinical Laboratory Standards (NCCLS).

Internal quality control

Internal quality control (IQC) is intended to ensure that measurements are sufficiently precise day by day or batch by batch within established limits. The advent of automation in the diagnostic laboratory and the increasing dependence on machine-generated results for analytical tests highlight the importance of an IQC programme. Results on patients' samples should not be issued until it is clear from the control data that there has been no significant problem in the analytical procedure. There are several methods of IQC which complement each other.

The best known method is to test a control sample at intervals alongside the routine specimens, and to plot the results on a Levey–Jennings control chart. This is a linear graph showing the mean and limits of standard deviation (SD) at 1SD and 2SD. The results of sequential (daily) measurements are plotted on the graph (Figure 62.1). When the system is in good control, not more than 1 in 20 measurements should fall outside 2SD. When two or more consecutive measurements are outside this limit there is likely to have been a random error, whereas several consecutive values within 2SD, but all on one side of the mean, indicate a consistent bias. A wildly deviant result outside 3SD may occur as a result of a gross error ('blunder').

Delta check

This refers to comparison between consecutive tests on a patient within 1–2 weeks. Account must be taken of the diurnal physiological variation and the expected coefficient of variance of the instrument. Provided that there is no clinical explanation, a difference outside these limits should alert the user to a technical error or a faulty specimen due to wrong labelling, clots, inadequate mixing or storage deterioration. This is, however, a relatively crude method of control: if a narrow limit is set, an excessive number of cases will be included, whereas a wider limit will be too insensitive. The following is a rough guide to acceptable limits of difference (i.e. increase or decrease) from the previous result for some tests: Hb 2 g/dL; mean corpuscular volume (MCV) 6 fL; mean corpuscular haemoglobin (MCH) 5 pg; platelet count 50% difference from previous result; white blood cell (WBC) normal count becoming high or low.

Statistical control with patient data

This method of control is based on the principle that the overall daily means of the blood count parameters will remain constant, provided that the proportion of different categories of patients in a hospital remains more or less the same. The calculations are adjusted by means of an algorithm to obtain a weighted moving average. This procedure has been incorporated in multichannel analysers to provide an automated continuously updated control of accuracy (Figure 62.2). It will detect analytic drift and a change in calibration; instrument imprecision will be detected by an increase in the SD.

Correlation assessment

A control chart will not detect 'blunders' in individual routine specimen, which can only be detected by finding that the test results do not correlate with other laboratory tests or the clinical condition. These discrepancies can be checked by (i) cumulative reports; (ii) blood film examination; (iii) patient's clinical state; and (iv) whether the blood count is consistent with the results of other investigations.

Cumulative reports may be computer printed or entered manually on a pre-printed record sheet. It is then possible to see, at a glance, whether there has been a single discrepant result or an unexpected alteration in the gradient of the rise or fall in blood count parameters, which would have been expected from the progression of the clinical condition or its predictable response to therapy. If no clinical reason is apparent to explain a

Figure 62.1 Quality control with the Levey–Jennings chart. (a) The established means with ± 2SD values of the control specimen for red cell parameters are indicated, and the results obtained in the laboratory are plotted sequentially. Note occurrence of a bias in HCT and MCV; recalibration of the instrument corrected this discrepancy. (b) The results on the control sample for WBC and differential count. The WBC (but not the differential count) showed some variable bias, indicating a fault that required correction.
Figure 62.2 Control of stability of daily means. The predetermined constant daily mean and ± 2SD limits for satisfactory control on each parameter are indicated on the left. The results obtained in the laboratory are displayed on the right. Note the highlighted (crosses) variant results which were subsequently corrected.

(a)

(b)

(c)
Figure 62.3 Examples of discrepancies in blood count parameters identified from blood film. (a) Low platelet count due to platelet clumping; (b) analyser fails to discriminate markedly microcytic red cells from platelets; (c) analyser fails to discriminate macrothrombocytes from red cells.

discrepancy, the test results must be suspect until it is confirmed by a repeat test on a fresh specimen. The occurrence of a similar discrepancy in two different specimens on the same day would indicate a specimen mix-up.

With the advent of fully automated analysers that include differential cell counting, the blood film is becoming sidelined. It is, however, important to appreciate that the analyser may fail to detect a diagnostically important feature or, conversely, misinterpret an artifact that would be identified on a blood film. Morphological features such as hypochromasia, macrocytosis and microcytosis are the basic criteria for identifying the cause of anaemia. Whereas flow cytometers are generally more reliable than examination of a blood film for judging the degree of hypochromasia and distinguishing marginal macrocytosis and microcytosis, gross discrepancies between the blood count parameters obtained by the analyser and the morphological impression should always be checked. A glance at a blood film will confirm or refute an abnormally high or low leucocyte or platelet count. This is especially important if there are no previous reports for reference.

Artefacts that give rise to spurious blood count parameters include:

1 An apparent leucopenia and thrombocytopenia due to partial clotting of the specimen. This may be detected in the film by the presence of a mass of aggregated platelets (Figure 62.3a).

2 Abnormally high MCH and mean cell haemoglobin concentration (MCHC) due to the presence of cold agglutinins or autoimmune haemolytic anaemia.

3 Erroneously high WBC count due to the presence of nucleated red cells or incompletely lysed red cells in haemoglobinopathies or liver disease.

4 Erroneously high haemoglobin as a result of turbidity when the WBC count is high.

5 Severe microcytosis, and, conversely, macrothrombocytes may affect the accuracy of the platelet count if the analyser is unable to discriminate between the populations of cells when their sizes approximate to each other (Figure 62.3b and c).

Paradoxically, as the automated blood count makes the blood film redundant in the routine laboratory, the film has an increasingly important role in the quality control of the count. A visual differential count provides a reference method for checking the reliability of the automated differential count, and inspection of a film is necessary to check any blood count that has been 'flagged' by the analyser.

External quality assessment (EQA)

Although IQC provides continuous vigilance, EQA checks test performance only on random occasions. However, by comparing results from different laboratories it is possible to establish between-laboratory and between-method performances. Thus, EQA schemes have an important educational role, not only for participating laboratories whose performance is under scrutiny,

Table 62.1 Clinically acceptable limits of test variance.

Hb	3–4%
RBC (by automated analyser)	3–4%
PCV	4–5%
MCV, MCH, MCHC	4–5%
Total leucocyte count	8–10%
Platelet count	10–15%
Serum vitamin B_{12}	20%
Red cell folate	20%
Serum iron	20%
Ferritin	20%
HbA_2	5–10%
HbF quantification	5–10%

but also for assessing the 'state of the art' overall, for identifying and recommending the best methods for various tests, and persuading participants to abandon unreliable methods. It is a valuable interface between users and manufacturers of instruments, reagents and kits, because the EQA data may indicate an otherwise unrecognized product failure, as well as the problem of lack of harmonization of results when different technologies are used in analysis.

When the results of blood count and other quantitative tests are returned to the organizing centre, they are analysed to establish the consensus median (or mean) and SD, against which the results from the individual participants are compared. Performance is expressed as deviation index (DI), which is the extent by which the individual's results vary from the established SD. When the DI is greater than 2, the problem should be investigated. However, to base acceptable limits of performance on statistical analysis alone is unrealistic. Thus, for example, the remarkably low coefficient of variance (CV) for haemoglobin means that even a measurement deviating from the mean by more than 3SD is unlikely to influence clinical decisions, whereas with reticulocyte counts, for example, where the CV is high, 3SD may represent a gross error. In reality, therefore, poor performance should be defined as a result that might lead to inappropriate clinical action. Suggested practical limits for acceptable performance are given in Table 62.1.

In qualitative tests, features that are correctly reported are awarded a credit score, whereas a penalty score is given for false-positives and -negatives. The scores are weighted to give a higher number of points (credit or penalty) for more important features, especially those that point to a specific diagnosis or, if reported falsely, could be diagnostically misleading. All members of the laboratory staff, technical/scientific and medical, should be encouraged to participate in in-house morphological exercises based on the EQA films. The UK national scheme is designated NEQAS.

Pre- and post-analytic control

Both IQC and EQA are concerned with the actual analytical tests at the laboratory bench. Clinical reliability is concerned primarily with the test results, whether they are useful and can be relied upon for patient care or for health screening. Thus, functions that may indirectly influence test reliability must also be taken into account. These include all stages from specimen collection, transport to the laboratory, registration and selection of the most appropriate methods for the required test(s), as well as validation of the results, their interpretation and transmission of a meaningful (and legible) report to the appropriate unit or individual.

Specimen collection

All haematology tests start with blood collection. It is essential to ensure that specimens are collected by a standardized procedure and reach the laboratory in good condition.

Phlebotomy

To avoid diurnal variation, the specimens should, as far as possible, always be collected at the same time of day. Using the wrong anticoagulant, using insufficient or conversely excess anticoagulant and inadequate mixing of the blood with the anticoagulant will give rise to flawed specimens. It is also necessary to be aware of various factors that may be responsible for discrepancies. These include smoking, eating and drinking within the previous 2–3 h and use of toilet immediately before collecting the specimen; the subject must be at rest and if possible free of stress – thus, the patient must not undertake vigorous physical activity (including rushing upstairs to the clinic!) within 20 min and the nervous patient must be reassured. Haemostasis from prolonged tourniquet pressure is likely to cause haemoconcentration, whereas excessive negative pressure on the blood sample when drawing it into a syringe may cause haemolysis.

There is debate on the differences between venous blood and 'capillary' blood obtained by skin puncture from finger, earlobe or heel (in infants). In blood obtained by skin puncture, the packed cell volume (PCV), red-cell count and haemoglobin of peripheral blood are often slightly greater than in venous blood, the total leucocyte and neutrophil counts higher by about 8%, the monocyte count by about 12% or more, and the platelet count lower by about 10% or more. However, these differences are likely to be due to inadequate sampling, as some studies have shown no significant differences between venous and capillary samples when the blood flows freely from the capillary puncture site.

As far as possible non-reusable syringes (glass or plastic), needles and lancets should be used and discarded immediately thereafter. If the local situation requires re-use of glass syringes,

they must be washed thoroughly in tap water to remove all traces of blood, then soaked in 10% bleach for 30 min or longer (needles and lancets overnight in freshly diluted 2% glutaraldehyde) followed by sterilization in an oven at 120°C for 30 min. Safety precautions for the user when collecting and handling the blood are described on p. 1014.

The phlebotomist is responsible for ensuring that all specimens and associated request forms are adequately identified, with appropriate indication of especially hazardous specimens. The specimens must then be transported to the laboratory without delay, and maintained during transit at an appropriate ambient temperature to minimize deterioration. When a pneumatic delivery system is in use, it must be checked on installation to ensure that it has no untoward effect on the specimens and that there is no leakage. As blood cell morphology requires films to be made and fixed as soon as possible, if specimens are sent from a distance it may be desirable to have the films prepared and fixed at the time of blood collection.

To take account of these various factors the International Society of Hematology and International Council for Standardization in Haematology have jointly published a standard for *Specimen collection, storage and transmission to the laboratory for hematological tests*.

Pre-analytic proficiency

The first clerical act is to record the time of arrival of specimen in laboratory. The container should then be checked for leakage, insufficient volume or incorrect anticoagulant for the requested test(s). The request and specimen are given a laboratory reference number and marked either for immediate attention ('stat'), or as 'urgent' or 'routine' and sent to the appropriate section(s) of the laboratory for testing.

Post-analytic proficiency

After the tests have been carried out, the following procedures are required to ensure proficiency in the post-analytic phase:
1 processing of results for transcription on to report forms;
2 immediate scrutiny of urgent results with issue of provisional report and its delivery to the requesting clinician;
3 assessment of the significance of results in the context of established reference values and decision for further tests;
4 transmission of final report without unreasonable delay to the location indicated on the request form;
5 contact with users to ensure that the reports arrive in due time for optimal use during clinical management and that the results are presented in a clear and unambiguous form; there should also be discussions on test selection, taking account of the clinical relevance of the tests that are undertaken, the introduction of new tests and evaluation of benefit versus cost, as discussed below.

Test selection

To decide whether or not to introduce a particular system, method or diagnostic kit, the following factors should be considered:
1 biological, chemical, radiation and mechanical safety;
2 clinical utility;
3 precision;
4 accuracy and comparability with existing methods;
5 cost efficiency;
6 routine servicing and maintenance contract conditions;
7 reliability and reputation of the manufacturer/supplier;
8 staff acceptability.

A system or method that gives no useful information or is unsafe should be discounted without further consideration. The choice should then be based on the following questions:
1 Is the test or set of tests to be used for clinical diagnosis and management of specific clinical disorders, patient screening and health monitoring, or for epidemiological studies?
2 Are the tests to be undertaken in the laboratory as routine, for urgent specimens, in an after-hours service, or outside the laboratory as a near-patient (point-of-care) facility?
3 What level of technical expertise is required?
4 Finally, are the levels of precision, accuracy, technical reliability and clinical utility adequate for the required purposes, and is the cost justified and budgeted for?

In the technical assessment, different laboratories may place different emphasis on the importance of these criteria. In general, the method giving the lowest coefficient of variance ($CV\%$) for each parameter is to be preferred, but the desired level of precision and accuracy will depend on the purpose for which the tests are carried out. When comparing methods, all of which are technically acceptable, a significant difference in annual cost and cost per test may be the deciding factors, but, with similar costs, choice may depend upon consideration of maintenance facilities, ease of handling, and, finally, personal preferences and prejudices.

Clinical utility

A test serves its purpose only if it triggers an appropriate clinical reaction. Its competence depends on its ability to distinguish between individuals with and without the particular medical conditions, without overlapping. This is best shown by comparison with an established reference method or by clearly defined clinical feature, in order to identify true-positives (TPs), true-negatives (TNs), false-positives (FPs) and false-negatives (FNs).

From these data one can calculate the sensitivity, specificity and predictive values of the test by the formulae of Galen and Gambino as follows: sensitivity = TPs/(TPs + FNs); specificity = TNs/(TNs + FPs); reliability = (TPs + TNs)/total number of tests;

Table 62.2 Calculation of clinical utility of a haemoglobin device against a reference method, on a number of sequential blood samples.

	Hb > 120 g/L	*Hb < 80 g/L*
True-positive	303	56
True-negative	218	491
False-positive	326	6
False-negative	17	17
Sensitivity	0.95	0.76
Specificity	0.87	0.99
Positive predictive value	0.90	0.93
Negative predictive value	0.92	0.97
Likelihood ratio	7.3	76
Youden index	+0.82	+0.75

To assess performance of the device with normal and severely anaemic bloods, 120 and 80 g/L were selected as cut-off points respectively. It was concluded that the device is slightly more reliable for measuring the lower haemoglobins.

positive predictive value = TPs/(TPs + FPs); and negative predictive value = TNs/(TNs + FNs).

Ideally, for a diagnostic test to be totally reliable, sensitivity and specificity should both be near 100%. In practice, as sensitivity and specificity tend to counter each other, test selection will depend on whether sensitivity or specificity is more important (Table 62.2). When calculating these indices, it is important to establish for what purpose the test is to be used. Thus, for example, haemoglobinometry may be required in a clinic for identifying patients *with* anaemia, but in blood donor selection for identifying individuals who are *not* anaemic. Thus, haemoglobin above the cut-off point for anaemia would be *true negative* in the context of the problem of anaemia, but *true positive* for selection of blood donors (Table 62.3).

The relative usefulness of two methods for the same test can be assessed by the *receiver–operator characteristic analysis* (ROC). This is obtained graphically by plotting *sensitivity* against *1-specificity* at a series of cut-off points for the two methods being compared, using a known reference method as the basis. This formula, which indicates the relative frequency of positive results in disease and negative results in normals, is also termed *likelihood ratio*. A result increasingly > 1 indicates the probability of disease, whereas < 1 lowers the possibility of the disease being diagnosed by that test.

An alternative method for *likelihood ratio* is that of Youden, which is obtained by calculating *sensitivity + specificity – 1*. Values range from –1 to +1; tests with positive ratio increasingly above zero strengthen the probability that the test will discriminate the presence or absence of the specified disease.

Table 62.3 Validation of utility of haemoglobin device for different purposes.

	For blood donor selection	*For checking anaemia*
True-positive	552	16
True-negative	16	552
False-positive	6	4
False-negative	4	6
Sensitivity	99.3	72.7
Specificity	72.7	99.3
Positive predictive value	98.9	80.0
Negative predictive value	80.0	98.9
Likelihood ratio	3.6	103.8
Youden index	+0.72	+0.72

When used in a blood transfusion service for identifying donors with normal haemoglobin, measurements of > 120 g/L are recorded as true positive, whereas when used at a clinic to establish if the patients are anaemic measurements of > 120 g/L are recorded as true negative.

Note the effect of using these different categories on the likelihood ratio (but no effect on the Youden index).

Cost analysis and efficiency

Total cost includes capital cost (i.e. replacement cost and mortgage factor) over the period of the nominal useful life of the instrument, operational costs for consumables and reagents, maintenance contracts and labour costs. The amount attributed to labour will depend on whether the instrument requires to be operated by a highly trained technologist, a more junior technician or a supervised medical laboratory assistant. Unit costs will depend upon laboratory work load (see p. 1015), which is usually calculated on a range of annual expectancies and then expressed as cost per test. This will provide the laboratory with a yardstick to judge the work load limits that justify the choice of one instrument over another, and whether a semi-automated or fully automated type may be more appropriate. Finally, the suitability of the instrument is judged in perspective of its clinical usefulness for its intended purpose.

The total annual cost can be calculated as: $L \times T + C \times T + A + M + HS + VO$, where T = throughput, L = labour costs per test, C = consumable cost per specimen, A = annual capital cost of leasing or amortization, M = maintenance costs, HS = intra-laboratory housekeeping and services, and VO = extra-laboratory unit overheads.

This calculation is useful for comparing the running costs of different systems when choosing a new analyser. It is also useful in deciding whether to use a commercial diagnostic kit or a home-made set of reagents for a test.

The true cost-effectiveness of tests must also take account of whether the laboratory results are utilized effectively by clinicians. This can be assessed from the following formula: (A × 100/C) × (100/B), where A = cost/test as described above; B = quality of test as indicated by its clinical reliability; C = clinical usefulness of test, which is assessed by the extent with which the test is relied upon in clinical decisions, compared with 'best practice' guidelines. For each test, an independent assessor needs to judge how many tests are appropriately requested and are used to influence patient management or public health decisions. The percentage that is not used to guide clinical decisions will provide a figure for 'clinical wastage' of the test and this can be entered into the formula. There is debate on the economics of providing an automated total screening programme or specifically selected tests. It is of interest to note that a study of American hospital practice has shown that clinicians in general are concerned with only a few of the eleven parameters that constitute the complete blood count, mainly haemoglobin, haematocrit, platelet count, WBC, sometimes MCV, and, surprisingly, reports on blood film morphology.

Selection of an *in vitro* diagnostic device

When a new analyser or diagnostic kit is introduced it should be evaluated by the manufacturer before it is marketed, and by the user before purchase. In some cases, type testing is carried out by a consumer organization in order to make recommendations at a national level. In the UK, this is undertaken by the Department of Health's Medicines and Healthcare Products Regulatory Agency (formerly the Medical Devices Agency (MDA)), which issues regular reports on instruments that have been evaluated on their behalf in specified laboratories.

An important document that concerns all laboratories in the European Union is the official *Directive on in-vitro diagnostic devices*, which aims to ensure the reliability of diagnostic analysers and apparatus, kits, calibrators, control materials and reagents. These are required to have an evaluation or performance verification carried out by a national 'competent authority'. This entitles them to be certified with a CE mark; from 2006, laboratories may not purchase any diagnostic device without it.

Guidelines for evaluation have been published by various bodies. A protocol specifically for evaluation of haematological equipment has been published by ICSH. This protocol is intended to be used for type-testing by a manufacturer, consumer organization or the notified body described above. The individual user should carry out a limited validation study on the specific instrument that is being purchased.

Reference values

Interpretation of test results is often based on inadequately defined '*normal*' *values*. There is an increasing awareness of the effects on test results of physiological variables and environ-mental conditions. This has led to the concept of *reference values*, which takes account of such factors as age, sex, ethnic group, pregnancy, menstruation, diurnal and seasonal fluctuations, climate and altitude, as well as life-style habits (smoking and alcohol).

The conditions in which samples are obtained are standardized at the same time of day, preferably in the morning before breakfast; data are analysed separately for different variables, such as individuals who are ambulant or in bed, smokers or non-smokers. The data will be found to fit one of three types of distribution pattern: normal Gaussian, log-normal ('skew') or non-parametric. Results can then be expressed as mean (if normally distributed) or median (if non-parametric), together with the limits (± 2SD) that will include 95% of the population.

The usefulness of reference values depends on the precision of the upper and lower limits. A reasonably reliable estimate can be obtained with 40 measurements, although a larger number, 120 or more, is generally recommended.

Laboratory safety

All laboratory staff should be aware of potential hazards and should know how to ensure adequate protection. Sensible everyday precautions should prevent accidents from the careless handling of toxic substances: physical injury from sharp instruments; needles or broken glassware; radiation exposure; electric shock and fire from the improper use of electrical fittings and connections; and fire caused by the handling of flammable substances such as alcohol and solvents near a naked flame.

Biohazard is a more difficult problem. All specimens from patients should be regarded as potentially infectious for HIV, hepatitis B and C viruses, and other blood-borne pathogens. They must always be handled carefully to minimize the exposure of skin and mucous membranes to patients' specimens. There are well established universal precautions against these hazards to be observed by all staff, and there are procedures to be followed when contamination has occurred to workers, laboratory areas or equipment.

Strategies for safety in handling blood, especially safety in injections and prevention of cross-infection, are described in an extensive and frequently updated WHO programme known as SIGN. The weekly bulletin can be obtained on application to sign@who.int. It is also available on the Internet (www.injectionsafety.org).

Waste disposal

Blood and other potentially infected body fluids can safely be poured down a drain, provided that the drain is connected to a sanitary sewer. Laboratory waste, such as blood specimen containers, used syringes, swabs, tissues and dressings, should be collected in special colour-coded bags for subsequent incinera-

tion or autoclaving, before being disposed of in a rubbish dump. Boxes containing needles and other sharp objects should be incinerated without opening.

Soiled laundry should be placed in leak-proof labelled bags for transport to the laundry, where the items should be either first soaked in disinfectant or washed in hot water (> 70°C) with detergent for 25–30 min before being rinsed. It should be emphasized that the laboratory is responsible for the waste disposal, even if the operation is contracted to an outside body.

Every laboratory should have a named staff member trained in general aspects of laboratory safety, whose responsibility it is to record all incidents, to ensure that immediate action is taken in accordance with an established and defined procedure for treating the exposed or injured person, and to take measures to prevent recurrence.

WHO has a useful website that provides up-to-date information on various aspects of waste management, including country-specific and region-specific problems and legal requirements (http://www.healthcarewaste.org).

Safety legislation

In many countries there are mandatory requirements for safety at work. In the UK the authority for this is the Health and Safety Executive. There are two essential sets of regulations for the laboratory – Control of Substances Hazardous to Health (COSHH) Regulations (1999), and Ionizing Radiation Regulations (1985). The toxicity of all chemical reagents, including those incorporated into kits, requires to be categorized and certified by COSHH with regard to degree of hazard, safety measure for use, handling of spillage and waste disposal.

Staff responses

'Job satisfaction' is essential in a dependable organization, and all members of the laboratory staff should be reassured with regard to their safety, their continuing training with opportunities for advancement, and their good relations with and confidence in the management of their department.

Professional training

Continuing professional development (CPD), linked with continuing medical education (CME), is a process of systematic learning that enables health-workers to be constantly brought up to date on developments in their profession and thus ensure their competence to practice throughout their entire career. Policies and programmes have already been established in a number of countries, and in some, participation may become a mandatory requirement for the right to practice. It must not be confused with accreditation (p. 1019), which concerns the performance (and licensing) of the laboratories themselves.

CPD schemes are run by national professional bodies who are responsible for the practice standards of their members. In the UK, schemes relevant to haematology are the responsibility of the Royal College of Pathologists for doctors, and the Institute of Biomedical Science for scientists/technologists. The process is based on obtaining 'credits' for various activities, such as attendance at approved lectures, workshops and conferences, using computer- or journal-based programmes, taking part in peer review discussions, giving lectures and writing professional papers.

Organization and management

The functioning of a modern laboratory with automated analysers is not unlike that of a factory, with the issue of reports as its end-product but, as each test result requires individual scrutiny, the work is also labour intensive. An efficient and effective laboratory service requires co-ordination of the work load compared with the available resources, which include capital investment in building, furnishing and equipment as well as income.

Strategic planning on 3- to 5-year cycles is essential to implement changes for improving the service, taking into account the advancing frontiers of technology as well as political and economic changes. Thus, for example a laboratory might be required to consider the implications of providing a full 24-h service with a shift system, or providing a fast result service to general practitioners linked to the laboratory computer system, or, in a laboratory with a relatively low work load, converting a manual or semi-automated service to a fully automated analytical system.

Financial management

Income may be fixed when its only source is a health authority, or when it is earned in long-term contracts to provide service to a private organization. Other sources of income include industrial workers screening tests, drug trials for pharmaceutical companies, testing of new equipment and kits for manufacturers, training grants, and grants from government or other organizations for innovative research.

The analysis of cost for running the laboratory must take account of both capital costs and recurrent revenue costs; the latter consists of labour costs, consumables, equipment maintenance, housekeeping and services, which include heating, lighting, water, waste disposal and cleaning services, and even a proportion of the general overheads of the institution. The capital costs will almost certainly have an element of recurrence to include interest on any loan to meet the initial outlay, allowance for depreciation and renewal of equipment after an agreed period of time.

As a rule, labour cost is by far the largest component. In a competitive market it is essential for the laboratory to keep careful control of this – in general it has little or no control over most of the other expenditures.

Price setting depends on an analysis of test costs (see also p. 1013). This will include labour, based on the salary rate per hour of workers of appropriate grades, and the medical staff services for the interpretation of results and consultation with clinicians. Out-of-hours service requires a different calculation of costs as it will vary with the work load and with the different organization of work and staffing to handle it.

Work load

Knowledge of the work load is essential for planning a schedule for laboratory work and its costs. Methods for estimating work load have been based on the number of units of time required for a test, where the unit is defined as being equal to 1 minute of technical, clerical and laboratory assistant's time. This encompasses all procedures from initial handling of specimen to reporting, including routine maintenance and repair of the analytical system, preparation of stock solutions and technical supervision. It does not include blood collection nor does it take account of any contribution by medical staff. Moreover, with automated technology there will be little difference between a discrete measurement of a single analyte and multiple tests in a single process. Thus, formal programmes such as that of the College of American Pathologists and the UK 'Welcan' system, have been found to be of limited value in present-day practice, which is better served by benchmarking (see p. 1019).

For budgetary and performance planning, it is useful to have a breakdown of the data into: (i) separate technical units for blood counting, haemostasis, blood transfusion serology, haematinic assays, haemoglobinopathy studies, etc; (ii) normal working hours and emergency after-hours services; and (iii) the different users such as outpatients, inpatients, specialist clinics, surgeons, physicians and general practitioners.

Assay turnaround time
Distinction must be made between throughput time for the analytic process on a sample and the total time taken from specimen collection to issue of a report. The most important determinant factor is the transport system at each end of the process. An excessively slow turnaround time may encourage point-of-care testing (see below).

Point-of-care testing

Point-of-care testing (POCT), also known as 'near-patient testing', operates either within a hospital as an adjunct to the laboratory or in primary health care outside the hospital. It should be considered if a clinical need is established and if it can be assured that it will be clinically effective. Its advantages are an improved assay turnaround time, potential for closer monitoring and immediate decisions on treatment and, for the patient, spending a shorter time at the clinic or not having to return when the laboratory report becomes available later.

Instrument manufacturers are increasingly aware of this market; they are now producing table-top or hand-held analysers that are simple to use, auto-calibrated and requiring minimum maintenance. However, there is no such thing as a completely foolproof device and a quality control programme must be in place to ensure that POCT performed by non-laboratory staff matches the standards of the laboratory. The haematology tests that are usually undertaken include haemoglobin, blood cell counting by simple analysers, erythrocyte sedimentation rate and prothrombin time for oral anticoagulation control.

Hospital point-of-care testing
This is of value when rapid results are especially important, for example for critical care of patients in intensive care units, or are convenient for the patients, for example for monitoring oncology outpatients whose therapy can then be adjusted promptly.

Organization of the POCT site should be the responsibility of the laboratory that should undertake selection, standardization, quality control and maintenance of the equipment. A designated member of laboratory staff should supervise this service, ensuring that all results and quality control results are integrated into the main laboratory database. Essential criteria for satisfactory near-patient procedures are described in guidelines of the *UK Joint Working Group on Quality Assurance* (see Selected bibliography)*;* suitable devices are described in a Medical Devices Agency Bulletin and there is also an ISO Standard (ISO15189: *Quality Management in the Medical Laboratory*) that is an essential document for laboratory practice, and includes a section on organization and management of POCT.

General practitioners and health centres
The laboratory should encourage local doctors and the clinics where tests are being undertaken to seek advice and help with selection of appropriate instruments, their calibration and quality control. This will ensure harmonization of reports with laboratory records when the patient is referred to the hospital. It is especially important to ensure correct calibration of the POCT device for prothrombin time to obtain the international normalized ratio (INR). This may be by means of calibrated reference plasmas or a standardized thromboplastin with defined ISI and by participation in an appropriate external quality assessment scheme. A major source of error in POCT outside the hospital is faulty specimen collection; clinic staff who undertake this procedure should be given supervised training.

Patient self-testing
There is an increasing trend towards self-testing by patients, and glucose checks for self-management of diabetes is now routine practice. Simple portable precalibrated coagulometers that use capillary blood to measure prothrombin time and INR are also now available for self-testing. It has been shown that patients are able to use these instruments correctly and, once their treatment has been established, the individual patients can be relied on

Table 62.4 List of standards relating to medical laboratory practice.

ISO9000	A series of standards and guidelines on selection and use of quality management systems and quality assurance (complementary aspects are specified in ISO 9001–9004)
ISO15189	Medical laboratories: particular requirements for quality and competence (Appendix D relates to quality management for point-of-care testing)
ISO22869	Guidance document on application of ISO 15189 (formerly ISO Guide 25)
ISO15190	Safety management for medical laboratories
ISO15198	Validation of manufacturers' recommendations for user quality control
ISO17593	Self-testing for oral anticoagulation therapy
ISO6710	Single-use containers for venous blood specimen collection
EN375	Information supplied by manufacturer with *in vitro* diagnostic reagents
EN591	Instructions for use of *in vitro* diagnostic instruments
EN12286	*In vitro* diagnostic medical devices; presentation of reference measurement procedures
EN13532	General requirements for *in vitro* diagnostic medical devices for self-testing
EN13612	Performance evaluation of *in vitro* diagnostic medical devices
EN13641	Elimination or reduction of risk of infection related to *in vitro* diagnostic reagents
EN14136	Use of external quality assessment schemes in assessment of performance of *in vitro* diagnostic procedures
EN61010	Electric safety standards (also IEC 1010)
BS4316	Specification for apparatus for measurement of packed cell volume
BS2554	Specification for Westergren tubes and support for measurement of erythrocyte sedimentation rate
BS3985	Specification for haemoglobincyanide solution for haemoglobinometry

BS, British Standards Institution; EN, Comité Européen de Normalisation; ISO, International Organization for Standardization.

See text for standards from International Council for Standardization in Haematology and World Health Organization.

to maintain their anticoagulation within the therapeutic range. There are ISO and European standards to ensure that such instruments are reliable and that the instructions for their use are clear and unambiguous (Table 62.4).

Laboratory services for general practitioners

The customers of a haematology laboratory include not only hospital clinicians but also general practitioners/family doctors who have different priorities from hospital practitioners. Close attention to the general practitioner's needs is an important demonstration of the quality of the laboratory and this will encourage continued referral of patients after the initial use of laboratory services. The service should include a users' handbook or wall chart (to show the correct specimen container and volume of blood required), reference ranges, requirements for patient preparation (e.g. fasting) and the timing of any medication that may affect the test result. There should also be advice on safety aspects, such as how to deal with blood spillage or a needle-stick injury.

A specimen transport system at an agreed time of day is particularly important so that patients can be given a suitable appointment for having blood samples collected. Information on the turnaround time for reports to reach the practice is helpful so that patients can be given a follow-up appointment when their results will be available. A fast report service for abnormal test results is an asset. This might be by a direct telephone number, fax or e-mail. With transmission of results by fax, a problem with confidentiality may require a call-back system to identify the correct recipient number before the data are transmitted. Direct transfer of encoded data by e-mail from the laboratory computer to that of the practice is likely to become the main process, especially for major users.

Laboratory computers

Developments in information technology have made available powerful microcomputers at moderate prices and sophisticated computer software for laboratory information management systems (LIMS). These provide the means for data processing

Table 62.5 Selected Internet sites with haematological content.

www.who.int	Home page of the World Health Organization; on it find *WHO sites* and click onto *Blood safety and clinical technology (BCT)*; this includes: *BTS* which concerns blood transfusion, *DIL* which provides information on laboratory practice, including listing of WHO publications, many of which can be downloaded, and *DCT*, which deals with devices and safety
www.icsh.org	International Council for Standardization in Haematology, with a listing of all its publications
www.bcshguidelines	Home page of the British Committee for Standards in Haematology; it provides the full text of all current and past guidelines, whether published in book or journal format
www.ukneqas.org	Home page of UK NEQAS; click onto *Haematology* for information on the various tests included in their surveys
www.isth.org	International Society of Thrombosis and Haemostasis; it includes bibliography and full reports of official communications from their scientific and standardization committees
www.haem.net	Web journal published from the Department of Haematology of Hammersmith Hospital; it includes information on laboratory management
www.bloodmed.com	An on-line journal of haematological research, practice and education, including review papers, guidelines and news of regulatory affairs [a subscription publication from Blackwell Publishing]
www.westgard.com	JO Westgard's 'Lesson of the month' and other tutorials on quality assurance
www.cpa-uk.co.uk	Clinical Pathology Accreditation website, with details of its functions and the procedures for a laboratory applying for accreditation
www.rcpath.org www.ibms.org	General information from Royal College of Pathologists and the Institute of Biomedical Science respectively

with multiple use of a common database, and for linking the haematology laboratory with central patient records, pathology disciplines and other investigational units. With this facility, laboratory results can be sent electronically to hospital wards as well as to linked external clinics and general practices. Computers also help with laboratory housekeeping (see below).

For users of personal computers, the Internet provides access to a vast amount of information. Medline, Excerpta Medica and a number of other libraries provide citations and abstracts of articles in almost every medical journal in the world; an increasing number of journals provide their full articles, which can be read directly on the computer or printed out. WHO, in partnership with leading journal publishers, has established a health inter-network access to research initiative (HINARI) by means of which access to the majority of the world's medical journals is provided at no charge or at greatly discounted prices to over 110 low-income countries.

Many individual experts have their own websites for presenting dissertations and comments in their specialties, whereas manufacturers provide up-to-date information on their products. It is impractical to provide a comprehensive index of all relevant Internet sites. In any event, entry of a key word is likely to provide access to a vast amount of information on virtually any subject as well as links to related topics. Some sites of general interest for laboratory haematology practice are listed in Table 62.5.

Record-keeping

Adequate records, both written and computer based, are necessary for an efficient and effective laboratory service. They are required to control and influence all interactions within the laboratory, and between the laboratory and its users. In addition to records of specimen receipt, test requests, results and reports, the following documentation is essential.

Laboratory technical manual
This provides a stepwise detailed account of all test procedures undertaken in the laboratory. It is updated when new or

modified methods are introduced and takes account of national and international guidelines and standards. It also includes the established normal reference values for various ages and each sex (see p. 1014).

Standard operating procedure manual

This provides a description of 'housekeeping' methods and complements the technical manual. It concerns the practice of the specified laboratory and includes: safety precautions for handling biohazardous specimens; disposal of waste materials; and general hygiene within the laboratory, care of equipment, preparation and storage of a listed set of reagents, a list of consumables that are required and details of specimens required for each test, together with information on anticoagulant, storage conditions and stability, criteria for specimen rejection, procedure for handling and reporting urgent specimens, after-hours procedure and major disaster procedure. The standard operating procedure (SOP) manual must be updated regularly in order to reflect any advances in practice.

Staff records

Rota of duties, training programme schedule and involvement in any health and safety accident incident (see below).

Quality control workbook

This includes the results of check tests on reagents and kits, calibration records, EQA performance and records of any corrective actions.

Device maintenance record

Manufacturer's servicing attendance, in-house preventative service, installation of new parts, introduction of new reagents or a new reagent lot, and downtime record.

Inventory records

Accurate inventory of instruments (with serial numbers), stocks of glassware, chemicals, reagents and kits, with batch identification (where available), expiry dates and suppliers' contact addresses. The cost of each item should be recorded.

Accident/incident record

In many countries, there is a legal obligation to have an accurate and detailed record of all accidents or incidents that are potentially hazardous to personnel (see p. 1017). The monitoring of such occurrences will often enable a change in operating procedures to avoid recurrence.

Laboratory handbook

Advises clinicians and other health-care personnel on procedures for specimen collection, handling and transport to the laboratory; this book should also include normal reference values and other information to help in the provision of an effective service.

Laboratory audit and regulatory control

The laboratory is a costly service on which clinical medicine has become increasingly dependent. It is thus essential for laboratories to provide a reliable and satisfactory service to the profession and also indirectly to the general public and to health agencies. Good management should ensure that the service is efficient and effective, with regular internal audit achieved by compliance with the quality assurance procedures described on p. 1008.

Accreditation

Many countries have formal regulations and a licensing system for the control of laboratories; in some, there are regular inspections with sanctions against those that fail to meet required standards. In the USA, for example, this is based on legislation termed the Clinical Laboratories Improvement Act (CLIA, 1988). The protocol for this sets out the levels of professional qualifications and training of personnel for carrying out tests of different degrees of complexity; it also requires evidence of successful performance in a government-approved proficiency testing programme such as that of the College of American Pathologists (CAP), adequate internal quality control protocols and competent laboratory management. Some simple point-of-care tests have received 'waiver status', which exempts them from this scrutiny.

In the UK, maintaining a high standard of laboratory practice is regarded as a responsibility of the professional bodies concerned with laboratory medicine; to this end, the Royal College of Pathologists established a scheme entitled *Clinical Pathology Accreditation UK Ltd*, with requirements broadly similar to those of CLIA'88, but with less restriction on the range of tests that a particular laboratory is permitted to carry out. It is based on independent audit of the ability of a laboratory to provide a service of high quality of practice, as demonstrated by adequate quality control, participation in an external quality assessment scheme and on-site inspection of its facilities, staffing and direction. Details of the requirements for accreditation are found on www.cpa-uk.co.uk.

There are not (as yet) legal sanctions against laboratories that do not comply with the requirements, but CPA is linked to the government-recognized UK Accreditation Service (UKAS), which validates the specified tests that are undertaken by a laboratory, certifying that the tests are up to date and are standard practice complying with the specifications of ISO and/or CEN (see below).

Benchmarking

This is defined as the criterion for comparison against an established point of reference. It has been used widely in commerce and industry and, more recently, it has been adapted to health services in order to establish best clinical and laboratory practice and to judge how any individual centre compares with leading centres. This has become an essential method for achieving

continuous sustainable improvement based on evidence rather than intuition. Benchmarking judges the quality of service of a laboratory by assessing whether it can be run more efficiently with improved cost-effectiveness and clinical effectiveness. It provides an assessment of the adequacy of staffing with realistic measure of work load parameters, how test throughput and reporting time might be improved, taking account of how variation in clinical practice might affect the laboratory service and whether cost-effectiveness and clinical benefit might be improved by decentralizing some components or, conversely, by eliminated satellite units.

In the USA, a scheme known as *Q-probe* was established in 1989 by the College of American Pathologists Laboratory Improvement Program in order to facilitate implementation of CLIA'88 requirements by providing laboratories with continuing peer review and education with periodic on-site audit. Reports of various Q-probe studies are published regularly in *Archives of Pathology and Laboratory Medicine*. In the UK, a similar scheme has been developed in keeping with the requirements of the Commission for Health Improvement (CHI). It is undertaken by *Clinical Benchmarking Company*, which is a partnership established by the Clinical Management Unit of the Centre for Health Planning at Keele University with Newchurch Ltd, an informatics service company. For haematology and other laboratory-based disciplines, this scheme operates with a team of advisers appointed by the Royal College of Pathologists. Assessment of performance of an individual laboratory is based on comparison with best performance in a comparable peer cluster. The internet site is www.newchurch.co.uk/consulting, and their contact e-mail address is benchmarking@newchurch.co.uk. Another Internet site with information on appropriate programs is www.4s-dawn.com/benchmarking.

Regulatory standards

The International Standards Organization has established written standards and guidelines relating to various aspects of laboratory practice, including quality management. A parallel organization is the Comité Européen de Normalisation (CEN), which is the standardizing authority of the European Union. The members of these authoritative bodies are the national standardization bodies of the various countries, for example BSI (UK), DIN (Germany), ANSI (USA) and JISC (Japan), so that ISO and CEN standards (which are harmonized with each other) will be automatically adopted, and some may become mandatory. Standards of special relevance to laboratory practice are listed in Table 62.4.

Appendix 1: Normal values

Normal values

	Males	Females	Males and females
Haemoglobin	13.5–17.5 g/dL	11.5–15.5 g/dL	
Red cells (erythrocytes)	$4.5–6.5 \times 10^{12}$/L	$3.9–5.6 \times 10^{12}$/L	
PCV (haematocrit)	40–52%	36–48%	
MCV			80–95 fL
MCH			27–34 pg
MCHC			20–35 g/dL
White cells (leucocytes)			
Total			$4.0–11.0 \times 10^{9}$/L
Neutrophils			$2.5–7.5 \times 10^{9}$/L
Lymphocytes			$1.5–3.5 \times 10^{9}$/L
Monocytes			$0.2–0.8 \times 10^{9}$/L
Eosinophils			$0.04–0.44 \times 10^{9}$/L
Basophils			$0.01–0.1 \times 10^{9}$/L
Platelets			$150–400 \times 10^{9}$/L
Red cell mass	30 ± 5 mL/kg	27 ± 5 mL/kg	
Plasma volume	45 ± 5 mL/kg	45 ± 5 mL/kg	
Serum iron			10–30 µmol/L
Total iron-binding capacity			40–75 µmol/L (2.0–4.0 g/L as transferrin)
Serum ferritin*	40–340 µg/L	14–150 µg/L	
Serum vitamin B_{12}*			160–925 ng/L
Serum folate*			3.0–15.0 µg/L
Red cell folate*			160–640 µg/L

* Normal ranges differ with different commercial kits.

MCH, mean corpuscular haemoglobin; MCHC, mean corpuscular haemoglobin concentration; MCV, mean corpuscular volume; PCV, packed cell volume.

Appendix 2: WHO classification of tumours of haemopoietic and lymphoid tissues

Chronic myeloproliferative diseases

Chronic myelogenous leukaemia	9875/3
Chronic neutrophilic leukaemia	9963/3
Chronic eosinophilic leukaemia/ hypereosinophilic syndrome	9964/3
Polycythaemia vera	9950/3
Chronic idiopathic myelofibrosis	9961/3
Essential thrombocythaemia	9962/3
Chronic myeloproliferative disease, unclassifiable	9975/3

Myelodysplastic/myeloproliferative diseases

Chronic myelomonocytic leukaemia	9945/3
Atypical chronic myeloid leukaemia	9876/3
Juvenile myelomonocytic leukaemia	9946/3
Myelodysplastic/myeloproliferative diseases, unclassifiable	9975/3

Myelodysplastic syndromes

Refractory anaemia	9980/3
Refractory anaemia with ringed sideroblasts	9982/3
Refractory cytopenia with multilineage dysplasia	9985/3
Refractory anaemia with excess blasts	9983/3
Myelodysplastic syndrome associated with isolated del(5q) chromosome abnormality	9986/3
Myelodysplastic syndrome, unclassifiable	9989/3

Acute myeloid leukaemias

Acute myeloid leukaemias with recurrent cytogenetic abnormalities

AML with t(8;21)(q22;q22), (*AML 1/ETO*)	9896/3
AML with inv(16)(p13q22) or t(16;16)(p13;q22), (*CBFβ/MYH11*)	9871/3
Acute promyelocytic leukaemia (AML with t(15;17)(q22;q12), (*PML/RARα*) and variants)	9866/3
AML with 11q23 (*MLL*) abnormalities	9897/3

Acute myeloid leukaemia with multilineage dysplasia

With prior myelodysplastic syndrome	9895/3
Without prior myelodysplastic syndrome	

Acute myeloid leukaemia and myelodysplastic syndrome, therapy related

Alkylating agent related	9920/3
Topoisomerase II inhibitor-related	

Acute myeloid leukaemia not otherwise categorized

Acute myeloid leukaemia, minimally differentiated	9872/3
Acute myeloid leukaemia without maturation	9873/3
Acute myeloid leukaemia with maturation	9874/3
Acute myelomonocytic leukaemia	9867/3
Acute monoblastic and monocytic leukaemia	9891/3
Acute erythroid leukaemia	9840/3
Acute megakaryoblastic leukaemia	9910/3
Acute basophilic leukaemia	9870/3
Acute panmyelosis with myelofibrosis	9931/3
Myeloid sarcoma	9930/3

Acute leukaemia of ambiguous lineage

	9805/3

B-cell neoplasms

Precursor B-cell neoplasm

Precursor B lymphoblastic leukaemia[1]/lymphoma[2]	9835/3[1]
	9728/3[2]

Mature B-cell neoplasms

Chronic lymphocytic leukaemia[1]/small	9823/3[1]
lymphocytic lymphoma[2]	9670/3[2]
B-cell prolymphocytic leukaemia	9833/3
Lymphoplasmacytic lymphoma	9671/3
Splenic marginal zone lymphoma	9689/3
Hairy cell leukaemia	9940/3
Plasma cell myeloma	9732/3
Solitary plasmacytoma of bone	9731/3
Extraosseous plasmacytoma	9734/3
Extranodal marginal zone B-cell lymphoma	
of mucosa-associated lymphoid tissue	
(MALT lymphoma)	9699/3
Nodal marginal zone B-cell lymphoma	9699/3
Follicular lymphoma	9690/3
Mantle cell lymphoma	9673/3
Diffuse large B-cell lymphoma	9680/3
Mediastinal (thymic) large B-cell lymphoma	9679/3
Intravascular large B-cell lymphoma	9680/3
Primary effusion lymphoma	9678/3
Burkitt's lymphoma[1]/leukaemia[2]	9687/3[1]
	9826/3[2]

B-cell proliferations of uncertain malignant potential

Lymphomatoid granulomatosis	9766/1
Post-transplant lymphoproliferative disorder,	
polymorphic	9970/1

T-cell and NK cell neoplasms

Precursor T-cell neoplasms

Precursor T lymphoblastic leukaemia[1]/lymphoma[2]	9837/3[1]
	9729/3[2]
Blastic NK cell lymphoma	9727/3

Mature T-cell and NK cell neoplasms

T-cell prolymphocytic leukaemia	9834/3
T-cell large granular lymphocytic leukaemia	9831/3
Aggressive NK cell leukaemia	9948/3
Adult T-cell leukaemia/lymphoma	9827/3
Extranodal NK/T-cell lymphoma, nasal type	9719/3
Enteropathy type T-cell lymphoma	9717/3
Hepatosplenic T-cell lymphoma	9716/3
Subcutaneous panniculitis-like T-cell lymphoma	9708/3
Mycosis fungoides	9700/3
Sezary syndrome	9701/3
Primary cutaneous anaplastic large cell lymphoma	9718/3

Peripheral T-cell lymphoma, unspecified	9702/3
Angioimmunoblastic T-cell lymphoma	9705/3
Anaplastic large cell lymphoma	9714/3

T-cell proliferation of uncertain malignant potential

Lymphomatoid papulosis	9718/1

Hodgkin's lymphoma

Nodular lymphocyte predominant Hodgkin	
lymphoma	9659/3
Classical Hodgkin lymphoma	9650/3
Nodular sclerosis classical Hodgkin lymphoma	9663/3
Lymphocyte-rich classical Hodgkin lymphoma	9651/3
Mixed cellularity classical Hodgkin lymphoma	9652/3
Lymphocyte-depleted classical Hodgkin lymphoma	9653/3

Histiocytic and dendritic cell neoplasms

Macrophage/histiocytic neoplasm

Histiocytic sarcoma	9755/3

Dendritic cell neoplasms

Langerhans cell histiocytosis	9751/3
Langerhans cell sarcoma	9756/3
Interdigitating dendritic cell sarcoma[1]/tumour[2]	9757/3[1]
	9757/1[2]
Follicular dendritic cell sarcoma[1]/tumour[2]	9758/3[1]
	9758/1[2]
Dendritic cell sarcoma, not otherwise specified	9757/3

Mastocytosis

Cutaneous mastocytosis	
Indolent systemic mastocytosis	9741/1
Systemic mastocytosis with associated clonal,	
haematological non-mast cell lineage disease	9741/3
Aggressive systemic mastocytosis	9741/3
Mast cell leukaemia	9742/3
Mast cell sarcoma	9740/3
Extracutaneous mastocytoma	9740/1

[1] Morphology code of the International Classification of Diseases (ICD-O), 3rd edition. Behaviour is coded /3 for malignant tumours and /1 for lesions of low or uncertain malignant potential.
