Preface to the fifth edition

Major changes for this new edition have occurred in the editorship, publishing and style of *Postgraduate Haematology* since the 4th edition was published 6 years ago. Mitchell Lewis, who played a major role in the design and writing of the first edition, which appeared in 1972, and was co-editor for the first four editions, has stepped down from this role. We are delighted that he has, nevertheless, contributed two chapters to this volume, one on the spleen and the other on laboratory practice. Daniel Catovsky has joined as co-editor to oversee particularly the section of the book dealing with malignant haematological disorders.

We are also pleased to welcome Blackwell Publishing Ltd, well respected for its impressive list of haematological books and journals, as publishers for this 5th edition. We are particularly grateful to Rebecca Huxley, who has taken on the publishing process, and to Jane Fallows, who has drawn all the scientific diagrams.

For the 5th edition, *Postgraduate Haematology* has been divided into smaller chapters. This has enabled us to bring in many younger authors with knowledge and expertise in particular areas. It has also facilitated the incorporation of the new information on mechanisms of disease, laboratory investigation and clinical management that has been gained over the last 6 years. Although the book has expanded to over 1000 pages, it is still aimed at providing haematologists in training and consultants with a text that is up to date and easy to read and that gives ready access to the information on diagnosis and treatment needed in the laboratory and clinic.

Microscopic appearances of the blood diseases are illustrated throughout the book. These illustrations are mainly reproduced from the 4th edition but we wish to thank Elsevier Inc. for permission to reproduce figures from the 3rd edition of the *Color Atlas of Clinical Haematology*, edited by A.V. Hoffbrand and J.E. Pettit and published by Harcourt Publishers Ltd.

Finally we wish to thank Megan Evans and Wanda Malinowski for their expert secretarial help throughout the preparation of this new edition.

AVH, DC, EGDT
2005

Preface to the first edition

In this book the authors combine an account of the physiological and biochemical basis of haematological processes with descriptions of the clinical and laboratory features and management of blood disorders. Within this framework, each author has dealt with the individual subjects as he or she thought appropriate. Because this book is intended to provide a foundation for the study of haematology and is not intended to be a reference book, it reflects, to some extent, the views of the individual authors rather than providing comprehensive detail and a full bibliography. For these the reader is referred to the selected reading given at the end of each chapter. It is hoped that the book will prove of particular value to students taking either the Primary or the Final Part of the examination for Membership of the Royal College of Pathologists and the Diplomas of Clinical Pathology. It should also prove useful to physicians wishing to gain special knowledge of haematology and to technicians taking the Advanced Diploma in Haematology of the Institute of Medical Laboratory Technology, or the Higher National Certificate in Medical Laboratory subjects.

Stem cells and haemopoiesis

1

Myrtle Gordon

Introduction

The lifelong production of blood cells occurs in haemopoietic tissue. This involves a very high level of cell turnover, demanded by the need to replace mature circulating blood cells at a rapid rate, and is necessitated by the limited lifespan of the mature cells. Granulocytes survive for only a few hours and erythrocytes for a few months, so that some 10^{13} new cells must be replaced each day to maintain steady-state blood counts. This is equivalent to an annual number of cells approximating the total body weight, but the total bone marrow of an adult human contains around 10^{12} cells, 10-fold less than daily needs. From these estimates it is clear that the blood cells required for lifelong haemopoiesis cannot be preformed in the body.

The bone marrow, which is the major site of haemopoiesis in adult humans, contains cells that represent the stages in the development of the different types of blood cells (Figure 1.1). The later stages are recognizable as belonging to the major lineages of haemopoiesis (granulocytes, erythrocytes, monocyte/macrophages, megakaryocytes, eosinophils, basophils, and T and B lymphocytes). They are the myelocytes, metamyelocytes, erythroblasts, reticulocytes, etc. Earlier stages of development become progressively less morphologically distinct in their lineage affiliation and fewer in number, whereas the least frequent cells, which cannot be discriminated morphologically, are the committed progenitor cell populations and the stem cells.

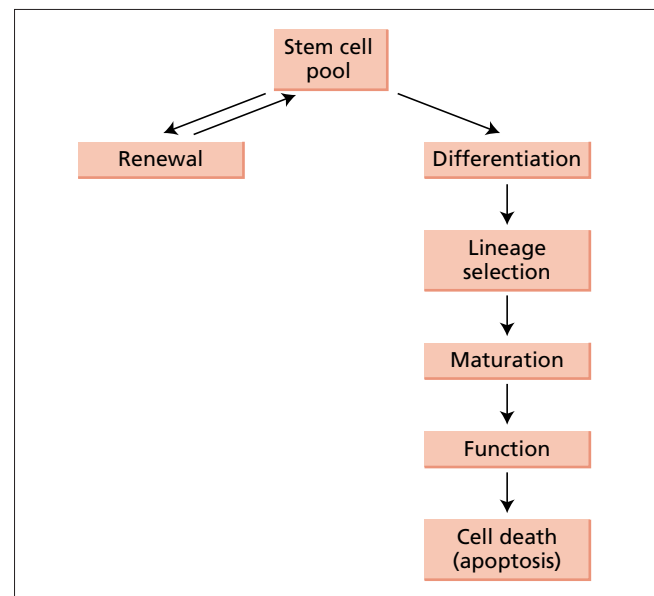
The stem cells are the most important cells in haemopoietic cell production. They are ultimately responsible for regenerating haemopoiesis following damage to the haemopoietic system by myelotoxic chemotherapy or after stem cell transplantation. This is accomplished by stem cell division, producing new stem cells to maintain the stem cell pool (stem cell renewal) and differentiating cells that are the progenitor cells of each of the blood cell lineages. Estimates of stem cell frequency in human bone marrow are about one stem cell per 20 million nucleated cells.


Figure 1.1 Stages in haemopoietic cell development.

They are very difficult to measure, although various assays for candidate human stem cells have been developed. These include both *in vitro* and *in vivo* assays such as long-term bone marrow culture (LT-BMC), cobblestone-area colony (CAFC) formation and the NOD/SCID mouse repopulating assay.

Haemopoiesis is regulated by soluble factors that were discovered when immobilization of bone marrow cells in a semisolid matrix containing medium 'conditioned' by the growth of a cell line in culture resulted in the growth of clonal colonies of granulocytes and macrophages. Identification of the active factors in the conditioned medium led eventually to cloning, production of recombinant protein and clinical use of cytokines in the therapy of haematological disease.

In addition to the haemopoietic system, the bone marrow contains stromal stem cells (mesenchymal stem cells), which are important for constructing the haemopoietic microenvironment. The microenvironment provides more than simply mechanical support and has been shown to be an essential component of the long-term bone marrow culture system. Moreover, damage to the microenvironment, for example by chemotherapy, has been implicated in haemopoietic insufficiency after treatment.

Studies in haemopoietic stem cell biology have now expanded to embrace the concepts of stem cell plasticity. This term refers to the ability of haemopoietic and stromal (mesenchymal) stem cells to produce cells associated with other tissues, such as liver, lung and muscle. Although this area remains highly controversial, the therapeutic applications of haemopoietic stem cell plasticity are obvious as it would provide an easily accessible source of cells that could be redirected to repair a variety of damaged tissues.

Sites of haemopoiesis

The development of the haemopoietic system is associated with the development of suitable microenvironments, which are colonized by migrating stem cells. The migration of stem cells from site to site must require mechanisms for their entry, transit and exit. These processes probably involve specific recognition and adhesive interactions between the stem cells and cells of the various microenvironments. Extracellular matrix-degrading enzymes such as the metalloproteinases have been implicated in the reversal of adhesion and exit from tissues.

There has been a long-accepted dogma that the adult haemopoietic system originates in the embryonic yolk sac. The mesenchyme of the yolk sac differentiates into endothelial cells, on the one hand, and haemopoietic stem cells on the other. At this stage, haemopoiesis consists of blood islands, consisting of primitive primordial cells (haemocytoblasts) and erythro-blastoid cells surrounded by endothelial cells. The observation that endothelial and haemopoietic cell development occur in close proximity led to the hypothesis that these two cell types are derived from a common precursor, the haemangioblast, which represents the origin of the circulatory system as well as the blood cells. Following the development of the circulation, stem cells can migrate into the embryo where they sequentially seed the liver, spleen and bone marrow.

Challenging the yolk sac origin of adult haemopoiesis, embryo-grafting experiments in birds revealed that adult haemopoiesis is derived from an intraembryonic source. This is the aorta–gonad–mesonephros (AGM) region, located in the para-aortic splanchnopleure. It is not overtly erythropoietic, unlike yolk sac haemopoiesis, but contains a spectrum of lymphoid and myeloid stem and progenitor cells. Similarly, active haemopoiesis is found in the AGM region of embryo mice. It is thought that a second wave of fetal liver colonization, originating in the AGM region, supplies stem cells for the eventual development of the adult haemopoietic system, in contrast with the primitive and temporary haemopoiesis derived from the yolk sac.

Primitive erythropoiesis persists as the major visible haemopoietic activity in the fetal blood vessels, liver and spleen but large numbers of granulocytes can be found in the connective tissue, outside the organs, for most of intrauterine life. Granulocytic cells are not produced in large numbers until haemopoiesis is established in the bone marrow. This occurs at different times in different bones and coincides with the process of ossification. Large numbers of stem cells are found in umbilical cord blood as well as in the fetal circulation, and this has led to the use of cord blood as an alternative to bone marrow as a source of cells for transplantation. At birth, haemopoietic activity is distributed throughout the human skeleton but it gradually recedes with time so that in normal adult life haemopoiesis is found mainly in the sternum and pelvis, with small amounts in other bones like the ribs, skull and vertebrae.

A small number of stem cells are present in the circulation of normal adult humans. This number increases physiologically in some circumstances, such as following exercise and during infections, and may be increased pharmacologically by administration of haemopoietic growth factors and/or cytotoxic chemotherapy. This phenomenon has been exploited to provide large numbers of circulating stem cells, which can then be collected by leucapheresis and used as a source of cells for stem cell transplantation.

The stromal microenvironment

The documentation of haemopoiesis migrating from site to site suggested that there might be specialized conditions that determine the sequence of colonization. Geiger *et al.* (1998) demonstrated the influence of the embryonic and fetal liver microenvironments by injecting adult marrow stem cells into blastocysts and finding they resumed the adult and fetal programmes of haemopoietic cell development. In contrast, when haemopoietic stem cells from fetal liver are injected into adults they develop along adult lines. Indeed, fetal liver has been used as a source of haemopoietic stem cells for clinical transplantation in some circumstances. Charbord and colleagues characterized a cell type in early-gestation fetal liver, but not in late-gestation fetal liver, with mixed endodermal and mesodermal features that supported haemopoietic cell proliferation *in vitro*. Thus, these fetal stromal cells were only present during the haemopoietic phase of liver development.

Early *in vivo* studies in adult mice demonstrated that the microenvironment in the spleen induced erythropoietic differentiation of transplanted bone marrow cells, whereas the microenvironment in the marrow induced granulopoietic differentiation, demonstrating quite clearly that different microenvironmental conditions can determine lineage expression. *In vitro*, adult bone marrow stromal cells form adherent layers that are believed to represent the haemopoietic microenvironment

and provide support for haemopoietic activity in long-term bone marrow cultures. The stromal cells consist of several cell types, namely macrophages, endothelial cells, fibroblasts and fat cells, together with their extracellular matrix, consisting of collagen, fibronectin and proteoglycan constituents.

Stem cell trafficking

The ability of stem cells to traffic around the body and to search out sites suitable for haemopoiesis is well demonstrated by (a) the 'homing' of transplanted stem cells to the bone marrow and (b) the chemotherapy and cytokine-induced 'mobilization' of stem cells into the circulation. Homing involves transendothelial migration from the bloodstream into the marrow microenvironment, whereas mobilization involves detachment from the microenvironment and transendothelial migration in the reverse direction. Together, these processes may provide a paradigm for stem cell trafficking in general (Figure 1.2). They are likely to involve multifactorial processes involving chemokines, cytokines, adhesion molecules and matrix-degrading enzymes.

In vitro experiments have shown that stromal cell-derived chemokine gradients across an endothelial barrier induce stem cells to migrate from one side to the other. Chemokines are cytokines with direct chemotactic effects on receptor-expressing target cells. However, stromal cell-derived factor 1 (SDF-1) is the only chemokine that acts on haemopoietic stem and progenitor cells. Once the stem cells have gained the extravascular spaces in the bone marrow, the stromal cells provide a plethora of potential sites for recognition by stem cells, including cell surface and extracellular matrix ligands for adhesion molecules (CAMs) on the stem cell surface. Haemopoietic stem and progenitor cells express a wide variety of cell adhesion molecules of different classes (e.g. selectins and integrins), but they are not specific for stem cells as they are also expressed by mature leucocytes.
Figure 1.2 Stages in the homing and mobilization of stem cells.

Cytokines and cytokine receptors may also act in cytoadhesion as stem cell factor (SCF; c-Kit ligand) is expressed on the cell surface by stromal cells and its receptor, c-Kit, is expressed by stem cells. Similarly, the Notch ligand, Jagged, is expressed by stromal cells, whereas Notch is expressed by stem cells.

Clearly, cytokines play a role in the release of stem cells from the marrow microenvironment as cytokine administration is used to induce stem cell mobilization into the peripheral blood. Cytokines increase metalloproteinase expression, release stem cell factor from the stromal cell surface and induce stem cell migration through the endothelial barrier. Thus, stem cell trafficking may be a dynamic and continuous process, depending on the prevailing haemopoietic activity.

Organization of haemopoiesis

The haemopoietic system is a hierarchy of cells in which multipotent haemopoietic stem cells give rise to lineage-committed progenitor cells, which divide to generate the maturing and mature blood cells (Figure 1.3).

Stem cells

Assays for stem cells

Stem cells are found at a very low frequency in haemopoietic tissue and cannot be recognized in stained smears of bone marrow. In animal models, the best assay for stem cells is a repopulating assay, which tests the ability of the cells to engraft and restore haemopoiesis in a myeloablated host. For human stem cells, a variety of *in vitro* assay systems have been used, but the most widely accepted is the long-term bone marrow culture system (LT-BMC). This method reproduces the microenvironment of the bone marrow *in vitro* by growing a feeder layer of stromal cells. When haemopoietic long-term culture-initiating cells (LT-CICs) are seeded onto the stromal layer, they are induced to proliferate and produce progenitor cells that can be measured in the clonogenic assays detailed below. However, the endpoint of this assay is indirect, in that committed colony-forming cells produced by the LT-CICs are enumerated. Consequently, limiting dilution analysis is necessary to determine LT-CIC numbers. However, limiting dilution is statistically based and the procedure is very cumbersome.

A variety of clonal assays for candidate stem cells have also been used. The cobblestone area-forming cell (CAFC) assay resembles the long-term culture assay in that haemopoietic cells are seeded onto stromal layers. In this case, however, the formation of colonies containing cells of a cobblestone-like morphology is observed. The blast colony-forming cell (Bl-CFC) assay and high proliferative potential colony-forming cell assay (HPP-CFC) detect cells that share certain characteristics with stem cells but are generally considered to be less primitive than stem cells.
Figure 1.3 Hierarchical organization of haemopoiesis.

Stem cell properties, phenotype and purification

Morphologically, haemopoietic stem cells are undifferentiated and resemble small lymphocytes. Normally, a large fraction is quiescent, in G_0 phase of the cell cycle, which protects them from the action of cell cycle-dependent drugs such as 5′-fluorouracil, and S-phase-specific agents such as cytosine arabinoside and hydroxyurea. The quiescent state of stem cells is maintained by transforming growth factor β (TGF-β). The activity of TGF-β is mediated by p53, a tumour suppressor that regulates cell proliferation and targets the cyclin-dependent kinase inhibitor p21. The cyclin-dependent kinase inhibitors regulate the activities of cyclin–cyclin-dependent kinase (CDK) complexes. Inhibition of the cyclin–CDK complexes prevents phosphorylation of the retinoblastoma proteins that remain bound to transcription factors belonging to the E2F family. As a consequence, genes required for progression of the cell cycle are not transcribed and cells remain quiescent (Figure 1.4). Stromal cells express TGF-β, which is involved in maintaining stem cell quiescence in the bone marrow microenvironment.

The immunophenotype of haemopoietic stem cells is summarized in Table 1.1 and consists of the presence of markers that are expressed by stem cells (CD34, Thy-1) and those that are absent (CD33, CD38, HLA-DR and lineage-specific (lin) markers). CD34 is the best-known marker of human stem and progenitor cells. It is a member of the sialomucin family of glycoproteins, which are heavily glycosylated molecules with potential adhesion and signalling capabilities. CD34 has been
Figure 1.4 Maintenance of stem cell quiescence.

implicated in the binding together of cells from the KG1a line and of primary human CD34+ progenitor cells.

The importance, interest and rarity of stem cells have led to extensive efforts to purify them, based on stem cell characteristics that distinguish them from other cells in the haemopoietic

Table 1.1 Basic immunophenotype of haemopoietic stem cells.

Positive	Negative
CD34	CD33
Thy-1	CD38
AC133	Lineage markers
c-Kit	HLA-DR

system. The resistance of stem cells to cell cycle-dependent drugs, particularly to 5′-fluorouracil, has been used as one of the stages in stem cell purification. Fluorescence-activated cell sorting of cells labelled by monoclonal antibodies to phenotypic markers is a widely used strategy for stem cell purification, as is magnetic bead sorting. Despite efforts to purify stem cells to phenotypic homogeneity, the resulting populations are not functionally homogeneous.

Stem cell renewal and differentiation

Stem cells are capable of self-renewal and differentiation when they divide and are responsible for producing all the mature blood cells throughout life. This means that when steady-state stem cells divide, only 50% of the daughter cells, on average, differentiate, the remaining 50% do not differentiate, but maintain stem cell numbers. This could be accomplished by asymmetric cell division, so that each dividing stem cell forms one new stem cell and one differentiated cell (Figure 1.5a). Alternatively, balanced numbers of stem cells could divide symmetrically to form either two new stem cells or two differentiated cells (Figure 1.5b). Clearly, the asymmetric model does not allow for regeneration of the stem cell population but, by altering the proportions of renewing and differentiating stem cells, the symmetric division model can account for stem cell recovery (Figure 1.5c) because it permits an increase in the proportions of symmetrical self-renewing divisions and a reduction in the proportion of differentiating divisions. The symmetrical model of stem cell division means that self-renewal and differentiation are likely to be properties of the stem cell population at large, rather
Figure 1.5 Models of stem cell self-renewal and differentiation.

than characteristics of each individual stem cell. However, this mechanism is accompanied by extinction of the differentiating stem cells because the clones they produce will not contain any stem cells.

Regulation of self-renewal

Control of haemopoietic stem cell proliferation kinetics is critically important for the regulation of haemopoietic cell production. Nonetheless, information about the control of stem cell renewal versus differentiation, and how this might be manipulated to improve haemopoietic cell regeneration, is still incomplete. Control mechanisms could be intrinsic or extrinsic to the stem cells, or a combination of both.

Extrinsic factors

Extrinsic control would mean that self-renewal and differentiation can be controlled by external factors, such as cell–cell interactions in the haemopoietic microenvironment or cytokines, and thereby be responsive to demands for increased haemopoietic cell production. Regulation in the bone marrow microenvironment, and in the stromal layers of long-term bone marrow cultures, may be mediated by adjacent cells or local cytokine production. SCF is produced by stromal cells and occurs as a transmembrane protein as well as a soluble protein. It binds to its receptor, c-Kit, expressed by haemopoietic stem cells and is essential for normal blood cell production. Flt3 ligand is also a transmembrane protein and is widely expressed in human tissues. It binds to Flt3 on haemopoietic cells and is important for cell survival and cytokine responsiveness. TGF-β reduces stem cell cycling and maintains stem cell multipotency.

The Notch-1–Jagged pathway may serve to integrate extracellular signals with intracellular signalling and cell cycle control. Notch-1 is a surface receptor on haemopoietic stem cells that binds to its ligand, Jagged, on stromal cells. This results in cleavage of the cytoplasmic portion of Notch-1, which can then act as a transcription factor. c-Kit, the receptor for SCF, and receptors for TGF-β and tumour necrosis factor α (TNF-α) may also act in this way.

Intrinsic factors

The expression of several transcription factors has been shown to be essential for haemopoietic cell development from the earliest stages. SCL (stem cell leukaemia haemopoietic transcription factor) and GATA-2 are required for the development of haemopoiesis in the yolk sac, whereas absence of AML-1 results in failure of fetal liver haemopoiesis, although erythropoiesis in the yolk sac is not affected. Candidate genes that are targeted by these transcription factors include c-Kit, the receptor for granulocyte colony-stimulating factor (G-CSF), globin genes and myeloperoxidase.

There is evidence from murine studies that haemopoietic progenitor cells from different inbred mouse strains vary widely in number and proliferative activity. These observations indicate

that genetically determined constitutional variation in human haemopoiesis is also likely to exist. This view is supported by the fact that parameters such as clonogenic cell frequency and numbers, proliferation ability and capacities for mobilization and expansion vary widely among individuals in the general human population. Associations have been reported between genetic markers and the frequency and activity of stem cells in mouse strains. De Haan and colleagues (2002) concluded that the expression levels of a large number of genes may be responsible for controlling stem cell behaviour. These collections of genes may be analogous to those responsible for the interindividual behaviour of human haemopoietic stem cells.

In contrast to the genetic basis for constitutional variation, certain specific genes have been demonstrated to influence haemopoietic cell kinetics. Growing evidence implicates gene products involved in cell cycle control, such as the cyclin-dependent kinase inhibitors (CKIs) p16, p21 and p27 (Figure 1.4) and the maintenance of stem cell quiescence. They have been shown to enhance proliferation and repopulating efficiency of bone marrow cells in gene knockout, knockin and gene transfer models. Loss of CKIs increases clonal expansion by haemo-poietic progenitor cells and the size of the stem cell pool; the Fas and Fas ligand genes, which generally are associated with the process of cell death by apoptosis, also influence haemopoiesis as part of a mechanism suppressing progenitor cell proliferation.

Finally, lessons can be learned from studies of disease patho-genesis. Many cell cycle control genes and genes promoting cell death by apoptosis are tumour-suppressor genes that have been found to be deleted or mutated in leukaemia and other cancers. Fanconi's anaemia is an autosomal recessive bone marrow failure syndrome associated with an increased tendency for spontaneous chromosome breaks. The disease can be caused by mutations in at least seven different genes. The genes *FANCA*, *FANCC*, *FANCD1*, *FANCD2*, *FANCE* and *FANCF* have been cloned, and the corresponding proteins play important roles in DNA repair. In dyskeratosis congenita mutations have been identified in the *DKC1* gene, which encodes dyskerin. Dyskerin is a component of small nucleolar ribonuclear protein particles and the telomerase complex, indicating that the disease is due to defective telomerase.

Overall, intrinsic and extrinsic control mechanisms may be considered separately, but a picture is emerging of the integra-tion of extracellular signalling, signal transduction, transcription factors and cell cycle control in the determination of stem cell fate.

Stem cell lineage selection

The 50% of daughter stem cells that differentiate supply cells that are destined to form all of the eight blood cell lineages. The mechanisms determining the blood cell lineages selected by the differentiating progeny of stem cells probably involve aspects of the transcriptional control of lineage-specific genes. Greaves and colleagues proposed that several lineage-specific genes are accessible to transcription factors or 'primed' in uncommitted

cells. Accordingly, individual primitive cells were found to exhibit low levels of transcription of lineage-affiliated genes. Moreover, single stem cells expressed low levels of several of these genes, indicating that final lineage selection had not yet occurred. The multilineage 'priming' of stem cells is supported experimentally by the results of replating colonies composed of blast cells. This revealed that the blast cells themselves were bipotent or oligopot-ent progenitors for various lineages of blood cell development, and that the combinations of lineages found within individual colonies appeared to be randomly distributed, although some combinations are more common than others.

It is likely that differences in the expression levels of transcrip-tion factors determine the lineage affiliation of a differentiating cell (Figure 1.6). The transcription factors PU1 and GATA-1 have been implicated in myeloid and erythroid/megakaryocyte lineage specifications respectively. The common precursors of the myeloid, erythroid and megakaryocytic lineages coexpress PU1 and GATA-1, but GATA-1 is downregulated during myeloid cell development and PU1 during erythroid/megakaryocytic cell development. The decision of bipotent granulocyte/monocyte precursors to proceed along the granulocytic or monocyte macro-phage lines of differentiation is influenced by C/EBP-α, which is required for granulocytic cell development.

Stem cell plasticity

Reports that transplanted bone marrow cells can contribute to the repair and regeneration of a spectrum of tissue types includ-ing brain, muscle, lung, liver, gut epithelium and skin have
Figure 1.6 Transcription factors involved in lineage selection by haemopoietic stem and progenitor cells.

attracted considerable attention. The important implication of these observations is that haemopoietic stem cells could be used clinically for tissue replacement therapies. The multipotential nature of haemopoietic stem cells appears to be well suited to a wider role in tissue repair as they already demonstrate the capacity to make renewal, differentiation and lineage choices. Moreover, cultured blood cells can transdifferentiate from one lineage to another. Cell fusion is an alternative mechanism accounting for the contribution of bone marrow cells to tissue repair (e.g. after myocardial infarction), possibly involving the macrophage component of the marrow infusion.

A second bone marrow stem cell population with tissue-regenerating potential, the multipotent adult progenitor cells (MAPCs), representing a subpopulation of mesenchymal (stromal) stem cells, was isolated by Verfaillie and colleagues. The MAPCs develop over a period of time in culture, during which they seem to lose tissue-restricted gene expression and become able to differentiate into mesenchymal cell types (osteoblasts, chondrocytes, adipocytes and sketetal myoblasts) endothelium, neuroectoderm and hepatocytes.

Progenitor cells

The progenitor cells are the progeny of stem cells, and it is likely that some of the candidate stem cells measured in the assays mentioned above are in fact intermediate between stem and progenitor cells. As haemopoietic cell development proceeds from stem cells to progenitor cells, the probability of renewal decreases and that of differentiation increases commensurately. Thus, although the probability of self-renewal is highest within the stem cell population, it is by no means a property of stem cells alone. This has been amply demonstrated by replating progenitor cell-derived colonies grown *in vitro* and observing secondary colony formation. It is uncertain at what stage the capacity for self-renewal is lost completely. Indeed, early kinetic studies revealed that even promyelocytes divide two or three times before they differentiate into myelocytes.

Beginning in the 1960s, *in vitro* colony assays have been developed for the enumeration of clonogenic progenitor cells in haemopoietic tissue. The availability of different assays has allowed the investigation of distinct cell populations at different stages of haemopoietic cell development. The mixed lineage colony-forming cells (CFU-mix) consist of combinations of granulocytes, eosinophils, monocytes, erythrocytes and megakaryocytes and are the most primitive cells in this class. Granulocyte–macrophage colony-forming cells (CFU-GM) are bipotential and succeeded by single-lineage CFU-G and CFU-M. The erythroid lineage is represented by the burst-forming unit erythroid (BFU-E) and colony-forming unit erythroid (CFU-E), whereas separate assays exist for megakarocyte precursors (CFU-Mk).

Colony formation *in vitro* is stimulated by haemopoietic growth factors and cytokines. Some of the growth factors are named after their target cells, such as granulocyte–macrophage colony-stimulating factor (GM-CSF) and G-CSF. Others indicate which cell types they act on, such as erythropoietin (erythropoiesis), thrombopoietin (megakaryopoiesis) and SCF.

Maturing and mature cells

The maturing and mature haemopoietic cells are recognizable on stained smears of blood or bone marrow. During maturation, the cells maintain some capacity for division that can influence the blood count because each additional division would double the blood count. Eventually, however, the capacity for cell division is lost because of expulsion of the nucleus (red cells), fragmentation (platelets) or nuclear distortion (polymorphonuclear granulocytes). In contrast, mature lymphocytes have a monomorphic nucleus and retain the ability to divide. The end-products of haemopoietic cell development are cells that are highly specialized for their different functions in the body.

Cell death (apoptosis)

The final stage in the life of a blood cell is death and disposal by apoptosis. Apoptotic cell death is a mechanism for disposing of unwanted or excess cells, and it occurs widely in biological systems. It ensures the destruction of cells without releasing any lysosomal or granule contents that would cause an inflammatory reaction. Apoptosis involves a complex series of events that culminate in the activation of the caspase proteases, fragmentation of DNA and phagocytosis of apoptotic bodies by macrophages.

In haemopoiesis, apoptosis is used to dispose of mature end cells once they have fulfilled their function. In addition, it has also been proposed as a mechanism for negative regulation of cell production. Accordingly, a reduction in cell death could account for an increase in haemopoietic stem and progenitor cell numbers. However, this mechanism presupposes that substantial numbers of stem and progenitors are lost by apoptosis in steady-state haemopoiesis. Haemopoietic cytokines and growth factors act as survival factors for haemopoietic progenitor cells and prevent the death of factor-dependent cell lines *in vitro*. Also, components of the apoptotic machinery have been implicated in the feedback negative regulation of erythropoiesis and myelopoiesis, cell cycle regulation and cell differentiation. These observations suggest that the apoptotic pathways may have regulatory functions that do not culminate in cell death.

Haemopoietic growth factors and receptors

The haemopoietic growth factors and cytokines are the soluble regulators of blood cell production and are produced by several cell types in different sites in the body. They are glycoproteins

Table 1.2 Haemopoietic cytokines and their target cells.

Cytokine	Target cell(s)
IL-3	CFU-GEMM, HPP-CFC, CFU-GM, CFU-Eo, CFU-Baso, BFU-E, CFU-Mk
GM-CSF	HPP-CFC, CFU-GEMM, CFU-GM, CFU-Eo, CFU-Baso, CFU-Mk, BFU-E, CFU-M, CFU-G, dendritic cells
G-CSF	HPP-CFC, CFU-GEMM, CFU-GM, CFU-G
M-CSF (c-Fms ligand)	HPP-CFC, CFU-GEMM, CFU-M
Epo	CFU-E
SCF (c-Kit ligand)	HPP-CFC, CFU-GEMM, CFU-GM, CFU-Baso, BFU-E
IL-1	HPP-CFC
IL-4	CFU-GM, CFU-Baso, BFU-E, dendritic cells
IL-5	CFU-Eo
IL-6	HPP-CFC, CFU-GM, BFU-E
IL-11	CFU-Mk, CFU-GM, BFU-E
Thrombopoietin	CFU-Mk
Flt3 ligand	LT-CIC, CFU-GEMM, CFU-GM, dendritic cells
Fibroblast growth factor (FGF2 and FGF4)	CFU-GM, BFU-E, stromal cells
Leukaemia inhibitory factor (LIF)	CFU-Mk, BFU-E

References and further details will be found in Garland *et al.* (1997) and Thomson and Lotze (2003).
Baso, basophil; BFU-E, burst-forming unit erythroid; CFU, colony-forming unit; Eo, eosinophil; GEMM, granulocyte, erythrocyte, monocyte, megakaryocyte; GM, granulocyte–macrophage; HPP-CFC, high proliferative potential colony-forming cell; LT-CIC, long-term culture-initiating cell; Mk, megakaryocyte.

with little primary amino acid homology, although molecular modelling of secondary structure suggests that they possess similar structural features, such as bundles of anti-parallel α-helices joined by loops and β-sheets. Different sequences have been identified by deletional mutagenesis, which are required for secretion, biological activity and receptor binding. Some cytokines, such as SCF, exist in membrane-bound form as well as a soluble form because they lack the signal sequence responsible for release from the cell as a result of alternative splicing.

Cytokine responses and signal transduction

The responses of haemopoietic cells to cytokines include survival, proliferation, differentiation and stimulation of mature cell function. Once cytokines have bound to their receptors on the cell surface, they activate signal transduction pathways that transmit the signal to the nucleus and ultimately stimulate the transcription of regulatory genes. Haemopoietic progenitors require multiple cytokines for their optimal growth and development (Table 1.2). These growth factors act in concert to coordinate the various cellular functions that are necessary for the cell division and progressive differentiation required for the formation of mature functioning end cells. There are many examples of cytokines acting in synergy when the outcome is greater than expected from the sum of the individual cytokines acting alone. Also, cytokines are pleiotropic in their actions, and several cytokines are known to share the same functions. This

level of complexity is very difficult to rationalize, but it is becoming apparent that intracellular coordination is achieved by co-localization of sequentially acting signalling proteins, or by binding interactions with adaptor complexes, cytoskeletal structures or molecular targets, for the selective activation of downstream targets. Outside the cell, haemopoietic cell responses may be modulated by controlled access of cytokines to target cell receptors, as discussed below.

Many haemopoietic growth factor and cytokine receptors belong to the haematopoietin receptor superfamily (Figure 1.7). These are type 1 transmembrane glycoproteins with modular extracellular domains. All members dimerize when they bind their ligand. G-CSF and erythropoietin (Epo) receptors homodimerize, whereas the β-chains of the interleukin (IL) 3, IL-5 and GM-CSF receptors dimerize with a common beta (β_c) chain to form a high-affinity receptor. Other members of the haematopoietin receptor superfamily (IL-6, IL-11, IL-12 and leukaemia inhibitory factor, LIF) require the presence of a transmembrane protein, gp130, to transduce a signal.

A separate group of receptors has intrinsic tyrosine kinase activity and contains receptors for SCF, hepatocyte growth factor (HGF) and Flt3 ligand (FL). It is evident that cytokine receptor systems not only act in a linear-independent manner, but also influence the activity of other cell-surface receptor systems. Biochemical studies have revealed interactions between haemopoietic cytokine receptors, including interactions of β_c with Epo and G-CSF receptors. However, it is not established
Figure 1.7 Representation of the modular structures of the haematopoietin receptor superfamily, exemplified by the receptors for GM-CSF and G-CSF (after Lewis and Gordon, 2003).

that these biochemically documented phenomena, such as receptor transmodulation, transphosphorylation and physical interaction, are biologically significant.

Cytokines regulate a variety of haemopoietic cell functions through the activation of multiple signal transduction pathways (Figure 1.8). The major pathways relevant to cell proliferation

and differentiation are the Janus kinase (Jak)/signal transducers and activators of transcription (STATs), the mitogen-activated protein (MAP) kinase and the phosphatidylinositol (PI) 3-kinase pathways. Jaks function upstream of STATs, which are activated by phosphorylation, and then dimerize and migrate to the nucleus, where they bind to specific DNA motifs. Thus, the Jak–STAT pathway represents the most direct pathway for transmitting a signal from the cytokine receptor to DNA. Ras regulates the best-characterized MAPK cascade, which consists of Raf isoforms MEK1/2 and ERK1/2 and controls proliferation. PI3 kinases phosphorylate inositol lipids, which, in turn, activate downstream targets (Akt, Erk, p70s6k, vav–rac) and influence many different cellular processes. These include cell survival, cell cycle progression, proliferation and reorganization of the actin cytoskeleton. The Jak–STAT pathway is implicated in IL-3, IL-6, Epo and G-CSF signalling, the MAP kinase pathway in Epo, GM-CSF, G-CSF and IL-3 signalling, and the PI3 kinase pathway in IL-6, Epo, GM-CSF, G-CSF and M-CSF signalling.

Thus, all of the haemopoietic growth factors appear to be capable of activating all of the major signal transduction pathways simultaneously. The several pathways that have been identified and the multiple responses, pleiotropism and redundancy that are well-known features of haemopoietic cytokines raise the possibility that a particular cytokine may have different effects in different cell types and possibly utilize different signal transduction pathways for specific functions. Moreover, combinations of cytokines may cooperate to activate further signal transduction pathways that are not activated when cytokines are used individually. Such interactions among receptor-mediated signals provide a mechanism for merging the activities of different ligand–receptor systems and achieving novel cellular outcomes.

Figure 1.8 Generalized diagram of the signal transduction pathways activated by cytokines and their receptors in haemopoietic cells.
Physiology of the cytokine response

Colony formation *in vitro* is a simple model of haemopoietic regulation by cytokines, which involves the interaction of soluble proteins with specific receptors on the surface of the target cells. In culture, the cytokines are freely available at a uniform concentration and any cell which expresses the corresponding receptor will be able to respond. However, this is unlikely to be the situation *in vivo* where stem and progenitor cells are located in the haemopoietic microenvironment and there is a need to control haemopoietic cell production more precisely.

Several mechanisms have the potential to control the access of cytokines to their target cells and are likely to be physiologically important. The first mechanism is the localization of the stem and progenitor cells. The fact that these cells are found predominantly in the haemopoietic microenvironment rather than freely distributed in the bloodstream and tissues indicates that there is a mechanism to retain them there, and it has been extensively demonstrated that stem and progenitor cells express cell adhesion molecules that bind them to proteins expressed by the stromal cells of the marrow microenvironment. Cytokines can also bind to components of the microenvironment, in this case to extracellular matrix proteins produced by the microenvironmental stromal cells, and this may act to direct the cytokine to the appropriate target cell and modify the concentration or duration of exposure. Several cytokines are produced in membrane-bound or soluble forms, which can have different activities. For example, soluble SCF is active for only a short time, whereas membrane-bound SCF is more durable. In the circulation, cytokines can bind to soluble proteins, including soluble receptors, and these interactions may function as carriers for transport of the cytokine in an inactive form from its site of production to its site of action, protect the cytokine from proteolytic degradation or, in some circumstances, inactivate it.

Negative regulation of haemopoiesis

Like all homeostatic systems, haemopoiesis is regulated by a balance of positive and negative influences. They include cytokines such as the macrophage inflammatory protein, MIP-1α, and TGF-β. As well as directly inhibitory factors, a variety of other mechanisms with the potential to block cytokine action have been described. Interleukin 1α and IL-1β have an endogenous receptor agonist that blocks IL-1 binding to its receptor; several cytokines (TNF, IL-2, IL-4) are blocked by soluble receptors that compete with cell-surface receptors and some cytokines inhibit the activities of others.

The location of haemopoiesis in the marrow microenvironment, represented *in vitro* by stromal cell cultures, and the predominantly quiescent nature of the haemopoietic stem cell population indicate a negative role of the microenvironment in suppressing stem cell activity. Early studies of haemopoiesis in long-term bone marrow cultures, in which stromal cells support haemopoiesis for a prolonged period of time *in vitro*, revealed periodic oscillations in the cell cycle activity of stem cells that could be related to the presence of positive and negative cytokines implicated in maintaining homeostasis of the haemopoietic system.

Clinical applications of stem cell research

Stem cell research has provided the growth points for several clinical activities as well as for advances in experimental haematology.

Stem cell transplantation

Bone marrow and stem cell transplantation is the most obvious application of stem cell research. It originated in early studies of the haematological reconstitution of mice whose bone marrow had been ablated by ionizing radiation. It soon became apparent that haematological rescue of these animals required infusion of syngeneic marrow because transplantation of cells from a different strain resulted in a wasting condition called 'secondary disease', which is now known as graft-versus-host disease (GvHD). Both the transplantation of stem cells into mice and the recognition of the importance of histocompatibility in the murine system were important contributions to modern clinical transplantation. The identification of the stem cell immunophenotype and the development of cell separation technologies facilitated the development of graft engineering to improve the results of clinical transplantation. One application of cell separation was to deplete the graft of T lymphocytes, either by removing T cells or purifying CD34$^+$ cells. However, it soon became apparent that a graft-versus-leukaemia activity (GvL) was removed, along with the potential for GvHD, and efforts to isolate GvL from GvHD continue today.

Haemopoietic growth factors

Haemopoietic growth factors such as G-CSF, GM-CSF and erythropoietin are administered to cytopenic patients to stimulate cell production. They were originally identified by their colony-stimulating activity *in vitro*.

Stem cell mobilization

G-CSF, in particular, is widely used to mobilize stem cells (peripheral blood progenitor cells, PBPCs) into the peripheral blood from where they can be harvested by leucapheresis and used as a source of stem cells for transplantation. Initially the procedure was used for autografting but mobilization of PBPCs from allogeneic donors is practised at present.

Stem cell expansion

In cases when insufficient stem cells are available for successful engraftment, it would be advantageous to be able to increase the number of stem cells during a period of *in vitro* culture. For this, 'stem cell expansion' is conducted in the presence of combinations of cytokines, with the aim of inducing stem cell renewal and population growth. A large number of studies have investigated a variety of culture conditions and combinations of cytokines. Frequently used cytokines include Flt3 ligand, thrombopoietin, IL-3 and stem cell factor. Although large increases in numbers of colony-forming progenitor cells have been reported, there is little evidence for expansion of long-term repopulating stem cells.

Gene therapy

The self-renewal and expansion capacities of haemopoietic stem cells make them the ideal vehicle for gene therapy of genetic disorders. The transduced genes will be expressed for long periods of time in the stem cell population and in their differentiating and mature descendants (see Chapter 27).

Erythropoiesis

Douglas R Higgs and William G Wood

2

Introduction

The process of erythropoiesis includes all steps of haemopoiesis, starting with the initial specification of haemopoietic stem cells (HSCs) from mesoderm during embryogenesis. This continues with the decisions of these cells to undergo self-renewal or differentiation, through the process of lineage specification and proliferation to form committed erythroid progenitors. Finally, erythroblasts undergo terminal differentiation and post-mitotic maturation as they develop into red blood cells.

In a normal adult, the numbers of circulating red blood cells and their precursors remain more or less constant with a balance between the continuous loss of mature cells by senescence and new red cell production in the marrow. This balance is maintained by an oxygen-sensing system that is affected by the red cell mass and responds via the production of erythropoietin (Epo), which, in turn, controls red cell production by binding and signalling to committed erythroid progenitors. Many other cytokines, growth factors and hormones also influence erythroid proliferation, differentiation and maturation.

Over the past 10 years, key transcription factors controlling the internal programmes of erythroid progenitors have been identified and some insights into their roles in lineage specification and erythroid differentiation have been discovered. Understanding the basic biology of erythropoiesis provides a logical basis for the diagnosis and treatment of the inherited and acquired anaemias that are so frequently encountered in clinical practice.

The origins of blood during development

Primitive haemopoiesis in man (predominantly erythropoiesis) first appears in the blood islands of the extraembryonic yolk sac at around day 21 of gestation. About 1 week later (days 28–40), definitive haemopoietic stem cells emerge from the vitelline artery and the ventral wall of the embryonic aorta within the aorta–gonad–mesonephros (AGM) region. Both primitive (embryonic) and definitive (fetal/adult) haemopoietic stem cells arise in close association with endothelial cells. Several lines of evidence now suggest that haemopoietic and endothelial cells may emerge from a common progenitor, the haemangioblast, giving rise to both blood cells and blood vessels (see Chapter 1). At about 30–40 days, definitive haemopoiesis starts to occur in the fetal liver and definitive erythroid cells are released into the circulation at about 60 days. By 10–12 weeks, haemopoiesis starts to migrate to the bone marrow, where eventually erythropoiesis is established during the last 3 months of fetal life (Figure 2.1).

Primitive and definitive erythropoietic cells are distinguished by their cellular morphology, cell-surface markers, cytokine responsiveness, growth kinetics, transcription factor programmes and more general patterns of gene expression. In particular, the types of haemoglobin produced are quite distinct in embryonic (Hb Gower I $\zeta_2\varepsilon_2$, Gower II $\alpha_2\varepsilon_2$ and Hb Portland $\zeta_2\gamma_2$), fetal (HbF $\alpha_2\gamma_2$) and adult (HbA $\alpha_2\beta_2$ and HbA$_2$ $\alpha_2\delta_2$) erythroid cells. These specific patterns of globin expression have provided critical markers for identifying the developmental stages of erythropoiesis. Nevertheless, it is still not clear whether primitive and definitive haemopoiesis in mammals have entirely separate origins or if they are both derived from common stem cells that arise during early development. Accurately defining the embryological origins of these cells continues be of considerable importance for understanding the normal mechanisms that establish and maintain haemopoietic stem cells and how these programmes are subverted in common haematological disorders.
Figure 2.1 An outline of the origin and development of erythropoiesis during embryogenesis. Although both primitive (blood islands) and definitive (AGM, liver and bone marrow) haemopoiesis are derived from mesoderm, probably via a haemangioblast, the true origin of these early cells is not yet clear. The figure shows the formation of embryonic blood islands in the extraembryonic yolk sac and the formation of definitive haemopoiesis initially in the aorta–gonad–mesonephros region, with subsequent migration to the liver and bone marrow. 'A' denotes a magnified image of the early embryonic aortic region. Ma denotes a macrophage. The specific types of haemoglobin formed at each stage of erythropoiesis are indicated. The approximate times at which CD34$^+$ cells first appear at each site are given in days of gestation (adapted from Dzierzak *et al.* (1998) *Immunology Today* **19:** 228–36).

Differentiation of haemopoietic stem cells to form erythroid progenitors

At all stages of development there is a continuous need to renew senescent blood cells that are ultimately lost from the peripheral blood days, weeks or months after undergoing terminal differentiation. For example, throughout adult life approximately 10^{11} senescent red cells must be replaced every day, and there are similar requirements for other mature blood cells (e.g. granulocytes). To prevent depletion of the haemopoietic cells requires a system that not only maintains a self-renewing stem cell pool, but also has the potential to differentiate into all types of highly specialized mature blood cells through a process referred to as lineage specification.

At present, the mechanisms underlying self-renewal and the early events committing multipotential haemopoietic stem cells (HSCs) to an increasingly restricted repertoire of lineage(s) are not fully understood. A popular interpretation is that commitment of multipotential haemopoietic cells to one or another lineage is a stochastic process. The probability of commitment to any particular lineage may be influenced by a complex interplay between the internal transcriptional programmes and epigenetic patterns (e.g. changes in nuclear position, replication timing, chromatin modification, DNA methylation) with external signals from the microenvironment (e.g. cytokines, growth factors and cell–cell interactions).

It is of interest that microarray analyses of haemopoietic stem cells and their progeny consistently show a very wide range of gene expression in the earliest cell populations. Furthermore, many of the genes that are specific to individual lineages (e.g. erythroid, myeloid or lymphoid) are already transcribed, albeit at low levels, in HSCs. In other words, HSCs appear to show 'multilineage priming' and, as their progeny become committed to one pathway of differentiation, that lineage-specific gene expression programme becomes reinforced, whereas those of other lineages are suppressed.

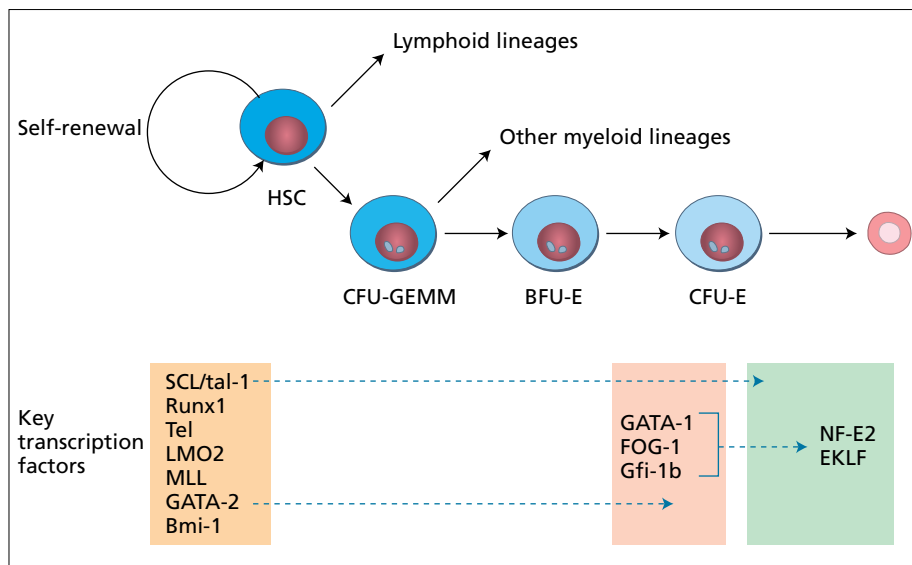
In human adult bone marrow, approximately 1 per 10^4–10^6 nucleated cells are long-lived, multipotential HSCs that can be enriched on the basis of their cell-surface markers (e.g. CD33$^+$ and CD34$^+$ and lack of lineage-specific markers; see Figures 2.2 and 2.3), but such markers do not exclusively select stem cells (see Chapter 1). The only rigorous assay for *bona fide* HSCs is to


Figure 2.2 Summary of some steps in self-renewal, lineage specification and differentiation of haemopoietic stem cells to red cells. Some of the key transcription factors involved in this process are summarized underneath.
Figure 2.3 The specification and terminal differentiation of erythroid cells from haemopoietic stem cells. Above, the estimated times for maturation of terminally differentiating cells are shown. The abbreviations are as follows; pronormoblasts (Pro), basophilic erythroblasts (Bas), polychromatic erythroblasts (Pol), orthochromatic erythroblasts (Ort), reticulocytes (retic), mature red blood cells (RBCs). The number of divisions from pronormoblasts to orthochromatic normoblasts (1–16) are also shown. Some examples of the expression patterns of key cell-surface markers are shown below.

measure their ability to contribute, throughout life, to all haemopoietic lineages *in vivo*. This has been amply demonstrated in mice, and the repeated, predictable success of human bone marrow transplantation clearly demonstrates the existence of such cells in man.

As stem cells differentiate, they form multipotential progenitor cells that have short-term repopulating ability but have lost long-term repopulating ability. Such cells can be assayed *in vitro* by their ability to form 'cobblestone' areas under stromal cells in long-term marrow cultures. Further differentiation

progressively restricts the lineage potential of these cells as well as reducing their proliferative capacity, resulting in tri-, bi- and unipotential progenitors. These progenitor cells are functionally defined by their ability to produce clonal colonies in semisolid medium supplemented with a cocktail of haemopoietic cell growth factors permissive for the growth of all lineages.

Erythroid cells are found in multilineage colonies (CFU-GEMM), which include granulocytes, macrophages and mega-karyocytes, and in bipotential colonies with megakaryocytes (CFU-E/Mk). The earliest progenitors that are restricted to the erythroid lineage produce large colonies *in vitro*, consisting of several subunits, known as erythroid bursts (BFU-E, containing from several hundred up to 30 000 cells) after 12–14 days of growth. Their frequency in bone marrow is ~4–10/10^4 nucleated cells. Late erythroid progenitors form colonies (CFU-E) of 8–64 cells after ~7 days *in vitro* and constitute 20–60/10^4 bone marrow cells. CFU-Es defined in these culture systems most closely correspond *in vivo* to pronormoblasts (also known as proerythroblasts), the earliest recognizable erythroid precursor in the bone marrow. Once formed, these cells are destined to undergo terminal differentiation to form mature red cells as discussed later.

Although erythroid progenitors and their progeny can be grown effectively in supplemented culture systems, erythroid differentiation and maturation within the adult bone marrow *in vivo* are dependent on the microenvironment provided by the stromal cells (fibroblasts, fat cells, endothelial cells, macrophages and smooth muscle cells). There are also immunoregulatory cells (monocytes, macrophages and lymphocytes) that contribute to local cytokine production. Erythroblasts are not randomly distributed in the bone marrow but are organized into erythroblastic islands containing one or two central macrophages, surrounded by layers of erythroblasts at different stages of maturation (Figure 2.1).

The transcription factor programme underlying erythropoiesis

As discussed above in the stochastic model of cell differentiation, many factors must be integrated for a cell to make the decision to undergo self-renewal or differentiation, become quiescent, proliferate or undergo apoptosis. Over the past few years, it has emerged that key transcription factors play a major role in regulating the formation, survival, proliferation and differentiation of multipotent stem cells as they undergo the transition to erythroid cells. These transcription factors may operate on their own or as members of multicomponent complexes involved in activation and/or repression. Many of the key transcription factors were originally identified because they are associated with chromosomal translocations found in leukaemia. This supports a model in which dysregulation of the normal transcriptional programme plays a causal role in haematological malignancies.

At present, the key transcription factors known to be involved in specifying haemopoietic stem cells as they develop during embryogenesis and in maintaining them throughout life include Runx1 (AML-1), SCL (tal-1), LMO2 (rhombotin), Tel (ETV6), MLL and GATA-2 (Figure 2.2). In addition, the homeobox (Hox) genes and proteins that modify their expression (e.g. Bmi-1) have also been shown to play a role in haemopoiesis. However, it is of interest to point out here that many of these factors (e.g. SCL, Runx1) appear to act quite differently in primitive as opposed to definitive haemopoiesis. Furthermore, not only is their importance in early definitive progenitors well established, but also many of these transcription factors play additional roles, later in differentiation, in specific haemopoietic lineages, including erythropoiesis.

Once progenitor cells have been committed to become erythroid cells, the most important transcription factors that enable them to proceed through terminal differentiation are GATA-1 and its cofactor FOG-1 (friend of GATA-1). GATA-1 was first identified by its ability to bind functionally important regulatory sequences in the globin genes. Since then, GATA-binding motifs have been found in the promoters and/or enhancers of virtually all erythroid-specific genes studied, including haem biosynthetic enzymes, red cell membrane proteins (including blood group antigens) and erythroid transcription factors (e.g. erythroid Kruppel-like factor, EKLF and GATA-1 itself). GATA-1 expression is restricted to erythroid, megakaryocytic, eosinophilic, mast cells and multipotential progenitors of the haemopoietic, system. However, GATA-1 expression is highly upregulated in pronormoblasts and basophilic erythroblasts (Figures 2.2 and 2.3).

Gene targeting studies in mice have shown that GATA-1 is essential for normal erythropoiesis. Mice that produce no GATA-1 die from severe anaemia. Although they produce adequate numbers of erythroid colonies (CFU-E), there is an arrest in erythroid maturation at the pronormoblast stage of differentiation. *In vitro* differentiated mouse embryonic stem (ES) cells lacking GATA-1 also fail to mature past the pronormoblast stage and undergo rapid apoptosis, indicating a role for GATA-1 in survival and maturation of erythroblasts.

GATA-1 may protect mature erythroblasts from apoptosis by directly or indirectly inducing expression of the anti-apoptotic protein Bcl-X_L. GATA-1 almost certainly regulates gene expression working as part of a multiprotein complex interacting, for example, with FOG-1, LMO2, SCL and a variety of ubiquitously expressed transcription factors. FOG-1 is a protein containing multiple zinc fingers, four of which interact with GATA-1. Like GATA-1, FOG-1 is expressed in erythroid and megakaryocytic cells and is coexpressed and directly interacts with GATA-1 during development. Genetically modified mice that express no FOG-1 also die in mid-gestation as a result of severe anaemia with arrest in erythroid maturation at the pronormoblast stage.

GATA-2 is a second member of the GATA family of proteins that is involved in haemopoiesis. Both GATA-1 and GATA-2 are

particularly relevant for erythropoiesis. Both are expressed in multipotent progenitors, although GATA-2 appears to be more important than GATA-1 at this stage, when GATA-2 plays an important role in the expansion and maintenance of haemopoietic progenitors. During erythroid differentiation the level of GATA-2 declines as GATA-1 increases. In mouse embryos lacking GATA-2, erythrocytes are present, but in severely reduced numbers. There appears to be some overlap and redundancy between the roles of GATA-1 and GATA-2; in the absence of GATA-1 increased levels of GATA-2 may fulfil some, but not all, of the normal roles of GATA-1. Furthermore, there is evidence that the level of GATA-2 is regulated by the level of GATA-1. During normal erythroid development, it has been suggested that GATA-2 may initiate the erythroid programme in early erythroid progenitors to be replaced later by GATA-1 during terminal erythroid maturation.

Expression of the two related zinc-finger DNA-binding proteins Gfi-1 and Gfi-1b is restricted to haemopoietic cells. Gfi-1b is expressed only in multipotent progenitors, megakaryocytes and erythroblasts, in which its pattern of expression mimics that of GATA-1. Gfi-1b-deficient mouse embryos die with a failure to produce mature red cells, although early precursors are formed normally. This is very similar to the phenotype observed in GATA-1-deficient embryos. However, from *in vitro* colony assays in which Gfi-1b is overexpressed, it appears that its effect is not on erythroid commitment, but rather it promotes the proliferation of erythroid progenitors as they undergo the transition from late BFU-Es to CFU-Es.

Erythroid Kruppel-like factor (EKLF) is a zinc finger-like protein of the Kruppel family, which binds the consensus sequence 5′-NCNCNCCCN-3′ and is mainly restricted to erythroid cells. These binding sites are found in the regulatory elements of several erythroid-specific genes, including the β-globin gene. Disruption of binding at this site gives rise to β-thalassaemia. Mice in which EKLF is absent die from severe anaemia at the fetal liver stage caused in part by β-thalassaemia, but also due to the failure to synthesize correctly other EKLF-regulated proteins (e.g. the red cell membrane protein Band3 and the α-globin-stabilizing protein AHSP) required for red cell maturation. Therefore, EKLF may play a wider role than originally predicted in coordinating erythroid cell maturation and globin gene regulation.

Sequence motifs of the general class (T/C)GCTGA(G/C) TCA(T/C), called Maf recognition elements (MAREs), have been found in the enhancers of many erythroid-specific genes (e.g. globins, haem synthesis enzymes), and it was shown that they bind the transcription factor NF-E2. Purification of NF-E2 revealed that it consists of two subunits, p45NF-E2 and p18NF-E2 (now known as MafK). Both proteins contain basic zipper (b-zip) domains through which they form heterodimers and bind DNA. p45 is expressed mainly in erythroid cells, whereas p18 is widely expressed, although it is the predominant small Maf family member in erythroid cells. Furthermore, it is now known that both p45 and p18 are members of larger groups of proteins with overlapping functions. Other p45-like molecules include Nrf1, 2 and 3 and Bach1 and 2. All of these proteins bind as obligate heterodimers with Maf proteins. It seems likely that binding to MARE elements is an important aspect of erythroid-specific activation, but it is not clear which proteins in this family bind the key sites or whether there is redundancy in the need for specific members of this family.

At present it is not fully understood how these transcription factors combine to commit cells to the erythroid lineage and terminal erythroid differentiation. However, this could involve the presence or absence of specific transcription factors, changes in the levels of the proteins and/or protein modification. One principle that seems to be emerging is that factors affiliated with different lineages such as GATA-1 (erythroid) and PU1 (lymphocytes and granulocytes) are both present in uncommitted progenitors, reflecting the potential to develop along alternative different pathways (so-called multilineage priming). It is now known that GATA-1 and PU1 interact and cross-antagonize each other. Therefore, as cells differentiate, reinforcement of the transcriptional programme of one lineage may actively suppress an alternative lineage.

Terminal maturation of committed erythroid cells

After the erythroid programme has been specified, the final phase of erythropoiesis involves the maturation of committed erythroid progenitors to fully differentiated red cells. The earliest recognizable erythroid precursor cell in the bone marrow is the pronormoblast (Figure 2.4a, i) – which, as discussed above, corresponds to the CFU-Es identified *in vitro*. The pronormoblast is a relatively large cell (12–20 microns) with a non-granular, deep-blue cytoplasm and a large nucleus occupying about three-quarters of the cell, having a finely stippled chromatin pattern that contains one or more prominent nucleoli. On electron microscopy, there appears to be relatively little heterochromatin in these cells.

The cytoplasm contains numerous ribosomes, several mitochondria, centrioles, a prominent Golgi apparatus and a few strands of rough endoplasmic reticulum. Division of these cells leads to smaller (10–16 microns) basophilic normoblasts (Figure 2.4a, ii). Again, the cytoplasm stains deep blue and the nucleus occupies a large proportion of the cell but has a coarser reticular chromatin pattern with a few small masses of condensed chromatin adjacent to the nuclear membrane. Further divisions form early polychromatic and late polychromatic normoblasts (10–12 microns), with increasing development of a pink cytoplasm and condensed (6 microns) nuclei (Figure 2.4a, iii). Late polychromatic/orthochromatic normoblasts (Figure 2.4a, iv) are non-dividing cells with deeply staining structureless nuclei.

As the cell proceeds through terminal differentiation, nucleoli disappear and the nucleus condenses further and is eventually

extruded. Such nuclei are phagocytosed and degraded by the macrophages of the bone marrow. Ultrastructural studies have shown that nuclear extrusion usually occurs outside the sinusoids of the bone marrow, and that newly formed reticulocytes usually pass through pre-existing gaps in the walls of these sinusoids by diapedesis. Thus, the mature reticulocyte has no nucleus but has a few mitochondria and ribosomes and its cytoplasm stains predominantly pink because of the high concentration of haemoglobin. The cytoplasm still has a greyish tint due to the presence of ribosomes. When stained supravitally, the ribosomes precipitate into basophilic granules or a reticulum. Reticulocytes continue to synthesize haemoglobin for 24–48 h after release from the bone marrow. On average, these cells are about 20% larger than mature red cells, which are circular flat, biconcave discs with a mean diameter of 8.5 microns.

It has been estimated that, on average, four divisions occur within the morphologically recognizable proliferating precursor pool, so that each newly formed pronormoblast develops into 16 red cells (Figure 2.3). As a small amount of cell death (ineffective erythropoiesis) normally occurs, the average amplification is slightly less than 16-fold. The majority (60–80%) of pronormoblasts, basophilic normoblasts and early polychromatic normoblasts are in cell cycle, mostly in S-phase, with G_1 and G_2 stages lasting for only a few hours. At any time, about 3% pronormoblasts, 5% basophilic erythroblasts and 6% polychromatic normoblasts are undergoing mitosis, which has been variously estimated to last for between 60 and 100 min. Erythroid cells eventually exit from the cell cycle and, consistent with this, late polychromatic/orthochromatic erythroblasts are post-mitotic, non-dividing cells.

Changes in the cell surface phenotype that accompany erythroid differentiation and maturation

The cell-surface phenotypes of erythroid progenitors and precursors are quite distinctive, reflecting the different signalling programmes of the cells as they differentiate. These markers are also of value in the analysis of erythroid progenitors and precursors as they can be used to identify and purify subpopulations of cells. CD34 is present on nearly all multipotent progenitors and committed BFU-E but is lost on later erythroid progenitors (CFU-E) and all precursors.

A similar pattern of expression is shown for the receptor c-Kit. Epo receptor (EpoR, see below) first appears in small numbers (20–50 copies per cell) on late BFU-Es, increases in CFU-Es and pronormoblasts (~1000 copies per cell) and subsequently declines and disappears in later erythroid precursors. CD71 (transferrin receptor, TfR) allows transferrin-bound iron to be taken into the cell and is present on early haemopoietic cells but is considerably upregulated on cells that are actively synthesizing haemoglobin, reaching a peak of 800 000 molecules

per cell on polychromatic normoblasts. CD71 levels diminish in the late phase of terminal differentiation and the receptor is not detectable on mature erythrocytes. Glycophorin A (GPA) is a membrane sialoglycoprotein whose expression is highly upregulated as erythroid progenitors mature from pronormoblasts. Combinations of these cell-surface markers can be used to distinguish early, intermediate and late erythroid precursors (Figure 2.4b). Developing erythroid cells express cell-surface adhesion molecules that interact with the extracellular matrix; these include ICAM-1 (a member of the immunoglobulin superfamily) and integrin $\alpha_4\beta_1$ VLA4 (CD29, CD49d), which interacts with fibronectin. These adhesion molecules are most

highly expressed in the early precursors and lost as maturation proceeds, freeing erythroid cells to exit the bone marrow.

Changes in gene expression in erythroid differentiation and maturation

As cells go through the final divisions of erythropoiesis and post-mitotic maturation there is progressive condensation of chromatin accompanied by complex changes in gene expression. When assessed by microarray analysis, many mRNAs are downregulated as multipotent progenitors enter terminal differentiation, reflecting the commitment of multipotent cells to a single specialized lineage. A subset of general mRNAs associated with proliferation, replication and cell cycle control show alterations as the growth characteristics of the cells change. mRNAs encoding proteins that characterize the red cell phenotype are, in general, upregulated. Examples include blood group antigens, red cell membrane proteins (e.g. spectrin, ankyrin, actin, protein 4.1), red cell glycolytic pathway enzymes, carbonic anhydrase and enzymes of the haem synthesis pathway (e.g. δ-aminolaevulinic acid synthase, ALA synthase). A full catalogue of these changes in gene expression can be found at http://hembase.niddk.nih.gov.

The main purpose of erythropoiesis is to synthesize large amounts of haemoglobin (Figures 2.3–2.5). Globin mRNA sequences are first expressed in pronormoblasts and early basophilic erythroblasts. Globin chain synthesis parallels accumulation of globin mRNA, increasing at the polychromatophilic and orthochromatic stages. The amount of globin mRNA reaches 20 000 molecules per cell in late polychromatic orthochromatic erythroblasts. During the later stages of erythroid cell maturation, the amount of RNA per cell and the rate of total protein synthesis declines, but the relative stability of globin mRNA ensures that globin becomes the predominant polypeptide made in late erythroblasts and reticulocytes.

The individual components of the haemoglobin synthetic pathway (iron, free porphyrins, haem and monomeric globin chains) are all extremely toxic to the cell, and consequently many positive and negative feedback loops have evolved and been incorporated into this process. The synthesis of globin must be very accurately matched with the synthesis of haem in which some steps take place in the cytoplasm and others occur in the mitochondria (Figure 2.5). mRNAs encoding many components of the haem biosynthetic pathway (e.g. ALA synthase and porphobilinogen deaminase, PBGD) are coordinately upregulated in terminal erythroid differentiation and their genes contain similar cis-regulatory elements.

Continued translation of globin chains from mRNA only occurs in the presence of adequate haem. Reduced levels of haem rapidly trigger the formation of the 'haem regulated inhibitor' (HRI), a kinase that interacts with the translation initiating factor eIF-2α and prevents translation of α- and β-globin mRNA. The synthesis of haem itself is also regulated at many points and is particularly sensitive to the levels of available iron. Via a well-characterized pathway involving the iron-regulatory proteins (IRP1 and IRP2), binding to iron response elements (IREs) in the mRNA transcripts of ferritin, TfR and ALA synthase, the level of intracellular iron thus controls the
Figure 2.5 The coordination of globin synthesis, haem synthesis and iron regulation. Blue lines indicate some of the known regulatory feedback systems. The red shaded box indicates reactions occurring in the mitochondria. Rate-limiting controls of haem synthesis are shown in black boxes.

translation of RNAs involved in iron storage, iron transport and haem synthesis (see Chapter 3). The recent discovery of hepcidin, which controls the uptake of iron from the gut, iron transport across the placenta and iron release from macrophages, adds another level of control to this complex system (see Chapter 3). Not surprisingly, diseases affecting the supply of iron (iron deficiency and the anaemia of chronic disease), the synthesis of haem (sideroblastic anaemia, lead poisoning, alcohol ingestion) or the synthesis of globin (thalassaemia) have inter-related effects on globin synthesis, haem synthesis and iron metabolism (Figure 2.5).

No mechanistic connection between haemoglobin synthesis and erythroid proliferation or differentiation has yet been established. However, it has been postulated that haemoglobin content and/or haemoglobin concentration *per se* may be a negative regulator of cell division. When haemoglobin synthesis is reduced or delayed, as in iron deficiency, the cells may undergo an extra division, yielding smaller hypochromic cells. Alternatively, when haemoglobin synthesis exceeds DNA synthesis, as in megaloblastic anaemias, the cells may skip a division and nuclear extrusion may occur early, resulting in macrocytosis. Although plausible, these hypotheses remain unproven.

The regulation of erythropoiesis by signalling pathways

The normal red cell lifespan is 120 days and therefore, to maintain equilibrium, approximately 1% of the circulating red cell pool must be replaced daily. For a total of $\sim 3 \times 10^{13}$ circulating erythrocytes and a lifespan of 120 days, the erythrocyte production rate needs to be maintained at $\sim 10^{10}$/h in the steady state.

Erythropoiesis accounts for about 20% of the nucleated cells in a normal bone marrow reflected in the myeloid–erythroid ratio (usually ~4:1). As committed erythroid cells become late BFU-E and CFU-E, they upregulate expression of the receptor for erythropoietin (EpoR). Signalling through this receptor is thought to prevent apoptosis and may also stimulate proliferation. Therefore, at the late BFU-E and CFU-E stages there is considerable potential for controlling the overall level of erythropoiesis. Soon after reaching the CFU-E stage, erythroid cells enter the phase of terminal differentiation, after which there is only limited potential for further expansion. The two major components regulating erythropoiesis include sensing hypoxia and regulating the supply of erythroid precursors, mainly by controlling the numbers of erythroid progenitors via the Epo–EpoR signalling pathway.

Sensing hypoxia

Tissue hypoxia induces a variety of physiological responses in addition to activation of the Epo–EpoR pathway (see below). Parallel responses include the stimulation of new blood vessels by vascular endothelial growth factor (VEGF) and metabolic changes (e.g. in glycolytic pathway enzymes) that enable continued energy production despite inadequate oxygen availability. In addition, expression of the transferrin receptor is upregulated. Over the past few years the mechanisms by which cells sense hypoxia and orchestrate their response have been discovered. It has been shown that the most important mediator of this cellular response is a transcription factor called HIF (hypoxia-inducible factor), which activates the genes that influence the adaptive responses to hypoxia including those encoding Epo, glycolytic pathway enzymes, transferrin receptor and VEGF (Figure 2.6).

Figure 2.6 The oxygen-sensing system. vHL indicates the von Hippel–Lindau protein. Ub indicates ubiquitination.

HIF is a heterodimer constituting one of three α-subunits (HIF1-α, HIF2-α or HIF3-α) bound to the aryl hydrocarbon receptor nuclear translocator (ARNT), also known as HIF1-β. HIF1-α is a member of the basic helix–loop–helix (bHLH) family of transcription factors in which the HLH domains mediate subunit dimerization, whereas the basic domains bind DNA HIF binds to hypoxia-response elements (HREs, 5'-TACGTG-3') located in the regulatory regions of hypoxia-inducible genes such as the gene encoding Epo (see below). Whereas changes in oxygen levels do not affect the levels of HIF1-β, which is expressed constitutively, hypoxia elevates the levels of HIF1-α subunits by increasing protein stability.

The oxygen sensor is probably a ferrous iron prolyl hydroxylase that requires molecular oxygen as a cosubstrate to hydroxylate specific proline residues in the α-subunits of HIF. Once hydroxylated, HIF1-α subunits become targets for ubiquitination by the widely expressed von Hippel–Lindau (vHL) protein and are thus targeted for proteosomal degradation. Under normal circumstances the α-subunits are undetectable, but, when cells are exposed to hypoxic stimuli, the oxygen sensor can no longer hydroxylate the α-subunits of HIF. In this situation, α-subunits accumulate as they are no longer polyubiquitinated and degraded. This allows the α-subunits to heterodimerize with HIF1-β and activate the hypoxia-response genes. If the vHL protein is mutated (vHL syndrome), there is prolonged stimulation by HIF, leading to the development of polycythaemia (Epo stimulation) and vascular tumours (VEGF stimulation).

Erythropoietin and the erythropoietin receptor

The Epo gene contains a hypoxia-response element at its 3'-end. Increased levels of the HIF heterodimer upregulate transcription of the Epo gene, increasing serum levels of the protein. The binding of Epo to the erythropoietin receptor (EpoR) results in signal transduction to the nucleus, and this constitutes the most important pathway for controlling definitive erythropoiesis. Careful clinical and haematological studies together with the analysis of experimental animal models have been important in establishing exactly which aspects of erythropoiesis are regulated by the Epo–EpoR system. Fetal livers of genetically modified mice, in which Epo or EpoR has been deleted, are devoid of late erythroid cells but contain normal numbers of BFU-E, demonstrating that this signalling system is not required for lineage specification but is essential for proliferation and differentiation of erythroid precursors into mature cells.

When tissue oxygenation is compromised owing to reduced ambient oxygen tension, blood loss, shortened red cell survival or any uncompensated need for increased oxygen delivery, the level of Epo rises, stimulating red cell production. Late BFU-E and particularly CFU-E are the key targets for Epo activity. When circulating Epo increases, apoptosis of these erythroid progenitors decreases and CFU-Es rapidly respond by proliferating and differentiating. Therefore, the most important effect of Epo is to increase the number of progenitor cells that develop into viable pronormoblasts. It has also been suggested that Epo is able to speed up the rate of terminal differentiation by shortening the cell cycle and maturation times of erythroblasts, thereby explaining the macrocytosis that often accompanies 'stress' erythropoiesis; this remains to be confirmed.

The erythropoietin signalling system is relatively well understood. Erythropoietin is a heavily glycosylated, 34-kDa protein. The level of Epo is controlled via the oxygen tension in the kidney. There are no preformed stores of Epo and it has a short plasma half-life of 6–9 h, allowing relatively rapid responses to changes in tissue oxygenation. Normally, 90% of the hormone is produced in the peritubular complex of the kidney and 10% in the liver and elsewhere.

The Epo receptor belongs to the cytokine receptor superfamily. Like other members of this family (growth hormone, prolactin and G-CSF), Epo was thought to induce dimerization of cell-surface receptors (EpoRs), triggering autophosphorylation and activation of the Janus family of protein tyrosine kinases (JAK2). More recent data suggest an alternative model in which unliganded EpoR dimers exist in a conformation that prevents activation of JAK2, but the receptor may undergo a ligand-induced conformational change that allows JAK2 to be activated. JAK2 and/or other kinases then phosphorylate specific tyrosine residues in the EpoR, creating docking sites for the SH2 domains of several signal transduction proteins, which eventually results in the activation of at least three signal transduction pathways: STAT5, Ras/MAP kinase and PI3 kinase (Figures 2.7 and 2.8).

Considerable interest has concentrated on the JAK2–STAT5 pathway. JAK2 is essential for erythropoiesis, and genetically modified mice in which JAK2 expression has been eliminated die as embryos, with a phenotype similar to mice deficient in Epo or EpoR. However, the numbers of erythroid progenitors are more severely diminished, suggesting that JAK2 is required earlier in erythropoiesis than Epo–EpoR. JAK2 is rapidly phosphorylated in response to Epo stimulation. Dimerization or conformational changes of the EpoR brings the associated JAK2 molecules into close proximity, enabling them to transphosphorylate and activate each other (Figures 2.7 and 2.8). STAT5 is phosphorylated and activated by EpoR. Phosphorylated STAT5 dissociates from the receptor, dimerizes and moves to the nucleus, where it activates gene expression and is thought to be important as an anti-apoptotic signal. Both fetal and adult mice defective in STAT5 have a defect in regulating survival of early erythroblasts, leading to a persistent anaemia.

Activation of the PI3 kinase and Ras–MAP kinase pathway (Figure 2.8) may be sufficient for normal erythroid differentiation, although they may not be essential as other pathways can compensate for loss of signalling through PI3 kinase. Therefore, in erythroid cells, activation of several, apparently redundant
Figure 2.7 A summary of signalling via the Epo receptor as described in the text. P denotes regions of phosphorylation. The diagram shows Epo-induced dimerization or conformational change with transphosphorylation of JAK2, followed by phosphorylation of the Epo receptor. This is followed by binding and phosphorylation of STAT5. Binding of SHP1 (far right) to the Epo receptor activates its phosphatase activity, which can then dephosphorylate JAK2 and terminate signalling.
Figure 2.8 A summary of the apoptotic pathways (Epo and Fas) in erythroid progenitors. These cells (BFU-E and CFU-E) undergo apoptosis in the absence of Epo signalling or in the presence of Fas signalling. Bcl-X_L may be the key pathway through which these effects are mediated.

intracellular signalling pathways can support differentiation. Nevertheless, it is thought at present that these pathways may converge by activating a few, important anti-apoptotic proteins, including Bcl-2, Bcl-X$_L$ and protein kinase B (also known as Akt) (Figure 2.8).

The full control of this system is complex and it should be noted that the EpoR pathway can also be activated by other mechanisms. For example, activation of c-Kit by its ligand, stem cell factor (SCF), causes tyrosine phosphorylation of the EpoR and a functional interaction between the two receptors is essential for normal erythropoiesis.

Mechanisms for switching off the Epo–EpoR signalling pathway also exist. Specific phosphorylated tyrosines that occur on the Epo-stimulated dimerized EpoR provide docking sites for the SH2 domains of protein tyrosine phosphatases such as SHP1. Binding activates the phosphatase, which removes the activating phosphates from JAK2, terminating the positive signal from this pathway (Figure 2.7).

Other signalling pathways

Erythropoiesis is also influenced by pathways other than Epo–EpoR. Erythroid progenitors express receptors for Epo, SCF, insulin-like growth factor (IGF-1) and insulin. After Epo, the second most important signalling system for erythropoiesis involves SCF (Kit ligand) and its receptor (c-Kit). Activation by SCF induces tyrosine phosphorylation of its own receptor. SCF was originally identified by its ability to stimulate proliferation of multipotent haemopoietic progenitors, but it is also effective in supporting growth of committed progenitors, including erythroid progenitors, acting synergistically with Epo.

In addition to SCF and Epo, recent observations have shown that stimulation of the nuclear hormone receptors for dexamethasone (glucocorticoid receptor) and oestrogen (oestrogen receptor) produces sustained proliferation of erythroid progenitors. Furthermore, the nuclear hormone receptors for thyroid hormone (c-ErbA/thyroid hormone receptor), all-*trans* retinoic acid (retinoic acid receptor) and 9-*cis*-RA (RXR) were found to promote erythroid differentiation. Such observations are consistent with previous reports showing that patients with a wide range of endocrine disorders (hypothyroidism, hypopituitarism, Addison's disease and male hypogonadism) all have variable degrees of normochromic normocytic anaemia. It appears, therefore, that many hormones of the endocrine system can modify erythropoiesis.

Apoptosis during normal erythropoiesis

Programmed cell death (apoptosis) plays an important role in normal erythropoiesis (Figure 2.8), helping to regulate the accumulation of erythroid precursors to match the need for new mature red cells. Excess erythroid precursors are removed by apoptosis, and at least two pathways seem to be involved. First, it appears that late BFU-E, CFU-E and pronormoblasts may all require continuous signalling via the erythropoietin receptor, which is highly expressed on the surface of these cells, to prevent apoptosis. In the absence of Epo, these cells rapidly undergo programmed cell death in culture. It has been shown that, in part, this reflects a need for signals from the EpoR, via the JAK2–STAT 5 pathway, to induce or stabilize expression of the anti-apoptotic protein Bcl-X$_L$.

Apoptosis of erythroid precursors may also occur as a result of activation of the Fas receptor (FasR, known as CD95) that is present on both early and late erythroid precursors, although its activating ligand (FasL, known as CD95L) appears only on late erythroblasts. Binding of FasL to FasR activates proteolytic caspases that cleave intracellular proteins, possibly including the erythroid transcription factor GATA-1, with subsequent loss of Bcl-X$_L$. This regulation of erythropoiesis by negative feedback is thought to take place in the erythropoietic islands of the bone marrow, where the number of mature erythroblasts may control the expansion and differentiation of their less mature precursors.

As well as extracellular anti-apoptotic signals, erythroblasts also use internal programmes to ensure their own survival. The transcription factor GATA-1 is essential for maturation of erythroblasts; the absence of GATA-1 leads to apoptosis and a block in maturation. Some of the target genes regulated by GATA-1 are likely to be important for cell survival. Although many of the targets are unknown, it is clear that GATA-1 strongly induces expression of Bcl-X$_L$ and may therefore cooperate with EpoR signalling. In this way, Epo signalling, Fas-mediated signalling and GATA-1 converge on Bcl-X$_L$, which represents a key target of the erythroid cell survival programme.

Erythropoiesis in clinical practice

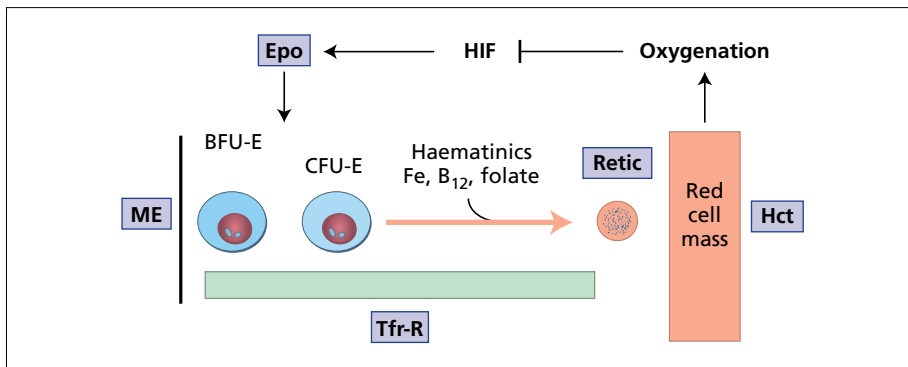
Erythropoiesis is disturbed to a greater or lesser extent in almost all multisystem diseases and so the reader is referred to other chapters and references for specific examples. The aim of this chapter is to provide a framework for thinking about the process of erythropoiesis in clinical practice. The first stage involves the production of committed erythroid progenitors. The second involves controlling red cell production, which is mainly achieved via the oxygen sensor influencing the level of Epo, which, in turn, controls the numbers of late BFU-Es and CFU-Es, although many other hormones cytokines and growth factors may modify the response. The third phase requires terminal erythroid differentiation to mature red cells containing large amounts of specific proteins such as haemoglobin. This phase makes significant demands on a variety of nutritional factors and cofactors, particularly iron, vitamin B$_{12}$ and folate, but also manganese, cobalt, vitamin C, vitamin E, vitamin B$_6$


Figure 2.9 Summary of the regulation of erythropoiesis with the key points for assessment boxed in blue. ME denotes assessment of the M/E ratio in the bone marrow.

(pyridoxine), thiamine, riboflavin, pantothenic acid and amino acids. Absolute or relative deficiencies of these cofactors can negatively regulate erythropoiesis. The output from this process (red cell mass) is required to meet the demands for adequate tissue oxygenation, which, itself, has a major influence on the production of erythropoietin, thus completing the regulatory loop (Figure 2.9).

Simple diagnostic tools are available to test the circuit in a logical manner (also see Chapter 6). First, one can evaluate the overall level of erythropoiesis by estimating the ratio of myeloid precursors–erythroid precursors in the marrow (normally ~4:1, but with a very broad normal range). Total erythropoiesis can be measured accurately using radioactive (^{59}Fe) ferrokinetic assays. The plasma iron turnover measures the total (i.e. effective and ineffective) amount of erythropoiesis, whereas the red cell iron utilization assay measures effective erythropoiesis. To a large extent, these two parameters can now be assessed much more easily by measuring the levels of soluble transferrin receptor (sTfR) and the reticulocyte count. Soluble sTfR is a truncated form of the receptor which circulates in a complex with transferrin. The erythroblasts rather than the reticulocytes are the main source of sTfR and, when iron stores are adequate and available, measuring the level of sTfR (NR 5.0 ± 1.0 mg/mL) is a good guide to the total level of erythropoiesis. STfR levels are increased when erythropoiesis is stimulated and decreased when diminished. The interpretation of sTFR levels is complicated in iron deficiency as this condition independently raises the level of sTfR. The reticulocyte count ($0.5–2.0\%$ or $25–75 \times 10^9$/L) is raised in proportion to the degree of anaemia when erythropoiesis is effective (e.g. uncomplicated response to bleeding), but is relatively low when erythropoiesis is ineffective (e.g. β-thalassaemia) or an abnormality prevents a normal response (e.g. nutritional deficiency).

The output of the system, the red cell mass, can be accurately measured by radioactive dilution techniques using ^{51}Cr, but can often be reliably estimated from the haematocrit or concentration of haemoglobin. Changes in red cell size, shape and haemoglobin content, often reflected in the red cell morphology, may provide important guides to specific abnormalities in red cell maturation (e.g. haemoglobinopathies, thalassaemia,

nutritional deficiencies). If the red cell mass is appropriate to meet the demands for oxygenation then Epo production will be suppressed and the serum level will be in the normal range of (~25–50 mU/mL in cord blood and ~10–30 mU/mL in adults). If there is inadequate oxygenation, the level of Epo will, in general, be raised in proportion to the degree of anaemia (e.g. up to 3–10 U/mL after severe blood loss) unless there is some impediment to Epo production (e.g. chronic renal failure, anaemia of chronic diseases). For any given degree of anaemia the level of Epo in the blood may vary depending on the underlying conditions. For example, the levels tend to be very high in aplastic anaemia and less than anticipated in thalassaemia. This may reflect the different numbers of precursors in the marrow that are able to bind available Epo molecules, thus altering the number of free Epo molecules that are measured.

These apparently straightforward assessments may be more difficult to interpret when there are multiple causes of abnormal erythropoiesis, and in particular when complicated by nutritional deficiencies, which should always be evaluated in parallel with these studies. In addition to the common nutritional anaemias, the vast number of specific diagnostic tests to determine the inherited or acquired disorders that may perturb each phase of erythropoiesis are described elsewhere in this book.

Proper oxygen delivery to the tissues requires sufficient circulating mature red cells, and any appropriate therapy should be aimed at correcting this. An important caveat is that excessive red cells may cause a sluggish circulation that can cause ischaemia, leading to serious complications (e.g. myocardial infarction and stroke). The simplified circuit presented here to describe the process of erythropoiesis (Figure 2.9) indicates three potential routes for therapeutic intervention. The first is to correct nutritional deficiencies, usually iron and less commonly folate or vitamin B_{12}. The recent discovery of the role of the iron-regulatory peptide hepcidin in the anaemias of chronic disorders suggests that some remaining common forms of anaemia related to this class (caused by inability to use stored iron) may be amenable to rational treatment in the not too distant future. A second frequently used approach is to correct anaemia, of any cause, with red cell transfusion, and the criteria for such treatment are set out in other sections of this book. The final

approach is to increase erythropoiesis by administering recombinant human erythropoietin (rHuEpo). Following its considerable benefit to patients with the anaemia of chronic renal failure who are not capable of making normal levels of Epo, rHuEpo has been assessed in a wide range of disorders (e.g. aplastic anaemia, red cell aplasia, thalassaemia intermedia, cancer of all types, haematological malignancy, myelodysplastic syndrome, rheumatoid arthritis, autologous blood donors, after stem cell transplantation and more). A review of its effectiveness in these situations is beyond the scope of this chapter, but the considerable expense involved in treating patients, often over relatively long periods of time, with a hormone that does not always directly address the known pathophysiology of the anaemia requires careful consideration.

Finally, there are some conditions in which hormonal deficiency is known to contribute to anaemia (e.g. hypothyroidism, Addison's disease). In these cases appropriate correction of the hormonal deficiency logically helps correct the anaemia. Some rare forms of anaemia respond to a variety of therapies for unexplained reasons. For example, some cases of Diamond–Blackfan anaemia (DBA) respond to corticosteroids, and some cases of congenital dyserythropoietic anaemia (CDA) respond to α-interferon, suggesting that there are still many unknown aspects to this clinically important and intellectually fascinating process of erythropoiesis.

Iron metabolism, iron deficiency and disorders of haem synthesis

Mark Worwood and A Victor Hoffbrand

Introduction

Iron (atomic weight = 55.85) is essential for many metabolic processes. It shares with other transition metals two properties of particular importance in biology – the ability to exist in more than one relatively stable oxidation state and the ability to form many complexes. Its ability to exist in both ferric and ferrous states underlies its role in critical enzyme reactions concerned with oxygen and electron transport and the cellular production of energy. As well as physiologically active iron compounds, many of which are haem proteins, there are also specialized proteins of iron transport and storage. The latter are necessary to enable iron to remain in solution at neutral pH, at which ferric iron is insoluble, and to limit the potential toxicity of this reactive metal. The insolubility of ferric iron also means that, although the earth's crust contains approximately 4% iron, and iron may be plentiful in the diet, much of this is unavailable. As a result, the body is limited in the adjustments it can make to excessive loss of iron, which frequently occurs due to haemorrhage, and iron deficiency is the most common cause of anaemia throughout the world. The general need to conserve the metal is reflected in the absence of any physiological mechanism for excretion of iron, control of iron balance being at the level of iron absorption. This is important in the rarer but potentially fatal disorders of iron overload.

Distribution of body iron

The concentration of iron in the adult human body is normally about 50 mg/kg in males and 40 mg/kg in females. The largest component is circulating haemoglobin, with 450 mL (1 unit) of whole blood containing about 200 mg of iron (Figure 3.1). Much of the remainder is contained in the storage proteins, ferritin and haemosiderin. These are found mainly in the reticuloendothelial (RE) cells of the liver, spleen and bone marrow (which gain iron from breaking down red cells), and in parenchymal liver cells (which normally gain most of their iron from the plasma iron-transporting protein, transferrin).

Functional iron-containing proteins

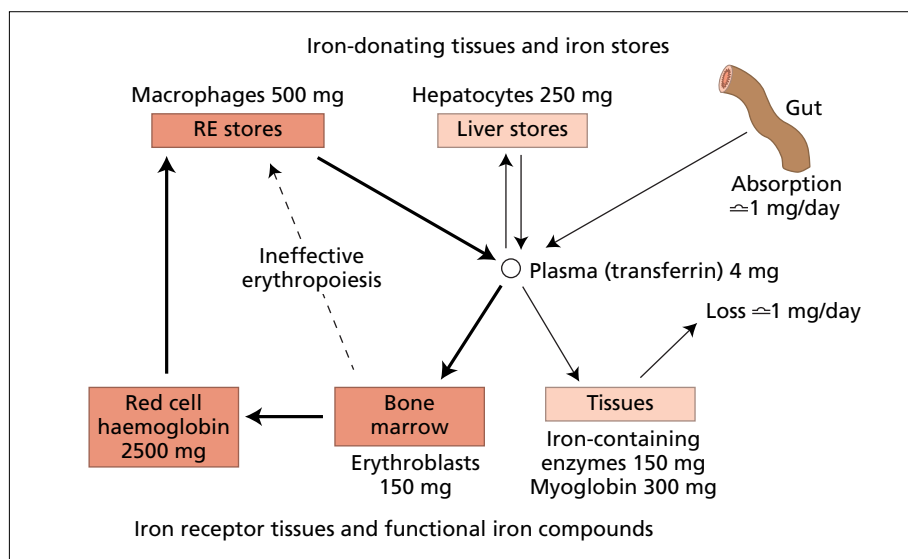
Haemoglobin (molecular weight = 64 500) contains four haem groups linked to four globin chains, and can bind four molecules of oxygen. Myoglobin (mol. wt = 17 000) accounts for 4–5% of body iron and has a single haem group attached to its one polypeptide chain. It has a higher affinity for oxygen than haemoglobin and behaves as an oxygen reserve in muscles. The mitochondria contain a series of haem and non-haem iron proteins (including the cytochromes a, b and c, succinate dehydrogenase and cytochrome oxidase) that form an electron transport pathway responsible for the oxidation of intracellular


Figure 3.1 The major compartments of iron in a 70-kg man. Iron supply for erythropoiesis and release of iron from senescent red cells dominate internal iron exchange.

substrates and the simultaneous production of adenosine triphosphate. Haem is an essential component of microsomal and mitochondrial cytochrome P450, which is concerned with hydroxylation reactions (including drug detoxification by the liver), and of cyclo-oxygenase, involved in prostaglandin synthesis. Other haem proteins include the enzymes catalase and lactoperoxidase, which are concerned with peroxide breakdown, and tryptophan pyrrolase, involved in the oxidation of tryptophan to formylkynurenine. There is a smaller group of iron sulphur proteins (e.g. xanthine oxidase, reduced nicotinamide adenine dinucleotide dehydrogenase and aconitase). Iron is also necessary for the function of ribonucleotide reductase, a key enzyme in DNA synthesis.

Ferritin and haemosiderin

Ferritin is the primary iron storage protein and provides a reserve of iron. It consists of an approximately spherical apoprotein shell (mol. wt = 480 000) enclosing a core of ferric hydroxyphosphate (up to 4000 iron atoms). Human ferritin is made up from 24 subunits (mol. wt c. 20 000) of two immunologically distinct types: H and L. These are coded by genes on chromosomes 11 and 19 respectively. There are multiple gene copies, many of which are presumably pseudogenes, on 12 different chromosomes. An intronless gene on chromosome 5 (q23.1) codes for mitochondrial ferritin – a novel H-type ferritin. The internal cavity of the ferritin molecule communicates with the exterior via six channels, through which ferrous iron may enter (to interact with a ferroxidase centre on the ferritin H subunit) or leave (after reduction, e.g. by dihydroflavins or ascorbic acid).

The way in which ferritin iron is mobilized is poorly understood, and a process in which the entire ferritin molecule is degraded within lysosomes prior to iron release has also been suggested. Variation in the proportion of H to L subunits explains the heterogeneity of ferritin from different tissues on isoelectric focusing: L-rich ferritins (from spleen and liver) are more basic than H-rich ferritins (from heart and red cells). There may be functional differences between different isoferritins (e.g. in iron storage or intracellular iron transport) but this is not established. The small amount of ferritin normally present in serum contains little iron and consists almost exclusively of L subunits. It is also heterogeneous, owing to glycosylation. This glycosylation and the direct relationship of serum concentration to storage iron in macrophages suggest that serum ferritin is secreted by macrophages in response to changing iron levels.

Haemosiderin, unlike ferritin, is a water-*in*soluble crystalline, protein–iron complex, visible by light microscopy when stained by the Prussian blue (Perls') reaction. It has an amorphous structure, with a higher iron–protein ratio than ferritin, and is probably formed by the partial digestion of ferritin aggregates by lysosomal enzymes. In normal subjects, the majority of storage iron is present as ferritin, and haemosiderin is predominantly found in macrophages rather than hepatocytes. In iron overload, the proportion present as haemosiderin increases considerably in both cell types.

Transferrin and transferrin receptors

Transferrin is a single chain polypeptide (mol. wt = 79 500) present in plasma (1.8–2.6 g/L) and extravascular fluid (Table 3.1). It has a plasma half life of 8–11 days. The protein is synthesized predominantly by the liver, synthesis being inversely related to iron stores. Two atoms of ferric iron bind to each molecule. Although transferrin contains only about 4 mg of body iron at any time, it is vital to iron transport, with over 30 mg iron passing through this compartment each day (Figure 3.1). The binding sites (N-terminus and C-terminus) contain three tyrosine

Table 3.1 Iron transport proteins, oxidoreductases, storage proteins and regulators.

Gene (protein)	Chromosome location	Tissue expression	Structure	Function	Regulation	Mutations and disease
DcytB (duodenal cytochrome b1)	–	Enterocyte +	TMP, 6TMD	Ferric reductase	Fe (hepcidin)	–
DMT1 (SLC11A2)	12q13	Widespread	TMP, 568 aa	Fe uptake	Fe (3′ IRE)	Mk mouse, Belgrade rat
Hemojuvelin (HJV)	1q21	Liver, heart, muscle	Membrane bound receptor or secreted protein	Regulator of hepcidin synthesis	?	Juvenile haemochromatosis
Ferroportin 1 (SLC11A3)	2q32	Liver, spleen, enterocyte	TMP, 571 aa 9TMD	Fe export	Fe (5′ IRE)	Human HC autosomal dominant
Hepcidin (HAMP)	19q13	Plasma (liver)	20–25 aa peptide	Regulator of iron transport	Fe (HFE)	Juvenile HC (digenic HC)
Hephaestin	Xq11–q12	Enterocyte	TMP, 1TMD copper protein with homology to caeruloplasmin	Fe^{2+} oxidase	–	Sla mouse
HFE	6p21.3	Widespread	HLA class I heavy chain	Regulates Tf iron uptake and hepcidin expression	?	Human HC autosomal recessive
Transferrin receptor (TFRC)	3q26.2–qter	Widespread – highest number in erythroblasts	TMP dimer of 90 000 kDa polypeptide	Binds transferrin	Fe (IRE)	(Lethal in knockout mouse)
Transferrin receptor (TFR2)	7q22	Widespread	60% similarity in extracellular domain to TFRC	Binds transferrin, iron haemostasis, regulator of hepcidin synthesis	No IRE	Human HC autosomal recessive
Transferrin	3	Plasma, extravascular space	Single chain polypeptide, glycoprotein	Iron transport	Iron stores	Atransferrinaemia
Ferritin heavy chain (FTH1)	11q13	Widespread, cytosolic	Subunit of ferritin	Iron storage (catalytic subunit for iron incorporation)	Fe (IRE)	Autosomal dominant Fe overload (very rare)
Ferritin light chain (FTL)	19q13.3–q13.4	Widespread, cytosolic	Subunit of ferritin	Iron storage	Fe (IRE)	Hyperferritinaemia and cataract syndrome
IRP1	9p22–p13	Widespread	Cytoplasmic, mol. wt 98 000 with 4Fe–4S cluster	Regulation of synthesis of FTH, FTL, TFRC, DMT1, ferroportin 1, ALAS2	Iron stores	Not known
IRP2	15	Widespread	Cytoplasmic, mol. wt 105 000. No 4Fe–4S cluster	As IRP1	Iron stores	Not known

aa, amino acid; HC, haemochromatosis; IRE, iron response element; IRP, iron regulatory protein; TMD, transmembrane domain; TMP, transmembrane protein.

and two histidine residues and an arginine group. The binding of iron involves simultaneous attachment of an anion, usually bicarbonate. The uptake of iron from transferrin requires that the protein is attached to specific receptors on the cell surface. The transferrin receptor gene (TFRC) codes for a transmembrane protein (mol. wt = 185 000), each of two subunits being able to bind one transferrin molecule. The human transferrin receptor can be identified with anti-CD71 antibodies. A second receptor, TFR2, also binds transferrin (Table 3.1); it may act as the homeostatic iron sensor, regulating hepcidin synthesis in response to diferric transferrin concentration (Fig. 3.2).

Lactoferrin is a glycoprotein (mol. wt = 77 000) that is structurally related to transferrin. It is found in milk and other secretions and in neutrophils. It is thought to have a bacteriostatic action at secreting surfaces by depriving micro-organisms of the iron needed for their growth.

Intracellular transit iron and plasma non-transferrin-bound iron

It is thought that there is a transit pool of 'metabolically active', or 'labile' iron both within and outside cells, which receives iron from degraded haem or ferritin, exchanges with transferrin and is incorporated into newly synthesized iron-containing proteins. It is also a major source of iron chelated by desferrioxamine (Chapter 4). Within cells, low-molecular-weight chelates (e.g. with citrate) may be present. Within plasma in iron overload, it may also exist as oligomeric iron oxide, either free or bound to albumin. Low-molecular-weight chelates are likely to be the form of iron sensed by the regulatory mechanisms of iron homeostasis and which is particularly toxic in iron overload conditions (Chapter 4). The detection of labile iron is difficult and relies on scavenging of the iron by chelators, followed by detection of the chelate. Fluorescent iron-scavenging molecules provide the best detection systems at present.

Cellular iron homeostasis

Synthesis of several of the proteins involved in iron metabolism is regulated at the level of RNA translation by two cytoplasmic iron-dependent proteins, namely IRP1 and IRP2 (Table 3.1). These are capable of binding to mRNAs that contain a sequence forming a stem and loop structure called an *iron-responsive element* or IRE (Figure 3.2). IRP1 (mol. wt = 98 000) contains an iron–sulphur (4Fe–4S) cluster and functions as a cytoplasmic aconitase with low affinity for the IRE when intracellular iron is abundant. When iron is scarce, however, the iron–sulphur cluster is no longer present and IRP1 binds to the IRE with high affinity. IRP2 (mol. wt = 105 000) is expressed ubiquitously but is less abundant than IRP1. There is in IRP2 an extra stretch of 73 amino acids between amino acids 37 and 38 of IRP1. This stretch is rich in proline, serine and cysteine and mediates
Figure 3.2 Coordinate regulation of expression of ferritin and transferrin receptor: the role of the iron response element (IRE)–IRP mechanism. When cellular iron levels are low, IRP binds to the IRE stem and loop structures of mRNA to inhibit translation of ferritin, but increase translation of transferrin receptors (TfR) by preventing degradation of the mRNA. When iron levels are high, the IRP functions as a cytoplasmic aconitase and no longer binds to the IREs. Ferritin synthesis can thus proceed, while TfR synthesis is reduced. IRP2 binds to IREs when iron levels are low, but is degraded after ubiquitination (initiated by haem-induced oxidation) when iron levels are high. The IRPs therefore provide two ways of sensing iron requirements either involving Fe–S proteins or haem proteins.

IRP2 degradation in iron-replete cells. Activation of IRP2 requires accumulation of the protein as a result of new synthesis. Degradation takes place after the addition of iron. IRP2 knockout mice exhibit disturbances of iron metabolism in the intestinal mucosa and the central nervous system.

The 3′-untranslated region (3′-UTR) of transferrin receptor mRNA contains five IREs, whereas the 5′-UTR region of ferritin mRNA contains a single IRE. Binding of IRP when there are low levels of intracellular iron protects the transferrin receptor mRNA from cytoplasmic degradation but inhibits translation of ferritin mRNA by interfering with the binding of initiation factors. In contrast, when intracellular iron is increased, the opposite effects occur. Thus, coordinated regulation of the two iron proteins acts to maintain a constant intracellular iron content over the short term by balancing cellular iron uptake and storage.

Erythroid δ-aminolaevulinic acid synthase (ALAS2) mRNA also has an IRE in its 5′-UTR region, whereas 'housekeeping'

Table 3.2 Daily iron losses and requirements (WHO 2001).

Group (age, years)	Daily loss (mg)		Requirement for growth (mg)	Total (mg)
	Urine, skin, faeces, etc.	Menses		
Children				
0.5–1	0.17	–	0.55	0.72
1–3	0.19	–	0.27	0.46
4–6	0.27	–	0.23	0.50
7–10	0.39	–	0.32	0.71
Males				
11–14	0.62		0.55	1.17
15–17	0.90	–	0.60	1.50
18+	1.05	–	–	1.05
Females

[‡]**Average dietary requirement during pregnancy is 3–4 mg.**

ALAS1 mRNA does not. This suggests that the IRP–IRE system may be involved in matching iron supply to haem synthesis, with repression of protoporphyrin synthesis in iron-deficient erythroblasts (p. 33). Mitochondrial aconitase interconverts citrate and isocitrate and has a putative IRE at the 5′-UTR of its mRNA. In the liver, its activity decreases in iron deficiency, suggesting a role in iron metabolism perhaps related to a role for citrate as an intracellular iron carrier. DMT1 has a 3′-IRE and ferroportin 1 has a 5′-IRE (Table 3.1) but binding of IRP is weak compared with the TFRC and ferritin IREs.

Normal iron balance

The amount of iron in the body at birth depends on the blood volume and haemoglobin concentration, the birth weight (which determines blood volume) being particularly important. Delay in clamping the cord leads to an increased red cell mass by placental transfusion. The level of maternal iron stores has little effect on fetal iron. The newborn contains about 80 mg/kg at full term. Neonatal iron reserves are utilized for growth, and from 6 months to 2 years virtually no iron stores are present. Thereafter, iron stores gradually accumulate during childhood to around 5 mg/kg. In men, there is a further increase between 15 and 30 years to about 10–12 mg/kg (total up to approximately 1 g), whereas iron stores remain lower in women (average 300 mg)

until the menopause. It would take 4 years or more for a man to deplete body iron stores and develop iron deficiency anaemia solely due to lack of dietary intake or malabsorption.

Requirements are higher in menstruating women and during periods of rapid growth in infancy and adolescence (Table 3.2). Menstrual loss has a median value of 30 mL, but the 95th centile value is 118 mL blood per month (equivalent to 1.9 mg iron per day), which has been found to be significantly associated with iron deficiency. Requirements are highest of all in pregnancy.

Iron absorption

Iron absorption depends not only on the amount of iron in the diet, but also, and more importantly, on the bioavailability of that iron, as well as the body's needs for iron. A normal Western diet provides approximately 15 mg of iron daily. Of that iron, digestion within the gut lumen releases about one-half in a soluble form, from which about 3 mg may be taken up by mucosal cells and only about 1 mg (or 5–l0% of dietary iron) transferred to the portal blood in a healthy man. Iron absorption can thus be influenced at several different stages.

Dietary and luminal factors

Much of dietary iron is non-haem iron derived from cereals

Table 3.3 Iron absorption.

Favoured by	Reduced by
Dietary factors	
Increased haem iron	Decreased haem iron
Increased animal foods	Decreased animal foods
Ferrous iron salts	Ferric iron salts
Luminal factors	
Acid pH (e.g. gastric HCl)	Alkalis (e.g. pancreatic secretions)
Low-molecular-weight soluble chelates (e.g. vitamin C, sugars, amino acids)	Insoluble iron complexes (phytates, tannates in tea, bran)
Ligand in meat (unidentified)	
Systemic factors	
Iron deficiency	Iron overload
Increased erythropoiesis (e.g. after haemorrhage)	Decreased erythropoiesis
Ineffective erythropoiesis	Inflammatory disorders
Pregnancy	(Hepcidin)
Hypoxia	

(commonly fortified with additional iron in the UK), with a lesser component of haem iron from meat and fish. Even in iron deficiency, the maximum iron absorption from a mixed Western diet is no more than 3–4 mg daily. This figure is much less with the predominantly vegetarian, cereal-based diets of most of the world's population.

Iron is released from protein complexes by acid and proteolytic enzymes in the stomach and small intestine, and haem is liberated from haemoglobin and myoglobin. Iron is maximally absorbed from the duodenum and less well from the jejunum, probably because the increasingly alkaline environment leads to the formation of insoluble ferric hydroxide complexes. Luminal factors enhancing or inhibiting absorption are listed in Table 3.3. Therapeutic ferrous iron salts are well absorbed on an empty stomach, but when taken with a meal, absorption is reduced as a result of the same ligand-binding processes that affect dietary non-haem iron.

Mucosal factors: molecular aspects of iron absorption and its regulation

A variety of mechanisms for the binding of non-haem iron to the mucosal membrane have been described. Both specific, saturable and receptor-mediated mechanism, and passive diffusion at higher doses may occur.

Recently discovered membrane transport proteins, regulatory proteins and associated oxidoreductases involved in iron transport through the intestinal cell are listed in Table 3.1. The proposed process is illustrated in Figure 3.3. Non-haem iron is released from food as Fe^{3+} and reduced by Dcytb to Fe^{2+}. This is transported across the brush border membrane by DMT1. It is assumed that iron enters the labile pool and some may be incorporated into ferritin and lost when the cells are exfoliated. Iron destined for retention by the body is transported across the serosal membrane by ferroportin 1 before uptake by transferrin as Fe^{3+}. Hephaestin is a copper-containing ferroxidase (Table 3.1) expressed predominantly in villous cells of the small intestine. It is implicated in conversion of Fe^{2+} to Fe^{3+} in the basolateral transfer step of iron absorption, which is impaired in mice with a defective hephaestin gene. Hephaestin appears to be located intracellularly, with a perinuclear distribution, however, and its role as a ferroxidase in basolateral iron release is still unclear.

Haem iron is initially bound by haem receptors at the brush border membrane and released intracellularly by haem oxygenase

Figure 3.3 Molecular pathways of iron absorption. The area enclosed in the dotted box refers to the uptake of iron from the plasma in the developing enterocyte in the intestinal crypt. Otherwise, the diagram refers to iron absorption by the villous epithelial cell. Cp, caeruloplasmin; FP1, ferroportin 1; Hp, hephaestin; Tf, transferrin; TfR, transferrin receptor. For further details see text and Table 3.1.
before entering the labile iron pool and following a common pathway with iron of non-haem origin.

Regulation of iron absorption

Iron absorption may be regulated both at the stage of mucosal uptake and at the stage of transfer to the blood. How each of these factors listed in Table 3.3 inform the mucosal cells of how much iron to take up or to transfer to the plasma is becoming clearer. It has been assumed that as epithelial cells develop in the crypts of Lieberkühn, their iron status reflects that of the plasma (transferrin saturation), and this programmes the cells to absorb iron appropriately as they differentiate along the villus. There are situations when this does not apply, however. In genetic haemochromatosis transferrin, saturation is high yet iron absorption is increased. One hypothesis concerning the transfer stage suggests that each of the iron-donating tissues (macrophages, liver and gut: see Figure 3.1) supplies iron to plasma transferrin in proportion to the amount of available iron in those tissues, the iron being transported to satisfy the needs of the main receptor tissue, the erythroid marrow. Within this framework, the amount of iron to be supplied by the intestinal cells would be dependent on the output from other donor tissues, being increased when there is tissue iron deficiency. Furthermore, when there is a rise in plasma iron turnover owing to increased erythron demands for iron, output from all the donor tissues, including the gut, might be expected to increase.

Hepcidin

There is now convincing evidence of a more direct regulation of iron absorption by hepcidin. This product of the *HAMP* gene (Table 3.1) is a small peptide (20–25 amino acids) with several isoforms released from a large prepropeptide of 84 amino acids. It is predominantly expressed in the liver and is downregulated when iron stores are reduced and upregulated when iron stores are increased or by inflammation. Hepcidin is the predominant negative regulator of iron absorption in the small intestine, iron transport across the placenta and iron release from macrophages, probably by binding to ferroportin and acclerating its destruction. The key role of hepcidin is confirmed by the presence of nonsense mutations in the hepcidin gene, homozygous in the affected members, in several families with severe juvenile haemochromatosis (Chapter 4). A deficient hepcidin response to iron loading may contribute to iron overload in HFE-linked and other genetic haemochromatosis (Chapter 4). In anaemia of inflammation, hepcidin production is increased up to 100-fold, and this may account for the defining feature of this condition, sequestration of iron in macrophages. HFE and transferrin receptor 2 and hemojuvelin probably have indirect roles in the control of iron absorption through the regulation of hepcidin synthesis. Also, in conditions of increased erythroid turnover, serum hepcidin levels are low in those with increased iron absorption.

Hemojuvelin

Juvenile haemochromatosis (Chapter 4) is most frequently associated with mutations in the hemojuvelin gene (Table 3.1). Mutations in this gene produce a phenotype very similar to that resulting from mutations in the HAMP gene. It has been suggested that both hemojuvelin and HFE may act by regulating hepcidin synthesis.

Internal iron exchange

Iron uptake by erythroid cells

The fate of iron bound to plasma transferrin has been studied by injecting a trace amount of radioactive ^{59}Fe bound to transferrin. About 85% of the ^{59}Fe normally enters developing red cells for incorporation into haemoglobin. This tissue distribution of transferrin-bound iron reflects the expression of transferrin receptors, which are present in high concentration on cells with a high iron requirement. The latter includes any rapidly dividing cells but is normally dominated by the cells of the erythron.

The expression of surface transferrin receptors is increased if cells have inadequate iron, and reduced if they are iron replete (p. 29). Cell transferrin receptors have the highest affinity for diferric transferrin. The transferrin–receptor complex is taken up by a process of receptor-mediated endocytosis (Figure 3.4). The iron is released at the low pH of the endosome, before the apotransferrin and receptor are recycled to the plasma and the

Figure 3.4 Incorporation of iron from plasma transferrin into haemoglobin in developing red cells. Uptake of transferrin iron is by receptor-mediated endocytosis.

cell membrane respectively. Iron release from the endosome is via DMT1 (Table 3.1) and the iron enters the mitochondria or ferritin. Direct transfer of storage iron from macrophages to erythroblasts (rhopheocytosis) is now thought to be of little physiological significance. A soluble, truncated form of the receptor derived from these cell surfaces is detectable in serum. It is bound to transferrin and increased concentrations provide an early indication of an impaired iron supply to the tissues (p. 36). In the absence of iron deficiency, the serum transferrin receptor concentrations reflect erythroid activity.

Breakdown of haemoglobin iron

After phagocytosis by macrophages, haem from senescent red cells is broken down by haem oxygenase (HMOX1) to release iron. As ferrous iron, it can then either enter ferritin (where it is oxidized to ferric iron by the ferritin protein) or be released into plasma (via ferroportin 1), where its binding to transferrin (also as the ferric form) may be facilitated by a plasma ferrous oxidase (e.g. caeruloplasmin). The release of macrophage iron is controlled by hepcidin, with high levels, as in inflammation or iron overload, reducing iron release. Changes in the release of iron from macrophages are thought to account for the diurnal rhythm of serum iron concentration, which is highest in the morning and lowest in the evening.

Role of liver

Hepatocytes have an important role in iron metabolism (Figure 3.1), being capable of taking up extra iron when the transferrin iron saturation (and thus the proportion of diferric transferrin) is increased, and of releasing iron from stores when there is greater need in other tissues for iron. An increased percentage saturation of the plasma transferrin (iron-binding capacity) is the earliest indication of a risk of parenchymal iron overload in hereditary haemochromatosis and the iron-loading anaemias. Through the iron-regulated synthesis of hepcidin, the liver also directly controls iron absorption from the intestine (p. 31).

Some 5–10% of haemoglobin from senescent red cells is normally released intravascularly and bound by haptoglobin prior to its removal by macrophages. An increase in this pathway is seen in haemolytic and dyserythropoietic anaemias, and may provide a further route by which the liver accumulates excess iron in such disorders, in addition to the uptake of transferrin iron and any free (non-transferrin-bound) iron from the plasma. Large particles of colloidal iron, including therapeutic parenteral iron preparations, are also removed from the circulation by macrophages of the RE system.

Fate of iron in the erythroid cell

Some 80–90% of iron taken into developing erythroblasts is converted to haem within 1 h. Any iron taken up in excess of the requirement for haem synthesis is incorporated in ferritin (Figure 3.4). The red cell ferritin content is therefore increased when haemoglobin synthesis is impaired, as in thalassaemia syndromes or sideroblastic anaemia. Excess iron may be seen in the cytoplasm of mature red cells as one or more siderotic granules. These are composed of haemosiderin and stain blue with Perls' reaction and purplish blue with Romanowsky stains, when they are called Pappenheimer bodies. The spleen removes these granules by its pitting action.

Haem synthesis

Haem consists of a protoporphyrin ring with an iron atom at its centre. Haem is synthesized from the precursors succinyl CoA and glycine, which condense to form δ-aminolaevulinic acid (ALA) under the action of ALA synthase (ALAS), with pyridoxal phosphate as a coenzyme (p. 19). 'Housekeeping' ALAS (ALAS1) is coded by a gene on chromosome 3, but, in erythroid cells erythroid-specific ALAS2 predominates and is coded on the X chromosome. ALA can be utilized for the formation of both purines and haem. Four molecules of porphobilinogen condense under the influence of porphobilinogen deaminase (PBGD) and uroporphyrinogen cosynthase to form the tetrapyrrole ring compound uroporphyrinogen III. The latter is converted to protoporphyrin IX. Finally, iron in the ferrous form is incorporated under the influence of the enzyme ferrochelatase. Iron in haem has six coordinating valencies: four link the iron to nitrogen atoms in each pyrrole ring, whereas the remaining two link haem to histidine residues in the globin chain, the distal bond being unstable and easily replaced by oxygen to form oxyhaemoglobin.

The mitochondria play a major role in haem synthesis as they contain ALAS, coproporphyrinogen oxidase and ferrochelatase, the enzyme sequence from ALA to coproporphyrinogen being situated in the cytoplasm. The mitochondria are also the site of the citric acid cycle, which supplies succinate. The mature red cell, which lacks mitochondria, is therefore unable to synthesize haem.

A number of porphyrins are formed by side reactions during the synthesis of protoporphyrin. In the porphyrias (p. 39), many of these compounds accumulate in the major sites of haem synthesis, the liver and the red cells.

Control mechanisms in haem synthesis

As well as the developmental regulation of haem formation during erythroid differentiation, synthesis of haem and globin is coordinated so that there is no significant excess of either. Moreover, the entry of iron into the cell and its incorporation into haem are regulated so that the normal cell obtains sufficient iron for its needs, but not more. ALAS2 is rate limiting in the erythroid–haem biosynthetic pathway. Its activity reaches a peak

in the polychromatic normoblast and then diminishes so that no activity is present in the mature cell. Interleukin 3 and erythropoietin act as inducers for transcription of mRNA for ALAS2 and PBGD, and this may be most important in the developmental regulation of haem production during erythroid differentiation. The coordination of haem and globin synthesis is further discussed in Chapter 2.

Diagnostic methods for investigating iron metabolism

The large amount of iron present as haemoglobin means that the degree of any anaemia must always be considered in assessing iron status. Reduced amounts of haemoglobin accompany an overall reduction in body iron in iron deficiency anaemia or after acute blood loss. In other anaemias, including the anaemia of chronic disease and the megaloblastic anaemias, iron is redistributed from the red cells to macrophage iron stores, with a corresponding increase in marrow-stainable iron and serum ferritin. The various measurements of iron status are listed in Table 3.4 and described below in more detail. No single measurement is ideal for all clinical circumstances, as all are affected by confounding factors (Table 3.4) and changes may develop sequentially (as in progressive negative iron balance) or may affect particular body iron compartments. Reference ranges for

haemoglobin and the various measures of iron status are given in Appendix 1. Table 3.5 summarizes the changes in measures of iron status accompanying various types of hypochromic anaemia. The assessment of *iron overload* is discussed in Chapter 4.

Storage iron

Serum ferritin

In healthy subjects, the serum ferritin concentration correlates with iron stores, as assessed by quantitative phlebotomy or tissue biopsy. This has led to the widespread use of immunoassays for serum ferritin as a convenient, non-invasive measure of iron stores. Normal concentrations of serum ferritin range from about 15 to 300 μg/L, and are higher in men (median about 90 μg/L) than in premenopausal women (median 30 μg/L). In women, after the menopause, serum ferritin concentrations increase but remain below levels in men. In neonates, the concentration in cord blood (median approximately 100 μg/L) rises further over the first 2 months of life as fetal haemoglobin is broken down, and thereafter falls to low levels (median 20–30 μg/L) throughout childhood and adolescence.

Values for serum ferritin concentration below 15 μg/L are virtually specific for storage iron depletion, but normal values do not exclude this and values above 300 μg/L do not necessarily, or even usually, indicate iron overload. This is because ferritin synthesis is influenced by factors other than iron (in

Table 3.4 Potential confounding factors in the interpretation of measures of iron status.

Measurement	Confounding factors
Iron stores	
Serum ferritin	Increased: as an acute-phase protein (e.g. in infection, inflammation or malignancy) and by release of tissue ferritins by damage, especially to iron-rich organs (e.g. with hepatic necrosis, chronic liver disease, splenic or bone marrow infarction in sickle cell disease)
	Decreased: by ascorbate deficiency
Tissue iron supply	
Serum iron and transferrin saturation	Labile measures: normal short-term fluctuations mean that a single value may not reflect iron supply over a longer period
Serum transferrin receptor	Directly related to extent of erythroid activity as well as being inversely related to iron supply to cells
Red cell protoporphyrin/red cell ferritin/% hypochromic red cells	Stable measures: reduced iron supply at time of red cell formation leads to increases in protoporphyrin and hypochromic red cells, and reduced red cell ferritin. However, values may not reflect current iron supply. May be increased by other causes of impaired iron incorporation into haem (e.g. lead poisoning, sideroblastic anaemias)
Functional iron	
Hb concentration	Other causes for anaemia besides iron deficiency; a reciprocal relationship with iron stores should be expected in all anaemias except in iron deficiency anaemia
Red cell MCV, MCH	May be reduced in other disorders of haemoglobin synthesis (e.g. thalassaemia, sideroblastic anaemias) in addition to iron deficiency

MCH, mean corpuscular haemoglobin; MCV, mean corpuscular volume.

Table 3.5 Differential diagnosis of hypochromic anaemia.

	Iron deficiency	Chronic disease	Thalassaemia trait (α or β)	Sideroblastic anaemia
MCV/MCH	↓	↓ or N	↓	↓ (congenital), ↑N (acquired)
Serum iron	↓	↓	N	↑
TIBC	↑	↓ or N	N	N
Transferrin saturation	↓	↓	N	↑
Serum ferritin	↓	N or ↑	N	↑
Serum TfR	↑	N	N	N or ↑
Bone marrow iron stores	↓	N or ↑	N	N or ↑
Erythroblast iron	↓	↓	N	Ring forms

N, Normal; TfR, transferrin receptor.

particular, it behaves as an acute-phase reactant in many inflammatory diseases). For this reason, serum ferritin concentrations of < 50 μg/L may be associated with a lack of storage iron in patients with the anaemia of chronic disease. A ferritin concentration of > 100 μg/L suggests the presence of storage iron. Algorithms designed to predict storage iron levels from serum ferritin concentration and an indicator of inflammation or infection (erythrocyte sedimentation rate or C-reactive protein) have not proved to be useful. Damage to tissues (particularly the liver) can release large amounts of tissue ferritin into the plasma.

There is a rare autosomal dominant genetic abnormality of ferritin synthesis (hereditary hyperferritinaemia with cataract syndrome) in which excess synthesis of ferritin L-chain is associated with high serum ferritin concentrations (in the absence of iron overload) and with cataracts. The latter are due to deposition of L-type ferritin (with little iron) in the lens. Over 20 point mutations and deletions of the IRE loop of L-ferritin mRNA, which prevent its interaction with IRP, have been described. There is no overall increase in body iron.

Bone marrow aspiration
Staining the bone marrow for iron gives an indication of RE iron stores as well as erythroblast iron (Figure 3.5a). In iron deficiency anaemia, RE iron and erythroblast iron are absent (Figure 3.5b).

Iron supply to the tissues

Serum iron and iron-binding capacity
The serum iron and, more particularly, the saturation of the total iron-binding capacity of transferrin (TIBC) give a measure of the iron supply to the tissues. In normal subjects, the serum iron shows a diurnal rhythm, with values being lower in the morning than in the evening. In iron deficiency and iron overload, however, values stabilize at low or high levels respectively. A serum transferrin saturation (serum iron/TIBC × 100) that is persistently less than 15% is insufficient to support normal erythropoiesis. A rise in TIBC is characteristic of iron deficiency (i.e. an absence of storage iron). A reduced serum iron con-

centration with a normal or reduced TIBC is a characteristic response to infection and inflammation. A sustained increase in transferrin saturation to more than 50% is an early change in the development of parenchymal iron loading (Chapter 4).

Serum transferrin receptors
Plasma concentrations reflect both the number of erythroid precursors and iron supply to the bone marrow. In clinical practice, these two factors must be considered in interpreting transferrin receptor levels. Increased erythropoiesis from any cause results in high serum concentrations so the assay has been used as a replacement for ferrokinetic procedures as a means of identifying increased erythropoiesis. In the anaemia of chronic diseases, the assay provides a valuable indicator of deficiency of body iron stores. Serum transferrin receptor levels only increase in this situation in the absence of storage iron. Further improvement in sensitivity and specificity has been described using various ferritin–transferrin receptor ratios. At the moment, several units and reference ranges are in use and the assay is therefore method specific. In general hospital practice, some consider that the serum transferrin receptor assay adds little to the diagnostic information provided by the ferritin assay.

Red cell protoporphyrin
When iron supply to the erythron is limited, iron incorporation into haem is restricted, leading to accumulation of the immediate precursor, protoporphyrin IX. This is lost only slowly from circulating red cells; concentrations greater than the normal upper limit of 80 μmol/mol haemoglobin therefore indicate that a reduction in iron supply has been present over the previous few weeks. Protoporphyrin levels may also increase in patients with side-roblastic anaemias and lead poisoning. Convenient analysers measure zinc protoporphyrin – the form in which most of the protoporphyrin exists in iron deficiency.

Red cell ferritin
The ferritin in the circulating erythrocyte is but a tiny residue of that present in its nucleated precursors in the bone marrow
(a)

(b)

(c)

Figure 3.5 (a) Normal bone marrow showing plentiful iron in macrophages (Perls' stain) with iron granules in erythroblasts (insets). (b) Iron deficiency: bone marrow showing absence of stainable iron (Perls' stain). (c) Iron deficiency: peripheral blood film showing hypochromic microcytic red cells.

and only about 10 ag/cell (10^{-18} g/cell) remains in the erythrocyte. In general, red cell ferritin levels reflect the iron supply to the erythroid marrow and tend to vary inversely with red cell protoporphyrin levels. Despite some advantages over serum ferritin as a measure of storage iron (e.g. not affected by release of ferritin from damaged liver cells) the assay of red cell ferritin has seen little routine application. This is largely because it is

necessary to prepare red cells free of white cells (which have much higher levels of ferritin).

Percentage of hypochromic red cells

As iron supply to the erythron diminishes, the new red cells produced are increasingly hypochromic. Assessment of the haemoglobin content of individual red cells, which is possible using some automated cell counters, allows measurement of the percentage of hypochromic cells. Values rising to above 6% may help in the early identification of impaired iron supply in patients with chronic renal failure who are receiving treatment with recombinant erythropoietin, when associated inflammatory disease means that other measures of iron status can be misleading.

Iron deficiency anaemia

Sequence of events

Depletion of iron stores

When the body is in a state of negative iron balance, the first event is depletion of body stores, which are mobilized for haemoglobin production. Iron absorption is increased when stores are reduced, before anaemia develops and even when the serum iron level is still normal, although the serum ferritin will have already fallen.

Iron-deficient erythropoiesis

With further iron depletion, when the serum ferritin is below 15 µg/L, the serum transferrin saturation falls to less than 15% due to a rise in transferrin concentration and a fall in serum iron. This leads to the development of iron-deficient erythropoiesis and increasing concentrations of serum transferrin receptor and red cell protoporphyrin. At this stage, the haemoglobin, mean corpuscular volume (MCV) and mean corpuscular haemoglobin (MCH) may still be within the reference range, although they may rise significantly when iron therapy is given.

Iron deficiency anaemia

If the negative balance continues, frank iron deficiency anaemia develops. The red cells become obviously microcytic and hypochromic (Figure 3.5c), and poikilocytosis becomes more marked. The MCV and MCH are reduced, and target cells may be present. The reticulocyte count is low for the degree of anaemia. The serum TIBC rises and the serum iron falls, so that the percentage saturation of the TIBC is usually less than 10%.

The number of erythroblasts containing cytoplasmic iron (sideroblasts) is reduced at an early stage in the development of deficiency, and siderotic granules are entirely absent from these cells when iron deficiency anaemia is established. The erythroblasts have a ragged, vacuolated cytoplasm and relatively pyknotic nuclei. The bone marrow macrophages show a total absence of iron, except where very rapid blood loss outstrips the ability to mobilize the storage iron. Platelets are frequently increased.

Tissue effects of iron deficiency

When iron deficiency is severe and chronic, widespread tissue changes may be present, including koilonychia (ridged nails, breaking easily), angular stomatitis (especially in those with badly fitting dentures), glossitis (hair thinning) and pharyngeal webs (Paterson–Kelly syndrome). Partial villous atrophy, with minor degrees of malabsorption of xylose and fat, reversible by iron therapy, has been described in infants suffering from iron deficiency, but not in adults. There is a higher incidence of atrophic gastritis and histamine-fast achlorhydria in iron-deficient patients than in control subjects, and acid secretion may increase with iron therapy in some of these patients. Gastric atrophy may also predispose to iron deficiency. Pica is sometimes present; in some who eat clay or chalk, this may be the cause rather than the result of iron deficiency.

Iron-dependent enzymes in the tissues are usually better preserved than other iron-containing compounds. In severe iron deficiency, however, these enzymes are not inviolate and their levels may fall. This may be partly responsible for the general tissue changes, with mitochondrial swelling in many different cells (including, in the experimental animal, hepatic and myocardial cells), poor lymphocyte transformation and diminished cell-mediated immunity, and impaired intracellular killing of bacteria by neutrophils.

A particular concern has been the finding that infants with iron deficiency anaemia may have impaired mental development and function, and that this deficit may not be completely restored by iron therapy. There is recent evidence that premature labour is more frequent in mothers with iron deficiency anaemia. It remains controversial whether impaired work performance seen in adults results from the anaemia or from depletion of mitochondrial iron-containing enzymes. It is also unclear to what extent some of the other tissue effects of iron deficiency can occur even in the absence of anaemia.

Causes of iron deficiency (Table 3.4)

Diet

Defective intake of iron is rarely the sole or major cause of iron deficiency in adults in Western communities. The diet may contain insufficient or poorly available iron as a result of poverty, religious tenets or food faddism. Iron deficiency is more likely to develop in subjects taking a largely vegetarian diet – the majority of the world's population – who also have increased physiological demands for iron.

Increased physiological iron requirements

Iron deficiency is common in infancy, when demands for growth may be greater than dietary supplies. It is aggravated by prematurity, infections and delay in mixed feeding. It is also frequent in adolescence, in females and in pregnancy (Table 3.1). The fetus acquires about 280 mg of iron and a further 400–500 mg is required for the temporary expansion of the maternal red cell mass. Another 200 mg of iron is lost with the placenta and with the bleeding at delivery. Although iron absorption increases throughout pregnancy and increased requirements are partly offset by amenorrhoea, this may not be sufficient to meet the resultant net maternal outlay of over 600 mg iron.

Blood loss

Blood loss is the most common cause of iron deficiency in adults. A loss of more than about 6–8 mL of blood (3–4 mg of iron) daily becomes of importance, as this equals the maximum amount of iron that can be absorbed from a normal diet. The loss is usually from the genital tract in women or from the gastrointestinal tract in either sex. The most common cause on a world basis is infestation with hookworm, in which anaemia is related to the degree of infestation. In the UK, menorrhagia, haemorrhoids and peptic ulceration are common, as well as gastric bleeding because of salicylates or other non-steroidal anti-inflammatory drugs, hiatus hernia, colonic diverticulosis and bowel tumours (Table 3.6). Some unusual causes of blood loss deserve mention. Cow's milk intolerance in infants may lead to gastrointestinal haemorrhage. Self-induced haemorrhage may occur as an unusual form of Munchausen syndrome. Chronic intravascular haemolysis, such as that in paroxysmal nocturnal haemoglobinuria or mechanical haemolytic anaemia, may be a serious source of urinary iron loss.

Malabsorption

Malabsorption may be the primary cause of iron deficiency or it may prevent the body adjusting to iron deficiency from other causes. Dietary iron is poorly absorbed in gluten-induced enteropathy, in both children and adults, although patients with this disease often show a response, albeit sluggish, to oral therapy with inorganic iron.

Management of iron deficiency

Management entails (i) identification and treatment of the underlying cause and (ii) correction of the deficiency by therapy with inorganic iron. Iron deficiency is commonly due to blood loss and, wherever possible, the site of this must be identified and the lesion treated.

Oral therapy

In most patients, body stores of iron can be restored by oral iron therapy. Iron is equally well absorbed from several simple ferrous iron salts, and, as ferrous sulphate is the cheapest, this is the

Table 3.6 Causes of iron deficiency.

Blood loss	
Uterine	Menorrhagia, post-menopausal bleeding, parturition
Gastrointestinal	Oesophageal varices, hiatus hernia, peptic ulcer, aspirin ingestion, hookworm, hereditary telangiectasia, carcinoma of the stomach, caecum or colon, ulcerative colitis, angiodysplasia, Meckel's diverticulum, diverticulosis, haemorrhoids, etc.
Renal tract	Haematuria (e.g. renal or bladder lesion), haemoglobinuria (e.g. paroxysmal nocturnal haemoglobinuria)
Pulmonary tract	Overt haemoptysis, idiopathic pulmonary haemosiderosis
Widespread bleeding disorders	
Self-inflicted	
Malabsorption	Gluten-induced enteropathy (child or adult), gastrectomy, atrophic gastritis, chronic inflammation, clay eating, etc.
Dietary	Especially vegetarian diet

drug of first choice; 200 mg of ferrous sulphate contains 67 mg of iron. Where smaller doses are required, 300 mg of ferrous gluconate provides 36 mg of iron. It is usual to give 100–200 mg of elemental iron each day to adults and about 3 mg/kg per day as a liquid iron preparation to infants and children. The side-effects of oral iron, such as nausea, epigastric pain, diarrhoea and constipation, are related to the amount of available iron they contain. If iron causes gastrointestinal symptoms, these can usually be ameliorated by reducing the dose, or taking the iron with food, but this also reduces the amount absorbed. Enteric-coated and sustained-release preparations should not be used, as much of the iron is carried past the duodenum to sites of poor absorption. Iron reduces absorption of tetracyclines (and vice versa) and of ciprofloxacin.

The minimum rate of response should be a 20 g/L rise in haemoglobin every 3 weeks, and the usual rate is 1.5–2.0 g/L daily. This will be slower when the dose tolerated is less than 100 mg per day, but this is seldom of clinical importance. It is usually necessary to give iron for 3–6 months to correct the deficit of iron in circulating haemoglobin and in stores (shown by a rise in serum ferritin to normal).

Failure to respond to oral iron is most commonly due to the patient not taking it, although there may be continued haemorrhage or malabsorption. It is important to reassess the diagnosis as other causes of microcytic anaemia include many of the iron-loading anaemias. For instance, many patients with thalassaemia trait, sideroblastic anaemia or other anaemias have been treated with iron before haemoglobin studies, bone marrow examination or other tests have revealed the correct diagnosis. A poor response may also be obtained if the patient has an infection, renal or hepatic failure, an underlying malignant disease or any other cause of anaemia in addition to iron deficiency.

Parenteral iron therapy

This is usually unnecessary, but it may be given if subjects genuinely cannot tolerate oral iron, particularly if gastrointestinal disease, such as inflammatory bowel disease, is present. It is also occasionally necessary in gluten-induced enteropathy and when it is essential to replete body stores rapidly (e.g. where severe iron deficiency anaemia is first diagnosed in late pregnancy), or when oral iron cannot keep pace with continuing haemorrhage (e.g. in patients with hereditary haemorrhagic telangiectasia). Patients with chronic renal failure who are being treated with recombinant erythropoietin are also likely to require parenteral iron therapy. In this situation, the demand for iron by the expanded erythron may outstrip the ability to mobilize iron from stores, leading to a 'functional' iron deficiency. Increased red cell loss at dialysis contributes to iron needs and oral iron therapy is usually inadequate to prevent an impaired response to erythropoietin. The use of '% hypochromic cells' for detection of functional iron deficiency is discussed on p. 36.

From all parenteral preparations, the iron complex is taken up by macrophages of the reticuloendothelial system, from which iron is released to circulating transferrin, which then takes it to the marrow. In the UK, three preparations are available. Iron sorbitol (Jectofer®) is given deep (to avoid skin staining) by intramuscular (i.m.) injection (50–100 mg of iron per day) but not intravenously. Iron dextran (CosmoFer®) is given intravenously by slow injection or infusion. An iron–sucrose complex, Venofer®, is given by slow intravenous infusion or injection and is now considered to be the safest form. The deficit in body iron should be calculated from the degree of anaemia; it is usually 1–2 g. In patients receiving erythropoietin treatment in chronic renal failure, smaller intravenous doses of Venofer® (25–150 mg/week) may be used, with regular monitoring of serum ferritin to avoid iron overload. With iron sorbitol, some low-molecular-weight iron is released into the circulation and about 20% is excreted in the urine; this may exacerbate urinary tract infection. Parenteral iron should not be used if there is a history of allergy as anaphylaxis occasionally occurs. For iron dextran, a test dose should therefore be given slowly, followed by close medical supervision of the rest of the infusion. Flushing, nausea, urticaria, shivering, general aches and pains, dyspnoea

Congenital erythropoietic porphyria	Autosomal recessive	Uroporphyrinogen cosynthase	P
Erythropoietic protoporphyria	Autosomal dominant	Ferrochelatase	P

*Acute attacks (A) of gastrointestinal and/or nervous system are related to the accumulation of porphyrin precursors (ALA and PBG). Photosensitive skin lesions (P) are seen when the level of the enzyme defect in the haem synthetic pathway leads to the accumulation of formed porphyrins.

and syncope are possible immediate adverse effects. Delayed reactions, including arthralgia, fever and lymphadenopathy, are well described and can persist for several days. An exacerbation of rheumatoid arthritis may also be precipitated.

Pathological alterations in haem synthesis

Porphyrias

These are a group of inherited or acquired diseases, each characterized by a partial defect in one of the enzymes of haem synthesis (Chapter 2). Increased amounts of the intermediates of haem synthesis accumulate, the disorders being classified by whether the effects are predominantly in the liver or the erythron (Table 3.7). A full discussion of these disorders is beyond the scope of this chapter, but those with a particular haematological overlap will be mentioned briefly.

Congenital erythropoietic porphyria

This is a very rare autosomal recessive disorder that is due to reduced uroporphyrinogen III synthase activity. Most patients are heteroallelic for mutations in the uroporphyrinogen III synthase gene. Large amounts of porphyrinogens accumulate, and their conversion by spontaneous oxidation to photoactive porphyrins leads to severe, and disfiguring, cutaneous photosensitivity and dermatitis, as well as a haemolytic anaemia with splenomegaly. Increased amounts of uroporphyrin and coproporphyrin, mainly type I, are found in bone marrow, red cells, plasma, urine and faeces. Ring sideroblasts have been found in the marrow in some cases but rarely in large numbers. The age of onset and clinical severity of the disease are highly variable, ranging from non-immune hydrops fetalis to a later onset in which there are only cutaneous lesions. Treatment, including avoidance of sunlight and splenectomy to improve red cell sur-

vival, is only partially effective. High-level blood transfusions to suppress erythropoiesis (combined with iron chelation therapy) have been used to reduce porphyrin production sufficiently to abolish the clinical symptoms. Allogeneic bone marrow transplantation has been successful.

Erythropoietic protoporphyria

This is the most common erythropoietic porphyria and is usually caused by an autosomal dominant inherited deficiency of ferrochelatase, which results in increased free (not Zn) protoporphyrin concentrations in bone marrow, red cells, plasma and bile. Bone marrow reticulocytes are the primary source of the excess protoporphyrin. This leaks from cells and is excreted in the bile and faeces. Molecular analysis of the ferrochelatase gene has revealed a variety of missense, nonsense and slicing mutations as well as deletions and insertions. The onset of the disease is usually in childhood. Expression of the gene is variable, and photosensitivity and dermatitis range from mild or absent to moderate in degree. There is little haemolysis, but a mild hypochromic anaemia may occur, and accumulation of protoporphyrins can occasionally lead to severe liver disease. Treatment is by the avoidance of sunlight; β-carotene may also diminish photosensitivity. Iron deficiency should be avoided as this may increase the amount of free protoporphyrin.

Porphyria cutanea tarda

This is the most common of the hepatic porphyrias and occurs worldwide. The incidence in the UK has been estimated at 2–5 per million. Type I or 'sporadic' porphyria cutanea tarda (PCT) accounts for 80% of cases of PCT. The underlying metabolic abnormality is decreased activity of uroporphyrinogen decarboxylase (UROD) in the liver. Type II disease is an autosomal dominant disorder caused by mutations in the UROD gene. Type III disease is a rare familial form and appears to result from unknown inherited defects that affect hepatic UROD activity.

Table 3.8 Sideroblastic anaemias.

Hereditary	
X-linked	Mutations of erythroid-specific ALAS2 (Xp11.21), associated with spinocerebellar ataxia – ABC7 mutations (Xq13.3)
Mitochondrial	DNA deletions (e.g. Pearson and Kearns–Sayre syndromes)
Autosomal	Thiamine responsive, mutations in THTR-1 (DIDMOAD), other
Acquired	
Primary	Refractory anaemia with ring sideroblasts in FAB classification of myelodysplasia
Secondary	Abnormal pyridoxine metabolism: pyridoxine antagonists (isoniazid, penicillamine), alcohol, pyridoxine deficiency
	Mitochondrial toxicity: chloramphenicol, lead poisoning
	Other diseases: e.g. rheumatoid arthritis, myxoedema, carcinomatosis

DIDMOAD, diabetes insipidus, diabetes mellitus, optic atrophy and deafness.

There is a marked increase in porphyrins in liver, plasma, urine and faeces. In the urine, uroporphyrin and heptacarboxyl porphyrin predominate with lesser amounts of coproporphyrin and penta- and hexacarboxylporphyrin. The disease is characterized by photosensitivity and dermatitis. It is precipitated in middle or later life, more often in men than women, by factors such as liver disease, alcohol excess or oestrogen therapy. A modest increase in liver iron is a common feature.

Either the homozygous or heterozygous presence of the *HFE* C282Y and H63D mutations may predispose to the development of PCT. Prevalence of the C282Y mutation is increased in both sporadic (type I) and familial (type II) PCT. In the UK, only homozygosity for C282Y (found in about 25% of patients) is significantly more common than in the general population (0.7%). In southern Europe, where C282Y is much less common, the H63D mutation is associated with PCT. Iron is known to inhibit uroporphyrinogen decarboxylase. Removal of the iron by repeated phlebotomy is standard treatment, usually leading to remission.

Lead poisoning

Chronic ingestion of lead in humans causes an anaemia that is usually normochromic or slightly hypochromic. Red cell lifespan is shortened and there is a mild rise in reticulocytes, but jaundice is rare. Basophilic stippling is a characteristic, although not universal, finding and it is thought to be due to precipitation of RNA, resulting from inhibition of the enzyme pyrimidine 5′-nucleotidase. Siderotic granules, and occasionally Cabot rings, are found in circulating red cells. The bone marrow shows increased sideroblasts, in some patients with ring sideroblasts. Red cell protoporphyrin and coproporphyrin are raised, as are urinary excretion of ALA, coproporphyrin III and uroporphyrin I.

The cause of the anaemia appears to be multifactorial. Haemolysis, probably due to the blocking of sulphydryl groups, with consequent denaturation of structural proteins, and damage to mitochondria with defective haemoglobin production due to inhibition of the enzymes of haem synthesis, are the major factors.

Sideroblastic anaemia

The sideroblastic anaemias comprise a group of refractory anaemias (Table 3.8), in which there are variable numbers of hypochromic cells in the peripheral blood, with an excess of iron in the bone marrow, many of the developing erythroblasts containing iron granules arranged in a ring around the nucleus (Figure 3.6). These ring sideroblasts (more than four perinuclear granules per cell and covering one-third or more of the nuclear circumference) are the diagnostic feature of the anaemia and, although they may form a small percentage of the erythroblasts in a wide variety of clinical disorders, they are present in large numbers (> 15% erythroblasts) in primary sideroblastic anaemias. The various types of sideroblast that may be seen in the marrow are classified in Table 3.9.

Figure 3.6 Sideroblastic anaemia. Erythroblasts showing perinuclear rings of iron (Perls' stain).

Table 3.9 Siderocytes and sideroblasts.

Siderocyte	Mature red cell containing one or more siderotic granules (Pappenheimer bodies)
Normal sideroblast	Nucleated red cell containing one or more siderotic granules, granules few, difficult to see, randomly distributed in the cytoplasm, reduced proportion of sideroblasts in iron deficiency and anaemia of chronic disorders
Abnormal sideroblasts	Cytoplasmic iron deposits (ferritin aggregates): increased granulation, granules larger and more numerous than normal, easily visible and randomly distributed, proportion of sideroblasts usually parallels the percentage saturation of transferrin (e.g. haemolytic anaemia, megaloblastic anaemia, iron overload, thalassaemia disorders) Mitochondrial iron deposits (non-ferritin iron): ring sideroblasts in inherited and acquired sideroblastic anaemias

Inherited sideroblastic anaemias

These are rare disorders manifesting mainly in males, usually in childhood or adolescence, but occasionally presenting late in life, when they need to be distinguished from the more common acquired 'refractory anaemia with ring sideroblasts'.

X-linked sideroblastic anaemia

In most reported families, inheritance has followed an X-linked pattern. More than 25 different mutations of erythroid-specific ALAS2, located at Xp11.2l, have been identified. All have been single-base substitutions. Most lead to changes in protein structure, causing instability or loss of function. They are found scattered over the seven exons (out of 11) encoding the C-terminal, catalytically active part of the protein. Mutations affecting the promoter have also been shown to cause disease. Function may be rescued to a variable degree by administration of pyridoxal phosphate – the essential cofactor for ALAS2 – the best responses occurring when the mutation affects the pyridoxal phosphate-binding domain of the enzyme. The response is better if iron overload is reduced by phlebotomy or chelation.

A rare form of X-linked sideroblastic anaemia (ASAT), refractory to pyridoxine, is caused by abnormalities in the ATP-binding cassette transporter gene (ABC7) at Xq13.3. This form is associated with early-onset, non-progressive cerebellar ataxia. A useful diagnostic distinction is the presence within the red cells of increased zinc protoporphyrin, despite adequate iron stores, rather than the low/normal levels found in patients with abnormalities in ALAS2. The anaemia is mild to moderately severe. Three abnormalities of protein structure have been described, and these lie within 34 amino acids of one another at the C-terminal end of the transmembrane domain.

Female carriers of X-linked sideroblastic anaemia may show partial haematological expression, usually with only mild or no anaemia, although, rarely, with a severe dimorphic anaemia. This may depend on variation in the severity of the defect, as well as the degree of lyonization of the affected X-chromosome. Late onset in some patients suggests that the degree of lyonization may change with age. Iron loading may also aggravate the defect in haem synthesis in both males and females with sideroblastic anaemia.

Patients with X-linked sideroblastic anaemia show a hypochromic, often microcytic, anaemia. There may be a few circulating siderocytes, normoblasts and cells with punctate basophilia, but these features become pronounced only if the spleen has been removed. The bone marrow shows erythroid hyperplasia and the erythroblasts tend to be microcytic with a vacuolated cytoplasm. There are many (> 15%) ringed sideroblasts. The ineffective erythropoiesis is not usually accompanied by bone deformities, but some bossing of the skull and enlargement of the facial bones may result from the erythroid expansion. The spleen may be enlarged. Patients may present with severe iron overload even when the anaemia is relatively mild, but the rate of iron loading is accelerated if red cell transfusions are needed. Iron loading, however, aggravates the anaemia.

Mitochondrial DNA mutations

Deletions of mitochondrial DNA, sometimes associated with duplications, are known to be the cause of Pearson marrow–pancreas syndrome, typically consisting of sideroblastic anaemia, pancreatic exocrine dysfunction and lactic acidosis. This is a severe disorder of early onset, presenting usually with failure to thrive, persistent diarrhoea and lactic acidosis. All haemopoietic cell lineages can be affected, and the anaemia is typically macrocytic with prominent vacuoles in cells of both myeloid and erythroid lineages.

Mitochondrial DNA has its own genetic code and encodes mitochondrial tRNA and ribosomal RNA as well as several mitochondrial proteins. In Pearson's syndrome, deletions may encompass tRNA as well as mitochondrial genes and therefore have an effect on the function of all mitochondrion-encoded proteins, causing a considerable loss of mitochondrial function. The presence of many different mitochondria within nucleated cells enable the coexistence of normal and abnormal species, the proportion of which is likely to vary within different tissues, a phenomenon known as *heteroplasmy*. The extent to which different tissues are affected depends to some extent on this proportion and detection often requires the study of different tissues. Inheritance is difficult to determine for the same reason and most cases are described as of 'sporadic' occurrence.

Abnormalities of a high-affinity transporter of thiamine

A gene (*SLC19A2*) encoding a putative thiamine transporter (THTR-1) that is widely and variably expressed has now been mapped to the long arm of chromosome 1 (1q23.3). Abnormalities in this gene are responsible for the thiamine-responsive megaloblastic anaemia (TRMA), or Roger's syndrome. This syndrome is inherited in an autosomal recessive manner and combines diabetes insipidus, diabetes mellitus, optic atrophy and deafness (DIDMOAD), which respond in varying degrees to pharmacological doses of thiamine (vitamin B_1). Ring sideroblasts in varying numbers are typically present and onset is usually in childhood, although some symptoms may be present in infancy. A direct link between the presence of the mutation and mitochondrial iron loading has yet to be demonstrated.

There are still a substantial number of cases of inherited sideroblastic anaemias in which the exact underlying genetic defect remains obscure. These cases may or may not show sex-linked inheritance and often show a macrocytic or dimorphic picture.

Acquired sideroblastic anaemias

Primary acquired sideroblastic anaemia (refractory anaemia with ring sideroblasts)

This is a form of myelodysplasia (refractory anaemia with ring sideroblasts), and arises as a clonal disorder of haemopoiesis. The anaemia is often macrocytic with raised red cell protoporphyrin concentrations, in contrast to X-linked sideroblastic anaemia. Marked erythroid hyperplasia may be present, together with increased iron stores. In these patients, abnormalities in the white cell or platelet precursors are usually absent and the risk of transformation to acute myeloid leukaemia appears less than in other myelodysplastic disorders. Smaller numbers (< 15%) of ring sideroblasts may be present in patients with any of the other myelodysplastic and myeloproliferative diseases. Recent data suggest that acquired defects of mitochondrial DNA may underlie iron transport abnormalities in primary acquired sideroblastic anaemia.

Secondary sideroblastic anaemias

Sideroblastic anaemia associated with pyridoxine deficiency has been described, although not completely documented, in a few patients with gluten-induced enteropathy, in pregnancy, and with haemolytic anaemias, such as sickle cell disease and mechanical or autoimmune haemolytic anaemia. Sideroblastic anaemia may be found as a complication of antituberculous chemotherapy, particularly with isoniazid and cycloserine (pyridoxine antagonists). Sideroblastic anaemia occurs in alcoholism if there is associated malnutrition and folate deficiency. Suggested mechanisms include interference with haem formation and pyridoxine metabolism. The anaemia rapidly reverses with abstinence from alcohol, a normal diet and pyridoxine therapy. Chloramphenicol inhibits mitochondrial protein synthesis and in some patients causes ring sideroblast formation, presumably as a result of impaired haem formation in the mitochondria. Lead inhibits several enzymes concerned in haem synthesis and may damage structural mitochondrial proteins. In some cases, ring sideroblasts are visible in the marrow.

Treatment

Pyridoxine

Some patients with X-linked sideroblastic anaemia respond to pyridoxine, given initially in doses of 100–200 mg per day. The response is usually partial. Some patients require only small doses (less than 10 mg per day) to maintain a higher haemoglobin concentration.

Pyridoxine therapy is almost always ineffective in primary acquired sideroblastic anaemias. Some secondary sideroblastic anaemias may, however, be completely reversed by pyridoxine therapy. This has been described in alcoholism, haemolytic anaemia and gluten-induced enteropathy, as well as in patients receiving antituberculous chemotherapy, in whom the drugs have been stopped and pyridoxine administered.

Other forms of treatment

Folic acid may benefit patients with secondary anaemia. For refractory patients, the anaemia may remain stable and, if the patient is transfusion independent, no treatment is needed. Patients requiring regular red cell transfusions require iron chelation therapy. Iron loading may aggravate the anaemia and, in some patients, improvement in the anaemia has followed iron removal by phlebotomy or iron chelation therapy. Splenectomy should usually be avoided, as it does not benefit the anaemia and leads to persistently high platelet counts postoperatively, with a high incidence of thromboembolism.

Iron overload

A Victor Hoffbrand and Mark Worwood

4

Introduction

Excessive iron accumulation may eventually lead to tissue damage. Iron overload of the parenchymal cells of the liver commonly arises when there is excessive iron absorption, whereas iron administered parenterally (e.g. as multiple transfusions) is first taken up in senescent red cells by macrophages. There is no absolute distinction, however, between the two sources of iron loading, as iron in macrophages is slowly released to transferrin, from which it can be taken up by parenchymal cells. A classification of iron overload is shown in Table 4.1. Severe iron overload, arbitrarily defined as more than a 5-g excess, is confined to the genetic haemochromatosis, together with the iron-loading anaemias and sub-Saharan (African) dietary iron overload.

Genetic haemochromatosis

Classification

Genetic haemochromatosis (GH) is now being classified according to the genetic defect causing iron overload (Table 4.2). The vast majority of cases are of type 1 – involving the *HFE* gene (Chapter 3). In populations of northern European origin about 90% of patients with GH are homozygous for the *HFE* Cys282Tyr mutation (C282Y). In southern Europe, homozygosity for C282Y is found in only about 60% of patients with GH. Types 1, 2 and 3 are autosomal recessive disorders, but type 4 haemochromatosis is inherited as a dominant condition. In type 4, mutations in the ferroportin 1 gene are associated with iron accumulation in macrophages with a raised serum ferritin concentration. The transferrin saturation may be normal.

Table 4.1 Causes of iron overload.

Severe iron overload (> 5 g excess)

Excess iron absorption	Hereditary haemochromatosis
	Massive ineffective erythropoiesis (e.g. β-thalassaemia intermedia, sideroblastic anaemia, congenital dyserythropoietic anaemia)
Increased iron intake	Sub-Saharan dietary iron overload (in combination with a genetic determinant of increased absorption)
	Excess parenteral iron therapy
Repeated red cell transfusions	Congenital anaemias (e.g. β-thalassaemia major, red cell aplasia)
	Acquired refractory anaemias (e.g. myelodysplasia and aplastic anaemia)

Modest iron overload (< 5 g excess)

	Chronic liver disease (e.g. alcoholic cirrhosis)
	Porphyria cutanea tarda
	Rare genetic disorders of iron metabolism (e.g. atransferrinaemia, aceruloplasminaemia)

*Focal iron overload**

	Pulmonary haemorrhage, idiopathic pulmonary haemosiderosis
	Chronic haemoglobinuria (e.g. paroxysmal nocturnal haemoglobinuria)

*May occur in association with general body iron deficiency.

Table 4.2 Classification of genetic haemochromatosis.

Type	Gene	Inheritance and phenotype	Severity	Incidence
1	HFE	AR parenchymal, iron overload	Highly variable	Common
	Digenic (HFE, HAMP, HJN)	AR parenchymal, iron overload	Unknown	Rare
2 (juvenile)	Hemojuvelin	AR parenchymal, iron overload	Severe	Rare
	HAMP	AR parenchymal, iron overload	Severe	Rare
3	TFR2	AR parenchymal, iron overload	Severe	Rare
4	Ferroportin 1	AD RE iron	Variable	Rare

AD, autosomal dominant; AR, autosomal recessive.
For gene symbols see Table 3.1.

Type 1 haemochromatosis

Inherited as an autosomal recessive trait, this is one of the most common genetic conditions found in populations of northern European origin. In the UK, about one in eight people are carriers of the C282Y mutation of the HFE gene, and about 1 in 200 are homozygous for this mutation. Homozygosity is strongly associated with GH, with about 90% of patients with genetic iron overload having this genotype. Digenetic disease has been described – patients being heterozygous for HFE C282Y and a mutation in the HAMP (hepcidin) gene. In homozygotes, there is a gradual accumulation of iron, leading to tissue damage, which may present as cirrhosis of the liver, diabetes, hypogonadism, arthritis and a slate-grey skin pigmentation. Hepatocellular carcinoma develops in 25% of established cases with cirrhosis. Most patients present between the ages of 40 and 60 years, but the clinical penetrance is low (see p. 48). Full phenotypic expression of the disorder is dependent upon other factors, including dietary iron intake, blood loss and probably other genetic factors modifying the genotype. Menstrual losses account for a lower frequency and generally delayed onset in women.

Nature of the defect
A defect in the regulation of intestinal iron absorption, at the stage of either mucosal iron uptake or mucosal transfer, is probable, but the molecular basis of the disorder is only now beginning to be understood. The responsible gene is known to be located on the short arm of chromosome 6, close to the human leucocyte antigen A locus (HLA-A), and association with HLA-A3 and, to a lesser extent, B7 suggested a founder mutation in a chromosome carrying the A3, B7 haplotype. Subsequent linkage analyses using multiple genetic markers have supported this suggestion, and positional cloning led to the identification of a novel MHC class I-like gene, 4 Mb telomeric to the HLA A locus. The gene, *HFE*, contains seven exons, and in over 80% of patients there is homozygosity for a missense mutation. This mutation, G to A at nucleotide 845, results in a cysteine to tyrosine substitution at amino acid 282 (C282Y) in exon 4. A second variant in exon 2 (187C→G) results in a histidine to aspartic acid substitution at amino acid 63 (His63Asp or H63D). This is carried by about 20% of the general population. In the UK, about 90% of patients presenting with haemochromatosis are homozygous for HFE C282Y, and another 4% are compound heterozygotes for the two mutations. *HFE* was therefore a strong candidate for the haemochromatosis gene and this was confirmed by the demonstration that HFE knockout mice and mice homozygous for the C282Y mutation develop iron overload.

How this abnormality might give rise to the iron loading has been the subject of much debate. After the demonstration that in some cell lines the normal HFE protein binds to the transferrin receptor and reduces iron uptake from transferrin, it was speculated that this would be the mechanism leading to increased iron absorption. It was difficult to explain, however, how increased iron uptake from transferrin in developing intestinal epithelial cells, as a result of the failure of expression of the mutated HFE protein, causes increased iron absorption. Moreover, duodenal mucosal iron levels in haemochromatosis are normal or reduced. More recently, it has been shown that hepcidin release from the liver requires expression of HFE and that in mice lacking HFE or expressing the C282Y protein hepcidin expression is low (Chapter 3). Hepcidin is a negative regulator of iron absorption possibly by binding ferroportin and causing its internalization. Lack of hepcidin upregulates expression of a number of iron transport proteins in the intestinal mucosa, thus increasing iron uptake and absorption. Hepcidin also controls iron release from macrophages. This explains the findings in the early stages of haemochromatosis – increased iron absorption, a raised serum iron and a paucity of iron in macrophages. Most recent data suggest that HFE, transferrin receptor 2 and hemojuvelin defects result in reduced hepcidin secretion.

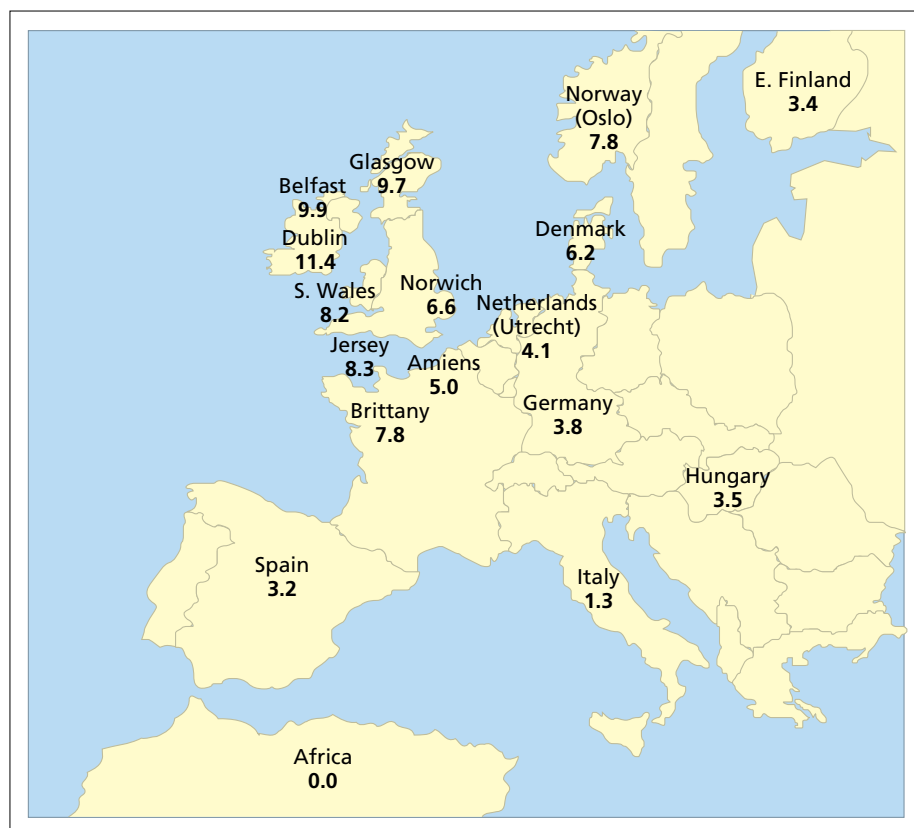
HFE mutation frequencies worldwide
Genotypes have been reported for over 50 000 subjects throughout the world. The C282Y mutation is confined to populations of European origin and within Europe is most frequent in the north. The highest frequencies for the allele are found in Ireland,


Figure 4.1 Frequency of chromosomes carrying the C282Y mutation in regions of Europe (from Worwood 2004 with permission).

Scotland, Wales, Brittany and Scandinavia (Figure 4.1) and the lowest frequencies in southern Italy and Greece. The H63D mutation is found throughout the world but is most common in Europe, where allele frequencies vary from 10% to 20% with a mean of 15%. The only other variant found throughout Europe is Ser65Cys (S65C), which has a frequency of about 2%. Other *HFE* gene mutations associated with iron accumulation have been described – mostly in individual families.

HFE mutations and iron status

The haemochromatosis gene may have increased in frequency because of a selective advantage for heterozygotes – protection against iron deficiency anaemia. Homozygotes would be unlikely to suffer the effects of iron overload before reproducing. About 25% of heterozygotes, identified by HLA typing of family members of haemochromatosis patients, have either a raised transferrin saturation or a raised serum ferritin. Coexistent disease may be the explanation for raised ferritin concentrations in many heterozygotes for *HFE* C282Y. In population surveys, slight but significantly higher values for serum iron and transferrin saturation have been found in heterozygotes for either C282Y or H63D compared with subjects lacking these mutations. The differences in ferritin levels are smaller and not significant. In compound heterozygotes, and

those homozygous for H63D, there are greater differences in both transferrin saturation and serum ferritin although significantion accumulation is rare. In heterozygotes for C282Y or H63D, haemoglobin levels are slightly higher than in subjects lacking mutations, but it has not been clearly demonstrated that this leads to a lower prevalence of anaemia among women carrying either mutation. There is little information about S65C, but in combination with C282Y or H63D it may be associated with mild iron accumulation.

HFE mutations and morbidity

Although advanced haemochromatosis is characterized by diabetes, arthritis and cirrhosis, there is little evidence that possession of HFE mutations is a risk factor for these conditions except through iron overload. The frequency of homozygosity or heterozygosity for C282Y or H63D mutations is not generally increased in patients with arthritis, diabetes and heart disease. Homozygosity for C282Y is more frequent in patients with cirrhosis and hepatoma than in the general population. In one study, homozygosity for C282Y was increased in patients with type 1, late-onset diabetes. Alcohol is a definite risk factor for the development of cirrhosis in patients homozygous for C282Y. The significance of other genetic modifiers remains uncertain.

Figure 4.2 Radiograph of hand – patient with haemochromatosis showing loss of joint space and erosion of cartilage at the metacarpophalangeal joints.

Diagnosis: clinical

The variety of clinical presentations and their lack of specificity for haemochromatosis means that a high degree of clinical suspicion is needed. Fatigue, diabetes mellitus, gonadal failure and arthritis may be present for several years before the diagnosis is made. Arthritis particularly affects the second and third metacarpophalangeal joints (Figure 4.2), and destructive arthropathy of hip and knee joints occurs in 10% of patients. There is chondrocalcinosis with pyrophosphate deposition in the joints. Abdominal pain may result from hepatic enlargement or hepatocellular carcinoma. Grey skin pigmentation results from excess melanin deposition.

Diagnosis: iron status

Transferrin saturation and serum ferritin

In asymptomatic subjects, iron accumulation is indicated by a raised transferrin saturation (> 55% for men and > 50% for women). Most men and about 50% of women who are homozygous for *HFE* C282Y will have a raised transferrin saturation. As iron accumulates, the serum ferritin concentration rises, and values of > 200 µg/L (women) and 300 µg/L (men) suggest iron overload. Serum ferritin concentrations largely reflect iron turnover in phagocytic cells and do not provide an early indication of iron accumulation in liver parenchymal cells. Thus, measurement of transferrin saturation is essential for early detection of iron loading. In patients with infection, inflammation or malignancy, or undergoing surgery, transferrin saturation may, however, be depressed and the serum ferritin concentration elevated. In most cases, genotyping will confirm the diagnosis of GH.

Liver biopsy

In patients homozygous for C282Y with normal serum transaminase activity, serum ferritin concentration < 1000 µg/L and without hepatomegaly there is no need for a liver biopsy in order to make a diagnosis of GH. A liver biopsy is essential to assess tissue damage in patients with evidence of liver disease or a serum ferritin concentration > 1000 µg/L. In patients with an unexplained raised transferrin saturation and serum ferritin, who are not homozygous for C282Y, a liver biopsy may be required to confirm iron overload (Figure 4.3a and b).

Part of the liver biopsy should be washed to remove extraneous blood before wrapping in aluminium foil and drying to constant weight for chemical measurement of iron concentration. Values in excess of 80 µmol/g dry weight (4.5 mg/g dry weight) indicate iron overload. In the differential diagnosis of GH, where there is a progressive increase in iron with age, it is useful to express the result as the 'hepatic iron index' (µmol iron/g dry weight divided by age in years). An elevated index (> 2.0) generally separates patients with homozygous GH from heterozygotes or those with alcoholic liver disease. The hepatic iron index may be helpful in distinguishing iron overload due to GH from the more modest iron overload that can occur secondary to chronic liver disease (usually alcoholic). As alcohol is one of the factors that may enhance the phenotypic expression of GH, this diagnostic distinction is important.

Desferrioxamine-induced iron excretion

The measurement of urine iron excretion following a single i.m. injection of 0.5 g of desferrioxamine (DFX) is still occasionally useful in the assessment of possible iron overload, particularly when clinical considerations rule out the more definitive liver biopsy. Urinary excretion of iron greater than 2 mg in 24 h indicates increased iron stores. A number of other factors influence iron chelation by DFX (p. 54) and, although hepatocytes are an important site of action of the drug, reticuloendothelial iron is also a major source of urine iron excretion in response to the drug. The value of the test as a measure of parenchymal iron overload is therefore limited.
(a)

(b)

Figure 4.3 Liver histology (Perls' stain). (a) Liver biopsy for a patient with type 1 haemochromatosis, showing staining predominantly in parenchymal cells. (b) Liver biopsy for a patient with type 4 haemochromatosis, showing iron staining predominantly in Kupffer cells.

Mobilization of iron by phlebotomy to calculate iron stores

This is carried out by once-weekly venesection (450 mL of blood) until the serum ferritin concentration is < 20 μg/L and transferrin saturation is < 16%. Haemoglobin (Hb) levels should be measured weekly and the rate of venesection reduced if anaemia develops. Serum ferritin should be monitored monthly. The transferrin saturation should be measured weekly when the ferritin concentration drops below 50 μg/L. Once storage iron has been removed the serum ferritin concentration will be less than 15 μg/L, the transferrin saturation < 16% and anaemia will develop. The amount of iron removed at each venesection is calculated by weighing the blood bag before and after venesection (density of blood is 1.05 g/mL) and assuming that 450 mL of blood (Hb concentration = 13.5 g/dL) contains 200 mg of iron. Iron absorption should be allowed for at a rate of 3 mg per day (20 mg per week). With these assumptions, 25 weekly venesections will remove 4.5 g of iron. The amount of storage iron measured by the technique in normal adults has been shown to be about 750 mg in men and 250 mg in women.

Non-invasive methods (see also p. 51)

The superconducting quantum interface device (SQUID) bio-susceptometry technique is sensitive, accurate and reproducible. It depends on the paramagnetic properties of haemosiderin and ferritin. Unlike magnetic resonance imaging (MRI), it does not distinguish parenchymal from reticuloendothelial iron, but the result closely correlates with chemical estimation of liver iron, except when fibrosis is present. Machines are expensive to build and run and at present there are only four worldwide (none in the UK).

Although MRI techniques are being increasingly used as indirect measures of both liver and heart iron (see p. 52), they require special analytical skills and have not been generally applied to type 1 haemochromatosis.

Treatment

Removal of excess iron by regular phlebotomy greatly reduces the mortality from cardiac and hepatic failure, although hepato-cellular carcinoma accounts for a substantial proportion of deaths in those with established disease. Early diagnosis is therefore a priority, as patients identified and treated before the onset of cirrhosis of the liver have a normal life expectancy.

Phlebotomy should be at a rate of 450 mL of blood each week, but the rate may need to be reduced if anaemia develops. Weekly phlebotomy will need to be continued for at least 6 months to remove a total iron excess, which is usually greater than 5 g in established symptomatic disease but may be more than 20 g. The amount of iron removed before anaemia develops should be calculated (see above). Since the advent of genetic testing, confirmation of iron overload by liver biopsy is not necessary in the absence of liver damage and quantitative phlebotomy provides the only practical way of confirming the presence of iron overload.

When iron stores are exhausted, the frequency of phlebotomy should be reduced to two to four units each year, to continue indefinitely. The aim is to maintain a normal transferrin saturation (< 50%) and a serum ferritin in the low normal range (< 50 μg/L).

Fatigue and transaminase elevation usually reverse on venesection. In some patients, diabetes mellitus, hypogonadism and arthralgia improve, but cirrhosis and arthritis are not reversible.

Iron chelation with DFX given as a continuous intravenous infusion (see below) may have a limited role in the short-term management of patients with life-threatening cardiac failure.

Clinical penetrance

Before the discovery of the *HFE* gene, it was assumed that every family member who was homozygous for haemochromatosis would eventually accumulate sufficient iron to cause tissue damage. Recent studies, in which subjects homozygous for *HFE* C282Y have been compared with 'wild-type' subjects, have shown that the frequencies of lethargy, arthralgia and diabetes are the same. There is, however, a small but significant increase

in the percentage of subjects with either raised serum transaminase activity or fibrosis/cirrhosis in the C282Y homozygous group. Furthermore, population surveys have shown that less than 5% of subjects homozygous for C282Y ever receive a diagnosis of haemochromatosis. Despite much debate about ascertainment bias in family and population surveys, it is becoming clear that most men who are homozygous for C282Y will have a raised transferrin saturation before the age of 30 years; a proportion will have an elevated serum ferritin concentration, but only a minority will eventually develop fibrosis and cirrhosis of the liver. Only about 50% of homozygous women have a raised transferrin saturation, and progression through iron accumulation and tissue damage is usually, but not always, slower. In one population study in the USA, the clinical penetrance was estimated to be as low as 1%.

Family testing

Physicians should discuss with the patient the desirability of testing all first-degree relatives over the age of consent in order to identify those at risk. Transferrin saturation and serum ferritin concentration should be measured along with *HFE* genotyping. Genetic testing may identify other family members homozygous for *HFE* C282Y. If the serum ferritin concentration is normal and there is no evidence of liver disease, transferrin saturation and serum ferritin should be measured at yearly intervals and treatment instituted if necessary. Compound heterozygotes are at lesser risk of iron overload but should also be tested by measuring transferrin saturation and serum ferritin – perhaps at 3-yearly intervals. For heterozygotes, iron status should be determined and, if normal, reassessed after 5 years to ensure that no other iron-loading genes are present. About 25% of heterozygotes for C282Y show minor abnormalities of iron metabolism, e.g. a raised transferrin saturation or serum ferritin concentration. Raised ferritin concentration may relate to chronic disease rather than increased iron stores. Iron accumulation similar to that in C282Y homozygotes is rarely seen.

Associations with other conditions

The *HFE* C282Y mutation is relatively common; heterozygosity, and even homozygosity, may occur with other haematological conditions, including inherited sideroblastic anaemia. The occasional presence of iron overload in patients with haematological disorders such as congenital spherocytosis, in whom it is otherwise uncommon, may be due to a combined effect on iron absorption of increased erythropoiesis and coincidental inheritance of the heterozygous state for GH. Porphyria cutanea tarda is discussed in Chapter 3.

Population screening

Widespread population screening on the basis of measures of iron status or by genetic testing has been proposed. Genetic testing of the whole population would, however, be premature, as the precise level of risk for a C282Y homozygote developing

iron overload is not yet known. Once the factors that convey a high risk of developing significant iron overload and tissue damage have been identified, it may be appropriate to reconsider this question.

Type 2 (juvenile) haemochromatosis

Juvenile haemochromatosis is a rare autosomal recessive disease, with clinical symptoms appearing in the second and third decades of life, characterized by cardiomyopathy and hypogonadism. The hemojuvelin locus has been mapped to chromosome 1q21. Iron absorption is greater than in type 1 haemochromatosis. Like hepcidin, hemojuvelin modulates hepcidin expression and hepcidin levels are low in homozygous individuals with hemojuvelin mutations. Mutations were found in Greek, Canadian and French families with G320V, accounting for two-thirds of these mutations. Like *HFE*, hemojuvelin modulates hepcidin expression and serum hepcidin was low in homozygous affected individuals with hemojuvelin mutations.

Mutations in the hepcidin (HAMP) gene (see Chapter 3) have been described in several families with a type of juvenile haemochromatosis not linked to chromosome 1. Affected subjects were homozygous for the mutation in each case.

Type 3 haemochromatosis

Haemochromatosis type 3 is phenotypically similar to *HFE*-associated haemochromatosis but is due to mutations in the transferrin receptor 2 gene (Table 4.2). TFR2 shows moderate homology to TFR, may bind transferrin but is not iron-regulated. Hepcidin levels are low in type 3, suggesting TFR2 has a role in hepcidin synthesis (see Table 3.1).

Type 4 haemochromatosis

Haemochromatosis type 4 has peculiar genetic and clinical features compared with the other forms. First, it is inherited as an autosomal dominant trait. Second, patients have increased serum ferritin levels, but may have a normal transferrin saturation. Third, at liver biopsy iron is increased in the reticuloendothelial cells, as well as in hepatocytes. These features suggest a different pathophysiology of the disease. Haemochromatosis type 4 is now known to be due to heterozygous mutations in the iron exporter, ferroportin 1, coded for on chromosome 2q32 (Figure 4.4). Along with missense mutations, a deletion of valine at amino acid 162 has been found in families from the UK, France, Italy and Australia, suggesting that this may be a relatively common cause of iron accumulation. The phenotype is similar to that found in the anaemia of chronic disease, and it is unlikely that a ferroportin 1 mutation would be suspected unless there was significant iron overload and a clear familial association. Figure 4.3 illustrates the difference between the parenchymal iron overload found in most cases of GH and the predominantly
Figure 4.4 Iron-loading mutations in the ferroportin 1 gene. The nine predicted transmembrane helices (1–9) are shown in relation to the lipid bilayer, with the mutations marked (red circles). The 12 Cys residues are marked with yellow circles and three putative exposed N-linked oligosaccharide sites (Y) are shown. The N- and C-termini are denoted (N and C). The residue lengths of the loops are denoted by numbers adjacent to each loop. Mutations are clustered at either end of TM helices 1 and 3 or at the extracellular loop at the C-terminal end of the helix (from Worwood 2004 with permission).

reticuloendothelial distribution in a case of type 4 haemochromatosis due to the valine 162 deletion. In one family, weekly venesection rapidly caused anaemia, and venesection with erythropoietin therapy was successful in reducing iron stores. It is not yet clear whether the degree of tissue damage at a given serum ferritin level is similar to type 1 haemochromatosis or whether the reticuloendothelial distribution is less toxic. In people of African origin, Gln248His in ferroportin 1 is a common variant that may be associated with a tendency to iron loading and mild anaemia.

Neonatal haemochromatosis

This is a condition that is recognized at birth but may occur *in utero*. It is characterized by heavy parenchymal iron deposition in several organs and irreversible liver failure. The only therapeutic option used to be liver transplantation. Neonatal haemochromatosis has been linked in some cases to the presence of a maternal factor, e.g. an antiribonuclear factor antibody. Infusions of gammaglobulin in pregnancy appear to reduce the severity of the condition and it has been proposed that the disease is due to an alloantibody (as rhesus incompatibility) but the target antigen is unknown. No mutations in the *HFE* gene are reported and chromosome 1q linkage has been excluded.

Increased iron intake

African iron overload (Bantu siderosis) results from the combination of a dietary component (a traditional beer that contains iron) and an unknown susceptibility gene. Mutations in the *HFE*

gene have been excluded but mutations of the ferroportin gene may play a role (see above). Iron deposition, as in type 4 haemochromatosis, occurs both in hepatocytes and in reticuloendothelial cells. Serum ferritin is usually elevated, but transferrin saturation may be normal. The condition occurs in sub-Saharan Africa. It is a cause of hepatic fibrosis and cirrhosis, and associations with diabetes mellitus, peritonitis, scurvy and osteoporosis have been described. The iron overload is associated with a poor outcome in tuberculosis, an infection that is highly prevalent in sub-Saharan Africa.

Other causes of iron overload

Atransferrinaemia
This is a rare recessive genetic disorder associated with a severe hypochromic anaemia with, in some cases, excessive iron deposition in the reticuloendothelial cells. In all cases tested, some iron–transferrin has been detected by iron-binding ability or immunologically. Complete absence of transferrin would presumably lead to fetal death.

Iron and neurodegeneration

Aceruloplasminaemia
This is also a rare recessive disorder in which there is a deficiency of ferroxidase activity as a consequence of mutations in the ceruloplasmin gene on chromosome 3q. Clinically, the condition presents in middle age, with progressive degeneration of the retina and basal ganglia and with diabetes mellitus. Iron accumulates in the liver, pancreas and brain with smaller amounts

in the heart, kidneys, thyroid, spleen and retina. The serum iron is low. The total iron-binding capacity of transferrin (TIBC) is normal and ferritin is normal or raised. Interestingly, there is evidence that iron chelation with DFX may decrease brain iron stores and halt the progression of the neurological degeneration.

Hallervorden–Spatz syndrome

This is an autosomal recessive neurodegenerative disorder associated with iron accumulation in the brain. Clinical features include extrapyramidal dysfunction, onset in childhood and a relentlessly progressive course. Histological study reveals iron deposits in the basal ganglia. Hallervorden–Spatz syndrome is caused by a defect in a novel pantothenate kinase gene that causes accumulation of cysteine. Iron binding by cysteine may cause iron accumulation and oxidative stress which is a likely explanation for the pathophysiology of the disease.

Neuroferritinopathy

A previously unknown, dominantly inherited, late-onset basal ganglia disease, variably presenting with extrapyramidal features similar to those of Huntington's disease or Parkinsonism also shows iron accumulation in the forebrain and cerebellum. The disorder was mapped 19q13.3, which contains the gene for ferritin light-chain polypeptide (FTL). An adenine insertion at position 460–461 was found that was predicted to alter carboxy-terminal residues of the gene product. Abnormal aggregates of ferritin and iron in the brain contrasted with low serum ferritin levels.

These diseases may serve as a model for complex neurodegenerative diseases, such as Parkinson's disease, Alzheimer's disease, and Huntington's disease, in which accumulation of iron in the brain is also observed. Possession of the C282Y mutation of the *HFE* gene does not appear to be a risk factor for these conditions.

Friedrich's ataxia

This is a neurodegenerative disease characterized by loss of sensory neurones in the spinal cord and dorsal root ganglia. There is mitochondrial iron overload and a loss of activity of iron–sulphur cluster-containing enzymes. Patients frequently die from cardiomyopathy. The majority of Friedrich's ataxia (FRDA) cases result from the expansion of triple nucleotide repeats within an intron of the *FRDA* gene (human chromosome 9q13), leading to reduced expression of frataxin mRNA and protein. Point mutations have also been identified in a small number of cases. Frataxin is found in the mitochondrion where, in FRDA, there is increased oxidative stress and decreased activity of iron–sulphur proteins. Oxidative damage following iron accumulation is thought to precipitate the neurone loss in FRDA. This is confirmed by experiments in yeast that show that iron is redistributed to the mitochondria of Yfh (yeast frataxin homologue)-deficient yeast and that this iron accumulation precedes oxidative damage. Frataxin shows structural similarity

to ferritin, suggesting that frataxin may regulate mitochondrial iron homeostasis by storing excess iron.

Iron loading anaemias

Removal of iron is essential in patients with transfusion-dependent anaemias, such as thalassaemia major, to prevent death from iron overload, usually due to cardiac failure or arrythmia. Intake of iron ranges from 0.32 to 0.64 mg/kg of body weight daily in splenectomized thalassaemia major patients, derived from 100–200 mL of pure red cells per kg per year. The iron content of each transfusion is: volume (mL) × haematocrit × 1.16 mg. Patients with anaemias associated with increased iron absorption, e.g. thalassaemia intermedia, who are too anaemic to be venesected to remove iron, may also require iron chelation therapy, although the rate of iron loading is considerably lower at about 0.1 mg/kg per day. The only iron-chelating drug widely available is desferrioxamine (DFX). This is orally inactive and given by slow subcutaneous or intravenous infusion. Deferiprone, an orally active iron chelator, first used clinically in 1987, is now licensed for DFX 'failures' in over 40 countries, whereas a third drug, ICL670, is undergoing phase III clinical trials (Table 4.3 and Figure 4.7).

Iron chelation therapy is monitored by:
1 tests of body iron burden (Table 4.4);
2 tests of function of the organs sensitive to iron overload (Table 4.5);
3 tests to detect potential side-effects of the particular chelating drug being used.

Tests (1) and (2) are discussed first. The results and side-effects with the individual iron-chelating drugs are then described.

Tests of body iron burden

Serum ferritin

Serum ferritin is useful in monitoring changes in body iron, although the absolute level is an imprecise measure of total body iron. There is a wide range of liver iron at any given serum ferritin level. This is partly because serum ferritin mainly reflects reticuloendothelial iron and partly because inflammation, e.g. hepatitis C infection, raises the level, whereas vitamin C deficiency, frequent in iron overload, lowers it. The Thalassaemia International Federation (TIF) guidelines recommend maintaining the level < 1000 μg/L in thalassaemia major. One study found that if two-thirds were at levels below 2500 μg/L, cardiac complications were infrequent. Others have found a level consistently less than 1500 μg/L to be associated with few complications.

Liver iron

Liver iron may be measured chemically after liver biopsy, by MRI or, in a few specialized units, by SQUID (see p. 48).

Table 4.3 Characteristics of desferrioxamine, deferiprone and ICL 670.

	Desferrioxamine	*Deferiprone*	*ICL 670 (Deferasirox)*
Structure	Hexadentate	Bidentate	Tridentate
Molecular weight	560	139	373
Iron–chelator complex	1:1	1:3	1:2
Plasma clearance $T^{1}/_{2}$	20 min	53–166 min	1–16 h
Absorption	Negligible	Peak 45 min	Peak 1–2.9 h
Iron excretion	Urine + faecal	Urine	Faecal
Therapeutic daily dose	40 mg/kg	75 mg/kg	20 mg/kg
Route	Parenteral	Oral	Oral
Clinical experience	30 years	18 years	1–2 years
Side-effects	Ototoxicity, retinal toxicity, growth defect, cartilage and bone abnormalities	Agranulocytosis, arthropathy, gastrointestinal disturbance, transient transaminitis, zinc deficiency	Skin rashes, gastrointestinal disturbance

Table 4.4 Tests of body iron burden.

1	Serum ferritin		
2	Serum iron and % saturation of iron-binding capacity		
3	Serum non-transferrin-bound iron

6	Urine iron in response to standard dose of chelator (desferrioxamine or deferiprone)		

CT, computerized tomography; MRI, magnetic resonance imaging; SQUID, superconducting quantum interface device.

Chemical estimation is the gold standard but can be inaccurate if fibrosis is present. Levels > 15 mg/g dry weight have been associated in DFX-treated patients with a high risk of cardiac disease, liver fibrosis and cirrhosis. Levels between 7 and 15 mg/g dry weight are associated with liver damage only if there is also hepatitis C infection and have been considered relatively safe from cardiac disease but associated with damage to the endocrine organs. Levels less than 7 mg/g are found in carriers of haemochromatosis.

MRI techniques are being increasingly used as indirect measures of liver and cardiac iron. They have the advantage of being non-invasive and are more widely available than SQUID (which is suitable for liver but not cardiac iron). MRI is also the only practical method of performing sequential studies of iron in the heart, pituitary or other endocrine organs. Different MRI techniques have been used. They all rely on a shortening of relaxation time and thus reduction in signal intensity with iron overload. Gradient-echo imaging with the calculation of the T2* has a short total imaging time, reducing movement artefacts. It also is extremely sensitive and reproducible. The spin-echo technique is less sensitive to iron in the form of haemosiderin and ferritin and requires a longer imaging time, allowing greater movement artefacts. It is improved by comparing the signal with that of a tissue (skeletal muscle) that does not develop iron load. Both methods show a close correlation between signal intensity and chemically estimated liver iron but have yet to be calibrated directly against chemically estimated heart iron.

Cardiac iron

As cardiac failure or arrhythmia is the usual cause of death in transfusional iron overload, it is essential to monitor cardiac iron. Iron is deposited in myocytes and interstitial fibrosis develops. Direct measurement of cardiac iron by endomyocardial biopsy is inappropriate as the technique is highly invasive

Table 4.5 Monitoring for iron-induced tissue damage organ.

1	Cardiac function		ECG ± exercise
			24-h monitor
			Echocardiography, MUGA ± stress tissue, Doppler echography, MRI

		Parathyroid	Calcium, phosphate
			PTH

ECG, electrocardiogram; FSH, follicle-stimulating hormone; GNRH, gonadotrophin-releasing hormone; HbAIC, glycated haemoglobin; IGF, insulin-like growth factor; LH, luteinizing hormone; MRI, magnetic resonance imaging; MUGA, multigated acquisition scan; PTH, parathyroid hormone; SHBG, sex hormone-binding globulin; TSH, thyroid-stimulating hormone.

and inaccurate as iron localizes mainly in the ventricular myo- and epicardium. MRI offers a reproducible, sensitive, albeit indirect measure: the lower the T2* value, the greater cardiac iron. The T2* technique appears to be most sensitive (Figure 4.5). A T2* value of < 20 ms correlates with the presence of cardiac dysfunction detected by echocardiography or 24-h rhythm monitoring or the need for cardiac therapy (Figure 4.6). Using this and the spin-echo technique, poor correlation has been found between derived myocardial iron and liver iron (MRI derived) or serum ferritin in patients receiving DFX. Others using the spin-echo technique have found a positive relation between MRI-determined liver iron and urine iron excretion after chelator administration in non-thalassaemic patients.

Urine iron excretion

Iron excretion after a single infusion of a standard dose DFX or oral dose of deferiprone is related to body iron. Urine iron is derived from the labile iron pool chelated mainly extracellularly with DFX and probably intracellularly with deferiprone. With DFX (but not deferiprone) urine iron excretion is increased by ascorbate and is proportionately higher if the haemoglobin is lower. The test is useful when commencing therapy with

deferiprone, with which iron excretion is highly dose related, and for monitoring therapy, in some studies correlating closely with liver and cardiac iron. Several estimations must be performed at any given dose, however, in view of the variability found.

Non-transferrin-bound iron

This is present in plasma in patients with gross iron overload. It is highly toxic, promoting the formation of free radicals causing peroxidation of membrane lipids. Part of the early improvement in liver and cardiac function with chelation therapy may be due to removal of this fraction, even before iron burden is substantially lowered. Its clearance by DFX is short lived as it reappears in plasma within hours of stopping an infusion. This provides a rationale for using 24-h continuous infusions in patients with iron-induced cardiomyopathy. Non-transferrin-bound iron is absent from plasma of well-chelated patients.

Tests of organ function

The tests that are usually needed are listed in Table 4.4. Heart function is best tested by measurement of left ventricular ejection

(a) (b) (c) (d)

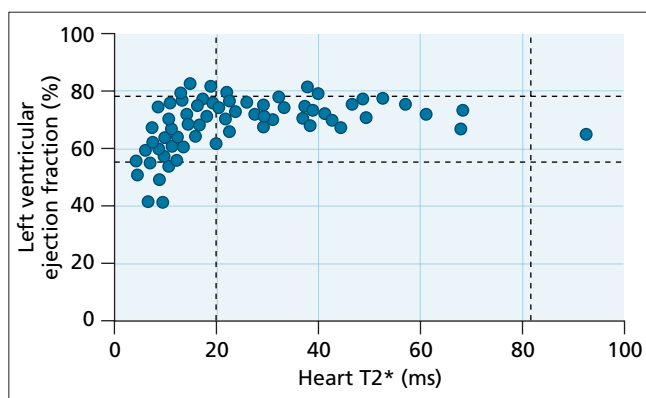
Figure 4.5 Magnetic resonance imaging T2* technique. Tissue appearances of liver and spleen: (a) normal; (b) tissue iron overload; (c) severe liver iron overload with normal cardiac iron; (d) severe cardiac iron deposition with minimal liver iron deposition (reproduced from Anderson *et al.* 2001 with permission).


Figure 4.6 Relationships of myocardial T2* and left ventricular ejection fraction in patients with thalassaemia major and iron overload (reproduced from Anderson *et al.* 2001 with permission).

fraction and by tests for rhythm disturbance. Liver function assessment requires routine liver function tests as well as liver biopsy to assess liver structure and liver iron burden (histologically and chemically). The endocrine system is also damaged by iron and appropriate tests are listed in Table 4.4. The anterior pituitary is particularly sensitive, with damage resulting in reduced growth and impaired sexual maturation. Direct damage to the ovaries or testes may also occur but is usually less important. Hypogonadic hypogonadism, defects of growth hormone secretion and in its receptor, and deficiency of insulin-like growth factor mainly account for growth failure; DFX may also cause this. Diabetes mellitus and pre-diabetes, due to iron deposition in the pancreatic islets, are frequent, especially in patients with genetic susceptibility. Hypothyroidism and hypoparathyroidism are also common in poorly chelated patients. Osteoporosis is well recognized in iron-overloaded thalassaemia patients; it is due to multiple factors and is detected by bone density studies.

Iron chelation therapy

Desferrioxamine

Pharmacokinetics

Desferrioxamine mesylate (DFX) is the main agent licensed in all countries in clinical use at present. It is not absorbed orally and, after parenteral injection, is rapidly cleared from the plasma, being excreted in the urine, taken up by hepatocytes or metabolized in the tissues (Table 4.3). This accounts for the much greater mobilization of iron by continuous intravenous (i.v.) or slow subcutaneous (s.c.) infusions, which allow more prolonged exposure of the drug to the chelatable iron than with i.m. injection.

DFX is a trihydroxamic acid (hexadendate) (Figure 4.7), one molecule binding covalently to all six oxygen sites on one ferric ion to form the red chelate, ferrioxamine. This is excreted in urine and bile. Faecal iron is derived from hepatocytes. Urine iron also derives, at least in part, from hepatocytes, although other body sources, especially iron released from macrophages, contribute. Urinary iron excretion tends to level off at higher doses, but this does not occur with bile excretion, which increases linearly with the dose. Bile iron may therefore predominate at high doses, and this is also the major route of excretion when total body iron has been reduced to relatively low levels. Urine iron excretion tends to be less immediately after blood transfusions, but this is accompanied by a reciprocal increase in faecal iron excretion. Increased erythropoiesis, as in haemolytic anaemias, is associated with an increase in urine iron excretion in relation to body iron stores.

Clinical studies

Therapy with DFX is expensive and inconvenient. Its use should, therefore, be restricted to those patients in whom iron overload is the main threat to life. Most studies have been with thalassaemia major, but patients with other inherited anaemias, e.g.
Figure 4.7 Chemical structures of three iron chelators. (a) ICL 670. (b) Deferiprone. (c) Desferrioxamine.

Diamond–Blackfan, Fanconi, sickle cell, sideroblastic anaemia or acquired disorders, especially myelodysplasia, myelofibrosis red cell aplasia or aplastic anaemia, may require iron chelation therapy. In elderly patients with acquired, transfusion-dependent, refractory anaemias, the prognosis of the underlying haematological disease may not justify the inconvenience of s.c. DFX therapy. In children, tissue damage from iron may be present from very early life; regular iron chelation should begin in thalassaemia major after transfusion of about 12 units of blood or when the serum ferritin exceeds 1000 μg/L. In young children, treatment should be started at 20 mg/kg to prevent tissue damage due to iron without causing toxicity due to excess DFX. A local anaesthetic cream (e.g. EMLA) reduces pain from the needle insertion.

The standard adult dose is 40 mg/kg, given as an 8- to 12-h infusion s.c. or at least 5 days each week. DFX may also be given intravenously via a separate line at the time of blood transfusion. To avoid toxic effects, the dose should be restricted to a maximum of 1 g with each unit of blood.

Repletion of ascorbic acid deficiency, which sometimes accompanies iron overload, or ascorbate therapy even in those with normal tissue levels of ascorbate, increases urinary iron excretion but has no effect on bile iron excretion. Supplements of vitamin C should be 100–200 mg per day. In some less severely anaemic patients with chronic ineffective erythropoiesis and iron loading from the gut (e.g. with thalassaemia intermedia or sideroblastic anaemia), cautious phlebotomy may be used instead of or added to regular s.c. DFX to produce a rate of

iron mobilization similar to that achieved in the treatment of hereditary haemochromatosis.

In patients unable to comply with s.c. DFX or those with iron-induced cardiomyopathy, continuous intravenous (i.v.) DFX may be given via an indwelling catheter (e.g. Hickman) or Port-a-Cath chamber. Removal of liver iron is more rapid than removal of cardiac iron with this intensive chelation regime. Continuous s.c. DFX can also be administered using a disposable balloon infuser system with pre-prepared DFX solution (e.g. 4 g of DFX to be infused over 48 h) rather than using a battery-operated infusion pump. Continuous infusion avoids the reappearance of toxic NTBI in plasma. Twice-daily i.m. injections of DFX produce significant iron excretion, but these are painful and the long-term efficacy of this approach is unproven. Trials of DFX bound to starch to prolong its action are in progress.

Body iron stores can be restricted to 5–10 times normal in well-chelated, regularly transfused patients. There is improved cardiac function and survival in patients who comply with the rigorous therapy. Iron-induced cardiomyopathy can be reversed in some, but not all, patients with continuous DFX therapy. Growth and pubertal development are improved in many, but not all, patients; diabetes and other endocrine abnormalities still occur frequently. Serum ferritin levels in well-chelated thalassaemia major patients usually plateau between 1500 and 2500 μg/L. Unfortunately, through lack of compliance, premature deaths usually from iron-induced cardiac damage occur in a substantial proportion of thalassaemia major patients. In Turin, 95% of compliant (250 or more DFX infusions per year) patients were alive at 30 years compared with only 12% of non-compliant patients. In the UK, only 50% of thalassaemia major patients were alive at 35 years, deaths being largely due to failure of compliance with DFX.

Side-effects
The adverse effects possible with DFX include rare generalized sensitivity reactions, local soreness related to the site of injection (usually due to the needle being inserted too superficially) and exacerbation of some infections, notably of the urinary tract and precipitation of *Yersinia enterocolitis*. Auditory (high-tone sensorineural hearing loss) and visual neurotoxicity (night blindness, visual field loss, retinal pigmentation and changes on electrical tests) are relatively frequent. Growth and bone defects may also occur. The spine may be affected, with sitting height reduced; rickets-like bone lesions, genu valgum and metaphysical changes are described, especially in children (Figure 4.8).

Auditory, visual and growth side-effects of DFX occur mainly if the body iron burden is low and doses of DFX high, and particularly in children. A therapeutic index = mean daily dose (mg/kg)/current serum ferritin (μg/L) can be calculated. If this is below 0.025 at all times, these side-effects of DFX do not occur.

Figure 4.8 Bone and cartilage defects due to DFX.

Deferiprone

Pharmacokinetics

Deferiprone is rapidly absorbed, appearing in plasma within 15 min of ingestion, with a peak plasma level within 45–60 min (Table 4.3). It forms a 3:1 chelator–iron complex, which is excreted with the free drug and glucuronide derivative in urine. Only 4% of a single oral dose of the drug is excreted bound to iron, even in heavily iron-loaded patients. Its iron chelation site is inactivated by glucuronidation, the speed of which varies from patient to patient. This explains much of the individual variation in response, the area under the curve of the concentration of free drug in plasma being related to amount of iron excreted.

Deferiprone mobilizes iron from parenchymal and RE pools and from transferrin, ferritin and haemosiderin. Unlike DFX, it is also capable of chelating iron from intact red cells *in vitro* and *in vivo*, shown in patients with sickle cell anaemia and thalassaemia intermedia. The enhanced ability of deferiprone to cross cell membranes may underlie what is emerging as its superior ability compared with DFX to protect the heart from iron and also the 'shuttle effect' for iron when the two drugs are given simultaneously (see later and Figure 4.9). Few balance studies have been performed. These suggest that on average deferiprone at 75 mg/kg is about 60% as effective as DFX at 60 mg/kg, but may be as effective as DFX 40 mg/kg. However, wide individual variations occur, especially with deferiprone. Moreover, it is easier for patients to comply with deferiprone than DFX on all 7 days each week.

Clinical studies

The usual dose used in most trials has been 75 mg/kg daily. Long-term studies show that serum ferritin levels tend to fall in those starting with the highest levels (> 3000 μg/L), but, in patients with lower levels, tend to remain unchanged or to increase so that levels usually plateau around 2000–2500 μg/L. The effect on liver iron is variable, but in studies of previously poorly chelated thalassaemia major patients from 10% to 30% show liver iron levels above 15 mg/g dry weight, i.e. in the so-called 'danger' zone. More and longer-term trials are needed to document this more exactly. MRI studies have also suggested that liver iron may on average be higher in patients treated with deferiprone (75 mg/kg 7 days per week) compared with those treated with DFX (40 mg/kg 5 days per week).

In the liver, DFX has the advantage of facilitated transport into cells by an active mechanism. Deferiprone, on the other hand, may have greater penetration of myocardial cells because of its lower molecular weight and because it is lipophilic. Retrospective studies have suggested, on the basis of T2* studies, echocardiography, clinical incidence of cardiac disease and need for cardiac therapy, that deferiprone 75 mg/kg is more effective at protecting the heart from iron-induced cardiomyopathy in routine clinical practice over 3–6 years than DFX. Prospective
Figure 4.9 The concept of combination therapy: DFO, desferrioxamine; DFP, deferiprone; NTBI, non-transferrin-bound iron (modified from Liu *et al.* 2002).

randomized studies are now in progress, comparing the efficacy of the two chelators.

For patients inadequately chelated by DFX, efforts at increased compliance with DFX are first needed. The use of deferiprone at the dose of 75 mg/kg for those inadequately chelated is now licensed in 43 countries. Increasing the dose of deferiprone to 100 mg/kg daily has been shown to improve iron status, and longer-term trials at this higher dose are in progress to establish whether it results in increased side-effects. An alternative to raising the dose of deferiprone for those inadequately chelated by 75 mg/kg per day is to combine DFX and deferiprone therapy, and this approach is discussed below.

Side-effects
The complications of deferiprone therapy are now well established. The most severe is agranulocytosis (neutrophils $< 0.5 \times 10^9$/L), with an estimated incidence of around 0.5–1.0%. Lesser degrees of neutropenia ($0.5–1.5 \times 10^9$/L) are more frequent, around 3%, occurring more frequently in non-splenectomized patients. Agranulocytosis and neutropenia spontaneously recover when the drug is discontinued, usually within 4–28 days but, occasionally, are more prolonged, e.g. up to 124 days. The mechanism appears to be idiosyncratic, more common in females, with no definite evidence of an immune mechanism established. Patients should be monitored by blood counts every week for at least the first 8–12 weeks of therapy and every 2 weeks thereafter for 2 years. There are no data to show agranulocytosis is more frequent in patients with stem cell or progenitor cell defects, e.g. aplastic anaemia, Diamond–Blackfan syndrome or myelodysplasia, but it seems sensible to monitor these patients particularly closely.

Painful joints, especially the knees, have been reported at around 5–10% in most large series. Some but not all studies show that this complication is most frequent in the most iron-loaded patients and with higher doses of deferiprone. It usually, but not invariably, resolves with withdrawal of the drug and it is often possible to reintroduce the drug, commencing with lower doses. There is no evidence for any immune abnormality induced by deferiprone underlying the arthropathy.

Gastrointestinal side-effects, e.g. nausea and abdominal pain, occur in about 8% of patients. In most the drug can be reintroduced long term, initially at a lower dose. Zinc deficiency has been described in diabetic and pre-diabetic patients. Rarely, it can lead to clinical features, e.g. skin rashes and hair loss. It is easily treated by oral zinc therapy. Liver fibrosis was suggested as a complication of deferiprone therapy in one study, but larger studies show that liver fibrosis in multiply transfused patients is not a direct consequence of deferiprone. Nevertheless, transient increases in liver enzymes have been associated with deferiprone therapy and a few patients have been withdrawn from therapy because of a persistent rise in liver enzyme levels. There have been no definite reports of renal, cardiac or neurological side-effects. Although immunological changes and systemic lupus

syndrome were suggested to occur in a few patients, these have not been confirmed as side-effects in large studies.

Combination therapy
Urine iron excretion when the two drugs DFX and deferiprone are given simultaneously is equivalent to the sum of the excretion when the drugs are given on separate days. There is evidence for a 'shuttle' effect in which deferiprone enters cells, chelates iron and then returns to plasma, where the iron is transferred to DFX for excretion in urine or bile (Figure 4.9). All studies of combination therapy, e.g. deferiprone on 7 days a week, DFX on 2 days, have shown a significant fall in serum ferritin levels over 6–18 months. Toxicities are also reduced by avoiding the necessity for high doses of either drug. The combination may also be effective at removing both cardiac and liver iron. Longer-term studies are needed, however, to establish that there are no increased side-effects when the two are used together. Alternating therapy has also been studied, e.g. 4 days of deferiprone and 2 days of DFX each week, with improved compliance and improved iron status in previously poorly compliant (with DFX) children over 6–12 months of therapy.

ICL 670 (bishydroxylphenylthiazole, Deferasirox, Exjade)
This compound, (4-[3,5-bis(2-hydroxyphenyl)-1,2,4-triazol-1-yl]benzoic acid (Figure 4.4), forms a 2:1 chelator–iron complex and increases predominantly faecal iron excretion. After a single oral dose, only 6% of iron excretion occurs in the urine (Table 4.3). It is highly selective for iron, rapidly absorbed and circulates for several hours. Peak plasma concentration after a single oral dose occurs at about 2 h, and the drug is still detectable in plasma in almost all patients at 24 h, with a mean elimination half-life of between 11 and 16 h after multiple-dose administration. At the dose of 20 mg/kg used in early studies, total body iron excretion ranged from 7.7 to 28.5 mg iron per day in thalassaemia major patients, and short-term trials suggest that it may be able to reduce liver iron to the same extent as s.c. DFX 40 mg/kg on 5 days per week over 12 months of therapy. Side-effects of ICL 670 in short-term trials include gastrointestinal symptoms and skin rashes.

Other potential iron chelators
GT56-252 (Deferitrin), a desferrithiocin derivative, is in phase I clinical trials at present. It is a 2:1 chelator with iron, with dominant faecal excretion. It has a half-life in plasma of several hours and is well tolerated in short-term trials. Pyridoxal isonicotinoyl hydrazone (PIH) is a tridentate iron chelator. It increases urine and faecal iron excretion but, in the main trial so far, was not sufficiently effective to produce a negative iron balance in thalassaemia major. Many derivatives of PIH await further studies. Other iron chelators that have been found too toxic, or not sufficiently effective, for clinical use include desferrithiocin, a

tridentate chelator, and HBED (*N,N′*-bis(2-hydroxybenzyl)-ethylenediamine-*N,N′*-diacetic acid), a hexadentate chelator. GT56-252, a desferrithiocin derivative, is in phase I clinical trials at present.

Thalassaemia intermedia

For these patients, and other severely anaemic patients who are not transfusion dependent or only need a few transfusions each year, iron loading occurs mainly through increased iron absorption. The anaemia may be too severe for venesections. DFX can be used to chelate iron but care must be taken to avoid side-effects of the drug in these moderately iron-loaded patients. Oral iron chelation with deferiprone has also been shown effective in 'de-ironing' such patients, potentially reducing serum ferritin and liver iron to normal. A rise in haemoglobin level may occur. This may be due to removing iron from the renal oxygen sensor, augmenting the effect of hypoxia and increasing erythropoietin secretion from the kidney. The role in haemoglobin may also result from deferiprone directly removing iron from erythroblasts and mature red cells, reducing ineffective erythropoiesis and haemolysis. Improved haemopoiesis has also been described in myelodysplasia after chelation with DFX.

Acute iron poisoning

Acute oral iron poisoning produces a severe necrotizing gastritis and enteritis, followed by metabolic acidosis and, after a day or two, cardiovascular collapse and evidence of liver damage. DFX should be given both orally and parenterally. The instillation of 5 g into the stomach after a 1% sodium bicarbonate gastric lavage (to reduce further absorption) and an injection of 1–2 g i.m. may be tried. If a large number of tablets have been taken, an i.v. DFX infusion up to a maximum dose of 80 mg/kg in 24 h should be used. Deferiprone has not yet been used in this setting.

CHAPTER 5

Megaloblastic anaemia

5

A Victor Hoffbrand and Ralph Green

Introduction

The megaloblastic anaemias are a group of disorders characterized by the presence of distinctive morphological appearances of the developing red cells in the bone marrow. The cause is usually deficiency of either cobalamin (vitamin B_{12}) or folate, but megaloblastic anaemia may arise because of genetic or acquired abnormalities affecting the function or metabolism of these vitamins or because of defects in DNA synthesis not related to cobalamin or folate (Table 5.1).

Underlying basic science

Biochemical basis of megaloblastic anaemia

The common feature of all megaloblastic anaemias is a defect in DNA synthesis that affects rapidly dividing cells in the bone marrow and other tissues. All conditions that give rise to megaloblastic changes share in common a disparity in the rate of synthesis or availability of the four immediate precursors of DNA: the deoxyribonucleoside triphosphates (dNTPs), dA(adenine)TP and dG(guanine)TP (purines) and dT(thymine)TP and

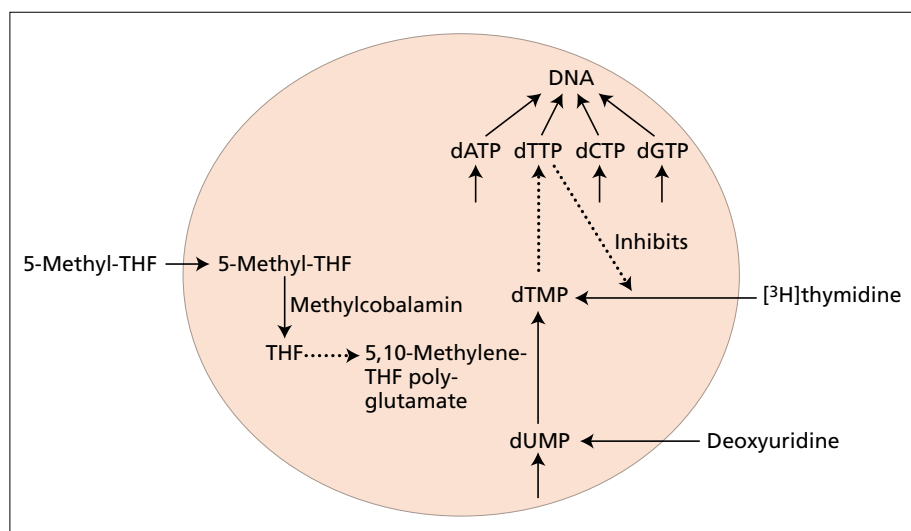
Table 5.1 Causes of megaloblastic anaemia.

Cobalamin deficiency or abnormalities of cobalamin metabolism (Table 5.4)
Folate deficiency or abnormalities of folate metabolism (Table 5.8)
Therapy with antifolate drugs (e.g. methotrexate)
Independent of either cobalamin or folate deficiency and refractory to cobalamin and folate therapy:
 Some cases of acute myeloid leukaemia, myelodysplasia*
 Therapy with drugs interfering with synthesis of DNA (e.g. cytosine arabinoside, hydroxyurea, 6-mercaptopurine, azidothymidine (AZT))
 Orotic aciduria (responds to uridine)
 Lesch–Nyhan syndrome (? responds to adenine)

*Folate deficiency also occurs frequently in these diseases.

dC(cytosine)TP (pyrimidines) required for ordered DNA replication during the S-phase of the cell cycle (Figure 5.1). In deficiencies of either folate or cobalamin, the defect in DNA synthesis is caused by a failure to convert adequate amounts of deoxyuridine monophosphate (dUMP) to thymidine monophosphate (dTMP). This is because folate is needed as the

60

Figure 5.1 Deoxyuridine suppression test. The circle represents a bone marrow or other haemopoietic cell. THF, tetrahydrofolate; MP, monophosphate; TP, triphosphate; d, deoxyribose; A, adenine; T, thymine; C, cytosine; G, guanine.


coenzyme 5,10-methylene tetrahydrofolate polyglutamate for conversion of dUMP to dTMP and the availability of this coenzyme is reduced in either cobalamin or folate deficiencies.

Synthesis of new strands of DNA during the S-phase of the cell cycle commences with separation of the two parent strands from each other at many points along the chromosome. At a number of points of origin, RNA primers are synthesized first and new DNA strands are then synthesized bidirectionally using the parent strands as templates, with A pairing with T and G with C. The RNA primer is ultimately hydrolysed and the gap filled with DNA. The small pieces of DNA (Okazaki fragments) are then joined up to make complete new chromosomal DNA.

The reduced supply of dTTP in megaloblastic anaemia owing to folate or cobalamin deficiency appears to slow elongation of newly originated replicating segments. Thus, small fragments accumulate, single-stranded areas become points of weakness, where mechanical or enzymatic breakage may occur, and the failure to form bulk DNA may impair contraction of newly replicated lengths of DNA, thus leaving the chromosomes elongated, despirillated and with random breaks. Late-replicating DNA is particularly affected, many of the gross defects in DNA appearing in late replication. Indeed, some cells become arrested and die at this stage. Apoptosis occurs particularly at the late stage of erythroblast differentiation and can be prevented by thymidine. Surprisingly, measurements of dTTP concentration in megaloblasts have not shown a deficiency. This may be because the overall cell concentration masks a localized deficiency at the multienzyme complex directly concerned with DNA replication.

An alternative theory for megaloblastic anaemia in cobalamin or folate deficiency is the misincorporation of uracil into DNA because of a build-up of deoxyuridine triphosphate (dUTP) at the replication fork in consequence of the block in conversion of dUMP to dTMP (Figure 5.1). As dUTP does not normally

occur in DNA, there is a mechanism for recognition of this aberrant material for excision and repair, but as long as dTTP remains in short supply this may not be possible. Repeated cycles of futile excision and misrepair may occur with disruption of the normal programme of DNA synthesis leading to apoptotic cell death. Data on this theory are conflicting. It does not explain megaloblastic anaemia due to defects of DNA synthesis at sites other than thymidylate synthesis (e.g. with drugs such as hydroxyurea, cytosine arabinoside or 6-mercaptopurine, or with enzyme deficiencies such as orotic aciduria or thiamine-responsive megaloblastic anaemia; see below). A reduced supply of one of three other deoxyribonucleoside triphosphates or malfunction of DNA polymerase is the likely cause of these megaloblastic anaemias.

Cobalamin–folate relationship

Folate is required for many other reactions in mammalian tissues, including two in purine synthesis (Table 5.2), but impairment of these is far less important clinically.

Only two reactions in the body are known to require cobalamin (Figure 5.2). Methylmalonyl CoA isomerization, which requires deoxyadenosyl(ado)-cobalamin, is discussed later. The methylation of homocysteine to methionine requires both 5-methyltetrahydrofolate (THF) as methyl donor and methylcobalamin as coenzyme (Figure 5.3). This reaction, which is almost completely irreversible, is the first step in the pathway by which methyl-THF, which enters bone marrow and other cells from plasma, is converted into all the intracellular folate coenzymes (Figure 5.3). The coenzymes are all polyglutamated (the larger size aiding retention in the cell), but the enzyme folate polyglutamate synthase cannot use methyl-THF as substrate. Tetrahydrofolate is needed as substrate for synthesis of folate polyglutamates. In cobalamin deficiency, methyl-THF

Table 5.2 Biochemical reactions of folate coenzymes of folate coenzymes.

Reaction	Coenzyme form of folate involved	Single carbon unit transferred	Importance
Formate activation	THF	–CHO	Generation of 10-formyl-THF
Purine synthesis			
Formation of glycinamide ribonucleotide	5,10-Methenyl-THF	–CHO	Formation of purines needed for DNA, RNA synthesis, but reactions probably not rate limiting
Formylation of amino-imidazole-carboxamide-ribotide (AICAR)	10-Formyl-THF	–CHO	
Pyrimidine synthesis			
Methylation of deoxyurine monophosphate (dUMP) to thymidine monophosphate (dTMP)	5,10-Methenyl-THF	$-CH_3$	Rate limiting in DNA synthesis Oxidizes THF to DHF Some breakdown of folate at the C-9–N-10 bond
Amino acid interconversion			
Serine–glycine interconversion	THF	$=CH_2$	Entry of single carbon units into active pool
Homocysteine to methionine	5-Methyl-THF	$-CH_3$	Demethylation of 5-methyl THF to THF; also requires cobalamin, flavine adenine dinucleotide, ATP and adenosylmethionine
Forminoglutamic acid to glutamic acid in histidine catabolism	THF	–HN–CH =	Basis of the Figlu test (now obsolete)

DHF, dihydrofolate; THF, tetrahydrofolate.

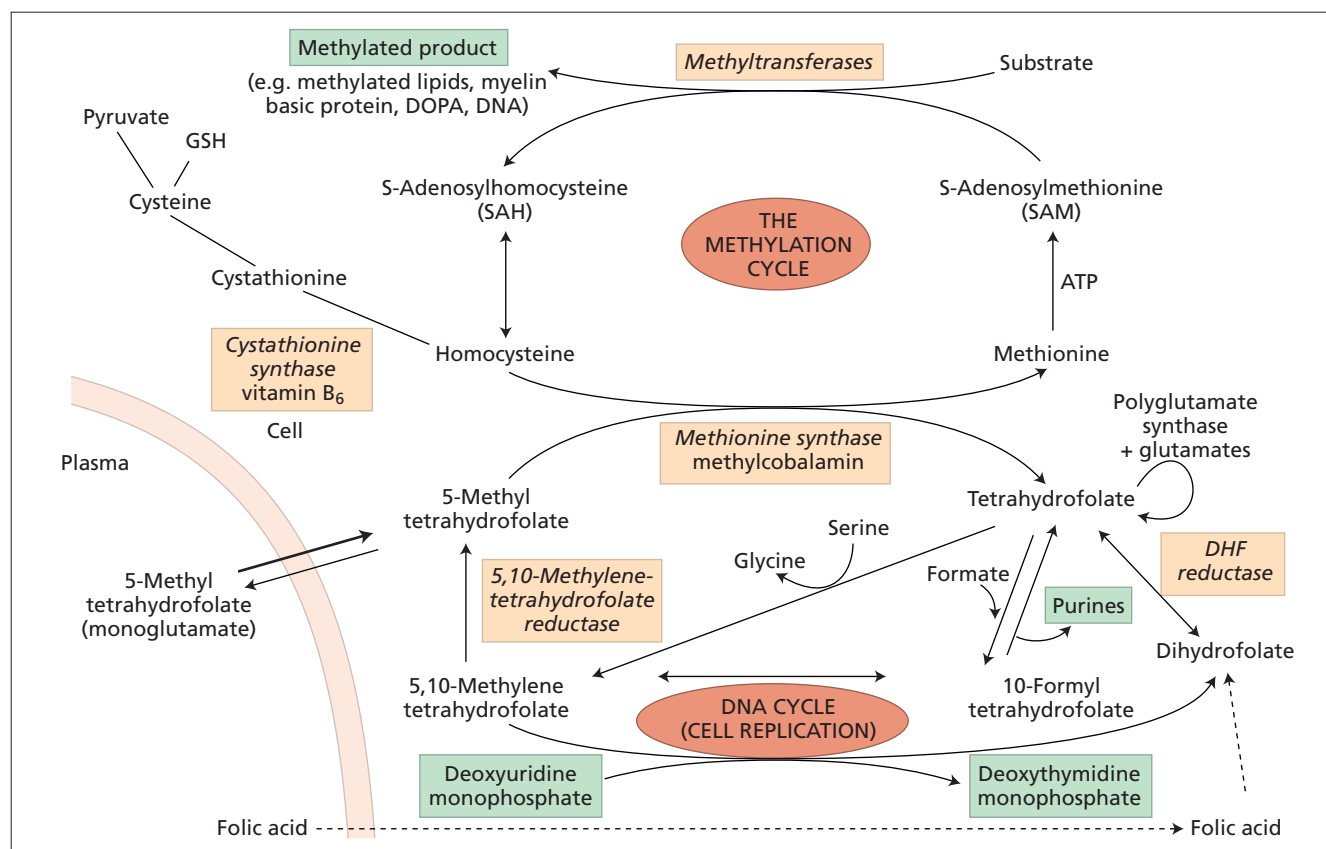

Figure 5.3 The role of folates in DNA synthesis and in formation on *S*-adenosylmethionine (SAM), which is involved in numerous methylation reactions. Enzymes are shown in yellow boxes (figure prepared in conjunction with Professor John Scott).

accumulates in the plasma, while intracellular folate concentrations fall due to failure of formation of intracellular folate polyglutamates because of 'THF starvation' or 'methylfolate trapping'.

This theory explains the abnormalities of folate metabolism, which occur in cobalamin deficiency (high serum folate, low cell folate, positive purine precursor AICAR excretion; Table 5.2) and also why the anaemia that occurs in cobalamin deficiency will respond to folic acid in large doses. The explanation of why the serum cobalamin falls in folate deficiency may also be related to impairment of the homocysteine–methionine reaction, with reduced formation of methylcobalamin, the main form of cobalamin in plasma, but other mechanisms may be responsible.

Clinical features

Many symptomless patients are detected through the finding of a raised mean corpuscular volume (MCV) on a routine blood count. The main clinical features in more severe cases are those of anaemia. Anorexia is usually marked and there may be weight loss, diarrhoea or constipation. Other particular features include glossitis, angular cheilosis, a mild fever in the more severely anaemic patients, jaundice (unconjugated) and reversible melanin skin hyperpigmentation, which may occur with either deficiency. Thrombocytopenia sometimes leads to bruising (and this may be aggravated by vitamin C deficiency in malnourished patients. The (anaemia and) low leucocyte count may predispose to infections, particularly of the respiratory or urinary tracts. Cobalamin deficiency has also been associated with impaired bactericidal function of phagocytes.

General tissue effects of cobalamin and folate deficiencies

Epithelial surfaces
These deficiencies, when severe, affect all rapidly growing (DNA-synthesizing) tissues. After the marrow, the next most affected tissues are the epithelial cell surfaces of the mouth, stomach, small intestine, respiratory, urinary and female genital tracts. The cells show macrocytosis, with increased numbers of multinucleate and dying cells. The deficiencies may cause cervical smear abnormalities.

Complications of pregnancy

The gonads are also affected and infertility is common in both men and women with either deficiency. Maternal folate deficiency has been implicated as a cause of prematurity and both folate and cobalamin deficiency have been implicated in recurrent fetal loss.

Neural tube defects

Folic acid supplements at the time of conception and in the first 12 weeks of pregnancy reduce by about 70% the incidence of neural tube defects (NTDs) (anencephaly, meningomyelocele, encephalocele and spina bifida) in the fetus. Most of this protective effect can be achieved by taking folic acid, 0.4 mg daily. The incidence of cleft palate and harelip can also be reduced by prophylactic folic acid. There is no clear simple relationship between maternal folate status and these fetal abnormalities, although the lower the maternal folate, the greater the risk to the fetus. NTDs can also be caused by antifolate and anti-epileptic drugs.

An underlying maternal folate metabolic abnormality has also been postulated. One abnormality has been identified: reduced activity of the enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR) (Figure 5.3) caused by a common 677C-T polymorphism in the *MTHFR* gene. The prevalence of the homozygous state in the general population varies from 5% to 15% in various populations. In one study, the prevalence of this polymorphism was found to be higher in the parents of NTD fetuses and in the fetuses themselves – homozygosity for the TT mutation was found in 13% compared with 5% in control subjects. The polymorphism codes for a thermolabile form of MTHFR. The homozygous state results in a lower mean serum and red cell folate compared with control subjects, as well as significantly higher serum homocysteine levels. Tests for mutations in other enzymes possibly associated with NTDs, e.g. methionine synthase or serine–glycine hydroxymethylase, have been negative. Autoantibodies to folate receptors (see p. 77) have, however, recently been detected in 9 out of 12 women who were or had been pregnant with a fetus with a NTD, but in only 2 out of 20 control women. Antiserum to folate receptors results in resorption or multiple developmental abnormalities in mouse embryos. It is possible, therefore, that the association of antibodies to maternal folate receptors and NTDs reflects a causal relation.

Cardiovascular disease

Children with severe homocystinuria (blood levels of 100 μmol/L or more) due to deficiency of one of three enzymes, methionine synthase, MHTFR or cystathionine synthase (Figure 5.3), suffer from vascular disease, e.g. ischaemic heart disease, cerebrovascular disease or pulmonary embolus as teenagers or in young adulthood. Lesser degrees of raised serum homocysteine and low levels of serum folate have been found to be associated with cerebrovascular, peripheral vascular and coronary heart disease and predisposition to deep vein thrombosis.

Meta-analysis shows a significant association between serum homocysteine (normal range 5–15 μmol/L) and ischaemic heart disease, stroke, deep vein thrombosis and pulmonary embolism. The odds ratios for a 5 μmol/L increase in serum homocysteine were 1.42 in 72 genetic (MHTFR) studies and 1.32 in 20 prospective studies of serum homocysteine, 1.60 for deep vein thrombosis with or without pulmonary embolism in genetic studies, and for stroke 1.65 in genetic studies and 1.59 in prospective studies. As the genetic and prospective studies do not share the same potential sources of error but both yield highly significant results, the authors considered the results strong evidence of a causal association between homocysteine and cardiovascular disease.

Heterozygosity for the C677T mutation has also been shown to increase the risk of thrombosis in subjects heterozygous for factor V Leiden. Men who consume relatively large amounts of folate have a significantly reduced risk of developing ischaemic (but not haemorrhagic) stroke. It remains possible that homocysteine levels may be high as a consequence of the vascular damage or may merely be a marker for some other underlying factor that is responsible for both the vascular damage and the raised homocysteine. Folate deficiency, for example, may be such a factor. Folate levels have been found in various studies to be lower in patients with myocardial infarct and carotid artery disease than control subjects. There are some reports of prevention of arterial disease recurrence or progression by prophylactic folic acid or cobalamin. In one study, combined folic acid, cobalamin and pyridoxine daily for 1 year was associated with increased patency of coronary arteries compared with placebo in patients who had undergone coronary angioplasty and stenting. Data from large multicentre prospective trials of folic acid in prevention of cardiovascular disease are needed. Extremely high levels of homocysteine (> 50 μmol/L) are toxic to endothelia. When homocysteine levels are only mildly (15–25 μmol/L) or moderately (25–50 μmol/L) elevated then another mechanism needs to be invoked to explain vascular damage or increased risk of thrombosis. Several mechanisms have been proposed, including oxidant damage through the generation of peroxide produced during thiol oxidation to form disulphides and interaction of free reduced homocysteine with cysteine residues on coagulation factors, platelets, adhesion molecules or endothelial cells. Promotion of vascular wall inflammation through the generation of proinflammatory cytokines and interference with key methylation reactions are also possible mechanisms.

Malignancy

Prophylactic folic acid in pregnancy has been found to reduce the subsequent incidence of acute lymphoblastic leukaemia (ALL) in childhood. A significant negative association has also been found with the *MTHFR* 677(CT) polymorphism and leukaemias with *MLL* translocations, but a positive association with hyperdiploidy in infants with ALL or acute myeloid

leukaemia or with childhood ALL. A second polymorphism in the *MHTFR* gene, A1298C, is also strongly associated with hyperdiploid leukaemia. Neither polymorphism is associated with the TEL–AML1 fusion. There are various positive and negative associations between polymorphisms in folate-dependent enzymes and the incidence of adult ALL.

The C677T polymorphism is thought to lead to increased thymidine pools and 'better quality' of DNA synthesis by shunting one-carbon groups towards thymidine and purine synthesis. This may also explain its reported association with a lower risk for colorectal cancer. The incidence of colon cancer was also lower in subjects taking vitamin supplements containing folic acid and with higher folate intake compared with control subjects in the Nurses Health Study. Other tumours that have been associated with folate polymorphisms or status include follicular lymphoma, breast cancer and gastric cancer.

Other tissues

Folate deficiency causes reduced regeneration of cirrhotic liver. Patients with gluten-induced enteropathy and those with sickle cell anaemia have also been reported to show stunted growth, which has been improved coincidentally with commencement of folic acid therapy, but it is not certain how much the growth improvement in these children was due to folic acid and how much to other, simultaneously administered vitamins. In the fragile X syndrome, sister chromatid exchange and DNA breaks are increased *in vitro* in a folate-deficient medium, apparently at the Xq28 site. No *in vivo* abnormality of folate metabolism can be detected.

Neurological manifestations

Cobalamin deficiency may cause bilateral peripheral neuropathy or degeneration (demyelination) of the posterior and pyramidal tracts of the spinal cord and, less frequently, optic atrophy or cerebral symptoms.

The patient classically presents with paraesthesiae, muscle weakness or difficulty in walking and sometimes dementia, psychotic disturbances or visual impairment. Long-term nutritional cobalamin deficiency in infancy leads to poor brain development and impaired intellectual development. Folate deficiency may cause mental changes such as depression and slowness and has been suggested to cause organic nervous disease, but this is uncertain. Methotrexate injected into the cerebrospinal fluid may, however, cause brain or spinal cord damage. Neural tube defects in the fetus are discussed above.

The biochemical basis for cobalamin neuropathy, however, remains obscure. Its occurrence in the absence of methylmalonic aciduria in transcobalamin (TC) deficiency, and in monkeys given nitrous oxide, suggests that the neuropathy is related to the defect in homocysteine–methionine conversion. Accumulation of *S*-adenosylhomocysteine in the brain, resulting in inhibition of transmethylation reactions, has been suggested. Measurements of methylation of arginine in myelin basic protein in fruit bats with cobalamin neuropathy, or in rats exposed to N_2O, however, show no defect of methylation.

Psychiatric disturbance is common in both folate and cobalamin deficiencies. This, like the neuropathy, has been attributed to a failure of the synthesis of *S*-adenosylmethionine (SAM), due to reduced conversion of homocysteine to methionine. SAM is needed in methylation of biogenic amines (e.g. dopamine), as well as of proteins, phospholipids and neurotransmitters in the brain (Figure 5.3). A reduced ratio of SAM to *S*-adenosylhomocysteine is postulated to result in reduced methylation. In cobalamin deficiency there is an intriguing inverse correlation between the degree of anaemia, on the one hand, and the severity of the myeloneuropathy on the other hand. Moreover, although pernicious anaemia is more frequent in women, the neuropathy is more frequent in men.

Plasma homocysteine is a risk factor for dementia and Alzheimer's disease, shown in a median follow-up period of 8 years in one study of 1092 subjects. Studies showing an association between lower serum levels of folate or cobalamin and higher homocysteine levels with Alzheimer's disease have been reported, subjects with the vitamin deficiencies being more likely to develop Alzheimer's disease in subsequent years than control subjects.

Haematological findings

Peripheral blood

Oval macrocytes, usually with considerable anisocytosis and poikilocytosis, are the main feature (Figure 5.4a). The MCV is usually > 100 fL unless a cause of microcytosis (e.g. iron deficiency or thalassaemia trait) is present, when there is a raised red cell distribution width (RDW) and the film is dimorphic. In other cases, the MCV may be normal owing to excess fragmentation of red cells. Some of the neutrophils are hypersegmented (more than five nuclear lobes). Both macrocytosis and hypersegmented neutrophils may also occur in other situations (Table 5.3). Together, however, they strongly suggest megaloblastic haemopoiesis. There may be leucopenia due to a reduction in granulocytes and lymphocytes, but this is not usually less than 1.5×10^9/L; the platelet count may be moderately reduced, rarely to less than 40×10^9/L. Occasionally, a leucoerythroblastic blood picture is seen. The severity of all these changes parallels the degree of anaemia (provided no other cause of anaemia is present): in the non-anaemic patient, the presence of a few macrocytes and hypersegmented neutrophils in the peripheral blood may be the only indication of the underlying disorder.

Bone marrow

In the severely anaemic patient, the marrow is hypercellular and there is an accumulation of primitive cells due to selective death

Macrocytosis	Alcohol
	Liver disease (especially alcoholic)
	Reticulocytosis (haemolysis or haemorrhage)
	Aplastic anaemia or red cell aplasia
	Hypothyroidism
	Myelodysplasia
	Myeloma and macroglobulinaemia
	Leucoerythroblastic anaemia
	Myeloproliferative disease
	Pregnancy
	Newborn
	Congenital dyserythropoietic anaemia (type II)
	? Chronic respiratory failure
Hypersegmented neutrophils	Renal failure
	Congenital (familial)
	? Iron deficiency

Table 5.3 Conditions in which macrocytosis or hypersegmented neutrophils may occur in the absence of megaloblastic anaemia.

Note: Falsely high MCV recorded when cold agglutinins, paraproteins or marked leucocytosis are present.

of more mature forms. The most characteristic finding is dissociation between nuclear and cytoplasmic development in the erythroblasts, with the nucleus maintaining a primitive appearance despite maturation and haemoglobinization of the cytoplasm; fully haemoglobinized (orthochromatic) erythroblasts, which retain nuclei, may be seen. The nucleus of the megaloblast has an open, fine, lacy appearance; the cells are larger than normoblasts and an increased number of cells with eccentric lobulated nuclei or nuclear fragments may be present (Figure 5.4b). Mitoses and dying cells are more frequent than normal. Giant and abnormally shaped metamyelocytes and enlarged hyperpolyploid megakaryocytes are characteristic. Severe florid megaloblastic changes may be confused with erythroleukaemia (acute myeloid leukaemia, FAB M6). Rarely, the marrow may be hypocellular or red cell precursors are lost almost completely from the marrow and a mistaken diagnosis of myeloid leukaemia may be made. Iron staining shows increase in both reticuloendothelial stores and in the developing megaloblasts.

In less anaemic patients, the changes in the marrow may be difficult to recognize. The terms 'intermediate', 'mild' and 'early' have been used to describe megaloblastic changes that are not so florid as those seen in the severely anaemic, uncomplicated case. The changes may be mild and difficult to recognize, even in a severely anaemic patient, if the anaemia is largely due to other factors (e.g. iron deficiency, infection, malignant disease, haemolysis) and the megaloblastosis is an incidental phenomenon. The term 'megaloblastoid' has several different connotations including the dysplastic changes seen in the myelodysplastic syndromes and is best avoided.

Chromosomes

Bone marrow cells, transformed lymphocytes and other proliferating cells in the body show a variety of changes including random breaks, reduced contraction, spreading of the centromere, and exaggeration of secondary chromosomal constrictions and overprominent satellites. Similar abnormalities may be produced by antimetabolite drugs (e.g. cytosine arabinoside, hydroxyurea and methotrexate) that either interfere with DNA replication or folate metabolism and that also cause megaloblastic appearances.

Ineffective haemopoiesis

There is an accumulation of unconjugated bilirubin in plasma due to the death of nucleated red cells in the marrow (ineffective erythropoiesis). Other evidence for this includes raised urine urobilinogen, reduced haptoglobins and positive urine haemosiderin, raised serum lactate dehydrogenase to values of between 1000 and 10 000 IU/dL and raised serum iron, non-transferrin-bound iron and ferritin levels. Carbon monoxide production is also increased. The serum lysozyme may also be raised, suggesting ineffective granulopoiesis.

In rare patients, ineffective haemopoiesis is associated with features of disseminated intravascular coagulation, with raised serum fibrin degradation products. Thrombocytopenia, when it occurs, is usually caused by ineffective megakaryopoiesis. A weakly positive direct antiglobulin test due to complement can lead to a false diagnosis of autoimmune haemolytic anaemia.

Cobalamin

Cobalamin (vitamin B_{12}) exists in a number of different chemical forms. The molecule consists of two halves: a 'planar group' and 'nucleotide' set at right angles to it (Figure 5.5). The planar group is a corrin ring and the nucleotide consists of the base, 5,6-dimethylbenziminazole, and a phosphorylated sugar, ribose-s-phosphate. In nature, the vitamin is mainly in the
Figure 5.5 The structure of vitamin B_{12} (cyanocobalamin).

5′-deoxyadenosyl (ado) form. This is the main form in human tissues and is located in the mitochondria. It serves as the cofactor for the enzyme methylmalonyl CoA mutase. The other major natural cobalamin is methylcobalamin, the main form in human plasma, as well as the cytosolic form in cells. It serves as the cofactor for the enzyme methionine synthase. There are also minor amounts of hydroxocobalamin, which is the form to which methyl- and ado-cobalamin are rapidly converted by exposure to light, hydroxocobalamin having its cobalt atom in the fully oxidized Cbl^{3+} state, whereas the cobalt exists as reduced Cbl^{1+} in the methyl- and ado-cobalamin forms (Figure 5.2). A glutathionyl cobalamin form has also been identified.

Dietary sources and requirements

Cobalamin is synthesized solely by micro-organisms. Ruminants obtain cobalamin from the foregut but the only source for humans is food of animal origin. The highest amounts are found in liver and kidney (up to 100 μg/100 g) but it is also present in shellfish, organ and muscle meats, fish, chicken and dairy products – eggs, cheese and milk – which contain small amounts (6 μg/L). Vegetables, fruits and all other foods of non-animal origin are free from cobalamin unless they are contaminated by bacteria. Cooking does not usually destroy cobalamin.

A normal Western diet contains between 5 and 30 μg of cobalamin daily. Adult daily losses (mainly in the urine and faeces) are between 1 and 3 μg (about 0.1% of body stores) and, as the body does not have the ability to degrade cobalamin, daily requirements are also about 1–3 μg. Body stores are of the order of 2–3 mg and are sufficient for 3–4 years if supplies are completely cut off.
Figure 5.6 (a) Intrinsic factor; (b) intrinsic factor–cobalamin complex. Intrinsic factor has been estimated to have a molecular radius of 3.6 nm, vitamin B_{12} 0.8 nm and the complex 3.2 nm.

Absorption

Two mechanisms exist for cobalamin absorption. One is passive, occurring equally through the duodenum and the ileum; it is rapid but extremely inefficient as less than 1% of an oral dose can be absorbed by this process. Passive absorption of cobalamin can occur through other mucous membranes such as the sublingual and nasal mucosae. Recently, oral, sublingual and intranasal preparations of cobalamin have become popular as an alternative to intramuscular (i.m.) injections for treatment of cobalamin deficiency and long-term maintenance of cobalamin status. The other mechanism is active; it occurs through the ileum in humans and is efficient for small (a few micrograms) oral doses of cobalamin. This is the normal mechanism by which the body acquires cobalamin and is mediated by gastric intrinsic factor (IF).

Dietary cobalamin is released from protein complexes by enzymes in the stomach, duodenum and jejunum; it combines rapidly with a salivary glycoprotein (R binder) related to plasma transcobalamin I (TCI). These belong to the family of cobalamin-binding proteins known as haptocorrins (HCs). Subsequently, the R binder is digested by pancreatic trypsin and the cobalamin transferred to IF. Binding of cobalamin to IF is favoured by an alkaline pH; it binds one molecule for one molecule. All forms of cobalamin are absorbed by the same IF mechanism. The nucleotide portion of cobalamin fits into a pit on the surface of the protein, whereas the –CN, –OH, –CH$_3$ or deoxyadenosyl group is opposite the site of attachment (Figure 5.6). Pseudo-cobalamin compounds, in which the 5,6-dimethylbenzimidazole nucleotide is replaced by other nucleotides that may attach to the R binder, do not attach to IF and therefore remain unabsorbed through the active physiological mechanism.

Intrinsic factor is a glycoprotein with a molecular weight of 45 000. It is produced in the microsomes or endoplasmic reticulum of the gastric parietal cells in the fundus and body of the stomach of humans. The IF–cobalamin complex, in contrast with free IF, is resistant to enzyme digestion. IF–cobalamin has a smaller molecular radius (3.2 nm) than free IF (3.6 nm) (Figure

5.6), and some peptide bonds that are open to attack by proteolytic enzymes when IF is free are protected in the complex.

The IF–cobalamin complex passes to the ileum, where IF attaches to a specific receptor (cubilin, mol. wt 460 000) on the microvillus membrane of the brush border surface of the ileal absorptive cells. Cubilin is also present in yolk sac and renal proximal tubular epithelium. The attachment of the IF–cobalamin complex requires calcium ions and a pH around neutral. It is probably a physical process, not requiring energy. Cubulin appears to traffic by means of amnionless (AMN), a 600 000-Da endocytic receptor protein that mediates the uptake of a number of ligands. Cubulin and AMN appear to be subunits of a novel complex in which AMN binds tightly to the amino-terminal third of cubulin and directs sublocalization and endocytosis of cubulin with its ligand (IF–cobalamin complex). Defects in cubulin and AMN are implicated in autosomal recessive megaloblastic anaemia, characterized by intestinal malabsorption of cobalamin (see p. 72).

Cobalamin then enters the ileal cell, but the exact fate of the IF is unknown. Intrinsic factor does not enter the bloodstream as such, as after a delay of about 6 h, absorbed cobalamin appears in portal blood, attached to transcobalamin (II) which is probably synthesized in the ileum, either by mucosal cells or by venous endothelial cells in the submucosa.

The ileum has a restricted capacity to absorb cobalamin because of limited receptor sites and, although 50% or more of a single dose of 1 μg of cobalamin may be absorbed, with doses above 2 μg the proportion absorbed falls rapidly. Moreover, after one dose of IF–cobalamin complex has been presented, the ileal cells become refractory to further doses for about 6 h.

Enterohepatic circulation

Between 0.5 and 5.0 μg of cobalamin enter the bile each day. This binds to IF and a portion of biliary cobalamin is normally reabsorbed together with cobalamin derived from sloughed intestinal cells. Bile may enhance cobalamin absorption. Because of the appreciable amount of cobalamin undergoing enterohep-

atic circulation, cobalamin deficiency develops more rapidly in individuals who malabsorb cobalamin than it does in vegans, who ingest no cobalamin, but in whom reabsorption of biliary cobalamin is intact.

Transport

Two main cobalamin transport proteins exist in human plasma; they both bind cobalamin one molecule for one molecule (Figure 5.7). One HC, also known as TCI, is a glycoprotein. It is closely related to other HCs (so-called 'R') cobalamin-binding proteins in milk, gastric juice, bile, saliva and other fluids. These HCs differ from each other only in the carbohydrate moiety of the molecule. TCIII was a name used to describe a minor isoprotein of TCI in plasma, which differs from TCI by its composition of sugars and cobalamin content. TCI and TCIII are derived primarily from the specific granules in neutrophils. Overall, HCs are normally about two-thirds saturated with cobalamin, which they bind tightly. HCs do not enhance cobalamin entry into tissues. Glycoprotein receptors on liver cells are concerned in the removal of HCs from plasma, and TCI may have a role in the transport of cobalamin analogues to the liver for excretion in bile.

The other major cobalamin transport protein in plasma is transcobalamin (TC, also known as transcobalamin II). TC is a β-globulin (mol. wt 38 000) synthesized by liver, and by other tissues including macrophages, ileum and endothelium. It normally carries only 20–60 ng of cobalamin per litre of plasma and
readily gives up cobalamin to marrow, placenta and other tissues, which it enters by receptor-mediated endocytosis; TC is not re-utilized. It has a 20% amino acid homology and more than 50% nucleotide homology with human HC and with rat IF. The regions of homology of HC, TC and IF are probably involved in cobalamin binding. Five different inherited isoproteins of TC, separated by polyacrylamide gel electrophoresis, have been described; all are functionally active. Recent evidence suggests that common polymorphisms in the TC gene may affect predisposition to cobalamin deficiency. TC occurs in cerebrospinal fluid and bind cobalamin (approximately 10 ng/L) there. Alterations may occur in the TC and HC levels in a variety of disease states (Table 5.4). In general, an increase in HC causes an increase in serum cobalamin, whereas an increase in TC does not.

Cobalamin analogues

Cobalamin analogues are corrinoids, which may be cobamides (which contain substitutions in the place of ribose, e.g. adenoside) or cobinamides (which have no nucleotide at all). The analogues are relatively inert for the microbiological assay organisms *Euglena gracilis* and *Lactobacillus leichmannii*. In competitive binding assays that use HC but not pure IF as the binding protein, cobalamin analogues lead to falsely high serum cobalamin levels. HC may carry analogues to the liver for excretion in the bile. It is unclear whether they are inert or inhibit cobalamin-dependent reactions. The proportion of analogues derived from diet, gut bacteria or endogenous breakdown of cobalamins is unknown. They are present in fetal blood and tissues.

Causes of cobalamin deficiency

Cobalamin deficiency is usually due to malabsorption. The only other cause is inadequate dietary intake. Cobalamin deficiency due to excess degradation occurs as a result of exposure to the anaesthetic gas nitrous oxide (N_2O). N_2O causes irreversible oxidation of the active Cbl^{1+} during catalytic shunting of labile methyl groups in the methionine synthase reaction (see p. 61).

Inadequate dietary intake

Adults

Dietary cobalamin deficiency arises in vegans who omit meat, fish, eggs, cheese and other animal products from their diet. The largest group in the world consists of Hindus, and it is likely that many millions of Indians are at risk for deficiency of cobalamin on a nutritional basis. Not all vegans, however, develop cobalamin deficiency of sufficient severity to cause anaemia or neuropathy, even though subnormal cobalamin levels have

Figure 5.7 The serum cobalamin-binding proteins (TCs, transcobalamins). Dark blue rectangles, endogenous serum cobalamin; light blue rectangles, unsaturated cobalamin-binding protein; HCs, haptocorrins.

Table 5.4 Alteration in plasma cobalamin-binding proteins in disease.

Haptocorrin	Increased (usually with elevated serum cobalamin)
	Myeloproliferative diseases, especially chronic myeloid leukaemia, myelosclerosis, polycythaemia vera
	Hepatoma
	Increased granulocyte production (e.g. inflammatory bowel disease, liver abscess)
	Eosinophilia due to hypereosinophilic syndrome
	Congenital absence: low total serum cobalamin; no clear clinical abnormality
Transcobalamin (II)	Increased (sometimes with no elevation of serum cobalamin)
	Liver disease
	Gaucher's disease
	Autoimmune disease
	Long-continued hydroxocobalamin therapy
	Congenital absence: normal or decreased total serum cobalamin; megaloblastic anaemia or pancytopenia within a few weeks of birth; impaired cobalamin absorption, may be associated with defective cellular and humoral immunity

been found in up to 50% of randomly selected, young, adult Indian vegans. Explanations of why nutritional cobalamin deficiency may not progress to megaloblastic anaemia include the following:

1 The diet of most vegans is probably not totally lacking cobalamin. The serum cobalamin level may not be an accurate measure of their body stores.

2 The enterohepatic circulation of cobalamin is still intact in vegans and thus losses are less than in conditions of malabsorption.

3 Daily losses of cobalamin are thought to be related to body stores; therefore, as the body stores become depleted, daily losses become smaller and the amount of cobalamin needed to maintain the status quo may also become smaller. There is, however, no evidence that the daily requirement for cobalamin changes.

Dietary cobalamin deficiency may also arise rarely in non-vegetarian subjects who exist on grossly inadequate diets because of poverty or psychiatric disturbance.

Infants

Cobalamin deficiency has been described in infants born to severely cobalamin-deficient mothers. These infants develop megaloblastic anaemia about 3–6 months of age, presumably because they are born with low stores of cobalamin and because they are fed breast milk of low cobalamin content. This occurs most commonly in Indian vegans, but a similar condition has also been described in unrecognized maternal pernicious anaemia and in strict practitioners of veganism living in Western countries whose offspring have shown growth retardation, impaired psychomotor development and other neurological sequelae.

Table 5.5 Causes of cobalamin deficiency causing megaloblastic anaemia.

Nutritional	Vegans
Malabsorption	Pernicious anaemia
Gastric causes	Congenital IF absence or functional abnormality
	Total or partial gastrectomy
Intestinal causes	Intestinal stagnant loop syndrome: jejunal diverticulosis, ileocolic fistula, anatomical blind loop, intestinal stricture, etc.
	Ileal resection and Crohn's disease
	Selective malabsorption with proteinuria
	Tropical sprue
	Transcobalamin deficiency
	Fish tapeworm

Gastric causes of cobalamin malabsorption
(Tables 5.5 and 5.6)

Pernicious anaemia

Pernicious anaemia (PA) may be defined as a severe lack of intrinsic factor due to gastric atrophy. It is a common disease in north Europeans but it occurs in all countries and ethnic groups. The overall incidence is about 120 per 100 000 population in the UK, but there is wide variation between one area and the next. The prevalence rate in Western countries may be as high as 2–3%. The ratio of incidence in men and women is approximately 1:1.6 and the peak age of onset is 60 years, with only 10%

Table 5.6 Malabsorption of cobalamin may occur in the following conditions but is not usually sufficiently severe and prolonged to cause megaloblastic anaemia.

Gastric causes
Simple atrophic gastritis (food cobalamin malabsorption)
Zollinger–Ellison syndrome
Gastric bypass surgery
Use of proton pump inhibitors

Intestinal causes
Gluten-induced enteropathy
Severe pancreatitis
HIV infection
Radiotherapy
Graft-versus-host disease

Deficiencies of cobalamin, folate, protein, ?riboflavin, ?nicotinic acid

Therapy with colchicine, para-aminosalicylate, neomycin, slow-release potassium chloride, anticonvulsant drugs, metformin, phenformin, cytotoxic drugs

Alcohol

of patients presenting being less than 40 years of age. In some ethnic groups, notably black people and Latin Americans, the age of onset of PA is generally lower. The disease occurs more commonly than by chance in close relatives, in subjects with other organ-specific autoimmune diseases (see below), in those with premature greying, blue eyes and vitiligo, and in persons of blood group A. An association with human leucocyte antigen (HLA) 3 has been reported in some but not all series and in those with endocrine disease, with HLA-B8, -B12 and -BW15. The life expectancy is normal in women once regular treatment has begun. Men have a slightly subnormal life expectancy as a result of a higher incidence of carcinoma of the stomach than in control subjects.

Diagnosis
This is usually suspected from the clinical picture and the findings of megaloblastic anaemia due to cobalamin deficiency. A lack of IF may be demonstrated by cobalamin absorption studies. Tests for circulating gastric autoantibodies are also important.

Tests of gastric secretion
Direct measurements on gastric juice following pentagastrin stimulation are now rarely performed. Hydrochloric acid or pepsin production and intrinsic factor output were previously measured.

Serum assays
The serum gastrin level is usually raised in PA (> 200 µg/L), the hormone coming from endocrine cells in the gastric fundus.

Raised serum gastrin also occurs in simple atrophic gastritis. Serum pepsinogen I levels are low (below 30 µg/L) in over 90% of those affected.

Gastric biopsy
This usually shows atrophy of all layers of the body and also fundal atrophy, with loss of glandular elements, an absence of parietal and chief cells and replacement by mucous cells, a mixed inflammatory cell infiltrate and perhaps intestinal metaplasia. The infiltrate of plasma cells and lymphocytes contains an excess of CD4 cells. The antral mucosa is usually well preserved. *Helicobacter pylori* infection is infrequent in pernicious anaemia, but it has been suggested that *H. pylori* gastritis may represent an early phase of atrophic gastritis, which is gradually replaced, in some individuals, by an immune process with disappearance of *H. pylori* infection.

Immune phenomena
In addition to the appearance of gastric mucosa, there is a large body of evidence that suggests that immune mechanisms play an important role in the pathogenesis of PA. This aspect of the disease is discussed next under four main headings.

Antibodies to gastric antigens
IF antibodies. Two types of IF antibody may be found in the sera of patients with PA: both are immunoglobulin (Ig) G. One, the 'blocking' or 'type I' antibody, prevents the combination of IF and cobalamin, whereas the other, the 'binding' 'type II' or 'precipitating' antibody, which attaches to IF whether joined to cobalamin or not, prevents attachment of IF to ileal mucosa. The blocking antibody occurs in the serum of about 55% of patients and the binding antibody in 35%. IF antibodies cross the placenta and cause temporary IF deficiency in the newborn infant. Pernicious anaemia patients also show cell-mediated immunity to IF. An increased CD4/CD8 lymphocyte ratio in blood has been described in PA patients with IF antibodies.

IF antibodies are rarely found in conditions other than PA. Type I antibody has been detected rarely in the sera of patients without PA but with thyrotoxicosis, myxoedema, Hashimoto's disease or diabetes mellitus, and in relatives of PA patients. IF antibodies have also been detected in gastric juice in about 80% of PA patients. These antibodies may reduce absorption of dietary cobalamin by combining with small amounts of remaining IF in the gastric juice. Achlorhydria favours the formation of this antigen–antibody complex.

Parietal cell and gastrin receptor antibodies. Parietal cell antibody is present in the sera of almost 90% of adult patients with PA, but it is frequently present in other subjects. Thus, it occurs in as many as 16% of randomly selected female subjects aged over 60 years and in a smaller proportion of younger control subjects; it is found more frequently than in control subjects in relatives of

PA patients. These antibodies are also found more frequently in patients with simple atrophic gastritis, chronic active hepatitis and thyroid disorders and their relatives, as well as in Addison's disease, rheumatoid arthritis and other conditions. The parietal cell antibody is directed against the α- and β-subunits of the gastric proton pump (H^+,K^+-ATPase). The sera of PA patients may also contain an autoantibody to the gastrin receptor, although this test is not used clinically.

Association with other 'autoimmune' diseases
There is a clinical association between PA and thyroid diseases, vitiligo, hypoparathyroidism and Addison's disease. These diseases are often found in close relatives of patients with overt disease due to one of these conditions.

Response to steroid therapy
Steroid therapy improves the gastric lesion, at least temporarily, in a proportion of patients with PA. There may be regeneration of the mucosa with a return of secretion of acid and IF, and an improvement in cobalamin absorption. When steroid therapy is withdrawn, there is a relapse within a few weeks. These findings suggest that an autoimmune process is continuously damaging the gastric mucosa in PA and preventing regeneration. Temporary remission of neurological symptoms has been observed in PA, erroneously diagnosed as multiple sclerosis and treated with steroids.

Hypogammaglobulinaemia
PA is found more often than by chance in patients with a deficiency of IgA or with complete hypogammaglobulinaemia. These subjects resemble others with PA, except that they often present relatively early (before the age of 40 years), they have a lower incidence of serum IF and parietal cell antibodies, and they may show intestinal malabsorption. They may also have a history of recurrent infections. The gastric lesion is similar to that in other causes, except that plasma cells are absent from the inflammatory cell infiltrate and the antrum is involved. Serum gastrin levels are normal.

Juvenile pernicious anaemia
This usually occurs in older children and resembles PA of adults. Gastric atrophy, achlorhydria and serum IF antibodies are all present, although parietal cell antibodies are usually absent. About one-half of these patients show an associated endocrinopathy such as autoimmune thyroiditis, Addison's disease or hypoparathyroidism; in some, mucocutaneous candidiasis occurs.

Congenital intrinsic factor deficiency or functional abnormality
The affected child usually shows no demonstrable IF but has a normal gastric mucosa and normal secretion of acid. The inheritance is autosomally recessive. These patients usually present with megaloblastic anaemia in the first, second or third year of life when stores of cobalamin accumulated from the mother *in utero* are used up; a few have presented as late as the second decade. Parietal cell and IF antibodies are absent. Variants have been described in which the child is born with IF that can be detected immunologically but is unstable or functionally inactive, being unable either to bind cobalamin or to facilitate its uptake by the ileum.

Gastrectomy
Following total gastrectomy, cobalamin deficiency is inevitable and prophylactic cobalamin therapy should be commenced immediately following the operation. After partial gastrectomy, 10–15% of patients also develop this deficiency. This usually manifests 4 years or more following the operation, but may occur sooner. The exact incidence and time of onset is most influenced by the size of the resection and the pre-existing size of the cobalamin body store.

Simple atrophic gastritis (food cobalamin malabsorption)
For the normal IF-mediated mechanism of cobalamin absorption, certain requirements in the gastrointestinal lumen must be met. These include adequate gastric output of acid and pepsin to ensure the release of food cobalamin. Failure of this mechanism is believed to be responsible for a condition more common in the elderly known as *food cobalamin malabsorption*, but there is no definitive proof of this. This is associated with low serum cobalamin levels, with or without evidence of cobalamin deficiency, such as raised serum levels of methylmalonic acid and homocysteine, and abnormal deoxyuridine suppression. Few show clinically important cobalamin deficiency and, typically, these patients have normal cobalamin absorption as measured by the standard Schilling test, which measures absorption of crystalline cobalamin. A modified test using food-bound cobalamin must be used to demonstrate the malabsorption. Some patients with food cobalamin malabsorption may go on to develop clinically significant cobalamin deficiency, but the frequency of occurrence and reasons for this progression are not clear.

Intestinal causes of cobalamin malabsorption

Intestinal stagnant loop syndrome
Malabsorption of cobalamin occurs in a variety of intestinal lesions in which there is colonization of the upper small intestine by faecal organisms. This may occur in patients with jejunal diverticulosis, enteroanastomosis, intestinal stricture or fistula, or with an anatomical blood loop due to Crohn's disease, tuberculosis or an operative procedure. It is not known with certainty which organisms are responsible for the consumption of cobalamin. Bacterial overgrowth in the small intestine may also cause spurious elevation of serum methylmalonate (see below). Some bacteria produce copious quantities of propionate, the immediate precursor of methylmalonate.

Ileal resection

Removal of 1.2 m or more of terminal ileum causes malabsorption of cobalamin. In some patients, following ileal resection, particularly if the ileocaecal valve is incompetent, colonic bacteria may contribute further to the onset of cobalamin deficiency.

Selective malabsorption of cobalamin with proteinuria (Imerslund syndrome: Imerslund–Gräsbeck syndrome: congenital cobalamin malabsorption: autosomal recessive megaloblastic anaemia MGA1)

This autosomally recessive disease is the most common cause of megaloblastic anaemia due to cobalamin deficiency in infancy in Western countries. More than 200 cases have been reported, with familial clusters in Finland, Norway, the Middle East and North Africa. The patients usually present with megaloblastic anaemia between the ages of 1 and 5 years, secrete normal amounts of IF and gastric acid, but are unable to absorb cobalamin due to a congenital defect of the ileum. In some cases, e.g. in Finland, impaired synthesis, processing or ligand binding of cubilin due to inherited mutations have been implicated. In others, e.g. in Norway, mutation of the gene for *AMN* has been reported. Other tests of intestinal absorption are normal. Over 90% of these patients show non-specific proteinuria but renal function is otherwise normal and renal biopsy has not shown any consistent renal defect. A few of these patients have shown aminoaciduria and congenital renal abnormalities, such as duplication of the renal pelvis.

Tropical sprue

Nearly all patients with acute and subacute tropical sprue show malabsorption of cobalamin; this may persist as the principal abnormality in the chronic form of the disease, when the patient may present with megaloblastic anaemia or neuropathy due to cobalamin deficiency. Absorption of cobalamin usually improves after antibiotic therapy and, in the early stages, after folic acid therapy.

Fish tapeworm infestation

The fish tapeworm (*Diphyllobothrium latum*) lives in the small intestine of humans and accumulates cobalamin from food, rendering this unavailable for absorption. People acquire the worm by eating raw or partly cooked fish. Infestation is common around the lakes of Scandinavia, Germany, Japan, North America and Russia. Megaloblastic anaemia or cobalamin neuropathy occurs only in those with a heavy infestation, with the worm high in the small intestine. Many carriers have no cobalamin deficiency.

Gluten-induced enteropathy

Malabsorption of cobalamin occurs in about 30% of untreated patients (presumably those in whom the disease extends to the ileum) and correlates with the degree of steatorrhoea. Cobalamin deficiency is not usually severe in these patients and

is probably never the cause of megaloblastic anaemia unless another lesion causing malabsorption of cobalamin (e.g. the stagnant loop syndrome) is present. The absorption improves when these patients are treated with a gluten-free diet.

Severe chronic pancreatitis

In this condition, lack of trypsin is thought to cause dietary cobalamin attached to gastric non-IF (R) binder to be unavailable for absorption. It has also been proposed that in pancreatitis, the concentration of calcium ions in the ileum falls below the level needed to maintain normal cobalamin absorption.

HIV infection

Serum cobalamin levels tend to fall in patients with HIV infection and are subnormal in 10–35% of those with AIDS. Increased levels of apoTC, possibly derived from macrophages, are usual. Malabsorption of crystalline cobalamin not corrected by IF has been shown in some, but not all, patients with subnormal serum cobalamin levels. Food cobalamin absorption studies have not been reported. Cobalamin deficiency sufficiently severe to cause megaloblastic anaemia or neuropathy is rare.

Zollinger–Ellison syndrome

Malabsorption of cobalamin has been reported in the Zollinger–Ellison syndrome. It is thought that there is a failure to release cobalamin from R binding protein due to inactivation of pancreatic trypsin by high acidity, as well as interference with IF binding of cobalamin.

Radiotherapy

Both total body irradiation and local radiotherapy to the ileum (e.g. as a complication of radiotherapy for carcinoma of the cervix) may cause malabsorption of cobalamin.

Graft-versus-host disease

This commonly affects the small intestine. Malabsorption of cobalamin due to abnormal gut flora, as well as damage to ileal mucosa, is frequent.

Drugs

Neomycin, colchicine, phenytoin (dephenylhydantoin), para-aminosalicylate, phenformin, metformin, slow-release potassium chloride and alcohol have all been reported to cause malabsoption of cobalamin and, rarely, megaloblastic anaemia due to cobalamin deficiency has been reported with phenformin therapy. The use of H_2-blockers for treatment of peptic ulcer disease causes a decrease in cobalamin absorption, and continued use may lead to lowering the serum cobalamin level.

Cobalamin and folate deficiencies

Both severe cobalamin and folate deficiencies affect the function of the small intestine; malabsorption of cobalamin due to ileal dysfunction may be found in patients with either deficiency. It

may take several weeks of cobalamin therapy to correct the ileal absorptive defect in patients with PA. Deficiencies of protein, riboflavin and pyridoxine have also been reported to cause malabsorption of cobalamin.

Abnormalities of cobalamin metabolism

Congenital TC (transcobalamin II) deficiency or abnormality

Infants with TC deficiency usually present with megaloblastic anaemia within a few weeks of birth. Serum cobalamin and folate levels are normal but the anaemia responds to massive (e.g. 1 mg three times weekly) injections of cobalamin, which cause free cobalamin to enter marrow cells by passive diffusion in the absence of functional TC. Some cases show neurological complications. In some cases, the protein is present in normal amounts but is unable to bind cobalamin or to attach to the cell surface and so is functionally inert. Genetic abnormalities so far found include nutations of an intra-exonic cryptic splice site, extensive deletion, single nucleotide deletion, nonsense mutation and an RNA editing defect. These infants do not show methylmalonic aciduria, but malabsorption of cobalamin occurs in all cases and reduced immunoglobulins occurs in some. Less severe cases present later in childhood. Failure to institute adequate cobalamin therapy or treatment with folic acid may lead to neurological damage.

Congenital methylmalonic acidaemia and aciduria

The infants with this abnormality are ill from birth with vomiting, failure to thrive, severe metabolic acidosis, ketosis and mental retardation. Anaemia, if present, is normocytic and normoblastic. The condition may arise as a result of a functional defect in either the mitochondrial methylmalonyl coenzyme A (CoA) mutase or its cofactor ado-cobalamin (Figure 5.2). Mutations in the methylmalonyl CoA mutase are not responsive, or only poorly responsive, to treatment with cobalamin. Two disorders result in cobalamin-responsive methylmalonic acidaemia. In Cb (cobalamin) 1A disease, there is failure of reduction of Cob(III) (Cbl^{3+}) alamin or Cob(II) (Cbl^{2+}) alamin to Cob(I) (Cbl^{1+}) alamin in mitochondria; in Cb1B disease there is a defect of an adenosyltransferase required for synthesis of ado-cobalamin (Figure 5.2). A proportion of the infants with CbIA and Cb1B respond to cobalamin in large doses, whereas the others are unresponsive. In those who do not respond to cobalamin, the enzyme methylmalonyl CoA mutase is lacking (mut^0) or defective (mut$^-$). Some children have combined methylmalonic aciduria and homocystinuria due to defective formation of both cobalamin coenzymes. The defects are in the transfer of cobalamin from the endocytic compartment to lysosomes to the cytoplasm (Cb1F) or in reduction of cobalamin after transfer to the cytoplasm from the Cob(III)alamin to the Cob(I)alamin state (Cb1C and Cb1D diseases). Over 100 cases of the Cb1C disease have been described. It usually presents in the first year of life with feeding difficulties, developmental delay, microcephaly, seizures, hypotonia and megaloblastic anaemia.

Some patients have homocystinuria and megaloblastic anaemia, often with neurological defects but without methylmalonic aciduria. There is a selective deficiency of methyl cobalamin. These conditions have been termed Cb1E and Cb1G disease (lack of association of methyl cobalamin with methionine synthase).

Acquired abnormality of cobalamin metabolism: nitrous oxide inhalation

Nitrous oxide irreversibly oxidizes methyl cobalamin from its active, fully reduced CobI state to an inactive precursor with the CobII state. This has been shown to inactivate methylcobalamin and methionine synthase. This occurs in both humans and experimental animals and is of importance in the megaloblastic anaemia that occurs in patients undergoing prolonged N$_2$O anaesthesia (e.g. in intensive care units). A neuropathy resembling cobalamin neuropathy has been described in dentists and anaesthetists who are repeatedly exposed to N$_2$O and in monkeys exposed to the gas for many months. In patients with low cobalamin stores, megaloblastic anaemia or cobalamin neuropathy may be precipitated after shorter exposure to N$_2$O. Recovery from N$_2$O exposure requires regeneration of methionine synthase, as this protein is damaged by active oxygen derived from the N$_2$O–cobalamin reaction. Methylmalonic aciduria does not occur at first as ado-cobalamin is not inactivated by N$_2$O. Later, however, after generalized depletion of cobalamin, methylmalonate levels in serum, urine and cerebrospinal fluid rise.

Diagnosis of cobalamin deficiency

The diagnosis of cobalamin or folate deficiency has traditionally depended on the recognition of the relevant abnormalities in the peripheral blood and/or bone marrow and subsequent analysis of the blood levels of the vitamins. Other causes of macrocytosis and hypersegmented neutrophils are listed in Table 5.3. Assays of serum methylmalonic acid and homocysteine (see below) have, however, shown these to be raised in some subjects without haematological abnormalities, including a proportion with normal levels of serum cobalamin and folate in whom, nevertheless, the levels of the metabolites fall to normal with cobalamin and/or folate therapy. The significance of these biochemical changes remains controversial. They may imply functional cobalamin or folate deficiency, not reflected by subnormal levels of the vitamins or by disturbed haemopoiesis. If so, it would imply that the accepted normal serum and red cell levels of the vitamins reflect body stores which are sufficiently high to prevent haematological changes but in some subjects may not be

optimal for prevention of other complications of the deficiencies including thrombosis and vascular disease and neural tube defect in the fetus.

Deoxyuridine suppression test

In normal bone marrow, deoxyuridine (dU) considerably suppresses the uptake of radioactive thymidine into DNA. This is thought to be due to conversion of dU to thymidine triphosphate (dTTO) via dU monophosphate (dUMP), which inhibits thymidine kinase, on which thymidine uptake depends (Figure 5.1). Deoxyuridine suppresses radioactive thymidine incorporation less effectively in megaloblastic anaemia due to folate or cobalamin deficiency because of the block in dUMP methylation to dTMP. In cobalamin deficiency, the test can be corrected with cobalamin or 5-formyltetrahydrofolate (5-formyl-THF, folinic acid) but not with 5-methyl-THF, whereas, in folate deficiency, both the folate analogues, but not cobalamin, correct the test. In refractory megaloblastic anaemia (e.g. of sideroblastic anaemia, erythroleukaemia, or due to antimetabolite drugs which inhibit DNA synthesis at a separate point from thymidylate synthesis), the test gives results as in a normoblastic marrow. Performance of the dU suppression test is laborious and the test is rarely performed other than in specialized laboratories.

Measurement of the serum cobalamin

Serum cobalamin is usually measured by one of a number of radioisotope dilution, or enzyme-linked immunosorbent assays. These are frequently automated. Normal serum cobalamin levels range from 160 to 200 ng/L to about 1000 ng/L (ng × 0.738 = pmol, so 200 ng/L = 148 pmol/L). In patients with megaloblastic anaemia due to cobalamin deficiency, the level is usually less than 100 ng/L. In general, the more severe the deficiency, the lower the serum cobalamin level. In patients with spinal cord damage due to the deficiency, levels are very low even in the absence of anaemia. Values of between 100 and 200 ng/L are regarded as borderline. They may occur, for instance, in pregnancy, in patients with megaloblastic anaemia due to folate deficiency and in patients with HC deficiency. The relative concentrations of HC and TC also influence the total serum cobalamin level. Raised serum cobalamin levels (if not due to recent therapy) are usually due to a rise in HC (Table 5.4), or to liver or renal disease with increased saturation of HC and TC.

The serum cobalamin level is still generally considered to be sufficiently robust, cost-effective and most convenient to rule out cobalamin deficiency in the vast majority of patients suspected of having this problem. The reliability of the serum cobalamin assay was established with microbiological assays. Using the newer assays, normal levels have been reported in patients responsive to cobalamin therapy.

Serum holotranscobalamin (HoloTCII; Holo TC)

Since TC is the plasma cobalamin transport protein that is responsible for cellular uptake and delivery of cobalamin, the notion was put forward that measurement of circulating cobalamin that was bound to TC (HoloTC), would provide a more meaningful measure of cobalamin status than total serum cobalamin. Since HoloTC represents only 20–30% of the total serum cobalamin, there have been formidable problems in establishing a HoloTC assay. Such an assay has been produced and recently became available in Europe. Validation of the clinical usefulness and limitations of this test indicate that it may, in conjunction with the serum cobalamin level, provide improved sensitivity for detection of cobalamin deficiency. Additionally, it may be useful as a confirmatory test to establish true cobalamin deficiency in patients with low serum cobalamin.

Serum methylmalonate and homocysteine levels

Deoxyadenosyl cobalamin is required as a coenzyme in the isomerization of methylmalonyl CoA to succinyl CoA. In patients with cobalamin deficiency sufficient to cause anaemia or neuropathy, the serum methylmalonate (MMA) level is raised. Sensitive methods for measuring MMA and homocysteine in serum have been introduced and recommended for the early diagnosis of cobalamin deficiency, even in the absence of haematological abnormalities or subnormal levels of serum cobalamin or folate. Serum MMA fluctuates, however, in patients with renal failure. Mildly elevated serum MMA and/or homocysteine levels occur in up to 30% of apparently healthy volunteers, with serum cobalamin levels up to 350 ng/L and normal serum folate levels; 15% of elderly subjects, even with cobalamin levels > 350 ng/L, have this pattern of raised metabolite levels. These findings bring into question the exact cut-off points for normal MMA and homocysteine levels. It is also unclear at present whether these mildly raised metabolite levels have clinical consequences and how many of the subjects will progress to clinically overt cobalamin deficiency. When cobalamin supplies to the cell are suboptimal, there may be preferential use as methylcobalamin for methionine synthesis compared with ado-cobalamin for MMA metabolism. Urine MMA excretion may also be used to screen for cobalamin deficiency but this also is increased in aminoaciduria (e.g. Fanconi's syndrome).

Homocysteine exists in plasma as single molecules, as two molecules linked together (homocystine) and as mixed homocysteine–cysteine disulphides. Serum homocysteine levels are raised in both early cobalamin and folate deficiency, but they may be raised in other conditions, e.g. chronic renal disease, alcoholism, smoking, pyridoxine deficiency, hypothyroidism therapy with steroids, cyclosporin and other drugs. Levels are

also higher in serum than in plasma, in men than in pre-menopausal women, women taking hormone replacement therapy or oral contraceptive users and in elderly subjects and patients with several inborn errors of metabolism affecting enzymes in trans-sulphuration pathways of homocysteine metabolism. Thus, homocysteine levels are not widely used for diagnosis of cobalamin or folate deficiency. Homocysteine levels are useful, however, in thrombophilia screening and in assessing for cardiovascular risk factors (see Chapter 58).

Tests for the cause of cobalamin deficiency

The principal methods used in diagnosing the cause of cobalamin deficiency are listed in Table 5.7. Many of these tests are mentioned elsewhere in this chapter, and others are described in texts of gastroenterology. Studies of cobalamin absorption are, however, of particular importance.

Cobalamin absorption

This is usually assessed by one of two different techniques: whole-body counting or urinary excretion (Schilling test). Hepatic uptake, faecal excretion and plasma radioactivity have also been measured but are not now used routinely. Whole-body counting is available at only a few specialized centres.

Table 5.7 Tests for the cause of cobalamin deficiency.

Clinical history: diet, drugs, operations, etc.
Cobalamin absorption using radioactive cobalamin: Alone; with food; with IF; after a course of antibiotics
Tests for tissue-specific antibodies in serum (e.g. IF, parietal, cell, thyroid, gliadin, endomysial, transglutaminase
Endoscopy with gastric biopsy
Measurement of IF in gastric juice after maximal stimulation (e.g. with pentagastrin); this test is rarely performed now
Small intestinal studies
Examination of urine for proteinuria
Stools for fish tapeworm ova

Cyanocobalamin labelled with the isotopes ^{57}Co or ^{58}Co is used clinically. The patient is fasted overnight. The test is performed giving radioactive cyanocobalamin (1 μg) orally. A 24-h urine specimen is collected for determination of radioactivity excreted alone. Then, 2 h later an i.m. injection of cyanocobalamin or hydroxocobalamin (1 mg) is given ('flushing dose'); if this shows malabsorption, the dose is given again after 48 h with IF. The results distinguish between gastric and intestinal causes of cobalamin malabsorption. If intestinal malabsorption is present, the test may be repeated after antibiotic therapy to reduce possible bacterial interference with cobalamin absorption. As the Schilling test involves the injection of 1 mg of non-radioactive hydroxocobalamin (or cyanocobalamin), this will also treat the patient. A combined test (Dicopac) is available, in which two isotopes of cyanocobalamin are given simultaneously, one alone and one attached to IF. The excretion of the two isotopes is compared in the same 24-h urine. The results are less clear-cut than when the two tests are performed separately because of some exchange of isotopes attached to IF. It is a useful test, however, when incomplete urine collections are likely.

The standard test is performed using crystalline radioactive cyanocobalamin. Tests using food-bound (e.g. egg ovalbumin) radioactive cyanocobalamin have been devised to parallel normal dietary cobalamin more closely. Such tests may detect malabsorption of cobalamin in some patients, for example those with atropic gastritis and low serum cobalamin levels, but with normal absorption of crystalline cyanocobalamin. Because of concerns with radioisotope use and disposal, Schilling tests are being used less frequently.

Folate

Dietary folate

Folic acid (pteroylglutamic acid) is a yellow, crystalline, water-soluble substance (mol. wt 441). It is the parent compound of a large family of folate compounds. Pteroylglutamic acid consists of three parts: pteridine, *para*-aminobenzoate and L-glutamic acid (Figure 5.8). It is only a minor component of normal food folates (probably less than 1%), which differ from it in three respects (Figure 5.8): (i) they are partly or completely reduced at
Figure 5.8 The structure of folic acid (pteroylglutamic acid).

positions 4, 5, 7 and 8 in the pteridine portion to di- or tetrahydrofolate (THF) derivatives; (ii) they usually contain a single carbon unit of varying degrees of reduction, such as a methyl group at N-5 or N-10; and (iii) 70–90% of natural folates contain a chain of three or more glutamate residues linked to each other by the unusual γ-peptide bond and are called pteroyl- or folate-polyglutamates. In human cells, four, five and six glutamate residues are usual.

Most foods contain some folate. The highest concentrations are found in liver and yeast (> 200 µg/100 g), spinach, other greens and nuts (> 100 µg/100 g). The total folate content of an average Western diet is about 250 µg daily, but the amount varies widely according to the type of food eaten and the method of cooking. Folate is easily destroyed by heating, particularly in large volumes of water; over 90% may be lost.

Body stores and requirements

Total body folate in the adult is about 10 mg, the liver containing the largest store. Daily adult requirements are about 100 µg. Up to 13 µg of folate is lost as such in the urine each day, but breakdown products of folate are also lost in urine. Losses of folate also occur in sweat and skin; faecal folate is largely derived from colonic bacteria. Stores are only sufficient for about 4 months in normal adults, so severe folate deficiency may develop rapidly.

Absorption

The principal site of folate absorption is the upper small intestine, and there is a steep fall-off in absorptive capacity in the lower jejunum and ileum. The absorption of all forms tested is rapid, a rise in blood level occurring within 15–20 min of ingestion.

The small intestine has a tremendous capacity to absorb folate monoglutamates, as about 90% of a single dose is absorbed regardless of whether this is small (100 µg) or large (15 mg). Absorption of pteroylglutamic acid occurs by a saturable process, although it is unclear whether an active mechanism or facilitated diffusion is involved. The existence of patients with a specific defect in absorption of folates, including pteroylglutamic acid itself, however, does suggest that a special mechanism exists.

The absorption of folate polyglutamates with higher numbers of glutamate residues is reduced. This may be due to the limited capacity of the small intestine to hydrolyse these compounds or to their limited transfer in the mucosal cell. On average, about 50% of food folates is absorbed.

Polyglutamate forms are hydrolysed by pteroylpolyglutamate hydrolase (PPH, also known as folylpoly-gamma-glutamate carboxypeptidase) to the monoglutamate derivatives, either in the lumen of the intestine or within the mucosa; they do not enter portal blood intact. The exact intracellular site of hydrolysis of dietary pteroylpolyglutamates in the enterocytes is unknown, although PPH has been shown to be concentrated in the lysosomes of the cells and is also present on the brush border. Mono- or polyglutamate forms of dietary folate, which are already partly or completely reduced, are converted to 5-methyltetrahydrofolate within the small intestinal mucosa before entering the portal plasma. The monoglutamates are actively transported across the enterocyte by a carrier-mediated mechanism. Pteroylglutamic acid at doses greater than 400 µg is absorbed largely unchanged and converted to natural folates in the liver. Lower doses are converted to 5-methyltetrahydrofolate during absorption through the intestine.

Enterohepatic circulation

About 60–90 µg of folate enters the bile each day and is excreted into the small intestine. Loss of this folate, together with the folate of sloughed intestinal cells, accelerates the speed with which folate deficiency develops in malabsorption conditions.

Transport

Folate is transported in plasma; about one-third is loosely bound to albumin and two-thirds is unbound. In all body fluids (plasma, cerebrospinal fluid, milk, bile) folate is largely, if not entirely, 5-methyl-THF in the monoglutamate form. A carrier-mediated active process is involved in the entry of folate into cells, the rate of uptake being linked to the rate of folate polyglutamate synthesis in the cell, which in replicating cells is related to the rate of DNA synthesis. Reduced folates are more rapidly taken up than oxidized folates. In most cells, folates are retained with tight binding to folate-binding proteins, three of which are enzymes involved in methyl group metabolism, sarcosine dehydrogenase, dimethylglycine dehydrogenase and glycine N-methyltransferase, until the cell dies. Intact liver cells can release folate. Two types of folate-binding protein are involved in entry of methyl-THF into cells. A high-affinity folate receptor takes folate into cells internalized in a vesicle (caveola), which is then acidified, releasing folate into the vesicle lumen. Folate is then carried by the membrane folate transporter into the cytoplasm; the caveola recycles to the cell surface, where its high-affinity receptors are re-utilized. The high-affinity receptor is attached to the outer surface of the cell membrane by glycosyl phosphatidylinositol linkages. They may be involved in transport of oxidized folates and folate breakdown products to the liver for excretion in bile. The congenital disease of folate-specific malabsorption, in which there is also a transport defect, may be a defect of a specific folate-binding protein, but this has yet to be established.

Biochemical functions

Folates (as the intracellular polyglutamate derivatives) act as

coenzymes in the transfer of single-carbon units from one compound to another (Figure 5.3 and Table 5.2). Two of these reactions are involved in purine and one in pyrimidine synthesis necessary for DNA and RNA replication. Folate is coenzyme in another reaction, methionine synthesis, in which cobalamin is also involved and THF is regenerated. THF is the acceptor of single carbon units newly entering the active pool via conversion of serine to glycine. Methionine, the other product of the methionine synthase reaction, is the precursor for *S*-adenosylmethionine (SAM), the universal methyl donor involved in over 100 methyltransferase reactions.

During thymidylate synthesis, 5,10-methylene-THF is converted to DHF (dihydrofolate) (Figure 5.3). The enzyme DHF reductase converts this to THF. The drugs methotrexate, pyrimethamine and, mainly in bacteria, trimethoprim inhibit DHF reductase, and this prevents formation of the active folate coenzymes from DHF. A small fraction of the folate coenzyme is not recycled during thymidylate synthesis but is degraded at the C-9–N-10 bond.

Causes of folate deficiency (Table 5.8)

Nutritional

Dietary folate deficiency is common. Indeed, in most patients with folate deficiency a nutritional element is present. Certain individuals are particularly prone to have diets containing inadequate amounts of folate, including the old, edentulous, poor, alcoholic and psychiatrically disturbed, and patients after gastric operations. In relation to the size of the total body folate stores, which are in the order of 15–25 mg, the daily requirement of 100–200 mg is large. Consequently, with total cessation of intake or absorption, depletion of stores will occur in 3–6 months. In the

Table 5.8 Causes of folate deficiency.

Dietary
Particularly in: old age, infancy, poverty, alcoholism, chronic invalids and the psychiatrically disturbed; may be associated with scurvy or kwashiorkor

Malabsorption
Major causes of deficiency
Tropical sprue, gluten-induced enteropathy in children and adults, and in association with dermatitis herpetiformis, specific malabsorption of folate, intestinal megaloblastosis caused by severe cobalamin or folate deficiency

Minor causes of deficiency
Extensive jejunal resection, Crohn's disease, partial gastrectomy, congestive heart failure, Whipple's disease, scleroderma, amyloid, diabetic enteropathy, systemic bacterial infection, lymphoma, salazopyrine

Excess utilization or loss
Physiological
Pregnancy and lactation, prematurity

Pathological
Haematological diseases: chronic haemolytic anaemias, sickle cell anaemia, thalassaemia major, myelofibrosis
Malignant diseases: carcinoma, lymphoma, leukaemia, myeloma
Inflammatory diseases: tuberculosis, Crohn's disease, psoriasis, exfoliative dermatitis, malaria
Metabolic disease: homocystinuria
Excess urinary loss: congestive heart failure, active liver disease
Haemodialysis, peritoneal dialysis

Antifolate drugs
Anticonvulsant drugs (dephenylhydantoin, primidone, barbiturates), sulphasalazine
Nitrofurantoin, tetracycline, anti-tuberculosis (less well documented)

Mixed causes
Liver diseases, alcoholism, intensive care units

Note: In severely folate-deficient patients with causes other than those listed under Dietary, poor dietary intake is often present.

USA and other countries where fortification of the diet with folic acid has been adopted to reduce the incidence of neural tube defects, the prevalence of folate deficiency has dropped dramatically and is now almost restricted to high-risk groups with increased folate needs. Nutritional folate deficiency occurs in kwashiorkor and scurvy, and in infants with repeated infections or who are fed solely on goats' milk, which has a low folate content (6 µg/L) compared with human or cows' milk (50 µg/L), as well as high concentrations of a high-affinity folate-binding protein.

Malabsorption

Malabsorption of dietary folate occurs in tropical sprue, in gluten-induced enteropathy in children and in adults, when it is associated with dermatitis herpetiformis. In the rare congenital syndrome of selective malabsorption of folate, there is an associated defect of folate transport into the cerebrospinal fluid, and these patients show megaloblastic anaemia, responding to physiological doses of folic acid given parenterally but not orally. These patients also show mental retardation, convulsions and other central nervous system abnormalities. Minor degrees of malabsorption may also occur following jejunal resection or partial gastrectomy, in Crohn's disease and in systemic infections but, in these conditions, if severe deficiency occurs, it is usually largely due to poor nutrition.

Malabsorption of folate has been described in patients receiving salazopyrine, cholestyramine and triamterene. It has also been associated with anticonvulsant drug therapy, alcohol abuse and folate deficiency, but these relationships are less well established. In the intestinal stagnant loop syndrome, the predominant effect of the small intestinal bacteria is to cause a rise in serum, red cell and urinary folate by synthesizing folate, which is then absorbed.

Excess utilization or loss

Pregnancy

Folate requirements are increased by 200–300 µg to about 400 µg daily in a normal pregnancy, partly because of transfer of the vitamin to the fetus, but mainly because of increased folate catabolism due to cleavage of folate coenzymes in rapidly proliferating tissues at the C-9–N-10 bond. Megaloblastic anaemia due to this deficiency is now largely prevented by prophylactic folic acid therapy. It occurred in 0.5% of pregnancies in the UK and other Western countries, but the incidence is much higher in countries where the general nutritional status is poor. The anaemia is more common in twin pregnancies, is most likely to occur in the last trimester, especially in the late winter and early spring months (in the UK), and may also present in the early post-partum period during lactation. The deficiency is more common in pregnant women who also suffer from iron deficiency, probably because these patients have a poor diet.

The usual presentation of the anaemia is similar to that of other megaloblastic anaemias, but occasionally, when there is an associated infection, acute arrest of haemopoiesis with pancytopenia may occur; this resembles aplastic anaemia, except that the marrow shows obvious megaloblastic changes.

A number of consequences of folate deficiency in pregnancy have been described, including antenatal and post-partum haemorrhages, prematurity and congenital malabsorption in the fetus. These have not been fully established, but several studies have shown that prophylactic folic acid therapy reduces the incidence of neural tube defects (see p. 64).

Prematurity

The newborn infant, whether full term or premature, has higher serum and red cell folate concentrations than the adult, but the newborn infant's demand for folate has been estimated to be up to 10 times that of adults on a weight basis and the neonatal folate level falls rapidly to the lowest values at about 6 weeks of age. The falls are steepest and are liable to reach subnormal levels in premature babies, a number of whom develop megaloblastic anaemia responsive to folic acid at about 4–6 weeks of age. This occurs particularly in the smallest babies (< 1500 g birth weight) and in those who have feeding difficulties or infections, or who have undergone multiple exchange transfusions. In these babies, prophylactic folic acid should be given.

Haematological disorders

Folate deficiency frequently occurs in chronic haemolytic anaemia, particularly in sickle cell disease, autoimmune haemolytic anaemia and congenital spherocytosis. In these and other conditions of increased cell turnover, folate deficiency arises because it is not completely re-utilized after performing coenzyme functions, and it is partly lost as pteridines in the urine due to cleavage at the C-9–N-10 bond. Patients with chronic myelofibrosis may develop folate deficiency at some stage of the illness. There is also a high incidence of mild folate deficiency in patients with leukaemia, lymphoma, myeloma or carcinoma, although it is unusual for this to progress to megaloblastic anaemia. Treatment with folic acid should be avoided (as it may 'feed' the tumour) unless severe megaloblastic anaemia due to folate deficiency is clinically important.

Inflammatory conditions

Chronic inflammatory diseases, such as tuberculosis, rheumatoid arthritis, Crohn's disease, psoriasis, exfoliative dermatitis, bacterial endocarditis and chronic bacterial infections, cause deficiency by reducing the appetite and by increasing the demand for folate. Systemic infections may also cause malabsorption of folate. Severe deficiency is virtually confined to the patients with the most active disease and the poorest diet. Fever per se has also been suggested to interfere with folate metabolism by inhibiting temperature-dependent folate enzymes. In patients with subclinical folate deficiency from causes other than infections,

intercurrent infections often precipitate severe megaloblastic anaemia.

Homocystinuria

This is a rare metabolic defect in the conversion of homocysteine to cystathionine. Folate deficiency occurring in most of these patients may be due to excessive utilization because of compensatory increased conversion of homocysteine to methionine.

Long-term dialysis

As folate is only loosely bound to plasma proteins, it is easily removed from plasma by haemodialysis or peritoneal dialysis (in contrast, cobalamin is not removed from plasma by dialysis as it is firmly protein bound). The amount of body folate that can be removed in this way is relatively small. Nevertheless, in patients with anorexia, vomiting, infections and haemolysis, folate stores may become depleted and megaloblastic anaemia can supervene. Routine folate prophylaxis is now given.

Congestive heart failure, liver disease

Excess urinary folate losses of more than 100 µg per day may occur in some of these patients. The explanation appears to be release of folate from damaged liver cells.

Antifolate drugs

A large number of epileptics who are receiving long-term therapy with diphenylhydantoin (phenytoin, Dilantin) or primidone (Mysoline®), with or without barbiturates, develop low serum and red cell folate levels. In some of these patients, megaloblastic anaemia supervenes. A number of mechanisms have been suggested: inhibition of folate absorption, inhibition of the action of or synthesis of folate-dependent enzymes, displacement of folate from its plasma transport protein and induction of folate-utilizing enzymes. None of these theories has been established. A dietary element is present in the patients with the severest deficiencies.

Alcohol may also be a folate antagonist, as patients who are drinking spirits may develop megaloblastic anaemia that will respond to normal quantities of dietary folate or to physiological doses of folic acid only if the alcohol is withdrawn. Macrocytosis is associated with chronic alcohol intake even when folate levels are normal. Resumption of alcohol intake rapidly inhibits the haematological response to small doses of folate. The mechanism is unknown. Inadequate folate intake is the major factor in the development of deficiency in spirit-drinking alcoholics. Beer is relatively folate-rich in some countries, depending on the technique used for brewing.

The drugs that inhibit dihydrofolate reductase include methotrexate, pyrimethamine and trimethoprim. Methotrexate has the most powerful action against the human enzyme, whereas trimethoprim is most active against the bacterial enzyme and is only likely to cause megaloblastic anaemia when used in conjunction with sulphamethoxazole in patients with pre-existing folate or cobalamin deficiency. The activity of pyrimethamine is intermediate. The antidote to these drugs is folinic acid (5-formyl-THF).

Congenital abnormalities of folate metabolism

A number of infants have been described with congenital defects of folate enzymes (e.g. cyclohydrolase or methionine synthase). Some had megaloblastic anaemia.

Diagnosis of folate deficiency

Serum folate

This may be measured microbiologically with *Lactobacillus casei*, by radioassay or by an enzyme-linked immunosorbence assay (ELISA) technique. The serum folate level is low in all folate-deficient patients. In most laboratories, the normal range is quoted as from 2.0 µg/L (11 nmol/L) to about 15 µg/L. The serum folate is markedly affected by recent diet; inadequate intake for as little as 1 week may cause the level to become sub-normal. Because of this, the serum folate assay is a very sensitive test and may show a low result before there is haematological or other biochemical evidence of deficiency.

The serum folate level rises in severe cobalamin deficiency because of blockage in conversion of methyl THF, the major circulating form, to THF; raised levels have also been reported in the intestinal stagnant loop syndrome, acute renal failure and active liver damage. (High levels are also obtained when the patient is receiving folic acid therapy, when the serum is contaminated with folate or folate-producing bacteria or, if a sample is haemolysed, because of the high concentration of folate in red cells.)

Red cell folate

The red cell folate assay is a valuable test of body folate stores. It is less affected by recent diet and traces of haemolysis than is the serum assay. In normal adults, concentrations range from 160 to 640 µg/L of packed red cells. Subnormal levels occur in patients with megaloblastic anaemia due to folate deficiency but also occur in nearly two-thirds of patients with megaloblastic anaemia due to cobalamin deficiency. If cobalamin deficiency is excluded, however, a low red cell folate can be used as an indication that severe folate deficiency is present and warrants full investigation and treatment. False normal results may occur if the folate-deficient patient has received a recent blood transfusion (as the folate content of the transfused red cells will be measured) or if the patient has a raised reticulocyte count (e.g. due to haemorrhage or haemolytic anaemia).

Serum homocysteine

General management of megaloblastic anaemia

It is usually possible to establish which of the two deficiencies, folate or cobalamin, is the cause of the anaemia and to treat only with the appropriate vitamin. In patients who enter hospital severely ill, however, it may be necessary to treat with both vitamins in large doses once blood samples have been taken for cobalamin and folate assay and a bone marrow has been performed (if deemed necessary). Transfusion is usually unnecessary and inadvisable. If it is essential, packed red cells should be given slowly and one or two units will be ample. Exchange transfusion, as well as the usual treatment for heart failure, should be considered in patients with extreme anaemia and congestive heart failure. Platelet concentrates are of value in reducing spontaneous bleeding in the rare patients with severe thrombocytopenia. Potassium supplements have been recommended to obviate the danger of the hypokalaemia that has been recorded in some patients during the initial haematological response.

Treatment of cobalamin deficiency

It is usually necessary to treat patients who have developed cobalamin deficiency with lifelong regular cobalamin therapy. In the UK, the form used is hydroxocobalamin; in the USA cyanocobalamin is used. In a few instances, the underlying cause of cobalamin deficiency can be permanently corrected, for instance the fish tapeworm, tropical sprue or an intestinal stagnant loop that is amenable to surgery.

The indications for starting cobalamin therapy are a well-documented megaloblastic anaemia or neuropathy due to the deficiency. It is also necessary to treat any patients with haematological abnormalities due to cobalamin deficiency, even in the absence of anaemia (e.g. hypersegmented neutrophils or megaloblastic erythropoiesis). Patients with borderline serum cobalamin levels but no haematological or other abnormality should be followed, for example, at yearly intervals to make sure that the cobalamin deficiency does not progress. If malabsorption of cobalamin or rises in serum MMA levels have also been demonstrated, they should also be given regular maintenance cobalamin therapy. Cobalamin should be given routinely to all patients who have had a total gastrectomy or ileal resection. Patients who have undergone gastric reduction for control of obesity or who are receiving long-term treatment with proton pump inhibitors should be screened and, as necessary, given cobalamin replacement.

Replenishment of body stores should be complete with six 1000-μg i.m. injections of *hydroxocobalamin* given at 3–7 day intervals. More frequent doses are usually used in patients with cobalamin neuropathy, but there is no evidence that these produce a better response. For maintenance therapy, 1000 μg of hydroxocobalamin i.m. once every 3 months is satisfactory. Hydroxocobalamin is the preferred form. In the USA, hydroxocobalamin has not yet been approved and marketed for purposes of routine cobalamin replacement. Because of the poorer retention of cyanocobalamin maintenance treatment, protocols generally use higher and more frequent doses (1000 μg i.m., monthly). Toxic reactions are extremely rare and are usually due to contamination in its preparation rather than to cobalamin itself. Because a small fraction of cobalamin can be absorbed passively through mucous membranes even when there is complete failure of the physiological IF-dependent mechanism, large daily oral doses (1000–2000 μg) of cyanocobalamin can be used for replacement and maintenance of normal cobalamin status. Sublingual therapy has also been proposed for those in whom injections are difficult because of a bleeding tendency and may not tolerate oral therapy. If this approach is used, it is important to monitor compliance, particularly with elderly, forgetful patients.

Treatment of folate deficiency

There is probably never any need to give folic acid parenterally, except in patients receiving parenteral nutrition who cannot swallow tablets. Oral doses of 5–15 mg folic acid daily are satisfactory, as sufficient folate is absorbed from these extremely large doses even in patients with severe malabsorption. The length of time therapy must be continued depends on the underlying disease. It is customary to continue therapy for about 4 months, when all folate-deficient red cells will have been eliminated and replaced by a few folate-replete populations.

Before large doses of folic acid are given, cobalamin deficiency must be excluded and, if present, corrected, otherwise cobalamin neuropathy may develop, despite a response of the anaemia of cobalamin deficiency to folate therapy. This applies particularly in the USA and other countries where folic acid fortification of the diet or widespread use of folic acid supplements occur. Recent studies, however, suggest that there is no increase in the proportion of subjects with low serum cobalamin levels and no anaemia since fortification of the diet.

Long-term folic acid therapy is required when the underlying cause of the deficiency cannot be corrected and the deficiency is likely to recur, for instance in chronic haemolytic anaemias such as thalassaemia major and sickle cell anaemia, and in chronic myelofibrosis. It may also be necessary in gluten-induced enteropathy if this does not respond to a gluten-free diet. Where mild but chronic folate deficiency occurs, it is preferable to encourage any improvement in the diet after correcting the deficiency with a short course of folic acid. In any patient receiving long-term folic acid therapy, it is important to measure the serum cobalamin level at regular (e.g. once yearly) intervals to exclude the coincidental development of cobalamin deficiency.

Folinic acid (5-formyltetrahydrofolate)

This is a stable form of fully reduced folate. It is given orally or parenterally to overcome the toxic effects of methotrexate or other dihydrofolate reductase inhibitors.

Prophylactic folic acid

In many countries, food is fortified with folic acid (in grain or flour) to prevent neural tube defects. Prophylactic folic acid is being increasingly used to reduce homocysteine levels to prevent cardiovascular disease. As yet there is no definite proof of this benefit, although circumstantial evidence does support this approach (see p. 64).

Pregnancy

Folic acid, 400 μg daily, should be given as a supplement throughout pregnancy. In women who have had a previous fetus with a neural tube defect, 5 mg daily is recommended when pregnancy is contemplated and throughout the subsequent pregnancy. In women of childbearing age, a supplementary intake of folic acid of 400 μg daily is recommended, so that this extra intake will be present from conception. Combined iron and folic acid preparations are generally satisfactory, except that they are usually expensive and, if the patient cannot tolerate the iron and stops taking the tablets, folic acid therapy will also be discontinued.

Prematurity

The incidence of folate deficiency is so high in the smallest premature babies during the first 6 weeks of life that folic acid (e.g. 1 mg daily) should be given routinely to babies weighing less than 1500 g at birth and to larger premature babies who require exchange transfusions or develop feeding difficulties, infections or vomiting and diarrhoea.

Haemolytic anaemia and dialysis

Prophylactic folic acid is usually also given to patients with chronic haemolytic anaemia or those who are undergoing long-term haemodialysis.

Megaloblastic anaemia not due to cobalamin or folate deficiency or altered metabolism

This may occur with many antimetabolic drugs (e.g. hydroxyurea, cytosine arabinoside, 6-mercaptopurine) that inhibit DNA replication at a particular point in the supply of precursor or by inhibiting DNA polymerase. In the rare disease orotic aciduria, two consecutive enzymes in purine synthesis are defective. The condition responds to therapy with uridine, which bypasses the block. In thiamine-responsive megaloblastic anaemia, there is a genetic defect in the high-affinity thiamine transport (*SLC19A2*) gene. This causes defective RNA ribose synthesis through impaired activity of transketolase, a thiamine-dependent enzyme in the pentose cycle. This leads to reduced nucleic acid production and consequent induction of cell cycle arrest or apoptosis. It may be associated with diabetes mellitus and deafness and the presence of many ringed sideroblasts in the marrow (p. 41). The explanation is unclear for megaloblastic changes in the marrow in patients with acute myeloid leukaemia (AML), especially $FABM_6$, and other leukaemias and myelodysplasia. When assessed by the dU suppression test (p. 75), the fault is not at the thymidylate synthase reaction.

Other nutritional anaemias

Protein deficiency

Anaemia is usual in children and adults with severe protein deficiency (kwashiorkor). The anaemia, which may be partly masked by haemoconcentration, is usually normoblastic, but megaloblastic changes have been described in 10–60% of patients in different series. Hypoplasia, or even aplasia, of the marrow has also been reported. The mechanism by which protein deficiency causes anaemia is not completely understood. Lack of protein does not seem to reduce haemoglobin synthesis directly. Studies on experimental animals suggest that the major faction is diminution or erythropoietin secretion. This is probably due to a reduction in general tissue metabolism and therefore oxygen consumption, with a consequent reduced stimulus for erythropoietin secretion. In most patients, other factors contribute to the anaemia. These include infections, deficiencies of folate and iron, and also, possibly, deficiencies of vitamins C, E and B_{12} and other trace substances. Riboflavin deficiency may also contribute to the anaemia and become apparent only during the response to protein.

Scurvy

There is usually a moderate or severe normocytic, normochromic anaemia in scurvy because of external haemorrhage and haemorrhage into tissues, and from impaired erythropoiesis. In some patients, the anaemia is megaloblastic, which appears to be partly due to associated nutritional folate deficiency and partly due to impairment of folate metabolism caused by vitamin C deficiency. Vitamin C is not established, however, as playing a role in normal folate metabolism.

Other deficiencies

Deficiencies of nicotinic acid and panthothenic acid cause anaemia in experimental animals but have not been shown to do so in humans. However, riboflavin deficiency may cause anaemia in humans, resembling the anaemia of protein deficiency. Copper is essential for haemopoiesis and normal iron metabolism. A deficiency of copper causes an anaemia resembling that in iron deficiency in experimental animals. Anaemia due to copper deficiency, however, has never been documented in humans. Copper excess (as in Wilson's disease) causes a haemolytic anaemia.

Haemoglobin and the inherited disorders of globin synthesis

6

David J Weatherall

Introduction

The inherited diseases of haemoglobin are the commonest single-gene disorders; the World Health Organization estimates that about 7% of the world population are carriers. In many developing countries, where there is a very high neonatal and childhood mortality from infection and malnutrition, these conditions are not yet recognized as an important public health problem. However, once economic conditions improve and infant death rates fall, the genetic disorders of haemoglobin start to place a major burden on the health services, a phenomenon that has already been observed in many parts of the world. As a result of migrations of populations, these conditions are being seen with increasing frequency in many countries in which they had not been recognized previously. Some of them, particularly sickle cell anaemia and the more severe forms of thalassaemia, cause life-threatening medical emergencies, chronic disability and distress for families and are a major drain on health resources.

The structure, genetic control and synthesis of haemoglobin

Structure and function

Different haemoglobins are synthesized in the embryo, fetus and adult, each adapted to their particular oxygen requirements. They all have a tetrameric structure made up of two different pairs of globin chains, each attached to one haem molecule (Figure 6.1). Adult and fetal haemoglobins have α-chains combined with β-chains (HbA, $\alpha_2\beta_2$), δ-chains (HbA$_2$, $\alpha_2\delta_2$) and
Figure 6. 1 The genetic control of haemoglobin.

γ-chains (HbF, $\alpha_2\gamma_2$). In embryos, α-like chains called ζ-chains combine with γ-chains to produce Hb Portland ($\zeta_2\gamma_2$), or with ε-chains to make Hb Gower 1 ($\zeta_2\varepsilon_2$), and α- and ε-chains combine to form Hb Gower 2 ($\alpha_2\varepsilon_2$). Fetal haemoglobin is itself heterogeneous. There are two kinds of γ-chains that differ in their amino acid composition at position 136, where they have either glycine or alanine; those with glycine are called $^{G}\gamma$-chains and those with alanine $^{A}\gamma$-chains. The $^{G}\gamma$- and $^{A}\gamma$-chains are the products of separate ($^{G}\gamma$ and $^{A}\gamma$) loci.

The sigmoid shape of the oxygen dissociation curve, which reflects the allosteric properties of haemoglobin, ensures that oxygen is rapidly taken up at the high oxygen tensions found in the lungs and is released readily at the low tensions encountered in the tissues. It is quite different to myoglobin, a molecule that consists of a single globin chain with haem attached to it and which has a hyperbolic dissociation curve. The transition from a hyperbolic to a sigmoid curve reflects cooperativity between the four haem molecules. When one haem takes on oxygen, the affinity for oxygen of the remaining haems of the tetramer increases markedly. This is because haemoglobin can exist in two configurations, deoxy(T) and oxy(R) (T and R stand for tight and relaxed states respectively). The T form has a lower affinity than the R form for ligands such as oxygen. At some point during the sequential addition of oxygen to the four haems, transition from the T to R configuration occurs and the oxygen affinity of the partially liganded molecule increases dramatically. The oxygen dissociation curve, which reflects these changes, can be modified in several ways. First, oxygen affinity is decreased with increasing CO_2 tensions – the Bohr effect. This facilitates oxygen loading to the tissues, where a drop in pH due to CO_2 influx lowers oxygen affinity. In contrast, in the lungs, efflux of CO_2 and an increase in intracellular pH increases oxygen affinity and hence uptake. Oxygen affinity is also modified by the level of 2,3-biphosphoglycerate (2,3-BPG) in the red cell. Increasing concentrations shift the oxygen dissociation curve to the right, i.e. reduce oxygen affinity, whereas diminishing concentrations have the opposite effect. The clinical relevance of the allosteric properties of haemoglobin and the factors that modify its oxygen dissociation curve are considered together with the pathological haemoglobins in later sections and in Chapter 7.

Genetic control, regulation and synthesis

Globin genes

The arrangement of the two main families of globin genes is illustrated in Figure 6.1. The β-like globin genes form a linked cluster on chromosome 11, which is spread over approximately 60 kb (kb = kilobase or 1000 nucleotide bases); they are arranged in the order 5′-ε-$^{G}\gamma$-$^{A}\gamma$-ψβ-δ-β-3′. The α-like globin genes also form a linked cluster, in this case on chromosome 16, in the order 5′-ζ-ψζ-ψα1-α2-α1-3′. The ψβ, ψζ and ψα genes are pseudogenes, that is they have sequences that resemble the β-,

ζ- or α-genes but contain mutations that prevent them from synthesizing any products. They may be 'burnt out' remnants of genes that were functional at an earlier stage of evolution. Like most mammalian genes, the globin genes have one or more non-coding inserts called intervening sequences (IVS) or introns at the same position along their length (Figure 6.2). The non-α-globin genes contain two introns of 122–130 and 850–900 basepairs between codons 30 and 31 and 104 and 105 respectively. Similar, although smaller, introns are found in the α- and ζ-globin genes. At the 5′ non-coding (flanking) regions of the globin genes, there are blocks of nucleotide homology that are found in analogous positions in many species. The first, the ATA box, is about 30 bases upstream from the initiation codon. The second, the CCAAT box, is about 70 basepairs upstream from the 5′ end of the genes. About 80–100 bases upstream, there is the sequence $GGGG^{T}G$, or $C^{A}CCC$, which may be inverted or duplicated. These promoter elements are involved in the initiation of transcription and hence play an important role in the regulation of the structural genes. At the 3′ non-coding regions of all the globin genes, there is the sequence AATAAA, which is the signal for cleavage and poly-A addition to RNA transcripts (see below).

Regulation

The globin gene clusters contain several types of regulatory elements that interact to promote erythroid-specific gene expression and to coordinate changes in globin gene activity during development. They include promoter elements, enhancers, i.e. regulatory elements that increase gene expression despite being located at a variable distance from the genes, and, in the case of the β-globin gene cluster, a master sequence called the 'locus control region' (LCR), or 'locus activating region' (LAR), which lies upstream from the cluster. The α-gene cluster has a homologous upstream sequence designated HS40 (HS stands for DNase 1 *hypersensitive site*, which is characteristic of these regions). Each of these sequences has a modular structure made up of an array of short motifs that represent the binding sites for transcriptional activators or repressors.

The regulation of globin gene expression is mediated at several levels; although most occurs at the transcriptional level, there is some fine-tuning during and after translation. Most DNA that is not involved in gene transcription is tightly packaged into a compact, chemically modified form that is inaccessible to transcription factors and polymerases and which is heavily methylated. Activity is associated with a change in the structure of the chromatin surrounding a gene, which can be identified by enhanced sensitivity to nucleases. Erythroid lineage-specific nuclease hypersensitive sites are found at several locations in the β-globin gene cluster. Four are distributed over a 20-kb region upstream from the ε-globin gene in the region of the β-globin LCR. This key regulatory region establishes a transcriptionally active domain spanning the entire β-globin gene cluster. Several enhancer sequences have been identified in this cluster. All
Figure 6.2 The genetic control of the synthesis of a globin chain. *Levels of action of mutations.

of these regulatory regions bind a number of erythroid-specific transcription factors, notably GATA-1 and NF-E2, as well as factors that are more ubiquitous in their tissue distribution (see Chapter 2).

The binding of haemopoietic-specific factors activates the LCR, which renders the entire β-globin gene cluster transcriptionally active. Transcription factors also bind to enhancer and promoter sequences, which work in tandem to regulate the expression of the individual genes in the clusters. Some of the transcription factors are developmental stage specific and may be involved in the (still poorly understood) differential expression of the embryonic, fetal and adult globin genes.

Transcription and processing

When a globin gene is transcribed, messenger RNA (mRNA) is synthesized from one of its strands by the action of RNA polymerase II. This process involves the interaction of a number of transcription factors, other proteins and, possibly, the LCR to form an initiation complex. The primary transcript is a large mRNA precursor that contains both introns and exons. While in the nucleus, it undergoes a number of modifications (Figure 6.2). First, the introns are removed and the exons are spliced together.

This too is a complex, multistep process involving several different proteins that constitute the spliceosome. The exon–intron junctions always have the sequence GT at their 5′ end, and AG and their 3′ end; if there is a mutation at these sites, normal splicing cannot occur. The mRNAs are modified at their 5′ end by the addition of a CAP structure, and at their 3′ end by the addition of a string of adenylic acid residues (poly-A). The processed mRNA now moves into the cytoplasm to act as a template for globin chain production.

Translation

Amino acids are transported to the mRNA template on carriers called transfer RNAs; there are specific transfer RNAs for each amino acid. The order of amino acids in a globin chain is determined by a triplet code, i.e. three bases (codons) code for a particular amino acid. The transfer RNAs also contain three bases, anticodons, which are complementary to mRNA codons for particular amino acids. The transfer RNAs carry amino acids to the template, where they find the right position by codon–anticodon basepairing. The mRNA is translated from the 5′ to the 3′ end (left to right). The transfer RNAs are held in appropriate steric conformation with the mRNA by the two

subunits that make up the ribosomes. There are specific initiation (AUG) and termination (UAA, UAG, UGA) codons. When the ribosomes reach the termination codon translation ceases, the completed globin chain is released, and the ribosomal subunits fall apart and are recycled. Individual globin chains combine with haem, which is synthesized through a separate pathway, and with themselves to form definitive haemoglobin molecules.

Classification of the disorders of haemoglobin

The genetic disorders of haemoglobin are divided into those in which there is a reduced rate of production of one or more of the globin chains, the thalassaemias, and those in which there is a structural change in a globin chain leading to instability or abnormal oxygen transport. In addition, there is a harmless group of mutations which interfere with the normal switching of fetal to adult haemoglobin production, known collectively as hereditary persistence of fetal haemoglobin; in many cases, these can be regarded as well-compensated forms of thalassaemia. Like all classifications, this way of splitting up the haemoglobin disorders is not entirely satisfactory; some structural variants, HbE for example, are synthesized in reduced amounts and hence produce the clinical picture of thalassaemia.

The thalassaemias and related disorders

The thalassaemias are the commonest single-gene disorders. The condition was first recognized in 1925 by a Detroit physician, Thomas B. Cooley, who described a series of infants who became profoundly anaemic and developed splenomegaly over the first year of life. In 1936, Whipple and Bradford, in describing the pathological changes of the condition for the first time, recognized that many of their patients came from the Mediterranean region, and hence invented the word 'thalassaemia' from the Greek θαλασσα, meaning 'the sea'. More recently, it has become clear that thalassaemia occurs widely throughout the world and that its clinical picture can result from the interaction of many different mutations. The high frequency reflects heterozygote protection against malaria.

Definition and classification

The thalassaemias are a heterogeneous group of genetic disorders of haemoglobin synthesis, all of which result from a reduced rate of production of one or more of the globin chains of haemoglobin (Table 6.1). They are divided into the α-, β-, $\delta\beta$- or $\gamma\delta\beta$-thalassaemias, according to which globin chain is produced in reduced amounts. In some thalassaemias, no globin chain is synthesized at all, and these are called α^0- or β^0-thalassaemias; in others, designated α^+- or β^+-thalassaemias, the globin chain is produced at a reduced rate. The $\delta\beta$-thalassaemias are subdivided in the same way. Because thalassaemia occurs in populations in which structural haemoglobin variants are common, it is not unusual to receive a thalassaemia gene from one parent and a gene for a structural haemoglobin variant from the other. Furthermore, both α- and β-thalassaemia occur commonly in some countries, and hence individuals may receive genes for both types. These different interactions produce a clinically diverse family of genetic disorders that range in

severity from death *in utero* to extremely mild, symptomless hypochromic anaemias.

Most thalassaemias are inherited in a Mendelian recessive fashion. Heterozygotes are usually symptomless, although usually they can be recognized by simple haematological analysis. More severely affected patients are either homozygotes for α- or β-thalassaemia or compound heterozygotes for different molecular forms of α- or β-thalassaemia or for one or other form of thalassaemia and a gene for a structural haemoglobin variant. Clinically, the thalassaemias are classified according to their severity into major, intermediate and minor forms. *Thalassaemia major* is a severe, transfusion-dependent disorder. *Thalassaemia intermedia* is characterized by anaemia and splenomegaly, though not of such severity as to require regular transfusion. *Thalassaemia minor* is the symptomless carrier state.

β-Thalassaemias

The β-thalassaemias are the most important types of thalassaemia because they are so common and usually produce severe anaemia in their homozygous and compound heterozygous states.

Distribution
The β-thalassaemias occur widely in a broad belt, ranging from the Mediterranean and parts of North and West Africa through the Middle East and Indian subcontinent to South-East Asia. The high-incidence zone stretches north through the former Yugoslavia and Romania and the southern parts of the former USSR and includes the southern regions of China. The disease is particularly common in South-East Asia, where it occurs in a line starting in southern China and stretching down through Thailand and the Malay peninsula and Indonesia to some of the Pacific island populations. In this region, and in some of the Mediterranean island and mainland countries, gene frequencies range between 2% and 30%. It should be remembered that β-thalassaemia is not confined entirely to these high-incidence regions and it occurs sporadically in every racial group.

Post-translational instability	Exon 3 mutations
	Other unstable β-chains

Molecular pathology
The main classes of mutations that cause β-thalassaemia are summarized in Table 6.2 and in Figure 6.3. They may involve any step in globin chain production: transcription, translation or the post-translational stability of the globin gene product.

Transcription
The mutations that involve transcription include deletions and point mutations involving the globin gene promoter regions. With the exception of a deletion of about 600 bases at the 3′ end of the β-globin gene, which is restricted to certain Indian populations, major deletions are uncommon. A large number of point mutations involve the promoters or adjacent regions, most of which downregulate the β-globin gene to a varying degree and hence cause relatively mild forms of β-thalassaemia.

Processing
A wide variety of mutations interfere with processing of the primary mRNA transcript. Those within introns or exons, or at

Figure 6.3 The classes of mutations that underlie β-thalassaemia. PR, promoter; C, CAP site; I, initiation codon; FS, frameshift; NS, nonsense mutation; SPL, splicing mutation; Poly-A, poly-A addition site mutation.
their junctions, interfere with the mechanism of *splicing* the exons together after the introns have been removed. Single-base substitutions at the invariant GT or AG sequences at intron–exon junctions prevent splicing altogether and cause β^0-thalassaemia. The sequences adjacent to the GT in the introns are also relatively conserved, so-called *consensus sequences*. Several β-thalassaemia mutations involve this region or other parts of the introns and are associated with variable degrees of defective β-globin production; alternative splicing sites are produced so that both normal and abnormal mRNA species are synthesized. An incorrectly spliced mRNA is not functional because it contains intron sequences; in some cases a nonsense mutation or frameshift is generated.

In exons, there are also sequences that resemble the consensus sequences at the intron–exon junctions. Mutations may activate these 'cryptic' sites, again leading to abnormal splicing.

Translation

Mutations that involve translation of β-globin mRNA fall into two groups. First, there are *nonsense mutations*, that is single-base changes that produce stop codons in the middle of the coding part of the mRNA. Mutations of this type would cause premature termination of globin chain synthesis but, as part of the surveillance mechanism that is active in quality control of the processed mRNA, it appears that message that contains mutations of this type is not transferred to the cell cytoplasm, a phenomenon called *nonsense-mediated decay*. Other exon mutations result in *frameshifts*, that is one or more bases are lost or inserted and the reading frame for the genetic code is thrown out of phase.

Post-translational stability

Finally, some forms of thalassaemia result from instability of the β-globin gene product. For example, it appears that nonsense mutations in exon 3 are not subjected to nonsense-mediated decay and hence abnormal mRNA is transported to the cytoplasm and translated. The result may be long, unstable β-globin gene products that form inclusion bodies in the red cell precursor. This is the basis for dominant β-thalassaemia. In other cases, highly unstable β-chains may be produced, which, although they form a viable haemoglobin molecule, are rapidly destroyed in the circulation, leading to a chronic haemolytic anaemia (see later in chapter).

Pathophysiology

The molecular defects in β-thalassaemia result in absent or reduced β-chain production. α-Chain synthesis is unaffected and hence there is imbalanced globin chain production, leading to an excess of α-chains. In the absence of their partners, they are unstable and precipitate in the red cell precursors, giving rise to large intracellular inclusions that interfere with red cell maturation. Hence there is a variable degree of intramedullary destruction of red cell precursors, i.e. ineffective erythropoiesis. Those red cells which mature and enter the circulation contain α-chain

inclusions that interfere with their passage through the microcirculation, particularly in the spleen. However, the damage to the red cell precursors and their progeny in β-thalassaemia is not entirely mechanical. The degradation products of excess α-chains, particularly haem and iron, produce a wide range of deleterious effects on red cell membrane proteins and lipids, which are manifest by marked abnormalities of electrolyte homeostasis and membrane deformability. The end result is an extremely rigid red cell with a shortened survival.

Thus, the anaemia of β-thalassaemia results from both ineffective erythropoiesis and haemolysis. It stimulates erythropoietin production, which causes expansion of the bone marrow and may lead to serious deformities of the skull and long bones. Because the spleen is being constantly bombarded with abnormal red cells, it hypertrophies. The resulting splenomegaly, together with bone marrow expansion, causes a major increase in the plasma volume, which also contributes to the anaemia.

As mentioned previously, HbF production almost ceases after birth. However, some adult red cell precursors (F cells) retain the ability to produce a variable number of γ-chains. Because the latter can combine with excess α-chains to form HbF, cells which make relatively more γ-chains in the bone marrow of β-thalassaemics are partly protected against the deleterious effect of α-chain precipitation. Hence, they come under selection in the marrow and peripheral blood and thus relatively large amounts of HbF are found in the red cells. It is possible that there may also be a genuine increase in HbF production as well as selection of F cells; the mechanism is not understood. Because δ-chain synthesis is unaffected, the disorder is characterized by a relative or absolute increase in HbA_2 $(\alpha_2\delta_2)$ production. These interactions are summarized in Figure 6.4.

It follows, therefore, that if the anaemia is corrected with blood transfusion, erythropoietin drive is shut off, growth and development are normal, bone deformities do not occur and splenomegaly is less marked. On the other hand, each unit of blood contains 200 mg of iron; with regular transfusion there is steady accumulation of iron in the liver, endocrine glands and myocardium. Thus, although well-transfused thalassaemic children grow and develop normally, they die of iron overload unless steps are taken to remove iron.

Phenotype–genotype relationships

The β-thalassaemias show remarkable phenotypic variability, ranging from severe life-threatening anaemia to an extremely mild condition that may be identified only by chance. The molecular basis for this diversity is at least partly understood (Figure 6.5).

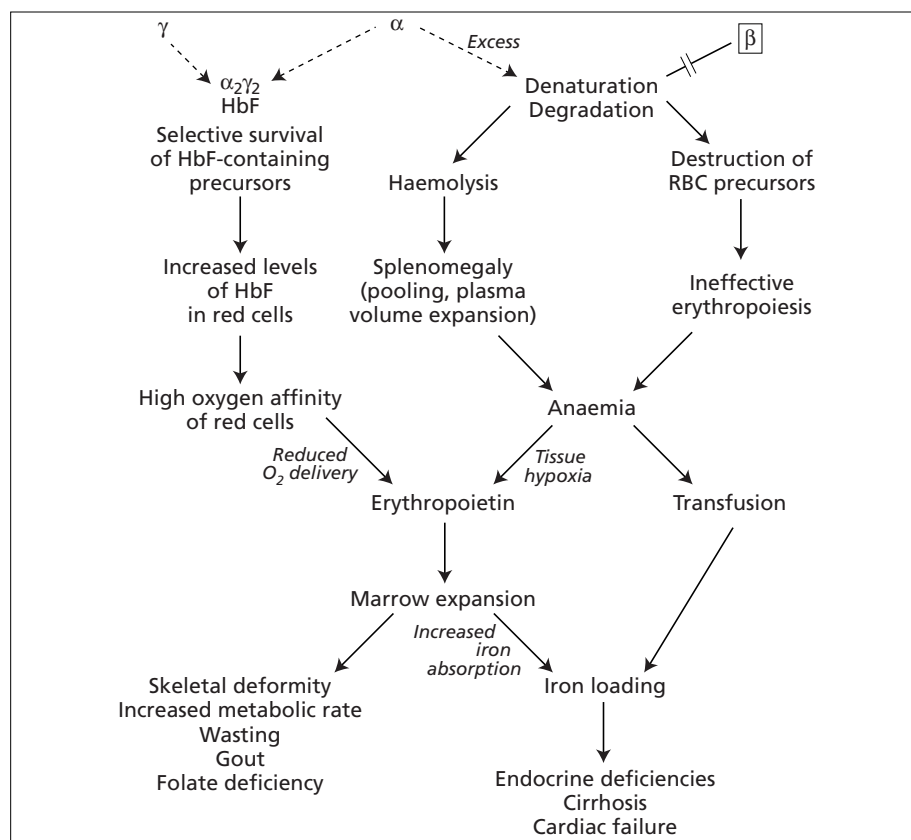
The genetic modifiers of the β-thalassaemia phenotype can be divided into primary, secondary and tertiary. Primary modifiers are the different mutations which, because of their variable effects on β-globin gene expression, may affect the output of β-globin chains, ranging from zero to a very mild reduction. Secondary modifiers are those that reduce the degree of imbal-


Figure 6.4 The pathophysiology of β-thalassaemia.

ance of globin chain synthesis. They include the co-inheritance of α-thalassaemia and a variety of ill-understood genetic modifiers of γ-chain production in adult life. Although several genes with the latter property have been identified, it seems likely that many remain to be discovered. Tertiary modifiers are those that affect the complications of disease; the severity of bone disease, iron loading and jaundice may be affected by polymorphisms of genes involved in the metabolic pathways concerned with these complications. Similarly, it seems very likely that the propensity to infection is modified by polymorphisms involving the immune system and its regulation. Finally, it should be remembered that environmental factors, long neglected, may also play an important role in modifying the β-thalassaemic phenotype.

Clinical findings

Most severe forms of β-thalassaemia present within the first year of life with failure to thrive, poor feeding, intermittent bouts of infection and general malaise; the infant is pale, and in many cases splenomegaly is already established. There are no other specific clinical signs and the diagnosis depends on the haematological changes outlined below. If the infant receives regular blood transfusion, early development is normal and further symptoms do not occur until puberty, when the effects of iron loading start to appear. If, on the other hand, the infant is not adequately

transfused, the typical clinical picture of β-thalassaemia major develops.

In the well-transfused child, early growth and development are normal and splenomegaly is minimal. However, without adequate iron chelation therapy, there is a gradual accumulation of iron and the effects of tissue siderosis start to appear by the end of the first decade. The adolescent growth spurt fails to occur and hepatic, endocrine and cardiac complications of iron overloading produce a variety of complications, including diabetes, hypoparathyroidism, adrenal insufficiency and progressive liver failure. Secondary sexual development is delayed, or does not occur at all. The short stature and lack of sexual development may lead to serious psychological problems. By far the commonest cause of death, which usually occurs towards the end of the second or early in the third decade, is progressive cardiac damage. Ultimately, these patients die either in protracted cardiac failure or suddenly due to an acute arrhythmia, often precipitated by infection.

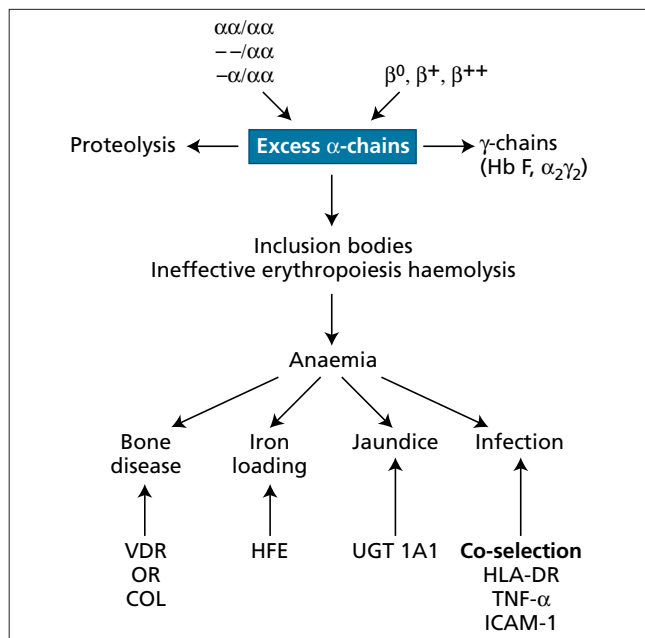
The clinical picture in children who are inadequately transfused is quite different. Early childhood is interspersed with a series of distressing complications and the rates of growth and development are retarded. There is progressive splenomegaly, and hypersplenism may cause a worsening of the anaemia, sometimes associated with thrombocytopenia and a bleeding


Figure 6.5 The modification of the β-thalassaemia phenotype. The different levels of genetic modification are shown; primary modifiers involve different β-thalassaemia alleles, secondary modifiers involve the reduction of globin chain imbalance due to either increased HbF production or the co-inheritance of α-thalassaemia, and the tertiary modifiers affect the different complications of the disease. Figure 6.6 The skull in β-thalassaemia.

tendency. Because of bone marrow expansion, there may be deformities of the skull with marked bossing and overgrowth of the zygomata, giving rise to the classical 'mongoloid facies' of β-thalassaemia. These signs are associated with radiological changes, which include a lacy, trabecular pattern of the long bones and phalanges and a typical 'hair on end' appearance of the skull (Figure 6.6).

These bone changes may be accompanied by recurrent fractures. There is increased proneness to infection that may cause a catastrophic drop in the haemoglobin level. Because of the massive marrow expansion resulting from the chronic anaemia, these children are hypermetabolic and develop intermittent fevers and fail to thrive. They have increased requirements for folic acid and may become acutely folate depleted with worsening of their anaemia. Because of the increased turnover of red cell precursors, hyperuricaemia and secondary gout occur occasionally. There is a bleeding tendency which, although partly due to thrombocytopenia secondary to hypersplenism, may also be exacerbated by liver damage. Because of the deformities of the skull, there may be distressing dental complications, with poorly

formed teeth and malocclusion, and inadequate drainage of the sinuses and middle ear may lead to chronic sinus infection and deafness. If these children survive to puberty, they develop the same complications of iron loading as the well-transfused patients. In this case, iron accumulation results from an increased rate of gastrointestinal absorption as well as the inadequate transfusion regimen.

Children who are adequately transfused and chelated may grow and develop normally although, presumably reflecting the extreme sensitivity of the endocrine system to even mild iron overload, there may still be problems with growth, sexual maturation and osteoporosis. Regardless of how they are managed they are prone to blood-borne infection, notably hepatitis B and C, HIV and malaria.

Haematological changes

Haemoglobin values on presentation range from 2 to 8 g/dL. The red cells show marked hypochromia and variation in shape and size, and many hypochromic macrocytes and misshapen microcytes, some of which are mere fragments of cells (Figure 6.7). There is moderate anisochromia and basophilic stippling. There are always some nucleated red cells in the peripheral blood, after splenectomy they appear in large numbers. There is a slight elevation in the reticulocyte count. The white cell and platelet counts are normal unless there is hypersplenism. The bone marrow shows marked erythroid hyperplasia with a myeloid–erythroid (M/E) ratio of unity or less. Many of the red cell precursors show ragged inclusions after incubation of the marrow with methyl violet; similar inclusions are found in the peripheral blood cells after splenectomy.

The bilirubin level is usually elevated and haptoglobins are absent. The ^{51}Cr-labelled red cell survival is shortened. The serum iron level rises progressively and most transfusion-dependent children have a totally saturated iron-binding capacity. This change is mirrored by a high plasma ferritin level, and liver
Figure 6.7 The peripheral blood appearances in β-thalassaemia (×750).

biopsies show an increase of iron in both the reticuloendothelial and parenchymal cells.

Haemoglobin changes

The HbF level is always elevated and it is heterogeneously distributed among the red cells. In β^0-thalassaemia, there is no HbA, whereas in β^+-thalassaemia the level of HbF ranges from 30% to 90%. The HbA_2 level is of no diagnostic value, reflecting the heterogeneity of the cell populations in the blood; those with high levels of HbF have low levels of HbA_2, whereas those which contain predominantly HbA have much higher levels; the measured level of HbA_2 represents an average value that is often in the normal range.

Heterozygous β-thalassaemia

Carriers for β-thalassaemia are usually symptom free except in periods of stress such as pregnancy, when they may become more anaemic. Splenomegaly is rare. Haemoglobin values are in the 9–11 g/dL range. The red cells show hypochromia and microcytosis with characteristically low values. The reticulocyte count is normal. The bone marrow shows moderate erythroid hyperplasia.

The characteristic finding is an elevated HbA_2 level in the 4–6% range. There is a slight elevation of HbF in the 1–3% range in about 50% of cases.

β-Thalassaemia in association with haemoglobin variants

In many populations, because there is a high incidence of β-thalassaemia and various haemoglobin variants; it is quite common for an individual to inherit a β-thalassaemia gene from one parent and a gene for a structural haemoglobin variant from the other. Although numerous interactions of this type have been described, only three are common: sickle cell β-thalassaemia, HbC β-thalassaemia and HbE β-thalassaemia.

The clinical manifestations of *sickle cell β-thalassaemia* vary from race to race. In African populations, extremely mild forms of β^+-thalassaemia occur, which, when they interact with the sickle cell gene, produce a condition characterized by mild anaemia and few sickling crises. The condition is compatible with normal survival and is often ascertained by chance haematological examination. On the other hand, in Mediterranean populations, and less commonly in Africans, individuals may inherit a β^0- or severe β^+-thalassaemia determinant. The phenotype of sickle cell β^0 or severe β^+-thalassaemia is often indistinguishable from sickle cell anaemia (see Chapter 7). The diagnosis can be confirmed by haemoglobin electrophoresis, which in sickle cell β^+-thalassaemia shows HbS together with 5–30% HbA and an elevated HbA_2 value. In sickle cell β^0-thalassaemia, the haemoglobin consists of HbS with an elevated level of HbF and HbA_2. One parent has the sickle cell trait and the other has the β-thalassaemia trait.

HbC β-thalassaemia is restricted to West Africans and some North African and southern Mediterranean populations. It is characterized by a mild haemolytic anaemia associated with splenomegaly. The peripheral blood film shows numerous target cells and thalassaemic red cell changes with a moderately elevated reticulocyte count. Haemoglobin electrophoresis shows a preponderance of HbC. The diagnosis is confirmed by finding the HbC trait in one parent and the β-thalassaemia trait in the other.

HbE β-thalassaemia is the commonest severe form of thalassaemia in South-East Asia and parts of the Indian subcontinent. HbE is inefficiently synthesized and hence, when it is inherited together with β^0-thalassaemia, there is a marked deficiency of β-chain production. The clinical and haematological changes are variable. There is usually severe anaemia and splenomegaly with typical thalassaemic bone changes. Although not always transfusion dependent, haemoglobin values are in the 4–9 g/dL range, with an average of 6–7 g/dL. There are thalassaemic red cell changes and the bone marrow shows marked erythroid hyperplasia with α-chain inclusions in many of the red cell precursors.

Although very little is known about the natural history of this disorder, it is clear that in many parts of South-East Asia and India it causes a very high mortality in early life. Complications include a marked proneness to infection, secondary hypersplenism, progressive iron loading, neurological lesions due to masses of extramedullary erythropoietic tissue extending in from the inner tables of the skull or vertebrae, folate deficiency, leg ulcers and recurrent pathological fractures. On the other hand, some patients grow and develop normally with few complications.

The diagnosis is confirmed by finding only HbE and HbF on haemoglobin electrophoresis and by demonstrating the HbE trait in one parent and the β-thalassaemia trait in the other. In cases of HbE β^+-thalassaemia, small quantities of HbA are present.

Variant forms of β-thalassaemia

Although most β-thalassaemia heterozygotes have HbA$_2$ levels in the 4–5% range, there is a subgroup with higher levels, in excess of 8% of the total haemoglobin. This condition results from small deletions which involve the 5′ end of the β-globin gene including its promoter region. Otherwise, the clinical and haematological pictures are identical to the common forms of β-thalassaemia. Some β-thalassaemia heterozygotes have normal HbA$_2$ levels. In most cases, this is due to the co-inheritance of δ-thalassaemia. There is an extremely mild form of β-thalassaemia that is completely silent in heterozygotes and is only identified when it is co-inherited with a common form of β-thalassaemia.

β-Thalassaemia occasionally follows a dominant pattern of inheritance, that is it is symptomatic in heterozygotes. The clinical picture is characterized by a moderate degree of anaemia and splenomegaly with marked thalassaemic changes of the red cells, and ineffective erythropoiesis with intracellular inclusion bodies. Although not usually transfusion dependent, such individuals load iron and may develop liver or endocrine damage. As described earlier most of these patients have mutations involving exon 3 of the β-globin gene.

δβ-Thalassaemias

Classification and molecular genetics

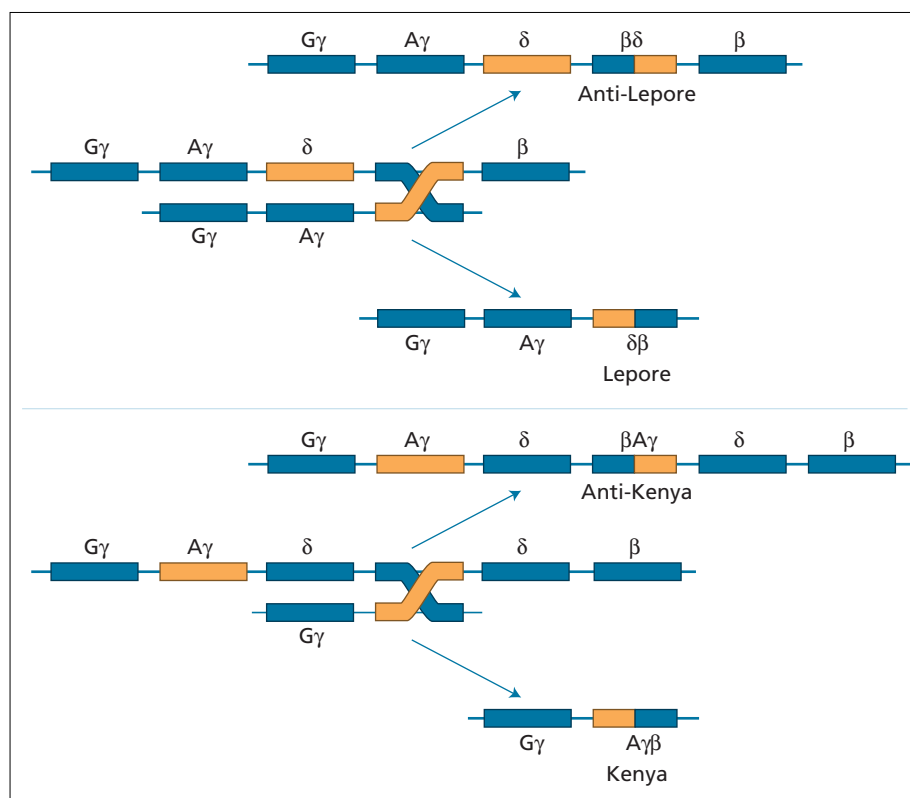
These disorders are much less common than the β-thalassaemias. In some cases, they result from deletions of the β- and δ-globin genes (Figure 6.8), whereas in others there appears to have been
Figure 6.8 The deletions that underlie δβ-thalassaemia and hereditary persistence of fetal haemoglobin. The upper arrows represent DNase I-hypersensitive sites (from Weatherall and Clegg 2001 with permission).


Figure 6.9 The mechanisms for the production of haemoglobin Lepore and related variants.

mispaired synapsis and unequal crossing over between the δ- and β-globin gene loci, with the production of δβ fusion genes (Figure 6.9). The latter produce δβ fusion chains, which combine with α-chains to form haemoglobin variants called the *Lepore haemoglobins* (Lepore was the family name of the first patient to be recognized with this disorder). Hence it is usual to classify this group of conditions into the $(\delta\beta)^0$ *thalassaemias* and the *Hb Lepore $(\delta\beta)^+$ thalassaemias*.

The $(\delta\beta)^0$ thalassaemias result from different length deletions of the β-globin gene cluster. In some cases these leave both the $^G\gamma$ and $^A\gamma$ genes intact, whereas in others the $^A\gamma$ genes are also involved, leaving only the $^G\gamma$ genes. Hence the disorders are called $(\delta\beta)^0$ or $(^A\gamma\delta\beta)^0$ thalassaemias (Figure 6.8). The deletions leave the γ-globin genes active in adult life and, although their output is not as high as in the fetus, it is usually sufficient to make these conditions relatively mild. The Lepore haemoglobins are also heterogeneous, depending on the precise site of the abnormal crossover event and hence the structure of the δβ fusion variant (Figure 6.9). γ-Chain production is not as high in these conditions and hence there is a more severe clinical phenotype.

Clinical and haematological changes

In homozygous δβ-thalassaemia there is mild anaemia and splenomegaly, with haemoglobin values of 8–10 g/dL and 100% HbF. Heterozygotes have thalassaemic blood pictures, elevated levels of HbF of 5–20% and normal levels of HbA_2. Homozygotes for Hb Lepore are usually similar to those for β-thalassaemia, although the disorder may be milder and non-transfusion dependent; the haemoglobin consists of F and Lepore only. Carriers have thalassaemic blood pictures associated with about 5–15% Hb Lepore.

Hereditary persistence of fetal haemoglobin

This is a heterogeneous group of conditions in which there is persistent fetal haemoglobin production in adult life in the absence of major haematological abnormalities. Although of little clinical importance, it may modify the phenotype of the β-haemoglobinopathies.

Some forms of hereditary persistence of fetal haemoglobin (HPFH) result from long deletions of the β-globin gene cluster, similar to those that cause δβ-thalassaemia (Figure 6.8). Homozygotes, with 100% HbF, have a mild thalassaemia-like blood picture and are mildly polycythaemic, reflecting the high oxygen affinity of HbF. Heterozygotes have no haematological abnormalities but have 20–30% HbF.

Another type of HPFH results from point mutations in the promoter regions upstream from either the $^G\gamma$ or $^A\gamma$-globin genes, which allow the γ-globin genes to be active in adult life; the linked β-globin genes also remain active. Hence they are called $^G\gamma\beta^+$ and $^A\gamma\beta^+$ HPFH. Heterozygotes have elevated levels of HbF

in the 10–15% range; this consists either of $^G\gamma$ or $^A\gamma$ HbF, depending on the particular mutation involved.

There is a third type of HPFH in which there are low levels of HbF, in the 1–5% range. It was first recognized in Switzerland and is sometimes called Swiss HPFH, although it is now clear that it is a heterogeneous condition. Genetic evidence suggests that the determinant is, at least in some cases, unlinked to the β-globin gene cluster, in one case on chromosome 6. The importance of this type of HPFH is that, when inherited with β-thalassaemia or sickle cell anaemia, it causes an unusually high level of HbF production and hence reduces the severity of the phenotype.

εγδβ-Thalassaemias

These rare conditions result from long deletions of the β-globin gene cluster, which involve the β-globin LCR (Figure 6.8). There is no output from the globin genes of the cluster. Clearly, the homozygous state would not be compatible with survival. Heterozygotes have severe haemolytic disease of the newborn, with anaemia and hyperbilirubinaemia. If they survive the neonatal period, they grow and develop normally; in adult life they have the haematological picture of heterozygous β-thalassaemia, with mild anaemia, hypochromic microcytic red cells and a haemoglobin pattern of normal HbA$_2$ β-thalassaemia.

α-Thalassaemias

Distribution

The α-thalassaemias occur widely throughout sub-Saharan Africa, the Mediterranean region, the Middle East, the Indian subcontinent and South-East Asia in a line stretching from southern China through Thailand, the Malay peninsula and Indonesia, to the Pacific island populations.

Classification and inheritance

Because both HbA and HbF have α-chains, genetic disorders of α-chain synthesis result in defective fetal and adult haemoglobin production. In the fetus, a deficiency of α-chains leads to the production of excess γ-chains, which form γ$_4$-tetramers, or Hb Bart's; in adults, excess of β-chains form β$_4$-tetramers or HbH.

There are two α-globin genes on chromosome 16 (Figure 6.1) and hence there are two main types of α-thalassaemia: α^0-thalassaemia, in which both genes are inactivated (–/αα), and α$^+$-thalassaemia, in which only one of the pair is affected (–α/αα). There are two important clinical disorders caused by α-thalassaemia, the Hb Bart's hydrops syndrome and HbH disease. The former results from the homozygous inheritance of α^0-thalassaemia (–/–). HbH disease usually results from the co-inheritance of both α^0 and α$^+$-thalassaemia (–α/–). These interactions are summarized in Figure 6.10.
Figure 6.10 The genetics of α-thalassaemia.

Molecular pathology

The α^0-thalassaemias result from deletions of both α-globin genes. There are many different-sized deletions; however, one is particularly common in South-East Asia and another occurs mainly in Mediterranean populations (Figure 6.11). α^0-Thalassaemia may also result from deletions about 40 kb upstream from the α-globin gene cluster, which involve the HS40 region.

The molecular basis of the α$^+$-thalassaemias is more complicated. In some cases, they result from deletions that remove one of the linked pairs of α-globin genes, leaving the other one intact (–α/αα). In others, both α-globin genes are intact but one of them has a mutation that either partially or completely inactivates it (α^{T}α/αα).

Each α-gene lies within a boundary of homology approximately 4 kb long. These regions were generated by a duplication, and subsequently were subdivided, presumably by insertions and deletions, to give three homologous subsegments that are
Figure 6.11 The α-globin gene cluster deletions that underlie α⁰-thalassaemia (from Weatherall and Clegg 2001 with permission).
Figure 6.12 The molecular mechanisms that underlie the deletion forms of α⁺-thalassaemia. (a) Normal cluster showing X, Y and Z homology boxes; (b) 3.7-kb deletion; (c) 4.2-kb deletion.

designated X, Y and Z (Figure 6.12). The duplicated Z boxes are 3.7 kb apart and the X boxes are 4.2 kb apart. Misalignment and reciprocal crossover between these segments at meiosis produces a chromosome with either single ($-\alpha$) or triplicated ($\alpha\alpha\alpha$) α-globin genes. If the crossover occurs between the Z boxes, 3.7 kb of DNA is lost, an event that is described as a *right-ward deletion*, written as $-\alpha^{3.7}$. A crossover between the two X boxes deletes 4.2 kb, the *leftward deletion*, $-\alpha^{4.2}$. There are at least three different subtypes of the 3.7-kb deletion.

In the non-deletion forms of α-thalassaemia, the α-globin genes are intact but one of them is inactivated by a mutation, many of which are similar to those that cause β-thalassaemia.

One particularly common form, found in South-East Asia, results from a single-base change in the chain termination codon UAA, which changes to CAA. The latter is the codeword for the amino acid glutamine. Hence, when the ribosomes reach this point, instead of the chain terminating, mRNA that is not normally transcribed is read through until another stop codon is reached. Thus, an elongated α-globin chain is produced, which is synthesized at a reduced rate. The resulting variant is called *Hb Constant Spring*. Because the termination codon can change in other ways, there is a family of variants of this kind.

Genotype–phenotype relationships

As the Hb Bart's hydrops syndrome follows the homozygous inheritance of α^0-thalassaemia, this condition occurs only in populations in which α^0-thalassaemia is common, notably those of South-East Asia and the Mediterranean islands. Similarly, because most forms of HbH disease are due to the co-inheritance of α^0- and α^+-thalassaemia, it is also restricted mainly to these regions. In South-East Asia, it may be due to the inheritance of α^0- and α^+-thalassaemia, or α^0-thalassaemia and Hb Constant Spring.

The homozygous states for the non-deletion forms of α^+-thalassaemia often have a more severe phenotype than those for the deletion forms and may result in HbH disease. Those homozygous for $(-\alpha/-\alpha)$ deletion forms have a mild hypochromic anaemia, very similar to the heterozygous state for α^0-thalassaemia; the results of having only two out of the normal four α-genes seem to be the same whether the two genes are missing from the *same* chromosome or *opposite pairs* of homologous chromosomes.

Pathophysiology

The pathophysiology of α-thalassaemia is different to that of β-thalassaemia. A deficiency of α-chains leads to the production of excess γ- or β-chains, which form Hb Bart's and HbH respectively. These soluble tetramers do not precipitate extensively in the bone marrow and hence erythropoiesis is more effective than in β-thalassaemia. However, HbH is unstable and precipitates in red cells as they age. The inclusion bodies produced in this way are trapped in the spleen and other parts of the microcirculation, leading, together with membrane damage mediated by haem and iron, to a shortened red cell survival. Furthermore, both Hb Bart's and HbH have a very high oxygen affinity and their oxygen dissociation curves resemble myoglobin. Thus, the severe forms of α-thalassaemia are due to defective haemoglobin production, the synthesis of homotetramers that are physiologically useless and a haemolytic component.

The haemoglobin Bart's hydrops syndrome

This is a common cause of fetal loss throughout South-East Asia and is also encountered in the Mediterranean region. There is no production of α-chains and hence neither fetal nor adult haemoglobin. The fetus is usually stillborn between 28 and 40 weeks, or, if liveborn, takes a few gasping respirations and then expires within the first hour after birth. Affected neonates show the typical picture of hydrops fetalis, with gross pallor, generalized oedema and massive hepatosplenomegaly. There is an increased frequency of congenital abnormalities and a very large friable placenta. All these findings are due to severe intrauterine anaemia. The haemoglobin is in the 6–8 g/dL range and there are gross thalassaemic changes of the red cells, with many nucleated forms in the blood. The haemoglobin consists of approximately 80% Hb Bart's and 20% Hb Portland ($\zeta_2\gamma_2$). It is believed that these infants survive to term because they continue to produce embryonic haemoglobin. Apart from fetal death, this syndrome is characterized by a high incidence of toxaemia of pregnancy and obstetric complications due to the large placenta.

Haemoglobin H disease

This condition is characterized by a variable degree of anaemia and splenomegaly but it is unusual to find severe thalassaemic bone changes or growth retardation. Patients usually survive into adult life, although the course may be interspersed with severe episodes of haemolysis associated with infection or worsening of the anaemia due to progressive hypersplenism. In addition, oxidant drugs may increase the rate of precipitation of HbH and exacerbate the anaemia. Haemoglobin values range from 7 to 10 g/dL and the blood film shows typical thalassaemic changes. There is a moderate reticulocytosis and, on incubation of the red cells with brilliant cresyl blue, numerous inclusion bodies are generated by precipitation of the HbH under the redox action of the dye. After splenectomy large, preformed inclusions can be demonstrated on incubation of blood with methyl violet. Haemoglobin analysis reveals 5–40% HbH, together with HbA and a normal or reduced level of HbA_2.

α-Thalassaemia traits

α^0-Thalassaemia trait is characterized by a mild hypochromic anaemia with red cell indices similar to those of the β-thalassaemia trait; the HbA_2 level is normal. There are no diagnostic tests with which to identify this condition with certainty except DNA analysis. Deletional α^+-thalassaemia carriers have near-normal haematological findings. The heterozygous states for the non-deletion forms of α^+-thalassaemia are sometimes associated with very mild hypochromic anaemia; the type associated with Hb Constant Spring can be identified by the presence of trace amounts of the variant on haemoglobin electrophoresis at an alkaline pH.

α^0-Thalassaemia carriers can be identified with more certainty in the neonatal period, when they have 5–10% Hb Bart's, which disappears over the first few months of life and is not replaced by HbH. Some α^+-thalassaemia carriers have slightly increased levels of Hb Bart's, in the 1–3% range, but its absence does not exclude the diagnosis.

Other forms of α-thalassaemia

There are several other forms of α-thalassaemia that are completely unrelated in their pathogenesis and distribution through the conditions described in the previous sections. They comprise the α-thalassaemia mental retardation syndromes and the association of α-thalassaemia with myelodysplasia.

There are two forms of α-thalassaemia associated with mental retardation, one encoded on chromosome 16 (ATR-16), the other on the X chromosome (ATRX). ATR-16 results from the loss of approximately two megabases from the subtelomeric end of the short arm of chromosome 16, as a result of either simple deletion or chromosomal translocations. Affected children usually have a relatively mild degree of mental retardation and no dysmorphic features. On the other hand, ATR-X, which because of its mode of inheritance affects boys, is associated with widespread dysmorphic features and severe mental retardation. It results from many different mutations of the *ATR-X* gene, the product of which has many features in common with DNA helicases, transcription factors that are involved in the modelling of chromatin, and gene regulation. The product of this gene appears to play an important role in the transcription of the α-globin genes and, undoubtedly, many other genes during early development.

An α-thalassaemic phenotype is also found in association with forms of myelodysplasia in elderly patients. Recently, it has been found that this condition is also caused by mutations of the *ATR-X* gene. The blood films of such patients show dimorphic features, with populations of red cells containing HbH inclusion bodies and a variable level of HbH in peripheral blood. The rela-

tionship of the mutations of *ATR-X* to the neoplastic phenotype remains to be determined.

Thalassaemia intermedia

Definition and molecular pathology

The term *thalassaemia intermedia* is used to describe patients with the clinical picture of thalassaemia which, although not transfusion dependent, is associated with a much more severe degree of anaemia than is found in carriers for α- or β-thalassaemia. Many conditions follow this clinical course, e.g. HbC or HbE thalassaemia, the δβ-thalassaemias, and the wide variety of disorders that result from the interactions of the different β- and δβ-thalassaemia determinants (Table 6.3). However, many children with thalassaemia intermedia have parents who are typical β-thalassaemia carriers. The mechanisms that underlie the phenotypic diversity of this condition were discussed earlier.

Clinical and haematological changes

At one end of the spectrum are individuals who, except for mild anaemia, are symptom free. At the other, there are patients who have haemoglobin values in the 5–7 g/dL range and who develop marked splenomegaly, severe skeletal deformities due to expansion of bone marrow, and, as they get older, become heavily iron loaded because of increased intestinal absorption of iron. Recurrent leg ulceration, arthritis, folate deficiency, symptoms due to extramedullary haemopoietic tumour masses in the chest and skull, gallstones and a marked proneness to infection are particularly characteristic of this group of thalassaemias. Because

Heterozygous β-thalassaemia with triplicated α-chain genes (ααα)

Dominant forms of β-thalassaemia

Interactions of β and $(\delta\beta)^+$ or $(\delta\beta)^0$-thalassaemia

of the heterogeneity of these disorders, it is possible to determine the course that is likely to evolve in an individual patient only by following the patient very carefully from early childhood. The haemoglobin constitution of the intermediate forms of β-thalassaemia is similar to that found in the major forms.

Prevention and treatment

Thalassaemia produces a severe public health problem and a serious drain on medical resources in many populations. Apart from marrow transplantation, there is no definitive treatment, and most countries in which the disease is common are putting a major effort into programmes for its prevention.

Prevention

There are two major routes to the prevention of the thalassaemias. As the carrier states for the β-thalassaemias can be easily recognized, it is possible to screen populations and provide genetic counselling about the choice of marriage partners. There is very little information about the effect of this approach on the frequency of births of affected babies, and such that is available is not encouraging. Hence, most countries are developing screening programmes at antenatal clinics. When heterozygous carrier mothers are found, their husbands are tested and, if they are also carriers, the couple are offered the possibility of prenatal diagnosis and termination of pregnancies carrying fetuses with severe forms of thalassaemia.

Prenatal diagnosis should be offered only to couples at risk for having children with severe disease. Termination of pregnancies at risk for milder forms of thalassaemia is undertaken, but should be considered only after very careful counselling of the parents; some children with intermediate forms of thalassaemia are symptom free and develop normally; others have more severe anaemia and bone deformity.

Prenatal diagnosis of thalassaemia can be made by globin-chain synthesis studies of fetal blood samples obtained by fetoscopy at 18–20 weeks' gestation, or by fetal DNA analysis on amniotic fluid cells obtained by amniocentesis earlier in the second trimester. These approaches have now been largely replaced by direct analysis of fetal DNA obtained by chorionic villus sampling between the 9th and 13th weeks of gestation.

Low error rates, less than 1%, have been reported from most laboratories using fetal DNA analysis. Potential pitfalls include maternal contamination of fetal DNA, non-paternity and technical problems with DNA analysis. Details of the DNA technology used in prenatal diagnosis are given in the Selected bibliography at the end of this chapter.

Bone marrow transplantation

The place of marrow transplantation for the treatment of β-thalassaemia is now much clearer. In centres with broad experience of the procedure, and if it is carried out within the first few years of life and before there is iron loading (provided that there is a good HLA match for the donor), the success rate appears to be close to 90%. It is lower if there is already iron loading of the liver or if the transplant is carried out in older patients. The main complications are severe infection during the period of transplantation and either acute or chronic graft-versus-host disease. So far, after over 15 years of surveillance, there have been no reports of secondary bone marrow malignancies in children treated in this way. A number of approaches are being tried to overcome the problem of lack of matched donors. In a few cases, HLA typing has been carried out after *in vitro* fertilization to attempt to obtain an HLA-matching sibling, although there is still considerable ethical concern about this approach. It is still too early to determine the role of haemopoietic stem cell therapy for the treatment of this disease.

Symptomatic treatment

The symptomatic management of severe β-thalassaemia involves regular blood transfusion, the judicious use of splenectomy if hypersplenism develops, and the administration of chelating agents to attempt to deal with the problem of iron overload from regular blood transfusion. When the diagnosis of severe β-thalassaemia is suspected during the first year of life, the infant should be followed for several weeks to make sure that the haemoglobin is falling to a level at which regular transfusion will be necessary, particularly important if he or she has presented with infection that may cause the haemoglobin level to fall. It is difficult to be dogmatic about exactly when transfusions should be started, but if the infant is severely anaemic and is feeding poorly or otherwise failing to thrive, transfusion will almost certainly be necessary. The object is to maintain the pre-transfusion haemoglobin level above 9 g/dL, and this usually requires transfusion every 4 weeks. Either washed or frozen red cells should be used, but whole blood should be avoided because of the danger of sensitization to serum or white cell components. A full blood group genotype should be obtained before the first transfusion. A careful check on the pre- and post-transfusion haemoglobin level should be kept and the transfusion requirements carefully plotted. It is vital that body iron status is assessed regularly in these children. Although this may be achieved in part by serum ferritin estimations, there is good evidence that this does not provide a completely accurate reflection of body iron, which is much better assessed by measuring the hepatic iron concentration. Whenever possible, these children should undergo regular liver biopsies, ideally annually but at least every 2–3 years; in experienced hands, this has a very low morbidity and provides a much better guide to the effectiveness of iron chelation therapy. Non-invasive approaches to assessing body iron load are discussed in Chapter 4.

The gold standard for iron chelation therapy is desferrioxamine. There is extensive evidence that if this drug is given at adequate doses, and if compliance is satisfactory, patients may be maintained indefinitely at safe body iron loads and may grow and develop normally. At present, it is recommended that the

drug is started at a dose of 25–35 mg/kg, given by an 8- to 12-h subcutaneous infusion overnight, approximately 1 year after the start of regular transfusion. The usual dose in older children and adults is 40 mg/kg. Patients should receive up to 200 mg of ascorbate on the day of infusion, approximately 30 min before it is started. Intolerance to desferrioxamine is extremely rare but, particularly at high doses, there may be ocular changes, including cataracts and retinal damage, or acoustic nerve impairment. Other complications, particularly if the drug is given to patients with low body iron levels, include reduction in linear growth, sometimes associated with evidence of cartilaginous dysplasia of the long bones and spine. Infection with *Yersinia enterocolitica* is a rare but well-documented complication. But these complications are rare in children who are kept under careful surveillance and the main problem posed by desferrioxamine is non-compliance; much can be done by intensive support by doctors, dedicated nursing staff and families. However, for this reason the search continues for an effective oral chelating agent. The place of these agents at present for the prevention and management of iron overload is discussed in Chapter 4.

If there is a marked increase in blood requirement, hypersplenism should be suspected. Any thalassaemic child with an easily palpable spleen probably has some degree of hypersplenism. Splenectomy should be carried out as late as is feasible and, if possible, not in the first 5 years because the incidence of post-splenectomy infection seems to be particularly high in early childhood. Apart from increased transfusion requirements, the presence of neutropenia or thrombocytopenia is a useful guide to the presence of hypersplenism. Pneumococcal vaccine should be administered before surgery, and after the operation children should be maintained on prophylactic penicillin indefinitely and the parents warned about the danger of overwhelming infection. Because of this risk it is becoming customary to also immunize these children against *Streptococcus pneumoniae* and *Haemophilus influenzae*.

Well-transfused children maintained on a good diet do not usually develop important vitamin deficiency states. However, folic acid deficiency occurs in poorly transfused children or in those with thalassaemia intermedia, and it is probably better to maintain these patients on regular folate supplements. In those who develop iron loading with end-organ failure, endocrine replacement therapy may be necessary to improve growth and secondary sexual development and, if necessary, to treat diabetes mellitus. These children require expert endocrinological assessment before treatment. Because the occurrence of osteoporosis is also likely to be due to hypogonadism, similar precautions should be followed. In those who develop cardiac abnormalities, intensive chelation therapy may improve cardiac function.

However well children are managed there is a serious risk of blood-borne infection, particularly hepatitis B and C, HIV and, in tropical countries, malaria. Much can be achieved by adequate screening of blood products, but the possibility of these complications should be constantly borne in mind and viral infec-tions treated with appropriate antiviral agents. In some tropical countries, particularly where screening of the blood is difficult, prophylactic antimalarial therapy is given after transfusion.

The role at present for more experimental forms of therapy, notably attempts to reactivate higher levels of fetal haemoglobin production, which, except in a few rare cases, have not been successful for the treatment of thalassaemia, is discussed in Chapter 7, and the current status of research into somatic gene therapy is reviewed in Chapter 26.

Structural haemoglobin variants related to thalassaemia

The unstable haemoglobin disorders

The unstable haemoglobin disorders are a rare group of inherited haemolytic anaemias that result from structural changes in the haemoglobin molecule, which cause its intracellular precipitation with the formation of Heinz bodies. Their true incidence is not known and there have been several well-documented instances in which patients with one of these variants have had no affected relatives, suggesting that they have arisen by a new mutation.

Molecular pathology and pathogenesis
Most of the unstable haemoglobins result from single amino acid substitutions or small deletions. For example, substitutions in or around the haem pocket can disrupt its anatomy and allow in water, with subsequent oxidative damage to haem, which leads to precipitation of haemoglobin. Some substitutions, such as those involving proline residues, cause a marked disturbance of the secondary structure of globin chains. A few variants result from deletions of either single amino acids or several residues. For example, in Hb Gun Hill, five amino acids are missing, including the haem binding site. As the unstable haemoglobins precipitate in the red cells or their precursors, they produce intracellular inclusions, or Heinz bodies, which, together with oxidant damage to their membranes, make the cells more rigid and hence cause their premature destruction in the microcirculation.

Clinical features
All these conditions are characterized by a haemolytic anaemia of varying severity, and splenomegaly. There may be a history of the passage of dark urine, particularly during episodes of infection. Like all chronic haemolytic anaemias, there is an increased incidence of pigment gallstones with their associated complications. The condition may become worse during periods of intercurrent infection and, in the more severe forms, such episodes are associated with life-threatening anaemia. There is a high risk of haemolytic episodes after the administration of oxidant drugs. Apart from intermittent icterus and splenomegaly, there are no characteristic physical findings.

Laboratory diagnosis

The peripheral blood film shows typical features of haemolysis but the red cell morphology may be normal. Occasionally, there is mild hypochromia and microcytosis. Heinz bodies are present in the peripheral blood after splenectomy. The most characteristic feature of the unstable haemoglobins is their heat instability. If a dilute haemoglobin solution is heated at 50°C for 15 min, the unstable haemoglobins precipitate as a dense cloud. A similar effect can be induced by isopropanalol. Some of these variants can be seen on haemoglobin electrophoresis but others, because they result from a neutral amino acid substitution, produce no electrophoretic changes and can be demonstrated only by the heat precipitation test.

Treatment

Because these haemoglobins are so rare there has been very little experience of the effects of splenectomy. From the information that is available, and from the author's personal experience, it appears that if a child has had several life-threatening episodes of anaemia or is running a steady-state haemoglobin level that is impairing development or well-being, splenectomy should be undertaken.

High-oxygen-affinity haemoglobin variants

We saw earlier how homozygotes for hereditary persistence of HbF are mildly polycythaemic because of the high oxygen affinity of fetal haemoglobin. There is a family of rare haemoglobin variants that produce the same effect.

Molecular pathology

The high-oxygen-affinity haemoglobin variants result from single amino acid substitutions at critical parts of the haemoglobin molecule which are involved in the configurational changes that underlie haem–haem interaction and the production of a sigmoid oxygen dissociation curve at the junctions between the α- and β-subunits. Others involve the amino acids that are involved with the binding of 2,3-biphosphoglycerate (2,3-BPG) to haemoglobin. As mentioned earlier, increasing concentrations of 2,3-BPG tend to push the oxygen dissociation curve to the right; fetal haemoglobin has a high oxygen affinity (left-shifted curve) because it cannot interact with 2,3-DPG; mutations of the DPG binding sites have a similar effect.

All the high oxygen affinity variants have a left-shifted oxygen dissociation curve with a reduced P_{50}. Thus, the haemoglobin holds on to oxygen more avidly than normal. This leads to tissue hypoxia, which, in turn, causes an increased output of erythropoietin and an elevated red cell mass.

Clinical features

Most affected persons are completely healthy and are identified only when a routine haematological examination shows an unusually high haemoglobin level or packed cell volume.

There have been one or two reports of arterial or venous occlusive disease. There is no splenomegaly and, apart from a raised red cell mass, there are no associated haematological findings. Although it might be expected that a high-oxygen-affinity haemoglobin would cause defective oxygenation of the fetus, none of the reported families has had a history of frequent stillbirths.

Diagnosis

The condition should be suspected in any patient with a pure red cell polycythaemia associated with a left-shifted oxygen dissociation curve. The diagnosis can be confirmed by haemoglobin analysis.

Treatment

In asymptomatic persons, no treatment is necessary. The difficulty arises if there is associated vascular disease with symptoms of coronary or cerebral artery insufficiency. There is insufficient published information to determine how this complication should be managed. As these patients require a high haemoglobin level for oxygen transport, venesection should be carried out with great caution.

Low-oxygen-affinity haemoglobin variants

At least six haemoglobin variants with reduced oxygen affinity have been reported. The first to be described, Hb Kansas, was found in a mother and son with unexplained cyanosis. The subjects were asymptomatic and had normal haemoglobin levels without any evidence of haemolysis. Like many of the high-affinity variants, the amino acid substitution in this variant was at the interface between the α- and β-globin chains. For reasons that are not clear, some substitutions in this region give rise to variants with a relatively low oxygen affinity. This condition should be thought of in any patient with an unexplained congenital cyanosis.

Congenital methaemoglobinaemia due to haemoglobin variants

Several α- and β-globin variants associated with methaemoglobinaemia have been discovered. These disorders, unlike the genetic methaemoglobinaemias due to enzyme defects, follow a dominant pattern of inheritance.

Sickle cell disease

Ashutosh Lal and Elliott P Vichinsky

7

Introduction

Sickle cell disease is an inherited chronic haemolytic anaemia whose clinical manifestations arise from the tendency of the haemoglobin (HbS or sickle haemoglobin) to polymerize and deform red blood cells into the characteristic sickle shape. This property is due to a single nucleotide change in the β-globin gene leading to substitution of valine for glutamic acid at position 6 of the β-globin chain ($\beta^{6glu \rightarrow val}$ or β^s). The homozygous state (HbSS or sickle cell anaemia) is the most common form of sickle cell disease, but interaction of HbS with thalassaemia and certain variant haemoglobins also leads to sickling. The term sickle cell disease (SCD) is used to denote all entities associated with sickling of haemoglobin within red cells (Table 7.1).

Geographic distribution of sickle mutation

Several distinct β-globin gene haplotypes are associated with the sickle mutation, and their distribution provides evidence for origin of the mutation in several locations within Africa (the Senegal, Benin and Bantu haplotypes) and Asia (the Arab–Indian haplotype). The sickle trait bestows survival benefit in areas endemic for falciparum malaria, and the distribution of SCD historically paralleled this disease. The sickle haemoglobin-containing red cells inhibit proliferation of *Plasmodium falciparum*, and are more likely to become deformed and removed

from the circulation. In recent times, the dissemination of the sickle mutation in different areas of the world took place from the movement of populations via trade routes and the slave trade (Table 7.2). Prevalence of SCD varies tremendously among ethnic and tribal groups within a geographic area. The disease is observed occasionally among the white population –10% of patients with HbSS identified by the California newborn screening programme are not of African descent.

Pathophysiology

Molecular basis of sickling

Deoxygenation of HbS leads to a conformational change that exposes a hydrophobic patch on the surface of the β^s-globin chain at the site of β^6 valine (Figure 7.1). Binding of this site to a complementary hydrophobic site on a β-subunit of another haemoglobin tetramer triggers the formation of large polymers. The polymers consist of staggered haemoglobin tetramers that aggregate into 21-nm-diameter helical fibres, with one inner and six peripheral double strands. The polymerization proceeds after a delay, the length of which is extremely sensitive to the intracellular deoxy-HbS concentration. Even a small increase in deoxy-HbS concentration, such as might occur with cellular dehydration, profoundly shortens the delay time and augments sickling. The process of polymerization is highly cooperative and its kinetics are best explained by the double nucleation model.

Table 7.1 The sickling syndromes.

Genotype	Mean haemoglobin (g/dL)	MCV	Haemoglobin electrophoresis (%)				
			S	A	F	A_2	Other

	Saudi Arabia: eastern province	25
	India: central India – tribal population	20–30

The haemoglobin tetramers first aggregate into a nucleus, which rapidly expands into a fibre (homogeneous nucleation). The newly formed fibre provides nuclei on its surface for aggregation of haemoglobin tetramers to form several more fibres (heterogeneous nucleation).

The polymerization of HbS in the circulating red cells is influenced by the oxygenation status, the intracellular haemoglobin concentration and the presence of non-sickle haemoglobins. Acidosis and elevated level of 2,3-diphosphoglycerate (2,3-DPG) promote polymer formation by reducing the oxygen affinity of haemoglobin. The presence of HbA within the red cells, as in sickle trait, inhibits polymerization by diluting HbS. The inhibitory effect of HbF on polymerization of HbS is more profound owing to the greater amino acid disparity between the β^s- and γ-globin chains.

Effect on erythrocytes

Red cells acquire the sickle or elongated shape upon deoxygenation as a result of intracellular polymerization of HbS, a phenomenon that is reversible upon reoxygenation. Even in the normally shaped red cells, however, the presence of HbS polymer reduces deformability, with consequent increase in blood viscosity. Repeated or prolonged sickling progressively damages the red cell membrane, which is a phenomenon of primary importance in the pathophysiology of SCD. Membrane damage causes movement of potassium ions and water out of the cell by the Gardos pathway and potassium–chloride co-transport, leading to dehydration of red cells. The intracellular haemoglobin concentration rises (producing dense cells), which shortens the delay time to sickle polymer formation. A
Figure 7.1 Induction of red cell sickling. As red cells traverse the microcirculation, oxygen is released from oxy-HbS (red circles), generating deoxy-HbS (purple circles). Conformational change exposes a hydrophobic patch at the site of the β^6-valine replacement, shown as a projection (left column), which can bind to a complementary hydrophobic site on a subunit of another haemoglobin tetramer, shown as an indentation. Only one of the two β^6-valine sites in each HbS tetramer makes this contact. The middle column shows the assembly of deoxy-HbS into a helical 14-strand fibre, shown as a twisted rope-like structure. The delay time is inversely proportional to the intracellular haemoglobin concentration raised to the 15th power. As deoxy-HbS polymerizes and fibres align, the red cell is distorted into an elongated banana or 'sickle' shape (right column) (from Bunn, HF, 1997, *New England Journal of Medicine* **337**: 762, with permission).

second key consequence of membrane damage is alteration of the chemistry of the red cell membrane. Perturbation of lipid organization causes negatively charged phosphatidylserine to appear on the red cell surface instead of its normal location in the inner monolayer. In addition, the red cells become abnormally adherent to the vascular endothelium through vascular cell adhesion molecule 1 (VCAM-1), thrombospondin and fibronectin.

Vaso-occlusion

Several processes contribute to development of vaso-occlusion in SCD. Slowing of blood flow arises from abnormal regulation of vascular tone as a result of diminished nitric oxide-induced vasodilatation. This is aggravated by increase in blood viscosity, resulting from less deformable red cells, a phenomenon called abnormal rheology. Vaso-occlusion is initiated by adhesion of young, deformable red cells to the vascular endothelium, and is followed by trapping of rigid, irreversibly sickled cells (Figure 7.2). Adhesion occurs in the post-capillary venules and is promoted by leucocytosis, platelet activation and inflammatory cytokines. Genetic influences independent of the sickle mutation probably modulate the tendency for vaso-occlusion in individuals and account for phenotypic variation seen in this disease.

Haemolysis

SCD is characterized by chronic intravascular and extravascular haemolysis. Sickling-induced membrane fragmentation and complement-mediated lysis cause intravascular destruction of red cells. Membrane damage also leads to extravascular haemolysis through entrapment of poorly deformable cells or uptake by macrophages. The red cell survival measured by ^{51}Cr assay is 4–25 days, with dense cells surviving for a considerably shorter time than red cells containing some HbF (F cells). Patients have greatly expanded bone marrow space, but the serum erythropoietin level is lower than expected for the extent of anaemia owing to decreased oxygen affinity of HbS. Individuals with concomitant deletion of one or two α-globin genes, or the Senegal or Arab–India haplotypes, have higher baseline haemoglobin levels.

Clinical manifestations

Clinical symptoms vary tremendously between patients with SCD for several reasons. The disease is more severe in patients with HbSS or HbS β^0-thalassaemia than in those with HbS β^+-thalassaemia or HbSC disease. The Arab–Indian haplotype produces a less severe disease than the African haplotypes. The
Figure 7.2 Endothelial red cell adhesion and vaso-occlusion in sickle cell disease. Adhesive sickle reticulocytes initiate vaso-occlusion by becoming attached to the endothelium of vessel walls. Thereafter, poorly deformable red cells begin to accumulate behind the site of adhesion, ultimately resulting in an occluded vascular segment containing many sickled red cells. The inset shows the site of red cell attachment to an endothelial cell and several adhesion mechanisms that could participate in the vaso-occlusive process. On the red cell, the relevant adhesion receptors include CD36, which binds thrombospondin (TSP), and integrin $\alpha_4\beta_1$, which binds both fibronectin (FN) and vascular cell adhesion molecule 1 (VCAM-1). On the endothelial cell, the receptors include CD36; integrin $\alpha_v\beta_3$; the complex of glycoproteins Ib, IX, and V (gp Ib–IX–V), which binds von Willebrand factor (vWF); and VCAM-1. Question marks indicate unidentified receptors (from Hebbel RP, 2000, *New England Journal of Medicine* **342:** 1910, with permission).

co-inheritance of one or two α-gene deletions also modifies the clinical picture. The high HbF level observed in hereditary persistence of fetal haemoglobin (HPFH) is associated with very mild disease. However, for poorly recognized reasons, the disease severity varies enormously even within the subgroup of patients with HbSS.

In countries with inadequate healthcare, SCD is associated with high mortality in the first 3 years of life as a result of sepsis and splenic sequestration. In the developed world, the typical patient with SCD has moderately severe anaemia, leads a relatively normal life interrupted by 'crises' as a result of vaso-occlusion, and has a life expectancy of over 45 years.

Anaemia

The underlying β-globin genotype primarily determines the baseline haemoglobin value in SCD, but exacerbation of anaemia can occur for numerous reasons. Patients with more severe anaemia at baseline have a greater probability of developing stroke and renal dysfunction. On the other hand, a higher haemoglobin level is associated with higher incidence of painful episodes, avascular necrosis and acute chest syndrome. Infants with SCD have lower than normal haemoglobin levels after the neonatal period, and the decline continues until it reaches a nadir between 12 and 15 months of age. Boys are slightly more anaemic than girls in the first decade, whereas adult men have higher haemoglobin values than women. Gradual exacerbation of anaemia is observed in both sexes beginning in the fifth decade.

A gradual decrease in haemoglobin level from the baseline value may indicate an underlying folate or iron deficiency. In older patients, however, inadequate erythropoietin production due to chronic renal insufficiency is the most important aetiology of worsening anaemia. Many such patients will become transfusion dependent, although recombinant human erythropoietin therapy can improve the anaemia.

Acute exacerbations of anaemia are observed with aplastic crises and splenic sequestration. The transient arrest of erythropoiesis and the resultant reticulocytopenia in aplastic crisis is

most often due to parvovirus B19 infection. Severe anaemia is the consequence of the shortened lifespan of red cells and the course is similar to other chronic haemolytic anaemias. Aplastic crisis is typically preceded by fever and upper respiratory or gastrointestinal symptoms, and several family members may fall ill over a period of days. The reticulocytopenia begins 5 days after exposure, lasts for 7–10 days and is followed by recovery with reticulocytosis and normoblasts in peripheral blood. Blood transfusion is often required in the short term. Parvovirus B19 infection is followed by development of lifelong protective immunity.

Splenic sequestration is a serious complication in young children whose spleen has not yet undergone fibrosis due to recurrent vaso-occlusion. The peak incidence of first episode of sequestration is between 6 and 12 months of age and it affects 30% of all patients. Approximately 15% of patients die during the acute episode and the condition recurs in one-half of the survivors. Episodes may be triggered by a viral illness and the rapid acute enlargement of the spleen traps a significant proportion of the blood volume. Clinically, the child presents with acutely worsening anaemia (> 2 g/dL fall in haemoglobin), reticulocytosis, enlarging spleen and hypovolaemic shock. Prompt restoration of the blood volume and correction of anaemia is required. Splenectomy is recommended following a sequestration crisis due to the risk of recurrences. Chronic transfusion therapy or partial splenectomy is sometimes used in infants with life-threatening anaemic episodes. Parent education to detect splenic enlargement and seek early medical attention significantly reduces the risk of death from sequestration crisis.

Acute painful episode

Acute episode of pain due to vaso-occlusion is the most frequent symptom for which patients with SCD seek medical attention. More frequent painful episodes are observed in patients with HbSS, low HbF level, α-thalassaemia and higher baseline haemoglobin levels. Painful episodes are more common in young adults and tend to diminish in older patients. One-third of the patients with SCD rarely experience pain, whereas a small subgroup of patients suffer from recurrent episodes. When patients maintain a pain diary, painful events are noted on up to half of the days but are not severe enough to require visit to a physician. Painful episodes vary in intensity and generally last for a few days. The majority of the episodes have no identifiable cause, although some attacks are precipitated by cold, dehydration, infection, stress or menses.

In young children, initial pain episode typically presents as dactylitis or hand–foot syndrome, with swelling over dorsal surface of hands and feet. It arises from bone infarction affecting the small bones and the swelling subsides over 1–2 weeks. The radiographs show thinning of cortex and destructive changes of the affected small bones several weeks after onset. In older children and adults, the common sites of pain are the back, chest,

extremities and abdomen. Chest pain is of special significance as it can precede development of acute chest syndrome. Frequent, incapacitating painful episodes that are inadequately managed have adverse psychosocial consequences and stress the physician–patient relationship.

Growth and development

Children with SCD are born with normal weight but fall behind other children by the end of the first year. The weight deficit persists through adulthood and imparts a thin habitus to the typical patient, although obesity is seen in some cases. The rate of growth is lower than normal in SCD patients, and the pubertal growth spurt is delayed by 1–2 years, but the final adult height is normal. Delays also occur in skeletal maturation and onset of puberty, and female patients achieve menarche 1–2 years later than their peers.

Infections

Early loss of splenic function from recurrent vaso-occlusion and the inability to make specific immunoglobulin G (IgG) antibodies to polysaccharide antigens increases the risk of fulminant sepsis. Pneumococcal infection is a serious problem in SCD, particularly in children under 3 years (Figure 7.3a–c). Meningitis can accompany pneumococcal sepsis, and the overall mortality rate is 20–50%. Patients who have had previous pneumococcal sepsis are at increased risk for recurrent episodes and must remain on lifelong penicillin prophylaxis. *Haemophilus influenzae* type B is the next most common organism and affects older children. There is considerable variation in the relative incidence of bacterial organisms causing sepsis in young children with SCD in various regions of the world. In Africa, *Salmonella* spp., *Klebsiella* spp., *Escherichia coli* and *Staphylococcus* spp. are more commonly isolated from the blood of febrile children than *Streptococcus pneumoniae*. Pneumococcal infections are particularly infrequent in the eastern province of Saudi Arabia and Nigeria. Furthermore, the incidence of pneumococcal and *H. influenzae* sepsis has declined owing to penicillin prophylaxis and vaccination of infants. The risk of death during septic episodes has decreased considerably owing to empirical use of antibiotics to treat fever in SCD.

Of the other infections, pneumonia is particularly common in SCD and can be difficult to differentiate from non-infective causes of acute chest syndrome. The most frequent organisms responsible for pneumonia are *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *S. pneumoniae* and *H. influenzae*. Lung infections can also arise due to respiratory viruses. In adults, bacteraemia and urinary tract infections due to *E. coli* and other Gram-negative organisms are more frequent. Patients with SCD are susceptible to osteomyelitis owing to bone infarction resulting from vaso-occlusion. The infection is typically due to *Salmonella* spp. or *Staphylococcus aureus*.

(b)

(c)
Figure 7.3 Overwhelming pneumococcal sepsis in 7-year-old child. (a) Numerous bacteria in the blood adjacent to the right ventricular wall. Massive sequestration of the spleen (b) and the liver (c).

Neurological complications

Neurological complications are an important cause of morbidity in SCD. Transient ischaemic attacks or stroke due to cerebral infarction or haemorrhage occur in 25% of patients with SCD (Figure 7.4a). The risk of stroke is increased with lower baseline haemoglobin, low HbF level, high leucocyte count or high systolic blood pressure. Vascular damage results from elevated cerebral blood flow velocities and interaction of rigid or adherent sickle cells with the vessel wall. Angiography demonstrates stenosis or occlusion of vessels in the circle of Willis and internal carotid arteries, sometimes with aneurysm formation or development of moya moya disease (Figure 7.4b). Increased blood flow velocity due to stenosis can be detected by transcranial Doppler ultrasonography in asymptomatic patients, and flow rates of > 200 cm/s correlate with a high risk of stroke.

Stroke due to infarction is more frequent in younger children and those over 30 years, whereas haemorrhage is more common between 20 and 30 years. Stroke is rare in infants, increases to 1 in 100 patients per year between 2 and 9 years, and then diminishes to half of that incidence in older patients. Focal seizures or transient ischaemic attacks (TIAs) are common presenting symptoms of stroke, followed by hemiparesis, coma, speech or visual disturbances. The site of bleeding in haemorrhagic stroke is frequently subarachnoid, and these patients present with severe headache, vomiting and coma. Death can occur during the acute event, particularly with haemorrhagic stroke. Patients with neurological symptoms should be evaluated by computerized tomography (CT) or magnetic resonance imaging (MRI) to distinguish thrombosis from haemorrhage. Immediate exchange transfusion to lower HbS level to < 30% is required. Patients with haemorrhage may require surgical intervention to ligate accessible aneurysms.

As stroke recurs in two-thirds of the survivors within 3 years, all such patients should be maintained on regular transfusions to lower HbS level for several years. Development of first stroke in children at risk, who are identified by elevated cerebral Doppler blood flow velocity, can be prevented effectively through regular transfusions. Even in the absence of overt stroke, silent cerebral infarcts are commonly observed on MRI in SCD and are linked to progressive neuropsychiatric and neurological damage, and poor school performance. Early detection and treatment is important in preventing further neurocognitive impairment.

Pulmonary complications

Acute and chronic pulmonary complications are the leading cause of death in older patients. The acute chest syndrome is characterized by hypoxia, tachypnoea, fever, chest pain and pulmonary infiltrate on chest radiographs (Figure 7.4c). Acute chest syndrome often follows a painful event, particularly in adults (Table 7.3). The pathogenesis of acute chest syndrome involves vaso-occlusion, infection or both. Infections due to *Mycoplasma*,

(d)

(e)
Figure 7.4 Complications of sickle cell disease. (a) Stroke; (b) moya moya transformation; (c) acute chest syndrome; (d) avascular necrosis of hip joint; and (e) chronic leg ulcer.

Table 7.3 Presenting symptoms of acute chest syndrome.

Symptom	Children (%)	Adults (%)
Fever	86	70
Shortness of breath	31	58
Chest pain	27	55
Extremity pain	22	58
Rib pain	14	30

Adults are more likely than children to have pain preceding the onset of pulmonary symptoms.

Chlamydia, *Legionella*, pneumococcus, *H. influenzae* and viruses are more likely in children. Fat-laden pulmonary macrophages in the airways due to fat embolization from the bone marrow are present in one-half of the cases. Hypoxia due to acute chest syndrome can result in widespread sickling and vaso-occlusion, with risk of multiorgan failure. Patients should receive supplemental oxygen, incentive spirometry and antibiotic therapy directed towards the common organisms. One commonly used regimen consists of cefuroxime and erythromycin, although antibiotics should be guided by local experience. Most patients have a bronchoreactive component and should receive bronchodilator therapy. Recent data suggest that early transfusion may prevent the progression of pneumonia. Urgent blood transfusion is always required for persistent hypoxia or worsening lung consolidation. Partial exchange transfusion and mechanical ventilation is sometimes needed in rapidly progressive cases. Nitric oxide and steroids may be beneficial in life-threatening cases.

Chronic pulmonary problems seen in SCD are restrictive and obstructive lung disease, hypoxaemia and pulmonary hypertension. Chronic complications are more frequent in patients with a history of acute chest syndrome. The prognosis for severe pulmonary hypertension is poor and no satisfactory management is available. Hydroxyurea, regular transfusions, vasodilators, anticoagulation and oxygen inhalation have been tried in some patients. Early treatment with transfusion therapy is being evaluated in asymptomatic patients with early pulmonary hypertension.

Hepatobiliary complications

The liver can be affected by intrahepatic trapping of sickle cells, transfusion-acquired infection and transfusional haemosiderosis. Episodes of cholestasis due to intrahepatic sickling can lead to liver failure in rare instances. Pigmented gallstones are seen in two-thirds of patients, particularly those with HbSS, and can occur in young children. Patients with abdominal symptoms attributable to gallstones should undergo cholecystectomy, although the management of asymptomatic gallstones is less clear. Laparoscopic cholecystectomy can be safely performed, but associated common duct bile stones first require endoscopic retrograde cholangiopancreatography.

Pregnancy

The steady-state haemoglobin level falls in SCD during pregnancy, similar to the decline in haemoglobin observed in normal pregnant women. Folate deficiency can exacerbate the anaemia and supplements should be provided throughout pregnancy. Painful episodes become more common in the last trimester. The incidence of pre-eclampsia is higher than normal in SCD patients and there is a slight increase in maternal mortality. Risk to the fetus from abortion, stillbirth, low birth weight and neonatal death is also increased. Prophylactic transfusions during pregnancy or the type of delivery do not alter the outcome for mother or newborn. It is safe to use oral contraceptives for birth control in SCD.

Renal complications

The hypoxic, acidotic and hypertonic renal medulla favours vaso-occlusion, leading to destruction of the vasa recta and hyposthenuria in the first year of life. It presents clinically as enuresis or nocturia, and patients are susceptible to dehydration in hot weather. Haematuria as a result of papillary necrosis usually originates from the left kidney. Management is generally by bed rest and hydration, although sometimes blood transfusion and ε-aminocaproic acid are required. Proteinuria due to glomerular injury precedes development of nephrotic syndrome and chronic renal insufficiency in the third or fourth decade. The progression to renal failure can be delayed by angiotensin-converting enzyme inhibitors. Careful control of blood pressure, avoidance of non-steroidal anti-inflammatory drugs and aggressive treatment of urinary tract infection and anaemia are important objectives for patients with chronic renal insufficiency. Patients with end-stage renal disease are treated with dialysis and renal transplantation. Some renal complications, such as hyposthenuria and haematuria, are also observed in individuals with sickle trait.

Priapism

Priapism occurs in two-thirds of males with SCD, with a peak incidence in the second and third decades. It is caused by vaso-occlusion leading to obstruction of venous drainage from the penis. It typically affects the corpora cavernosa alone, resulting in a hard penis with a soft glans. Episodes can be brief (stuttering) or prolonged, when they last for longer than 3 h. Recurrent priapism leads to fibrosis and eventual impotence. Young boys require explanation of symptoms and the need to seek early help for priapism. At the onset of priapism, patients should drink extra fluids and attempt to urinate. Persistent priapism

requires intravenous hydration and analgesia. Partial exchange transfusion, aspiration of the cavernosa or the creation of fistula between glans and corpora cavernosa (Winter procedure) are performed for resistant cases. Agents used to prevent recurrences of priapism include etilefrine, gonadotropin-releasing hormone analogues, stilbestrol and pseudoephedrine.

Ocular complications

Vaso-occlusion of retinal and other vascular beds in the eye can lead to grave complications. Patients with SCD can develop abnormal (comma-shaped) conjunctival vessels, iris atrophy, retinal pigmentary changes and retinal haemorrhages. Much more serious, however, is neovascularization causing proliferative retinopathy appearing as a 'sea fan' with its potential for vitreous haemorrhage and retinal detachment. Such patients are treated with laser photocoagulation or vitrectomy. The incidence of proliferative changes is substantially higher in HbSC and S-β⁺-thalassaemia patients than in HbSS. All patients with SCD should have annual ophthalmological evaluation, beginning in the second decade.

Sudden change in vision in a patient with SCD is an ocular emergency. Central retinal artery occlusion requires immediate treatment with hyperoxygenation and reduction of intraocular pressure, but the prognosis for vision is poor. Hyphaema, which can arise after minor trauma, leads to glaucoma due to sickling of blood in the anterior chamber. The elevated intraocular pressure causes ischaemic optic atrophy and retinal artery occlusion. Individuals with sickle trait are also vulnerable to this complication. Urgent surgical attention is required to wash out blood from the anterior chamber.

Bone complications

The chronic haemolytic process results in expansion of the medullary space, although the resultant bony changes are less pronounced than in thalassaemia. Bone infarction due to vaso-occlusion produces tenderness, warmth and swelling, which can be difficult to distinguish from osteomyelitis. In such cases, cultures from blood and direct aspiration are negative and radiographs later show patchy sclerosis and cortical thickening. Collapse of vertebral end plates due to infarction produces the codfish appearance. Patients are managed with analgesia and hydration until resolution of symptoms.

Avascular necrosis of the femoral head is a serious complication that is difficult to treat and leads to chronic disability and pain (Figure 7.4d). Patients with coexisting α-thalassaemia have a higher incidence of osteonecrosis at a younger age. The condition also affects the humeral head but with less functional consequences. The outcome is better in young patients with immature capital epiphysis, who should be treated with analgesics and avoidance of weight bearing for 3–6 months. In older adolescents and adults the condition is more likely to progress to degenerative arthritis with conservative management. Core decompression and osteotomy have been tried, but hip arthroplasty is required for patients with severe symptoms.

Leg ulcers

Chronic leg ulcers are frequent in adult patients with SCD, particularly affecting males with HbSS genotype (Figure 7.4e). Ulcers arise near the medial or lateral malleolus and may be single or multiple. Occlusion of skin microvasculature from sickle red cells predisposes to ulcers, which are made worse by trauma, infection or warm climate. Ulcers are always colonized with pathogenic bacteria (*Pseudomonas aeruginosa*, *S. aureus*, and *Streptococcus* spp.) and acute infection can occur. The ulcers are painful and resistant to healing and, although bed rest and elevation of the leg are efficacious, they may not be practical owing to the chronic nature of the problem. Treatment requires debridement, elastic dressings, zinc sulphate and, in some cases, red cell transfusions and skin grafting.

Variant sickle cell syndromes

Sickle cell trait

Sickle cell trait (HbAS) is a benign condition that has no haematological manifestations and is associated with normal growth and life expectancy. Sickle cell trait affects 8–10% of African–Americans and up to 25–30% of the population in West Africa. Upon electrophoresis, the ratio of HbA–HbS is 60:40, owing to the greater affinity of α-globin chains for β^A-globin chains. Impaired urine-concentrating ability and haematuria can occur, and an increased incidence of urinary tract infection is observed in pregnant women with sickle cell trait. A slight risk of sudden death during military training has been reported, and splenic infarction is possible at very high altitudes. Genetic counselling should be provided to individuals with sickle cell trait.

HbSC disease

HbC is found among individuals of African descent and the compound heterozygote state HbSC accounts for 25–50% of patients with SCD. The vaso-occlusive complications seen in patients with HbSC resemble those of HbSS but are less severe. Splenomegaly and the risk of sequestration can persist into adult life. Of particular note is the higher incidence of proliferative retinopathy in HbSC beginning in the second decade. The haemoglobin level (10–12 g/dL) is higher than in HbSS, and the red cells are relatively microcytic with a higher mean cell haemoglobin content (MCHC). Peripheral blood smear reveals frequent target cells, intraerythrocytic crystals and rare sickle cells. The pathogenesis of sickling in HbSC involves membrane damage with resultant water and cation loss and increase in

intraerythrocytic concentration of HbS. Equal amounts of HbS and HbC are present in the red cells and the solubility test for sickle haemoglobin is positive. The electrophoretic appearance of HbSC, HbSE and HbSO-Arab at pH 8.4 is similar, but a distinction can be made based upon ethnicity and by performing isoelectric focusing or agar gel electrophoresis at pH 6.5.

Sickle cell–β-thalassaemia

Sickle cell–β-thalassaemia compound heterozygotes account for less than 10% of patients with sickle syndromes. The majority of these patients have the β^+-phenotype, with the proportion of HbA ranging from 3% to 25%. The clinical phenotype is mild and disease severity correlates with the amount of HbA present. The clinical manifestations of less frequent HbS-β^0 genotype are similar in severity to those of HbSS. The red cells are microcytic and hypochromic, and variable number of target cells and sickle cells are observed. Reticulocytosis (10–20%) is present and the level of HbA_2 is elevated.

Sickle cell anaemia with coexistent α-thalassaemia

Co-inheritance of α-thalassaemia (−α/αα or −α/−α) with SCD is common, and such patients have less severe anaemia and demonstrate hypochromia and microcytosis. In general, the clinical severity is similar to that seen in HbSS patients with a normal complement of α-globin genes.

Sickle cell–HPFH

Approximately 1 out of 100 patients with HbSS has an elevated HbF level due to deletional or non-deletional mutations that maintain γ-globin gene expression after birth. Such individuals have 20–30% HbF and < 2.5% HbA_2. The haemoglobin level is normal with microcytosis, and target cells are observed in peripheral smear. The clinical course is benign, and vaso-occlusive complications are rare because of the inhibition of sickling by elevated HbF.

Other sickling syndromes

Sickle cell–Hb Lepore disease
Co-inheritance of Hb Lepore with sickle cell mutation produces a clinical picture similar to that of S-β-thalassaemia but with a low HbA_2 level.

Sickle cell–HbD disease
Of all the D or G haemoglobins, HbD Punjab (D Los Angeles) alone interacts with HbS to produce moderately severe haemolytic anaemia in compound heterozygotes. Target cells and irreversibly sickled cells (ISCs) are observed in the peripheral smear, and the clinical manifestations resemble mild sickle cell anaemia.

Sickle cell–HbO Arab disease
HbO Arab resembles HbC on alkaline electrophoresis and produces a moderately severe haemolytic anaemia in association with HbS. The disease is more severe than HbSC, and numerous sickled erythrocytes are observed on peripheral smear.

Sickle cell–HbE disease
HbSE disease causes mild haemolysis and no remarkable abnormality of red blood cell morphology. HbE makes up only 30% of the total haemoglobin because of the thalassaemic nature of the mutation. Patients are generally asymptomatic, although occasionally significant vaso-occlusive complications and anaemia have been observed.

Diagnosis

Peripheral blood findings

The peripheral blood picture depends upon the type of sickle cell syndrome. The haemoglobin level is normal in the newborn period, but anaemia develops and sickle or cigar-shaped ISCs can be observed in the peripheral blood by 3–4 months of age as HbF declines. In HbSS disease, the red cells are normocytic and normochromic, with polychromasia, many ISCs and fewer target cells (Figure 7.5a). The average reticulocyte count is 10% (4–20%) and normoblasts may be observed. Red cells are microcytic in the presence of coexisting α-thalassaemia or iron deficiency. In S-β-thalassaemia ISCs, target cells and hypochromic microcytic red cells are prominent. The red cell morphology in HbSC disease is characterized by predominant target cells and rare ISCs. The occasional Howell–Jolly body, indicative of loss of splenic function in SCD, may be observed. The white cell count is elevated ($12–20 \times 10^9$/L) as a result of an increase in mature neutrophils. The platelet count is also elevated to $300–500 \times 10^9$/L as a result of decreased splenic function.

Other laboratory tests

The measurement of clotting factors in SCD indicates mild ongoing activation of the coagulation system, even in the steady state. The erythrocyte sedimentation rate is consistently low. The serum levels of unconjugated bilirubin and lactate dehydrogenase are elevated, and haptoglobin is decreased.

Haemoglobin electrophoresis

HbS can be identified by cellulose acetate electrophoresis at pH 8.4 (Table 7.1 and Figure 7.5b). HbD and HbG have the same electrophoretic mobility with this method, but can be distinguished using citrate agar electrophoresis at pH 6.2 or thin-layer isoelectric focusing. Distinction cannot be made between HbSS and HbS β^0-thalassaemia on electrophoresis. The diagnosis of

(a)

(b)

(c)
Figure 7.5 Peripheral blood smear from an individual with sickle cell anaemia (a). Haemoglobin electrophoresis (b), showing a-standard, b- and c-HbSS, d-HbSC, e-sickle trait. Sickle solubility assay (c) is positive (tube a) in all three conditions.

S-β^0-thalassaemia is suggested by microcytosis and elevated HbA$_2$, and confirmed by finding β-thalassaemia trait in one of the parents. HbA and HbS are observed upon electrophoresis in both sickle cell trait and HbS β$^+$-thalassaemia; however, the HbA fraction is greater than 50% in the former, but ranges from 5% to 30% in the latter. The level of HbF is variably elevated with higher levels observed in patients with the Arab–Indian and Senegal haplotypes.

Other tests to detect sickle haemoglobin

Sickling of red cells can be induced by sealing a drop of blood under a coverslip to exclude oxygen or by adding 2%

sodium metabisulphite. The solubility test for HbS utilizes a reducing agent such as sodium dithionite, which is added to the haemolysate. The deoxy-HbS is insoluble and renders the solution turbid (Figure 7.5c). Both these tests are unable to distinguish sickle cell trait from sickle cell anaemia and cannot be used for primary diagnosis. They are useful to aid in the identification of an abnormal electrophoretic band as HbS and for identifying sickle cell trait in units of red cells prior to transfusion.

Newborn screening

Universal newborn screening is recommended to identify SCD in the neonatal period. The efficacy of penicillin prophylaxis

in preventing death from early sepsis in SCD provided the rationale for development of screening programmes. Blood samples obtained by heel prick are spotted onto filter paper and tested by electrophoresis or chromatography. Neonates with HbSS disease and HbS β^0-thalassaemia have an FS pattern (the order of haemoglobins indicates their relative abundance in the sample). In sickle cell trait, the haemoglobin pattern is FAS, whereas newborns with HbS β^+-thalassaemia have an FSA pattern. Finally, the presence of the FSC pattern suggests HbSC disease. Family studies help to make the definitive diagnosis and, when both parents are unavailable, DNA-based testing is useful.

Prenatal diagnosis

Prenatal diagnosis is available through direct detection of the GAG → GTG mutation responsible for SCD in the fetal cells. Genetic counselling is difficult owing to the marked variability in clinical manifestations within the same genotype, and the lack of ability at present to predict individual phenotype. Preimplantation diagnosis and selection of healthy embryos may offer a solution to this ethical problem.

Therapy

This section discusses general issues in management of sickle cell disease. The treatment of specific complications is addressed under clinical manifestations.

Routine health care

The majority of children with SCD can be managed by paediatricians or community physicians in coordination with a haematologist. Adults with SCD should also continue to have routine office visits. Patients who suffer from more severe complications or need therapy to modify the course of SCD require specialized care at experienced centres.

The level of healthcare available to patients with SCD varies tremendously in different countries. Where resources are limited, the primary focus should be on penicillin prophylaxis, vaccination, education and analgesia for painful episodes. Where comprehensive care is available, both medical and psychosocial needs should receive attention (Figure 7.6). Sickle cell centres should have specialists in several fields, who are available to address complications that may affect different organs.

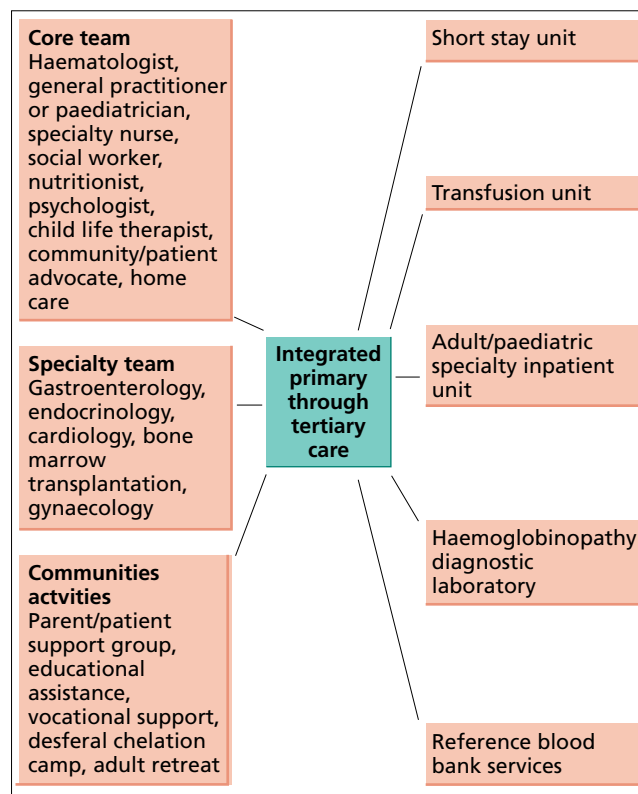
In cases when diagnosis is made on newborn screening, the infant should be seen within 1–2 months to instruct parents about infections and splenic enlargement. Routine immunization should include pneumococcal, *H. influenzae*, hepatitis B and influenza vaccines. All children receive prophylactic penicillin (penicillin V orally twice daily or benzathine penicillin by


Figure 7.6 Comprehensive care of patients with sickle cell disease.

i.m. injection once per month), which may be stopped after the age of 5 years in the absence of any episode of pneumococcal sepsis or splenectomy. Folic acid supplementation (1 mg per day) is recommended. Evaluation of cerebral blood flow by transcranial Doppler should be performed on all children after 2 years to identify those at risk for stroke. Annual retinal examination is begun at 10 years. Sexually active women should have routine pelvic examinations and receive instructions about birth control.

Infections

Fever in children with SCD requires urgent attention in the office or emergency room. A complete blood count (CBC), blood and urine cultures and chest radiographs should be obtained, and lumbar puncture should be performed if meningitis is suspected. Very young children with fever or older children who appear septic should be hospitalized for intravenous antibiotics. The choice of antibiotics depends upon causative agents prevalent locally and the pattern of resistance. In the USA, cefuroxime or ceftriaxone are preferred, whereas high-dose penicillin is used in several other countries. Many patients older than 2 years who do not look septic or seriously ill can be managed at home after receiving ceftriaxone in the emergency department. Antibiotics should continue for 1 week when bacteraemia is documented.

In the presence of pneumonia, a macrolide should be added to cover *Mycoplasma* or *Chlamydia*. Antibiotics for osteomyelitis should provide coverage for *Salmonella* and *S. aureus* and are given for a period of 4–6 weeks.

Transfusion therapy

Blood transfusion in SCD is used to treat severe anaemia or to reduce the amount of circulating sickle haemoglobin. Only sickle-negative blood, which can be identified by negative sickle solubility test, is used for transfusions. The blood should also be leucodepleted, and matched for common minor E, C and Kell antigens. A simple transfusion is used to treat severe anaemia that is often associated with aplastic crisis and splenic sequestration. Older patients with renal failure may also need transfusions for declining haemoglobin level.

Dilution of circulating sickle haemoglobin can be accomplished by simple transfusion if the baseline haemoglobin level is low. Exchange transfusion or erythrocytopheresis is required to prevent hyperviscosity from the significant rise in haemoglobin when the patient has high baseline haemoglobin or when a greater reduction in HbS is desired. The final haemoglobin level should not exceed 12 g/dL after simple or exchange transfusion. Conditions in which a reduction in the proportion of HbS is required are stroke, progressive acute chest syndrome, persistent priapism or preparation for general anaesthesia. Longer-term reduction in HbS through regular transfusions is advocated to prevent recurrence of stroke and sequestration, and in selected patients with leg ulcers or chronic pain. Routine blood transfusion is not needed for pain episodes, infections, minor surgery or uncomplicated pregnancy.

It is possible to eliminate most complications of SCD with the use of chronic transfusions to suppress endogenous sickle haemoglobin production. However, alloimmunization, iron overload and transmission of viruses are significant risks that limit the use of transfusions to the management of severe complications. In addition, because of the limited availability and decreased safety of blood, criteria for transfusion are more stringent in less developed countries. The high incidence of alloimmunization from minor blood group incompatibility (Rh, Kell, Duffy and Kidd) between donors and recipients can be avoided by use of phenotypically matched units. Patients on long-term transfusions develop iron overload, which requires chelation with desferrioxamine. Liver biopsies are usually necessary to measure iron burden because the serum ferritin is unreliable. As iron accumulation can be reduced or prevented by erythrocytopheresis, this technique is now preferred when venous access is available.

Pain management

Prompt management of pain is essential, given its frequent occurrence and potential adverse psychological consequences. Patients with recurrent pain are best managed in a familiar ambulatory setting rather than the emergency ward. The patient should be evaluated for potential infectious, traumatic or surgical causes of pain. Pain assessment tools are available for young patients and are also helpful in older patients to follow the response to therapy. Adequate hydration should be provided along with analgesia with narcotics and non-steroidal anti-inflammatory agents. Several narcotic agents are available for oral and parenteral use and the choice of medicine depends upon local experience as well as the patient's preference. The use of incentive spirometry reduces the potential for developing hypoxia and acute chest syndrome secondary to hypoventilation. Undertreatment of pain can be avoided by using patient-controlled analgesia, which has the added benefit of reducing apparent drug-seeking behaviour. Narcotic addiction is no more frequent in sickle cell patients than in others requiring analgesia. Non-steroidal anti-inflammatory agents improve pain control with or without narcotics. Providing psychosocial support and reassurance, and allaying anxiety are important goals. Chronic pain is rare in SCD and may require long-acting narcotics for management.

Hydroxyurea

Hydroxyurea (HU) is a tremendously important drug in the management of patients with SCD who have severe clinical manifestations. HU inhibits ribonucleotide reductase, leading to S-phase arrest of replicating cells, and is used in SCD because of its ability to stimulate production of HbF. HU increases HbF as a result of stress erythropoiesis induced by its myelosuppressive effect. Patients show variable response in the degree of rise in HbF, and some experience no change from the baseline value. Other biological effects of HU play an equally significant role in the beneficial clinical effects observed during HU therapy. Erythrocytes of patients on HU have increased water content and deformability and decreased adherence to vascular endothelium. There is elevation of the haemoglobin level, mean cell volume (MCV), HbF and F cells, whereas total white cell and neutrophil count, reticulocyte count and the number of dense sickle cells decrease. Patients on HU experience 50% reduction in the incidence of acute painful episodes and acute chest syndrome. The transfusion needs and the risk of death are also decreased, but the incidence of stroke remains unaffected.

HU therapy is offered to patients (adults and children over 6 years) with frequent pain episodes or acute chest syndrome. Use of HU in very young children should carefully balance the anticipated benefit with potential unknown risks in this age group. HU is started at a dose of 15 mg/kg per day and increased to 25 mg/kg per day provided that there are no side-effects. Patients require frequent monitoring of blood counts, as well as renal and hepatic function. Myelosuppression is the most commonly encountered side-effect and temporary cessation of therapy and dose reduction is required for neutropenia,

Table 7.4 Advances in the management of sickle cell disease.

Category	Intervention
1 Newborn screening	Counselling
	Comprehensive care
2 Infection	Prophylactic penicillin
3 Brain injury prevention	Screening with TCD, MRI
	Neurocognitive testing
4 Transfusion safety and iron overload prevention	Phenotypically matched RBC
	Erythrocytopheresis
5 Lung injury prevention	Incentive spirometry
	Antibiotics (including macrolides)
	Transfusion
	Nitric oxide
	Prevention with hydroxyurea
6 Surgery/anaesthesia	Preoperative transfusion
7 Avascular necrosis of the hip	Decompression coring
8 Priapism	Adrenergic agonist
	Anti-androgen therapy
9 Pain	Prevention with hydroxyurea
	Patient-controlled analgesic devices
	Non-steroidal anti-inflammatory drugs
10 Renal	ACE inhibitors for proteinuria
	Improved renal transplantation
11 Gall bladder disease	Laparoscopic cholecystectomy
12 Severe disease	Allogeneic bone marrow transplantation
	Chronic transfusions
	Hydroxyurea

ACE, angiotensin-converting enzyme; MRI, magnetic resonance imaging; TCD, transcranial Doppler.

thrombocytopenia, reticulocytopenia or fall in haemoglobin. Dose modification is necessary for patients with renal failure. Skin pigmentation affecting the nails, palms and soles is commonly observed. Despite concerns about the leukaemogenic and teratogenic effects of HU, no convincing increase has been reported in SCD so far.

New therapeutic modalities

A better appreciation of the pathophysiology of SCD will make it possible to exploit new therapeutic mechanisms (Table 7.4). Agents under development include membrane-active chemicals that improve hydration of sickle cells by blocking Gardos channels and potassium–chloride co-transport, or inhibit red cell adherence to endothelium. Decreased availability of nitric oxide (NO) has an important role in vaso-occlusion in SCD, and agents that correct NO deficiency may have significant therapeutic benefit. Newer agents to induce HbF synthesis that are being studied include orally effective butyrate compounds and analogues of azacytidine.

Bone marrow transplantation

Allogeneic bone marrow transplantation (BMT) from matched sibling donor cures 85% of children with SCD less than 16 years of age. However, 5–10% of patients die of complications related to BMT and another 10% experience graft rejection with the return of SCD (Figure 7.7). Additional long-term risks after BMT are infertility and second malignancy. Selection of candidates for BMT is complex owing to the uncertain long-term course of the disease. Although it is clear that high-risk patients benefit from this treatment, the role of BMT in asymptomatic children is not defined. Indications accepted at present to consider transplantation include stroke, recurrent acute chest syndrome or recurrent vaso-occlusive episodes in patients under 16 years old who have an HLA-matched sibling.

Gene therapy

Correction of SCD by gene therapy requires efficient insertion of a gene into repopulating haemopoietic cells and regulated
Figure 7.7 Outcome after transplantation for 59 children with advanced, symptomatic sickle cell disease. Kaplan–Meier estimates for survival and event-free survival following marrow transplantation are shown. An event is defined as death, graft rejection or recurrence of sickle cell disease. A cumulative incidence curve for graft rejection and return of sickle cell disease is also depicted (from Walters *et al.*, 2001, *Biology of Blood and Marrow Transplantation* 7: 665, with permission).

expression in erythropoietic lineage. An anti-sickling haemoglobin, constituting 20–30% of the total haemoglobin, would be enough to produce clinical response. Mouse models of sickle cell disease have considerably helped in the effort to develop gene therapy, and correction of sickling phenotype has been demonstrated in such animals.

Psychosocial issues

Recurrent pain and the unpredictable course of the illness place SCD patients at higher risk of depression and poor family relationships. Despite this, with integrated medical care and social support most patients with SCD are well adjusted. Addiction to narcotics is an uncommon phenomenon and is the result of social influences rather than analgesic therapy. Attention to psychological well-being as well as educational and vocational support are important components of the care provided to SCD patients.

Hereditary disorders of the red cell membrane

Edward C Gordon-Smith

Introduction

This chapter and the next deal with genetically determined disorders of the red cell, other than those of haemoglobin, which cause its premature destruction. In this chapter, genetic changes that affect the structure and function of the red cell membrane are described. Chapter 9 describes the inherited defects in red cell metabolism that shorten red cell survival.

Whereas the primary genetic changes underlying these disorders are quite heterogeneous, many of the manifestations are similar, as they result mainly from the increased rate of red cell destruction and from the consequent hyperactivity of the erythroid component of the bone marrow. Therefore, the description of individual conditions will be prefaced with a brief consideration of the pathophysiology of haemolysis.

Haemolysis

Definitions

Haemolysis means that the destruction of red cells is accelerated. Normally, in adults, the bone marrow output is well below its maximal capacity. Red cell production can be increased about sixfold in the adult by increasing the cellularity of existing haemopoietic marrow, as well as by expansion of haemopoietic marrow into the long bones. In the newborn, and during infancy, marrow expansion depends on expanding the medullary cavity of bones, leading to thinning of cortical bone. These bony changes are most extreme in the β-thalassaemia syndromes, but some skeletal changes, usually some bossing of the frontal bones, may be seen in more extreme hereditary haemolytic anaemias of other causes.

Increased red cell destruction is often completely matched by increased production, resulting in compensated haemolysis. When the rate of haemolysis exceeds the maximum erythropoietic capacity of the bone marrow, or when the latter is limited (e.g. because of inadequate supply of iron or folate or by ineffective erythropoiesis), the result is haemolytic anaemia. As in any haemolytic disorder, with or without anaemia, the consequences of haemolysis are always present and, as the same underlying pathogenetic process may cause at different times, even in the same patient, either a compensated haemolytic disorder or haemolytic anaemia, the two terms are often used, somewhat loosely, as though they are interchangeable.

General features of haemolysis

The clinical and laboratory aspects of haemolysis depend on the consequences of increased red cell destruction and production as well as the main process by which destruction takes place. Increased red cell destruction leads to an increase in unconjugated bilirubin from increased haemoglobin turnover. Unconjugated bilirubin does not appear in the urine, although there will be an increase in urinary urobilinogen. The bilirubin level is usually not more than two to three times normal because the normal liver is able to increase excretion to compensate for at least some of the increased production. Jaundice is usually mild in hereditary haemolytic anaemias although there are important exceptions.

In the neonate, particularly premature infants, liver function is not fully developed and more severe jaundice requiring urgent therapeutic intervention may occur. A rare but potentially confusing problem is the co-inheritance of Gilbert's syndrome, which comprises a group of congenital liver enzyme deficiencies that impair bilirubin conjugation. On its own, Gilbert's

Table 8.1 Main features of haemolytic anaemia.

Increased red cell destruction		Unconjugated hyperbilirubinaemia	Mild jaundice
			Increased risk of gallstones
		Increased urinary and faecal urobilinogen	
		Decreased serum haptoglobin and haemopexin	
	Extravascular	Increased iron stores	
		Splenomegaly

		Haemosiderinuria	
		Methaemalbuminaemia	
		Decreased iron stores	
Increased red cell production		Marrow expansion	Bone changes
		Increased erythropoiesis ↓M:E ratio	
		Reticulocytosis	Polychromasia
		Increased folate requirements	Macrocytosis

syndrome does not produce clinical jaundice except when there is inadequate calorie intake, but in conjunction with haemolytic anaemia the hyperbilirubinaemia may be considerable. The increased bilirubin of haemolysis does increase the risk of gallstones and cholecystitis, which in turn may lead to an increase in serum bilirubin.

In the degradation of haemoglobin, the molecule is broken down to two αβ subunits, which are bound to haptoglobin, the complex being rapidly internalized in the hepatocyte after binding to the haptoglobin complex receptor. In the presence of haemolysis, serum haptoglobin levels are greatly reduced or absent. Haptoglobin is, however, an acute-phase protein and levels will increase in the presence of inflammation. Haemopexin is another haem-binding protein produced by the liver, which is decreased in haemolysis. Chronic haemolytic anaemia may increase iron content of the body through increased iron absorption as a result of anaemia coupled to the retention of the haem iron following binding to haptoglobin and haemopexin. In rare cases of inherited haemolytic anaemia, this iron overload may be sufficient to produce clinically important effects, particularly if there is co-inheritance of a haemochromatosis gene. In most haemolytic anaemias, owing to membrane defects, the destruction of red cells takes place extravascularly in the reticulo-endothelial system and the iron is retained as described. When destruction is intravascular, free haemoglobin will be released into the plasma, producing haemoglobinaemia and methaemalbinaemia, and will pass through the glomerulus to produce haemoglobinuria and haemosiderinuria. Iron deficiency is thus more likely than overload in intravascular haemolysis.

Increased red cell production leads to expansion of the red cell precursor compartment of the bone marrow as described above. There are also changes in the structure of the marrow as a consequence of the chronic anaemia, which allows the early release of reticulocytes and, in more marked cases, of haemolytic anaemia

nucleated red cells and even myelocytes. In the peripheral blood, the polychromasia and macrocytosis of reticulocytosis are the result of this increased throughput and release. The increased cell production requires an increased supply of folate, which, at least theoretically, can produce folate deficiency unless supplements are given. It is usual to give folic acid (e.g. 400 μg or 5 mg weekly) daily to people with chronic haemolytic anaemia. The main features of haemolytic anaemia are summarized in Table 8.1.

Classification

Because of the unique structural and functional specialization of the mature red cell, the impact on it of a wide range of exogenous or endogenous changes is relatively uniform: the cell will be destroyed prematurely. According to the site of the primary change, haemolytic disorders have been traditionally classified as being due either to intracorpuscular or to extracorpuscular causes. According to the nature of the primary change, haemolytic disorders have also been classified as inherited or acquired. These two classifications correlate almost completely with each other, in that extracorpuscular causes are usually acquired, whereas intracorpuscular causes are usually inherited. One notable exception is paroxysmal nocturnal haemoglobinuria, a disease in which an intracorpuscular defect is acquired as a result of a somatic mutation (see Chapter 11).

Although in every cell all molecules and organelles are naturally interdependent, it is convenient to consider the red cell as a conveyance for a large amount of haemoglobin contained in a plasma membrane, the stability of which is maintained by an appropriate metabolic machinery. Unfavourable genetic changes in any of these components may cause haemolysis. Accordingly, inherited haemolytic disorders can be classified into three major groups: (i) genetic disorders of haemoglobin (see Chapter 6); (ii)

abnormal membrane (including the cytoskeleton); and (iii) abnormal metabolism (enzymopathies) (see Chapter 9).

Red cell metabolism

The details of red cell metabolism are considered in Chapter 9. Suffice to say in this chapter that the red cell membrane requires a supply of both ATP and reducing power to maintain its proper integrity. The way in which energy is supplied to the membrane is intimately related to its structure. The main pathway for metabolizing ATP in the membrane is via Na^+,K^+-ATPase. The enzyme glyceraldehyde-3-phosphate dehydrogenase (Ga3PD) is closely associated with the inner layer of the membrane. It catalyses the conversion of Ga3P to 1,3-diphosphoglycerate (1,3-DPG), with the production of NADH. ATP is produced in the next step of the glycolytic pathway, the conversion of 1,3-DPG to phosphoglycerate, which occurs in intimate contact with the membrane.

The red cell membrane

The red cell membrane, like all other cell membranes, consists of a lipid bilayer that is stabilized and given specific properties by the proteins, glycolipids and other specialized molecules and structures with which it is associated.

The lipid bilayer consists of approximately equal molar quantities of phospholipids and cholesterol molecules. The charged phosphatidyl groups of the phospholipids are hydrophilic and form the outer and inner surfaces of the bilayer. The interior of the membrane is formed by hydrophobic bonding of the acyl chains and cholesterol, which form the internal parts of the two leaflets (Figure 8.1). The arrangement is energy efficient but the two leaflets are not symmetrical. The outer leaflet consists mainly of phosphatidylcholine and sphingomyelin, inner leaflet phosphatidylethanolamine and phosphatidylserine (Figure 8.2). The maintenance of the asymmetry and the proper function of the membrane requires energy. In the mature red cells; this is provided by ATP from the glycolytic pathway and reducing power mainly in the form of glutathione.

The normal biconcave shape and function of the red cell membrane are determined by the membrane proteins and their interactions with the lipid bilayer and with each other. There are two main sorts of protein–membrane associations. The integral proteins have strong hydrophobic domains that associate with the hydrophobic part of the bilayer. Many of these integral proteins span the membrane and provide channels between the plasma and cytosolic compartments. The cytostolic, inner domains of these proteins interact with each other and with the second main group, the proteins of the cytoskeleton. The integral proteins that provide the links between the plasma surface and the cytoskeleton have conveniently been referred to as 'vertical con-
Figure 8.1 Arrangement of membrane lipids. The acyl chains of the diacyl phosphatidyl glycerides are hydrophobic non-polar domains and they form hydrophobic bonds with the acyl groups of the opposite layer. Cholesterol is present in roughly equimolar amounts and determines the fluidity of the membranes.
Figure 8.2 Main lipids of the red cell membrane. The outer, plasma layer, contains most of the neutral lipids sphingomyelin and phosphatidylcholine (lecithin). The inner, cytoplasmic layer, contains mostly acidic groups, phosphatidylserine, ethanolamine and inositol. 'R' may be choline, serine, ethanolamine or inositol.

nections', whereas the proteins of the cytoskeleton that make up the inner network of the cell membrane are characterized as 'horizontal connections'. Genetic abnormalities that produce spherocytes mainly have mutations affecting the vertical connections. Mutations of the horizontal system usually produce elliptocytosis or more bizarre-shaped changes. The main proteins are listed in Table 8.2, and their arrangement is shown schematically in Figure 8.3.

In addition to the compartments mentioned so far, there are numerous surface proteins that provide the main interface with the plasma, including the blood group systems and other

receptors. Many of these molecules are heavily glycosylated, as are the integral proteins the glycophorins. Sialic acid, which is the main side-chain of the glycophorins, contributes the most part to the negative surface change of the erythrocyte. Many of these surface proteins are linked to the membrane by the glycosyl phosphatidylinositol (GPI) anchor, which provides the hydrophobic domain required for association with the inner hydrophobic part of the membrane. Somatic mutations in the gene phosphatidylinositol glycan A (PIG-A) leads to a failure to produce the anchor and to paroxysmal nocturnal haemoglobinuria (PNH), as discussed in Chapter 11.

The integral proteins and vertical interaction

The two major integral proteins that span the lipid bilayer are band 3 (the anion channel protein) and the glycophorins

A, B and C. Band 3 and associated molecules, 4.2 (pallidin) and ankyrin (2.1), form one major vertical interactive pathway with binding to the β-chain of the spectrin tetramer through ankyrin. Glycophorin C and protein 4.1 also provide a vertical interaction but the association with spectrin is through a link with actin, which is a key part of the horizontal network.

The band 3–4.2–ankyrin–spectrin complex is a central part of the organization of the lipid bilayer and loss of part of this complex leads to loss of lipid from the outer leaflet of the bilayer, reducing the surface area–volume ratio of the red cell and leading to the characteristic spherocytes of the phenotype hereditary spherocytosis.

The main protein of the cytoskeleton is spectrin. Spectrin consists of two subunits, α and β, which associate side by side to produce a heterodimer. The dimers associate head to head to form tetramers about 200 nm long. The tail end of the dimer makes contact with the specialized domain in the actin molecule, a contact stabilized by protein 4.1. The actin molecule has binding domains for a number of spectrin dimers, which produce the more or less hexagonal network of spectrin tetramers on the inner surface of the membrane associated with the lipid bilayer. Spectrin–actin–4.1 interactions provide much of the flexibility of the red cell membrane. Deficiencies of spectrin that affect these horizontal interactions tend to induce a loss of rigidity in the membrane and elliptocytosis.

The clinical phenotypes of hereditary membrane disorders

Mutations in the genes that control the proteins of the membrane and their interaction mainly produce changes in the shape of the red cells, which is characteristic in any individual. Many of the conditions are inherited as an autosomal dominant disorder, homozygosity for major defects mainly being lethal. Severe, bizarre or unexpected red cell morphology is often produced by double heterozygosity or inheritance of more than one defect of the membrane proteins. The mutations affecting the red cell membrane are many and heterogeneous, but the effect on the phenotype can be classified in five main categories. These are: (i) hereditary spherocytosis (HS); (ii) hereditary elliptocytosis (HE) and hereditary pyropoikilocytosis (HPP); (iii) South-East Asian ovalocytosis (SAO); (iv) hereditary acanthocytosis; and (v) hereditary stomatocytosis (HSt).

Hereditary spherocytosis

As the name implies, hereditary spherocytosis (HS) is a genetically determined haemolytic anaemia characterized by the spherical shape of the affected red cells. The spherical shape produces a characteristic appearance in the stained blood film of round cells with smaller than normal diameter, which lack the area of central pallor of the normal biconcave discs (Figure 8.4). The
Figure 8.4 Hereditary spherocytosis, peripheral blood. Small spherocytic red cells lack area of central pallor. Large polychromatic red cells (reticulocytes) result in normal MCV, although MCHC may be increased.

old name, 'familial acholuric jaundice', emphasizes the presence of jaundice in the absence of bile in the urine, distinguishing this jaundice from that caused by hepatobiliary problems. The disorder is generally inherited as a dominant condition with a wide spectrum of severity. The usual clinical picture is of mild to moderate haemolytic anaemia but varies from severe neonatal haemolysis with kernicterus (rare) to clinically silent and asymptomatic (usual) haemolysis. Autosomal recessive inheritance occurs in a few mutations, often producing severe haemolysis.

In Caucasian populations, HS is one of the most common haemolytic anaemias due to membrane defects, with a prevalence of clinically apparent disease of 200–300 per million of the population. The occurrence of clinically silent cases probably means that the overall prevalence is slightly higher.

Clinical features

The commonest forms of HS present as mild anaemia and jaundice, with a modestly enlarged spleen. However, the genetic heterogeneity of HS (see below) is reflected in the clinical presentation. As the main site of increased red cell destruction in HS is the spleen, it is not surprising that the size of the spleen tends to reflect the severity of the haemolysis, although splenomegaly is rarely marked – enlargement below the umbilicus being very uncommon. When HS presents in adolescence or adult life, it needs to be distinguished from other causes of microspherocytosis, particularly warm autoimmune haemolytic anaemia.

HS may present at birth. The functions of the spleen become mature only after birth, so severe anaemia *in utero* is rare. Erythropoiesis is highly active before birth but enters a phase of reduced activity in the neonatal period. Severe anaemia, developing over 5–30 days post delivery and requiring transfusion, may result from this double physiological development of reduced production and increased destruction, but the anaemia may greatly reduce during the first year of life as compensatory erythropoiesis develops. Decisions about splenectomy do not need to be taken during this time.

Molecular pathology

About 60% of HS cases result from a defect in the ankyrin–spectrin complex, with both α and β (genes *SPTA1*, *SPTB*) of the spectrin dimer or ankyrin (*ANK1*) being implicated in different genetic types (Table 8.2). A further 25% involve deficiency in band 3, the anion channel. In the remainder of the dominantly inherited HS families there is a deficiency of protein 4.2 or no abnormality has yet been identified. Deficiency of protein 4.2 is particularly common in Japanese families with HS (Table 8.2). These defects involving spectrin–ankyrin–band 3 interactions affect the 'vertical interactions' described by Jiri Palek and colleagues.

It will be appreciated that the genetic defect that produces the dominant form of HS affects only one of a pair of genes. The presence of one abnormal protein influences the protein–protein interactions of these complexes, leading to partial deficiency of several proteins, even if they are not genetically disturbed. This is particularly true of spectrin. Complete loss of complex function is probably not viable, so homozygous children are not found. Double heterozygosity or inheritance of separate membrane defects does occur and is associated with usually severe haemolytic anaemia. Other recessive forms of HS are also seen in which the inheritance of one defective gene involving the spectrin subunit produces no clinical effect, whereas homozygosity produces a severe defect and haemolysis.

Laboratory diagnosis

The typical findings of extravascular haemolysis are present in HS (Table 8.1). The diagnosis is usually made on the basis of morphology of the blood, backed up where possible with a family history. The mean cell haemoglobin concentration (MCHC) is often increased above 35 g/L in HS, but the presence of macrocytic reticulocytes usually results in a low normal mean cell volume (MCV) rather than true microcytosis. These changes result not only from the reduction of surface area–volume ratio but also from the slight dehydration of HS cells. A number of variants of the typical HS features have been described, usually the more severe forms that may have denser and less perfectly round cells in the peripheral blood. In infancy, the morphology may be more difficult to interpret. The effect of immature splenic function and the macrocytosis and anisocytosis of infancy combine with the HS phenotype to produce red cell appearances not typical of the developing HS. Family studies may assist in the diagnosis.

Osmotic fragility test

The osmotic fragility test measures the sensitivity of red cells to lysis *in vitro* to swelling caused by incubation in increasingly hypotonic saline solutions. Red cells are able to swell with increasing volume until the pressure disrupts the unstretchable membrane and lysis occurs. In normal red cells with the biconcave disc shape, 50% lysis occurs when the saline solution reaches about 0.5% sodium chloride. The more rigid HS cells have less ability to swell and so lyse at higher concentrations – a right-shifted osmotic fragility curve. One of two patterns may be seen in HS, a generally right-shifted curve, which is the more common finding, and one where there appears to be a 'tail' of lysis-sensitive cells. Incubation of blood for 24 h at 37°C accentuates the fragility (Figure 8.5).

The acidified glycerol lysis test (AGLT) uses glycerol to slow the entry of water into the cells *in vitro*. The time taken for lysis to occur is a function of the osmotic resistance of the cells. HS cells lyse more rapidly than normal cells. The test is easier to perform than the osmotic fragility test.
Figure 8.5 Osmotic fragility test in hereditary spherocytosis. Osmotic fragility is increased in the microspherocytes (right shift), but there is also a small population of resistant cells due to increased reticulocytes. After splenectomy, the microspherocytes remain but the proportion of reticulocytes is reduced to normal values and the resistant cells are not seen.

Autohaemolysis test

The autohaemolysis test examined the ability of red cells to withstand metabolic deprivation by incubation *in vitro* for 24 h with and without the addition of glucose. It is a crude, insensitive test which has generally been abandoned.

Identification of protein abnormalities or gene defects

Methods that identify the defective gene or its product are the most specific for membrane defects but are beyond the scope of most routine haematology laboratories. The original identification of membrane proteins using sodium dodecyl sulphate-solubilized polyacrylamide gel (SDS-PAGE) electrophoresis has led to the classification according to the banding system indicated in Table 8.2. The identification of specific genetic abnormalities may be important in compound haemolytic syndromes but requires specialist laboratories.

One screening test for HS makes use of the binding of eosin-labelled maleimide, in the form of eosin-5 maleimide, to lysin 430 in band 3 and cysteine molecules in surface proteins, particularly rhesus blood groups. In about 25% of HS patients there is a deficiency of band 3 and a loss of surface proteins caused by the instability of the lipid bilayer. HS red cells bind eosin-5 maleimide less than normal cells, by about 25–30%. Even when the main defect is not in band 3, there may be sufficient loss of eosin-5 maleimide binding to indicate HS. The screening test has to be used in conjunction with morphology because South-East Asian ovalocytosis, congenital dyserythropoietic anaemia type II and cryohydrocytosis also give reduced fluorescence.

Clinical course and complications

In most kindred, the course of the disorder is similar in affected members although, as with most inherited defects, there is some variable penetrance and it is not rare to find a very mildly affected parent with more severely affected offspring.

As with all congenital haemolytic anaemias, the anaemia may be aggravated by environmental factors. This may be consequent on an increase in the red cell destruction or a decrease in production. Increased jaundice may occur during viral infections or bacterial sepsis, the anaemia also being aggravated by a decrease in production consequence on the effects of the acute-phase response or the inhibition of erythropoiesis by interferon gamma (IFN-γ).

Primary infection with parvovirus 19 produces a specific and marked inhibition of erythropoiesis, often characterized as an aplastic crisis. In patients with a shortened red cell survival, severe anaemia may be produced by the inhibition, which lasts for some 4–7 days. In normal individuals with a red cell lifespan of 120 days, such an inhibition produces no clinical effect. The anaemia associated with parvovirus infection in HS may require urgent transfusion. The diagnosis is made by finding absent parvovirus antibodies with subsequent appearance of IgM antibodies. The presence of IgG antibodies at the time of the anaemia excludes the diagnosis.

Acute anaemia due to splenic sequestration is a relatively uncommon complication of HS in childhood. The pathogenesis is probably increased splenic size and activity leading to increased trapping of HS cells within the spleen. This complication may also require urgent transfusion.

Malnutrition may increase anaemia because of folate deficiency but also from increased jaundice through the effect of low-calorie input on unconjugated bilirubin levels in the blood.

The anaemia of pregnancy may aggravate a haemolytic anaemia and hence bring the condition to the attention of clinicians and patients. Classical HS is not a risk to mother or child in pregnancy.

Gallstones are an expected complication in HS as in other chronic haemolytic anaemias. Silent gallstones require no intervention. Recurrent cholecystitis or biliary colic may require cholecystectomy accompanied by splenectomy (see below). Leg ulcers are a rare but well-recognized complication of HS, as with other chronic haemolytic anaemias. Extramedullary haemopoietic masses, usually paravertebral, occur rarely in more severe HS.

Management

Patients with well-compensated haemolysis and no transfusion requirements need no treatment other than reassurance and folic acid supplements (e.g. 400 μg daily or 5 mg weekly). For people with a well-balanced and adequate diet, folic acid supplements are probably unnecessary, but custom dictates the practice should be continued. Radiolucent gallstones, if detected by chance on ultrasound, are common and need no treatment unless complications arise. Gallstones without recurrent inflammation are not a risk factor for a carcinoma of the gall bladder. Recurrent cholecystitis or obstruction would be an indication for cholecystectomy, which would also be an indication for splenectomy.

Splenectomy

For the great majority of patients with autosomal dominant forms of HS, and most patients with *de novo* disease, splenectomy restores the lifespan of the red cells to normal and hence cures the haemolysis and hyperbilirubinaemia. In HS, the spleen is responsible for the removal of the older red cells that have lost the most surface through lipid loss from the outer layer. This removal of damaged but functional cells shortens the lifespan and causes jaundice and reticulocytosis. However, splenectomy carries short- and long-term risks that must be weighed against the benefits in any individual patient. Post splenectomy, the blood film continues to show spherocytosis together with changes of a splenectomy film. The osmotic fragility remains increased.

Risks of splenectomy (see also Chapter 21)

The immediate risks associated with splenectomy include those of any abdominal operation together with an increased risk

of thrombosis, associated with a marked rise in platelet count that occurs promptly after splenectomy. In HS, in which the erythropoietic drive returns to normal following splenectomy, the platelet count also returns to normal and the risk diminishes. In conditions in which haemolysis persists, the platelet count remains elevated, sometimes markedly, and the increased risk of thrombosis continues.

The major hazard of splenectomy is the long-term susceptibility to severe infection, the so-called overwhelming postsplenectomy infection (OPSI) (see also Chapter 21). The spleen plays an important role in filtering and phagocytosing bacteria, and removing parasitized red cells from the blood. The spleen is the major source for mounting the rapid, specific immunoglobulin M (IgM) response to organisms that enter through the gut. The main organisms of this class are the encapsulated organisms, *Streptococcus pneumoniae*, *Haemophilus influenzae* type B and *Neisseria meningitidis*. Pneumococcal infection is responsible for about 70% of OPSI and has a 60% mortality. Lack of a spleen greatly increases the virulence of the infection, with progression from the first feeling of fever and non-specific flu-like symptoms to irreversible endotoxic shock occurring in a matter of hours. Patients may present with purpura, evidence of disseminated intravascular coagulation (DIC), multiorgan failure, hypotension and peripheral limb ischaemia. Diarrhoea and vomiting are common prodromes. It is this speed of progression that makes the prophylaxis of this fortunately uncommon complication so important. Prophylaxis depends on education and awareness for the patient, specific measures to reduce the risk from particular organisms and the provision of information concerning the splenectomy for healthcare workers (Table 8.3). There is no direct evidence that phenoxymethylpenicillin (e.g. 250 mg twice daily) reduces the risk of OPSI in splenectomized patients, but good evidence that it does so in homozygous sickle cell patients who have functionally inactive spleens. It is on this evidence that such antibiotic prophylaxis (or erythromycin 250 mg b.d. for those sensitive to penicillin) is recommended (see also Chapter 21). The actual incidence of OPSI is difficult to calculate. The overall risk has been stated as 0.04 per hundred patient-years for patients without added immunosuppression, but considerably higher for those immunocompromised by malignancy or chemotherapy. The risk is greatest in the first 2 years post splenectomy but continues lifelong. Children under the age of 5 years are particularly susceptible and splenectomy should be avoided in this group if at all possible.

Indications for splenectomy
Patients with marked haemolysis producing symptoms or requiring transfusion should be splenectomized, although preferably not before the age of 5 years (later if possible). Recurrent aplastic crises are also an indication. Attacks of cholecystitis or biliary colic warrant cholecystectomy and splenectomy, but symptomless gallstones are not a necessary indication.

Table 8.3 Guidelines for prevention and management of infection for the splenectomized patient*.

All patients receive polyvalent, pneumococcal immunization, preferably 2 weeks prior to splenectomy, with a booster dose every 5–10 years

Any unimmunized patient should receive *Haemophilus influenzae* type B vaccine

Meningococcal immunization (types A and C) are not routinely recommended but should be given to travellers to countries where meningitis is possible, and during outbreaks in the UK

Influenza immunization may be beneficial and should be given

Lifelong, prophylactic antibiotics (oral phenoxymethyl penicillin or an alternative)

Awareness of risks of malaria and scrupulous prophylaxis if at risk

Animal, particularly dog and tick bites, may be dangerous

Leaflet card for patients to alert health professionals to risk of OPSI

Patients developing infection despite measures should receive systemic antibiotics and be admitted urgently to hospital

Hereditary elliptocytosis and hereditary pyropoikilocytosis

Deficiency of spectrin tetramers, the horizontal links of the cytoskeleton, produces a wide spectrum of disease from fully compensated haemolysis with mildly elliptocytic red cells to severe and life-threatening anaemia with grossly distorted cells. When the morphological characteristic is a relatively uniform elliptical shape, the condition is referred to as hereditary elliptocytosis (HE). Haemolytic anaemia associated with the more distorted forms, which are also heat labile, is called hereditary pyropoikilocytosis (HPP). Within a family, HE and HPP may both be present, the more severely affected individuals having both a total spectrin deficiency as well as a relative deficiency of spectrin tetramers. This may be caused by co-inheritance of a low-expression allele for α-spectrin, compound heterozygosity for two HE alleles or HE homozygosity. A number of families have been described in which mutations involving the initiation codon of the protein 4.1 gene result in failure to produce the protein. In heterozygotes with this variant, elliptocytosis occurs without haemolysis; in homozygotes, there is a severe haemolysis with pyropoikilocytosis.

Clinical features
As mentioned above, the HE/HPP group of haemolytic anaemias has a heterogeneous clinical presentation and molecular basis. Heterogeneity is amplified by the not uncommon co-inheritance of a mutated gene *in trans* (see below) with the HE gene, usually resulting in more marked heterotetramer deficiency.
Figure 8.6 Hereditary elliptocytosis, peripheral blood. Characteristic elliptocytes of mild common HE.

Figure 8.7 Hereditary pyropoikiloctosis, peripheral blood. Marked anisocytosis and poikilocytosis in the film from a child with homozygous hereditary elliptocytosis.

Mild common hereditary elliptocytosis

Frequently, HE is discovered by chance from a blood film (Figure 8.6) or the presence of marginally raised bilirubin. Some affected people have no evidence of shortened red cell survival, whereas others have a well-compensated haemolytic anaemia. No treatment is required, although the blood film of partners should be examined if there is consanguinity, making homozygosity in offspring possible. For patients with mild haemolysis, anaemia may increase during infections, in pregnancy, with folate deficiency or with other conditions that are likely to enhance anaemia.

Silent carriers: low-expression genes

Mutations that produce low expression (LE) of α-spectrin, may lead to no haematological abnormality because of the normal overexpression of α-spectrin in red cells when compared with β-spectrin. However, when these defects are inherited *in trans*, on the other allele from an HE gene, HPP may result. Several mutations have been described, particularly commonly in codon 28, which produces LE genes. A common polymorphism, intron 45 C → T, is spectrin α^{LELY}, standing for 'low-expression allele Lyon'.

Hereditary elliptocytosis and poikilocytosis in the neonate

In the neonate, the manifestations of HE may be a more marked pyropoikilocytosis resembling HPP, with more fragmented red cells. These red cells are susceptible to fragmentation above 40°C, whereas normal cells only fragment above 50°C. The morphological changes and haemolysis gradually decrease over the first year until the typical picture of mild HE remains. Treatment of neonatal pyropoikilocytosis is required only if the anaemia is such as to warrant transfusion.

Spherocytic hereditary elliptocytosis

In rare Caucasian families with HE, haemolysis with modest splenomegaly is found with a blood film that has a low proportion of abnormally shaped cells, ranging from spherocytes to elliptocytes. Splenectomy is not usually indicated.

Hereditary pyropoikilocytosis

The characteristics of hereditary pyropoikilocytosis (HPP) are densely contracted and fragmented cells (Figure 8.7), moderate to severe haemolysis and heterogeneity of manifestations within a family. In general, patients with HPP have spectrin deficiency in addition to the abnormalities of spectrin–spectrin contacts that produce the heterotetramer deficiency of HE. One parent of an HE propositus may have normal haematology but carry a mutation *in trans*, which leads to spectrin deficiency. The affected cells show thermal lability and fragmentation at lower temperatures than normal. HPP is more common in black people.

Hereditary elliptocytosis in Africa

In some parts of West Africa, a high incidence (up to 1.6% of the

population) of HE has been found. Interestingly, there is a considerable molecular heterogeneity for the basis of the condition in this area. *In vitro*, *Plasmodium falciparum* is less able to parasitize HE cells that have mutations in α-spectrin, glycophorin C or protein 4.1. Invasion is reduced in red cells from homozygous patients, and intracellular multiplication reduced, particularly in homozygous 4.1(−) red cells. It seems possible that the varieties of HE offer some protection against the clinical manifestations of falciparum malaria.

Laboratory investigation

The standard approach to the diagnosis of HE/HPP is the identification of haemolysis, coupled to a careful examination of the blood film of the patient and as many first-degree relatives as possible. Examples of blood films are shown in Figures 8.6 and 8.7. Other acquired causes of elliptocytic or fragmented red cells need to be excluded, including iron, folate or vitamin B_{12} deficiency, and the microangiopathic haemolytic anaemias. Congenital dyserythropoietic anaemia and thalassaemia intermedia also need to be excluded.

As with the investigation of HS, SDS-PAGE may reveal protein abnormalities, although more specific identification requires a sophisticated approach beyond the abilities of most haematology laboratories.

Treatment

Patients with chronic haemolysis should be given folate supplements. Splenectomy is indicated for severe haemolytic anaemia in patients with HPP or homozygous HE. Response in HPP may not be complete, but the anaemia is usually markedly alleviated. There may be a theoretical risk of increased thrombotic tendency due to remaining high platelet count, but the risk is small. The precautions against OPSI are the same as for HS.

Hereditary stomatocytosis and related disorders

Stomatocytes are so called from the mouth-like slit or 'stoma' that appears on blood films (Figure 8.8). The appearance seems to be produced by folding of cells during preparation. Stomatocytes are leaky to cations. There are other variations with Na^+ or K^+ leaks that are clinically similar to stomatocytosis without the obvious morphological changes.

All of these conditions are inherited in autosomal dominant fashion, they mostly produce moderate haemolytic anaemia, with haemoglobin of 10 g/dL or above, and they have macrocytosis. There are two main variants: overhydrated HSt, in which the MCHC is low, and dehydrated HSt, with an increased MCHC.

The blood film may show stomatocytosis but, more commonly, the film is unremarkable, apart from macrocytosis and polychromasia. The group is rare, estimates suggesting 1 in 10 000 to 100 000 of the population being affected. Associated
Figure 8.8 Hereditary stomatocytosis, peripheral blood.

features, however, make the conditions important beyond their rarity (Table 8.4). Pseudohyperkalaemia may occur because K^+ leaks rapidly from the red cells at room temperature. In some individuals, there is no evidence of haemolysis, only macrocytosis and pseudohyperkalaemia. Unless the cause of the apparent hyperkalaemia is diagnosed, unnecessary, and even dangerous, investigation and treatment may be undertaken. In some families, the K^+ leak is greatly increased *in vitro* by cold (cryohydrocytosis). In dehydrated HSt, there may be marked perinatal ascites that resolves spontaneously over the first year of life, but which again can lead to extensive unnecessary investigation. The third problem with HSt, both over- and dehydrated varieties, is that splenectomy is followed by very marked thrombotic tendencies such that splenectomy should not be performed.

Laboratory investigations

Tests for haemolysis and examination of the blood film of the patient and close relatives are the first steps in diagnosis. The finding of a raised serum potassium, together with macrocytosis, especially with some evidence of haemolysis, indicates the pseudohyperkalaemia of dehydrated HSt.

The definitive studies involve the measurement of intracellular $[Na^+]$ or $[K^+]$ and their flux through the membrane at different temperatures. Four subgroups have been defined according to the intracellular sodium concentration (normal values 5−10 mmol/L). Patients with pseudohyperkalaemia may have normal or slightly high values in dehydrated HSt sodium

Table 8.4 Features of hereditary stomatocytosis and related disorders.

Characteristic	Expression	Group affected
Haemolytic anaemia	Mild to moderate	All variants
	Absent	H pseudohyperkalaemia
Morphology	Macrocytosis	All variants
	Stomatocytosis	Variable
MCHC	Increased	Overhydrated HSt (hydrocytosis)
	Decreased	Dehydrated HSt (H xerocytosis, desiccocytosis)
Serum [K$^+$]	Raised *in vitro*	Pseudohyperkalaemia
		Dehydrated HSV
		Cryohydrocytosis
Thrombotic tendency	Post splenectomy	All variants
Fluid balance	Perinatal oedema	Dehydrated HSt

concentration 12–18 mmol/L, in families with cryohydrocytosis (temperature-sensitive leak) 20–50 mmol/L and in overhydrated HSt 60 mmol/L or more.

Treatment

There is rarely a need for measures to raise the haemoglobin and splenectomy should be avoided because of the risk of thrombosis, including hepatic and portal vein thrombosis. If splenectomy is necessary lifelong, anticoagulation should be introduced.

Rh$_{null}$ syndrome

The Rh system forms a large complex traversing the lipid bilayer several times, containing extracellular thiol groups. In the Rh$_{null}$ phenotype, the complex is absent. The condition is very rare and is inherited as a recessive disorder. Patients have mild to moderate haemolytic anaemia that may respond to splenectomy, and the blood film shows occasional stomatocytes. The Rh complex involves two genes, one encoding for the D polypeptide, the other for the Cc and Ee polypeptide, depending on post-translational splicing. Mutation of one or other of the genes encoding these proteins is the molecular basis underlying Rh$_{null}$ phenotype.

South-East Asian ovalocytosis

A dominantly inherited ovalocytosis is found in parts of South-East Asia, where falciparum malaria is common, particularly in Papua New Guinea, Borneo and the Philippines. The red cell morphology is ovalo-rather than elliptocytic. Stoma-like slits may be present and transverse banding in the red cells is seen (Figure 8.9). Most individuals have no haemolysis, but, in a few, mild anaemia may be present. Cells have increased rigidity, unlike HE in which rigidity is decreased. The molecular defect is a deletion of nine amino acids at the transmembrane cytosol junction of band 3, a defect that possibly limits the mobility of band 3 within the membrane. Homozygosity is not found and is presumably lethal *in utero*.
Figure 8.9 South-East Asian ovalocytosis, peripheral blood films. Mild ovalocytosis and some stomatocytosis. Some cells have apparent transverse ridge.

Abnormalities of membrane lipids

Acanthocytosis
Acanthocytes, or spur cells, show prominent, somewhat regular projections on the surface, best demonstrated by scanning electron microscopy. They are formed when the outer lipid layer of the membrane acquires additional lipid. Acanthocytosis is an acquired characteristic of severe liver disease, usually end stage, and the result of interaction of altered plasma lipids.

A-β-lipoproteinaemia
A-β-lipoproteinaemia is a rare inherited defect with absent β-apolipoprotein, which results in low serum cholesterol but increased sphingomyelin, which enters the cell membrane and produces the acanthocytes. The main clinical features are retinitis pigmentosa, fat malabsorption and hepatic encephalopathy.

McLeod phenotype
In the McLeod phenotype, acanthocytosis occurs (Figure 8.10), together with decreased expression of the Kell antigen. The defective gene is on the X chromosome, Xp21, close to genes for Duchenne muscular dystrophy and retinitis pigmentosa, conditions with which the phenotype has been linked. The gene codes for the Kx protein that carries the Kell blood group protein. There may be mild anaemia.
Figure 8.10 McLeod syndrome, peripheral blood. Note the marked acanthocytosis.

Disorders of red cell metabolism

9

Edward C Gordon-Smith

Introduction

The main function of the red cell is to carry haemoglobin (Hb) around the circulation in high concentration and in a functional state so that gas exchange may occur efficiently in the lungs and in the tissue capillaries. Oxygen is thus taken up in the lungs in exchange for carbon dioxide and delivered to the tissues at physiological pH and gas pressure. The structure and function of Hb is discussed in Chapter 6. In order to fulfil its function, the red cell needs a supply of energy in the form of ATP and a source of reducing power. A mature red cell has no DNA or RNA and hence is incapable of protein synthesis, and the mitochondria that are present in reticulocytes have been lost during maturation, so that the only source of energy as ATP is derived from anaerobic glycolysis and the linked reducing system of the hexose monophosphate shunt (pentose phosphate pathway) and the glutathione cycle. ATP is required to maintain the membrane in its deformable state, with asymmetric lipid layers, and to regulate ion and water exchange.

Reducing power is required to reduce methaemoglobin (MetHb) back to its functional state of deoxyhaemoglobin and to counteract the strong oxidative stresses that a cell carrying molecular oxygen around the circulation is likely to encounter. The main process that reduces MetHb utilizes reduced nicotine adenine dinucleotide (NADH), reduced from nicotine adenine dinucleotide (NAD$^+$) by the glycolytic pathway. Reduction and detoxification of free oxygen radicals and hydrogen peroxide produced during reactions to infection is provided by reduced nicotine adenine dinucleotide phosphate (NADPH) generated by the first steps of the pentose phosphate pathway, catalysed by glucose-6-phosphate dehydrogenase (G6PD) and the linked enzyme 6-phosphogluconate dehydrogenase. NADPH drives the glutathione cycle, glutathione (GSH) being the major reducing agent within the red cell.

The lack of protein synthesis in the mature red cell means that none of the enzymes in the metabolic pathways can be replaced during the red cell lifespan. Over the 120 days of normal red cell survival, enzyme activities decline at variable but predictable rates. This decline probably contributes to the ageing process of the red cell. Many of the mutations that affect red cell metabolism and provoke haemolytic anaemia cause instability and premature inactivation of the enzyme; other mutations directly affect the catalytic activity.

The glycolytic pathway (Embden–Meyerhof pathway)

Glycolysis (or, more correctly, glucolysis) is the process by which glucose is converted to pyruvate through a number of steps, with a net gain of two moles of ATP generated for each mole of glucose metabolized by the pathway. Glucose is derived from the plasma by a facilitated transfer through the membrane. Pyruvate and lactic acid are in equilibrium as determined by the redox potential of the cell (NAD$^+$/NADH) and can diffuse out. The internal milieu of the cell, with its high K$^+$ concentration and presence of other cations, such as magnesium, necessary for efficient glycolysis, is maintained through the activity of various ion and cation channels in the membrane, with energy linked by appropriate ATPases. The glycolytic pathway also provides the redox reaction to convert MetHb to deoxyhaemoglobin through utilizing NADH, in a reaction catalysed by MetHb-NADH reductase (cytochrome b_3). The various products and functions of the glucose metabolism are shown schematically in Figure 9.1 and in more detail in Figure 9.2.

The Rapoport–Luebering shunt

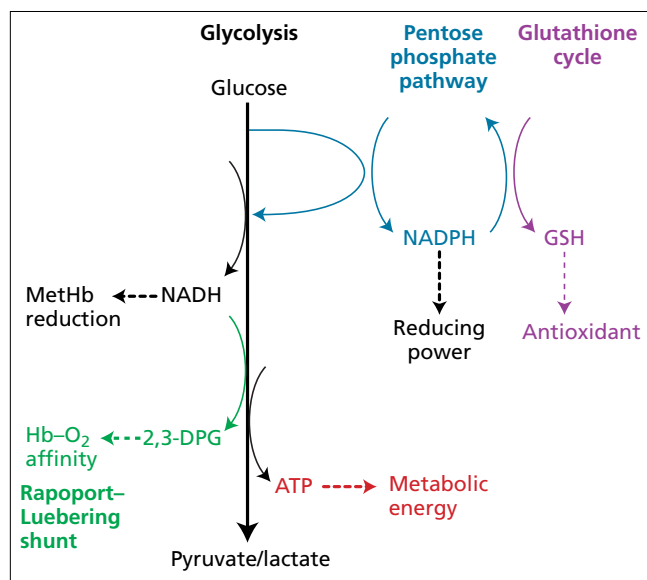
One of the essential roles of metabolism in the red cell is to provide sufficient 2,3-diphosphoglycerate (2,3-DPG) to regulate


Figure 9.1 Principal pathways of energy production in the mature red cell. The glycolytic pathway provides energy in the form of ATP. Under normal conditions, MetHb is reduced by the coupled reaction with $NADH^+$. The Rapoport–Luebering shunt provides 2,3-DPG for control of Hb oxygen affinity. Reducing power is produced by the pentose phosphate pathway and is linked to redox reactions through the glutathione cycle.

the oxygen affinity of Hb. 2,3-DPG is produced from 1,3-DPG under the influence of the enzyme diphosphoglycerate mutase in linked reactions that form the Rapoport–Luebering shunt (Figure 9.2). 2,3-DPG is broken down to 3-phosphoglycerate by a phosphatase and thus re-enters the glycolytic pathway. It should be noted that, when metabolism takes place by the Rapoport–Luebering shunt, there is a bypass of the stage of ATP production. The shunt thus not only provides the 2,3-DPG for interaction with the Hb tetramer but also acts as an energy control mechanism for glycolysis.

Disorders of the glycolytic pathway

Mutations of most of the enzymes in the glycolytic pathway have been described in association with congenital non-spherocytic haemolytic anaemia (CNSHA). However, deficiency of pyruvate kinase (PK) is far and away the most common defect. The haemolysis is the result of a failure to produce sufficient ATP.

Pyruvate kinase

PK catalyses the final steps of the glycolytic pathway with the conversion of phosphoenolpyruvate (PEP) to pyruvate, with the concomitant phosphorylation of ADP to ATP, leading to overall net gain of ATP from this pathway. There are four types of PK

in different tissues derived from two separate genes. The *PKM* gene, on chromosome 15, produces PKM1 and PKM2 through differences in post-transcriptional splicing. PKM1 is present in skeletal muscles, PKM2 in leucocytes, kidneys, adipose tissue and lungs. The second PK gene, on chromosome 1, gives rise to PKL in the liver and PKR in red cells. The isoenzymes are transcribed differently through the influence of tissue-specific promoters. The active enzymes are homotetramers. PKM2, PKR and PKL all demonstrate marked allosteric reactions with several ligands. PKM1, on the other hand, has no allosteric interactions.

The main ligands that are involved in the allosteric control of PKR in the erythrocyte are shown in Figure 9.3. PK is one of the dominant controlling steps in glucose metabolism (together with hexokinase), exerting its effect through major feedback loops, especially through the requirement of activation by fructose 1,6-diphosphate.

Pyruvate kinase deficiency

PK deficiency leads to a chronic CNSHA with extravascular haemolysis.

Molecular biology

PK deficiency is the commonest of the enzymopathies of the glycolytic pathway, at least 300 times more common than any other. Best estimates based on gene frequency in the white population suggest a prevalence of about 50 per million. Well over 100 different mutations have been described in PK deficiency, the majority involving point mutations or deletions in the transcribed gene, but a substantial number involving the promoter region. Haemolytic anaemia due to PK deficiency is an autosomal recessive disorder. Many individuals are compound heterozygotes. Not surprisingly, there is enormous genetic heterogeneity between affected individuals reflected in the multiplicity of quantitative and kinetic defects detected (Figure 9.3). Because PKR is a homotetramer composed of four chains derived from the products of the two alleles, enzyme kinetic variations are many and genotype/phenotype correlates are not predictable. Within families, however, the severity of the haemolysis tends to be similar in affected individuals. PK catalyses the ultimate step in the glycolytic pathway. Deficient activity leads to accumulation of substrates further up the pathway, including 2,3-DPG. The increased concentration of 2,3-DPG in PK-deficient red cells shifts the oxygen dissociation curve to the right, indicating low oxygen affinity. Patients with PK deficiency tolerate apparent anaemia well because the lower Hb content will deliver the same amount of oxygen to tissues as the normal Hb, at least under normal conditions, although oxygen reserve would be limited.

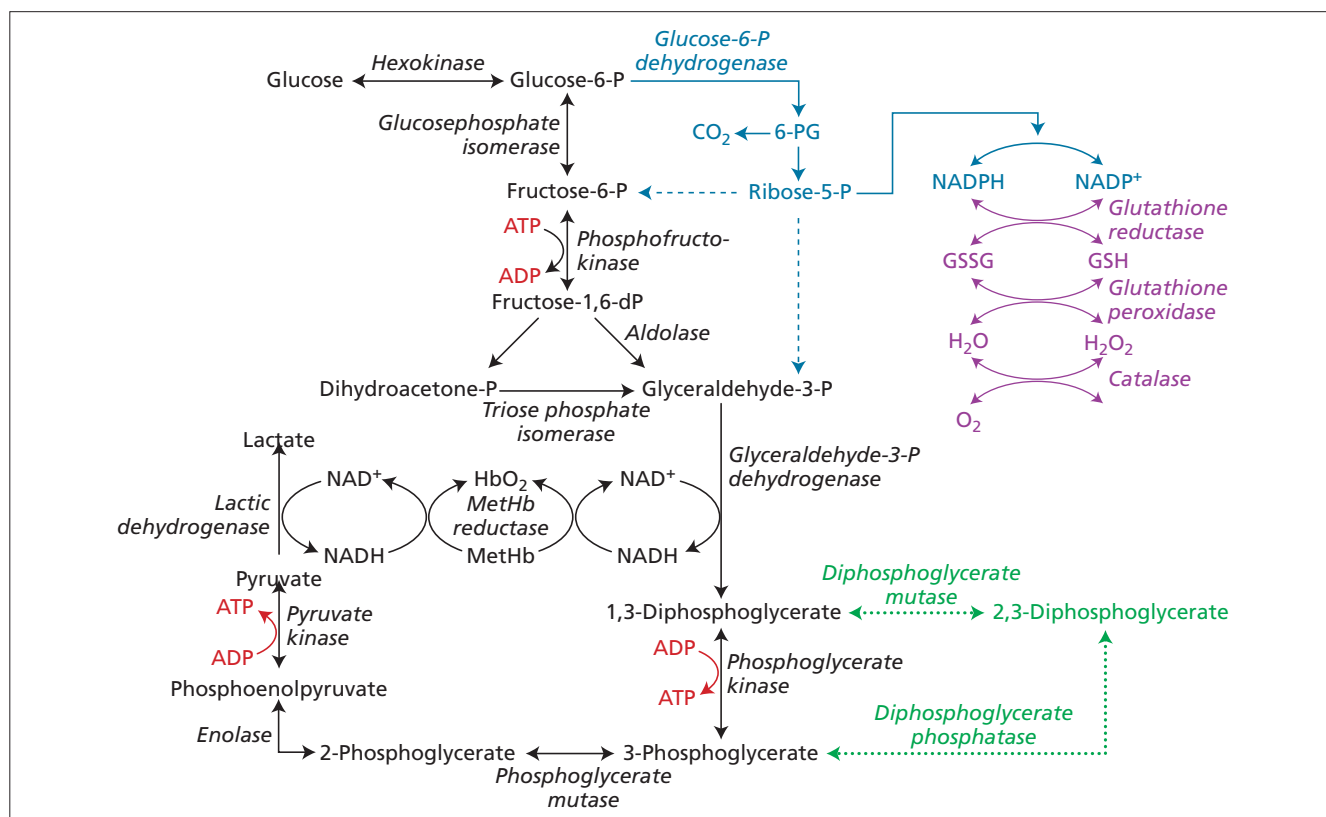
Reticulocytes have alternative means of producing energy in the form of ATP, through oxidative respiratory pathway of the remaining mitochondria. They can also synthesize enzyme in those defects where lack of stability is the major cause of enzyme deficiency in the mature cell. Reticulocytes thus have a metabolic advantage over mature red cells in PK deficiency.


Figure 9.2 The glycolytic pathway and its interactions with the pentose phosphate pathway and the Rapoport–Luebering shunt.

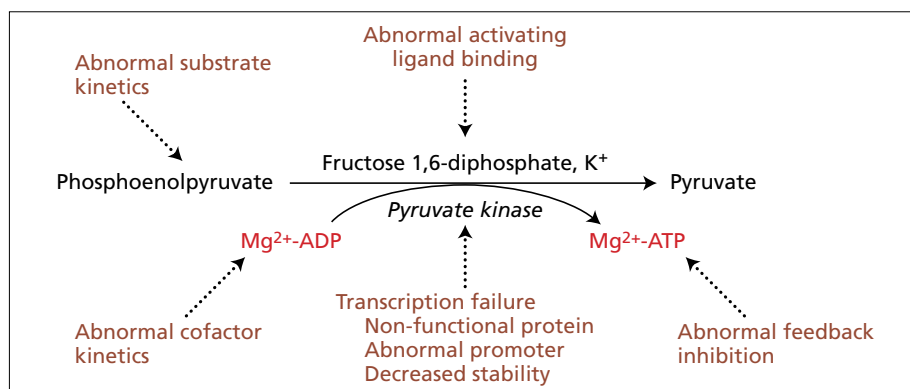
Figure 9.3 The reactions of pyruvate kinase, showing the main ligands that influence activity and the sites affected by various mutations encountered in PK deficiency.


Clinical features

The genetic heterogeneity is reflected in the wide variation of the phenotype. The presenting features may vary from severe neonatal jaundice and anaemia (Figure 9.4), rarely even presenting with hydrops fetalis, severe CNSHA requiring repeated transfusions, moderate haemolysis with exacerbation during infections or pregnancy, to symptomless compensated haemolysis with only a minor apparent anaemia. The majority of reported cases

have presented in childhood. PK deficiency does not usually have an adverse effect on the outcome of pregnancy, although occasionally transfusion may be required to compensate for the added dilutional anaemia (Figure 9.5).

Jaundice, as with other congenital haemolytic anaemias, may be exacerbated by co-inheritance of other genes, for example, of Gilbert's syndrome. The haemolysis is nearly always extravascular, although rare examples with some intravascular haemolysis

135
Figure 9.4 Effect of splenectomy in a child with severe CNSHA due to PK deficiency. Splenectomy was delayed until the child was 3 years old. Note the marked reticulocytosis post splenectomy (V, viral infection; Uti, urinary tract infection). The child grew normally despite Hb of around 8 g/dL (see text).
Figure 9.5 Multiple successful pregnancies in a splenectomized patient with PK deficiency. Transfusion was required during pregnancy (p) and before surgery (st, sterilization) and during infection (u, urinary tract infection; s, sepsis).

have been detected. Gallstones are common in PK deficiency and may lead to bouts of cholecystitis and biliary colic (Figure 9.6). Jaundice may also be increased by administration of drugs that affect bile excretion. As with other cases of congenital haemolytic anaemias with extravascular haemolysis, excess iron accumulation may occasionally develop even in the absence of transfusion or co-inheritance of a haemochromatosis gene.

The spleen is usually palpable in cases where there is significant haemolysis, although in milder cases, it may be evident only by using ultrasound or other imaging techniques.

Pyruvate kinase deficiency is not associated with abnormalities of other tissues, as the deficient enzyme is unique to the red cells, but occasionally individuals are seen with associated abnormalities due to deletions within chromosome 1, close to the PK gene.

Laboratory diagnosis

The blood count reveals a normochromic anaemia with reticulocytosis, sometimes producing a slight macrocytosis. An increased mean cell Hb concentration (MCHC) is occasion-

ally seen in severe cases as a result of dehydration brought about by ATP deficiency. This dehydration also produces the characteristic spur cells or acanthocytes seen on the blood film (Figure 9.7a and b). Apart from the spur cells (which are not specific) and the very large reticulocytosis post splenectomy (Figure 9.7c), there is nothing to distinguish PK deficiency from other causes of CNSHA.

The autohaemolysis test, involving the incubation of defibrinated red cells with and without glucose for 48 h at 37°C, has traditionally been used for screening tests. The haemolysis in the unfortified aliquot is uncorrected by the addition of glucose (type II). The test is not specific and has mainly been abandoned in favour of the enzyme assay.

The definitive diagnosis depends on the analysis of enzyme activity and kinetics, although the finding of an elevated 2,3-DPG level (2–3 times normal) may be a useful pointer. Characterization of the enzyme requires measurement of maximal activation under optimal conditions (V_{max}), kinetic studies to determine substrate(s) concentration at which the enzyme shows 50% V_{max} (K_m), thermal stability, pH optimum and

electrophoretic mobility. Meaningful enzyme levels can be achieved only after the total removal of leucocytes, which have up to 300 times the PK activity of red cells. The effect of reticulocytes also has to be taken into account. International guidelines for investigation of PK deficiency have been published. Typically, homozygotes have about 25% of the normal V_{max} activity, allowing for the age of the red cells and heterozygotes 50–60%, but the range is great and there is much overlap in the V_{max} between the groups, emphasizing the need for kinetic and other studies (Figure 9.8).

Management
The mainstay of management of patients who have severe enough haemolysis to warrant treatment is splenectomy. Assessment of the need for splenectomy should take into account the symptoms of the patient, not the Hb level. The low Hb (even as low as 7.0 g/dL) may be well tolerated because of the right-shifted oxygen dissociation curve. Indications for splenectomy include severe neonatal haemolysis and chronic transfusion

requirements. The dangers of splenectomy, particularly the risk of overwhelming sepsis, are discussed in Chapters 8 and 21. Splenectomy raises the effective Hb so that transfusion is not required but does not prevent hyperbilirubinaemia, so biliary complications may still arise after splenectomy.

Following splenectomy for PK deficiency, there is a huge elevation of the reticulocyte count, which may reach 80%
Figure 9.8 PK activity V_{max} measured in patients, obligate heterozygotes and normal control subjects. Note the wide overlap of values between the two groups, indicating importance of kinetic studies as well as effect of reticulocytosis.

or more of the peripheral blood cells (Figure 9.7c). Although pregnancy may exacerbate this anaemia, there is no indication that PK deficiency itself has an adverse effect on the pregnancy or outcome, as long as the anaemia is managed as necessary (Figure 9.5). As with all chronic haemolytic anaemias, folic acid, 5 mg per week or 400 μg daily, is a sensible supplement.

Other defects of the enzymes of the glycolytic system

Compared with PK deficiency, the other defects of the glycolytic pathway are very rare. The main features of these disorders are summarized in Table 9.1.

Hexokinase

Hexokinase (HK1) catalyses the phosphorylation of glucose to G6P, the first step in the glycolytic pathway. The enzyme in the red cell differs from that in nucleated cells, which have oxidative respiration, by lacking a porin-binding domain that links the enzyme to the mitochondrial membrane. The red cell enzyme is derived from alternative splicing of the gene product. The enzyme provides a major rate-limiting step in glycolysis and has extensive allosteric interactions, being highly pH sensitive and regulated in its activity by its products, G6P, P_i, 2,3-DPG and disulphide compounds. The enzyme activity decays predictably with age of the normal red cell, and may be used as a comparator

for other enzyme activities, when absolute levels may be difficult to interpret because of the age distribution of the red cells.

Hexokinase deficiency

Hexokinase deficiency has been recorded in fewer than 30 cases but, even within this small number, there is evidence of molecular and phenotypic heterogeneity. Complete hexokinase deficiency is probably lethal. Most patients have moderately reduced activity for the age of the red cell and, in the majority of cases, it is the stability of the enzyme that is affected by the mutation. Combined heterozygosity for complete gene deletion and a nonsense mutation affecting activity has been recorded as a typical example of compound genetic inheritance. In most recorded cases, the activity of the enzyme is reduced to between 10% and 20% of normal. As with other glycolytic enzyme deficiencies, there is variable non-spherocytic haemolytic anaemia, in this case mostly relatively mild. Obligate heterozygotes have reduced levels of the enzyme, but assays of the activity in patients with haemolytic anaemia due to hexokinase deficiency may be difficult to interpret because of the higher activity in reticulocytes and in young cells. Typically, the reduced hexokinase activity is associated with a fall in the concentration of 2,3-DPG within the cells. Patients have less exercise tolerance for a given level of Hb than would be expected because of the left shift in the oxygen dissociation curve.

Glucosephosphate isomerase

Glucosephosphate isomerase (GPI) catalyses the second step of the Embden–Meyerhof pathway, the interconversion of G6P to fructose 6-phosphate (F6P). The enzyme is also known as phosphohexose isomerase, phosphoglucose isomerase, autocrine motility factor and neuroleukin (NLK). The names 'autocrine motility factor' and 'neuroleukin' indicate that the protein has other actions in other cells. The interconversion of the hexose phosphates is driven towards F6P by the rapid metabolism of that product along the metabolic pathway, so that the concentration of F6P in the red cell is low and drives the reaction towards its formation.

Glucosephosphate isomerase deficiency

Deficiency of GPI is one of the commonest causes of CNSHA after G6PD deficiency and PK deficiency. It is about as equally common as pyrimidine 5′-nucleotidase deficiency (see later). The mutations that give rise to GPI deficiency are very heterogeneous – out of the 20 characterized mutations, 14 appear in only a single family and 11 of the 20 occur in compound heterozygotes. The clinical picture perhaps reflects this genetic heterogeneity. Most reported cases are of mild to moderate haemolytic anaemia, but in one Indian family stillbirths and hydrops occurred in several siblings before early delivery and exchange transfusion for hydrops allowed survival. The mutations described mainly affect the stability of GPI, which is perhaps why no associated anomalies are found in nucleated cells. In T lymphocytes, GPI

Table 9.1 Main features of glycolytic enzyme deficiencies.

Enzyme	Genetics (chromosome/inheritance)	Haematology	Other systems affected	Comment
Hexokinase (HKI)	10q11.2 AR	CNSHA High O_2 affinity	None directly*	Very rare, occasional AD
Glucose phosphate isomerase (GPI)	19cen–q12 AR	CNSHA	None directly*	Most common after PK deficiency
Phosphofructokinase (PFK)	1(M) and 21(L) Complex	Erythrocytosis Minimal haemolysis	Dominated by myopathy	Tarui's disease, subunit genes
Fructose diphosphate aldolase (ALDOA)	16q22–q24 AR	CNSHA Intermittent HA	Dysmorphism, myopathy	Very rare (three families)
Triose phosphate isomerase (TPI)	12p13 AR	CNSHA Infections	Neuromuscular, cardiac	Neuromuscular defects dominate, sudden death, Splx not helpful
Phosphoglycerate kinase (PGK)	Xq13 X-linked	CNSHA	CNS, myopathy, rhabdomyolysis	Rare (28 families), variable systems involved
Diphosphoglycerate mutase (DPG mutase)	7q23–q34 AR	Erythrocytosis	None	Very rare, low 2,3-DPG
Glyceraldehyde-3-P-dehydrogenase	12p13 AD	None	None	Membrane protein band 6, associated with HS, gene syntenic with TPI
Pyruvate kinase (PK)	1q21–q22 (PKLR) AR rarely AD	CNSHA	None	Commonest CNSHA

AD, autosomal dominant; AR, autosomal recessive; CNSHA, congenital non-spherocytic haemolytic anaemia; Splx, splenectomy.
*Neurological signs may be secondary to hypoxia or ischaemia.

acts as NLK, a lymphokine that induces the formation of antibody-secreting cells. It is also present in neutrophils, but there is no increase in infections in deficient subjects. In some severely deficient patients, neurological retardation has been thought to be related to hypoxia or ischaemia *in utero* rather than to direct metabolic effects.

Phosphofructokinase

Phosphofructokinase (PFK) catalyses a reaction in which F6P is phosphorylated to fructose-1,6-diphosphate, ATP being the donor of the phosphate group. Under normal physiological conditions, this may be the major rate-limiting step in glycolysis in the red cell. PFK is a tetramer, which in the red cell is a heterote-

tramer made up from M or L subunits. Two separate genes code for the two subunits. In muscle, PFK is a homotetramer (M_4) and in liver a homotetramer (L_4). In the red cell, there may be five isoenzymes composed of different numbers of L- and M-type subunits. A third subunit is found in platelets.

Phosphofructokinase deficiency

Deficiency of the M subunit leads to glycogen storage disease type 7 (Tarui's disease). It is characterized by muscle cramps and myoglobinuria on exertion. Shortened red cell viability may be a minor component of this disease. Evidence of haemolysis may be accompanied by mild erythrocytosis as a result of the decreased production of 2,3-DPG.

Fructose diphosphate aldolase A (ALDOA)

Fructose-1,6-diphosphate aldolase catalyses the conversion of fructose 1,6-diphosphate to glyceraldehyde 3-phosphate (Ga3P) and dihydroxyacetone phosphate (DHAP). There are three aldolases in human tissues (A, B and C), of which only A is expressed in the red cell. ALDOA is produced in the developing embryo and forms also the bulk of the enzyme in muscle, where it may be as much as 5% of the total cellular protein. In the red cell, the reaction catalysed by the enzyme is for all intents and purposes irreversible.

Fructose diphosphate aldolase A deficiency

The condition is extremely rare, with only three families having been definitely identified as having ALDOA deficiency. Two families have been described in which the propositus presented with CNSHA, mental retardation and dysmorphic features that are similar in the two families. In at least one family, the mutation produced an unstable enzyme. In a third patient, symptoms were mainly of myopathy, with weakness and premature fatigue. Anaemia and jaundice were intermittent and rhabdomyolysis occurred. There was severe deficiency of both muscle and red cell enzyme activity.

Triose phosphate isomerase

Triose phosphate isomerase (TPI) catalyses the interconversion of DHAP and Ga3P. In the glycolytic pathway of the red cell, all DHAP is converted to Ga3P, which is then metabolized down the glycolytic pathway, providing the ultimate two molecules of ATP for each molecule of glucose metabolized by that pathway. The enzyme is a homodimer, present in all tissues. In tissues other than the red blood cell, DHAP is an important precursor for the biosynthesis of ether glycerolipids (plasmalogens).

Triose phosphate isomerase deficiency

Triose phosphate isomerase deficiency produces a severe syndrome present from birth, consisting of CNSHA, a progressive neurological disorder with spasticity and CNS degeneration. Cardiac failure and sudden death due to arrhythmias are also features. Death occurs usually about 5 years of age. There is, as usual, some variation, and haemolysis without neurological degeneration, and the opposite, have been described. Splenectomy does not appear to be effective in modifying the haemolysis and does not influence the neurological complications. The diagnosis is made based on clinical suspicion, together with the appropriate enzyme assay. A number of point mutations that lead to the syndrome have been identified, but far and away the most predominant is Glu104Asp, a mutation linked by common haplotypes, suggesting descent from a common ancestor.

Phosphoglycerate kinase

Phosphoglycerate kinase (PGK) catalyses the reversible conversion of 1,3-DPG to 3-phosphoglycerate, generating one molecule of ATP for each molecule of 1,3-DPG metabolized by this pathway. It should be noted that two molecules of the 1,3-DPG are produced for each molecule of glucose metabolized by this pathway. PGKA, the active enzyme in the red blood cell, is the product of a gene on the X chromosome. The enzyme is monomeric and is expressed in all tissues (a testis has an additional PGKB gene coded on an autosome).

Phosphoglycerate kinase deficiency

In total, 28 families with PGK deficiency have been reported, and sequencing data are available for 16 families. Overall, 15 different *PGK1* gene mutations have been identified. CNSHA occurred in 17 out of the 28 families, CNS disorders in 13 and myopathy with or without rhabdomyolysis in 13. All three systems were involved in only one of the families. Anaemia, when present, is usually well tolerated because of the increased concentration of 2,3-DPG produced by the increased flow of 1,3-DPG to 2,3-DPG via the Rapaport–Leubering shunt in the presence of the mutated PGK deficiency. Splenectomy has been effective in some cases of severe anaemia, but less so in others.

Defence against oxidative stress – the production of reducing power

As with all cells, but perhaps more urgently, the red blood cell needs to be protected against the effects of free radicals, hydrogen peroxide and other highly oxidative material in order to maintain the membrane integrity and functional activity. In addition, Hb has to be maintained in its functional state, and the steady production of MetHb reversed back to deoxyhaemoglobin, which is able to combine reversibly with oxygen. The major generator of reducing power within the red cell is the pentose phosphate pathway (hexose monophosphate shunt), which generates reducing power in the form of NADPH from NADP$^+$ coupled to the oxidation of G6P to 6-phosphogluconate and the subsequent oxidation of that compound to ribose 5-phosphate, the two reactions catalysed by the enzyme G6PD and 6-phosphogluconate dehydrogenase (6PGD) (Figure 9.9).

Glutathione (GSH) is important for the protection of cells from oxidative damage by these free radicals, protection against the effects of infection, the maintenance of protein sulphydryl groups in the reduced state and the maintenance of membrane transport. A constant supply of GSH is provided by the glutathione cycle, linked to the pentose phosphate pathway through the action of glutathione reductase (Figure 9.10).

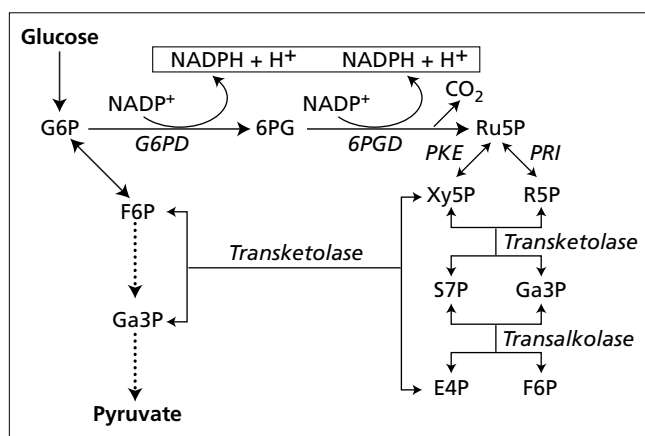
An excess of oxidative stress over the reducing power of the red cell leads to intravascular haemolysis following denaturation of the Hb and precipitation as Heinz bodies and peroxidation of the red cell membrane. Methaemoglobinaemia may occur. The clinical features that emerge, acute intravascular haemolysis, Heinz body haemolytic anaemia or methaemoglobinaemia, depend upon the nature of the oxidative stress and the size of the imbalance between the stress and the redox potential.


Figure 9.9 The pentose phosphate pathway. Substrates: G6P, glucose-6-phosphate; 6PG, 6-phosphogluconate; Ru5P, ribulose-5-phosphate; R5P, ribose-5-phosphate; Ga3P, glyceraldehye-3-phosphate; F6P, fructose-6-phosphate; Xy5P, xylose-5-phosphate; S7P, septulose-7-phosphate; E4P, erythrothrose-4-phosphate. Enzymes: G6PD, glucose-6-phosphate dehydrogenase; 6PGD, 6-phosphogluconate dehydrogenase; PKE, phosphoketoepimerase; PRI, phosphoribose isomerase.

Pentose phosphate pathway (hexose monophosphate shunt)

The reactions of the pentose phosphate pathway are shown schematically in Figure 9.2 and in more detail in Figure 9.9. In most cells, the pentose phosphate pathway is an essential pathway for the production of ribose and incorporation into RNA. In the red cell, its only function is the production of reducing power in the form of NADPH. The first step of the pathway, catalysed by G6PD, utilizes G6P as the substrate. G6P is also a substrate for the glycolytic pathway. Under normal circumstances, about 10% of glucose is metabolized by the pentose phosphate pathway, the activity of that pathway being determined by the availability of NAD^+ and feedback inhibition by ATP. Under conditions of oxidative stress, the flux through the pentose phosphate pathway can be greatly increased. The products of the pathway re-enter the glycolytic pathway through F6P or Ga3P.

From the point of view of haematological disorders, G6PD deficiency is by far the most important step in the pathway. However, other enzymes of the pathway can be important in acquired disorders, some steps being inhibited by drugs, including oestrogen–progesterone contraceptive pills.

Glucose-6-phosphate dehydrogenase

G6PD catalyses the first step of the pentose phosphate pathway and is the enzyme controlling flux through that pathway. The activity is controlled by the availability of $NADP^+$. Conversion of G6P to 6PG is accompanied by the reduction of $NADP^+$ to NADPH, and the second step in the pathway, the oxidation of 6PG to ribose 5-phosphate, produces a second molecule of NADPH.

The gene for G6P is located on the X chromosome at Xq28. The gene has 13 exons and 12 introns. The gene is transcribed as

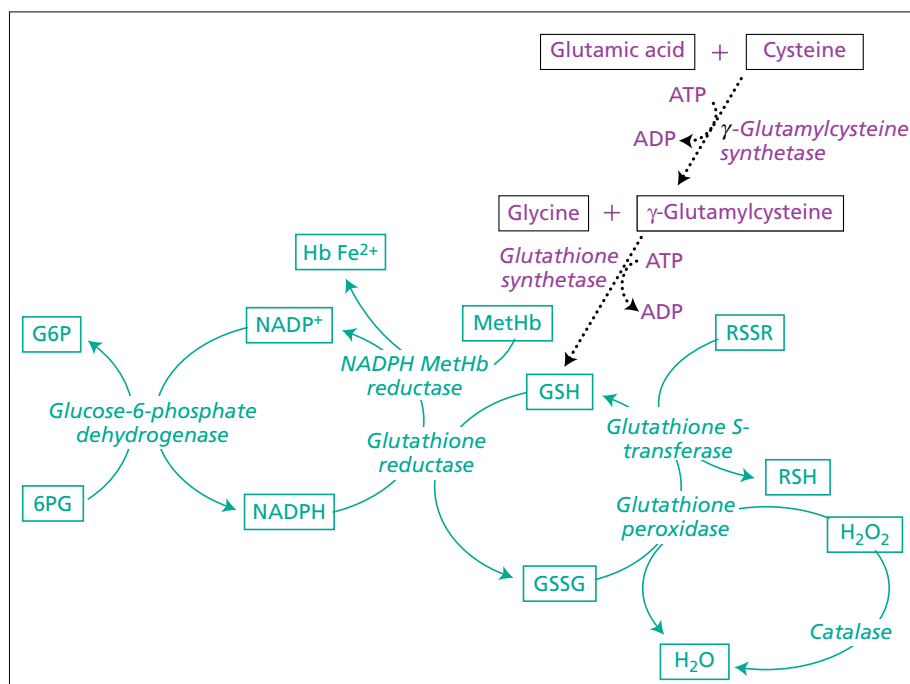
Figure 9.10 The glutathione cycle and synthetic pathways. GSH is synthesized in two linked steps. The redox control is exercised by the glutathione cycle linked to the NADPH of the pentose phosphate pathway by glutathione reductase.


Figure 9.11 Structure of G6PD in dimer form, showing active sites for G6P and NADP⁺. Mutations that affect interactions of the monomers lead to CNSHA.
Figure 9.12 G6PD gene map showing mutation sites (courtesy of Tom Vulliamy, Hammersmith Campus, Imperial College, London). Numbered boxes refer to the location of *G6PD* exons: yellow circles, class I and II variants; yellow ellipses, class IV variants; red circles, polymorphic variants; green circles and squares, class I variants caused by amino acid substitutions and small in-frame deletions, respectively.

a monomer of 514 amino acids that come together to produce an equilibrium of dimers and tetramers (Figure 9.11). Each monomer has an NADP⁺-binding domain and a large domain, with the active site between the two. The gene is a household gene, active in all cells, with an essential role in the production of RNA in nucleated cells. Not surprisingly, the gene is highly conserved in evolutionary history. Complete inactivity of the enzyme in nucleated cells would not be compatible with life. The clinical consequences of G6PD deficiency are virtually confined to the red blood cell, with occasional evidence of leucocyte malfunction in some variants. The majority of mutations affect the stability of the transcribed enzyme so that there is a rapid decline in activity in the mature enucleate red cell as it ages.

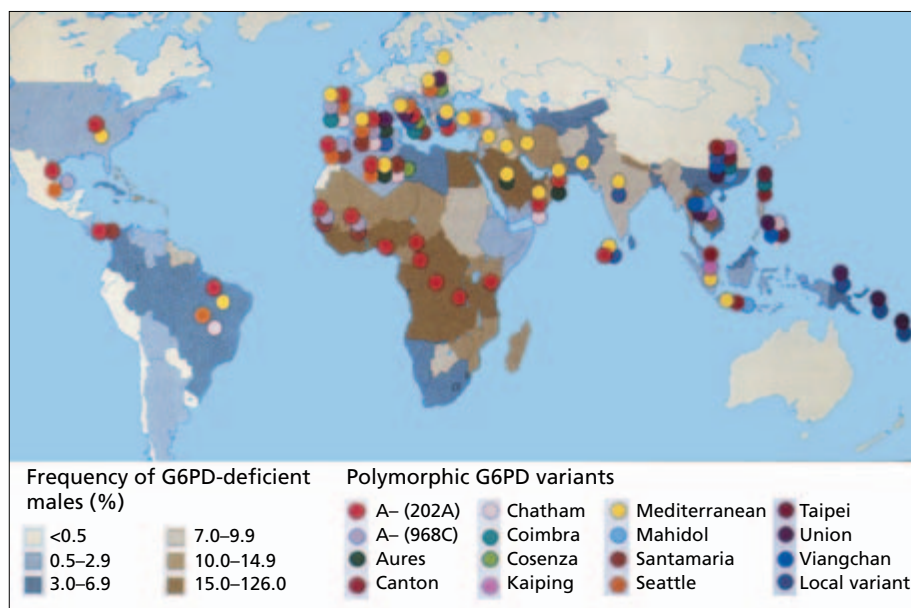
In the red blood cell, G6PD catalyses the first reaction of the pentose phosphate pathway, the conversion of G6P to 6-phosphogluconate through the reduction of NADP⁺ to NADPH (Figure 9.9). The availability of NADP⁺ is determined by the activity of the glutathione cycle, which is linked to the pentose phosphate pathway through the activity of the enzyme glutathione reductase (Figure 9.12). The availability of NADP⁺ is the major rate-limiting step for the pentose phosphate pathway.

Glucose-6-phosphate dehydrogenase deficiency

G6PD deficiency is the commonest genetically determined enzyme deficiency in the world population, with an estimated 400 million people being affected. At least 127 different variants associated with deficient enzyme activity have been described, as well as a number of polymorphisms that do not affect the enzyme activity. The G6PD variants have been classified into four groups according to their activity relative to the 'wild-type' G6PD type B (Table 9.2). In Africa, the variant G6PD A⁻ is the predominant polymorphism with equivalent activity to G6PD type B.

Table 9.2 Classification of G6PD deficiency (WHO).

Class	Enzyme activity (% normal)	Examples	Clinical Effects
I	Severe (usually < 20)	Santiago de Cuba (Gly447Arg)	CNSHA, acute exacerbations
II	< 10	Mediterranean (Ser188Phe) Canton (Arg459Leu) Orissa (Ala44Gly)	Favism AIVHA (drug induced) Neonatal jaundice
III	Moderate (> 10, < 60)	A⁻ (Val68Met; Aas126Asp)	AIVHA (drug induced), neonatal jaundice
IV	100	B⁻ (wild type) A (Asn126Asp)	None None

Figure 9.13 Global distribution of *G6PD* gene variants causing G6PD deficiency. Shaded areas indicate the prevalence of G6PD deficiency. The coloured dots depict the distribution of 14 of the most common variants (from Luzzatto & Notaro, 2001, *Science* **293**: 442, with permission).


Epidemiology

G6PD deficiency is widely disseminated throughout Africa, the Mediterranean basin, the Middle East, South-East Asia, and indigenous populations of the Indian subcontinent. G6PD A⁻ is common in Africa (it has a second mutation in the G6PD A⁻ gene – see Figure 9.12), the Mediterranean variant in southern Italy, Sardinia and other places around the Mediterranean basin, and G6PD Canton in southern China. These variants are only the most common amongst many different mutations in these areas and throughout the rest of the affected world (Figure 9.13). This distribution of the deficiency equates with areas where *Plasmodium falciparum* malaria is common, and this is thought to be the evolutionary drive that produced such widespread polymorphisms (Figure 9.13). It has subsequently been confirmed that G6PD deficiency does indeed protect against lethal falciparum malaria, particularly in childhood, and this protection, especially in hyperendemic areas, more than outweighs the haematological problems associated with deficiency.

Clinical features

There are four main syndromes associated with G6PD deficiency. In all four syndromes, haemolysis is aggravated or promoted by exposure to oxidative stress through infection or ingestion of oxidative foods or drugs, but the clinical presentations differ. Age always modifies the clinical effects although not always as might be expected. The four syndromes are neonatal jaundice, favism, CNSHA and drug-induced haemolytic anaemia. The neonatal jaundice syndrome has been described in class I, II and III variants: favism in mainly, although not exclusively, class II, CNHSA in class I and the drug-induced haemolysis mainly class III. Although G6PD deficiency is most common in males, the prevalence of the gene in many parts of the world (Figure 9.13) means that female homozygotes are not uncommon, and heterozygous females are often susceptible to oxidative stress because of the effects of X-inactivation and marked lyonization in leaving a significant population of deficient red cells.

Neonatal jaundice and G6PD deficiency in infancy
Neonatal jaundice is a severe manifestation of G6PD deficiency and is a major source of potential morbidity from kernicterus. Most common variants have been associated with the syndrome, including the A⁻ and Mediterranean variants. In parts of the world where the mutations are common, the deficiency is the most prevalent cause of neonatal jaundice. The jaundice probably starts *in utero* in the perinatal period, but the clinical problem becomes apparent only about the second or third day after birth. Between 10% and 50% of deficient infants are affected. Phototherapy or exchange transfusion may be required to prevent neurological sequelae. Anaemia is not a feature, and it is thought that this is a manifestation of liver enzyme deficiency, coupled perhaps to the physiological underdevelopment of neonatal liver function or the co-inheritance of UDP-glucuronyl transferase 1 deficiency of Gilbert's syndrome.

Acute haemolytic crises may occur in G6PD-deficient infants, usually through exposure to oxidative stress, including nitrites or nitrates in water or the ingestion of fava beans by the mother but, in some cases of severe acute haemolysis, even fatal, no cause has been obvious.

Favism
Favism is the term given to the G6PD syndrome when acute intravascular haemolysis may be precipitated by exposure to the broad bean *Vicia fava*. Fresh, dried or frozen beans or even exposure to pollen may precipitate the crisis. The offending agent is divicine, or its aglycone isouramil, which can produce free oxygen radicals on autoxidation. Divicine is not present in peas or beans of other types, which may be eaten without effect. The amount of haemolysis is dose related, which may explain the marked variation in susceptibility not only between children and adults, but also in the same individual at different times. There is variation in divicine content between different cultivars; some fungi can break down the compound and the amount may vary in different seasonal environments. In children, acute haemolysis, sometimes life-threatening, is common, but renal failure is uncommon although there may be systemic symptoms of fever and loin pain. Renal failure occurs more often in adults, possibly because of comorbidity. Favism is usual in class II variants, for example Mediterranean and Canton, but may occur in others, including the African A⁻ variant. Although fava beans give the syndrome its name, some other compounds with which affected individuals may come in contact can cause acute haemolysis, including topical henna and some of the pulses used to make up local sweetmeats.

In between attacks of favism or exposure to oxidizing substance, the blood count is normal, with no evidence of haemolysis. The coincidence of infection, which promotes the formation of hydrogen peroxide following the oxygen burst in neutrophils and macrophages, with ingestion of oxidizing substances, even mild ones such as chloramphenicol, may promote haemolysis even although the drug on its own does not.

Chronic non-spherocytic haemolytic anaemia
Sporadic cases in virtually all populations of CNHSA are found with underlying G6PD deficiency. Many of the mutations that cause CNHSA occur on exon 10 and affect the formation of dimers or tetramers (Figures 9.11 and 9.12). The haemolysis is extravascular, although additional oxidative stress may provoke an acute intravascular episode.

Drug-induced acute haemolysis
The introduction of primaquine and its derivative pamaquine as antimalarials to replace quinine during the Pacific phase of the Second World War and the later Korean War revealed that a portion of men exposed, particularly in the black population, suffered from sever acute intravascular haemolysis. Intensive studies by Carson and others from the University of Chicago, working at the Statesville Penitentiary Malaria Project, finally identified the problem as G6PD deficiency and identified that young red cells and reticulocytes had sufficient activity to withstand the oxidative stress so that haemolysis lessened as the reticulocyte level rose. It became apparent that many other drugs could also produce haemolysis, but mostly fava beans did not. The common A⁻ variant of Africa is the main example of class III mutations producing this type of haemolysis.

The haemolysis is dose related and may be self-limiting. Although it is important to recognize which drugs are likely to produce haemolysis (Table 9.3), it is also important to realize that the disease for which the drugs may be needed, for example falciparum malaria, may be fatal and the haemolysis is a lesser problem.

Laboratory diagnosis
The acute intravascular haemolysis raises the suspicion of G6PD deficiency. The blood film shows red cells with contracted Hb in 'ghost' membrane (Figure 9.14). Haemoglobinuria may be gross, producing almost black urine without red cells in the centrifuge deposit.

Several screening tests have been devised to identify G6PD deficiency in red blood cells. The most widely used tests have been the brilliant Cresyl blue decolorization test, the MetHb reduction test and an ultraviolet spot test. These tests can reliably distinguish between deficient or not deficient individuals, but are not reliably quantitative. Hemizygous deficient males and homozygous deficient females will be identified, the threshold being a G6PD activity of about 30% of normal.

If a screening test indicates deficiency or is doubtful, the ideal follow-up test for definitive diagnosis is quantification of G6PD activity by spectrophotometric assay. Standardized methods have been published. There are two clinical situations in which quantification is especially important. First, during a haemolytic attack, the oldest red cells (with the least G6PD activity) are destroyed selectively, and therefore the surviving red cells have a relatively higher (but still deficient) G6PD activity. This increases further as the reticulocyte response sets in over the

Table 9.3 Drugs to be avoided in G6PD deficiency*.

Antimalarials	Analgesics
Primaquine (can be given at reduced dosage, 15 mg daily or 45 mg twice weekly under survelliance)	Acetylsalicylic acid (aspirin); moderate doses can be used
Pamaquine	Acetophenetidin (phenacetin); safe alternative, paracetamol
Sulphonamides and sulphones	**Antihelminthics**
Sulphanilamide	β-Naphthol
Sulphapyridine	Stibophan
Sulphadimidine	Niridazole
Sulphacetamide (Albucid)	
Salicylazosulphapyridine (Salazopyrin)	**Miscellaneous**
Dapsone[†]	Vitamin K analogues (1 mg menaphthone can be given to babies)
Sulphoxone[†]	Naphthalene (mothballs)[†]
Glucosulphone sodium (Promin)	Probenecid
Septrin	Dimercaprol (BAL)
	Methylene blue
Other antibacterial compounds	Toluidine blue
Nitrofurans	
Nitrofurantoin	
Furazolidone	
Nitrofurazone	
Nalidixic acid	

*This list is compiled on the basis of data available for patients with the 'A⁻' variant of G6PD deficiency. It can be generally assumed to be applicable to patients from Africa and of African descent. For patients with the Mediterranean type of G6PD deficiency, with an unknown variant, or with CNSHA, the following should also be added: acetanilide, chloramphenicol, chloroquine (may be used under surveillance when required for prophylaxis or treatment of malaria), mepacrine, *p*-amino salicylic acid and thiazosulphone. Many other drugs may produce haemolysis in particular individuals.

[†]These drugs may cause haemolysis in normal individuals if taken in large doses.
Figure 9.14 G6PD deficiency. Peripheral blood film following acute oxidant drug-induced haemolysis shows an erythroblast and damaged red cells, including 'blister' and 'bite' cells.

following days. During this time, a screening test might yield a false-normal result and, rarely, even a quantitative test might do so. In such cases, the best counsel is to repeat the test a couple of weeks later. Alternatively, the oldest remaining cells can be isolated by differential centrifugation and they can be shown to have a low G6PD activity. The diagnosis of heterozygous females can be especially difficult; in extreme cases, it can only be done by family studies. However, from the practical point of view, it must be borne in mind that the probability of clinically significant haemolysis in a heterozygote roughly correlates with the proportion of G6PD-deficient red cells in her blood. Therefore, if a normal level of G6PD activity is found in a heterozygote, she is unlikely to be at risk of G6PD-related haemolysis. In regions where G6PD has a high prevalence and the main variants are known, DNA analysis is the most effective way of identifying heterozygotes.

Management

Mostly, management is dictated by the symptoms and signs in

Table 9.4 Association between G6PD deficiency and jaundice in male newborns.

Groups of newborns	n	G6PD deficiency %
Normal	500	22.5
Mild jaundice (bilirubin 150–200)	38	45
Severe jaundice (bilirubin >230)	70	60
Admitted with kernicterus	20	78

Data collected in Ibadan, Nigeria.
Bilirubin values in μmol/L.

the patient, although education in the avoidance of oxidizing substances is important (Table 9.3). In many populations, the condition is well known and the need for avoidance recognized. Neonatal jaundice may need urgent therapy to prevent neurological damage (Table 9.4). Extreme hyperbilirubinaemia can be prevented by administration of Sn-mesoporphyrin if the diagnosis is known at birth. Acute intravascular haemolysis may require transfusion but the anaemia is often self-limiting (Table 9.5). High fluid intake should be encouraged to prevent renal damage. CNSHA may be severe enough to warrant active treatment and splenectomy may be helpful.

Glutathione

Glutathione (GSH) is the major intracellular thiol in aerobic cells and is equally important in the red blood cell. It is thought to have a number of critical functions: protecting cells against oxidative damage, participation in detoxification of foreign compounds, maintenance of protein sulphydryl groups in a reduced state and, possibly, transport of amino acids. In the red

cell, its main function is as an antioxidant. GSH is synthesized from glutamate, cysteine and glycine by the link reactions of two enzymes; γ-glutamylcysteine synthetase and glutathione synthetase (Figure 9.10). GSH exerts its function in preserving thiol groups and reducing hydrogen peroxide and free oxygen radicals through reactions catalysed by the enzymes glutathione-S-transferase and glutathione peroxidase respectively. The oxidized glutathione (GSSG) is reduced back to GSH by the action of glutathione reductase, the hydrogen donor being NADPH (Figure 9.10). Failure to maintain the GSH level as a result of deficiency in the synthetic pathways or deficiency in the recycling process leads to chronic haemolytic anaemia and increased susceptibility to oxidative stress.

Glutathione deficiency

Complete loss of GSH synthesis is probably lethal. Severe deficiency leads to 5-oxoprolinuria, metabolic acidosis and mental retardation. A milder deficiency limited to red cells is associated with haemolytic anaemia aggravated by oxidative stress. Low levels of GSH caused by γ-glutamylcysteine synthetase or glutathione synthetase deficiency, with CNSHA, have been described. Haemolytic anaemia due to glutathione reductase and glutathione peroxidase deficiency have also been reported (Table 9.6).

Nucleotide metabolism

Adenosine nucleotides, ATP (85–90%), ADP (10–12%) and AMP (1–3%), constitute the main nucleotide pool in the mature red cell. The cell has no mechanism for making nucleotides once the RNA of the reticulocytes has been degraded. The cell does have an effective salvage mechanism for maintenance of the adenine pool, with the enzymes adenosine deaminase (ADA)

Table 9.5 Characteristic features of haemolytic attack in G6PD deficiency.

Phase	Clinical	Laboratory
Acute	Abrupt onset	
	Malaise, prostration	
	Pallor	Anaemia; Heinz bodies; reticulocytosis; G6PD deficient
	(Abdominal pain)	
	Fever	Leucocytosis
	Dark urine	Haemoglobinuria; haptoglobin absent
	Haemoglobinaemia	
	Methaemalbuminaemia	
	Jaundice	Hyperbilirubinaemia
	(Renal failure)	↑Urea ↑creatinine
Recovery	Gradual but rapid cessation of haemolysis	Reticulocytes peak days 5–8
	Urine clears in few days	G6PD increases but rarely to normal range
	Jaundice clears in 1–2 weeks	

Table 9.6 Enzymopathies of the glutathione cycle and synthetic pathways.

Enzyme	Genetics	Haematology	Other systems	Comments
Glutathione synthetase	20q11.2, AR	CNSHA, Heinz bodies, oxidative HA	Neurological, metabolic acidosis	5-Oxoprolinaemia/uria, RBC deficiency, may have no neurological disease, nine families
γ-Glutamylcysteine synthetase	6p12 GLCLC, C 1p21 GLCLR, AR	CNSHA, oxidative HA, basophilic stippling	Neurological	Variable neurological features, five families
Glutathione reductase	8p21, AR	Favism	None	Most reports due to FAD deficiency, one family
Glutathione peroxidase (GPx1)	3p21.3, AR	HDN, acute IVHA	None	Self-limited neonatal jaundice, one Japanese family

AR, autosomal recessive; FAD, flavine adenine dinucleotide; HDN, haemolytic disease of the newborn; IVHA, intravascular haemolytic anaemia.

and adenylate kinase involved in the regulation. Deficiency of the enzymes in the salvage pathway does not lead to haemolysis. ADA deficiency is associated with severe combined immune deficiency and excess activity is found in Diamond–Blackfan anaemia. During maturation of reticulocytes, the RNA is broken down to pyrimidine and purine nucleotides, which are dephosphorylated to nucleosides that can diffuse out of the cell. The purine nucleotides enter the salvage pathway. Deficiency of pyrimidine 5′-nucleotidase leads to accumulation of pyrimidine nucleotides, which interferes with the adenine nucleotide pool, producing haemolysis.

Pyrimidine 5′-nucleotidase

Pyrimidine 5′-nucleotidase (P5N1), also called pyrimidine 5′-monophosphate hydrolase, catalyses the dephosphorylation of the pyrimidine 5′-monophosphates, uridine monophosphate (UMP) and cytodine monophosphate (CMP), to the corresponding nucleosides (Figure 9.15). In red blood cells, there are two isoforms of P5N, type 1 (P5N1), which has a high affinity for UMP and CMP, and type 2 (P5N2), which hydrolyses deoxypyrimidine nucleotide monophosphates. It is deficiency of P5N1 that leads to haemolytic anaemia. The gene (P5′N1)

Figure 9.16 Peripheral blood film from P5N1-deficient patient, showing basophilic stippling (a similar appearance is seen in chronic lead poisoning).

Figure 9.15 Pyrimidine nucleotide catabolism in the reticulocyte. P5N1 converts the nucleotides to monophosphates, which diffuse out of the cell.

is localized on chromosome 7p15–14. The gene consists of 10 exons, with alternative splicing at exon 2, which gives rise to isoforms with 286 and 297 amino acids. The 286 protein has the characteristics of P5′N1. The enzyme is strongly inhibited by lead.

Pyrimidine 5′-nucleotidase deficiency

Pyrimidine 5′-nucleotidase deficiency is not uncommon, although only some 40 or 50 families have been reported in the literature. It is probably the third most common enzyme deficiency causing haemolytic anaemia, perhaps equal to GPI deficiency. Nearly all reported cases have shown homozygosity for the mutation, and the mutation has been specific for individual families. There is, however, a suggestion that certain mutations (Del G576 and INS GG743) might be more prevalent in southern Italy or southern Mediterranean regions. One compound heterozygote was found in this region.

Deficiency of P5N1 is associated with a recessively inherited haemolytic anaemia characterized by marked basophilic stippling in the red cells (Figure 9.16) and accumulation of high concentrations of pyrimidine nucleotides. The haemolysis is usually mild to moderate, although more severe cases have been reported. Splenectomy is usually of little value, though benefit has been reported in some cases. The appearance of the blood film is similar to that seen in lead poisoning, and the mechanism of the anaemia in lead poisoning certainly involves the inhibition of pyrimidine 5′-nucleotidase.

Acquired haemolytic anaemias

Edward C Gordon-Smith and Judith CW Marsh

10

Introduction

Acquired haemolytic anaemias are usually divided into two main categories depending on the mechanism by which the premature destruction of red blood cells is produced. In the immune haemolytic anaemias, antibodies are the main agents of destruction. The non-immune-acquired haemolytic anaemias include diverse causes and mechanisms of haemolysis. In most anaemias, there is some shortening of the red cell survival, but in the haemolytic anaemias this shortening of red cell lifespan is the major cause of the anaemia and produces the classical features of haemolysis.

Immune haemolytic anaemias

Antibody-mediated haemolysis is an important cause of acquired haemolytic anaemia. Antibodies may be autoantibodies produced by the patient's own immune system and directed against epitopes of his/her own red cell antigens or they may be alloantibodies. Alloantibodies may be produced by the patient and directed against antigens not present on that person's own red cells, but either introduced as foreign red cell antigens by blood transfusion or are secondarily acquired by the patient's red cells, as in drug-induced haemolysis. Alloantibodies directed against the patient's red cell antigens might also be introduced from outside the patient, most notably from the mother in haemolytic disease of the newborn. A simple classification of immune haemolytic anaemias is given in Table 10.1. Typically, the immune haemolytic anaemias are distinguished from the non-immune by detecting antibody on the surface of the red cells by the direct antiglobulin test (DAT), also known as the Coombs test. The DAT is an essential investigation required in identifying the cause in any case of acquired haemolytic anaemia.

Autoimmune haemolytic anaemia

The site and severity of red cell destruction depend on structural and functional characteristics of the antibody and efficiency of the mechanism of destruction. The degree of anaemia depends on the rate and acuteness of the destruction and the capacity of the bone marrow to compensate.

Antibody characteristics

Antibody characteristics that influence the site and intensity of red cell destruction in autoimmune haemolytic anaemia (AIHA) can be evaluated using the DAT. The thermal range of antibody binding also characterizes the antibody.

Immunoglobulin class

Monospecific antihuman globulin reagents for the DAT are routinely available for the detection of immunoglobulin G (IgG), IgM, IgA and for complement components C3c and C3d. Multispecific reagents are also available, as are reagents specific for IgG subclasses, but the latter are difficult to standardize and are not in routine use.

Warm-acting antibodies

Warm-acting antibodies are most active *in vitro* at 37°C. The antibodies are polyclonal, and IgG antibodies predominate. Where the specificity of the antibody can be determined, it is most commonly in the rhesus blood group complex. The most frequent patterns detected by the DAT on the red cell surface ar: IgG alone; IgG and complement; and complement alone. Antibodies may be detected in the serum at 37°C by the indirect antiglobulin test in about 50–60% of patients; this will rise

Table 10.1 Classification of immune haemolytic anaemias.

Autoimmune haemolytic anaemia	Warm antibody type	Primary – idiopathic	
		Secondary – associated with:	Autoimmune disease
			Lymphoproliferative disorders
			Infections
			Ovarian cysts
			Some cancers
			Drugs
	Cold antibody type	Cold haemagglutinin disease	
		Cold antibody syndromes associated with:	Infections
			Lymphoproliferative disorders
	Paroxysmal cold haemoglobinuria	Post viral	
		Syphilis	
Alloimmune haemolytic anaemia	Induced by red cell antigens	Haemolytic transfusion reactions	
		Haemolytic disease of the newborn	
		Post-stem cell allografts	
	Drug dependent	Antibody/macrophage mediated	
		Antibody/complement mediated	

to > 90% when the red cell membrane of the reagent cells is modified with papain or another proteolytic enzyme. Antibody may also be eluted from the red cell membrane in a majority of cases and the specificity determined. A subtype of warm AIHA has been defined in which both warm- and cold-type antibodies are found. Both tend to be lytic, and this 'mixed type' AIHA tends to produce severe haemolysis with an intravascular component. It is most commonly associated with systemic lupus erythematosus (SLE) or lymphoproliferative disease.

Cold-acting antibodies

Cold-acting antibodies are predominantly IgM and are most actively bound to antigen in the cold (4°C). Cold antibodies act as both agglutinins and lysins *in vitro*; the two functions may have different thermal ranges. The higher the titre and range of the lysin, the greater the propensity to produce haemolysis as well as agglutination. Cold agglutinin titres may reach very high levels (> 10^{24} at 4°C), but are not necessarily associated with active haemolysis. The IgM antibodies have specificity mainly for the I antigen, although 'i' specificity may be found in Epstein–Barr virus (EBV)-associated antibodies and some cases of lymphoproliferative disease. Rarely, anti-P activity is found. *In vitro*, the IgM antibodies elute off the red cell membrane, usually leaving bound complement to be detected by anti-C3d in the DAT. In cold haemagglutinin disease and most cases associated with lymphoproliferative disease, the cold antibodies are monoclonal. Those associated with infection are polyclonal.

The antibodies in paroxysmal cold haemoglobinuria (PCH) are IgG in type and bind to antigen below 20°C. When the temperature is raised to 37°C in the presence of complement, lysis occurs. This biphasic reaction is the basis of the Donath–Landsteiner reaction.

Complement activation

Autoantibodies against red cell antigens may activate complement on the red cell membrane. Antibody binding to two adjacent sites on the red cell membrane is required to activate the Cl complement component by the classical pathway. IgM molecules are pentameric and a single molecule can bind adjacent sites; IgG molecules will activate complement if they form a 'doublet': IgG1, IgG2 and IgG3 can activate complement, whereas IgG4 and IgA do not. In AIHA, complement activation usually stops at the C3 stage, where C3b is bound to the membrane and further proteolysed to form the inactive component C3d, which is detected by the appropriate DAT. Complement beyond the C3 stage may lead to the formation of the membrane attack complex and intravascular haemolysis. Autoimmune haemolytic anaemia due to IgG_2 alone is very rare, and that due to IgG4 or IgA alone is uncommon. It is interesting that in the rare case of IgA AIHA, complement does become activated on the cell surface. In general, when there is more than one class or subclass of antibody on the cell surface the haemolysis is more intense and may be intravascular.

Specificity of red cell autoantibodies

Warm-type autoimmune haemolytic anaemia

In most cases, the antibody detected in the patient's serum is pan reacting with all cells in a routine group O panel. Some 10–15%

of antibodies show specificity for rhesus antigens, particularly anti-e, anti-D or anti-c. A greater proportion show specificity by reacting with all cells except –/– Rh^{null} cells. Other rare specificities against high-frequency antigens include anti-En^a, anti-Wr^b or anti-U. Usually, autoantibodies show reactivity against a number of antigens and are not as specific as alloantibodies.

Cold-type autoimmune haemolytic anaemia

In cold agglutinin syndrome, anti-i specificity is usually seen. Occasionally, there is specificity for anti-I, and even more rarely for anti-Pr, anti-P, anti-M or anti-N, and even cold-reacting anti-A or anti-B. In PCH, the specificity is anti-P.

Effector mechanisms for immune red cell destruction *in vivo*

Two main effector mechanisms exist *in vivo*: (i) cell-mediated, predominantly extravascular, immune destruction and (ii) complement-mediated intravascular haemolysis.

Cell-mediated immune red cell destruction

Human macrophages and monocytes have cell-surface receptors for the Fc portion of IgG and for antigenic determinants present on activated C3. Cellular immune destruction is mediated through these receptors. Neutrophils and lymphocytes also have these receptors, but macrophages of the reticuloendothelial system within the spleen, liver and bone marrow are the main site of destruction *in vivo*.

Fc receptor mechanism

Macrophages have Fc receptors for IgG1, and IgG3 molecules, but not for IgG2, IgG4, IgM or IgA. Only IgG-coated red cells are destroyed in this way, but, in warm AIHA, this is clinically important, as 70–75% of autoantibodies are IgG. Phagocytosis and antibody-dependent cell-mediated cytotoxicity are the major Fc receptor-dependent modes of antibody-coated cell destruction.

The role of the spleen

The splenic vasculature is adapted to make the spleen an efficient filter for such particles as effete red cells, bacteria and immune complexes. As blood passes through the central arteries towards the red pulp, the branches of the central artery have a plasma-skimming effect, which raises the haematocrit of the blood within the central artery as they pass towards the splenic cords. There, red cells come into close contact with the splenic macrophages. The low plasma content and the relative lack of free plasma IgG molecules allow the red cell-bound IgG to interact preferentially with the macrophage Fc receptors, leading to phagocytosis of the coated red cells. When phagocytosis is partial, so that only portions of the cell membrane are removed, the remaining circulating red cell becomes spherocytic, although the somewhat rigid spherocytes may themselves be trapped in the splenic sinusoids and destroyed.

The spleen is thus most commonly the major site of red cell destruction when IgG alone is the main Fc binding protein on the red cell surface (see Chapter 21).

The role of the liver

Kupffer cells are macrophages that are present in the liver sinusoids and which express Fc receptors on their surface. The blood flow through the sinusoids is rapid compared with the spleen and there is no plasma-skimming effect. IgG-coated red cells are not preferentially destroyed in this situation, where there is competition for Fc receptors from circulating IgG. Here, red cell destruction is more dependent on cells being coated with C3.

C3 receptor mechanisms

Two types of C3 receptor have been identified on macrophages, CR_1 and CR_3. CR_1 is specific for an antigenic site in the C3c region of activated C3b which is not exposed on native C3. The breakdown product of C3b ($_iC3b$) is also a major ligand for the CR_1 receptor and is the only ligand for CR_3. Immune adherence of C3b-coated red cells to macrophages occurs mainly through the CR_1 receptor, whereas CR_3 receptor binding triggers phagocytosis. The largest concentration of C3b-binding macrophages is found in the liver sinusoids so that the liver becomes the major site for trapping and phagocytosing C3b-coated red cells. There is no competition for complement receptor sites from non-activated C3 in the plasma. If the spleen is very large, this too becomes an important site of cell destruction.

In cold AIHA, the IgM agglutinins bind most avidly to red cells in the peripheral circulation, where the temperature may be as low as 10–20°C. Complement activation occurs and leads to C3b and $_iC3d$ expression on the red cell membrane. Macrophage destruction of red cells is the main mechanism of haemolysis in IgM cold antibody-coated cells and also occurs in warm AIHA as a result of complement fixing IgG and IgM antibodies.

Complement-mediated intravascular haemolysis

Intravascular complement-mediated haemolysis is a minor mechanism for red cell destruction in most patients with AIHA. In a small proportion of patients, such a mechanism may predominate and produce severe intravascular haemolysis. Complement-induced intravascular haemolysis in warm AIHA is most likely to occur when more than one class or subclass of Ig is present on the red cell surface. Intravascular haemolysis has been reported with IgA-coated red cells, although the mechanism is obscure, as IgA does not itself fix complement.

In cold AIHA syndromes, intravascular haemolysis may be precipitated by exposure to cold. In such cases, lytic as well as agglutinating antibodies with a high thermal range may be demonstrated *in vitro*. This pattern is not uncommon in cold AIHA associated with *Mycoplasma pneumoniae*. Acute intravascular haemolysis is the usual presentation in paroxymal cold haemoglobinuria, where the antibody is lgG in type.

Other factors influencing red cell destruction and production

Bone marrow function

The ability of the marrow to increase erythropoiesis may be impaired. Autoantibodies may be produced, which act against reticulocytes and erythroblasts, as well as mature red cells. Red cell production may also be reduced by folate deficiency secondary to the increased demand. Lymphoproliferative diseases may impair production through infiltration of the marrow.

Reticuloendothelial function

The severity of cellular immune red cell destruction depends overall on macrophage function. Reticuloendothelial function may be reduced in SLE by the clearance of immune complexes, a process known as reticuloendothelial blockade. In methyldopa-induced AIHA, the drug has been shown to reduce reticuloendothelial clearance of lgG-coated red cells, which might explain why many patients with a strongly positive DAT due to methyldopa have little or no haemolysis.

Hypocomplementaemia

Partial protection from complement-mediated lysis may occur in patients with chronic cold haemagglutinin disease (CHAD), in which continuous complement activation may lead to relative complement deficiency. Hypocomplementaemia is common in SLE and may also be caused by chronic activation of the complement pathway. In addition, there is a strong association between SLE and the occurrence of null alleles for the C_2 and C_4 genes, which causes a genetically determined complement deficiency.

Warm-type autoimmune haemolytic anaemias

Clinical features

Presentation is variable and depends upon the speed with which anaemia develops, the capacity of the bone marrow to compensate and the effects of any associated disease. Most commonly, the onset is insidious, with the gradual awareness of symptoms of anaemia or the observation of pallor or icterus by friends or relatives. Occasionally, the onset is acute, with rapidly developing anaemia and, in older patients, the risk of heart failure. If there is an acute onset with intravascular haemolysis, haemoglobinuria may be noticed. Mild jaundice is present. More marked icterus (bilirubin > 90 μmol/L) suggests coexisting liver disease or biliary tract obstruction due to pigment gallstones or biliary sludge. Splenomegaly is common, but rarely at more than 2–3 cm below the costal margin at presentation. Marked splenomegaly suggests the possibility of a lymphoproliferative disease. The peripheral blood film is characterized
Figure 10.1 Warm autoimmune haemolytic anaemia. Blood film showing spherocytosis, polychromasia and nucleated red blood cell (×40).

by spherocytosis and polychromasia (Figure 10.1), circulating nucleated red cells, and, in some cases, red cell agglutination. Rarely, there may be reticulocytopenia associated with a positive DAT. There is a moderate increase in bilirubin, which is unconjugated, so bilirubin does not appear in the urine, which contains excess urobilinogen. There is an increase in lactate dehydrogenase (LDH) due to lysis of red cells, but other liver function tests are normal unless there is associated liver or biliary tract disease. The DAT is positive except in very rare cases where the amount of antibody remaining on the red cell surface is insufficient to be detected by the conventional DAT.

Idiopathic warm AIHA

In approximately 30% of patients with a DAT-positive haemolytic anaemia, no associated disorder is found. Idiopathic AIHA may occur at any age. There is a peak incidence during infancy and early childhood, a second rise during the third decade, with the majority of cases occurring after the fifth decade. There is a preponderance of female patients in both idiopathic and secondary AIHA. A careful drug history should always be taken to exclude drug-induced AIHA, and chemical exposure at work or in the domestic environment must be assessed. In girls, AIHA may precede clinical or immunological evidence of SLE, so that negative serology for SLE does not exclude that disease at a later date. As mentioned above, the presentation may vary from the gradual onset of anaemia to an acute haemolytic process. Systemic symptoms are rare other than those of anaemia. Pallor and jaundice are present. The spleen is nearly always enlarged, usually to between one and a half to five times its normal size. Enlargement to the umbilicus or below is not a feature of idiopathic AIHA and suggests a secondary AIHA.

Evans syndrome

A small subgroup of patients with idiopathic AIHA also have immune thrombocytopenia (ITP). The thrombocytopenia may coincide with the haemolysis or may arise as separate episodes. This is known as Evans's syndrome. The platelet and red cell antibodies are distinct and do not cross-react. The diagnosis is important because there appears to be a higher incidence of underlying illness such as immunodeficiency or autoimmune lymphoproliferative disease in children and SLE and T-cell lymphoma in adults. Management is as for warm AIHA or immune thrombocytopenic purpura (see Chapter 56) but patients with Evans's syndrome tend to be more resistant to initial therapy with prednisolone. Episodes of immune neutropenia or pancytopenia have also been described in association with a positive DAT.

Warm autoimmune haemolytic anaemia in infancy and childhood

AIHA of unknown cause occurs in infancy and in young children. In infancy, the onset is often acute and anaemia may be profound and difficult to control. The majority of cases in children are transient, although the onset may also be acute. It is interesting that in this group the sex difference is reversed, with more boys being affected. In childhood, the haemolytic episode is frequently precipitated by infection. IgG antibodies may be transferred from a mother with AIHA across the placenta to produce haemolysis in the newborn.

Warm autoimmune haemolytic anaemia associated with other autoimmune diseases

AIHA is often associated with SLE, especially in young women. Autoantibodies are usually IgG, and both IgG and C3d are found on the red cell surface. Occasionally, the DAT may be positive owing to immune complexes absorbed on to the red cell surface. The spleen is important for clearing such coated cells and splenectomy should be avoided if possible. Otherwise, treatment is as for idiopathic AIHA (see below). This condition is also described with other autoimmune, or presumed autoimmune, diseases notably rheumatoid arthritis, Sjögren's syndrome and ulcerative colitis; AIHA is also part of the spectrum of autoimmune diseases associated with agammaglobulinaemia.

Warm autoimmune haemolytic anaemia in lymphoproliferative diseases

The most common association is with B-cell chronic lymphocytic leukaemia (CLL), low-grade B-cell non-Hodgkin's lymphoma or Hodgkin's disease. The antibodies are polyclonal and have no distinct pattern of antibody type or specificity. The formation of antibodies in this group is thought to be due to immune dysregulation rather than direct production by the malignant clone. The AIHA may precede the diagnosis of lymphoma, sometimes by months or years. On other occasions, the presentations may be simultaneous or the AIHA may be delayed.

Warm autoimmune haemolytic anaemia due to drugs

Warm AIHA has most frequently been associated with methyldopa. Mefenamic acid, L-dopa and procainamide have also been reported to provoke this condition. About 20% of patients receiving methyldopa develop a positive DAT, but only 1–2% develop haemolytic anaemia. IgG is always present on the red cell surface, and antibodies usually show rhesus specificity, most commonly anti-e or anti-c. The other drugs are more likely to produce clinically important haemolysis. The mechanism by which AIHA is produced by exposure to drugs is not known. Alteration to the red cell membrane or modulation of the immune response by the drug have both been suggested. Treatment of patients with CLL with fludarabine and other purine analogues may provoke a very severe and life-threatening acute autoimmune haemolytic anaemia and, less commonly, other autoimmune cytopenias. The mechanism may be related to a decrease in autoregulatory T cells caused by treatment with fludarabine.

Warm autoimmune haemolytic anaemia and carcinoma

AIHA has been recorded with a number of malignancies, but it is not clear that there is a true association. It may be associated with ovarian cysts, with the cyst fluid containing the agglutinin. It has been suggested that there is also an association with ovarian carcinoma.

Warm autoimmune haemolytic anaemia and viral infections

In children, but rarely in adults, AIHA may follow a viral infection. Haemolysis is usually brisk but self-limiting. It is possible that the virus alters the red cell membrane, which provokes 'auto' antibodies against the altered antigens or that antiviral antibodies cross-react with membrane antigens. A third possibility is that immune complexes form between the virus and specific antibodies are secondarily absorbed onto the red cell surface, leading to immune destruction.

Treatment

Corticosteroids

First-line treatment of warm AIHA is with corticosteroids. The initial dose should be prednisolone 1–2 mg per kg of body weight per day. The dose may be given once daily if tolerated. A proton pump inhibitor or H_2 antagonist should be given at the same time as the steroids to reduce the risk of gastric erosions. High doses of corticosteroid should be continued for 10–14 days, according to response. In patients who respond, the dose should then be reduced steadily, down to one-half of the starting dose over the next 2 weeks and more gradually thereafter. In practice, the reduction in the dose is tailored to individual patients and their response. It is important not to stop the steroids too quickly and allow relapse. For patients who do not respond or who require unacceptably high doses

of prednisolone to maintain a reasonable haemoglobin, other measures should be tried.

Cytotoxic immunosuppressive drugs

Azathioprine, 1.5–2.0 mg/kg per day, may be given to patients who respond poorly to prednisolone. On its own, azathioprine is mostly ineffective and is given for its steroid-sparing action. It should be continued for at least 3 months to assess its value, as response is not usually seen for 4–6 weeks. Cyclophosphamide 1.5–2.0 mg/kg per day may also be used in this way. It should be emphasized that there are no controlled trials to prove the worth of the use of these cytotoxic drugs and that their use is not without hazard, particularly bone marrow depression. Mycophenolate mofetil is an alternative immunosuppressive agent that is currently being assessed in refractory AIHA and ITP.

Cyclosporin

Oral cyclosporin has been used in steroid-resistant cases. No randomized clinical trials have been conducted but there are single case reports of success. A starting schedule of 5 mg/kg per day in two divided doses is appropriate. Close monitoring of renal and hepatic function is necessary and trough plasma levels of 100–200 mg/L must be maintained. The dose should be reduced if there is marked jaundice. Response may not be seen for 2–3 months.

Intravenous immunoglobulin

Intravenous immunoglobulin has been used in AIHA, particularly when IgG is the main component on the red cell surface. The dose used is the same as for ITP, 0.4 mg/kg per day for 4 5 days. AIHA responds less frequently to intravenous immunoglobulin than does ITP.

Splenectomy

Splenectomy is considered if there is no response to corticosteroids after 3 months' trial. Patients with predominantly IgG on the red cell surface respond best, and those with complement often respond poorly. Out of selected patients, about one-third achieve a complete remission and do not require steroids, one-third have a significantly reduced steroid requirement and the remainder show no or only transient response. There is no certain way to determine who will respond to splenectomy, although isotope studies may help in coming to a decision. The problems of splenectomy are dealt with in more detail in Chapter 8.

Monoclonal antibody therapy

The use of the monoclonal antibodies Campath-1H (anti-CD52) and rituximab (anti-CD20) for refractory AIHA is being explored at present for both warm and cold types of AIHA. Rituximab has produced remissions in some cases of warm AIHA but also in about 50% of patients with CHAD. Anecdotal success with Campath-1H in warm AIHA is also recorded. The

success rate for AIHA does not seem to be as high as for ITP (rituximab) or immune neutropenia (Campath 1H).

Blood transfusion

Blood transfusion must be given if the clinical situation demands it, despite the impossibility of achieving a satisfactory cross-match in the presence of a positive DAT. The least incompatible, grouped blood should be used and transfused slowly. Some authors recommend the use of blood lacking antigens to which the autoantibodies react, but others point out that specificity is rarely absolute and that there is the risk of provoking an alloantibody response.

Prognosis

The prognosis in warm AIHA depends on a number of variables, including age, associated diseases and severity of haemolysis. In all patients, AIHA should be considered a serious and potentially life-threatening disease. Estimates of mortality of idiopathic AIHA in adults vary from 10% at 5 years to 40% at 7 years. The higher figures are mainly in patients aged over 50 years. Most deaths occur in the first 2 years after diagnosis. In children, mortality is much lower, probably about 5%, with the majority of patients recovering completely. Apart from death, AIHA may carry considerable morbidity, particularly from prolonged high-dose steroid therapy.

Cold-type autoimmune haemolytic anaemias

The clinical features of the cold haemagglutinin syndromes vary with the pathogenesis of the disorder. Serological tests are useful in identifying the cause and in determining treatment. The serological characteristics of the antibodies found in these syndromes are shown in Table 10.2.

Clinical features

Idiopathic cold haemagglutinin disease

Cold haemagglutinin disease is mainly seen in older people and runs a chronic course. Although the condition is mostly benign, the clinical features may be very distressing and disabling. Purplish skin discoloration, maximal over the extremities (acrocyanosis), may be present in cold weather. Acrocyanosis is due to stasis in the peripheral circulation secondary to red cell agglutination. On warming the skin, the colour returns to normal or there is transient erythema. This sequence distinguishes acrocyanosis from Raynaud's syndrome. Haemolysis is usually present and the patient may be mildly icteric. Occasionally, haemolysis dominates the clinical picture, depending on the ability of the antibody to activate complement on the red cell surface. The cold agglutinins are monoclonal IgG_K, but serum

Table 10.2 Serological characteristics of cold acting antibodies in the cold agglutinin syndromes.

Disorder		Specificity		
		Anti-I	*Anti-i*	*Anti-P*
Idiopathic (CHAD)		Mono IgMκ		Mono (rare)
Secondary to:	Lymphoproliferative disease	Mono IgMκ/λ (IgG)	Mono	
	Mycoplasma pneumoniae	Poly		
	Infectious mononucleosis	Poly	Poly	
Paroxysmal cold haemoglobinuria				Poly

Mono, monoclonal; poly, polyclonal.

electrophoresis may not reveal a monoclonal band because the concentration of the protein is too low. Cold haemagglutinin disease may be thought of as a pre-malignant B-cell disorder, which only presents clinically because of the specificity of the antibody for red cell surface antigens.

In the laboratory, spontaneous agglutination of red cells is frequently observed, both macroscopically and on the peripheral blood film if made at room temperature (Figure 10.2). Automated blood cell counters detect the agglutinates and record errone-ously high mean corpuscular volume and low Hb values, unless the sample is tested at 37°C. The DAT shows only C3d on the red cell surface; IgM cold agglutinins are not detected because they elute from the cell surface *in vitro*.

Cold agglutinin syndromes and lymphoproliferative disorders

Occasionally, the cold agglutinin syndrome accompanies or precedes a B-cell lymphoma or CLL. In these cases, the antibody is monoclonal and is a product of the malignant clone. The serological specificity is either anti-I or anti-i. Haemolysis is
Figure 10.2 Cold haemagglutinin disease. Blood film showing gross haemagglutination (×20).

often more troublesome than symptoms of agglutination. The prognosis is usually that of the underlying lymphoproliferative disease.

Cold agglutinin syndromes and infections

Haemolysis due to cold agglutinins may follow infections, almost always due to *M. pneumoniae*, or infectious mononucle-osis. Rare cases following *Listeria* or *Toxoplasma* infections have been reported. The antibodies are mostly polyclonal IgM in type but occasional IgG cold antibodies are found. The antibodies develop in response to the infecting organism and cross-react with the red cell antigens. Haemolysis appears 2–3 weeks after the infection and is usually mild and self-limiting. Occasion-ally, very severe and even fatal acute intravascular haemolysis develops after *M. pneumoniae* infection. Blood transfusion through a blood warmer may be urgently required.

Treatment

General

Management of cold haemagglutinin syndromes is difficult. All patients should avoid exposure to cold, and electrically heated gloves and socks are available for use in winter. Wintering in a warm climate is a pleasant alternative. Folic acid supplements should be given to patients with chronic haemolysis.

Alkylating agents

Chlorambucil may be effective in reducing antibody produc-tion. Intermittent regimens such as 10 mg/day for 14 days every 4 weeks or continuous treatment of 2–4 mg/day are both effect-ive. Long-term treatment carries the risk of marrow suppres-sion and the development of myelodysplasia and acute myeloid leukaemia. Chlorambucil is most effective when there is an underlying B-cell neoplasm and may be less so in the idiopathic CHAD.

Corticosteroids

Corticosteroids are rarely of use in cold haemagglutinin

syndromes. They should be used only in exceptional circumstances when the antibodies are present in low titres and have a high thermal range. Their use should be avoided in other cases.

Splenectomy

Removal of the spleen is rarely of any use. The cells are coated with C3b and destruction occurs mainly in the liver.

Blood transfusion

Blood transfusions should be given with due regard to the difficulty in cross-matching in the presence of cold haemagglutinins. Blood should be given through an in-line blood warmer. The patient should be in a warm environment, preferably at 37°C. Special precautions are needed for surgical procedures to keep the patient warm.

Plasma exchange

The titre of cold agglutinin may be lowered temporarily by plasma exchange. The procedure may be useful in the control of severe symptoms.

Monoclonal antibody therapy

Both rituximab and Campath-1H monoclonal antibodies have been used anecdotally in the treatment of refractory cold-type AIHA. Rituximab is particularly appealing for idiopathic cold haemagglutinin disease and cold agglutinin syndromes with associated B-lymphoproliferative disorders because the antibody targets the CD20 molecule present on mature B-cells, which proliferate in low-grade lymphoproliferative disease, and are the precursors of autoantibody-producing plasma cells in autoimmune cytopenias associated with underlying malignancy as well as in idiopathic autoimmune cytopenia.

Paroxysmal cold haemoglobinuria

The rare syndrome usually occurs in children following acute viral infections. The original cases were described by Donath, Landsteiner and Ehrlich in congenital and tertiary syphilis but such cases are no longer encountered. A history of cold exposure is not always present and presentation is with sudden intravascular haemolysis, haemoglobinuria, abdominal pain, pallor and prostration.

The cold antibody is IgG, which is biphasic, reacting with red cells below 20°C in the peripheral circulation and causing lysis by complement activation as the red cells are warmed to 37°C in the central vessels. The antibody has specificity for the P antigen.

Treatment depends on keeping the patient warm, preferably at 37°C ambient temperature and giving transfusion, as required. The rare pp cells are not usually available and transfusion of ABO and rhesus compatible, P-positive blood should be given through a blood warmer.

Alloimmune haemolytic anaemia

Drug-induced immune haemolytic anaemia

Features and diagnosis

Immune haemolytic anaemia produced by drugs is rare but, in some cases, it may be very severe and even life-threatening. There are three main mechanisms by which red cell destruction is increased by antibodies bound to the red cell surface. Auto-immune haemolytic anaemia induced by methyldopa has been described in the previous section. Immune antibodies which require the presence of the drug to produce a positive DAT may react with red cells when the drug is bound to the red cell surface (drug adsorption mechanism) or when immune complexes are produced between the drug and the antibody, which is absorbed on to the red cell surface where complement is fixed and activated, leading to acute intravascular haemolysis.

The diagnosis of drug-induced immune haemolytic anaemia should be made in three stages: (i) diagnosis of a DAT-positive haemolytic anaemia; (ii) careful drug history; and (iii) serological demonstration of drug-specific antibody, which interacts with red cells.

Pathogenesis
Drug adsorption (hapten) mechanism
Penicillin is the prototype drug, although cephalosporins and other penicillin derivatives have also been implicated. Drugs in this group readily form hapten–carrier complexes with plasma proteins, which enhance drug-specific antibody production. It has been estimated that 90% of individuals receiving penicillin produce clinically insignificant lgM antipenicillin antibodies. When high-dose intravenous penicillin is administered, the drug is absorbed on to the red cell surface, where it becomes non-specifically attached to red cell surface proteins. A minority of patients on high-dose intravenous penicillin therapy (> l Mu daily) develop high-titre IgG antipenicillin antibodies that attach to the drug bound to the red cell surface and cause predominantly extravascular haemolysis. The clinical picture is usually of mild to moderate haemolysis but, if it is unrecognized, so that large doses of the drug are continued in the presence of increasing antibody levels, complement fixation and acute intravascular haemolysis may occur. The DAT becomes positive after some weeks of treatment and is due to IgG only on the red cell surface. When the drug is stopped, the DAT rapidly becomes negative and haemolysis stops. Antibody in the patient's serum or eluate from the red cells will react with normal red cells only in the presence of the drug. The clinical and serological features are shown in Table 10.3.

Membrane modification mechanism
Cephalosporin, in addition to the drug absorption mechanism, can cause a positive DAT by modifying red cell membrane components. Cisplatin and carboplatin have also been reported

Table 10.3 Drug-induced immune haemolytic anaemias: clinical and serological features.

	Drug absorption	Mechanism	
		Immune complex	Autoimmune
Examples	Penicillin	Many Few cases each	Methyldopa Mefenamic acid
Dose/duration	Large therapeutic doses Prolonged	Very low dose Short	Usually about 6 weeks
Haemolysis	Extravascular Subacute	Intravascular Acute	Extravascular Minimal/subacute
DAGT	IgG or IgG + C′	C′ only	IgG only
Serum antibody reaction	To drug-treated cells	Reacts only in presence of drug or metabolite	To normal red cells
Eluate reaction	To drug-treated cells	Non-reactive	To normal red cells

to cause immune haemolytic anaemia by this mechanism. As a result, a variety of plasma proteins, including immunoglobulin and complement, may attach through a non-immune mechanism to the red cell membrane. This may result in the finding of a positive DAT but rarely causes immune haemolytic anaemia.

Immune complex innocent bystander mechanism

Several drugs have been reported to cause immune haemolytic anaemia by this mechanism. Those most frequently reported are rifampicin, phenacetin, quinine, quinidine, nomifensine, hydrochlorothiazide and chlorpropramide and, more recently, intravenous cephalosporins and diclofenac (see below). Hapten–carrier complexes are formed between these drugs and plasma proteins, leading to the production of drug-specific antibodies. Once drug antibodies are present, reintroduction of the drug causes immune complexes to form, which are absorbed on to the red cell membrane and complement is activated.

Classically, haemolysis occurs on the second or subsequent exposure to the drug and may develop within minutes or hours of drug ingestion. Severe intravascular haemolysis may occur with fever, rigors or nausea and, in extreme cases, acute renal failure. Several groups have reported fatal immune haemolysis with the third-generation cephalosporin ceftriaxone, and cefotaxime and ceftazidime have also been reported to cause immune haemolytic anaemia. Second-generation cephalosporins have also been implicated, although there are fewer reports with them than with third-generation antibiotics. Diclofenac can also cause an immune haemolytic anaemia with intravascular haemolysis, and this is thought to be mediated by both immune complex and drug adsorption mechanisms.

Autoimmune mechanism

Methyldopa is the paradigm drug in autoimmune drug-induced haemolytic anaemia. Typically, the DAT becomes positive about

6 weeks after the drug is started and is strongly positive due to lgG on the red cell surface. Haemolysis is usually absent or trivial, although this is not true with some other drugs that produce haemolysis by this route, notably mefenamic acid (Ponstan®). The antibodies usually show no Rh specificity when tested against Rh_{null} cells. It should be noted that some drugs may produce haemolysis by both the immune complex and autoimmune mechanisms, depending on the circumstances.

Serological diagnosis of drug-induced haemolytic anaemia

Drug absorption and membrane modification mechanisms

The DAT is usually positive with IgG1, or IgG and C3 on the red cell surface. The red cell eluate and serum do not react against normal or enzyme-modified red cells. Warm-reacting drug-specific antibody in the eluate and serum is only detected after preincubation of the test red cells with the appropriate drug.

Immune complex mechanism

The DAT is usually positive but may be negative if performed immediately after a brisk 'episode' of haemolysis. The red cell eluate is not reactive even in the presence of the drug. The drug-specific antibody is best detected by preincubating the patient's serum with the drug in solution to allow immune complexes to form. The preincubated serum is then tested against normal and enzyme-modified groups of cells in the presence of fresh complement. In some cases (e.g. nomifensine), the antibodies may be specific for metabolites rather than for the parent drug. Drug metabolite antibodies may be detected by preincubating drug metabolite obtained from the serum or urine of a volunteer (who has taken the drug) with the patient's serum. A simplified summary of the serological investigation of a patient with suspected drug-induced immune haemolysis is shown in Table 10.3.

Table 10.4 Non-immune acquired haemolytic anaemias.

Cause	Examples	Mechanisms
Infections	Falciparum malaria	Intracellular organisms
	Babesiosis	
	Bartonella	
	Meningococcal sepsis	Endotoxin-induced DIC
	Pneumococcal sepsis	
	Gram-negative sepsis	
	Atypical mycobacterial infections	Haemophagocytic syndromes
	Viruses	
	Clostridium perfringens	Enzyme toxins
	Snake, spider bites	
Chemical and physical agents	Drugs	Oxidative damage
	Industrial/domestic substances	
	Burns	Heat, osmotic lysis (freshwater)
	Drowning	
	Lead poisoning	Dehydration of RBC (salt)
	Copper (Wilson's disease)	Enzyme inhibition
Fragmentation (mechanical) haemolysis	Cardiac haemolysis	Lysis on prosthetic surfaces
	Microangiopathic haemolytic anaemia (MAHA)	Vasculitis, endothelial cell swelling, fibrin shear
	March haemoglobinuria	
Acquired membrane disorders	Liver disease	Lipid/cholesterol changes
	Paroxysmal nocturnal haemoglobinuria	Somatic mutation

The non-immune acquired haemolytic anaemias

Haemolysis and haemolytic anaemia may be the consequence of a wide variety of acquired conditions that do not lend themselves to a precise and logical classification. Classification tends to be based on causes rather than mechanisms, although there are some common pathogenetic mechanisms that lead to red cell destruction. The main groups of agents causing haemolysis are infections, vascular disorders (mechanical disorders), chemical and physical agents, and disorders affecting the red cell membrane. A classification is shown in Table 10.4.

Infections causing haemolytic anaemia

A variety of infections may produce haemolysis through several different pathways. Haemolysis may be a consequence of direct invasion of the red cell by a micro-organism or may arise from alterations in the microcirculation, leading to mechanical haemolysis. The intracellular organisms tend to produce the more severe haemolysis.

Malaria

Some degree of haemolysis is seen in all types of malarial infection, but the most severe abnormalities are found in *Plasmodium falciparum* infection. *P. falciparum* infection is one of the most common causes of anaemia in the world. Many factors may contribute to the anaemia, including marrow suppression, dyserythropoiesis, folate deficiency, hypersplenism and red cell sequestration, as well as haemolysis. The condition has two main components: extravascular destruction of parasitized cells in the reticuloendothelial system, particularly the spleen, and intravascular lysis when the sporozoites break out of the red cells in the circulation. In most patients, the systemic symptoms of malaria dominate the clinical picture but, occasionally, acute intravascular haemolysis is the presenting emergency problem. Haemolysis in malaria is often associated with a positive Coombs test.

Blackwater fever

Acute intravascular haemolysis leading to the passing of black or dark-red urine is an uncommon but well described and feared complication of falciparum malaria. The syndrome usually occurs after a few days of typical malaria fever. The

appearance of black urine is usually accompanied by further fever and often back pain in the renal angle. Oliguric renal failure may ensue, particularly if the patient becomes hypotensive and hypovolaemic from dehydration. Pulmonary and cerebral symptoms may develop. The condition was first described in white people, most of whom had been treated with quinine, and the importance of this association was stressed. However, the condition is seen in all populations in endemic areas and certainly does not seem to be confined to non-immune individuals. In these indigenous populations, glucose-6-phosphate dehydrogenase (G6PD) deficiency may play a part in the pathogenesis as well as quinine exposure. The spread of chloroquine-resistant malaria in the Far East has led to an increased use of quinine and an increase in the incidence of blackwater fever.

The degree of parasitaemia is very variable. In about one-half of the cases the parasite count may be high, whereas in others the count may be low, perhaps because of the intense intravascular haemolysis. The red cell count may fall to 1×10^{12}/L within 24 h of the start of the haemoglobinuria. There is usually a rise in fibrin degradation products in the serum, but this rise is not often marked and is compatible with a degree of renal failure. Intravascular coagulation does not seem to play a major role in pathogenesis.

Immediate treatment is directed towards correction of the fluid and electrolyte loss, counteracting the anaemia, and eradication of the parasite. Renal dialysis may be required and may have to be continued for 1 month or more before renal function returns. Subsequent attacks of falciparum malaria are likely to produce further episodes of blackwater fever in susceptible individuals, so scrupulous prophylaxis should be followed.

Babesiosis

Infection with the intracellular protozoan *Babesia* is uncommon and symptomatic disease is mostly confined to splenectomized patients, at least in the European variety. *Babesia* is a tick-borne organism, the tick in Europe being *Lxodes vicinus*, associated with cattle, and in America, *Lxodes dammini*, carried by rodents and deer.

In splenectomized patients, the disease has an acute onset and is often fatal. There is a 1- to 3-day period of malaise, sometimes with vomiting and diarrhoea, followed by high fever, rigors, jaundice, acute intravascular haemolysis, haemoglobinuria, renal failure and death. In North America, unsplenectomized patients may experience a milder self-limiting disease, although intravascular haemolysis does occur.

The diagnosis is made from the peripheral blood film, where the parasites, looking very similar to *P. falciparum*, are seen in the red cells. There may be a history of tick bite or of exposure to potential vectors. Treatment is difficult. Clindamycin may be effective and imidocarb diprorinate, a drug used in veterinary practice, 0.6 mg/kg i.m. 12-hourly for four doses, proved effective in one desperate case. Exchange transfusion and renal support may be required in severely affected patients.

Bartonella (Oroya fever)

Infection with *Bartonella bacilliformis* is found only in the western Andes of Peru and neighbouring countries. The diagnosis is made from the peripheral blood film. The organism is an intracellular, Gram-negative rod during the acute attack, becoming coccoid in recovery. In non-immune individuals, there may be intense haemolysis, partly intravascular, partly through erythrophagocytosis. The organism is rapidly killed by chloramphenicol, tetracyclines, penicillin or aminoglycosides.

Clostridium perfringens

Clostridium perfringens septicaemia causes an intense intravascular haemolysis with prominent microspherocytosis. The spherocytosis is the result of membrane destruction by lipases and proteases produced by the organism. Although the organism is sensitive to a variety of antibiotics, the appearance of intravascular haemolysis is usually a harbinger of death because of the toxaemia.

Toxoplasmosis

Infection with *Toxoplasma gondii* acquired *in utero* may produce haemolysis and a syndrome similar to haemolytic disease of the newborn. In adults, toxoplasmosis is not associated with haemolysis, except perhaps in the immunocompromised host.

Bacterial infections

Intravascular coagulation produced by bacterial infection may be accompanied by some degree of intravascular haemolysis with fragmentation of red cells. Septicaemia from meningococcal or pneumococcal infection may show evidence of haemolysis, but such features are not clinically significant compared with the other effects of the septicaemia.

Haemorrhagic fevers

Haemorrhagic fevers may be accompanied by haemolysis. Dengue fever is widespread in many parts of the world and may cause intravascular haemolysis. Other haemorrhagic fevers, for example, yellow fever and West African haemorrhagic fevers, may also produce haemolysis.

Haemophagocytic syndrome

The haemophagocytic syndrome (HPS) is characterized by proliferation of macrophages in the bone marrow, spleen, liver and lymph nodes, with inappropriate phagocytosis of erythroid precursors, granulocytes and platelets. In some variations, the skin may be involved. It may occur in severe systemic infections such as cytomegalovirus (CMV), fungal infection and tuberculosis. Clinically, the patient presents with persistent fever, pancytopenia, jaundice and evidence of liver dysfunction, often with a coagulopathy. The manifestations may be acute or subacute, with the patient exhibiting severe malaise, weight loss and rapidly developing pancytopenia. The jaundice in part is the

result of the destruction of red cells and their precursors in the marrow, spleen or liver, usually associated with a marked rise in lactic dehydrogenase. There is an acute-phase response, with elevated serum ferritin levels and increases in interferon-γ and tumour necrosis factor α with variable changes in other cytokines. The syndrome seems to associated with an abnormal T-cell activation, which triggers the macrophage response and which may be the consequence of a T-cell lymphoma or may be unmasked by a variety of infections. The two main subdivisions of the syndrome are infection-associated HPS (IAHPS) and malignant HPS (MHPS). Clinically, the distinction may be very difficult because in the lymphomas the proliferation may be trivial, the syndrome being derived from the release of cytokines, and, in MHPS, superadded infection is common. Likewise, in IAHPS it may be impossible to identify the underlying infection. In children, IAHPS seems to be more common, whereas, in adults, the majority of cases are associated with lymphoma.

Fragmentation haemolysis – mechanical haemolytic anaemias

The relationship between the vascular endothelium, the cellular elements of the blood and the mechanisms of haemostasis and fibrinolysis is clearly intricate and complex. The integrity of the red blood cell may be destroyed by contact with abnormal endothelial surfaces, although not all abnormalities of vessels cause haemolysis. It may be that some adherence between the red cell and the abnormal vessel wall is necessary for fragmentation of the red cell to occur, and that this usually happens in the context of abnormal flow as well as an altered endothelium. The situations in which fragmentation haemolysis may occur are the presence of prosthetic material and altered flow following cardiovascular surgery, the trapping or adherence of red cells in arteriovenous malformations, and the destruction of red cells
Figure 10.3 Microangiopathic haemolytic anaemia. Blood film from a patient with carcinoma and bone marrow metastases. Note fragmentation of red cells, leucoerythroblastic changes with nucleated red cell and metamyelocyte and low platelets suggesting possible DIC (×40).

in pathologically altered small blood vessels (microangiopathic haemolytic anaemia).

The characteristic features of fragmentation haemolysis are the appearance of the blood film (Figure 10.3) and the presence of intravascular haemolysis. Depending on the underlying vascular pathology, there may be a reduction in the platelet count and evidence of disseminated intravascular coagulation (DIC). The rate of red cell destruction also varies according to the pathogenesis, so the signs of intravascular haemolysis vary from absence of haptoglobin, elevated LDH and minimal haemosiderinuria, to acute intravascular destruction with haemoglobinaemia and haemoglobinuria. The major causes of fragmentation haemolysis are shown in Table 10.5.

Table 10.5 Mechanical anaemias – fragmentation haemolysis: classification.

Vascular origin	Pathogenesis	Platelets
Cardiac haemolysis	Prosthetic heart valves	Normal
	Patches, grafts	
	Paraprosthetic or perivalvular leaks	
Arteriovenous malformations	Kasabach–Merritt syndrome	Very low
	Malignant haemangioendotheliomas	
Microangiopathic	TTP-HUS	Low
	Malignant disease	Normal/low
	Vasculitis	Normal/low
	Pre-eclampsia, HELLP	Low
	Renal vascular disorders	Normal/low
	Disseminated intravascular coagulation	Low

TTP, thrombotic thrombocytopenic purpura; HUS, haemolytic uraemic syndrome; HELLP, haemolysis with elevated liver function tests and low platelets.

Cardiac haemolytic anaemia

This syndrome was so called because it mainly occurred after cardiac surgery in which prosthetic valves, patches or grafts were inserted. Haemolysis usually becomes significant only when there is turbulent flow that brings the circulating red cells into intimate contact with the prosthetic material. There are certain situations in which the haemolysis may be of considerable clinical importance.

Periprosthetic or perivalvular leaks

If after insertion of a prosthesis or repair of a heart valve a leak occurs around the valve or through a suture track, there may be severe intravascular haemolysis without any evidence of haemodynamic distress. A difficulty may be that fragmentation of red cells is not always prominent, although spherocytes may be present. However, once autoimmune haemolysis is ruled out, the diagnosis can scarcely be anything other than cardiac haemolysis in a patient who has had cardiac surgery. The haemolysis can be cured only by further surgery.

Ambulatory haemolysis

A patient who has undergone valve replacement may show only slight evidence of haemolysis while in hospital but produce significant anaemia after discharge. This is thought to occur because the higher cardiac output associated with the greater exercise as an outpatient produces more turbulence and hence greater opportunity for red cell fragmentation. A similar mechanism is thought to operate if the patient becomes iron deficient as a result of chronic intravascular haemolysis. Iron replacement and advice about the level of exercise may prevent or delay the need for further surgery.

Cardiopulmonary post-perfusion syndrome

Acute intravascular haemolysis may occur in patients who have undergone cardiopulmonary bypass surgery. The haemolysis may be accompanied by neutropenia and pulmonary distress. The syndrome does not strictly belong in this section, as the haemolysis seems to be caused by complement activation and binding of the membrane attack complex to the red cell surface. The blood film shows ghost red cells rather than fragmentation. The condition is self-limiting and the patient requires only supportive care.

Arteriovenous malformation

Fragmentation of red cells may be seen in the Kasabach–Merritt syndrome, in which platelets are trapped in the vascular network of giant arteriovenous malformations, sometimes with evidence of a consumption coagulopathy. The bleeding disorder is of greater significance than the haemolysis in these patients. A similar picture, usually with clear evidence of a consumptive coagulopathy with evidence of DIC, may be seen in malignant haemangio-endothelioma, in which the tumour tends to invade and grow along veins.

Microangiopathic haemolytic anaemias

This term is used to describe intravascular haemolysis with fragmentation of red cells caused by their destruction in an abnormal microcirculation. Proof of microangiopathy may be lacking in those not subjected to a post-mortem, and MAHA should be considered a clinical syndrome. The three main pathological lesions that give rise to microangiopathic haemolytic anaemias (MAHA) are deposition of fibrin strands, often associated with DIC; platelet adherence and aggregation; and vasculitis. The vessel abnormalities may be generalized or confined to particular sites or organs. In most cases, the haemolysis is of less consequence than the underlying cause of the microangiopathy, but the fragmentation of red cells may be important in pointing to the diagnosis. Some of the disorders producing MAHA are given in Table 10.6. Only well-defined clinical syndromes will be described here in detail.

Microangiopathic haemolytic anaemia and malignant disease

Fragmentation of red cells with chronic intravascular haemolysis may occur in malignant disease. Clinically significant anaemia may occur, especially when there is invasion of the tumour into a large blood vessel (as in haemangiopericytoma), but, more commonly, the haemolysis is trivial or well compensated. The fragmentation may simply be noted on the blood film. A blood film that shows evidence of MAHA together with leuco-erythroblastic changes is virtually diagnostic of malignant disease with secondary deposits in the bone marrow (Figure 10.3). Mucin-secreting tumours are most likely to produce MAHA.

In acute leukaemia, particularly, but not exclusively, promyelocytic (M3), there may be intense intravascular coagulation that may be accompanied by MAHA. The coagulation changes dominate the clinical picture.

Microangiopathic haemolytic anaemia and infection

Infections, particularly septicaemia, may provoke intravascular coagulation and MAHA. Generally, the coagulation changes and septic shock overshadow the mild fragmentation but, occasionally, infections produce a chronic state of partially compensated intravascular and marked red cell fragmentation.

Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura (TTP) (see also Chapter 52) is an acute syndrome characterized by fever, neurological signs, haemolytic anaemia with fragmented red cells and thrombocytopenia. Mild proteinuria is common but major renal impairment is less usual. Two main categories exist: congenital and acquired. The underlying pathological process is of abnormal platelet aggregation in small blood vessels. The congenital TTP is mainly due to mutations in the gene *ADAMTS 13*, which encodes for a metalloprotease of the ADAMTS family, which specifically degrades von Willebrand factor (vWF). The mutations lead to deficiency of the protease ADAMTS 13, persistence

Disease	Microangiography
Haemolytic-uraemic syndrome	Endothelial cell swelling, microthrombi in renal vessels
Thrombotic thrombocytopenic purpura	Platelet plugs, micro-aneurysms, small vessel thrombi
Renal cortical necrosis	Necrotizing arteritis
Acute glomerular nephritis	
Malignant hypertension	
Pre-eclampsia	Fibrinoid necrosis
HELLP	
Polyarteritic nodosa	Vasculitis
Wegener's granulomatosis	
Systemic lupus erythematosus	
Homograft rejection	Microthrombi in transplanted organ
Mitomycin C	Uncertain
Cyclosporin	Renal vessel anomalies
Carcinomatosis	Abnormal tumour vessels, intravascular coagulation, disseminated or localized
Primary pulmonary hypertension	Abnormal vasculature
Cavernous haemangioma(Kasabach-Merritt)	Local vascular changes, thrombosis

HELLP, haemolysis with elevated liver function tests and low platelets.

of unusually large vWF (ULvWF) multimers, which, in turn, can induce platelet aggregation and the formation of platelet VWF plugs in small blood vessels. The acquired form, which is also associated with low levels of ADAMTS 13, is the result of the formation of autoantibodies to the metalloproteinase. Although the association of ADAMTS 13 deficiency with TTP has clarified much of the pathogenesis, it should be remembered that not all cases show this association and other pathways will certainly be described.

Epidemiology

TTP is a rare condition. In the USA the incidence is about 3–4 cases per million. Acquired cases are much more common than congenital. Affected families may be found with autosomal recessive inheritance. The acquired disease has the age and sex distribution seen in most antibody-mediated autoimmune diseases. Women are more frequently affected than men; the disease may occur at any age but is more common between 20 and 50 years. The female preponderance is enhanced by the association of TTP with pregnancy. The most common course is of a single episode, which may be fatal but relapsing and chronic subacute forms exist, particularly, but not exclusively, in the familial or congenital cases.

Clinical features

The typical presentation is of an acute illness presenting with neurological signs, fever and a blood film showing fragmented red cells and thrombocytopenia. Frequently, the presentation is not typical but more insidious, with episodes of headache, personality change or vague neurological disturbances. These disturbances may be sensory or motor deficits, seizures or even coma. Often the neurological signs fluctuate considerably. Renal impairment is demonstrated by proteinuria but frank renal failure is not a feature at presentation.

Gastrointestinal involvement may present as diarrhoea. Pallor and icterus may indicate haemolysis but frank haemorrhagic signs are rare. Chest pain due to cardiac ischaemia may occur.

Laboratory findings

The diagnosis is made on the basis of the clinical presentation and the evidence for haemolytic anaemia with fragmented red cells and thrombocytopenia. Bilirubin is elevated, as is the serum LDH, indicating intravascular haemolysis. LDH is a useful marker for measuring the activity of the microangiopathic process. Coagulation abnormalities are not a consistent feature, in contrast to MAHA associated with DIC. The presence of ULvWF may be demonstrated at presentation. More specific diagnosis showing ADAMTS deficiency and or autoantibodies requires specialist laboratories. At post-mortem, platelet plugs and fibrin plugs may be found in capillaries (Figure 10.4a and b). The pathophysiology is discussed further in Chapter 52.

Treatment

Plasmapheresis

Until the introduction of repeated plasmapheresis, the mortality of TTP was about 80%, death usually being caused by myocardial

(a)

(b)
Figure 10.4 Thrombotic thrombocytopenic purpura. Microthrombi in capillaries. (a) Section from the myocardium; (b) thrombus in a bone marrow capillary (haemotoxylin and eosin, ×100) (courtesy of Dr Margaret Burke).

infarction (Figure 10.4). Removal of antibody in the patient's plasma and replacement of the metalloproteinase by fresh-frozen plasma has reduced the mortality to less than 15%. Presentation in coma or a very low platelet count is a poor prognostic sign. Treatment should be started with plasmapheresis as an emergency as soon as the diagnosis is made. The initial procedure for an adult aims for a 1 to 1.5 plasma volume exchange. Replacement fluid is mainly virally inactivated fresh-frozen plasma, with cryosupernatant being preferred or added in some centres as it lacks the highest vWF multimers. As very large volumes of plasma are used virally inactivated product should be used where possible. The plasmapheresis needs to be repeated daily for up to 20 days and sometimes longer. Treatment effect is monitored by examination of the blood film for fragments, by platelet count and LDH. Remission is judged to have occurred when the platelet count is within the normal range for three successive days and the LDH is normal. Plasmapheresis may then

be reduced in frequency, but relapse is not uncommon if it is stopped early.

Plasma infusion
Infusion of FFP alone may achieve remission in congenital cases with primary deficiency of ADAMTS 13 but is not as effective as plasma exchange in acquired disease.

Immunosuppression
During the acute management, corticosteroids are not usually of benefit, and indeed there is little evidence from randomized trials of their efficacy at any time. However, they may have a role in resistant or relapsing disease. Likewise, vincristine has been advocated in resistant cases. It should be noted that there are overlaps between TTP, ITP and the antiphospholipid syndrome, which make the use of such measures reasonable in some cases. Cyclosporin may have a place in maintaining remission in chronically relapsing disease.

Antibiotics
Many cases present with features suggesting infection and infections may precipitate relapse. The possibility of occult infection, particularly a Gram-negative urinary tract infection, should be considered and appropriate antibiotics given if there is a suspicion of infection. Plasma exchange itself provides a portal for infection and antibiotics, including Gram-positive cover, administered if fever returns during treatment.

Splenectomy
Splenectomy has been used for many years in resistant cases, but there are no proper studies to support this. However, stable long-term remissions may be achieved in some patients with both resistant and relapsed disease.

Antiplatelet and antithrombotic treatment
Aspirin and dipyridamole are both used in conjunction with plasma exchange in many series. There is some soft evidence to support their use. Clopidogrel and ticlopidine have each been associated with promoting TTP and so are not recommended. Defibrotide is an antithrombotic agent of unknown action which has been used with some success in refractory cases, but it is not a licensed treatment.

Haemolytic uraemic syndrome
Haemolytic uraemic syndrome (HUS) has some of the features of TTP, but the kidney is the main organ targeted rather than the CNS. Some cases may be associated with ADAMTS 13 deficiency but the majority are not. Infants, young children and the elderly are mainly afflicted. HUS may be caused by infection with *Escherichia coli* O157, a strain that produces a verotoxin. Haemolysis is less marked than in TTP, and coagulation abnormalities are more prominent. The role of plasma exchange in

management is less certain. The syndrome is discussed further in Chapter 52.

March haemoglobinuria

Haemoglobinuria following running has been documented for about 100 years. Its origin is mechanical, with destruction of red cells occurring in the feet. It can be cured by wearing soft shoes or running on soft ground. The disorder may arise in joggers and is benign except that it may lead to extensive invasive investigations unless recognized. The blood film does not show any red cell fragmentation or consistent abnormality. Occasionally, haemoglobinuria after running is accompanied by nausea, abdominal cramps and aching legs, and enthusiastic athletes with this condition may exhibit mild splenomegaly and jaundice.

Chemical and physical agents

Oxidative haemolysis

Oxidative substances may cause haemolysis in people with normal red cell metabolism and normal HbA if the oxidative stimulus is large enough. The major causes of oxidative haemolysis in normal subjects are shown in Table 10.7. The clinical features of this condition are dependent on the main sites of oxidative attack, whether on the membrane of the red cell, the globin chains or the haem group.

Chronic intravascular haemolysis with Heinz bodies

Dapsone and Salazopyrin (salicylazosulphapyridine) will cause oxidative intravascular haemolysis in normal subjects if taken in high enough dosage. Red cells show the 'bite' abnormality of the chemically damaged cell (Figure 10.5). Heinz bodies may be absent or scanty in patients with an intact spleen. Dapsone is used in the treatment of G6PD-deficient subjects with leprosy and in the treatment of dermatitis herpetiformis, in which functional hyposplenism occurs; Heinz bodies appear in the latter case, acute intravascular haemolysis in the former.

Haemosiderinuria may be detected in patients taking these drugs, and there may be polychromasia and macrocytosis. Haemolysis is usually well compensated and there is no need to
Figure 10.5 Oxidative haemolysis caused by drug (phenacetin). Note red cells with contracted haemoglobin.

stop the treatment unless the anaemia is severe. A dose reduction may sometimes be needed.

Methaemoglobinaemia is uncommon unless the patient is partially deficient in NADH methaemoglobin reductase. The gene for this abnormality may not be very uncommon, and it may account for some people becoming cyanosed after taking dapsone-containing antimalarial preparations.

Methaemoglobinaemia with or without haemolysis

Nitrites in water or vegetable juices may cause methaemoglobinaemia in infants who have a physiological impairment of the reducing systems. Well water that comes from land with an excess of nitrites and which is used to reconstitute artificial feeds has produced cyanosis in infants. Cases have also been described following the enthusiastic feeding of juice from carrots grown on organically fertilized land and of spinach juice (spinach has a high concentration of nitrogen-fixing bacteria on its leaves).

Nitrate drugs, for example amyl nitrate, also produce methaemoglobinaemia and have proved fatal when taken in high enough dosage for 'recreational' purposes.

Table 10.7 Substances causing oxidative haemolysis and/or methaemoglobinuria in normal people.

Substance	Use	Remarks
Dapsone	Leprosy; dermatitis herpetiformis	Chronic haemolysis; slow acetylators more susceptible
Maloprim	Antimalarial	Methaemoglobinaemia in NADH-MetHb reductase-depleted subjects
Salazopyrine	Ulcerative colitis	Chronic intravascular haemolysis
Phenazopyridine	Analgesic in urinary tract infections	Methaemoglobinaemia
Menadiol	Water-soluble vitamin K analogue	Haemolysis/kernicterus in infants
Nitrites	Fertilizer; present in well water and some vegetable juices	Methaemoglobinaemia in infants
Nitrates, 30 g	Amyl nitrate, butyryl nitrite; abused recreationally	Acute i.v. haemolysis; renal failure; fatal
Arsine	Gas produced in smelting and other industrial processes	Acute i.v. haemolysis; renal failure

Water-soluble analogues of vitamin K (menadiol sodium diphosphate) cause haemolysis with or without methaemoglobinaemia in infants and *in utero* if given to the mother during the third trimester. Fat-soluble vitamin K preparations must be used if required in these situations.

Methaemoglobinaemia due to oxidative drugs may be treated with intravenous methylene blue in doses of 1–2 mg/kg. Ascorbic acid by mouth may also be used. These measures are ineffective in G6PD-deficient patients and when very strong oxidant substances are implicated. In these circumstances, methylene blue should be avoided because it acts as an oxidant and makes the condition worse.

Acute intravascular haemolysis, methaemoglobinaemia and renal failure

These conditions occur following exposure to strong oxidizing substances that are found mainly in industrial or horticultural pursuits, e.g. sodium chlorate is a popular weed killer and arsine is a gas that is produced in various industrial settings. Acute intravascular haemolysis and haemoglobinuria develop. The serum becomes brown, often very dark, so that blood cells cannot be seen in anticoagulated preparations, due to the presence of methaemalbumin, methaemoglobin and free haemoglobin. Oliguric renal failure usually develops over about 24 h. The blood film shows microspherocytosis and bizarre forms.

Plasma exchange and renal dialysis are the mainstays of treatment, methylene blue being ineffective. Poisoning with arsine is usually reversible with these measures. Chlorate poisoning is more difficult, 30 g being a generally fatal dose. It is mostly ingested deliberately in suicide attempts.

Thermal injury

Normal red cells when heated *in vitro* show no changes when heated to 46°C for 1 h but show temperature- and duration-dependent changes above 47–50°C. Some hereditary membrane defects produce red cells that have increased thermal fragility (see Chapter 8).

Haemolysis following burns

Severe burns may be accompanied by intravascular haemolysis with haemoglobinuria. The intravascular haemolysis is related to the extent and severity of the burns. The gross haemoglobinuria occurs over the first 24 h after the burns and ceases thereafter. The blood film shows spherocytosis and schistocytes, the morphological abnormalities reflecting the thermal damage and the amount of lysis. Prolonged anaemia post burning is related to inflammation, occult blood loss and infection rather than haemolysis.

Acquired disorders of the red cell membrane

The mature red cell does not have the capacity for the repair of its membrane. The lipids of the membrane are in equilibrium with the lipids of the plasma and changes in the ratio of free cholesterol to phospholipids in plasma may affect the red cell shape and, in some instances, lead to haemolysis. This is most commonly seen in liver disease, but other inherited lipid disorders may affect the red cell secondarily.

Liver disease

Some degree of shortening of the red cell survival occurs in most cases of acute hepatitis, cirrhosis and Gilbert's disease, but anaemia is not present and there is only a slight rise in reticulocytes, which may not be detectable. Biliary obstruction is associated with the appearance of target cells and fulminant hepatitis with acanthocytosis, both consequent on changes in the plasma lipid composition.

Zieve's syndrome is an uncommon disorder, seen mainly in alcoholics. It comprises intravascular haemolysis and acute abdominal pain. These patients usually have cirrhosis and jaundice. The cause is unknown but is probably related to lipid changes in the blood. Spherocytes are seen in the peripheral blood.

Wilson's disease may present as acute intravascular haemolysis. This is probably not a membrane disorder but is consequent on the high levels of copper ions in the blood. The haemolysis may antedate the development of hepatic or neurological features, but Keyser–Fleischer rings are usually present. The blood film may show spherocytosis. The diagnosis is made once the condition is suspected. Apart from caeruloplasmin deficiency, patients have a specific aminoaciduria.

Hereditary acanthocytosis (a-β-lipoproteinaemia)

This rare inherited deficiency of low-density lipoproteins is characterized by retinitis pigmentosa, steatorrhoea, ataxia and mental retardation. The haemolysis that occurs is of minor importance to such patients, but the blood film may indicate the diagnosis, with the red cells showing marked acanthocytosis.

Vitamin E deficiency

Deficiency of vitamin E may occur in infants who are fed a diet rich in polyunsaturated fatty acids. There is haemolysis with contracted cells and a thrombocytosis. Oedema may be present. Vitamin E is an antioxidant, and oxidative damage to the red cell membrane is thought to be the cause of the haemolysis.

Paroxysmal nocturnal haemoglobinuria

11

Lucio Luzzatto and Rosario Notaro

Introduction

Paroxysmal nocturnal haemoglobinuria (PNH) is an acquired chronic haemolytic anaemia in which haemolysis is largely intravascular. In addition to haemolytic anaemia, the patient may have thrombosis and pancytopenia. This triad, when present, is highly characteristic of PNH.

PNH is a rare disorder (estimated prevalence of less than 1 in 100 000) that can occur anywhere in the world. There is no evidence of family clustering and PNH has been observed at all ages from 1 to 72 years; however, it is most common in young adults.

Clinical features

The commonest initial complaint in PNH is fatigue, due to anaemia, which may range from mild to very severe. Sometimes the patient reports that one morning he or she passed very dark urine (e.g. 'it looked like Coca-Cola'; or 'it looked like blood rather than urine'). This 'classical' presentation occurs in only a minority of patients. However, if specific questions are asked, or if serial urine specimens are collected and inspected (Figure 11.1), haemoglobinuria can be documented at some time in virtually all patients.

Apart from pallor and mild jaundice, there may be no *physical findings* in a patient with PNH in the *steady state*. In some patients, one may elicit on deep palpation abdominal tenderness (usually on the midline above the umbilicus). Enlargement of the spleen is rare, and it suggests there has been thrombosis in the splenic or in the portal vein. Liver enlargement is also relatively rare, and it suggests hepatic vein thrombosis, which may present abruptly, giving the clinical picture of a full-blown Budd–Chiari syndrome, including ascites. On questioning, it is not unusual to elicit a history of attacks of abdominal pain,
Figure 11.1 Consecutive urine samples from a patient with PNH. The patient had stated that she had had haemoglobinuria in the past, but not at the moment. The figure illustrates the marked variability in haemoglobinuria over a short time interval and that subjective self-assessment of haemoglobinuria may be deceptive. After this test, the same patient's assessment of her haemoglobinuria became more reliable.

which may last from hours to several days, may be associated with either diarrhoea or constipation, and perhaps with more intense haemoglobinuria. Recurrent dysphagia and erectile dysfunction may also occur.

The natural history of PNH is that of a very chronic disorder that may afflict the patient continuously for decades, although in many cases a good quality of life is possible. Without treatment, the median survival is estimated to be about 10 years. In some cases, after many years, full spontaneous recovery may take place. Not infrequently, at some stage in the disease, the anaemia may be associated with other cytopenias; indeed, when a PNH patient becomes less haemolytic and more pancytopenic he or she becomes very similar to a patient with aplastic anaemia (AA). Conversely, a patient with AA may subsequently develop PNH: the term 'PNH-AA syndrome' has been used to designate

Table 11.1 Diagnosis of dark urine.

Different sorts of dark urine	Causes	Additional tests	Possible diagnosis
Haematuria	Many	Clears on centrifugation	Mostly urinary tract pathology
Myoglobinuria	Rhabdomyolysis	Ultrafiltration, spectroscopy	March myoglobinuria
Haemoglobinuria	Intravascular haemolysis	Serology after blood transfusion	Incompatible blood transfusion
		Donath–Landsteiner antibody	Paroxysmal cold haemoglobinuria
		G6PD activity	G6PD deficiency
		Blood film for malaria parasites	'Blackwater fever'
		Blood culture	*Clostridium welchii* septicaemia
		History of marching	March haemoglobinuria
		History of heart prosthetic valve	Microangiopathic haemolytic anaemia
		Ham, flow cytometry for CD59	PNH

Modified from Luzzatto L, Notaro R (2003). Paroxysmal nocturnal hemoglobinuria. In: *Blood: Principles and Practice of Hematology* (RI Handin, SE Lux, TP Stossel, eds), 2nd edn, pp. 319–334. Lippincott Williams & Wilkins, Philadelphia.

these patients. Several lines of evidence (see below) suggest that in fact there is a component of AA (bone marrow failure) in every PNH patient.

There may be also some overlap between PNH and MDS: however, this is difficult to assess in an individual case, because the bone marrow morphology of PNH has in itself features of myelodysplastic syndrome (MDS). Unlike MDS, however, it is very rare that PNH evolves to AML; the estimated frequency is less than 2%.

Laboratory findings and diagnosis

The anaemia may be normocytic, but it is often macrocytic on account of an absolute reticulocytosis, which may be quite high (200×10^9/L or even higher). If the mean corpuscular volume (MCV) is normal rather than high, there probably is superimposed iron deficiency. Apart from polychromasia, the red cell morphology is not characteristic. The neutrophils may range from normal to below 1.0×10^9/L; the platelets may range from normal to below 20×10^9/L; the lymphocytes are usually normal, but there may be lymphopenia and there may be an increase in large granular lymphocytes. The bilirubin level is usually only moderately increased, in striking contrast to lactate dehydrogenase (LDH), which is often in the thousands (U/L), while haptoglobin is markedly decreased. The serum iron and transferrin saturation index (TSI) may be decreased, indicating secondary iron deficiency, even when the serum ferritin is normal. The bone marrow aspirate will usually yield a cellular marrow with erythroid hyperplasia, which may be very marked. As stated above, there may be MDS-like changes in one or more cell lineages. The bone marrow trephine usually confirms erythroid hyperplasia, but it proves often to be less cellular than might have been expected from the aspirate.

In many cases, the telltale sign of PNH is haemoglobinuria (which, of course, must be differentiated from haematuria, by simply centrifuging the urine – Table 11.1). Haemoglobinuria by itself, and especially if combined with some other features, must lead to the suspicion of PNH (Table 11.2). The definitive diagnosis of PNH is carried out by either the Ham test (still highly reliable) or by flow cytometry with appropriate antibodies. The Ham test gives no false-negative results; it can give rise to false-positive results only in congenital dyserythropoietic anaemia type II (but not if the patient's serum is used), or if the patient's red cells are already coated with a lytic antibody. Therefore, direct Coombs' test ought to be carried out always in parallel to a Ham test: when the former is positive, the latter becomes unreliable (and the likely diagnosis is autoimmune haemolytic anaemia rather than PNH).

Flow cytometry is now regarded as the gold standard; it provides an accurate quantification of the size of the PNH cell population and the best antibody in our hands is anti-CD59 (Figure 11.2). In contrast to conventional 'phenotyping' of

Table 11.2 When PNH should be suspected.

1. Haemoglobinuria due to intravascular haemolysis (see Table 11.1)
2. Haemolytic anaemia with a low platelet and/or low neutrophil count
3. Haemolytic anaemia and recurrent abdominal pain with or without blood in the stool
4. Hepatic vein thrombosis (Budd–Chiari syndrome)
5. Any venous thrombosis anywhere in young adult with low platelet and/or the neutrophil counts
6. Idiopathic pancytopenia (IAA)
leukaemic cells, one is looking for a CD59⁻ cell population, and it is important to see a bimodal distribution in both red cells and granulocytes (a 'tail' of negative cells is not diagnostic and could be a technical artifact). In a typical patient there may be, for instance, 30% CD59⁻ red cells and 90% CD59⁻ granulocytes. Flow cytometry is, of course, very sensitive, and therefore very small PNH cell populations can be detected, and they are detected (especially in granulocytes), particularly in patients with non-severe aplastic anaemia. This raises the issue of what size of PNH cell population should be regarded as diagnostic of PNH. Any cut-off point is bound to be arbitrary, but we have never seen appreciable haemolytic anaemia in a patient in whom less than 5% red cells are of the PNH type. It does not seem sensible to change the diagnosis from, for example, non-severe aplastic anaemia to PNH just because 3% of the granulocytes have the PNH phenotype (in jargon this situation is sometimes referred to as 'lab PNH'), because it should not affect clinical decisions.

Pathogenesis and pathophysiology

Haemolytic anaemia

Haemolytic anaemia in PNH is a due to an intracorpuscular abnormality of the red cell. In this respect, PNH is similar to inherited haemolytic anaemias, such as those caused by an enzyme defect. However, PNH is an acquired disorder, and there is no evidence that it is inherited. The abnormality of red cells in PNH is indeed an enzyme defect, but it is caused by a somatic mutation rather than by an inherited mutation. This explains the 'mosaicism' found in the blood of PNH patients, whereby cells belonging to the PNH clone, which have arisen through a somatic mutation, coexist with the remaining qualitatively normal cells.

We now know that the somatic mutation is in an X-linked gene that has been called *PIG-A*, for phosphatidylinositol glycan complementation group A. *PIG-A* encodes one of the subunits

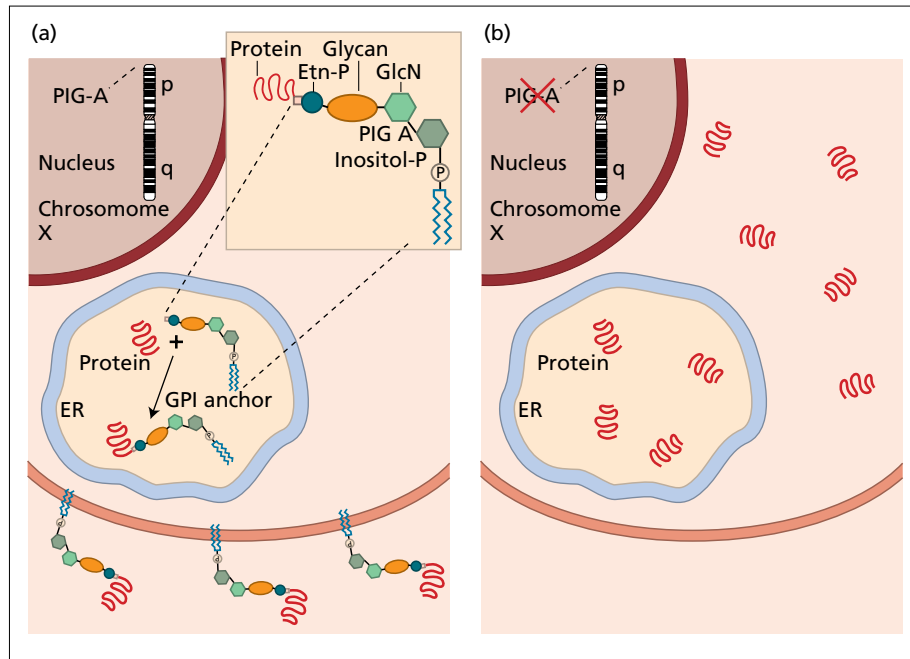
Figure 11.2 (*left*) Different patterns of PNH red cells populations in several PNH patients. The top panel is from a normal individual. Patient MB has 57% red cells that lack CD59 completely (PNH III red cells). Patient CJ has only 4% normal red cells; 96% of her red cells have a partial deficiency of CD59 (PNH II red cells), indicating that virtually her entire haemopoiesis is supported by a PNH clone with a missense mutation of *PIG-A*. The trimodal distribution of red cells in patient RK indicates the coexistence, along with normal red cells, of a PNH III clone (22%) and a PNH II clone (12%) (modified from Dacie JV, Lewis SM, Luzzatto L *et al.* (1995) Laboratory methods used in the investigation of paroxysmal nocturnal haemoglobinuria (PNH). In: *Practical Haematology* (JV Dacie, SM Lewis, eds), 8th edn, pp. 287–96. Churchill Livingstone, London).


Figure 11.3 The molecular basis of the cellular abnormality in PNH. In a normal cell (a) a complex biosynthetic pathway produces in the endoplasmic reticulum (ER) a glycophospholipid molecule (see inset) called glycosylphosphatidylinositol (GPI). An early step in the biosynthetic pathway is catalysed by an acetylglucosaminyl transferase; one of the subunits of this enzyme is encoded by the gene *PIG-A*, located on the short arm of the X chromosome (band Xp22). A number of cellular proteins become covalently linked to the GPI molecule, which serves to convey and anchor them as extracellular surface proteins to the cell membrane. The PNH cell (b) has a mutation in the *PIG-A* gene, causing a serious defect in the acetylglucosaminyl transferase. This in turn causes a total or partial block in the synthesis of the GPI molecule. As a result, the proteins that require a GPI anchor are unable to become membrane bound and will be lacking from the cell surface (modified from Luzzatto L, Notaro, R. (2003) Paroxysmal nocturnal hemoglobinuria. In: *Blood: Principles and Practice of Hematology* (RI Handin, SE Lux, TP Stossel, eds), 2nd edn, pp. 319–34. Lippincott Williams & Wilkins, Philadelphia).

of the enzyme responsible for the transfer of *N*-acetylglucosamine (GlcNAc) onto phosphatidylinositol. This is the first step of the complex biosynthetic pathway that in the end produces the glycosylphosphatidylinositol (GPI) anchor required for anchoring many proteins to the cell membrane (Figure 11.3 and Table 11.3). One of these proteins, CD59 or membrane inhibitor of reactive lysis (MIRL), normally protects the red cell from being lysed by the membrane attack complex (C5–C8) that forms when complement (C) is activated. In essence, the hypersusceptibility to C of PNH red cells is the consequence of CD59 deficiency. Chronic intravascular haemolysis in PNH is probably explained by activation of C through the 'alternative' pathway, which goes on at a low rate all the time, whereas the dramatic exacerbation of haemolysis that is characteristically associated with intercurrent viral or bacterial infection in patients with PNH is probably explained by brisk activation of C by an antigen–antibody reaction (i.e. through the 'classical' pathway).

Molecular analysis

More than 180 mutations in the *PIG-A* gene have been identified in patients with PNH. In the majority of cases (about 75%), these mutations are such (small insertion/deletions producing frameshifts, nonsense mutations, only two large deletions) that they can be expected to cause complete absence of the product of the *PIG-A* gene, thus, they account for the PNH III phenotype. The remaining mutations are either missense or, in a few cases, small in-frame deletions; these may account for PNH cases with partial deficiency of GPI-anchored proteins (PNH II). In almost every patient with PNH, the *PIG-A* mutation underlying the PNH phenotype is different, which is not surprising as we are dealing not with inherited mutations, but with somatic mutations that take place *de novo* in haemopoietic stem cells. In fact, when PNH cells are investigated in detail, it is not at all rare to find that more than one PNH clone may be present in the same PNH patient, either simultaneously or in sequence.

Table 11.3 Some GPI-linked molecules on human haemopoietic cells.

*Expressed only upon 'activation' or only in a subset of cells.

†Present in both GPI-linked and transmembrane form.

‡Present only in transmembrane form in this cell type.

The GPI-linked form is present only in B cells (1), only on T lymphocytes (2).

CD52, target of alemtuzumab (Campath-1H); CD157, ectoenzyme of the family of cyclic ADP-ribose-generating cyclases; DAF, decay accelerating factor: may cooperate with CD59 in protecting against C-mediated lysis; HSC, haemopoietic stem cells; LFA-3, leucocytes functional antigen-3; lymph, lymphocytes; MIRL, membrane inhibitor of reactive lysis; Mono, monocytes; Plts, platelets; PMN, granulocytes; RBC, red blood cells; u-PAR, urokinase plasminogen activator receptor.

Thrombosis

Thrombosis is one of the most immediately life-threatening complications of PNH, and yet one of the least understood in its pathogenesis. It could be due to impaired fibrinolysis, because the urokinase plasminogen activator receptor (uPAR) is a GPI-linked protein; alternatively, C activation could cause hypercoagulability or hyperactivity of platelets, or both. For instance, it could be speculated that deficiency of CD59 on the PNH platelet could lead to abnormal insertion of the C5b–9 complex in the platelet membrane, as is the case with the red cell. Although all of these three factors may play a role in producing a thrombophilic state in PNH, it seems very likely that the primary cause lies in the PNH platelets, which are abnormal precisely because they belong to the PNH clone. This notion is supported by the occurrence of cerebral infarction in a patient who did not have PNH, but who had congenital CD59 deficiency and chronic haemolysis.

Bone marrow failure and relationship between paroxysmal nocturnal haemoglobinuria and acquired aplastic anaemia (AAA)

PNH has an intimate link with AAA, for several reasons. As stated above, sometimes a patient with PNH becomes 'less haemolytic' and more pancytopenic and ultimately evolves to frank AAA. In terms of pathogenesis, it is believed that AAA is essentially an organ-specific autoimmune disease that is mediated by 'activated' cytotoxic (CD8[+]) T lymphocytes, which are able to inhibit haemopoietic stem cells. Recently, skewing of the T-cell repertoire indicating the presence of abnormally expanded T-cell clones has been observed also in PNH. Most importantly, intensive immunosuppressive treatment is standard of care in AAA, and a beneficial response to the same treatment can be obtained also in PNH (see below).

In view of these facts, it seems that an element of BMF in PNH is the rule rather than the exception; an extreme view is that

PNH is a form of AAA in which BMF is masked by the enormous expansion of the PNH clone that populates the patient's bone marrow. In other words, it appears that two different mechanisms cooperate in producing PNH: autoimmune damage to stem cells and a somatic mutation in the *PIG-A* gene. This notion is supported by two further lines of evidence. Using targeted inactivation of the *PIG-A* gene in mouse embryonic stem cells, one can produce mice with a PNH cell population. However, this population does not grow further, as it does in PNH patients. Using refined flow cytometry technology, PNH cells harbouring *PIG-A* mutations can be demonstrated in normal people at a frequency of the order of 10 per million. Both of these findings indicate that some other factor is required in addition to a somatic mutation in the *PIG-A* gene in order to cause PNH. Most likely, the same cytotoxic damage to stem cells that would otherwise cause PNH spares the PNH stem cells, thus allowing the PNH clone to grow to the size when it gives clinical PNH. The mechanism whereby the PNH cells escape damage is not yet known.

Management of paroxysmal nocturnal haemoglobinuria

In dealing with a patient with PNH, we must always consider that, unlike other acquired haemolytic anaemias, PNH may be lifelong. In addition, we must keep in mind the triad that defines the disease, namely haemolysis, BMF and the tendency to thrombosis. At the same time, we must consider, for each individual patient and upon discussion with the patient, whether to be content with supportive treatment or whether to aim for radical treatment.

Supportive treatment

Supportive treatment, supervised by somebody who has experience of PNH, can help the patient to 'live with PNH' for years, sometimes for decades, and often with good quality of life. The increased rate of erythropoiesis consequent on haemolysis requires supplements of folic acid (at least 3 mg per day) inde-

finitely. Whenever there is evidence of iron deficiency, it is equally important to provide iron supplementation, until the iron status is normalized. Blood transfusion of filtered red cells should be given whenever necessary. Some patients may require blood transfusion at bimonthly or even monthly intervals. Compared with other conditions requiring periodic blood transfusion, one advantage in PNH is that iron overload is not a problem in most cases, because it is prevented by iron loss through the urine. Prednisone is credited with controlling episodes of massive haemoglobinuria and, when this is associated with intercurrent infection, a short course of prednisone may sometimes appear helpful. However, the haemoglobinuria usually subsides anyway when the infection is controlled.

On the other hand, long-term administration of prednisone, even at a low dosage, is always *contraindicated*, in view of the serious potential side-effects. Any patient who has had deep vein thrombosis at any one site in the abdomen or in a limb should be on regular anticoagulant prophylaxis. During an episode of abdominal vein thrombosis, *thrombolytic therapy* with tissue plasminogen activator (tPA) must be seriously considered because, although it is not free of risk (especially if the patient is thrombocytopenic), it may be highly effective and it may prevent irreversible damage (Figure 11.4). Unlike with arterial thrombosis, tPA is worth a trial, even several days from the clinical onset of the thrombotic event.

Bone marrow transplantation and immunosuppressive treatment

At the moment, the only form of treatment that can provide a cure for PNH is *allogeneic bone marrow transplantation* (BMT); when an HLA-identical sibling is available, BMT should be offered to any young patient with PNH, especially if there is severe pancytopenia. Results similar to those for AA can be expected, with long-term disease-free survival ranging from 60% to 100% in the few series that have been published. Recently, BMT from unrelated donors in PNH has been also successful. The majority of patients will not have a potential sibling donor, and some of those who do may not wish to undergo BMT. Given the common pathogenesis of PNH and
(a) (b)

Figure 11.4 Successful thrombolytic therapy in PNH. (a) Magnetic resonance venography in a 29-year-old woman who presented with acute Budd–Chiari syndrome, and who also had a thrombus partially occluding the inferior vena cava. (b) Repeat study after a 48-h infusion of tissue plasminogen activator (from R Thertulien *et al.*, unpublished).

AA, a logical alternative is immunosuppressive treatment with ALG (ATG) and cyclosporin A. Although no formal trial has ever been conducted, this approach has helped particularly to relieve severe thrombocytopenia and/or neutropenia in patients in whom these were the main problem(s): by contrast, there is often little beneficial effect on the haemolysis itself.

A new approach to controlling haemolysis

One of the most frustrating aspects of the management of PNH has been, until now, the absence of an effective way to control haemolysis. Eculizumab, a humanized antibody against complement protein C5 that inhibits the activation of terminal components of complement, has been tested in a small group of transfusion-dependent PNH patients. The results thus far appear very promising; indeed, reduced intravascular haemolysis and less haemoglobinuria have been documented, as well as a marked decrease in transfusion requirement in most patients.

Inherited aplastic anaemia/bone marrow failure syndromes

12

Inderjeet S Dokal

Introduction

A number of inherited (constitutional/genetic) disorders are characterized by aplastic anaemia (AA)/bone marrow (BM) failure, usually in association with one or more somatic abnormalities (Table 12.1). The features of some of these are summarized in Table 12.2. The precise incidence/prevalence of these remains unclear but, collectively, they represent approximately 10–20% of patients presenting with AA and constitute a significant clinical burden, as many are associated with premature

Table 12.1 The inherited bone marrow failure syndromes.

Pancytopenia
Fanconi anaemia (FA)
Dyskeratosis congenita (DC)
Shwachman–Diamond syndrome (SDS)
Reticular dysgenesis
Pearson syndrome (PS)
Familial aplastic anaemia (autosomal and X-linked forms)
Myelodysplasia
Non-haematological syndromes (Down, Dubowitz syndromes)

Single cytopenia (usually)
Anaemia (Diamond–Blackfan anaemia, DBA)
Neutropenia (severe congenital neutropenia, SCN, including
    Kostmann syndrome)
Thrombocytopenia (congenital amegakaryocytic
    thrombocytopenia, CAMT, amegakaryocytic
    thrombocytopenia with absent radii, TAR)

mortality. The BM failure may present at birth or at a variable time thereafter, including in adulthood in some cases. The BM failure may involve all or a single lineage; in some cases it may initially be associated with a single cytopenia and then progress to pancytopenia. Scientifically, they constitute an important group of diseases as recent advances in understanding the genetics of some of these are not only beginning to unravel their pathophysiology but are also providing important insights into normal haemopoiesis.

The two syndromes that are frequently associated with generalized BM failure/aplastic anaemia (AA) are Fanconi anaemia (FA) and dyskeratosis congenita (DC). These two syndromes are now also two of the best characterized and will be discussed in some detail in this chapter [followed by sections on Shwachman–Diamond syndrome (SDS), Diamond–Blackfan anaemia (DBA), congenital neutropenia, thrombocytopenia with absent radii (TAR) and congenital amegakaryocytic thrombocytopenia (CAMT)] to demonstrate their clinical and genetic heterogeneity, management and possible impact on our understanding of the pathophysiology of the more common 'idiopathic aplastic anaemia'. Indeed, both FA and DC patients can sometimes present with AA alone as their initial manifestation and can thus pose a diagnostic/management challenge.

Fanconi anaemia

Clinical features

Since the first description by Fanconi in 1927, FA has become to be recognized as an autosomal recessive disorder in which there is progressive BM failure and an increased predisposition

Table 12.2 Characteristics of the bone marrow failure syndromes.

	FA	*DC*	*SDS*	*DBA*	*TAR*	*SCN*	*IAA*
Inheritance pattern	AR	XLR, AR, AD	AR	AD and AR	AR	AD, AR	?
Somatic abnormalities	Yes	Yes	Yes	Yes	Yes	Rare	? None
Bone marrow failure	AA (> 90%)	AA (~80%)	AA (20%)	RCA	Megs	Neutropenia	Yes (100%)
Short telomeres	Yes	Yes	Yes	?	?	?	Yes

Genes identified	7	2	1	1	No	1	?

AA, aplastic anaemia; AD, autosomal dominant; AR, autosomal recessive; DBA, Diamond–Blackfan anaemia; DC, dyskeratosis congenita; FA, Fanconi anaemia; IAA, idiopathic AA; Megs, low megakaryocytes; RCA, red cell aplasia; SCN, severe congenital neutropenia; SDS, Shwachman–Diamond syndrome; TAR, thrombocytopenia with absent radii; XLR, X-linked recessive.

to malignancy, especially acute myeloid leukaemia. Most, but not all, affected individuals also have one or more somatic abnormalities including skin (café-au-lait spots), skeletal (absent thumbs, radial hypoplasia, scoliosis), genitourinary (under-developed gonads, horseshoe kidneys), gastrointestinal, cardiac and neurological anomalies (Table 12.3). Some of these somatic abnormalities are shown in Figure 12.1. The course of the disease and the pattern of somatic abnormalities show considerable variation, with approximately one-third of patients having no somatic abnormalities. This makes diagnosis based on clinical criteria alone difficult and unreliable.

Table 12.3 Somatic abnormalities in FA (modified from Auerbach *et al.* 1998).

Abnormality	Percentage of patients
Skeletal (radial ray, hip, vertebral, scoliosis, rib)	71
Skin pigmentation (café-au-lait, hyper- and hypopigmentation)	64
Short stature	63
Eyes (microphthalmia)	38
Renal and urinary tract	34
Male genital	20
Mental retardation	16
Gastrointestinal (e.g. anorectal, duodenal atresia)	14
Heart	13
Hearing	11
Central nervous system (e.g. hydrocephalus, septum pellucidum)	8
No abnormalities	30

The cumulative incidence of BM failure by the age of 40 years is 90%. At birth the blood count is usually normal. Pancytopenia develops insidiously and presents in most cases between the ages of 5 and 10 years (median age 7 years). However, in some cases the pancytopenia develops in adolescence or even in adult life. The haemoglobin (Hb) and platelet count are usually first to fall; the granulocytes are usually well preserved in the early stages. As the pancytopenia develops, the BM becomes progressively hypocellular. There is often a marked increase in macrophage activity with evidence of haemophagocytosis. BM failure leading to fatal haemorrhage or infection is the main cause of death in FA patients. In a recent analysis from the International Fanconi Anemia Registry (IFAR), the median survival time was 24 years.

FA is associated with an increased risk of leukaemia and other malignancies. The leukaemias are usually of the acute myeloid type, particularly FAB types M4 (myelomonocytic) and M5 (monocytic). In some cases, leukaemia may be the initial event leading to the diagnosis of FA. The cumulative incidence of haematological malignancy by the age of 40 years is 33%. Besides these haematological malignancies, there is a significant risk of hepatic tumours and squamous cell carcinoma, including squamous cell carcinomas of the vulva, oesophagus, head and neck. The cumulative incidence of solid tumours is calculated to be 28% by the age of 40 years. The impression is that malignancies occur mainly in patients with late-onset BM failure and longer survival, with a median age of 13 years for leukaemia and 25 years for solid tumours. Furthermore, long-term follow-up in FA patients who have been treated by haemopoietic stem cell transplantation (SCT) is showing a higher incidence of non-haematological malignancies in patients with FA than patients with other types of BM failure who underwent SCT, again emphasizing the predisposition to malignancy.

Cell and molecular biology

Cells from FA patients show an abnormally high frequency of spontaneous chromosomal breakage and hypersensitivity to the clastogenic effect of DNA cross-linking agents such as diepoxybutane (DEB) and mitomycin C (MMC). A laboratory test is available for FA. This is based on the increased chromosomal breakage seen in FA cells compared with normal control subjects after exposure to low concentrations of DEB or MMC ('DEB/MMC stress test') (Figure 12.2). Other features of the FA cell phenotype include abnormal cell cycle kinetics (prolonged G_2 phase), hypersensitivity to oxygen, increased apoptosis and accelerated telomere shortening.

There is considerable genetic heterogeneity in FA. Complementation analysis of somatic cell hybrids has provided evidence for eight complementation groups (FA-A, FA-B, FA-C, FA-D1, FA-D2, FA-E, FA-F and FA-G), suggesting that there are several FA genes. Table 12.4 shows the approximate prevalence of the different FA subgroups and shows that a large number of FA mutations have been identified. Thus, although it is now possible to undertake molecular analysis in FA patients (including the use of retroviral complementation with cloned FA cDNAs and immunoblots for FA proteins), the considerable molecular heterogeneity means that the DEB/MMC stress test remains the front-line diagnostic test.

Identification of the first five FA genes (*FANCA*, *FANCC*, *FANCE*, *FANCF* and *FANCG*) provided no immediate clues to their function as they showed no significant homology to each other or to other known genes in the databases. Subsequent studies have demonstrated that the FANCA, FANCC, FANCE, FANCF and FANCG proteins encoded by these genes interact with each other and are part of a larger nuclear complex. The

Table 12.4 FA complementation groups/genetic subtypes.

Complementation group/gene	Approximate percentage of FA patients	Chromosome location	Protein(amino acids)	Mutations identified
A (*FANCA*)	65–70	16q24.3	1455	> 120
B (*FANCB**)	< 2	?	?	?
C (*FANCC*)	5–10	9q22.3	558	10
D1 (*FANCD1**)	< 2	13q12–13	3417	9
D2 (*FANCD2*)	< 2	3p25.3	1451	5
E (*FANCE*)	2–5	6p21.3	536	3
F (*FANCF*)	< 2	11p15	374	6
G (*FANCG*)	10–15	9p13	622	21

*FANCD1, and possibly *FANCB*, were recently shown to be *BRCA2*.
The percentages of the different subgroups refer to the EUFAR (European Fanconi Anaemia Registry) data.

179

identification of the *FANCD2* gene provided an important link between the FA proteins and DNA repair. The nuclear complex containing the FA proteins (A/C/E/F/G) is required for the activation of the FANCD2 protein to a mono-ubiquitinated (a post-translational modification of a protein by the addition of a single ubiquitin molecule) isoform (FANCD2-Ub). In normal (non-FA) cells, FANCD2 is mono-ubiquitinated at lysine 561 in response to DNA damage (e.g. MMC) and is targeted to discrete nuclear foci.

Activated FANCD2 protein collocalizes and co-purifies with the breast cancer susceptibility protein, BRCA1, a protein that is important in many DNA damage-response pathways. These nuclear foci appear in cells after DNA damage and in those cells undergoing DNA replication. Proteins such as the recombination molecule RAD51, and those in the RAD50–NBS1–MRE11 DNA repair pathway are also present in BRCA1-containing foci (NBS1, complex Nijmegen breakage syndrome 1; MRE11, meiotic recombination 11). In cells from A, C, E, F or G patients, FANCD2 ubiquitination is not observed and it is not targeted to nuclear foci. ATM (ataxia telangiectasia mutated) can phosphorylate both FANCD2 and BRCA1. The ATM-dependent phosphorylation of FANCD2 (at serine 222) occurs in response to ionizing radiation. Therefore, this puts FANCD2 in a central position in signalling DNA damage; double-strand DNA breaks caused by ionizing radiation result in ATM-dependent phosphorylation of FANCD2 at serine 222, whereas interstrand DNA cross-links caused by MMC produce mono-ubiquitination of FANCD2 at lysine 561 via the FA nuclear complex.

Recently, it has been shown that cell lines derived from FA-D1 (and possibly FA-B) patients have biallelic mutations in *BRCA2*. This finding now links the cloned FA genes (*FANCA*, *FANCC*, *FANCD2*, *FANCE*, *FANCF*, *FANCG*) with *BRCA1* and *BRCA2* in a common pathway. BRCA2 protein is important in the repair of DNA damage by homologous recombination, in part by regulating the activity of RAD51. Cells lacking BRCA2 inaccurately repair damaged DNA and are hypersensitive to DNA cross-linking agents. These recent scientific developments therefore suggest that BRCA2 and other FA proteins cooperate in a common DNA damage response pathway, 'the FA/BRCA pathway'. A schematic representation of the FA/BRCA pathway is given in Figure 12.3. The precise functions of BRCA1 and BRCA2 in this pathway remain to be elucidated. It is also possible that the FA proteins have other functions in addition to their role in this pathway.

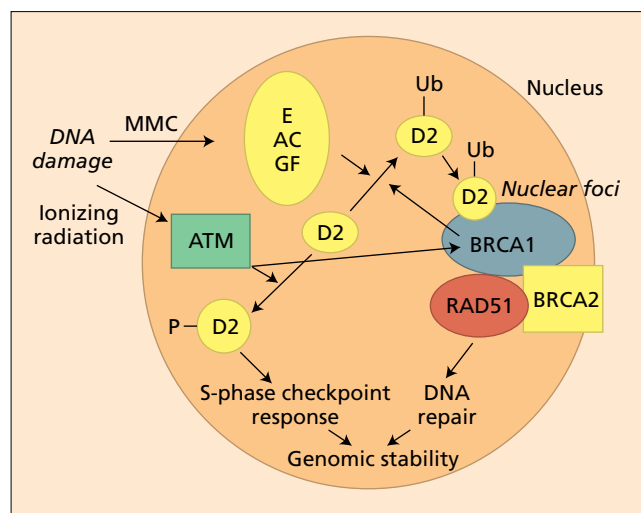
In vitro gene transfer studies have demonstrated that introduction of the appropriate wild-type FA gene into FA human lymphoid and haemopoietic cells markedly enhances their growth and normalizes their response to MMC; and in lymphoid lines, cell kinetics (G_2 phase) and chromosomal breakage are normalized. Thus, the transfer of the wild-type FA genes corrects the extreme sensitivity to DNA cross-linking agents, the hallmark of the FA cell phenotype. These studies provide the rationale for haemopoietic gene therapy (discussed below).


Figure 12.3 Schematic representation of the FA/BRCA pathway. In response to DNA damage (MMC) the FA protein complex (A/C/E/F/G complex) is formed and results in mono-ubiquitination of FANCD2 (D2). Mono-ubiquitination targets D2 to DNA repair nuclear foci containing BRCA1, BRCA2, and RAD51, which are important in maintaining genomic stability by promoting homologous recombination repair. D2 phosphorylation by ATM in response to DNA damage induced by ionizing radiation is important in S-phase checkpoint response.

Murine mouse models of FA have shown that haemopoietic progenitors are hypersensitive to tumour necrosis factor α (TNF-α) and interferon-γ. This differential hypersensitivity to interferon-γ is thought to be mediated by *fas*-induced apoptosis and may turn out to be an important mechanism in the development of progressive BM failure in FA. It is noteworthy that patients with idiopathic AA usually have raised interferon-γ levels, thus providing a possible link in the pathophysiology of BM failure in both idiopathic and FA-associated AA. The presence of short telomeres in cells from both FA and idiopathic AA patients can also be expected to be important in the pathophysiology of BM failure in both diseases. This issue is discussed further in relation to DC.

Treatment

The main cause of premature mortality in FA patients is the development of BM failure. Until the advent of haemopoietic SCT, treatment consisted largely of supportive care and attempts to stabilize and improve haemopoietic function by administrating androgens (oxymetholone) and corticosteroids (prednisolone). Although oxymetholone treatment can produce useful, trilineage responses in more than 50% of patients the majority will become refractory. Oxymetholone is associated with side-effects, including liver dysfunction and increased risk

of hepatic tumours. It is a very good holding treatment until more definitive treatment can be planned using haemopoietic SCT, which has now become the treatment of choice. From the *in vitro* and *in vivo* studies it has become clear that cells from FA patients are hypersensitive to agents such as cyclophosphamide and high-dose irradiation compared with non-FA patients. Therefore, SCT conditioning regimens have been modified by reducing the dose of cyclophosphamide and radiation. Using the low-dose cyclophosphamide (20 mg/kg) and 4.5–6 Gy of thoracoabdominal irradiation, the actuarial survival for patients transplanted using HLA-identical sibling donors is around 70% at 2 years. The results using unrelated donors have been less good, with 2-year survival between 20% and 40%. In order to improve these results, the role of conditioning protocols using fludarabine is being investigated. Additionally, long-term follow-up of patients who have survived after SCT shows a much higher incidence of malignancies, particularly of the head and neck, usually 8–10 years after the transplant. This in part relates to the inherent predisposition of FA patients to malignancy (which can perhaps now be explained given the link to BRCA1 and BRCA2) and in part to factors such as the use of radiotherapy in the conditioning. Some groups are therefore exploring low-dose cyclophosphamide (20–40 mg/kg) SCT protocols that avoid the use of radiotherapy. Preliminary results using fludarabine (120–150 mg/m^2) in association with low-dose cyclophosphamide are very encouraging for both sibling and unrelated stem cell transplants. Longer follow-up is necessary to determine if such protocols will be associated with a lower risk of malignancy.

In addition to SCT, alternative treatment strategies are being explored. The identification of the FA genes, combined with the *in vitro* gene transfer data that show that FA haemopoietic stem cells rescued by gene therapy should have a *selective growth advantage* within the hypoplastic BM environment, has resulted in clinical studies of retroviral-mediated gene therapy for FA patients. The pilot study on FA-C patients was associated with no serious side-effects but efficacy was limited. Further studies on this approach are needed.

The identification of FA *mosaic* patients strengthens the case for future trials of gene therapy. In such cases, the DEB/MMC test may be negative or only demonstrate chromosomal instability in a subgroup of cells. Somatic mosaicism is due to reversion of a pathogenic allele to 'wild' type in a single haemopoietic (somatic) cell. The mechanism of how this occurs can vary, but in each case it generates one 'normal' FA allele and the resulting cell effectively becomes a 'heterozygous cell', which would be expected to have a growth/survival advantage in the background of FA cells. These mosaic patients can have an improvement in their haematological profile, suggesting that a single pluripotent stem cell may be sufficient to restore adequate haemopoiesis. FA patients with somatic mosaicism can thus be regarded as having undergone 'natural haemopoietic gene therapy'.

Dyskeratosis congenita

Clinical features

Classical dyskeratosis congenita (DC) is an inherited disease characterized by the triad of abnormal skin pigmentation, nail dystrophy and mucosal leucoplakia (Figure 12.4). Since its first description in 1906 by Zinsser, a variety of non-cutaneous

Figure 12.4 Photographs of DC patients showing abnormal skin pigmentation (A, B, C), nail dystrophy (D, E) and leucoplakia of tongue (F).

Table 12.5 Somatic abnormalities in dyskeratosis congenita.

Abnormality	Percentage of patients
Abnormal skin pigmentation	89
Nail dystrophy	88
Bone marrow failure	85.5
Leucoplakia	78
Epiphora	30.5
Learning difficulties/developmental delay/mental retardation	25.4
Pulmonary disease	20.3
Short stature	19.5
Extensive dental caries/loss	16.9
Oesophageal stricture	16.9
Premature hair loss/greying/sparse eyelashes	16.1
Hyperhiderosis	15.3
Malignancy	9.8
Intrauterine growth retardation	7.6
Liver disease/peptic ulceration/enteropathy	7.3
Ataxia/cerebellar hypoplasia	6.8
Hypogonadism/undescended testes	5.9
Microcephaly	5.9
Urethral stricture/phimosis	5.1
Osteoporosis/aseptic necrosis/scoliosis	5.1
Deafness	0.8

(dental, gastrointestinal, genitourinary, neurological, ophthalmic, pulmonary and skeletal) abnormalities have also been reported (Table 12.5). BM failure is the principal cause of early mortality, with an additional predisposition to malignancy and fatal pulmonary complications. X-linked recessive, autosomal dominant and autosomal recessive forms of the disease are recognized. It is therefore now acknowledged that DC is a very heterogeneous disorder, both clinically and genetically.

Clinical manifestations in DC often appear during childhood. The skin pigmentation and nail changes typically appear first, usually by the age of 10 years. BM failure usually develops below the age of 20 years; 80–90% of patients will have developed BM abnormalities by the age of 30 years. In some cases, the BM abnormalities may appear before the mucocutaneous manifestations and the patients may be categorized to have 'idiopathic aplastic anaemia'. The main causes of death are BM failure/immunodeficiency (~60–70%), pulmonary complications (~10–15%) and malignancy (~10%).

Cell and molecular biology

DC has many features in common with FA, in which cells display hypersensitivity to clastogenic agents such as MMC. Although the occasional DC patient may show some evidence of chro-

mosome breakage, in general there is no significant difference in chromosomal breakage between DC and normal lymphocytes with or without the use of bleomycin, DEB, MMC and γ-irradiation. This observation enables DC patients to be distinguished from FA.

Primary DC skin fibroblasts are abnormal both in morphology and in growth rate. Furthermore, they show unbalanced chromosomal rearrangements (dicentrics, tricentrics, translocations) in the absence of any clastogenic agents. In addition, peripheral blood (PB) and BM metaphases from some patients show numerous unbalanced chromosomal rearrangements in the absence of any clastogenic agents. These studies provide evidence for a defect that predisposes DC cells to developing chromosomal rearrangements. DC, like FA, may thus be regarded as a chromosomal instability disorder but with a predisposition principally to chromosomal rearrangements rather than the gaps and breaks seen in FA.

Haemopoietic progenitor studies have shown reduced numbers of all progenitors compared with control subjects and there is usually a downward decline with time. The degree to which the progenitors are reduced can vary from patient to patient and they can be reduced even when the PB count is normal. The demonstration of abnormalities of growth and chromosomal rearrangements in fibroblasts suggests that the BM failure is likely to be a consequence of abnormalities in both haemopoietic stem cells and stromal cells.

X-chromosome inactivation patterns (XCIPs) have been studied in PB cells of women from X-linked DC families by investigating a methylation-sensitive restriction enzyme site in the polymorphic human androgen receptor locus (HUMARA) at Xq11.2–Xq12. All carriers of X-linked DC showed complete skewing in XCIP. The presence of the extremely skewed pattern of X-inactivation in PB cells suggests that cells expressing the defective gene have a growth/survival disadvantage over those expressing the normal allele. Furthermore, a skewed XCIP provides important information about carrier status for use in the counselling of families at risk of DC. In addition, XCIPs data allow us to distinguish an inherited mutation from a *de novo* event in sporadic male DC cases, as well as autosomal from X-linked forms of the disease.

The majority of DC patients recruited on the DCR (Dyskeratosis Congenita Registry, Hammersmith Hospital, London) are male. This observation suggests that the X-linked recessive form of DC represents a major subset of cases. Initially, through linkage analysis in one large family with only affected males, it was possible to map the gene for the X-linked form to Xq28. The availability of polymorphic genetic markers from the Xq28 and additional X-linked families facilitated positional cloning of the gene (*DKC1*) that is mutated in X-linked DC. The identification of the *DKC1* gene in 1998 made available a genetic test that can be used to confirm diagnosis in suspected cases and antenatal diagnosis in X-linked families. It also led to the demonstration that another rare syndrome, the Hoyeraal–

Hreidarsson (HH) syndrome, is due to mutations in the *DKC1* gene. HH is a severe multisystem disorder characterized by severe growth failure, abnormalities of brain development (usually cerebellar hypoplasia), aplastic anaemia and immunodeficiency (T$^+$ B$^-$ NK$^-$ severe combined immunodeficiency). The recognition that HH is a severe variant of DC has further highlighted the considerable variability of the DC phenotype.

In addition to providing an accurate diagnostic test, this genetic advance has provided insights into the pathogenesis of DC. The *DKC1* gene is expressed in all tissues of the body, indicating that it has a vital 'housekeeping function' in the human cell. This correlates well with the multisystem phenotype of DC. The *DKC1* gene and its encoded protein, dyskerin, are highly conserved throughout evolution. Dyskerin is a nucleolar protein that is associated with the H/ACA class of small nucleolar RNAs (snoRNAs) and is involved in pseudo-uridylation of specific residues of ribosomal RNA (rRNA). This step is essential for ribosome biogenesis and therefore initially suggested that DC arises largely because of defective ribosome biogenesis.

Subsequent studies have shown that dyskerin also associates with the RNA component of telomerase (hTR), which also contains an H/ACA consensus sequence. Telomerase is an enzyme complex that is important in maintaining the telomeres of chromosomes. The precise composition of the telomerase complex is unknown, but two essential components, the RNA component (hTR) and the catalytic reverse transcriptase (hTERT), have been well characterized. Telomerase activity can be reconstituted *in vitro* using just the hTR and hTERT. In patients with X-linked DC, it was initially demonstrated that the level of hTR was reduced and that telomere lengths were much shorter than in age-matched normal control subjects. Subsequently, it was found that telomeres are also shorter in cells from patients with autosomal forms of DC. This therefore suggested that DC might principally be a disease of telomere maintenance rather than of ribosomal biogenesis. Further clarification came from linkage analysis in one large DC family, which showed that the gene for autosomal dominant DC is on chromosome 3q, in the same area where the gene for *hTR* had been previously mapped. This led to *hTR* mutation analysis in this and other DC families and the demonstration that autosomal dominant DC is due to mutations in the *hTR* gene.
Figure 12.5 Putative associations between dyskerin and hTR (human telomerase RNA) in the telomerase complex. hTERT represents human telomerase reverse transcriptase. GAR1, NHP2 and NOP10 are ribo-nucleoproteins (RNPs) that are known to associate with dyskerin and the H/ACA class of small nucleolar RNAs (snoRNAs).

As the *DKC1*-encoded protein dyskerin and hTR are both components of the telomerase complex (Figure 12.5), it now appears that DC arises principally from an abnormality in telomerase activity. Affected tissues are those that need constant renewal, consistent with a basic deficiency in stem cell activity due to defective telomerase activity. The demonstration of *DKC1* and *hTR* mutations in DC families provides an accurate diagnostic test, including antenatal diagnosis, in a significant subset of cases (Table 12.6). For DC patients, this now also provides the basis for designing new treatments. For the wider community it provides the first direct genetic link between a human disease that is characterized by features of premature ageing (premature grey hair/hair loss, early dental loss, abnormalities of skin pigmentation, nail dystrophy, bone marrow failure,

Table 12.6 Dyskeratosis congenita genetic subtypes.

DC subtype	Approximate percentage of DC patients	Chromosome location	Gene product	Mutations identified
X-linked recessive	40	Xq28	Dyskerin	30
Autosomal dominant	5	3q21–3q28	hTR	6
Autosomal recessive*	50	?	?	?

*The genetic basis of this subtype is unknown and may represent more than one genetic locus.
Data are based on the DCR registry.

increased predisposition to malignancy) and short telomeres. Therefore, unravelling the biology of this rare disease has important implications not only for patients with DC but also for the more common disorders, such as ageing, cancer and AA, that are also associated with abnormal telomeres. It is noteworthy *that* hTR mutations have been identified recently in patients with AA but who lacked diagnostic features of DC. Furthermore, AA patients with *hTR* mutations had significantly shorter telomeres than age-matched control subjects. These data indicate that in a subset of patients with AA the disorder is associated with a genetic lesion in the telomere maintenance pathway. They also highlight the diverse manifestations of DC: its severe variant form as the HH syndrome, its classical form and its mildest form as ' aplastic anaemia'. The similarities between DC and AA are given in Table 12.2.

Treatment

As in FA, the anabolic steroid oxymetholone can produce an improvement in haemopoietic function in many (> 50%) patients for a variable period of time. Transient successful responses to granulocyte–macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF) and erythropoietin have also been reported. The use of oxymetholone and growth factors may be synergistic in some patients. The main treatment for severe BM failure, however, is allogeneic SCT, and there is some experience using both sibling and alternative stem cell donors. Unfortunately, because of early and late fatal pulmonary/vascular complications after SCT, the results of conventional transplants have been less successful than in FA. The presence of pulmonary disease in a significant proportion of DC patients perhaps now explains the high incidence of fatal pulmonary complications in the setting of SCT. It also highlights the need to avoid agents (such as busulphan and radiotherapy) that are associated with pulmonary toxicity. As BM failure is the main cause of premature death in DC patients and SCT is the only curative option for the BM failure at present, SCT should continue to be performed on carefully selected patients. Perhaps the best candidates for SCT are patients with no pre-existing pulmonary disease and who have sibling donors. SCT using fludarabine-based protocols that avoid radiotherapy and busulphan appears to be giving encouraging preliminary results.

DC is theoretically a good candidate for haemopoietic gene therapy. In any given patient, DC is a single-gene disorder and the cells that need to be targeted (haemopoietic stem cells) are accessible. Furthermore, there is evidence from fibroblast culture studies and from skewed XCIPs in X-linked DC carriers that cells transfected with the normal gene would have growth/survival advantage compared with the uncorrected cells. Such an advantage would also be predicted from the role of dyskerin and hTR in telomere maintenance.

Shwachman–Diamond syndrome

Clinical features

Shwachman and Bodian and their colleagues first reported this disease independently in 1964. It is now recognized as an autosomal recessive disorder characterized by exocrine pancreatic insufficiency (100%), bone marrow dysfunction (100%) and other somatic abnormalities (particularly involving the skeletal system). Signs of pancreatic insufficiency (malabsorption, failure to thrive) are apparent early in infancy (note that the pancreatic function can improve in a subset of Shwachman–Diamond syndrome (SDS) patients by 4 years of age). Other common somatic abnormalities include short stature (~70%), protuberant abdomen and an ichthyotic skin rash (~60%). Metaphyseal dysostosis is seen on radiographs in ~75% of patients. Other abnormalities include hepatomegaly, rib/thoracic cage abnormalities, hypertelorism, syndactyly, cleft palate, dental dysplasia, ptosis and skin pigmentation.

The spectrum of haematological abnormalities includes neutropenia (~60%), other cytopenias (approximately 20% have pancytopenia), myelodysplasia and leukaemic transformation (~25%). The age at which leukaemia develops varies widely from 1 to 43 years. Acute myeloid leukaemia is the commonest category and there is an unexplained preponderance of cases of leukaemia in males (M/F ratio = ~9:1).

Exocrine pancreatic insufficiency and haematological abnormalities are also seen in Pearson's syndrome (PS), and this is therefore an important differential diagnosis. In PS, the anaemia is usually more prominent than neutropenia and the marrow usually shows ringed sideroblasts along with vacuolation of myeloid and erythroid precursors. In addition, acidosis, abnormalities of liver function and mitochondrial DNA rearrangements are seen in PS. PS has a worse prognosis than SDS, with many patients dying before the age of 5 years from liver or marrow failure. Other differential diagnoses to be excluded are cartilage hair syndrome and cystic fibrosis.

The SDS gene (*SBDS*) on 7q11 was identified in 2003. The majority (> 90%) of SDS patients have been found to have mutations in this gene. Its precise function is unknown but, based on the function of its homologues, it is predicted to have an important role in RNA metabolism and/or ribosome biogenesis. Several abnormalities in SDS cells have been observed, including haemopoietic stem and stromal defects, increased rates of apoptosis and short telomeres. It will be now interesting to see how mutations in the *SBDS* gene lead to all these cell defects, the increased frequency of isochromosome 7q[i(7q)] and the clinical abnormalities characteristic of SDS. More immediately, this advance provides a genetic test that will facilitate diagnosis in difficult cases. It will also enable researchers to determine the role of the *SBDS* gene in AA, myelodysplastic syndrome (MDS) and leukaemia in general.

Treatment

The malabsorption in SDS responds to treatment with oral pancreatic enzymes. For those with neutropenia, G-CSF may produce an improvement in the neutrophil count. Some patients with anaemia and/or thrombocytopenia may achieve haematological responses with oxymetholone treatment. As in other cases of bone marrow failure, supportive treatment with red cell and platelet transfusions and antibiotics is very important. The main causes of death are infection or bleeding.

Recent analysis of SDS patients has showed that the incidence of myelodysplasia and transformation to acute myeloid leukaemia (~15–25%) is higher than reported previously. The development of leukaemia, often with features of myelodysplasia, usually has a poor prognosis. SDS patients with leukaemia treated with conventional courses of chemotherapy usually fail to regenerate normal haemopoiesis. As this is a constitutional disorder all somatic cells, including haemopoietic stem cells, are abnormal. In addition, the haemopoietic stem cells may have accumulated secondary abnormalities as suggested by complex karyotypes (especially involving chromosome 7) often observed in the BM from such patients. Therefore, for those who develop leukaemia the only approach likely to be successful is allogeneic SCT, perhaps in the future using low-intensity conditioning regimens that include fludarabine. The similarities between SDS and the other common inherited bone marrow failure syndromes emphasize that SDS should be regarded as a disorder with high propensity to develop both AA and leukaemic transformation, particularly acute myeloid leukaemia with erythroid differentiation (AML-M6). As these complications may not develop until adult life, it is important to continue close haematological follow-up throughout life.

Diamond–Blackfan anaemia

Clinical features

Red cell aplasia was first reported in 1936 by Josephs. In 1938, Diamond reported on four children with hypoplastic anaemia, and this has now come to be recognized as Diamond–Blackfan anaemia (DBA) or congenital pure red cell aplasia. DBA usually presents in early infancy, with symptoms of anaemia such as pallor or failure to thrive. The hallmark of classical DBA is a selective decrease in erythroid precursors and normochromic macrocytic anaemia associated with a variable number of somatic abnormalities such as craniofacial, thumb, cardiac and urogenital malformations. Hitherto the diagnostic criteria for DBA have been (i) normochromic, usually macrocytic, but occasionally normocytic anaemia developing in early childhood; (ii) reticulocytopenia; (iii) normocellular BM with selective deficiency of erythroid precursors (erythroblasts < 5%); (iv) normal or slightly decreased leucocyte counts; and (v) normal or often increased platelet counts.

There is considerable heterogeneity in the associated somatic abnormalities, pattern of inheritance and response to therapy. Analysis of 350 cases recruited to the DBA Registry of North America (DBAR) has confirmed previous findings as well as highlighting new features. The annual incidence of DBA is ~5 per million live births. The median age at presentation was 8 weeks and 93% of patients presented in the first year of life. In total, 82% were initially responsive to steroids, 16% were non-responsive and 1.6% were never treated with steroids; 36% of patients were receiving transfusions at analysis. The actuarial survival rates at older than 40 years were 100% for those in sustained remission, 88% for steroid-maintained patients and 58% for transfusion-dependent patients. The 23 deaths reported to the registry included severe AA (1), infections (4), complications of iron overload (2), vascular access-related death (1), malignancy (6) and transplant-related toxicity (9).

In the DBAR, 7% of families had more than one affected individual. Most of the familial cases displayed autosomal dominant pattern of inheritance. Somatic anomalies, excluding short stature, were found in 47% of patients. Of these, 50% were of the face and head (high-arched palate, cleft lip, hypertelorism and flat nasal bridge), 38% were upper limb and hand (flat thenar eminence, triphalangeal thumb), 39% genitourinary and 30% cardiac. Height was below the third centile for age in ~30%.

MDS and AML have been reported in a few patients with DBA, suggesting an increased predisposition to haematological malignancies. There are also cases that have evolved into AA; neutropenia and thrombocytopenia are relatively common after the first decade. Giri and colleagues (2000) reported on moderate to severe BM hypocellularity in 21 out of 28 (75%) patients with steroid-refractory DBA; marrow hypoplasia correlated with the development of neutropenia (9 out of 21; 43%) and/or thrombocytopenia (6 out of 21; 29%). Furthermore, using *in vitro* long-term culture-initiating cell (LTC-IC) assay, they provided evidence for a trilineage haemopoietic defect in patients with refractory DBA. Thus, although DBA has been regarded classically as a pure red cell aplasia, a more global haemopoietic defect is likely to be present, and this may be seen more frequently in the future as patients are surviving longer due to improved medical care.

Cell and molecular biology

The classical haematological profile in DBA patients consists of normochromic macrocytic anaemia, reticulocytopenia and a normocellular marrow with selective deficiency of red cell precursors. A number of different defects of *in vitro* erythroid progenitor proliferation, differentiation and cytokine responsiveness

have been reported but have not clarified the mechanism of *in vivo* erythroid failure. For many years, based on the typical selective deficiency in red cell precursors, many researchers believed that DBA is due to an intrinsic problem with erythroid proliferation/differentiation. On the other hand, the observation of a wide range of somatic abnormalities in a significant proportion of patients and case reports of thrombocytopenia, neutropenia and AA, together with the recent evidence for a trilineage haemopoietic defect, suggest that the primary problem in DBA is not confined to the erythroid lineage.

The establishment of DBA registries, recent advances in genetics and the identification of a female with a balanced X;19 translocation has facilitated a change in research strategy in DBA. Genetic mapping studies localized a gene responsible for DBA to a 1-Mb region on 19q13 on the basis of (i) the identification of a *de novo* balanced reciprocal X;19 translocation breakpoint in a girl with DBA; (ii) linkage analysis in multiplex DBA families; and (iii) *de novo* microdeletions associated with the disease. Cloning of the chromosome 19q13 breakpoint demonstrated that this breakpoint interrupts the gene (*RPS19*) encoding ribosomal protein S19. The subsequent finding of *RPS19* mutations in 10 out of 40 unrelated DBA patients provided good evidence for the primary role of this gene in the pathogenesis of DBA in approximately 25% of DBA cases.

Further analysis of 172 DBA families (190 patients) by the DBA Working Group of the European Society of Paediatric Haematology and Immunology (ESPHI) has demonstrated heterozygosity for mutations affecting the *RPS19* gene in 42 out of 172 index patients (24.4%), thus confirming the genetic heterogeneity of DBA. Interestingly, mutations in the *RPS19* gene were also found in some apparently unaffected individuals from DBA families presenting only with an isolated elevation of erythrocyte adenosine deaminase activity (eADA). The lack of a genotype–phenotype correlation implies that other factors modulate the phenotypic expression of the primary genetic defect in families with *RPS19* mutations.

Further linkage analysis in DBA families has identified a second DBA locus on chromosome 8p23.2–23.1 to which ~40% of DBA families map; however, a significant proportion of families map to neither the locus on chromosome 8 nor the locus on chromosome 19. This suggests that there are likely to be at least three DBA genes.

The *RPS19* gene shows a ubiquitous expression profile and encodes a 145-amino-acid protein with a predicted molecular weight of 16 kDa. This protein has significant homologies with proteins from diverse species. It is one of many ribosomal proteins that constitute a major component of cellular proteins, but their functions, apart from being part of the ribosome, are unknown.

The demonstration of *RPS19* mutations in ~25% of DBA families now makes it possible to confirm the diagnosis in a subset of DBA patients. This is useful when counselling families. However, the observed poor genotype–phenotype correlations means that predictions about prognosis are not easy. Functional assays would be useful and may become available in the future. Furthermore, identification of the other DBA genes may now follow more rapidly.

Treatment

The first line of treatment for DBA remains corticosteroids. Once a maximal Hb response has been achieved, the dose of prednisolone should be tapered slowly until the patient is on the lowest dose possible on an alternate-day regimen. The dose required to achieve this can vary considerably from patient to patient. For those patients who fail to respond or become refractory to steroids, blood transfusion is the mainstay of treatment. As in thalassaemia, the major complication from transfusions is iron overload, and chelation of iron with desferrioxamine should therefore be commenced as soon as patients have increased iron stores. Splenectomy may be indicated in the event of an increased transfusion requirement secondary to hypersplenism. For patients who are transfusion dependent and who have a compatible sibling donor, haemopoietic SCT may be appropriate and is potentially curative. A recent pilot study reported on haematological response in three out of nine patients who were treated with metoclopramide. This observation suggests an alternative therapy for steroid-resistant patients. It also suggests a role for prolactin in erythropoiesis as metoclopramide is known to release prolactin from the pituitary.

Congenital and cyclical neutropenias

Congenital neutropenia is a heterogeneous disorder. It includes Kostmann's syndrome, which was first described in 1954. Although the original description by Kostmann was of an autosomal recessive disorder, other congenital neutropenia subtypes (both sporadic and autosomal dominant) have been included subsequently in this category. The neutropenia is usually recognized at birth and the neutrophil count is often $< 0.2 \times 10^9$/L. The Hb and platelet count are usually normal and the bone marrow shows a 'promyelocyte maturation arrest' with abundant promyelocytes but with a selective reduction in myelocytes, metamyelocytes and neutrophils.

The neutropenias are associated with severe infections and early death. No patient has developed AA but myeloid leukaemias (~10%) can occur. The availability of G-CSF has revolutionized the outcome of these children and probably has no aetological role in the evolution to leukaemia. However, somatic mutations in the gene that encodes the G-CSF receptor have been documented during the evolution to leukaemia in some neutropenic patients receiving G-CSF. For patients who become refractory to G-CSF or who develop leukaemia, SCT may be appropriate and curative.

Table 12.7 Laboratory tests useful in the investigation of patients with bone marrow failure.

Test		Diagnostic value
Peripheral blood		
Fetal haemoglobin		High level suggestive of generalized BM failure
DEB/MMC-chromosomal breakage		Increased in FA
Mutation analysis of specific genes	*FANCA to FANCG*	Mutated in FA
	DKC1 and *hTR*	Mutated in X-linked and autosomal dominant DC
	SBDS	Mutated in SDS
	RPS19	Mutated in ~25% of DBA
	ELA2	Mutated in congenital and cyclic neutropenia
	c-mpl	Mutated in CAMT
Mitochondrial DNA analysis		Deletions seen in Pearson syndrome
X-Chromosome inactivation patterns		Skewed in carriers of X-linked DC
Ham's (CD59 analysis)		Abnormal in paroxysmal nocturnal haemoglobinuria
Telomere length		Short in AA patients including DC, FA, SDS
Constitutional karyotype		Abnormality suggestive of constitutional AA
Other investigations		
To identify somatic abnormalities	Skeletal survey	Presence of somatic abnormalities in association
	Ultrasound of abdomen	with AA is suggestive of constitutional AA
	Pulmonary function tests	
	Echocardiogram	
Exocrine pancreatic function		Abnormal in SDS and PS
Neutrophil chemotaxis		Abnormal in SDS
Fibroblast cultures		Abnormalities seen in DC

Cyclical neutropenia is characterized by a neutrophil count that usually reaches a nadir with a 21-day periodicity. Around the nadir, patients may develop fever and mouth ulcers. In cyclical neutropenia, the pattern of inheritance is usually autosomal dominant. Linkage analysis in affected families resulted in the localization of the disease to 19p13.3. Subsequent studies identified mutations in the gene encoding neutrophil elastase (*ELA2*). An extraordinary twist to the story was the identification of *ELA2* mutations also in many patients with congenital neutropenia. In cyclical neutropenia, the mutations are usually clustered around the active site of the molecule, whereas the opposite face of the molecule tends to be mutated in congenital neutropenia patients. Neutrophil elastase is a serine protease that is synthesized predominantly at the promyelocytic stage and can be expected to be important in neutrophil development. Further studies are needed to understand the precise mechanism of how *ELA2* mutations result in neutropenia and to identify the genetic defects in other congenital neutropenic patients who lack *ELA2* mutations.

Thrombocytopenia with absent radii

Thrombocytopenia with absent radii (TAR) is an autosomal recessive disorder characterized by hypomegakaryocytic thrombocytopenia and bilateral radial aplasia. Babies with TAR often have haemorrhagic manifestations at birth when the diagnosis is usually made, owing to the characteristic physical appearance combined with thrombocytopenia. Additional skeletal (absent ulnae, absent humeri, clinodactyly) and other somatic (microcephaly, hypertelorism, strabismus, heart defects) abnormalities may be seen in some patients.

The platelet count is usually below 50×10^9/L. The leucocyte count can be normal or raised, sometimes up to 100×10^9/L ('leukaemoid reaction'). BM cellularity is normal and myeloid and erythroid lineages are normal or increased. Megakaryocytes are absent or decreased. Most patients bleed in infancy and then improve after the first year. The mainstay of management is prophylactic and therapeutic use of platelet transfusions. TAR patients have a very good prognosis after infancy. There have been no reports of AA or leukaemia.

The pathophysiology of TAR is unknown. Thrombopoietin levels are usually elevated and thrombopoietin receptor expression on the surface of TAR platelets is normal. Therefore, defective megakaryocytopoiesis/thrombocytopoiesis does not appear to be caused by a defect in thrombopoietin production. There is some evidence that it may be due to a lack of response to thrombopoietin in the signal transduction pathway of the thrombopoietin receptor (*c-mpl*).

Congenital amegakaryocytic thrombocytopenia

Congenital amegakaryocytic thrombocytopenia (CAMT) is a rare disorder that usually presents in infancy and is characterized by isolated thrombocytopenia and reduction/absence of megakaryocytes in the bone marrow, usually with no somatic abnormalities. It is genetically heterogeneous with autosomal recessive and X-linked subtypes. Approximately 50% of patients will develop AA usually by the age of 5 years. For patients with severe thrombocytopenia or AA, the treatment of choice is SCT if a compatible donor is available.

In a subgroup of CAMT patients, mutations in the gene encoding for the thrombopoietin receptor (c-Mpl) have been identified. As patients with c-*mpl* mutations can also have abnormalities in the leucocyte count, Hb level and CNS abnormalities (e.g. cerebral and cerebellar hypoplasia), this study highlights the important role of the c-Mpl receptor in haemopoiesis in general and in CNS development. It also substantiates the genetic heterogeneity of CAMT.

Conclusion

Since the identification of the first FA gene (*FANCC*) in 1992, there have been significant advances in our understanding of FA, DC and other BM failure syndromes. This is already facilitating diagnosis, as highlighted in Table 12.7. It can be anticipated that a further understanding of the pathophysiology of these disorders is likely to lead to a better knowledge of normal haemopoiesis and how this becomes defective in many patients presenting with the more common forms of aplastic anaemia. Indeed, recent studies have already established a link between DC and AA and, in turn, to defective telomerase. These advances also suggest that new treatment strategies, based on correction of the primary defect in each syndrome, may now emerge.

Acquired aplastic anaemia, other acquired bone marrow failure disorders and dyserythropoiesis

13

Edward C Gordon-Smith and Judith CW Marsh

Introduction – bone marrow failure

Bone marrow failure implies that peripheral blood cytopenia has arisen primarily as a result of a specific failure of bone marrow precursor cells to produce mature cells, rather than the production of abnormal cells that have a shortened survival or the production of normal cells that are subjected to an abnormal environment. In bone marrow failure, the remaining cells in the marrow appear morphologically normal, or near normal, reflecting only minor changes produced by 'marrow stress', including a mild increase in dyserythropoietic forms, often with some macrocytosis of red cells. The stroma of the marrow does not appear to be disturbed. These observations distinguish the true marrow failures from myelodysplastic and myeloproliferative syndromes.

There are two major groups of bone marrow failure: the aplastic anaemias, in which the failure lies in the pluripotent stem cell, and the single-cell cytopenias, in which the failure lies in one of the committed cell lines. There is overlap between these groups, for single-cell failure may occasionally progress to total marrow failure, and, following partial recovery, aplastic anaemia may continue with a prolonged period of single-cell deficiency. It is convenient to consider the two groups separately.

Aplastic anaemias

Aplastic anaemia is defined as the presence of pancytopenia in the peripheral blood and a hypocellular marrow in which normal haemopoietic marrow is replaced by fat cells. The diagnosis of aplastic anaemia requires at least two of the following in addition to a hypocellular marrow: (i) haemoglobin < 10 g/dL; (ii) platelet count $< 100 \times 10^9$/L; and (iii) neutrophil count < 1.5 $\times 10^9$/L. Abnormal cells are not found in either the peripheral blood or the bone marrow. The diagnosis is based on the absence of cells, not the presence of any characteristic feature.

There are a variety of ways in which this haematological pattern can be produced, as indicated in Table 13.1. Distinguishing between these forms of aplastic anaemia is a matter of awareness, careful observation of haematological material, particularly the granulocyte and megakaryocyte morphology, history and physical examination.

Inevitable aplastic anaemia

Most cytotoxic drugs, penetrating ionizing radiation and radioactive substances concentrated in the marrow are capable of producing aplastic anaemia through their effects on actively dividing cells. The timing and duration of the aplasia and the order in which cell lines recover depend to some extent on the nature of the cytotoxic agent and the dose. Recovery is usual, with the exception of marrow rendered aplastic by whole-body irradiation given in a critical dose that destroys the haemopoietic system without killing the patient from additional toxicity. Although, in general, the development and recovery of aplasia following exposure to cytotoxic drugs are predictable, there are exceptions. Repeated or prolonged exposure to small doses of alkylating agents, particularly busulphan, may lead to a prolonged and unpredictable aplasia, even when given for myeloproliferative disorders such as chronic myeloid leukaemia, essential thrombocythaemia or myelofibrosis.

Table 13.1 The aplastic anaemias.

Aetiology	Examples	Clinical course
Inevitable	Ionizing radiation Cytotoxic drugs	Predictable Recovery usual
Idiosyncratic	Idiopathic Drug induced Viral Commercial solvents	Prolonged Unpredictable recovery Clonal evolution
Inherited	Fanconi anaemia Dyskeratosis congenita Others	Usually progressive Increased malignancy
Industrial	Benzene	Dose dependent Proliferative disorders more common
Immune	Drug induced Viruses (e.g. Epstein–Barr virus) Systemic lupus erythematosus	Usually recovers spontaneously or with treatment of primary disorder
Malignant	Acute lymphoblastic leukaemia Hypoplastic acute myeloid leukaemia Hypoplastic myelodysplastic syndrome	Usually but not exclusively in children

Idiosyncratic acquired aplastic anaemia

Acquired aplastic anaemia may occur spontaneously or appear following exposure to drugs or viruses that do not produce marrow failure in the great majority of persons exposed to these agents. The disease is characterized by its unpredictable onset and prolonged course, death usually occurring as a result of a deficiency of granulocytes or platelets and a failure in support measures.

Incidence

In Western countries, the incidence is about 2–3 per million of the population per year. Higher figures given in the past were probably the result of including cases of pancytopenia that were not aplastic by strict criteria but included cases of myelodysplasia. In the East, the incidence appears to be 5- to 10-fold higher, the reason apparently lying in the environment rather than in genetic factors, as people who move from the East to the West have the same incidence as the local population.

Aetiology

In about one-third of the patients with acquired aplastic anaemia, suspicion may be directed to a particular agent, usually a drug, chemical or virus. Thus, in at least two-thirds of patients, no aetiological agent can be identified (idiopathic aplastic anaemia).

Drugs

The list of drugs recorded as 'causing' aplastic anaemia is long, but mostly only a single or a few cases have been reported for each drug, and it is not profitable to detail them all because the

evidence against many of these drugs is slim. Some of the more commonly implicated drugs are listed in Table 13.2. A difficulty in determining the role of drug exposure to the development of aplastic anaemia is the delay between exposure to the drug and the identification of marrow damage. Typically, there is a delay of 2–3 months between first exposure and the onset of pancytopenia. This delay may be longer, although an exposure that took place for a short period 6 months to a year previously weakens the association, and exposure more than 1 year earlier makes the association unlikely.

Perhaps most attention has been given to chloramphenicol. It is estimated that somewhere between 1:25 000 and 1:40 000 people exposed to oral chloramphenicol will develop aplastic anaemia. The evidence is purely epidemiological, as there are no tests to demonstrate that chloramphenicol is responsible for aplastic anaemia in any particular case The aplasia is unpredictable and prolonged. Chloramphenicol also causes a dose-dependent suppression of haemopoiesis, particularly affecting erythropoiesis, through its action on mitochondrial DNA, but this suppression is not related to the development of prolonged aplastic anaemia. The majority of patients who develop aplastic anaemia following chloramphenicol have been on standard therapeutic doses and received the drug for an appropriate length of time. Some of the early reports concerned patients who had received prolonged treatment. Subsequently, reports appeared of only patients who had been exposed to the drug for 1 day, giving credence to the idea that this adverse reaction was not dose dependent. There have been only 24 reported cases of aplastic anaemia following exposure to chloramphenicol eye

Table 13.2 Drugs associated with idiosyncratic acquired aplastic anaemia.

Class	Examples
Antibiotics	Chloramphenicol
	Sulphonamides
	Cotrimoxazole
Antimalarials	Chloroquine
Anti-inflammatories	Phenylbutazone
	Indomethacin
	Naproxen
	Diclofenac
	Ibuprofen
	Piroxicam
Antirheumatics	Gold salts
	D-Penicillamine
Antithyroids	Carbimazole
	Methylthiouracil
	Propylthiouracil
Psychotropic/antidepressants	Phenothiazines
	Mianserin
	Dothiepin
Anticonvulsants	Carbamazepine
	Phenytoin
Antidiabetics	Chlorpropamide
Carbonic anhydrase inhibitors	Acetazolamide

drops in the 45 years since the drug was first introduced, which suggests that the association is no greater than background and that eye drops are not a hazard.

Sulphonamides have also been thought to cause aplastic anaemia, and there are several reports of aplasia following cotrimoxazole administration. Again, it is difficult to be sure of the strength of the association, especially as the antibiotics may be given for an infection that is the first marker of an undetected marrow dyscrasia. The association of co-trimoxazole with neutropenia and aplastic anaemia may not be due to the sulphonamide moiety, as trimethoprim alone has a similar adverse event profile.

A few case reports have appeared associated with other antibiotics, but there is no clear evidence that this is not a chance association in most instances. Most are more likely to produce single cytopenias, mainly through antibody-mediated peripheral destruction.

Non-steroidal anti-inflammatory drugs (NSAIDs) have been incriminated in causing aplastic anaemia. The pyrazalone derivatives, phenylbutazone and oxyphenbutazone, have the highest incidence of aplasia in this group, but the indole derivatives,

indomethacin and sulindac, have both been reported in association with aplastic anaemia. Other NSAIDs that have been linked to the cause of aplastic anaemia are listed in Table 13.2. It seems possible that the development of aplastic anaemia in response to NSAIDs is, at least in some respects, a class effect in that there have been cases of relapse of aplastic anaemia, which followed exposure to one NSAID when the patient was subsequently given another, chemically unrelated NSAID. This group of drugs illustrates well the difficulties in establishing causal relationships with aplastic anaemia. They are widely used by patients with an underlying disease that may have an autoimmune basis (e.g. rheumatoid arthritis) and who might have an increased risk of developing blood dyscrasias as a result of their disease.

Gold salts deserve a special mention. Neutropenia and eosinophilia are common with their use. Gold-induced autoimmune thrombocytopenia may also occur; the autoantibody targets platelet glycoprotein V. Persistence with gold injections in the face of a falling neutrophil count may lead to aplasia or aplasia may appear without warning. Gold salts are one of the few drugs for which careful monitoring of blood counts may prevent the development of aplasia. Gold may be removed from the body by chelation with dimercaprol (British anti-Lewisite, BAL), which is usually given by intramuscular injection, which makes it difficult to administer to patients with aplastic anaemia. There is no evidence that removal of gold in this way accelerates recovery, and it is possible to detect gold in the marrow of patients who have recovered from gold-induced aplasia more than 1 year after recovery.

Aminosalicylates are used in the management of ulcerative colitis and rheumatoid arthritis. Sulphasalazine (Salazopyrin®) has long been known to be associated with blood dyscrasias, including aplastic anaemia. It was thought that the haemopoietic toxicity was due to the sulphonamide moiety, but cases of aplastic anaemia following exposure to mesalazine (5-aminosalicylic acid) and osalazine have also been reported.

Industrial and domestic chemicals have also been implicated. Solvents have long been linked to aplastic anaemia. Benzene is a myelotoxin. Exposure to sufficient levels leads inevitably to marrow damage but there seems to be wide variation between individuals in the dose required, and it is doubtful whether it produces aplasia of the idiosyncratic variety (see below). Insecticides, in particular lindane (γ-hexachlorocyclohexane), pentachlorophenols and DDT, have each been debated in this regard. Self-reported house treatment for woodworm has recently been strongly associated with risk of aplastic anaemia, along with exposure to radiation in the workplace.

Viruses

Hepatitis, presumably of viral origin, is a precursor of aplastic anaemia in about 5–10% of cases in the West; it is perhaps double that in the Far East. In the majority of patients, no specific hepatitis virus can be identified and the association is based on clinical grounds and the presence of abnormal liver

function tests. In most cases, no identifiable virus is found, although occasionally it occurs following hepatitis A, B or C or Epstein–Barr virus infection. The delay between the clinical hepatitis and the onset of pancytopenia is of the order of 2–3 months, a similar period to that between drug exposure and aplasia. Further evidence to support the association is a finding that 28% of patients who underwent orthotopic liver transplantation for fulminant liver failure following viral hepatitis developed aplastic anaemia, whereas patients transplanted for other reasons had no marrow failure. A recent study from the European Blood and Marrow Transplantation (EBMT) Severe Aplastic Anaemia Working Party has shown that the outcome of treatment of post-hepatitic aplastic anaemia compared with idiopathic aplastic anaemia is similar whether treated with bone marrow transplantation or immunosuppressive therapy.

Parvovirus B19 infection in non-immune individuals may lead to a transient pure red cell aplasia of clinical importance to people with haemolytic anaemia (see below). The virus specifically infects the erythroid burst-forming units (BFU-E) and is not associated with true aplastic anaemia.

Epstein–Barr virus infection is commonly accompanied by neutropenia or thrombocytopenia, probably of an immune origin. Rarely, there may be true marrow aplasia, which behaves like other cases of acquired disease, although within this group there are some patients who have transient aplasia with spontaneous recovery in 4–6 weeks. Human immunodeficiency virus (HIV) is often accompanied by cytopenias; pancytopenia with a hypocellular marrow occurs in some cases.

Other causes of aplastic anaemia

Aplastic anaemia may occasionally occur in association with systemic autoimmune disorders such as systemic lupus erythematosus (SLE). As well as producing a hypocellular bone marrow, SLE may also be associated with a truly autoimmune pancytopenia with a cellular bone marrow. Aplastic anaemia can present in pregnancy, although this may be due to chance, and other possible causes listed above should also be sought. The disease may remit spontaneously after termination, whether spontaneous or therapeutic, and after delivery, but not in all cases, and much support may be needed. Aplastic anaemia often progresses during pregnancy, but not always.

Pathogenesis

The pathogenesis of aplastic anaemia remains unclear, but an autoimmune mechanism appears to be important. There may also be an as yet unidentified underlying genetic predisposition. There is some association of human leucocyte antigen (HLA) DR2, specifically the DR15 split, with acquired aplastic anaemia. There is debate about whether the primary defect is in the haemopoietic stem cell itself or is the result of environmental factors, particularly immunological attack, on the cell. There is evidence of both quantitative and qualitative stem cell defects in aplastic anaemia and increased apoptosis of remaining early haemopoietic progenitor cells. Not only do cytotoxic suppressor T lymphocytes release cytokines, such as interferon-γ and tumour necrosis factor α (TNF-α), that are inhibitory to haemopoietic progenitor cells, but TNF-α also upregulates Fas antigen expression on CD34$^+$ cells, which may be one of the possible mechanisms for the reduced survival of aplastic anaemia marrow progenitor cells. However, the most persuasive evidence for the autoimmune pathogenesis for aplastic anaemia remains the clinical response to antilymphocyte globulin (ALG) in about two-thirds of patients.

Telomere shortening

Prolonged survival of patients with aplastic anaemia has provided the opportunity to study the effects of increased proliferative demand on remaining stem cells over time, both during the aplastic phase and following remission. Somatic cells show progressive shortening of the terminal restriction fragments (TRFs) of chromosomes with age. Haemopoietic stem cells show this age-related shortening as measured in the TRF length of their progeny, the circulating leucocytes. The telomere length is determined by the number of divisions that a cell undergoes, modified by the capacity of the enzyme telomerase to replace the fragments. Patients with acquired aplastic anaemia show increased TRF loss in leucocytes compared with age-matched control subjects, and the extent of the loss correlates with the duration of disease. In patients who make a full haemopoietic recovery, the rate of TRF loss returns to normal for ageing. Telomeres, which are complex structures located at the ends of eukaryotic chromosomes, have a role in preventing aberrant recombination at the chromosome ends. It is at least theoretically plausible that the accelerated TRF loss in aplastic anaemia provides the background for the increased risk of transformation to myelodysplastic syndrome (MDS) or acute leukaemia with cytogenetic anomalies.

In the inherited disorder dyskeratosis congenital, in which aplastic anaemia usually develops in the second or third decade, the underlying genetic defects affect the telomerase complex, which has both RNA and protein components. In the X-linked form of the disease there are mutations in the gene *DKC1*, which codes for the protein dyskerin. In the autosomal dominant form there is a mutation that leads to a large deletion in telomerase RNA. Stem cells from patients with both types have markedly short telomeres. Although the phenomenon of telomere shortening is different in acquired AA compared with age-matched control subjects, it is intriguing to speculate that perturbation in telomere turnover might be related to the pathogenesis of bone marrow failure in both types.

Haematology

The peripheral blood film shows pancytopenia without gross morphological abnormalities in the circulating cells. There may be some macrocytosis of remaining red cells, usually with an absolute reticulocytopenia. A relative reticulocytosis should

always raise the possibility of associated paroxysmal nocturnal haemoglobinuria (PNH). Granulocytes often show increased staining of granules, the so-called toxic granulation of neutropenia. Monocytes are usually reduced in proportion to the granulocytes. Platelets are reduced and of small and uniform size. There is a variable reduction in the lymphocyte count between individuals; the count is sometimes normal or even increased so that the total white cell count is normal or near normal but, more commonly, the lymphocyte count is reduced. Abnormal cells are not seen. The bone marrow aspirate is normally easily obtained, typically with many fragments, which appear hypocellular (Figure 13.1a). The cell trails are hypocellular, with a relative increase in lymphocytes and plasma cells and other non-haemopoietic forms. Remaining haemopoietic precursors are normal in appearance.

In the early stages of aplastic anaemia, haemophagocytosis may be prominent. In a high proportion of cases, the hypocellularity of the marrow is patchy, with quite extensive areas of cellular marrow remaining. The bone marrow aspirate may, under these circumstances, be misleadingly cellular. A trephine biopsy (sometimes more than one) is necessary to assess cellularity properly.

The bone marrow trephine shows the fat replacement of marrow with or without the remaining islands of cellularity (Figure 13.1b and c). Non-haemopoietic cells remain, sometimes giving the impression of a chronic inflammatory infiltrate. Reticulin is not increased. The most common mistake in the diagnosis of aplastic anaemia is to make the diagnosis on the basis of a bone marrow aspirate in the presence of pancytopenia without obtaining adequate trephine specimen. Other conditions that can also present with pancytopenia and a hypocellular bone marrow include hypocellular myelodysplastic syndrome, hypocellular acute myeloid leukaemia, hypocellular acute lymphoblastic leukaemia, hairy cell leukaemia, lymphoma, myelofibrosis, mycobacterial infections and anorexia nervosa or prolonged starvation, emphasizing the importance of careful examination of not only the bone marrow but also a well-stained peripheral blood film.

Cytogenetic analysis of the bone marrow should be performed, although it is often difficult to obtain sufficient metaphases in a very hypocellular bone marrow. Abnormal cytogenetic clones occur in up to 11% of patients with otherwise typical aplastic anaemia, and their presence does not necessarily indicate a diagnosis of myelodysplastic syndrome. The most frequently observed abnormalities include trisomy 8, trisomy 6, 5q– and anomalies of chromosomes 7 and 13. Often the abnormal clone is small, constituting only a small proportion of total metaphases, and not infrequently it may be transient and disappear spontaneously or after haematological response to immunosuppressive therapy.

Peripheral blood lymphocytes should also be examined cytogenetically in all patients under the age of 35 years for spontaneous and di-epoxybutane (or mitomycin C)-induced increase

in chromosome breakages and aberrations characteristic of Fanconi anaemia, an inherited from of aplastic anaemia (see Chapter 12).

Paroxysmal nocturnal haemoglobinuria (PNH) should be excluded by performing a Ham test and/or flow cytometry. Analysis of phosphatidylinositol glycan (PIG)-anchored proteins such as CD55 and CD59 by flow cytometry is the much more sensitive test for PNH. Small PNH clones occur in around 25% of patients with aplastic anaemia, but the clinical significance of a small PNH clone is uncertain. Such clones can remain stable, diminish in size, disappear or increase. What is clinically important is the presence of a significant PNH clone with clinical or laboratory evidence of haemolysis, which will be detected by the Ham test. Urine should also be examined for haemosiderin to exclude intravascular haemolysis, which is a constant feature of haemolytic PNH. Evidence of haemolysis associated with PNH should be quantified with the reticulocyte count, serum bilirubin, serum transaminases and lactate dehydrogenase (see Chapter 11).

Special tests may be of interest in the diagnosis and prognosis of aplastic anaemia. Short-term clonogenic cultures of bone marrow show a uniform reduction in aplastic anaemia in both committed and multipotent progenitor cells. The more primitive long-term culture initiating cells are markedly reduced or absent. Stroma from aplastic marrow may be difficult to grow to confluence *in vitro*, but aplastic stroma is able to support haemopoiesis from normal stem cells but normal stroma is unable to reverse the defect in colony formation from AA stem cells.

Clinical presentation

The clinical features derive from the decrease in peripheral blood cells and are non-specific. The patient may be feeling completely well at the time when easy bruising or petechiae appear or may have a more or less prolonged period of feeling tired from anaemia. Sometimes infection is the presenting feature, but this is less common in idiosyncratic aplastic anaemia than bleeding manifestations. The spleen, liver and lymph nodes are not enlarged and jaundice is only a feature in those patients with post-hepatitis aplasia who have a prolonged cholestatic phase after the infection.

At presentation, it is necessary to take a detailed drug, occupational and symptomatic history to try to establish any aetiological agent so that this may be avoided in the future. Unfortunately, this is not always easy. It is difficult to dissuade someone who may have been exposed to industrial chemicals, for example, to give up work on the possibility that the chemicals just might be involved in the cause of the disease.

Clinical course

The clinical course is modified by the transfusion support and antibiotic therapy that the patient receives. There are some events that may interrupt the clinical course, apart from the catastrophes associated with the low platelet count and neu-

Table 13.3 Definition of disease severity of aplastic anaemia (AA).

Severe AA	BM cellularity < 25%, or 25–50% with < 30% residual haemopoietic cells
	Two out of three of the following: neutrophils < 0.5×10^9/L, platelets < 20×10^9/L, reticulocytes < 20×10^9/L
Very severe AA	As for severe AA but neutrophils < 0.2×10^9/L
Non-severe AA	Patients not fulfilling the criteria for severe or very severe AA
	With a hypocellular marrow, with two out of three of the following: neutrophils < 1.5×10^9/L, platelets < 100×10^9/L, haemoglobin < 10 g/dL

tropenia. The proliferative capacity of the marrow is greatly reduced, but the marrow also appears to be unstable in that abnormal clones of cells, PNH, myelodysplasia or leukaemia, may appear during the disease, sometimes all three in the same individual. In patients who have a remission or partial response, about 25–40% will develop a clonal disorder or relapse within 5–10 years, although this is not necessarily associated with a poor prognosis. The degree of aplasia may vary. In an attempt to categorize aplastic anaemia according to its severity and prognosis, Camitta and colleagues devised a system for scoring the disease in individual patients into severe aplastic anaemia (SAA) and non-severe aplastic anaemia (NSAA). Subsequently, as support and treatment improved, a third category of very severe aplastic anaemia (VSAA) was added (Table 13.3). One of the most important attributes of this scoring system is the ability it gives to compare different treatments for similar degrees of severity at all ages.

The initial assessment will characterize the severity of the condition at that time but will not indicate the course in a particular patient. SAA or VSAA tends not to improve without definitive treatment. NSAA may remain stable or slowly worsen with time, even without the development of abnormal clones.

Treatment

The treatment of aplastic anaemia depends first on providing total support for the patient while awaiting bone marrow recovery and, second, on attempts to accelerate that recovery. It should be emphasized that support and encouragement may be required for months or years before some sort of remission occurs and that disappointment and anxiety bedevil the management of aplastic anaemia. Patients, relatives and staff all need help in maintaining morale.

Support for the aplastic anaemia patient

This consists of providing blood product support and protecting patients from infection by isolating them from sources of

infection as far as possible and in the use of antibiotics, both prophylactic and therapeutic.

Blood product support is mainly with packed red cells and platelet transfusions, to maintain a safe blood count. Patients are usually transfused with packed cells as required; in non-bleeding patients this is about 1 unit per week, given as three or four units every 3 or 4 weeks. Prophylactic platelet transfusions should be given when the platelet count is $< 10 \times 10^9$/L (or $< 20 \times 10^9$/L in the presence of fever), rather than giving platelets only in response to bleeding. Prediction of bleeding is difficult in an individual patient. Fatal haemorrhage, usually cerebral, is more common in patients who have $< 10 \times 10^9$/L platelets, retinal haemorrhages, buccal haemorrhages or rapidly spreading purpura. However, cerebral haemorrhage may be the first major bleed in patients who have none of these other bleeding manifestations. A proportion of patients will become sensitized to platelet transfusions if random donors are used. Those who are sensitized will have to receive HLA-matched platelets. Family members should be avoided unless bone marrow transplantation has been ruled out as treatment. Platelets given twice per week are usually sufficient to prevent bleeding.

Antibiotics may be used prophylactically, particularly in patients with severe neutropenia ($< 0.2 \times 10^9$/L). These patients may acquire infection from the gastrointestinal tract (particularly aerobic pathogens) or from the upper respiratory passages. Good mouth care with chlorhexidine mouthwash is of benefit. Patients should be in reverse-barrier isolation while in hospital. Measures to decrease potential intestinal pathogens include the use of non-absorbable antibiotics and antifungal agents, and the provision of low-bacterial food. When fever or signs of infection develop, fevers should be treated immediately in severely neutropenic patients, that is, with the prompt administration of broad-spectrum intravenous antibiotics, particularly those active against Gram-negative organisms. Treatment should be started after taking appropriate samples for microbiology but before the results are available. The antibiotics should be continued until at least 72 h of normal temperature has been achieved, but, unfortunately, in the severely neutropenic patient, infection is rarely eradicated and all too frequently fever returns after stopping the therapy.

Staphylococcus epidermidis is a common cause of bacteraemia in patients who have a central line in place. If fever in the neutropenic patient does not resolve within 24 h, vancomycin or teicoplanin (or other antibiotic active against *S. epidermidis*) should be added to the Gram-negative antibiotic regimen. Failure of the fever to resolve after this in the absence of a positive blood culture suggests the possibility of a fungal infection and intravenous amphotericin should be added early to the regimen. Granulocyte colony-stimulating factor (G-CSF) may raise the neutrophil count and improve their function, and may have a role to play in the eradication of infection in aplastic patients, although no formal trials have been conducted. G-CSF tends to have the weakest effect in the most severely aplastic patients.

Restoration of marrow activity

Spontaneous remission of aplastic anaemia may occur, but this may not happen for several months or even years and the majority of patients with SAA die from the complications of neutropenia or thrombocytopenia before this can occur. Bone marrow transplantation is a therapeutic option open to younger patients who have an HLA-matched sibling donor and is discussed in detail below.

Immunosuppressive therapy

Immunosuppressive therapy with ALG and/or cyclosporin has proved to be effective in increasing the remission rate in aplastic anaemia. There is no role for the use of corticosteroids in the treatment of aplastic anaemia, other than a short course when used with ALG to help prevent serum sickness. Coticosteroids are ineffective in the treatment of aplastic anaemia; they encourage bacterial and fungal colonization and can precipitate serious gastrointestinal haemorrhage in the presence of severe thrombocytopenia.

Antilymphocyte globulin

The use of ALG in the treatment of aplastic anaemia was pioneered by George Mathé and his colleagues in Paris in the 1960s and developed by Bruno Speck in Basle. The benefit of ALG in promoting marrow recovery in aplastic anaemia was later confirmed in randomized trials conducted in the USA.

Preparations. Antilymphocyte globulin is available from a number of commercial companies. The antihuman lymphocyte globulin is raised either in horses or in rabbits. A variety of immunogens are used in the preparation of the spectrum of polyclonal antibodies, which make up the various preparations of ALG. In many preparations, the immunogen is a thymocyte-derived cell line or thymocytes obtained from thymuses removed during cardiac surgery in children. These preparations are usually called antithymocyte globulin (ATG). The main combinations used in the preparation of ALG or ATG and the range of antibodies obtained are shown in Table 13.4. During preparation, unwanted antihuman antibodies are removed by absorption with specific tissues, but most preparations still have some antiplatelet activity. Although, clearly, there is not biological equivalence between preparations, no proper comparative studies have been carried out to identify essential characteristics or antibody components. Most preparations have been developed for the prevention of graft rejection in cardiac or renal transplants, but it is not evident that the same antibody profile is needed for the treatment of aplastic anaemia.

Administration. Antilymphocyte globulin is a highly immunosuppressive drug. It should be prescribed only by physicians familiar with using the drug. It must be given only as an inpatient therapy, and patients should be nursed in isolation facilities with reverse-barrier nursing. Prophylactic antibiotics

Table 13.4 Antilymphocyte (ALG) and antithymocyte globulin (ATG) preparations. Variations in animal origin, immunogens and antibody content.

Animal	Immunogens used	Range of antibodies from different preparations
Horse	Lymphocytes	CD3 (< 0.03–0.58)
	Thymocytes	CD5 (0–12.2)
	Lymphocytes + thymocytes	CD11a (3.15–20.3)
	T lymphoblasts	CD18 (18.7–269)
	B lymphoblasts	CD45 (0.16–4.01)
		β_2-Microglobulin (0.8–12.5)

and antifungal therapy should be used routinely. It is sclerosing to veins and should be given through a central line. A test dose of the preparation should be given before starting the full dosage, to test for anaphylaxis. A test dose (10 mg in 100 mL of saline) intravenously over half an hour must be given beforehand. Providing that the patient does not show evidence of anaphylaxis to the test dose, the full dose may be administered, starting on the same day as the test dose. Because of the anti-platelet activity of ALG, platelets should be given before and after the infusion, although not during the administration of the ALG. The full dose is given over 12–18 h.

Reactions are common. Fever, rigors, rashes, hypotension or hypertension are usual on the first day of treatment but become less troublesome as the therapy continues. These effects can usually be ameliorated by slowing the rate of infusion and giving corticosteroids, antihistamine (e.g. Piriton®) and pethidine. Although the test should exclude patients with anaphylaxis, pulmonary haemorrhage and capillary leak have been seen occasionally during the first day of administration of the full dose.

The treatment schedule is by no means established on the basis of clinical trials. The original European trials used administration of ALG daily for 5 days. This is the most widely followed regimen, but other schedules have been described, so far without any clear superiority over the 5-day course. The dosage varies from preparation to preparation, and the instructions of the manufacturers should be followed.

Serum sickness. Serum sickness occurs in about three-quarters of the patients given ALG. Some 7–10 days after its administration, fever, rash and severe joint pains may appear. Proteinuria may be seen, but frank renal failure has not yet been reported. The syndrome is self-limiting, but symptoms may respond to corticosteroids, requiring high doses for about 7 days. Prophylactic prednisolone (1 mg/kg per day) should be given to
help prevent or ameliorate serum sickness. Ideally, patients should be kept under observation as an inpatient until the risk of serum sickness is over; this is usually 2–3 weeks from the start of ALG treatment.

Response. Response to ALG is delayed, with improvement in marrow function rarely being seen before 6 weeks. Approximately 50% of patients respond by 3 months and up to 67% by 6 months (Figure 13.2). Patients with severe aplastic anaemia respond less well than non-severe patients, particularly if the neutrophil count is $< 0.2 \times 10^9$/L. Age does not seem to be a factor in response.

Further treatment. If there is no response to ALG after 4–6 months, a second course may be tried, either rabbit ATG if horse ALG has been used in the first instance, or a second course of horse ALG. In responding patients, the marrow does not usually return entirely to normal and some degree of cytopenia may persist for several years, although the patient may not require transfusion support.

Relapse occurs in 25–40% of responders over 10 years. Relapse does not always indicate a return to transfusion dependence but may herald the development of PNH, myelodysplastic

syndrome or acute myeloid leukaemia (AML). Even when a stable recovery has been observed, patients treated with immunosuppression should be followed regularly for many years with screening for PNH and cytogenetic studies.

Cyclosporin

Cyclosporin has been used both with ALG and alone in the treatment of aplastic anaemia. When used immediately following ALG, cyclosporin accelerates recovery in blood counts without significantly improving overall survival. However, the combination of cyclosporin with ALG results in improved failure-free survival, meaning that fewer patients require a second course of ALG for non-response or relapse, compared with ALG alone, and the combination delays the onset of relapse after ALG. A significant proportion of patients are dependent on continued cyclosporin long-term after ALG. For patients with NSAA, the use of cyclosporin alone is associated with a significantly lower response rate and failure-free survival than the combination of ALG and cyclosporin. Nevertheless, cyclosporin may be used on its own if there are contraindications to using ALG in a particular patient. An appropriate starting dose of cyclosporin is 5 mg/kg per day in divided doses, the dose being adjusted according to blood pressure, renal function tests and blood levels of the drug.

Haemopoietic growth factors

Circulating levels of haemopoietic growth factors are markedly elevated in most patients with aplastic anaemia. They should not be used on their own in newly diagnosed patients in the mistaken belief that they may cure the disease. G-CSF will raise the neutrophil count in patients with aplastic anaemia, although the smallest benefit is seen in those with the most severely affected marrow. One study from Europe showed that G-CSF given after a course of ALG and cyclosporin appears to reduce the risk of severe infections after ALG, but does not improve the response rate and survival. Other growth factors, including erythropoietin, granulocyte–macrophage colony-stimulating factor (GM-CSF), interleukin 3 (IL-3), IL-6 and stem cell factor have proved to be largely ineffective and/or toxic to patients with aplastic anaemia. Trials with thrombopoietin in aplastic anaemia have not been reported, but it is not yet known whether it will be effective in the presence of already high plasma levels of the growth factor in aplastic anaemia, and there is potential concern about the development of anti-thrombopoietin antibodies.

Androgens

Historically androgens, or anabolic steroids, were the first specific form of therapy used in aplastic anaemia. They have a temporary benefit in the management of Fanconi anaemia and appeared to be effective in some cases of acquired aplastic anaemia, with some patients being androgen dependent. A European trial demonstrated that the addition of oxymetholone to ALG resulted in improved response compared with ALG alone, although their use has diminished since the introduction of cyclosporin to immunosuppressive protocols for treatment of aplastic anaemia. The androgens are usually given in high doses (for example, oxymetholone 2.5 mg/kg per day), starting after the period of serum sickness. Side-effects include virilization (and so are often unacceptable to female patients), prostatic enlargement, salt retention and hepatotoxicity, including the development of peliosis hepatitis and/or hepatocellular carcinoma after prolonged usage. If there is no response after 6 months, the androgens should be stopped. If there is a response, androgens should be slowly reduced, first to an alternate day therapy and then increasing the interval between doses.

Other treatments

The use of high-dose cyclophosphamide without stem cell support has been advocated as an alternative treatment for aplastic anaemia on account of its highly immunosuppressive qualities and the observation that autologous haematological recovery may occur following graft rejection after allogeneic bone marrow transplantation (BMT) in aplastic anaemia patients. Its use in this manner is generally not recommended, however, because of the perhaps predictably prolonged delayed neutrophil and platelet recovery and high risk of serious infective, particularly fungal, infections that are often fatal when the drug is administered at high doses without stem cell support. Furthermore, its use does not prevent the later onset of clonal disorders such as PNH or myelodysplasia. Mycophenolate mofetil is an immunosuppressive drug that inhibits proliferation of B and T lymphocytes and has been used in refractory aplastic anaemia in a recent European pilot study but found to be ineffective.

Allogeneic bone marrow transplantation for severe aplastic anaemia

Allogeneic bone marrow transplantation (BMT) for aplastic anaemia was first introduced by E Donnall Thomas and Rainer Storb and colleagues in 1969. BMT or peripheral blood stem cell (PBSC) transfusion is the treatment of choice for young patients with SAA who have an HLA-identical sibling donor. The age at which transplantation is no longer the treatment of choice depends upon the severity of the disease, the general health of the patient and the nature of the presenting symptoms. The results of BMT collected by the European Blood and Marrow Transplant Registry (EBMTR) are shown in Figure 13.3. Overall survival is around 75–90%. There is a marked age effect, most notably with poor outcome for patient over the age of 40 years compared with younger patients. BMT has a better long-term survival than immunosuppressive treatment once the graft is firmly established and the patient is off immunosuppressive treatment. Patients are not at increased risk of later clonal disorders following a successful transplant. This has to be weighed against the increased risk of transplant-related mortality in the early post-transplant period and the poor quality of life if
Figure 13.3 Survival following HLA-matched sibling donor stem cell transplantation. Data from EBMTR SAA working party, showing effect of age on outcome (with permission). The groups are not strictly similar, the oldest age group being transplanted significantly later than the youngest.

the patient develops chronic graft-versus-host disease (GvHD) Early and late graft failure occur in 10–15% of patients. For patients over the age of 40 years, transplantation using a 'low-intensity' conditioning regimen may be reserved for those who fail to respond to ALG and have an HLA-identical sibling donor.

Bone marrow is the preferred source of stem cells rather than G-CSF-mobilized PBSCs due to a worse survival and higher incidence of chronic GvHD with PBSC. At least 3×10^8/kg of body weight of the recipient nucleated marrow cells (3×10^6 CD34+ cells) should be given; a lower stem cell dose increases the risk of graft failure.

The main causes of failure of BMT for aplastic anaemia are graft failure and post-graft infections. Patients with aplastic anaemia are immunocompetent apart from the neutropenia and indeed may be immunostimulated by infections and blood transfusions. Infection may be present before the transplant and become unmanageable afterwards. Chronic GvHD occurs in about 25% of successful transplants. Improvements in survival since 1969 may be attributed mainly to a reduction in graft failure and better support for the patient.

Conditioning for bone marrow transplantation

The most widely used regimen includes cyclophosphamide alone. High-dose irradiation was too toxic and low-dose total body or total lymphoid irradiation, although reducing the risks of rejection, did not improve overall survival. More recent schedules include ALG or Campath-1H with cyclophosphamide or low cyclophosphamide with fludarabine.

Cyclophosphamide

Cyclophosphamide, at a dose of 50 mg/kg per day intravenously for 4 days, has been used alone in the immunosuppression of patients with aplastic anaemia, although the rejection rate with this regimen is high unless additional post-graft immunosuppression is given, especially in multiply transfused patients (see below).

Cyclophosphamide is given intravenously, usually in 250–500 mL of saline over 0.5–1.0 h. Side-effects include nausea and vomiting (usually relatively mild), haemorrhagic cystitis, cardiomyopathy, fluid retention and alopecia. The haemorrhagic cystitis may be prevented or greatly modified by giving mesna (2-mercapto-ethane sulphonate) intravenously to neutralize the effects of metabolites of cyclophosphamide in the urine. Mesna (40% of the daily cyclophosphamide dose) is given intravenously 30 min before each cyclophosphamide infusion and the same dose is given at 3, 6, 9, 12, 16 and 20 h after each cyclophosphamide dose. This regimen is repeated on each day that the cyclophosphamide is given and the day after the last dose. The cardiotoxicity of cyclophosphamide is not usually a problem at the doses quoted unless there is already cardiac damage. Late haemorrhagic cystitis (after 20 days) may occur in transplant patients but is usually caused by virus infections (particularly adenovirus) rather than cyclophosphamide.

Antilymphocyte globulin

Additional immunosuppression is given with cyclophosphamide to help reduce graft failure. It is given daily on the first 4 days of cyclophosphamide.

For patients over the age of 40 years, in whom HLA identical sibling BMT is being considered, a 'mini' or reduced-intensity conditioning regimen is now recommended, similar to that for matched unrelated donor BMT (see later).

Irradiation

There is now no role for the use of irradiation in BMT for aplastic anaemia. Total body irradiation (TBI) or total lymphoid irradiation (TLI) were previously used in an attempt to reduce graft failure because of their immunosuppressive properties. Their use did reduce graft failure but at the expense of increasing GvHD, interstitial pneumonitis and the later risk of solid tumours, as well as developmental delay and sterility.

Cyclosporin

Cyclosporin was introduced into BMT regimens for aplastic anaemia both to reduce graft failure and to minimize GvHD. Results of BMT for aplastic anaemia have improved considerably since its introduction, mainly because of the reduction in graft failure. It was recognized early in the use of cyclosporin that graft failure may follow if the drug is stopped early and it is usual to continue cyclosporin for a year post transplantation for aplastic anaemia. The dose is adjusted to keep the blood level between 250 and 300 µg/L.

Methotrexate

Methotrexate is added to cyclosporin to reduce GvHD at a dose of 10 mg/m^2 intravenously on day 1, then 8 mg/m^2 on days 3, 6 and 11. There is an increase in mucositis and liver toxicity with this drug.

Results of allogeneic transplant

Figure 13.3 shows the survival of patients who received allogeneic BMT for severe aplastic anaemia. Patients who have successful transplants without chronic GvHD have a good quality of life. Children grow normally and have normal endocrine function. Males and females remain fertile and there seems to be no increased risk of congenital abnormalities or miscarriages compared with the normal population. Fertility returns rapidly after the transplant and patients may become pregnant within 3 months while still on cyclosporin. They should be warned of this possibility, although it should be noted that cyclosporin is not teratogenic. Chronic GvHD is the main problem in long-term follow-up, with about 25% of patients being affected.

There are two main types of graft failure seen in aplastic anaemia transplantation. Primary failure is probably related to the disease in that these patients never show any evidence of engraftment. No neutrophils or reticulocytes are seen in the peripheral blood post graft. These patients have a poor outlook and second transplants are usually unsuccessful. Secondary failure occurs after some evidence of engraftment and is probably a true immunological rejection event, although it should be remembered that reactivation of cytomegalovirus infection will also lead to a fall in blood counts. Autologous recovery may still take place, providing that the patient is kept fully supported. Second transplants from the same or another sibling donor have a success rate of about 25%.

Bone marrow transplantation from donors other than HLA-matched siblings

BMT from unrelated volunteer donors and mismatched family donors has been carried out for severe aplastic anaemia. Until fairly recently, the major problems encountered have been increases in graft failure, GvHD and infection. The overall survival in collected series was very poor, with only about 30% disease free survival (Figure 13.4). Better survival has been reported over the last few years, probably due to better matching using DNA high-resolution HLA typing and avoiding any degree of mis-match and improved conditioning regimens as well as improved supportive care. The EBMT has recently proposed a low-intensity conditioning regimen of cyclophosphamide 300 mg/m^2 for 4 days, fludarabine 30 mg/m^2 for 4 days and ALG for 4 days, with cyclosporin starting earlier on day −6 instead of day −1, along with methotrexate.

Benzene-induced aplastic anaemia

Benzene is a carcinogen. Chronic exposure to benzene used as a
Figure 13.4 Survival following stem cell transplant from matched unrelated volunteer donors, showing improved outcome with time. Data from the EBMTR SAA working party (with permission). These results were obtained with full dose conditioning.

solvent produces pancytopenia associated with a hyperplastic or dysplastic marrow, which may later become leukaemic or, more rarely, be associated with aplastic anaemia. In China, the incidence of aplastic anaemia in workers chronically exposed to high concentrations of benzene has been reported as 9 cases out of 74 828 that were exposed. Benzene has been used experimentally to produce aplastic anaemia in rabbits. Benzene itself is now rarely used as a solvent, having been replaced by non-aromatic organic solvents, but it is still encountered in the petroleum industry and benzene derivatives are ubiquitous in occupations such as photographic development. However, the evidence that these compounds produce aplastic anaemia at the very low concentrations permitted by industrial safety guidelines (1 p.p.m.) is lacking, although there is some evidence that low doses (10 p.p.m.) may have an effect on erythropoiesis.

Malignant aplastic anaemia

Acute leukaemia

Acute lymphoblastic leukaemia (ALL) may present as aplastic anaemia, particularly, although not exclusively, in childhood. The aplasia is not distinguishable from true aplastic anaemia on haematological grounds, but there are some clinical observations which raise the possibility that the aplasia is a prodrome of ALL. Fever and documented infection are more common presentations than in aplastic anaemia. The platelets tend to be relatively better preserved than neutrophils compared with acquired aplasia. The spleen is frequently enlarged, although it may be only just palpable or evident only on ultrasound. The

aplasia usually lasts 3–6 weeks, when spontaneous or corticosteroid induced 'remission' occurs. The ALL usually follows after a period of apparently normal haemopoiesis, often 1–3 months after recovery. The phenotype of the ALL does not differ from primary ALL and the prognosis is not affected.

AML may present in a similar way to ALL in childhood, with a period of aplasia, but this is much less common. Rarely, AML may present with a relatively stable degree of aplasia, which may persist for several months before the blood becomes frankly leukaemic. In these patients, suspicion may be aroused by finding occasional circulating blasts in the peripheral blood or in a buffy coat preparation, by a low neutrophil alkaline phosphatase, and by the presence of an excess of myeloblasts in the cells remaining in the bone marrow. It is important to be aware of this possibility in the differential diagnosis of aplastic anaemia because these patients are probably best treated by early bone marrow transplantation when an HLA identical sibling donor is available, using TBI and some additional chemotherapy. Patients without a donor may be supported with blood transfusion until they become frankly leukaemic. Attempts to produce remission are often, but not always, unsuccessful because the aplastic marrow remains aplastic.

Hypoplastic myelodysplastic syndrome

Some patients with MDS may present with a hypoplastic marrow. The remaining haemopoietic cells usually show the changes of MDS with hypogranular neutrophils and micromegakaryocytes, and there may be an increase in reticulin in the bone marrow. Dyserythropoiesis is not a useful feature to confirm MDS as it is also a common feature in aplastic anaemia. Cytogenetic analysis of the bone marrow may reveal abnormalities more suggestive of MDS, such as monosomy 7, but cytogenetic abnormalities can occur in around 11% of patients with otherwise typical aplastic anaemia. There have been some therapeutic studies that suggest that ALG (ATG) may be effective in producing at least partial remission in hypoplastic MDS and possibly in refractory anaemias.

Single lineage acquired bone marrow failure syndromes

Acquired pure red cell aplasia

Failure of erythropoiesis may be inherited or acquired (Table 13.5). The acquired disorder may be primary or secondary and may be transient or chronic. Whatever the cause, pure red cell aplasia (PRCA) is characterized by anaemia and reticulocytopenia, with reduction of red cell precursors in the marrow. The marrow usually shows a complete absence of red cell precursors, but some forms of either the inherited or acquired disease may be associated with the absence of the late forms of erythropoietic precursors: a picture of maturation arrest. Granulocyte and megakaryocyte series are normal or increased.

Failure of erythropoiesis may occur as a primary acquired event or may be associated with other disorders. The condition presents as anaemia with reticulocytopenia and bone marrow with either a total lack of erythrocyte precursors or a maturation arrest with a lack of late erythroid precursors.

Primary acquired pure red cell aplasia

The majority of patients with this rare condition are aged between 20 and 50 years. They have the symptoms of a slowly progressive anaemia. There are no additional physical findings. The Coombs' test may be weakly positive but it is not normally possible to demonstrate a humoral inhibitor to erythropoiesis in the peripheral blood or cellular inhibition in the marrow. The bone marrow is cellular, with an absence of red cell precursors. In some, there is an increase in reticulin. It is important to exclude other causes of red cell aplasia (see below).

Secondary acquired pure red cell aplasia

Pure red cell aplasia is a well known association with thymoma. About 5% of thymomas are associated with PRCA and about 10–20% of patients with PRCA have a thymoma. The majority of tumours show spindle cell morphology but some are

Table 13.5 Clinical classification of pure red cell aplasia.

Congenital	*Diamond–Blackfan anaemia*

		Hypogammaglobulinaemia
		Drugs: azathioprine, isoniazid, phenytoin, rHuEPO
		Hepatitis, Epstein–Barr virus, parvovirus
		Others: major ABO mis-match BMT, pregnancy

lymphomas. The tumour may usually be diagnosed on plain radiography but tomography or computerized tomography scanning may be required. There may be associated abnormalities of other systems linked to the thymoma, for example myasthenia gravis. The response to thymectomy is unpredictable. About one-half of the patients respond to surgery but some relapse later. Some patients develop PRCA only after removal of the thymoma and some show no response. For patients who fail to respond to thymectomy, immunosuppressive treatment is used (see below).

Pure red cell aplasia may be associated with a variety of lymphoid disorders including B- and T-cell lymphomas and particularly T-large granular lymphocytosis. The main conditions are shown in Table 13.5. The PRCA may precede the appearance of the lymphoma but the latter may be identified in some patients at the time of diagnosis of the PRCA by immunoglobulin or T-cell receptor gene rearrangement studies. The anaemia usually, but not always, responds to treatment of the lymphoma.

Pure red cell aplasia is associated with a number of autoimmune disorders. There may be a positive direct antiglobulin test (DAT) that indicates the nature of the aplasia. It occurs in patients with agammaglobulinaemia, and may also be associated with systemic lupus erythematosus, Sjögren's syndrome or rheumatoid arthritis. The majority of these anaemias will respond to treatment with corticosteroids, with or without azathioprine. The response may be steroid-dependent or there may be a relapsing and remitting course.

A long list of drugs have been incriminated in the aetiology of PRCA, but the association is very rare and mostly there is only a single case for each drug. Exceptions are azathioprine, phenytoin, procainamide and isoniazid, for which several cases each have been reported. More recently, recombinant human erythropoietin (rHuEpo), when used predominantly in chronic renal failure patients, has been reported to cause PRCA associated with anti-erythropoietin antibodies, resulting in a sudden and severe anaemia that is unresponsive to increased dose of rHuEpo. In this situation the rHuEpo must be discontinued immediately and regular blood transfusional support given; immunosuppressive therapy may be required for the PRCA.

Treatment of acquired pure red cell aplasia
Any drugs that have been implicated in pure red cell aplasia being given to the patient should be discontinued. Prednisolone is the initial treatment of choice at a dose of 1 mg/kg daily for 4 weeks. If response occurs, the dose is slowly tapered and discontinued. For non-responders, remission may be induced by azathioprine, or cyclosporin with or without ALG, and there have been anecdotal reports of response with cyclophosphamide and vincristine. There is increasing interest in the use of monoclonal antibody therapy with, for example, Campath-1H (anti-CD52) or rituximab (anti-CD20) in the treatment of refractory PRCA and other autoimmune cytopenias.

Transient red cell aplasias

Parvovirus B19 aplastic crisis
Infection with parvovirus 19, the wild-type human virus, produces the syndrome of fifth disease (fever, rash, arthralgia) in non-immune subjects. B19 specifically infects and lyses erythroid precursor cells. The cellular receptor is the blood group P antigen, globoside, which is expressed on some colony-forming unit erythroid (CFU-E) and all pro-erythroblasts and subsequent erythroid cells. Viral DNA can be identified not only in serum but also in bone marrow erythroid precursors by *in situ* PCR, as well as in proliferating CFU-E. Erythropoiesis virtually ceases for the duration of acute infection, which is some 5–10 days. This is unimportant in patients who have a normal red cell survival but produces an acute, and sometimes life-threatening fall in haemoglobin in patients with haemolytic anaemia. Recovery begins with the emergence of immunoglobulin M (IgM) antibodies to the virus. At this time, the marrow may contain giant pro-erythroblasts with marked vacuolation. Immunosuppressed patients or those with immunodeficiency may develop prolonged PRCA and patients with PRCA should be checked for IgG antibodies to the virus. Absence of the antibody raises the possibility of parvovirus-induced PRCA, which can be confirmed by PCR for viral DNA.

Transient erythroblastopenia of childhood
This syndrome is characterized in children by the development of normocytic, normochromic anaemia with reticulocytopenia and absent erythroid precursors in the marrow. There is nearly always a prodromal viral illness. The red cell aplasia lasts a few weeks and recovers spontaneously. There are no associated physical anomalies. The differential diagnosis is from Diamond–Blackfan anaemia.

Amegakaryocytic thrombocytopenias

Thrombocytopenia with absent megakaryocytes may be congenital or acquired. Acquired amegakaryocytic thrombocytopenia may develop at any age and result in a prolonged thrombocytopenia. The condition may remain stable for many years or may progress to total aplasia, a myelodysplastic syndrome or AML. The marrow in the early stages is normo- or hypercellular, with absent megakaryocytes. Treatment is supportive, although isolated case reports have suggested an improvement with ALG or cyclosporin.

Dyserythropoiesis

Dyserythropoiesis is caused by defects in erythropoiesis, which lead to the production of abnormal erythroid cells; some of these cells are destroyed within the marrow during maturation, whereas those that reach maturity and enter the circulation may show morphological abnormalities and are liable to have

a shortened lifespan. Conditions that may be referred to as dyserythropoiesis include a wide range of diseases that primarily affect either the nucleus or the cytoplasm. Examples affecting the nucleus are cobalamin and folate deficiencies (see Chapter 4), where there is a defect in DNA production due to enzymatic abnormalities in the pathways of pyrimidine and purine synthesis.

Disorders that primarily involve cytoplasm include disturbances in haemoglobin production that may be due to impaired availability of any component of the haemoglobin molecule. The most common cause is iron deficiency. When there is an adequate amount of iron available but it is not utilized, sideroblastic anaemia may occur: there is failure of mitochondrial synthesis of protophorphyrin with accumulation of iron within the mitochondria, which is seen as ring sideroblasts (see Chapter 3). Impairment in globin synthesis results in thalassaemic syndromes. It is apparent that dyserythropoiesis is a very common phenomenon and is associated primarily or secondarily with a large number of different diseases that seem to have little in common with each other to justify their inclusion in a single category. The term is, however, a useful one, as it suggests an important aspect of the pathogenesis of the anaemias, and indicates the fact that there is an inter-relationship of the various aspects of the erythropoietic mechanism, whereby a defect at any stage will lead to a similar end result.

Morphological features

These include: binuclearity and multinuclearity, asynchrony between nuclear and cytoplasmic maturation, and premature nuclear extrusion; nuclear budding, fragmentation and degeneration (karyorrhexis); and various abnormalities of mitosis. There is also persistence of intercellular connection by cytoplasm and abnormalities of the cytoplasm itself, such as vacuolation, basophilic stippling and the presence of an excessive amount of siderotic granules. The extent to which these abnormalities are apparent in a bone marrow varies considerably between cases, but all the features can be seen readily in certain conditions (e.g. megaloblastic anaemias, AML M6 or myelodysplasia). The morphology of megaloblastic anaemia demonstrates the effect of uncoupling of nuclear and cytoplasmic maturation including the immature open nuclear chromatin in the megaloblasts.

Other indications of dyserythropoiesis

Ferrokinetic studies show an accelerated clearance of plasma iron with decreased erythrocyte incorporation of the order of 25–50%, increased plasma iron turnover and an accumulation and retention of the iron in the bone marrow. A useful parameter of ineffective erythropoiesis is the serum bilirubin. An unconjugated hyperbilirubinaemia is observed in many dyserythropoietic conditions; this is evidence of increased haemoglobin catabolism. Intramedullary destruction of progenitor cells results in the liberation of various enzymes, notably lactic dehydrogenase and aldolase, and destruction of nuclear material leads to an increased level of uric acid. Red cell survival is usually reduced.

Congenital dyserythropoietic anaemias

In addition to the non-specific phenomenon of dyserythropoiesis described above, there is a group of disorders of variable severity with recessive inheritance, known as congenital dyserythropoietic anaemias (CDA). They are characterized by chronic anaemia with a relatively low reticulocyte count, jaundice and haemosiderosis. Peripheral blood films show anisocytosis, poikilocytosis and irregularly crenated and contracted cells. The marrow shows one of three patterns:

Type I. Megaloblastic changes, macrocytosis, internuclear chromatin bridges, but binuclearity not prominent; proerythroblasts and basophilic erythroblasts especially affected (Figure 13.5).

Type II. Binuclearity, especially of late erythroblasts, multinuclearity, pluripolar mitoses, karyorrhexis (Figure 13.6).
Figure 13.5 CDA type I. Bone marrow aspirate showing internucleur bridging in normoblasts.
Figure 13.6 CDA type II (HEMPAS). Bone marrow aspirate showing typical multinuclearity.
Figure 13.7 CDA type III. Giant multinucleated erythroblast from the marrow.

Type III. Multinuclearity with up to 12 nuclei, gigantoblasts, macrocytosis (Figure 13.7).

There is an overlap between types I and II and there are variants of each type. There are also a number of reports of congenital ineffective erythropoiesis, which do not fit into any of the three categories given.

CDA type II

Type II will be described first as it is the most common type of CDA. It is transmitted as an autosomal recessive disease; the geographical distribution of the earlier recorded cases suggests a particularly high frequency in north-west Europe, in Italy and in North Africa. It is usually diagnosed in the first few years of life.

Some cases have presented with anaemia and/or jaundice at birth, and this should be considered in the evaluation of non-immune hydrops fetalis. The clinical manifestations include a variable degree of jaundice, hepatomegaly and splenomegaly, cirrhosis, and diabetes, even in patients who have neither been transfused nor treated with iron. A few patients have been mentally retarded. The serum iron and transferrin saturations are increased.

Type II has an eponym, 'Hempas' – hereditary erythroblast multinuclearity with positive acidified serum – because of the unique feature that the red cells are haemolysed by some acidified normal sera but not by the patient's own serum, unlike PNH. In Hempas, there is a specific antigen on the erythrocytes, which reacts with an lgM anti-Hempas antibody present in the sera of about 30% of normal people in sufficient amounts to cause lysis. This susceptibility to lysis is probably due to abnormal complement control resulting from a defect in the complement-regulating protein glycophorin A (see below).

In common with other types of dyserythropoiesis, there is enhanced I and i antigen activity, demonstrated *in vitro* by increased agglutination and by a positive cold-antibody (anti-I) lysis test.

Type II shows the abnormal features described above. In addition, there is a characteristic peripheral arrangement of endoplasmic reticulum giving the appearance of a 'double membrane' (Figure 13.8).

Pathogenesis appears to be an enzymatic defect in the glycosylation pathway leading to abnormalities in glycoprotein bands 3 and 5.5 and glycophorin A. Two different enzyme defects have been identified, namely deficiency of alpha-mannosidase II and *N*-acetylglucosaminyl transferase II.
Figure 13.8 CDA type II. Electron micrographs of erythroblast, showing peripheral arrangement of endoplasmic reticulum with 'double membrane' appearance.

CDA type I

Type I has been identified far less frequently than CDA II. It has an autosomally recessive inheritance; no method is available to identify heterozygous subjects. Clinical features are similar to those of CDAII. Most patients present with splenomegaly and mild to moderate macrocytic anaemia. Two cases have been reported with skeletal defects in fingers and toes resembling the features seen in congenital aplastic anaemias. Haematologically, it differs from type II by its bone marrow morphological appearance, and electron microscopy shows a high proportion of cells with a 'Swiss cheese' nuclear abnormality. Serological reactions are negative, especially in the acidified serum lysis test. It has been suggested that the primary defect is in the nucleoprotein or the nuclear membrane, with various secondary effects, including failure of protein synthesis and altered globin chain synthesis.

CDA type III

Type III is the rarest form. It is notable for the multinuclearity and gigantoblasts in the bone marrow. Indeed, the erythroblasts are especially remarkable for being present with up to 12 nuclei in a cell (Figure 13.7). Morphologically, the condition is more likely to be confused with erythroleukaemia than with other types of CDA, but the clinical picture is of a mild anaemia with a good prognosis, and there is no granulocytopenia or thrombocytopenia.

As with other types of CDA, there is ineffective erythropoiesis. In the few cases studied, the red cells have been strongly haemolysed by both anti-I and anti-i sera, but the acidified serum lysis test has been negative. In a few reported cases, it appears to have been inherited as an autosomal recessive, but in one Swedish family it appears to be an autosomal dominant trait, and the abnormal gene has been localized to chromosome 15q21–q25.

Management

Patients with only mild anaemia require no intervention. Even if anaemia is more severe, blood transfusion should be kept to a minimum because of the predisposition of the patients to develop iron overload and secondary haemochromatosis. If regular transfusions are necessary the patients should be monitored for evidence of iron overload and desferrioxamine therapy should be given careful consideration. Splenectomy may be of benefit in CDAII, especially in cases with severe anaemia, when it is likely to reduce transfusion requirements. The benefit of splenectomy in CDAI is more problematic.

There have been two reports of the effectiveness of interferon-α in cases of CDAI with severe anaemia: after several weeks of treatment (e.g. 3 million units 2–3 times per week), the haemoglobin became normal and there was substantial reduction in the extent of ineffective erythropoiesis; the haemoglobin level fell when treatment was discontinued or when the dose was reduced, and it recovered when treatment at the previous dose level was resumed. There is insufficient evidence on the effects of long-term continuous treatment.

Red cell immunohaematology: introduction

14

Marcela Contreras and Geoff Daniels

Introduction

The primary purpose of transfusion medicine is to provide 'safe' blood when the clinician requires it. However, blood groups and immunohaematological problems of blood transfusion and transplantation are extremely interesting in their own right and their solutions have much to offer to haematology in general.

Blood group serology or immunohaematology includes the study of antigenic molecules present on the various cellular and soluble components of whole blood, together with study of the antibodies and lectins that recognize them and their interactions. However, in practice, the term blood group serology generally is restricted to red cell surface antigens and their interactions with specific antibodies. In this narrower sense, the complexities of HLA, granulocyte, platelet and plasma protein determinants do not normally fall within the blood group serologist's realm, even though all are likewise genetically polymorphic and play a role in blood transfusion.

The narrower definition of blood group serology encompasses the following: (i) the determination of the phenotype of red cells with antibodies and reagents of known specificity; (ii) the search for and identification of antibodies with red cells of known phenotype; and (iii) compatibility testing of patients' sera against cell samples from donor units of the same ABO and RhD groups. At present, more than 2 million units of red cells are transfused to patients each year in the UK alone.

The aim of this chapter is to provide an introduction to blood group serology and to include aspects of immunology and biochemistry that contribute to our understanding of blood group antigens, antibodies and antigen–antibody reactions.

The red cell membrane and chemistry of blood group antigens

The red cell membrane is composed of about 40% (w/w) lipids and up to 10% carbohydrates, the remainder being proteins. The exact arrangement of its components is still unresolved, but a rough model is shown in Figure 14.1.

The lipids of the red cell membrane can be subdivided into 60% (w/w) phospholipids, 30% (w/w) neutral lipids (mainly cholesterol) and 10% (w/w) glycolipids. The phospholipids and glycolipids play a role in the structure of the membrane and are thought to be important in the maintenance of red cell shape. These lipids have a molecular arrangement reminiscent of a tuning fork, with the hydrophobic fatty acids forming the 'prongs' and the polar group the 'handle'. They are arranged in a bilayer with the 'prongs' pointing inwards and the hydrophilic 'handle' pointing out towards the plasma or towards the cytoplasmic surface of the membrane. Cholesterol is inserted between the other lipids. This arrangement allows the interior of the membrane to be in a semifluid state and the whole membrane to be very flexible. The lipid bilayer does not allow the passive transfer of ions.

The carbohydrates are attached to the lipids and proteins, and occur only on the external surface of the membrane. They are
Figure 14.1 Diagrammatic representation of red cell membrane.

composed of chains of monosaccharides, the majority of which are hexoses.

About 20–40% of the proteins of the membrane are released relatively easily (e.g. by changing the ionic strength of the medium) and are therefore not very firmly attached (peripheral proteins). The remaining 60–80% are released only after drastic treatment with detergents or bile salts; these integral proteins penetrate the lipid bilayer and, in some cases, are bound to the cytoskeleton. After red cell membranes have been treated with the detergent sodium dodecyl sulphate, the proteins can be separated electrophoretically on a polyacrylamide gel according to their molecular mass. If the gel is stained for protein, up to eight bands are seen, as shown in Figure 14.2. Bands 1 and 2 are proteins that are easily released by a low-ionic-strength medium. They are monomers and dimers of the contractile protein spectrin, which form a network of tetramers on the inner surface of the membrane, contributing to the maintenance of the red cell shape. Band 5 (actin) links the spectrin tetramers together. Band 3, the anion exchanger, exists in the membrane as dimers and higher oligomers linked to the cytoskeleton through ankyrin (band 2.1), band 4.2 and band 4.1.

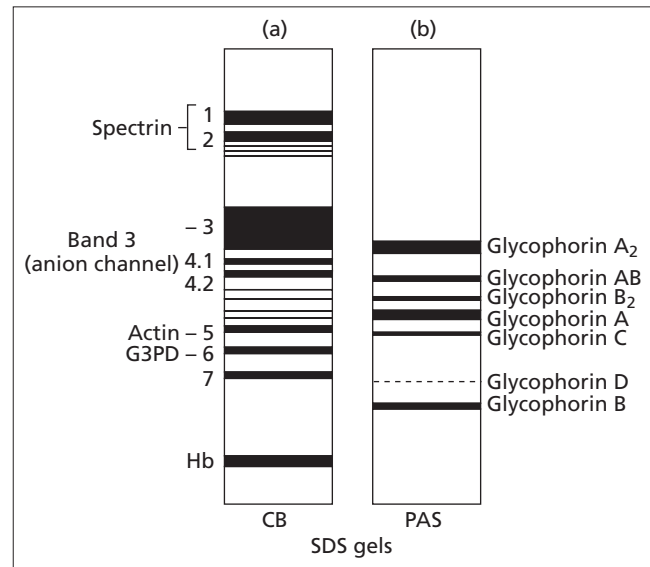
If the polyacrylamide gel is stained for sialic acid with periodic acid–Schiff (PAS) stain, four or five bands are seen (Figure 14.2). These bands contain four sialic acid-rich glycoproteins called glycophorins, and their dimers. The genetically related glycophorins (GP), GPA and GPB, exist as monomers, dimers and as a heterodimer of GPA and GPB. Additional bands represent the minor glycophorins, GPC and its truncated isoform, GPD. The genes for all these glycophorins have been cloned and sequenced, and the amino acid sequence deduced. All of the carbohydrate of these molecules (60%, w/w) is located on the external domains, which extend far beyond the lipid bilayer, allowing charged groups to extend some distance into


Figure 14.2 The proteins of the red cell membrane after separation by electrophoresis in sodium dodecyl sulphate (SDS) gels. (a) Stained for protein (Coomassie blue, CB); (b) stained for carbohydrate (periodic acid–Schiff reagent, PAS).

the plasma. The molecules cross the lipid bilayer once. GPA, GPC and GPD extend well into the cytosol and appear to interact with the cytoskeleton, whereas GPB extends only a short distance into the cytosol (Figure 14.1).

Blood group antigens have been found in the polypeptide and carbohydrate moieties of membrane glycoproteins and in the carbohydrate moieties of glycolipids (Table 14.1). Most blood groups represent amino acid sequence changes in glycoproteins,

Table 14.1 Blood group active proteins.

Protein	Blood group	Mol. wt (kDa)*	Copies per cell (×10³)	Function
Band 3 (CD233)	Diego; ABH†	100	1000	Anion transport; cytoskeletal attachment

†Carbohydrate antigens.
gp, glycoprotein.

although the Rh antigens are non-glycosylated proteins containing two or three molecules of palmitic acid. ABH and Ii antigens are found predominantly on the carbohydrate moieties of the major red cell glycoproteins band 3 (anion exchanger) and on GLUT-1, the glucose transporter, although they are also present on some other minor glycoproteins and on the carbohydrate portions of membrane glycolipids. P, P1 and P^K antigens are expressed on the carbohydrate of glycolipids. The M and N antigens arise from interactions between the carbohydrate and polypeptide in the glycoprotein GPA. In addition to the antigens on integral membrane components, some are adsorbed passively from plasma (e.g. Lewis, Chido/Rogers). Structural details of selected antigens are given in Chapter 15.

Antigens

Originally, an antigen was defined as the part of a molecule that is bound by a specific antibody. More recently, it has become customary to define an antigen as a substance that can stimulate an immune response (immunogenicity). Immune responses can be either positive or negative. Positive responses lead to the production of antibodies (humoral immunity) and/or proliferation of immunocompetent cells (cellular immunity) that can bind and eliminate their stimulatory antigen. In negative responses, the cells that mediate humoral and cellular immune responses are rendered non-responsive. This state is described as acquired immunological tolerance and is important in preventing autoimmune disease, as well as in establishing the 'take' or acceptance of transplanted syngeneic and allogeneic tissues.

The hallmark of the adaptive immune response is its specificity: specific immunocompetent cells and/or antibodies are produced, which can distinguish molecules that differ only by two or three atoms (e.g. TNP versus DNP). As described later, even the difference between the A and B antigens is minimal. However, antibodies can often react with antigens similar to, but not identical to, the stimulatory antigen (cross-reactivity). As far as is known, specific immune responses to human red cells are

mediated by antibodies only; *specific* cell-mediated immunity to red cell alloantigens or autoantigens has not been described.

The parts of an antigen that bind antibodies or cellular receptors are called antigenic determinants or epitopes, and those parts of the antibodies that bind to them are called paratopes. Most antigens that occur naturally are of high molecular weight, and each antigenic molecule may have several different or several identical epitopes. As antibodies are specific for the individual epitopes and not for the antigen as a whole, antisera will usually be a collection of antibodies specific for different regions of the antigen in question, arising from different clones of immunocompetent cells (polyclonal antibodies); such antibodies can sometimes be distinguished serologically by anti-idiotype reagents (see below).

The biological significance of blood group antigens

The functions of several red cell membrane protein structures bearing blood group antigenic determinants are known, or can be deduced from their structure (Table 14.1). Some are membrane transporters, facilitating the transport of biologically important molecules through the lipid bilayer: band 3 membrane glycoprotein, the Diego antigen, provides an anion exchange channel for HCO_3^- and Cl^- ions; the Kidd glycoprotein is a urea transporter; the Colton glycoprotein is aquaporin 1, a water channel; the GIL-antigen is aquaporin 3, a glycerol transporter; and the Rh protein complex might function as an ammonium transporter or a CO_2 channel. The Lutheran, LW, and Indian (CD44) glycoproteins are adhesion molecules, possibly serving their functions during erythropoiesis. The Duffy glycoprotein is a chemokine receptor and might function as a 'sink' or scavenger for unwanted chemokines. The Cromer and Knops antigens are markers for decay accelerating factor and complement receptor 1, respectively, which protect the cells from destruction by autologous complement. Some blood group glycoproteins have enzyme activity: the Yt antigen is acetylcholinesterase and the Kell antigen is an endopeptidase with the ability to cleave a biologically inactive peptide to produce the vasoconstrictor endothelin-3. The C-terminal domains of the Gerbich antigens, GPC and GPD, and the N-terminal domain of the Diego glycoprotein, band 3, are attached to components of the cytoskeleton and function to anchor the membrane to it skeleton. The carbohydrate moieties of the membrane glycoproteins and glycolipids, especially those of the most abundant glycoproteins, band 3 and GPA, constitute the glycocalyx, an extracellular coat that protects the cell from mechanical damage and microbial attack.

The difference between allelic red cell antigens (e.g. A and B, K and k, Fy^a and Fy^b) is small, often being just one monosaccharide or one amino acid. The biological importance of these differences is unknown and there is little evidence to suggest that one antigen confers any significant advantage over another. Most blood group systems have a null phenotype in which the whole blood group protein is absent from the red cells or any other cells. These usually result from homozygosity for gene deletions or inactivating mutations within the genes. In most cases, individuals with these null phenotypes are apparently healthy, suggesting that, whatever the precise function of the missing structure may be, some other structure must be able to substitute in its absence. However, there are exceptions; 15% of Caucasians lack the D protein of the Rh system with no ill effect, but those rare individuals who lack both D and CcEe Rh proteins have chronic haemolysis, which may be compensated by increased red cell production, but may require splenectomy for stabilization. Absence of the Kx protein causes weakness of expression all Kell system antigens, as a result linkage between the two proteins in the membrane, but is also associated with acanthocytosis and neurological and muscular disorders. Individuals lacking the Diego antigen, the anion transporter, can only survive with extreme medical intervention, and no person with Yt-null phenotype and absence of the neurotransmitter acetylcholinesterase has been found. People with the rare Bombay phenotype lack ABH antigens from all tissues, with no apparent ill effect or red cell abnormality.

Some blood group antigens are exploited by pathological micro-organisms as receptors for attaching and entering cells. Consequently, in some cases absence of antigens can be beneficial. The Duffy glycoprotein, expressing Fy^a or Fy^b, is used by *Plasmodium vivax* to penetrate red cells. The Fy(a–b–) phenotype is common in Africans and confers resistance *P. vivax* malaria. Fy(a–b–) in Africans results from homozygosity for a mutation in an erythroid-specific transcription factor binding site, meaning that the Duffy glycoprotein is absent from red cells but is expressed in other tissues. It is likely that interaction between cell surface molecules and pathological micro-organisms has been a major factor in the evolution of blood group polymorphism.

Antibodies

Antibodies are immunoglobulins (Ig) produced by the B lymphocytes of the adaptive immune system in response to an antigen for which they exhibit specific binding.

Depending on the origin of the antigenic stimulus, antibodies can be termed: (i) alloantibodies, when produced by an individual against epitopes present in another individual of the same species; (ii) autoantibodies, when reactive with determinants present on the individual's own antigens; and (iii) heteroantibodies (or xenoantibodies), when produced against antigenic determinants present on the cells of another species. The first two are the antibodies encountered routinely in the blood bank; heteroantibodies can be used as antiglobulin sera or typing reagents when raised in animals against human antigens and are often present in reagents as monoclonal antibodies.

There are five classes of immunoglobulins: IgM, IgG, IgA, IgD and IgE. Antibodies with specificity for blood group antigens are

Table 14.2 Effector functions of the immunoglobulin isotypes*.

	IgG1	IgG2	IgG3	IgG4	IgA1	IgA2	Se IgA	IgM	IgE

Se IgA, secretory IgA.

found only in the IgG, IgM and, rarely, IgA classes. IgA antibodies play a minor role in blood group serology as they only appear as alloantibodies together with IgM and/or IgG. Some of the biochemical and biophysical differences between IgG, IgM and IgA are listed in Table 14.2.

Biochemistry of immunoglobulins

Figure 14.3 shows a diagram of the basic immunoglobulin molecule. This consists of four polypeptide chains arranged as two L (light) chains and two identical H (heavy) chains. The
Figure 14.3 Structure of the basic immunoglobulin molecule.

light and heavy chains are usually held together by disulphide (S–S) bonds. IgG and serum IgA molecules are mainly monomers of this basic immunoglobulin structure; secretory IgA is mainly dimeric. IgM molecules are pentamers, with the basic immunoglobulin molecules held together by S–S bonds and a J (joining) chain (Figure 14.4).

There are two distinct types of light chain, kappa (κ) and lambda (λ). These are common to all immunoglobulins. Either of these chains may combine with any heavy chain, but in any one immunoglobulin both light chains are of the same type and are identical. Kappa chains occur in about 65% and lambda chains in about 35% of the normal immunoglobulins in each class. Each class has an immunologically distinct heavy chain: γ for IgG, μ for IgM, α for IgA, δ for IgD and ε for IgE (Figure 14.4). There are four subclasses of human IgG (IgGI, IgG2, IgG3 and IgG4, with γ1, γ2, γ3 and γ4 heavy chains), and two IgA subclasses (IgA1 and IgA2, with αl and α2 chains).

Analyses of various light chains from different sources show that the amino acid sequence differs in one-half of the chain (variable region), whereas in the other half the sequence remains remarkably constant (constant region) between light chains of the appropriate kappa or lambda groups. Similarly, in the corresponding heavy chain, there is a variable region and a constant region when different chains are analysed.

Papain can split the basic Ig molecule into three fragments at a site near the S–S bonds that hold the heavy chains together (Figure 14.3). One fragment contains the C-termini of the heavy chains and is called the Fc fragment. The other two are called Fab fragments, each of which consists of the N-terminus of the heavy chain (Fd portion) and the whole of the light chain, and contains the antigen binding site of the molecule.

Repetition of amino acid sequences within the heavy chain constant regions indicates that there are either three (for IgG and IgA) or four (for IgM, IgD, IgE) constant region domains for H chains. These are designated C_H1, C_H2, C_H3 and C_H4. In
Figure 14.4 Structure of IgG, IgM and IgA molecules.

contrast, there is only one constant region domain for light chains and only one variable region domain for heavy and light chains. The segment between the C_H1 and C_H2 is called the *hinge region*. This area imparts flexibility to the immunoglobulin molecule so that antigen binding sites can span varying distances.

The vast majority of the differences between antibodies of various specificities occur in three or four short amino acid sequences in the L- and H-chain variable regions. These hypervariable sequences contact the antigen on binding and provide the basis of antibody specificity.

The remaining sequences within the variable region are known as the framework determinants. These are believed to provide the general skeleton of the antigen-recognizing region, within which variations in and between hypervariable sequences generate specificity for the different epitopes bound by different antibodies.

Amino acid sequences within framework and hypervariable segments can sometimes be recognized by specific antisera, usually from another species, raised by deliberate immunization with a particular antibody. The sequences recognized are referred to as idiotopes, and the sera that define them are called anti-idiotypes.

The idiotype of the particular immunoglobulin molecule represents the sum of all the idiotopes of all its framework and hypervariable sequences.

The binding of anti-idiotype sera that recognize idiotopes within hypervariable sequences of the immunizing immunoglobulin can be inhibited by the specific hapten recognized by that immunizing antibody. This is because contact between the hapten and the hypervariable sequences blocks access of the idiotype-specific antibody. In contrast, binding of anti-idiotypes to framework determinants of the immunizing antibody is usually not blocked by the binding of the hapten recognized by that antibody.

The great diversity in the repertoire of antibodies generated by the immune system in response to the immense variety of antigens that it encounters is a direct reflection of the immune system's ability to generate variations within the three hypervariable sequences. This ability is partly genetic in origin and arises from the random selection and joining of several separate genetic elements that produce a single intact variable region gene coding for the final variable region amino acid sequence.

The variable region genes comprise: (i) genes coding for a

large number of V-region sequences, with approximately 150 κ-chain, 125 λ-chain and 500 or so H-chain variable region genes; each of these genes is arranged in three exons, the random joining of which provides the variations that generate the first and second hypervariable sequences; (ii) in H chains only, approximately 10–20 D ('diversity') genes; and (iii) in both H and L chains, five or six J ('joining') genes.

The random joining of numerous choices, in a variety of combinations of V–J genes in L chains and V–D–J genes in H chains, during ontogeny of the immune response, generates the third hypervariable sequence and provides an additional somatic contribution for increasing the repertoire of the immune system. Following V–J/V–D–J joining, which is achieved by splicing together of certain DNA sequences and deletion of others during B-cell maturation, a further increase in antibody diversity is achieved by mutation in the spliced V gene DNA of mature B cells, during their proliferation in an ongoing immune response.

Biological and physical properties of immunoglobulins

Immunoglobulins are essentially multifunctional; not only do they bind antigen, but they also perform various other functions depending on the Ig class. Most of these additional functions reside in the Fc fragment and are listed in Table 14.2. The most important include: (i) complement fixation (lgM > IgG3 > lgG1 > IgG2); IgA does not bind complement in the classical pathway; (ii) binding to Fc receptors of mononuclear phagocytic cells, in particular monocytes and macrophages (IgG3 » IgG1); and (iii) transplacental passage; there is preferential active transport of IgG1 relative to the other IgG subclasses.

Some functions can be ascribed to particular domains. For example, C_H2 or C_H2/C_H3 for complement (Clq) binding and control of catabolic rate; the hinge region for binding to the Fc receptors of macrophages and monocytes; $C_H2 + C_H3$ for binding to staphylococcal protein A (IgG3 does not bind) and to the Fc receptors on placental syncytial trophoblasts and lymphocytes.

For blood group-specific antibodies, these class-dependent biological functions contribute to their clinical significance. In the majority of cases, antigen–antibody binding does not cause red cell destruction per se; immune-mediated red cell destruction is usually a consequence of these secondary effector functions.

As only IgG passes the placental barrier, only IgG blood group antibodies can cause haemolytic disease of the fetus and the newborn, although only IgGl and IgG3 will mediate significant immune red cell destruction. The IgG level in cord blood will be much the same as the level in the mother. The passively transferred maternal IgG gradually disappears from the infant after birth and is almost gone by 3 months of age. The serum of newborn infants contains a small amount of IgM of fetal origin but almost no IgA; the production of IgA and IgG starts at about 1–2 months of age.

There are many ways of separating IgG and IgM molecules by physical methods (e.g. gel filtration and affinity chromatography). In routine serology, IgG is easily distinguishable from IgM by treating sera with mild reducing agents such as 2-mercaptoethanol or dithiothreitol (DTT) at low concentrations. These agents split the S–S bonds of the J chains, which link the IgM subunits, thereby rendering them non-agglutinating; IgA is either slightly affected or not affected by such reducing agents.

Blood group antibodies

There are several terms that have been used in the past and are still sometimes used to describe different types of blood group antibodies. These are 'naturally occurring' and 'immune' antibodies, 'cold' and 'warm' antibodies, and IgM, 'complete' (or saline) and IgG, 'incomplete' antibodies. They are described below and an attempt is made to correlate these terms with the class of immunoglobulin involved.

Naturally occurring and immune antibodies

Antibodies are naturally occurring when they are produced without any obvious immunizing stimulus such as pregnancy, transfusion or injection of blood. These antibodies are not present at birth and, in the case of anti-A and anti-B, start to appear in the serum of children with the appropriate ABO groups at about 3–6 months of age. ABO antibodies are probably produced in response to antigens of bacteria, viruses and other substances that are inhaled or ingested; many Gram-negative organisms have antigens that are structurally similar to the A and B antigens. Despite this probable antigenic stimulus, the term 'naturally occurring' is retained for these 'non-red cell-induced' antibodies. 'Immune' blood group antibodies are only produced after pregnancy or following transfusion or injection of blood or blood group substances.

Cold and warm antibodies

Cold antibodies give higher agglutination titres at low temperatures (0–4°C) and many of them will not agglutinate red cells at 37°C. Most naturally occurring antibodies are cold reacting. Some, such as naturally occurring anti-A and -B, have a wide thermal range and will still react at 37°C, at which temperature they will activate complement and lyse red cells, but the titre will be much higher at 0–4°C. Cold antibodies that fail to react above 30°C are of no clinical significance and can be ignored for blood transfusion purposes.

The thermal optimum of warm antibodies is 37°C and this implies that higher titres are obtained at this temperature. Immune antibodies are warm reacting. Any red cell antibody reacting above 30°C should be considered potentially capable of destroying red cells *in vivo*.

IgM and IgG antibodies

IgM or 'complete' antibodies agglutinate red cells when they are suspended in saline. They are often called saline or directly agglutinating antibodies in laboratory parlance. Conversely, 'incomplete', IgG antibodies will not agglutinate saline-suspended red cells. However, lack of agglutination does not mean that the antibodies have not bound to their antigen, and it can be shown that they have reacted by using antiglobulin reagents, which facilitate agglutination (see below). Most naturally occurring antibodies are cold reacting, complete, IgM. Immune antibodies are always warm reacting; most are partly IgG, but some may be IgM. Exceptionally, IgG complete antibodies are found.

Monoclonal antibodies

Animal sera have, in general, been a poor source of blood grouping reagents. Deliberate immunization of laboratory animals to produce blood group-specific heteroantibodies has had limited success as only a few polyclonal specificities have been made in rabbits, goats and chickens. The most useful reagents have been anti-A, -B, -M, -N, -P1, -Le[a], -Le[b] and -LW.

The advent of monoclonal antibody technologies has increased the repertoire of blood grouping reagents. By fusing the spleen cells of immunized mice or rats with drug-sensitive myeloma cells and selecting for drug-resistant hybrids, it has been possible to establish permanently growing cloned cell lines in tissue culture that secrete antibodies of desired specificities. Several murine hybrids secreting human blood group-specific monoclonal antibodies have now been established, many of which were raised using immunogens other than intact red cells (e.g. anti-A, -B, -Le[a], -Le[b], -M and -N).

Attempts to produce human monoclonal antibodies by the cell fusion approach have been of limited success due to the lack of suitable human myelomas. Nevertheless, human monoclonal antibodies specific for RhD, C, c, E and e, the ABO blood group antigens, and several other antigens including Jk[a] and Jk[b] have been obtained by the alternative approach of transforming isolated peripheral blood lymphocytes from immunized individuals with Epstein–Barr virus. Monoclonal antibodies of murine and human origin have widely replaced polyclonal blood grouping reagents in everyday ABO and D grouping.

The future of antibody reagent production may lie in recombinant DNA technology, but a useful blood grouping reagent is still to be produced by these methods.

Lectins

Lectins are sugar-binding proteins, mostly extracted from plants and lower vertebrate animals. They are useful tools for routine and experimental blood group serology. They combine with simple sugars (e.g. fucose, galactose, *N*-acetylgalactosamine) present on the glycolipids and glycoproteins of cell membranes and body fluids. Most lectins agglutinate red cells irrespective of target cell phenotype; hence only a handful are used with any regularity in blood group serology. The three most commonly used blood group-specific lectins are extracts from *Dolichos biflorus* (the hyacinth bean), *Vicia graminea* (horse gram) and *Ulex europaeus* (common gorse), which have anti-A₁, anti-N and anti-H specificities respectively. Several other lectins have proven valuable in investigating red cell polyagglutinability (see Chapter 15). In addition to blood grouping, lectins are also used for determining ABH secretor status, separating mixtures of red cells, and for partially purifying and identifying blood group active membrane glycoproteins.

Lectins are not immunoglobulins. They are not produced as a result of a specific immune response and do not possess the uniform molecular structure of immunoglobulins. Some exist as simple monomers (e.g. *Ulex*), whereas others are polymers (e.g. *Dolichos*). The lectins used in blood grouping are highly specific for monosaccharides. For example, *U. europaeus* and *D. biflorus* lectins recognize L-fucose and *N*-acetyl-D-galactosamine respectively. This specificity does not depend solely upon the presence of the particular sugar, but is also influenced by its orientation and conformation, the nature of the carrier molecule, and the number and distribution of reactive molecules in the red cell membrane. There are only seven monosaccharides on the red cell membrane, in various combinations with each other and their lipid and protein carriers; the similarities in these combinations lead to cross-reactivity of many lectins.

Complement

Complement consists of a series of proteins, mainly enzymes present in fresh plasma as inactive precursors, which react sequentially with each other to form products that are important in the immune destruction of cells, including bacteria. In complement activation, there are two stages of relevance. The first stage is the generation of the active form of the third component, C3b, which leads to the coating, or opsonization, of the cell with a large amount of protein. There are two pathways by which active C3b may be generated: the classical and alternative pathways (Figure 14.5). The second stage is the lytic stage: activation of the proteins of the membrane attack complex (MAC), components C5 through to C9, which leads to the destruction of red cells in the circulation.

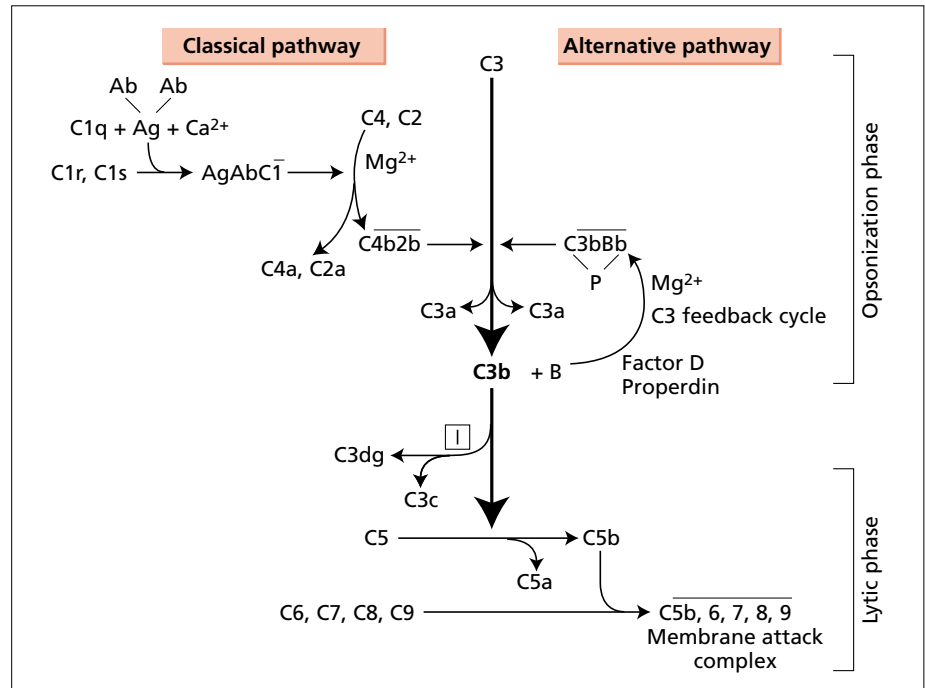
In general terms, the complement cascade is analogous to the clotting sequence. Activation of one component or group of components leads to the generation of enzyme activity for activation of the next components. However, to lead to haemolysis, the activated components in the plasma must bind to the red cell membrane (except Cl, which binds only to a specific binding site on the antibody); they do this with varying degrees of efficiency. Moreover, some activated components, for example Cl, C4 and


Figure 14.5 The complement cascade. Component C3b plays a central role in the classical and alternative pathways.

C3, have specific inactivators in the plasma as well as (for C3b and C4b) in the red cell membrane itself, and, even though these components bind to the red cell membrane, their active life may be very short (half-life, $T_{1/2}$, of 2–25 min). As a consequence, and as happens with several IgG blood group antibodies such as anti-Jk^a and -Fy^a, the whole sequence is not completed and there is no intravascular haemolysis; in these cases, early components can be detected on the red cell surface with suitable antiglobulin reagents.

Complement components in the classical pathway are called C1 to C9 in their native form. Apart from C4, which is activated before C2 and C3, the components are activated sequentially according to their numerical order. Complement components in the alternative pathway include factor B, factor D and properdin. In the activation of the 'classical' components, small-molecular-weight fragments, C4a, C3a, C5a, are released, which have important chemotactic and anaphylactic activity. C3a and C5a, as well as the release of vasoactive amines and cytokines, lead to most of the signs and symptoms observed in severe haemolytic transfusion reactions and also in febrile non-haemolytic transfusion reactions.

The opsonization phase of the complement sequence (Figure 14.5)

The classical pathway

The classical pathway can be activated by many factors, including antigen–antibody complexes, enzymes (trypsin, plasmin, lysosomal enzymes), endotoxins and low-ionic-strength media.

Only one molecule of IgM on a cell membrane is necessary to activate the complement system, although at least two out of the five IgM subunits must attach to the cell membrane for activation to occur. At least two IgG molecules must combine with antigen sites very close together on the cell membrane to bring about complement activation.

The first component of complement is a complex of three protein molecules Clq, Clr and C1s. After complement-fixing antibodies have bound to their red cell antigens (EA is often used to denote the resulting erythrocyte–antibody complex), C1 binding sites are exposed on the Fc fragments. If two such sites are sufficiently close together (approximately 25–40 nm), the Cl complex is fixed through its Clq subunits. Clq is a complex molecule with six immunoglobulin binding sites. Binding of Clq activates Clr, which, in turn, cleaves the third molecule, C1s, yielding the active enzyme form of the Cl complex, which is held together by calcium. In the presence of EDTA or other chelating agents, the complex falls apart and the whole process of complement fixation will not occur.

C1s can now activate sequentially C4 and C2 in the presence of magnesium, generating a second enzyme, $\overline{C4b2b}$, called C3 convertase.

The cell-bound $\overline{C4b2b}$ can optimally activate several thousand C3 molecules. As C3 is present in large amounts (100–150 mg/dL) in the serum, the fixation of C3 can considerably increase the globulin coating of the red cells. Although C3b is still intact, opsonized red cells will adhere to monocytes and macrophages through their C3b receptors and may then be phagocytosed. C3b has a short half-life and there is no free C3b in plasma.

Hence, C3b coating of IgG-sensitized cells neutralizes the inhibitory effect of free plasma IgG on macrophage immune adherence and amplifies erythrophagocytosis 100-fold. Thus, C3b-coated, IgG-sensitized cells are destroyed mainly in the liver, where there are numerous phagocytic cells with receptors able to bind cells coated with IgG and C3b. The active phase of C3 is transient because it is rapidly degraded by an enzyme (C3b inactivator, C3bINA or factor I) and its accelerator (βIH or factor H) so that only C3dg remains on the red cell surface. C3dg is an end-product of the complement sequence and, by occupying the C3 sites, can prevent further binding of C3b and therefore haemolysis of the red cell. C3dg, unlike C3b, is not capable of adhering to receptors on macrophages and monocytes, so that cells coated with C3dg may return to the circulation and will be resistant to further lysis. This explains the existence of a population of C3dg-coated cells refractory to lysis in chronic cold haemagglutinin disease. C3dg-coated cells can be detected by anticomplement in the antiglobulin test.

C4b2b3b will 'trigger' the fixation of C5, C6, C7, C8 and C9 leading to the membrane attack complex on normal red cells and bringing about their lysis.

The alternative pathway
The alternative pathway does not necessarily involve antibody and represents non-specific 'innate' immunity. The proteins of the alternative pathway form a feedback loop for the conversion of C3 to C3b; the latter is both a product and reactant of this loop.

The alternative pathway can be activated by aggregated IgA, zymosan, bacterial cells or lipopolysaccharides. Initiation of the alternative pathway is a two-step process: (i) binding of C3b to an activator and (ii) interaction of bound C3b with neighbouring surface structures. Initially, spontaneously generated fluid-phase C3b interacts with factor B to form a complex. Factor B is activated through cleavage by the protease factor D, releasing a fragment Ba into the plasma and yielding a transient alternative C3 convertase, C3bBb. The latter can be stabilized by properdin, which is essential for preventing the dissociation of C3bBb by factor H.

The alternative C3 convertase splits serum C3 into C3a and C3b. C3b attaches to the cell surface and can then combine with more factor B and D, thereby restarting the feedback loop. The amount of C3b deposited by the alternative pathway is low owing to the small amount of convertase generated and to the inefficient deposition of C3b from plasma. This contrasts with the vast numbers of C3b molecules generated by the classical pathway. The two sources of C3b are indistinguishable; both act on C5 to start the lytic phase.

The classical and alternative pathways cannot be separated from each other *in vivo*. The alternative pathway amplifies the classical pathway because, when C3b is generated, factors B and D may be activated and complexed with it to generate further C3b.

The lytic phase of the complement sequence
(Figure 14.5)

The lytic phase starts with the activation of C5 by C3b, yielding membrane-bound C5b and fluid-phase C5a. This step is followed by non-enzymatic interaction of C5b with C6, C7, C8 and C9. These molecules adhere to each other to form the MAC and insert themselves into the lipid bilayer of the red cell membrane. C8 catalysed by C9 produces protein-lined cylinders in the red cell membrane and are about 10 nm in diameter. They form pores through which ions and water can enter. The osmotic pressure exerted by haemoglobin draws water into the cell until it swells and bursts.

Optimum temperature and pH for complement lysis
Many of the active complement components are enzymes and as such are very sensitive to changes in pH and temperature. The optimum pH for haemolysis to occur is 6.8 and the optimum temperature is 32–37°C. At temperatures below 15°C, the red cell cannot be haemolysed by complement and it is assumed that the last stages of complement fixation do not occur. However, the early stages of complement fixation can occur at 15°C and the components can be detected on the red cell surface with anticomplement reagents.

The ability of the antibody to bind complement
Why some antibody molecules bind complement easily and others do not is not fully understood, but several factors seem to be important.
1 The immunoglobulin class and subclass of the antibody, as discussed later.
2 At least two Clq binding sites properly aligned and close together are necessary for complement fixation. One molecule of IgM antibody carries several Clq binding sites, whereas one molecule of IgG carries only one, and will therefore need another molecule of IgG alongside it (IgG doublet) in order to fix C1q. Therefore, for IgG antibodies to cause lysis by complement, there must be many more molecules available. It has been shown that only one molecule of IgM anti-sheep red cell antibody is needed to lyse a sheep red cell, but at least 700–1000 molecules of IgG antibodies are needed to ensure that the two IgG molecules are aligned so that the whole process of the complement cascade can start.
3 If the antigen site density is low or moderate, it may be difficult for two IgG molecules to be properly aligned however much antibody is available. This may partly explain the poor performance of IgG antibody molecules in complement fixation when compared with IgM.
4 Flexibility at the hinge region is important; the wider the angle at the Y junction, the greater the ability of the IgG antibody to fix complement.

In red cell destruction caused by complement-fixing lytic antibodies, the number of red cells that can be rapidly destroyed is

limited only by the amount of antibody and complement available. In ABO-incompatible transfusions, there may be no surviving A or B red cells in the circulation within 1 h of transfusion. However, if antibodies are only weakly or partially able to fix complement (most anti-Jk[a], -K and -Fy[a]), red cell destruction will be extravascular and will proceed more slowly. Anti-Le[a] will destroy only a proportion of transfused Le(a+) red cells intravascularly; the remaining cells will become Le(a−) and will have normal survival (see Chapter 15). This explains the two-component red cell survival curves seen when labelled Le(a+) cells are injected into subjects with anti-Le[a].

Clinical significance of red cell antibodies

The clinical significance of different red cell antibodies depends partly on their destructive capacity and partly on their frequency. For example, anti-PP1P[K] (anti-Tj[a]) is a very potent haemolysin, but it is of minimal importance in blood transfusion practice owing to its great rarity. Conversely, ABO and D antibodies are by far the most significant, due to their high frequency and destructive capacity.

Several factors influence immune red cell destruction *in vivo*. These include:

1 *Plasma concentration and avidity of the antibody*.

2 *Thermal amplitude of the antibody*.

3 *Immunoglobulin class and subclass*. The complement-fixing ability of most warm-reacting IgM antibodies makes them clinically significant. Of the IgG subclasses, IgG1 and IgG3 have clinical importance because of the ability of some to fix complement and their avidity for the Fc receptors of mononuclear phagocytic cells, the effector cells of *in vivo* extravascular immune red cell destruction.

4 *Antibody specificity*. Several warm-reacting antibodies are incapable of causing *in vivo* red cell destruction (e.g. anti-Ch, -Rg, -Cs[a], -Kn[a], -Xg[a] and most examples of anti-Yt[a]).

5 *Antigen density on the red cell membrane*. The likelihood and degree of sensitization of a red cell with antibody and complement increases with the number of antigen sites on the surface.

6 *Volume of incompatible red cells transfused*. A small volume of incompatible red cells will be destroyed more rapidly than a large volume from the same donor. Larger volumes of cells may exhaust the circulating antibody available and saturate the mononuclear phagocytic system (MPS). This difference is important in interpreting ^{51}Cr survival tests, which employ small volumes of red cells and therefore might overestimate the destruction of larger volumes.

7 *Presence of antigen in donor plasma*. Lewis antigens (Le[a] and Le[b]) and the Chido and Rogers antigens are primarily in plasma and are only secondarily adsorbed onto red cells. The free antigen in plasma, especially when whole blood is transfused, will react with the antibody and inhibit its binding to red cells. In addition, group A and B cells have less Le antigens than group O

red cells used in antibody screening and identification. Hence, cross match-compatible blood unscreened for Lewis phenotype is transfused to patients with Lewis antibodies. Furthermore, when Lewis-positive blood is transfused to patients with antibodies, the cells lose their Lewis antigens and become Le(a−b−). For this reason, Lewis antibodies are unable to cause delayed haemolytic transfusion reactions.

8 *Activity of cells of the mononuclear phagocyte system*. The ability of macrophages to remove sensitized red cells varies between individuals. Splenectomy and drugs such as corticosteroids will decrease the clearance of IgG-sensitized cells.

9 *Sensitivity of red cells to complement*. Resulting from absence of cell bound complement regulators, patients with paroxysmal nocturnal haemoglobinuria have red cells that are highly sensitive to lysis by complement activation.

10 *Extent of complement activation*. Some antibodies regularly bind complement and others do so rarely or not at all. Of the complement-binding antibodies, IgM (e.g. anti-A, -B, -PP1P[K]) will activate the complement cascade through to C9, but for most (e.g. IgG anti-Fy[a], -Jk[a], -K) the cascade is interrupted at the C3 stage. Red cells coated with IgG and C3b will be destroyed extravascularly in the liver. As a rule, Rh antibodies do not fix complement.

Blood group antigen–antibody reactions

In blood group serology, the interaction between the antigen sites on the cells and the corresponding antibody is normally detected by observing agglutination of the cells concerned. Agglutination is the result of the cross-linking of individual red cells by antibody molecules and can be thought of as occurring in two stages. The first stage is the fundamental reaction, i.e. the combination of the antibody molecules with their specific antigen sites. The second stage is the actual linkage of the individual antibody-coated red cells.

First stage of agglutination: combination of antibody with antigen

The combination of antigen with antibody cannot be observed directly; it arises from the fit of the antigen into a structurally complementary site within the antibody molecule. The resulting complex is then stabilized by various short-range forces between the chemical groups of the antigen-binding site in the antibody and the antigenic determinant itself. These weak, short-range forces include ionic attraction (e.g. between COO^- and NH_3^+), hydrogen bonding (e.g. between -OH, -NH$_2$ and -CO), van der Waals' forces and hydrophobic interactions. Individually, these forces are weak; however, when in close apposition, the simultaneous formation of a large number of bonds stabilizes antigen binding. The greater the interface between antigen and antibody, the stronger are the binding

forces generated and the greater the affinity of the antibody for its specific antigen.

The association of antigen (Ag) with antibody (Ab) is reversible and obeys the law of mass action so that, at equilibrium:

$$(Ag) + (Ab) \underset{k_2}{\overset{k_1}{\rightleftharpoons}} (AgAb)$$
where k_1 and k_2 are rate constants of association and dissociation respectively. Hence, at equilibrium:

$$K = \frac{k_1}{k_2} = \frac{(AgAb)}{(Ag)(Ab)}$$

where K is the equilibrium constant for the reaction and reflects the strength of association between antigen and antibody. The greater the value of K, the greater the amount of antigen–antibody complex formed.

Factors affecting the first stage of agglutination

Factors that affect the equilibrium constant include pH, ionic strength and temperature.

pH

Most antibodies are not affected by changes in pH within the range 5.5–8.5. However, this is not true for all antibodies, and, in order to make one day's work similar to the next, routine serology should be carried out with saline buffered to pH 7.0–7.4. Below pH 4 and above pH 9, antigen–antibody complexes are largely dissociated and the antibody can be recovered in the supernatant. This is the basis of some elution techniques.

The ionic strength of the medium

In saline of normal ionic strength, the ionized groups of both antigen and antibody are partially neutralized by oppositely charged ions in the medium. By lowering the ionic strength while maintaining tonicity, the ions become exposed and theoretically there should be an increase in attraction. Decreasing the ionic strength increases the rate of association (k_1) of antigen with antibody but has little effect on their rate of dissociation (k_2). For example, a 1000-fold increase in k_1 with a threefold fall in k_2 has been observed for anti-D by reducing the ionic strength to 0.03 mol/L. Low-ionic-strength solutions (LISS) containing 0.03 mol/L NaCl in a solution of sodium glycinate are used routinely in some blood banks to increase the speed and sensitivity of pretransfusion tests. Regrettably, LISS can lead to a failure in detection of some clinically important antibodies, in particular anti-K.

Low-ionic-strength solutions are also used to coat red cells with complement components via the alternative pathway. A few drops of fresh whole blood can be taken into 1–2 mL of 10% sucrose, incubated for 10 min at 37°C and washed, to provide control cells coated with C3 and C4 for the antiglobulin test. For this reason, the use of LISS under uncontrolled conditions can lead to unwanted positive direct and indirect antiglobulin tests.

The temperature of the reaction

The effect of temperature on antigen–antibody reactions includes: (i) an alteration in the equilibrium constant of the antibody and (ii) an alteration of the rate of encounter. With warm antibodies, the equilibrium constant is not changed by variations in temperature, but decreasing the temperature from 37°C to 4°C slows the rate of reaction 20-fold. With cold antibodies, there is an increase in the equilibrium constant with decreasing temperature and, even though the rate is reduced, stronger reactions and higher titres are found at lower temperatures.

Second, or 'visual', stage of agglutination

Factors that affect the second stage of agglutination

These include the degree of contact of the antibody-coated red cells with each other, the span of the antibody molecules, the electrical charge of the red cells, the location and density of the antigen sites on the red cells and the capacity of the antibody to bind complement after reacting with the antigen.

The degree of contact of antibody coated cells

It is obvious that the antibody molecules cannot form bridges between individual cells until the cells are close together. This contact can be achieved by allowing the cells to settle by gravity; full settling does not occur in a saline serum medium until 1–2 h have elapsed. Settling can always be accelerated by centrifugation. However, as red cell drifts mimicking agglutination may be formed, it is best to centrifuge at quite low speeds for not more than 1 min.

In a colloidal medium (e.g. albumin), settling of the red cells occurs after 3–6 h of incubation of serum and cells. However, if albumin is added to the mixture after centrifugation, incubation times can be reduced to 1 h.

The electrical charge of the red cells

Red cells suspended in 9 g/L of NaCl are negatively charged; because of this charge and the repulsive force that it generates, there is always a gap between individual red cells. The minimum distance of approach of unsensitized cells is approximately 18 nm between their actual membranes. This is considerably greater than the maximum distance between the two arms (valencies) of an IgG molecule (12 nm). IgM molecules, with a greater distance (approximately 30 nm) between the antigen-combining sites, are able to bridge this gap and thus cause agglutination of appropriate cells suspended in saline. Conversely, IgG anti-D cannot cross-link two D-positive cells in saline. Cells coated in this way approach each other to within 6 nm between the Fc ends of the coating IgG. Agglutination of IgG-coated cells can then be brought about by various agents that bring them closer together or by molecules that cross-link coating IgG.

The treatment of cells with proteases (trypsin, papain, bromelin, ficin) or neuraminidase removes negatively charged neuraminic acid from the red cell membrane. Proteases, but not

neuraminidase, also remove hydrophobic membrane glycoproteins, thus enabling enzyme-treated cells to come sufficiently close together to allow agglutination by IgG antibodies.

The span of the antibody molecule

The span of an IgG molecule can be increased by mild reduction and alkylation, which opens up the hinge region by cleaving S–S bonds. Antibodies treated in this way can be used as direct agglutinins and are available as 'saline' reagents from commercial companies.

The location and density of antigen sites

The fourth factor that affects the second stage of agglutination is the number of antigen sites on each red cell and, therefore, the number of possible sites for antibody combination. IgG anti-A, -B, -M and -N may agglutinate the appropriate red cells in saline; this may be due to the comparatively high number of the corresponding antigen sites (see Chapter 15 and Table 14.1). For those antigens that protrude from the cell surface (e.g. ABO, MN, I, i), agglutination by the corresponding antibodies will occur more readily than for antigens embedded in the membrane (e.g. Rh).

The number of antigen sites is, for some blood group systems, a reflection of the genotype; *MM* cells will carry twice the number of M antigens as *MN* cells and will be more readily agglutinated by the appropriate antibody (dosage effect). In other systems (e.g. ABO, D), dosage is not apparent.

The capacity of the antibody to bind complement

The last factor that affects the second stage of agglutination is the ability of antibody to bind complement after reacting with its antigen. Here it should be remembered that if an antibody binds complement there might be no agglutination. The simplest explanation of this absence of agglutination is that the added presence of complement molecules, close to the antibody, prevents the antibody molecules from linking up individual cells. This lack of agglutination can be very important. For instance, in grouping or compatibility tests, anti-A and -B in a patient's fresh serum may cause partial lysis of the red cells and no agglutination of the unlysed cells. If this lysis is not noticed, the test may be read as negative and grossly incompatible blood might be regarded as compatible.

The use of enzyme-treated red cells

Several proteases (papain from papaya, trypsin from calf spleen, bromelin from pineapple, ficin from figs) are used under strictly standardized conditions to treat red cells and potentiate agglutination.

Whether or not enzyme treatment of the red cells enhances agglutination by an antibody depends on the nature of the appropriate antigen. Agglutination by Rh, Lewis, P1, Kidd, I and i antibodies is enhanced regardless of whether the antibodies are

IgM or IgG. Agglutination by most examples of anti-K is not enhanced with enzyme-treated cells. Some protein antigens are destroyed by protease treatment of intact red cells. These include M, N, S, Fy^a, Fy^b, Xg^a, In^a, In^b, Yt^a, Ch, Rg, Pr and Tn (see Chapter 15).

Detection of red cell antigen–antibody reactions

Principles of agglutination techniques

There are various ways of detecting antigen–antibody reactions *in vitro*. In manual methods, tubes, microplates or gels can be used. The most widely used methods employ the following techniques.

Direct agglutination

Most IgM antibodies will directly agglutinate the appropriate red cells suspended in saline. This method is used routinely for ABO and RhD grouping using monoclonal antibodies.

Indirect agglutination

Apart from ABO, antibodies against most blood group antigens are IgG and generally will not bring about direct agglutination of red cells. Such antibodies can be detected with the aid of agents that enhance agglutination, for example, proteases, albumin and other colloids, and aggregating agents such as polybrene. When proteases are used, more reproducible and reliable tests are achieved if the cells are enzyme-treated before incubation with the relevant serum.

The antiglobulin or Coombs' test

The antiglobulin test is used to detect IgG antibodies that do not cause direct agglutination of red cells carrying the corresponding antigen when suspended in saline. The technique can be used to test directly, with an antiglobulin reagent, for the presence of antibodies or complement components that have been bound to the red cells *in vivo* – the direct antiglobulin test (DAT). Second, the test can be used to detect IgG antibodies in a patient's serum by adding the appropriate test red cells and then, after incubation and thorough washing of the cells, adding an antiglobulin reagent that will agglutinate cells coated *in vitro* with antibody or complement components. This is the indirect antiglobulin test (IAT).

Whereas this was mainly carried out in tubes, the use of microplates and microcolumns containing a matrix of either a gel or glass beads is becoming increasingly popular. With columns, the wash phase, as described below, has been eliminated. IATs are also used with many reagent antibodies for determining blood group phenotypes. If an IAT is undertaken with red cells suspended in normal ionic strength saline (NISS), maximum antibody uptake, and hence maximum sensitivity, is

achieved within a 60- to 90-min incubation period. However, the incubation phase for IATs can be reduced to 10–15 min by using low-ionic-strength solutions (LISS). LISS IATs may be performed by either suspending the test red cells in LISS before adding the patient's serum or by adding LISS to the red cell–serum mixture. LISS IAT is less sensitive than NISS IAT for the detection of some examples of anti-K if the incubation time is reduced below 15 min. A further disadvantage of LISS IAT is that, if used in the cold, clinically insignificant antibodies such as anti-P1 and anti-Le^a may be detected more readily because of their increased uptake under low-ionic-strength conditions. In view of the many LISS preparations available, it is important that the manufacturer's instructions are followed strictly.

When the DAT and IAT are performed in tubes, it is essential that the red cells are washed three or four times with a large volume of saline before adding the antiglobulin reagent, as any free IgG or complement will neutralize the anti-IgG or anti-complement reagent and lead to false-negative reactions.

Antihuman globulin (AHG) serum was originally made by injecting animals, usually rabbits, sheep or goats, with human serum. The animal's immune system is able to differentiate very well between the large collection of foreign proteins that make up human serum, and, under optimum conditions, an animal can make distinct antibodies against a wide variety of serum proteins. Of particular relevance to the antiglobulin test are antibodies against IgG and complement, which should always be present in polyspecific AHG serum. The anti-IgG component is essential for pretransfusion antibody screening and cross-matching, as the vast majority of clinically significant antibodies, apart from anti-A and -B, are IgG. The anti-complement component is needed for the detection of occasional examples of weak complement-binding antibodies (e.g. some anti-Jk^a) and for the detection of *in vivo* complement coating of red cells (i.e. in the DAT). Antiglobulin reagents are now generally produced from monoclonal antibodies to C3d and polyclonal antibodies to IgG.

The basic composition of a polyspecific reagent is a blend of anti-IgG and -C3d. Anti-C4d should be avoided and antibodies against IgA and IgM are not necessarily always present in polyspecific reagents. Pure anti-IgG, anti-IgA and -IgM serum can be made in animals by injecting the appropriate purified immunoglobulin and removing any antibody against L chains by absorption.

Most IgM blood group antibodies can be detected readily by direct agglutination. On those occasions when it is desirable to detect subagglutinating amounts of IgM active at 37°C, the lack of anti-IgM in polyspecific reagents can be offset by the ability of the IgM antibody to fix complement in the presence of fresh serum. Moreover, as only a few molecules of IgM are needed to start the complement sequence and can then lead to the binding of many hundreds of molecules of C3, the agglutination of complement-coated cells by anti-complement sera can be a very sensitive method of detecting IgM antibodies. Some

anti-IgG preparations will agglutinate red cells coated with sub-agglutinating quantities of IgM owing to the presence of anti-L-chain activity. Of course, complement-fixing IgG antibodies will also be detected with anti-complement sera but, in most cases, they can be detected effectively by anti-IgG. However, there are exceptional examples of complement-fixing IgG red cell alloantibodies (e.g. anti-Jk^a), that are not detectable with anti-IgG, and anti-complement is essential for their identification.

Polyspecific antiglobulin reagents composed of anti-IgG and anti-C3d are perfectly suitable for pretransfusion testing, including the cross-match. For those rare cases of autoimmune haemolytic anaemia in which the test with polyspecific AHG is negative, it is necessary to test with anti-IgA and anti-IgM, which are now available ready for use in gel microcolumns. Polyclonal and monoclonal reagents against the four human IgG subclasses are commercially available and are generally used in research for characterizing clinically significant red cell alloantibodies.

Standardization of anti-human globulin reagents
All antiglobulin reagents available at present, monospecific or polyspecific, are standardized by the producer and issued pre-diluted for immediate use or within the gel or bead matrix of a microcolumn.

Antiglobulin reagents standardized for use in haemagglutination tests should not agglutinate red cells, regardless of their ABO type, after incubation with compatible serum (i.e. they should be free of unwanted antibodies, especially anti-species). The antiglobulin reagent should not agglutinate washed red cells taken from units of blood intended for transfusion when they are nearing the end of their shelf-life. The final dilution of the anti-IgG component should be sufficient to allow the optimal detection of weak examples of incomplete non-complement-fixing IgG alloantibodies (e.g. anti-D, -c) coated on single antigen dose (heterozygous) target cells (e.g. *D/d* or *C/c*). The anti-C3d component should be optimized so that complement bound to the cells will be detected but not so strong that stored cells, with traces of bound C3d and C4d, react non-specifically. As plasma is now used by most laboratories for pretransfusion testing, alloantibodies that theoretically might only react with the anti-C3 in an AHG reagent will be missed. However, there is no evidence that significant antibodies are not being detected.

When new batches of an AHG reagent or IAT microcolumns are acquired by a laboratory, they should be subjected to a minimum *verification* with several IgG antibodies of different specificities to ensure that all are detectable. Laboratories should confirm that, on each day of use, the AHG reagent is reacting according to the manufacturer's specifications, with control red cells coated weakly with IgG. The control IgG-coated cells are the same cells as those used to check the validity of negative antiglobulin tests when a washing step is part of the process; the weakly coated cells are added to each tube giving a

negative result, followed by repeat centrifugation and reading. Agglutination of these cells confirms that the AHG reagent in the tube had not been neutralized by residual unbound IgG that was not removed during washing of the original test cells.

Agents that enhance agglutination

Various agents may be added to serological mixtures to enhance the agglutinability of red cells. These include albumin and LISS, as described above, as well as polybrene and polyethylene glycol (PEG). Whereas albumin and LISS work by reducing interfacial red cell surface tension and increasing electrostatic attraction, respectively, the mode of action of polybrene and PEG is not so clear. Polybrene is the bromide salt of polymerized hexadimethrine and, as a quaternary amine, is thought to interact with negatively charged sialic acid groups. Hence, polybrene appears to enhance agglutinability by cross-linking red cells via their glycophorins.

In the polybrene test, red cells are first incubated briefly with serum in a low-ionic medium; polybrene is then added and, after a brief incubation, centrifuged and the supernatant decanted. A resuspending solution composed of a mixture of dextrose and citrate (to neutralize excess polybrene) is then added, and the red cell pellet gently agitated and assessed for agglutination. Polybrene will have aggregated the red cells non-specifically; red cells coated with antibody will persist as agglutinates, whereas uncoated cells will readily disperse on agitation due to neutralization by citrate. Polybrene tests can subsequently be processed for an indirect antiglobulin test (IAT) if so desired (see below).

Polyethylene glycol is relatively easier to use than polybrene. A 20% solution of PEG (M_r 3350) in phosphate-buffered saline (PBS) is added to a red cell–serum mixture, which is then treated as for a standard IAT. It is essential to use anti-IgG as the AHG agent in PEG IAT in order to prevent false-positive results owing to non-specific binding of complement to the red cells. A few clinically significant antibodies that have caused red cell haemolysis (e.g. anti-Jk[a]) were detected only by PEG IAT.

Inhibition of agglutination

Expected agglutination reactions with known antigens and antibodies can be neutralized by soluble antigens of the appropriate specificity. For example, the saliva of group A secretors inhibits the agglutination of group A cells by anti-A. Hydatid cyst fluid with P1P[K] activity can be used to confirm the presence of anti-P1 in sera. Soluble antigens produced by recombinant DNA technology will become useful in reference laboratories as aids to sorting out complex serological problems.

Haemolysis

Red cell lysis indicates a positive antigen–antibody reaction mediated by complement-fixing antibodies. A pink or red coloured supernatant after settling or centrifugation of red cell–antibody mixtures is an indication of red cell lysis.

Absorption and elution tests

Specific antibodies can be removed from serum by absorption with red cells carrying the corresponding antigen. Bound antibodies can be subsequently recovered from the washed sensitized red cells by elution with heat treatment, freeze–thawing, low pH or chloroquine treatment.

Specialized methods

These include radiolabelling, flow cytometry and enzyme-linked immunosorbent assays (ELISAs) used for the estimation of the number of antigen sites on red cells and when more sensitive antiglobulin techniques are required. The essence of these approaches is the use of a labelled antiglobulin: for radiometric assays, ^{125}I is usually used to 'tag' the antiglobulin molecules; in flow cytometry, fluorescent anti-IgG is used (or antibodies can be directly coupled with a fluorescent dye); in the case of ELISA, enzymes are attached covalently (i.e. conjugated) to the antiglobulin.

The execution of these assays requires antibody-coated cells or particles to be incubated with the labelled antiglobulin reagent. After incubation, excess unbound antiglobulin is washed away and bound, labelled antiglobulin is then measured. For radiometric assays, this is achieved by simply counting radioactivity in a gamma counter. For flow cytometry, a cytofluorimeter is used to measure fluorescence of each cell. For ELISA tests, the bound enzyme conjugate is detected through the enzyme's ability to modify, and usually effect a colour change, in its substrate (Figure 14.6). The colour intensity of the modified substrate can then be measured with a spectrophotometer.

Figure 14.6 The enzyme-linked immunosorbent assay (ELISA) for cell-bound antibodies. Enzyme substrate is represented by open and closed stars, for colourless and coloured derivatives respectively.
Microcolumn tests (gel and beads)

The principle of microcolumn tests is the separation of agglutinated from non-agglutinated red cells by centrifugation through a miniature filtration column. For blood grouping, red cells are layered on microcolumns impregnated with blood grouping sera; for antibody screening and identification, phenotyped panel red cells are mixed with patients' sera within the incubation chamber of the microcolumn. After centrifugation, agglutinated red cells are retained towards the top of the microcolumn because the agglutinates are trapped by the column matrix, whereas unagglutinated red cells form a button at the bottom of the column.

Positive and negative results are discriminated by the appearance of cells trapped within the matrix or at the bottom of the microcolumn respectively. Antiglobulin tests can be accomplished by centrifuging the mixture of red cells and patient's serum through a column impregnated with anti-IgG or polyspecific AHG. Any red cells coated with IgG antibody will be agglutinated by the free anti-IgG in the matrix of the column, giving a positive result. No washing of sensitized cells is required as IgG in the serum does not penetrate the column and so does not neutralize the anti-IgG in the column. The advantages of microcolumn techniques are the ease of reading and reproducibility, and the fact that the tests can be stored for later examination or checking. In the Diamed ID system, Sephadex gels are used. The Ortho Biovue system uses glass beads rather than gels. Both systems can be automated and the agglutination results evaluated by image analysis.

Microplate techniques

Semi-automated blood grouping and antibody screening can be performed in microtitre plates, which can also be used for extended phenotyping of red cells, antibody identification and large-scale screening for rare red cells and antibodies. A single microplate is equivalent to 96 short test tubes and the same basic principles of discrete analysis of agglutination apply. The advantages of these techniques include enhanced sensitivity, speed of performance, reduced reagent requirements, simplicity and reduced requirements for laboratory space and expensive equipment. Several commercial microplate-based blood grouping systems are now available (e.g. IBG system). These incorporate the use of bar codes to identify samples, automated liquid handling of samples and reagents, and plate readers linked to computers for easy and accurate record-keeping.

Microplates containing red cells adhered to the surface of the plastic, solid-phase systems help to reduce the variability between tests that is inherent in liquid-phase systems when undertaken by different operators, and easily lend themselves to automated reading of results. Blood grouping (e.g. for ABO and D groups) by solid phase can be accomplished by the use of U-shaped microplate wells coated with the relevant antibody (e.g. anti-A, -B, -D); suspensions of patients' or donors' red cells are added to the wells and then centrifuged. Positive results appear as a carpet of cells coated over the bottom of the well. Negative results appear as a tight pinhead of unattached cells in the centre of the well.

Antibody screening and identification by a solid-phase technique can be achieved with microplates coated with a panel of phenotyped red cell ghosts, following chemical activation of the plastic. The wells are incubated with patient serum and LISS, washed and then anti-IgG is added. Anti-IgG will bind to those wells where the patient's IgG red cell antibody has bound to the relevant red cell ghost of the phenotyped panel; the presence of bound anti-IgG is then easily detected by adding indicator red cells coated with IgG (e.g. D+ cells coated with anti-D), followed by brief centrifugation, as described above.

Automated techniques

Fully automated blood grouping and antibody screening are carried out in transfusion centres where large numbers of donor samples are tested daily and increasingly in hospital transfusion laboratories using microcolumn techniques or microplates as described above. In automated systems such as the Olympus PK, test samples are mixed with typing sera and screening cells in individual wells of a special microplate, which are constructed to have a terraced surface at the bottom of the well. After incubation and settling of the red cells in the reaction mixtures, agglutination patterns are distinguished either on the basis of light transmission (model 7100) or through image analysis with the aid of a computer-controlled CCD camera (model 7200).

Other automated systems are available for use with microcolumns (e.g. Diamed's Gel-Station and Ortho AutoVue systems). These are fully automated, walk-away, systems using bar codes to identify both samples, reagents and test cards. Each has a pipetting (liquid handling) station, incubator, centrifuge and reader linked to a computer to maintain the identity of the sample being tested throughout the entire testing process. Similar walk-away systems are available for use with solid-phase microplate systems, e.g. Biotest's Tango, Immucor's Galileo.

In another automated system, reactions take place in small cuvettes and reactions are read by the principles of changes in light scatter properties utilized in aggregometry to detect agglutinates (e.g. Menarini Boss system).

A continuous flow analyser is commonly used for quantification of anti-D or -c, especially in antenatal serology, and for antibody detection. There are several different methods to quantify the anti-D concentration in samples from antenatal patients and immunized volunteers, as well as in plasma pools used for the manufacture of anti-D immunoglobulin.

Manual titration, the most common method, is simple, but provides only a fairly crude semi-quantitative estimate of the concentration of anti-D. Radioisotope methods give more accurate estimates and do not require standards, but their sensitivity is poor and they are too laborious for routine use.

Quantitative haemagglutination methods using continuous-flow automated analysers and appropriate anti-D/c international standards are sensitive (e.g. down to 0.02 IU anti-D/mL), relatively simple, objective, rapid, of acceptable reproducibility, and amenable to routine use and standardization. The method involves the agglutination of D+ red cells by the anti-D to be quantified, in the presence of an agglutination enhancer, while being pumped through a series of coils at set temperatures to allow the desired incubation of the segments of reactants. The agglutinates are sedimented and removed, whereas the remaining unagglutinated red cells are haemolysed by a detergent. The absorbance of the haemolysate is proportional to the amount of haemoglobin and is thus inversely proportional to the number of agglutinated cells removed. This reflects the antibody concentration, which can be calculated using the values obtained from the standard, run in parallel, in iu/mL.

Blood grouping reagents

To avoid potential fatalities due to errors in ABO and D grouping, it is essential that the chosen ABO typing reagents have suitable potency and comply with the European Directive on *in vitro* diagnostic devices and the associated Common Technical Specifications and carry the 'CE' mark to show they are in conformance.

Blood grouping reagents prepared from polyclonal antisera should be free of unwanted antibodies and should have been exhaustively tested with an extensive panel of cells to exclude common and rare specificities (e.g. anti-Bg (HLA), -Vw, -Wr^a), before they are issued for routine use. Unwanted contaminating antibodies are generally not a problem with monoclonal reagents as they have to be extensively tested before being placed on the market. Good IgM monoclonal reagents are now available for ABO, Rh and K typing.

Strict adherence to the manufacturer's instructions for each reagent is essential. Standard operating procedures should include writing out the worksheet prior to testing, labelling all tubes, microplates, or gels, recording results immediately after reading, repeating discrepancies and using adequate controls. Any other equipment used in an investigation (centrifuge, incubator) must be calibrated and in range at the time that the investigation is undertaken.

ABO grouping has an in-built control in the reverse grouping (serum check, see Chapter 15). However, controls for D typing must always be used in order to prevent a D-negative patient being mistyped as D-positive. At least two potent anti-D reagents should be used in Rh typing.

Antibody screening and identification

Patients' sera should be screened against unpooled group O cells from selected individuals known to carry the following antigens between them: D, C, E, c, e, M, N, S, s, P1, Le^a, Le^b, K, k, Fy^a, Fy^b,

Jk^a and Jk^b. Ideally, one cell sample should be R$_1$R$_1$ (DCe/DCe) and the other R$_2$R$_2$ (DcE/DcE), and a minimum homozygous expression of Fy^a and Jk^a should be present on one of the red cell samples. It is generally possible to meet these requirements with two cells but, if more antigens are required with homozygous expression, it might be necessary to use three cells.

The techniques employed for antibody screening need only include a well-controlled IAT, commonly now using microcolumn techniques. For antibody identification, a second sensitive technique, in addition to the IAT, such as the use of enzyme-treated cells, PEG or the manual polybrene tests, should be used. Saline tests are not essential and all incubations should be performed at 37°C; antibodies reacting at lower temperatures are of no clinical importance.

It is recommended that an autologous control be used by incubating the patient's serum with the patient's cells, by the methods used for antibody identification. All tests must follow a written standard operating procedure. Blood bankers should not forget that the main aim of blood group serology is to provide hazard-free transfusions.

Molecular techniques for blood grouping

Almost all the genes for human blood groups have now been cloned and the molecular bases for most of the blood group polymorphisms have been determined. Consequently, it is now possible to predict blood group phenotypes from DNA with a high degree of accuracy. The usual requirement for such tests is the determination of fetal blood groups. When a pregnant woman has a blood group antibody with the potential to cause haemolytic disease of the newborn (HDN, see Chapter 16) it is beneficial to be able to determine whether her fetus has the corresponding antigen and, consequently, whether it is at risk from HDN. Such tests usually involve D typing, but may also involve typing for c and K antigens, and, rarely, other blood group antigens. The usual source of fetal DNA is amniocytes, obtained by amniocentesis, an invasive procedure with a small risk of spontaneous abortion and a 20% risk of transplacental haemorrhage, which could boost the mother's antibody. Non-invasive tests for D are now being introduced, from 16 weeks' gestation onwards, in which fetal D type is predicted from the small quantity of free fetal DNA present in the maternal plasma.

The other use of molecular methods for blood grouping is for regularly transfused patients, where serological methods are not possible because of the presence of transfused red cells that are always present in the patient's blood. If genotypes can be determined for all clinically important blood group polymorphisms in transfusion-dependent patients then matched blood can be provided to prevent the patient from making multiple antibodies to blood group antigens. Tests are carried out on DNA that is isolated from whole blood from the transfused patient,

and accurate results can be obtained despite the potential for contamination with DNA from the donors.

Five types of tests are commonly used in blood group genotyping, all involving the polymerase chain reaction (PCR).

1 Amplification of a portion of a blood group gene to determine whether it is present. This only applies to *RHD* of the Rh system. Presence of the amplified product is usually detected by gel electrophoresis, although monitoring of the amplification by the use of a fluorescent probe in a 'real-time' system is the usual method for detecting fetal *RHD* in maternal plasma.

2 Amplification of a portion of a gene followed by detection of the polymorphism with restriction endonucleases (see Chapter 15).

3 Selective amplification of a specific allele by the use of an allele-specific primer (see Chapter 15).

4 Amplification of a portion of a gene followed by direct sequence of the amplified product.

5 Allelic discrimination by real time quantitative PCR, in which relative quantities of a pair of alleles are measured.

It is unlikely that molecular genetics will be used for routine ABO and Rh typing of donors and patients, at least in the near future. However, there may be other roles for molecular blood grouping in the future. One such function could be genotyping large numbers of blood donors for multiple blood groups in order to establish a database of donors typed for all clinically significant blood groups. This would be valuable for the treatment of transfusion-dependent patients, as it would facilitate the provision of compatible blood for those patients who have made blood group antibodies and matched blood for those who have not. To perform such testing, high throughput methods will be required. Many techniques for detecting DNA polymorphisms are now available, and some are being developed for blood group testing.

CHAPTER 15

Antigens in human blood

15

Marcela Contreras and Geoff Daniels

Introduction

The main topic of this chapter is red cell antigens and their antibodies. However, in human blood there are many other antigenic structures that stimulate the production of antibodies in recipients of blood transfusions. Leucocyte antibodies are an important cause of febrile transfusion reactions in patients who have had previous transfusions or pregnancies. Lympho-cytotoxic antibodies and, rarely, platelet antibodies may be a cause of failure of the platelet count to rise after platelet transfusions. Thus, a description of granulocyte and platelet antigens and antibodies is also included. The HLA system is covered in Chapter 23. Antibodies against proteins present in plasma may lead to urticarial or anaphylactic transfusion reactions; these will be considered briefly.

Approximately 280 red cell antigens have now been recognized and authenticated by the International Society of Blood Transfusion; of these, 245 belong to one of 29 blood group systems (Table 15.1). Each system represents a single gene locus, or two or more very closely linked loci of homologous genes, and each system is genetically discrete from all the others. In addition, there are about 40 antigens that have not been included in systems. Most blood groups are inherited as mendelian characters, although environmental factors may occasionally affect blood group expression. The genes representing the 29 systems

have been located on a specific chromosome (Table 15.1). All are autosomal except *XG* and *XK*, which are X-borne, and *MIC2*, which is on both the X and Y chromosomes. All the genes have been cloned, with the exception of *P1*.

Blood group antigens may be integral proteins or glycoproteins of the red cell membrane, or they may be membrane glycolipids. In proteins and glycoproteins blood group polymorphisms and variants may represent differences in the amino acid sequence (e.g. Rh and Kell antigens). In glycoproteins and glycolipids, the blood group activity may reside in the carbohydrate moiety and polymorphism is associated with difference in oligosaccharide sequence (e.g. ABO). In some glycoproteins, blood group polymorphism may be caused by amino acid substitutions, but antigen expression is also dependent on glycosylation of the polypeptide.

The ABO system

The clinical importance of a blood group system in blood transfusion lies in the frequency of its antibodies and in the possibility that such antibodies will destroy incompatible cells *in vivo*. The ABO system was the first to be recognized and remains the most important in transfusion and transplantation (histo-blood group system). The reason for this is that almost everybody over the age of about 6 months has clinically significant anti-A and/or

225

anti-B in their serum if they lack the corresponding antigens on their red cells. Thus, if we consider the incidence of ABO blood groups in the UK (Table 15.2), transfusions given without regard to ABO groups would result in a major incompatibility (patient has the antibody and the antigen is in the transfused red cells) about once in every three cases.

The antigens of the ABO system

The vast majority of human bloods can be grouped into six main ABO phenotypes (Table 15.3), although several other rare weak variants can be distinguished serologically. The incidence of ABO groups varies very markedly in different parts of the world and in different races. Even in the UK, there is some variation between north and south, and cities in some areas with large immigrant populations will reflect racial differences. In such areas, the blood groups of the patient population do not reflect those of the predominantly white blood donors.

Table 15.2 Incidence of ABO groups in southern England.

Phenotype	Frequency (%)	
O	44.9	
A_1	30.8	41.1
A_2	10.3	
B	10.1	
A_1B	2.7	3.9
A_2B	1.2	

A_1 and A_2 subgroups

The distinction between the A_1 and A_2 subgroups is usually made by using anti-A_1, which will agglutinate A_1, but not A_2, red cells. Anti-A_1 can be obtained in several ways: (i) it can be made by absorbing anti-A (from group B people) with A_2 red cells; (ii)

Table 15.3 ABO grouping.

Agglutination of test cells with				Agglutination by test serum of			ABO group of test sample	Possible genotype
Anti-A	Anti-A$_1$	Anti-B	Anti-A,B*	A cells	B cells	O cells		
−	−	−	−	+	+	−	O	O/O
+	+	−	+†	−	+	−†	A$_1$	A^1/A^1, A^1/O, A^1/A^2
+	−	−	+	−/+‡	+	−	A$_2$	A^2/A^2, A^2/O
−	−	+	+	+	−	−	B	B/B, B/O
+	+	+	+	−	−	−†	A$_1$B	A^1/B
+	−	+	+	−/+‡	−	−	A$_2$B	A^2/B

*Anti-A,B (group O serum) is not generally used in routine laboratories.

†Some group A$_1$ and A$_1$B individuals may have weak anti-H in their plasma.

‡Serum from a proportion of A$_2$ (1–8%) and A$_2$B (22–35%) individuals will contain anti-A$_1$.

it is found in the serum of some A$_2$ and A$_2$B persons (Table 15.3); (iii) it can be made from a saline extract of the seeds of the hyacinth bean, *Dolichos biflorus*; and (iv) mouse monoclonal anti-A$_1$. Anti-A$_1$ is not used routinely as it is not necessary to distinguish group A$_1$ from group A$_2$ blood for most transfusion recipients. There is no specific antibody for A$_2$ red cells; if anti-A is absorbed with A$_1$ cells, all the antibody is removed. Group B serum can therefore be thought of as containing two antibodies: anti-A, which agglutinates both A$_1$ and A$_2$ red cells, and anti-A$_1$, which agglutinates only A$_1$ red cells. The anti-A component of group O serum also has both antibodies.

The presence of the A^2 allele in the presence of A^1 cannot be determined by serology. Among people who are genotypically *A/O* or *A/B*, approximately three possess the A^1 gene for every one who possesses A^2 (Table 15.2).

The difference between the A$_1$ and A$_2$ subgroups is partly quantitative: the red cells of A$_1$ and A$_1$B subjects have more A antigen sites than A$_2$ and A$_2$B subjects respectively (Table 15.4). There is also good evidence for a qualitative difference between

A$_1$ and A$_2$. Relatively low abundance A-active oligosaccharide structures, called repetitive type 3A and type 4A (see p. 230) are present on A$_1$, but not A$_2$ red cells. This qualitative difference must be very subtle, because A$_2$ red cells can absorb all the anti-A from group B serum if the absorption is carried out at 0−4°C for sufficient time.

For practical purposes, A$_2$ can be regarded as a weaker form of A. Table 15.4 shows quantitative differences in the number of A antigen sites on A$_1$ and A$_2$ red cells. The table also shows that when both the A and B antigens are present, there are less sites for each than when either is present alone. The practical importance of this lies in the fact that the A antigen of A$_2$B red cells may give an extremely weak reaction with anti-A, which could be missed in routine grouping tests if reagents of inadequate potency are used. Moreover, if the same person's serum contains anti-A$_1$ and is tested in the reverse grouping only with A$_1$ and not A$_2$ red cells, they will be grouped as B. For this reason, potent anti-A reagents reacting with A$_2$B cells should be used in routine blood grouping.

Table 15.4 Numbers of A and B antigen sites on red cells of various ABO groups.

Blood group of red cell	Approx. no. of A antigen sites	Approx. no. of B antigen sites
A$_1$ adult	1 000 000	−
A$_1$ cord	300 000	−
A$_1$B adult	500 000	−
A$_1$B cord	220 000	−
A$_2$ adult	250 000	−
A$_2$ cord	140 000	−
A$_2$B adult	120 000	400 000
B adult	−	700 000

The H antigen

Group O cells have no antigens in the ABO system (Table 15.3). However, they do possess H antigen, the precursor upon which the products of the *ABO* genes act. The H gene (called *FUT1*) segregates independently from *ABO* and is on a different chromosome: *ABO* on chromosome 9, *FUT1* on chromosome 19. The H antigen is present to some extent on almost all red cells, regardless of the ABO group, but the amount of H antigen varies with the ABO group as follows: O > A$_2$ > A$_2$B > B > A$_1$ > A$_1$B.

Individuals with the rare Bombay phenotype are homozygous for inactive H genes (*h/h*). Their red cells are not agglutinated by anti-A or -B, regardless of *ABO* genotype, but are not group O as they are also not agglutinated by anti-H. The serum of Bombay subjects contains anti-H, anti-A and/or anti-B. Parents and offspring of Bombay individuals, who are heterozygous for the

inactive H allele (*H/h*), have H and red cells of normal ABO phenotype.

Development of the A, B and H antigens

The A and B antigens can be detected on the red cells of very young fetuses, but their reactions are weaker than those of adults. Table 15.4 shows that there are fewer A and B antigen sites on cord than on adult red cells. Similarly, the H antigen is less well developed at birth than in adult life. After birth, the expression of the A, B and H antigens increases until about 3 years of age, and thereafter, in health, remains stable throughout life.

Distribution of the A, B and H antigens

ABH antigens are often referred to as histo-blood group antigens because they are widely distributed in the body. They are therefore very important in transplantation. They are present on white cells, platelets and epidermal and other tissue cells. They are also present in an alcohol-soluble form in the plasma of people of suitable ABO groups, whether they are secretors or non-secretors of A, B or H, and in the saliva and other secretions of ABH secretors (see later).

Rare ABO variants

Rare ABO variants are usually disclosed because an expected ABO antibody is missing. A sample typed as group O that has anti-B but no anti-A will usually prove to be a weak A variant. The presence of weak A or B antigens can be demonstrated either by using potent antisera or by absorption and elution.

Rare ABO variants can arise from:
1 *Rare* ABO *genes*. These include A_3, A_x, A_{end}, A_m and A_{el} variants. All are extremely rare and are usually recognized by their variable reactions with anti-A and/or anti-A,B sera. Similarly, subgroups of B have been described; all are very rare.
2 *Genes segregating independently of* ABO. These rare variants are the H-deficiency or Bombay phenotypes described on p. 231.
3 *Environmental effects*. Weakening of the A antigen can occur in various types of leukaemia (usually acute myeloid). The A antigen may revert to almost normal in remission. Similar weakening of B, H, I and RhD has been described. B-like antigens may be acquired by group A individuals who are suffering from bowel infections, usually associated with carcinoma or strictures of the large bowel. Red cells with an acquired B antigen are agglutinated by some anti-B, including some monoclonal anti-B, but not by the patient's own anti-B. Bacterial deacetylases convert *N*-acetylgalactosamine, the immunodominant sugar of the A antigen, into galactosamine, a structure similar to galactose, the immunodominant sugar of the B antigen (see p. 230). In some cases, acquired B may also be associated with polyagglutination (see p. 243).

Antibodies of the ABO system

Anti-A, -B and -A,B

Sera taken from people over the age of about 6 months which do not contain the expected A and B antibodies (Table 15.3) are very rare. They should always be investigated thoroughly; often, some interesting explanation will be found, for example a rare subgroup of A, a blood group chimera or congenital absence of IgM.

It is likely that ABO antibodies arise in response to A- and B-like antigens present on bacterial, viral or animal molecules. Titres of ABO antibodies vary considerably with age, reaching a peak in young adults and then declining in old age. Titres vary depending on the techniques used; normal adult sera can have anti-A titres, by direct agglutination in saline medium, in the range 16–1024 and anti-B titres in the range 4–256, but most have saline titres below 100. The anti-A and anti-B titres of group O subjects are much higher than in group B or A subjects respectively.

Naturally occurring anti-A and -B are antibodies that react better at lower temperatures than at 37°C. The antibodies always have some IgM component and, in group A and B persons, they are almost entirely IgM. However, the antibodies from group O individuals, even before immunization, usually have some IgG anti-A,B, an antibody that cross-reacts with both A and B structures.

Immune anti-A and -B can be produced by persons of the appropriate ABO group after immunization with red cells or blood group substances. Immune anti-A and anti-B can also arise after various vaccinations and inoculations for the prophylaxis of infections. Here, the A-like antigens come from the hog pepsin digest used in their preparation.

Following immunization, the thermal characteristics of the antibodies change, but group A and B subjects continue to produce antibodies that are mainly IgM. Most group O persons, however, will produce IgG as readily as IgM anti-A,B. This correlates with the fact that mothers of children with ABO haemolytic disease of the newborn (HDN) are almost always group O. Immune anti-A,B are mainly IgG2, which does not cause HDN because there are no Fc receptors for IgG2 on the cells of the mononuclear phagocyte system. When the maternal serum contains potent IgG1 and/or IgG3 ABO antibodies, HDN may occur, although this is usually mild compared with Rh HDN. Some IgA anti-A or -B is produced following immunization with A or B substances. Some differences in the serological properties of immune and naturally occurring anti-A and -B are shown in Table 15.5, which also gives an indication to ways of detecting IgG anti-A or -B in the presence of IgM anti-A or -B, which has relevance to ABO HDN, as discussed in Chapter 17.

Dangerous 'universal' donors

Good practice in pretransfusion testing requires compatibility testing, which consists of incubating the patient's serum with the

Table 15.5 Some properties of immune and naturally occurring anti-A and -B.

	Naturally occurring IgM	Immune IgM	IgG
Complement binding (at 37°C)	++/+++	+++	++
Agglutination of appropriate cells	+++	+++	+++
Cross the placenta	–	–	+++
Enhanced by anti-IgG	–	–	+++
Inhibited by soluble A or B substances (e.g. saliva)	+++	+++	–*
2-ME or DTT sensitive	+++	+++	–

*IgG ABO antibodies are usually inhibited only by large amounts of specific substance.
2-ME, 2-mercaptoethanol; DTT, dithiothreitol.

donors' red cells. Group O red cells can be given to A, B or AB recipients and group O donors were formerly, inappropriately called 'universal donors'. Group O donors have anti-A, -B and -A,B in their plasma, which will react with the recipient's A or B cells. Normally, if group A, B or AB recipients are transfused with a relatively small number of group O units of whole blood, the anti-A or -B that is transfused will be diluted out and neutralized by the plasma of the adult recipient, especially if plasma-reduced blood is used. However, if the transfused units contain potent immune haemolytic antibodies, this neutralization and dilution effect may be insufficient and the antibodies may cause a marked destruction of the A or B red cells of the recipient, leading to a severe acute haemolytic transfusion reaction (HTR). For this reason, the practice of transfusing group O blood to non-O recipients should be strongly discouraged.

Moreover, there is usually a shortage of group O blood, and not infrequently a surplus of group A blood. In the vast majority of cases, including emergencies, there is enough time to perform a rapid ABO group on the patient's cells, which will allow the transfusion of group-specific blood. If there is no time to do an ABO group before transfusion, red cells in optimal additive solution, devoid of plasma, should be given until the patient's blood group is known. The practice of transfusing group O platelets to non-O patients should be discouraged, as the dose of adult platelets will contain at least 300 mL of plasma, unless part of it has been replaced by platelet-additive solution. Group O fresh-frozen plasma (FFP) and cyroprecipitate should only be given to group O recipients. This matter is discussed again in Chapter 17.

Anti-A$_1$

Anti-A$_1$, reactive at room temperature (18–22°C), can be found in the serum of 1–8% of group A$_2$ and 22–35% of group A$_2$B persons. Most of these antibodies are more of a nuisance in compatibility tests than of clinical importance because they often do not agglutinate A$_1$ red cells at 30°C and above, and so are unable to cause increased *in vivo* red cell destruction. Very rarely, anti-A$_1$ able to agglutinate A$_1$ red cells at 37°C may lead to significant destruction of A$_1$ red cells *in vivo*. The appropriate group A$_2$ or A$_2$B red cells should be cross-matched in these rare instances.

Anti-H

Several forms of anti-H exist.

1 *Clinically significant 'true' anti-H* occurs in the serum of persons with Bombay phenotype and is very rare. When it does occur, it is very important from the point of view of selecting blood for transfusion; as the antibody is active at 37°C, only Bombay phenotype blood may be transfused.

2 *Anti-H and anti-HI*, commonly found in the serum of group A$_1$, B and A$_1$B persons, react much more strongly with adult than with cord red cells. Anti-H is inhibited by secretor saliva; anti-HI is not. Although these antibodies agglutinate O red cells at 20°C, they do not usually agglutinate them at temperatures above 30°C. Very occasionally, anti-H/-HI may cause rapid destruction of at least some of the transfused O red cells *in vivo*. However, these antibodies will not interfere with the survival of transfused cells if ABO identical units, i.e. A$_1$, B or A$_1$B donor units are chosen for A$_1$, B or A$_1$B recipients respectively.

ABH secretor status

About 80% of the UK population are ABH secretors as they have H antigen, plus A or B according to their ABO genotype, in a water-soluble form in their body secretions. The remaining 20% are non-secretors and have no secreted ABH antigens, regardless of ABO genotype.

Biochemistry and biosynthesis of ABH antigens

ABH antigens

A, B and H antigens on red cells are predominantly glycoproteins, the majority being on the N-glycans of the anion exchanger (band 3) and the glucose transporter. ABH antigens on red cells are also expressed on glycosphingolipids, which include paraglobosides (Table 15.6). Soluble ABH antigens are

Cer, ceramide; Fuc, fucose; Gal, galactose; GalNAc, *N*-acetylgalactosamine; Glc, glucose; GlcNAc, *N*-acetylglucosamine.

glycoproteins. Differences in the terminal sugars of the glyco-proteins and glycolipids determine the specificity of these anti-gens: L-fucose (Fuc) for H; L-fucose + *N*-acetyl-D-galactosamine (GalNAc) for A; and L-fucose + D-galactose (Gal) for B.

Two major types of carbohydrate chain endings serve as acceptors for the fucosyltransferases that synthesize H antigen. Type 1 and type 2 chains have Gal joined to *N*-acetylglu-cosamine (GlcNAc) through 1→3 and 1→4 linkages respect-ively. A- and B-transferases synthesize the transfer of Ga1NAc

and Gal, respectively, from their donor substrates UDP-GalNAc and UDP-Gal, to the terminal galactosyl residue of type IH and type 2H, creating A and B epitopes and masking H specificity (Figure 15.1).

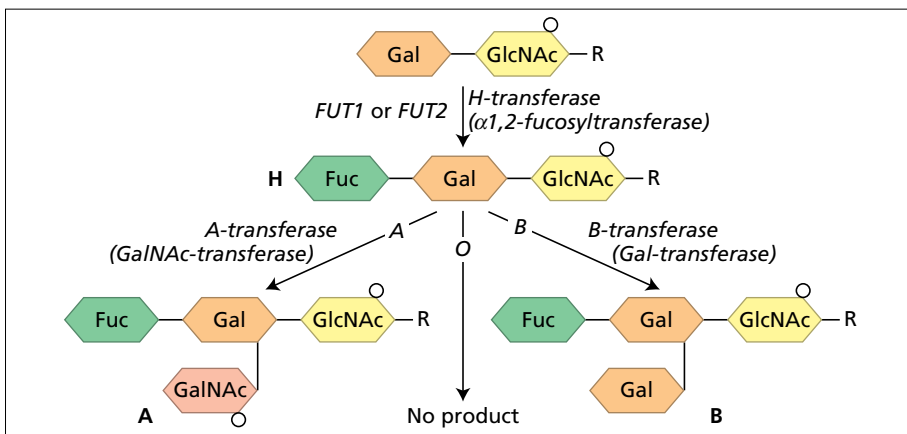
Secretory glycoproteins possess both type 1 and type 2 link-ages, whereas red cells synthesize type 2 chains only. Plasma glycolipids, passively adsorbed onto the red cells have only type 1 chains; these also carry Lewis antigens (see p. 231). Other chains, called type 3 and 4, are also present in low numbers on


Figure 15.1 Biosynthetic pathway of H antigen from its precursor, and of A and B antigens from H. H remains unconverted in the absence of *A* or *B* gene products. R, remainder of molecule.

red cells, but probably only on glycolipids. Type 3, 4 and 6 chains are found in heart and kidney tissues, and may be target epitopes for the rejection of transplanted organs.

ABO genes

The *ABO* gene is located on the long arm of chromosome 9, comprises seven exons and encodes proteins with a structure characteristic of glycosyltransferases. Products of the *A* and *B* alleles differ by four amino acids encoded by exon 7, two of which determine whether the enzyme product has GalNAc-transferase (A) or Gal-transferase (B) activity.

The majority of *O* alleles (called O^1) resemble *A*, but have a single base deletion in exon 6, which creates a shift in the reading frame and scrambles the amino acid sequence after the first quarter of the transferase polypeptide; introduction of a premature stop codon truncates any putative polypeptide. About 3% of *O* alleles (called O^2) have a single nucleotide polymorphism (SNP) that changes one of the vital amino acids in the catalytic site, inactivating the enzyme.

The A^2 allele has a single base deletion immediately before the usual termination codon, creating a reading frameshift and abolition of this stop codon. This creates an A-transferase with an extraneous 21 amino acids on its C-terminus, which accounts for its reduced efficiency as a GalNAc-transferase. A^1, A^2, *B*, O^1 and O^2 genotypes can be identified by polymerase chain reaction (PCR) with allele-specific primers or followed by analysis with restriction enzymes.

Gene sequences for many variants of *A*, *B*, and *O* alleles have been determined and, in most cases, there is heterogeneity, with more than one mutation accounting for the same phenotype.

H genes

At least two genes, *FUT1* and *FUT2*, are responsible for production of H antigen. Both encode α1,2-fucosyltransferases that catalyse the transfer of fucose to the terminal galactose residue of the H precursor chain (Figure 15.1). *FUT1* is active in mesodermally derived tissues, including haemopoietic tissues, and is responsible for H expression on red cells. Homozygosity for inactivating mutations in *FUT1* gives rise to Bombay and related phenotypes. *FUT2* is responsible for the expression of H antigen in endodermally derived tissues, including those responsible for secretions, and hence is the gene responsible for ABH secretion. Secretors are homozygous or heterozygous for an active allele (*Se*) at *FUT2*; non-secretors are homozygous for an inactive allele (*se*).

The Lewis system

Antigens of the Lewis system and their biosynthesis

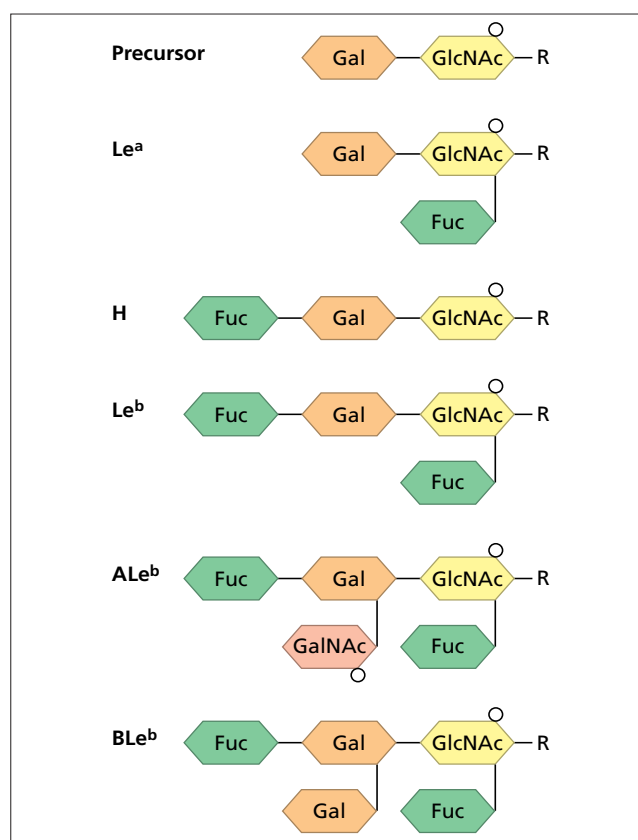
The Lewis system differs from all other blood group systems in that it is primarily a system of soluble antigens present in secre-


Figure 15.2 Diagrammatic representation of H and Lewis antigens. Le^a requires the action of the Lewis α1,4-fucosyltransferase, H the action of the H α1,2-fucosyltransferase, Le^b the action of both Lewis and H fucosyltransferases, and ALe^b and BLe^b the action of Lewis and H fucosyltransferases and the A or B glycosyltransferases.

tions and in plasma. The Lewis antigens on red cells are adsorbed passively from the plasma, and the constant presence of plasma is needed to maintain Lewis antigen on the red cells. There are two basic Lewis antigens; Le^a and Le^b. Expression of either requires the presence of an active Lewis gene, but Lewis phenotypes are also governed by the gene controlling H secretion (*FUT2*). Lewis antigens in saliva and plasma are glycoproteins and glycolipids respectively.

The Lewis gene, *FUT3*, encodes an α1,4-fucosyltransferase that catalyses the addition of L-fucose in 1→4 linkage to the subterminal *N*-acetylglucosamine of type 1 chains (Figure 15.2). If the type 1 core structure has been unmodified, Le^a antigen is produced. If the secretor α1,2-fucosyltransferase has already modified the type 1 chains to produce type 1H, the action of the Le-transferase leads to the formation of Le^b. In a white population, 75% have active Lewis and secretor genes and hence, Le(a−b+) red cells, 20% have an active Lewis gene, but are H non-secretors and have Le(a+b−) red cells, and 5% are homozygous for Lewis genes with inactivating mutations and are

Table 15.7 The Lewis system and secretion of ABH.

Genotype		Antigens in Saliva			Plasma/red cells*	
FUT2 (Secretor)	FUT3 (Lewis)	Le^a	Le^b	ABH	Le^a	Le^b
Se/Se, Se/Se^w or Se/se	Le/Le or Le/le	+	++	++	w/−	++
Se/Se, Se/Se^w or Se/se	le/le	−	−	++	−	−
Se^w/Se^w or Se^w/se	Le/Le or Le/le	++	++	++	++	++
Se^w/Se^w or Se^w/se	le/le	−	−	++	−	−
se/se	Le/Le or Le/le	+++	−	−	++	−
se/se	le/le	−	−	−	−	−

*Le^a and Le^b on red cells are passively adsorbed from plasma.

Le, active allele at *FUT3* locus; *le*, inactive allele; *Se*, active allele at *FUT2* locus; *Se^w*, weakly active allele; *se*, inactive allele; w, weak.

Le(a−b−) (Table 15.7). In Oriental populations there is a low incidence of non-secretors, but a high incidence of a weak secretor allele of *FUT2*. Competition between the Lewis and weak-secretor transferases leads to the Le(a+b+) red cell phenotype.

Adsorption of the Lewis substances by red cells

Le(a+b−) and Le(a−b+) red cells incubated in Le(a−b−) plasma lose their Lewis antigens into the plasma. Similarly, if Le(a+b−) or Le(a−b+) red cells are transfused to an Le(a−b−) person, the transfused cells will gradually lose the Le^a or Le^b antigens and will group as Le(a−b−) within 1 week of transfusion. So, if the patient has anti-Le^a or -Le^b, the red cells that were not destroyed in the first few days, will not be haemolysed once they become Le(a−b−).

Development of Lewis antigens on red cells

The Lewis antigens are poorly developed at birth and red cells from cord blood are usually Le(a−b−). Thereafter, Le^a develops first, followed by Le^b if the relevant Lewis and secretor genes are present. The cells of children between the ages of 6 months to 4 years often type as Le(a+b+) if they are destined to become Le(a−b+). The definitive adult Lewis phenotype may not be reached until the age of 4–5 years.

Antibodies of the Lewis system

Lewis antibodies are generally made only by individuals with the Le(a−b−) red cell phenotype. Anti-Le^a occurs fairly frequently. As only 5% of the UK population are Le(a−b−), approximately 20% of individuals potentially able to make anti-Le^a appear to make the antibody. The incidence of Le(a−b−) is much higher in people of African origin and Lewis antibodies detectable at 22°C or above may be found in up to 10% of random serum samples from black people.

Anti-Le^b commonly accompanies anti-Le^a. Pure anti-Le^b is uncommon and is made by people who are non-secretors and whose red cells are Le(a−b−). Very rarely, anti-Le^b can be made by Le(a+b−) individuals.

Serological characteristics of Lewis antibodies

Lewis antibodies are predominantly IgM, even after deliberate stimulation. They usually agglutinate the appropriate cells at 20°C. All Lewis antibodies bind complement and may lyse the appropriate cells. Usually, Lewis antibodies do not agglutinate red cells in saline at 37°C, but can be detected with anticomplement in an indirect antiglobulin test (IAT).

Clinical significance of Lewis antibodies

Some patients may have Lewis antibodies reacting at 37°C. Anti-Le^a is usually more haemolytic than anti-Le^b, and there are some anti-Le^{a+b} that can be very potent, leading to increased intra-vascular red cell destruction in the initial stages of transfusion. However, all Lewis antibodies lead to two-component survival curves of transfused incompatible red cells; i.e. the first cells are destroyed at an accelerated rate and the remainder will have a normal survival. The red cells that survive normally have been stripped of their adsorbed Lewis antigens and have become Le(a−b−), the same as the recipient.

It is therefore recommended that, for patients with Lewis antibodies reacting at 37°C, ABO identical red cells compatible in an IAT cross-match at 37°C should be transfused. It is important to choose ABO identical cells as group A, B and AB cells carry less Lewis antigens than any group O cell routinely used in antibody screening. This is because the A and B transferases compete with the Lewis transferase for the same precursor substrate. The provision of pre-typed Le(a−b−) blood for patients with Lewis antibodies is not necessary, as it is always easy to find cross match-compatible red cells at 37°C.

Lewis antibodies do not cause HDN as they are almost always IgM and newborn infants have Le(a−b−) red cells.

P blood groups

P1 was discovered by Landsteiner and Levine, who used suitably absorbed sera of rabbits injected with human red cells.

About 75% of subjects tested were positive for P1, which is inherited as a mendelian dominant character. P1 frequency varies in different populations and the P1-negative phenotype is called P_2. P1 is weakly expressed at birth and its strength varies considerably in adults. For this reason, identification of anti-P1 can be difficult, as panel cells will have varying expression of the antigen.

Anti-P1 is a naturally occurring antibody commonly found in the serum of P_2 individuals. Unlike anti-A and -B, anti-P1 rarely causes transfusion reactions because it is usually a cold-reacting IgM antibody, often not reactive above 30°C. Potent anti-P1 can be found in patients with hydatid disease and can be inhibited by hydatid cyst fluid.

P1 is a structure in the paragloboside series of glycolipids. The *P1* gene is probably an α1,4-galactosyltransferase that adds galactose to the P1-precursor, paragloboside, although the biosynthetic pathway has not been fully elucidated (see Table 15.6). A precursor of paragloboside is lactosylceramide, which is converted to the P^K antigen by α1,4-galactosyltransferase-1. In most people, almost all P^K is further converted to P antigen (globoside) by β1,3-*N*-acetylgalactosaminyltransferase-1. The very rare p phenotype results from deficiency of α1,4-galactosyltransferase-1 and leads not only to absence of P^K and P, but also P1, giving rise to suggestions that α1,4-galactosyltransferase-1 might also be the enzyme responsible for P1 synthesis. Deficiency of β1,3-*N*-acetylgalactosaminyltransferase-1 causes the P^K phenotype, in which the red cells express P^K antigen strongly, but no P (globoside). P^K red cells may be P_1 or P_2.

Anti-PP1P^K and anti-P invariably occur in the sera of the very rare individuals with p and P^K phenotypes respectively. Anti-PP1P^K react with all red cells except those of the p phenotype; anti-P react with all red cells except those of the P^K and p phenotypes. They are usually strong IgM antibodies, are often lytic at 37°C, and can cause severe transfusion reactions if incompatible red cells are transfused. Occasionally, IgG anti-P or anti-PPl P^K are found and have been associated with spontaneous early abortion. The biphasic Donath–Landsteiner antibody is found in the sera of patients suffering from paroxysmal cold haemoglobinuria. It is always IgG, usually has anti-P specificity and is an autoantibody.

I and i antigens

The antigens I and i are not controlled by allelic genes: i is the biosynthetic precursor of I. I and i antigens are carbohydrates and are on the interior structures of the complex oligosaccharides that carry ABO, H and Lewis antigens. The i antigen represents linear structures that are converted to I-active branched structures by the product of the I gene (*GCNT2*), a β1,6-*N*-acetylglucosaminyltransferase. This enzyme is not active in newborn infants. Consequently, red cells of most adults are agglutinated strongly by anti-I and only weakly by anti-i, whereas red cells from cord blood give the opposite result. The agglutinability of an infant's red cells with anti-I increases, and with anti-i decreases, with maturity; at about 18 months of age the red cells give the reactions of adult cells. Adults who are homozygous for rare inactivating mutations in *GCNT2* have the adult i phenotype; their red cells react weakly with anti-I and strongly with anti-i, and their serum contains anti-I.

In haematological disorders such as thalassaemia, megaloblastic anaemia, sideroblastic anaemia, hereditary spherocytosis, paroxysmal nocturnal haemoglobinuria and some aplastic and dyserythropoietic anaemias, agglutinability by anti-i is increased without a reciprocal decrease in the agglutinability by anti-I.

Anti-I

Autoanti-I that agglutinates the patient's own and other adult ABO-compatible red cells at 20°C, but not at 30°C, occurs in a variety of disorders and after blood transfusions. These patients' red cells give a negative direct antiglobulin test. A transient increase in strength, titre and thermal range of anti-I regularly occurs after infections with *Mycoplasma pneumoniae* and occasionally leads to acute haemolysis; red cells of such patients give a positive direct antiglobulin test, as do those of patients suffering from chronic cold haemagglutinin disease (CHAD). In CHAD, the autoantibody is nearly always monoclonal and usually has anti-I specificity. All anti-I in CHAD are IgM and complement binding.

Anti-i

Autoanti-i is found transitorily in many patients suffering from infectious mononucleosis. Very occasionally, the titre and thermal range of this antibody may lead to acute haemolysis, particularly if the patient's red cells are more agglutinable than normal with anti-i. Red cells of these patients give a positive direct antiglobulin test.

Autoanti-i may occasionally be the antibody specificity in chronic CHAD. Such patients often have an underlying lymphoma.

The Rh system

The Rh blood group system, the fourth system to be discovered, is the second most important in blood transfusion. This is not because Rh antibodies are usually present when the Rh antigen is absent, but because anti-RhD is formed readily when RhD-positive blood is transfused to an RhD-negative person. Moreover, as these immune antibodies are normally IgG, they are able to cross the placenta and cause HDN. The Rh system now contains a total of 49 antigens, but D (RH1), because of its high immunogenicity, is by far the most important. This is due to the ability of anti-D to cause severe HDN and HTRs.

The Rh antigens

The D antigen (RH1)

In 1939, Levine and Stetson reported that a patient, who had delivered a stillborn infant and then suffered a severe reaction to transfusion of her husband's blood, had an antibody that agglutinated the red cells of 85% of ABO-compatible donors. In 1940, Landsteiner and Wiener found that guinea pigs and rabbits injected with rhesus monkey red cells made an antibody that not only agglutinated rhesus monkey red cells, but also the red cells of 85% of people of European origin. The human and animal antibodies were originally thought to be the same, and the human antibody was called anti-Rhesus.

Many years later, it was realized that the human antibody (now called anti-D of the Rh system) does not identify the same antigen as the rabbit and guinea pig rhesus antibody, the error arising out of a phenotypic association between the antigens. As it was now too late to change the name of the whole system, Levine suggested that the antigen defined by the original rhesus antibody should be called LW in honour of Landsteiner and Wiener. The blood group system originally identified by the human antibody is now called the Rh system.

For clinical purposes, individuals can be classified as Rh-positive (have the D antigen) and Rh-negative (lack the D antigen).

The expansion to include C, E, c and e (RH2 to RH5)

By the end of 1943, four antisera detecting genetically related antigens were available to Fisher and Race, who noticed that two of them appeared to give antithetical results. They proposed that the antigens recognized by these two antisera were allelic and called them C and c. They gave further letters, D (the original Rh antigen) and E, to the antigens recognized by the other two antisera and postulated that each had an alternative, which they called d and e. Anti-e was found in 1945. Anti-d has never been found as no d antigen exists. Fisher and Race proposed that the Rh antigens were controlled by three closely linked genes, giving

rise to eight gene complexes or haplotypes: *CDe*, *cDE*, *cDe*, *CDE*, *cde*, *Cde*, *cdE* and *CdE*. At about the same time, Wiener proposed that there was only one Rh gene, controlling a number of blood factors, equivalent to C, c, D, E and e.

Molecular genetics has shown that there are two Rh genes, one encoding D, the other encoding the Cc and Ee antigens. However, as the Cc and Ee polymorphisms are determined by separate regions of a single gene, the CDE terminology of Fisher and Race is still suitable for understanding Rh at most levels (although the Wiener terminology is often used as a shorthand – Table 15.8). The approximate frequencies of the Rh gene complexes in three populations are shown in Table 15.8. In a white population, the first three complexes form 94% of the total and combinations of these three will give the most common genotypes (Table 15.9). Genotype frequencies vary considerably in different parts of the world. For instance, *dce/dce* varies from about 35% in Basques to 0.3% in Japanese and Chinese.

Numerous variants of e are known, generally found only in people of African origin.

Probable Rh genotype

When a person's Rh phenotype is known, the probable genotype can be discerned and its likelihood calculated from known genotype frequencies within the same population. In people of white European origin, the phenotype is usually determined initially with anti-D, -C, -c and -E. If there is no agglutination with anti-E, homozygosity for *e* is assumed. If there is agglutination with anti-E, anti-e is used to distinguish between *E/E* and *E/e*. Phenotype determinations and the genotypes that they most commonly represent are shown in Table 15.10. When probable genotype determinations are carried out, it is very important that the ethnic origin of the person is known; figures for one population will not apply to people of other populations. For example, in Caucasian populations, *dce* is 15 times more common than *Dce*, whereas in African populations *Dce* has a

Table 15.8 Eight Rh haplotypes and their frequencies in English, Nigerian and Hong Kong Chinese populations.

Haplotype			Frequencies (%)		
CDE	Rh-Hr	Numerical	English	Nigerian	Chinese
DCe	R^1	RH 1,2,–3,–4,5	42	6	73
dce	r	RH –1,–2,–3,4,5	39	20	2
DcE	R^2	RH 1,–2,3,4,–5	14	12	19
Dce	R^0	RH 1,–2,–3,4,5	3	59	3
dcE	r″	RH –1,–2,3,4,–5	1	Very rare	Very rare
dCe	r′	RH –1,2,–3,–4,5	1	3	2
DCE	R^z	RH 1,2,3,–4,–5	Rare	Very rare	Rare
dCE	r^y	RH –1,2,3,–4,–5	Very rare	Very rare	Rare

Results of testing with anti-D, -C, -c, -E and -e, red cells from 2000 English donors, 274 Yoruba of Nigeria and 4648 Cantonese from Hong Kong.

Table 15.9 The most common Rh genotypes in the UK population.

Genotype		Frequency (%)
DCe/dce	R^1r	31
DCe/DCe	R^1R^1	16
dce/dce	rr	15
DCe/DcE	R^1R^2	13
DcE/dce	R^2r	13
DcE/DcE	R^2R^2	3

slightly higher frequency than *dce*. Consequently, the phenotype D+C+c+E−e+ represents a probable genotype of DCe/dce in a white person, but of DCe/Dce in a black person.

Variations in antigen strength and site density with phenotype

Red cells of a person who is homozygous for the allele producing a red cell antigen will often react more strongly with the appropriate antisera than red cells of a person who is heterozygous at the same locus. For example, red cells of persons who are homozygous for the gene producing the C antigen (i.e. genotypically *C/C*), give stronger reactions with anti-C than the red cells of persons who are heterozygous for the same gene (*C/c*). Similarly, this dosage effect occurs with the c, E and e antigens, but is not clearly apparent for D. Table 15.10 shows the number of D antigen sites on red cells of different phenotypes as estimated by the use of ¹²⁵I-labelled anti-IgG to quantify bound IgG

anti-D. D antigen expression is affected by the presence of other Rh antigens on the red cells. The *DcE* haplotype produces high levels of D expression and, for reasons still to be explained, *C* causes depression of D antigen produced by the Rh haplotype on the opposite chromosome.

Molecular genetics of Rh

Rh genes and proteins

Rh antigens are encoded by two, closely linked genes, with 92% homology. *RHD* encodes the D antigen and *RHCE* encodes the Cc and Ee antigens. Each consists of 10 exons and, unusually for homologous genes, the two genes are in opposite conformation on the chromosome (Figure 15.3). The two genes are separated by an unrelated gene, *SMP1*. Each gene encodes a 416-amino-acid polypeptide (M_r 30–32 kDa), which is palmitoylated but not glycosylated. The polypeptides encoded by *RHD* and *RHCE* differ by 31–35 amino acids, depending on the *RHCE* genotype.

There is substantial evidence that the Rh polypeptides traverse the lipid bilayer 12 times, with both termini in the cytoplasm and six extracellular loops that provide the putative sites for antigenic activity (Figure 15.3). Rh antigen activity is very dependent on the conformation of the proteins within the membrane and may involve interactions between two or more of the extracellular loops. Removal of the proteins from the membrane generally ablates all antigenic activity.

D, C/c and E/e polymorphisms

In white people, the D-negative phenotype results from homozygosity for a complete deletion of the *RHD* gene. Consequently,

Table 15.10 Determining probable Rh genotype in the UK population and the number of D antigen sites on red cells of those phenotypes.

Reactions with anti-					Common genotypes	Genotype incidence (%) for each phenotype		No. of D antigen sites
D	C	c	E	e		Unselected persons	Fathers of infants with anti-D HDN	
+	+	+	−	+	DCe/dce*	94	79	9900–14 600

					DCe/dcE			
					DCE/Dce			
−	−	+	−	+	dce/dce	100	0	0

*Probable genotype.
Figure 15.3 Rh and related genes and the polypeptides they encode, showing the 10 exons of *RHD* and *RHCE* in reverse orientation on chromosome 1 and of *RHAG* on chromosome 6, and the RhD and RhCcEe polypeptides and RhAG glycoprotein crossing the membrane 12 times.

D-negative represents the absence of the whole RhD protein from the membrane and anti-D can detect epitopes on any of the external loops of the RhD protein. D-positive people may be homozygous or hemizygous for the presence of *RHD*. Most D-negative black Africans, however, have an inactive *RHD*, called the *RHD*-pseudogene (*RHDψ*), that contains a 37-basepair duplication in exon 4 and a translation stop codon in exon 6.

The Cc polymorphism is associated with three or four amino acid substitutions encoded by exons 1 and 2 of *RHCE*, although the definitive change is Ser103 for C and Pro103 for c in the second extracellular loop of the RhCcEe protein. E and e are associated with Pro226 and Ala226, respectively, in the fourth extracellular loop.

The Rh molecular complex

The two Rh proteins are closely associated in the red cell membrane with a glycoprotein, the Rh-associated glycoprotein (RhAG). RhAG is homologous to the Rh proteins and has a similar conformation in the membrane, spanning the membrane 12 times, but is glycosylated on the first extracellular loop (Figure 15.3). Unlike *RHD* and *RHCE*, which are on chromosome 1, the gene encoding RhAG is on chromosome 6. The complex of Rh proteins and RhAG is probably also associated with several other red cell membrane proteins – the LW glycoprotein (ICAM-4), band 3 (the anion exchanger and Diego blood group antigen), CD47, the Duffy glycoprotein and glycophorin B – to form the Rh molecular complex.

The function of the Rh complex is unknown, although evidence exists that RhAG might function as an ammonium transporter or a CO_2 channel. The Rh proteins are only present on erythroid cells, but RhAG and related proteins are more widely distributed and homologues are found throughout the animal and plant kingdoms.

Variants of D

Weak D (D^u)

Cells that have the weak D phenotype (previously known as D^u) should, for most transfusion purposes, be regarded as D-positive. Weak D red cells have fewer D sites per cell than normal D-positive red cells. In a white population, the gene for weak D is commonly accompanied by *RHCE* encoding C or E antigen (D^u*Ce* or D^u*cE*), and D^u*ce* is rare. Weak D is more common in Africans and is usually produced by D^u*ce*. It is important that anti-D typing reagents should detect most weak D phenotypes, especially in blood donors. However, very weak forms of D will be typed as D-negative. The weakest form of weak D, named DEL, can only be detected serologically by absorption and elution tests.

In the UK, the recommended method for D typing of patients requires direct agglutination tests, in duplicate, with potent IgM monoclonal anti-D reagents. An antiglobulin test is not required. This means that very weak D red cells will by typed as D-negative. This is not important, as the patient will be harmlessly transfused with D-negative red cells. Donors are not typed any longer for D by an antiglobulin test, as this is not necessary because it is unlikely that transfusion of very weak D red cells to a D-negative patient will result in immunization of the patient. One point in favour of abolishing the antiglobulin test in D-typing is that it might lead to the dangerous misclassification of a D-negative mother or blood transfusion recipient whose red cells give a positive direct antiglobulin test as D-positive.

By definition, individuals with weak D phenotype cannot make anti-D, as they have low levels of a complete D antigen on their red cells. However, in a few cases the boundaries between weak D and partial D (see below) have been blurred, and a few individuals with a phenotype previously considered to be weak D have in fact been weak partial D and have produced anti-D.

Weak D results from missense mutations in *RHD* that encode amino acid changes in the cytoplasmic or membrane-spanning domains of the D protein, but not in any of the loops exposed to the exterior of the cells. Based on molecular genotype, over 20 different types of weak D have been identified. Most weak D antigens represent three types: type 1, 70%, Val270Gly; type 2, 18%, Gly385Ala; and type 3, 5%, Ser3Cys.

Partial D

The D antigen comprises a mosaic of many epitopes. Most D-positive individuals have normal D antigens with all epitopes present, but there are some persons with rare D-positive red cells in which some D epitopes are missing. If immunized with normal D-positive red cells, individuals with partial D can make antibody to those D epitopes which they lack. This antibody will not react with their own cells, or with partial D red cells of the same type, but will behave as anti-D when tested with red cells of common Rh phenotypes. In some cases, the D epitopes of a partial D antigen will be expressed weakly, and the term partial weak D applies. Over 20 different types of partial D have been

recognized and the classification of these D variants can only be made by a few specialized reference laboratories. About 30 D epitopes have been defined by using monoclonal antibodies.

In the UK, it is recommended that anti-D reagents for typing patients should not detect DVI, the most commonly encountered partial D antigen associated with anti-D production. Consequently, DVI patients will be transfused with D-negative red cells and DVI pregnant women will be given anti-D prophylaxis. Ideally, one of the anti-D reagents used for typing donor red cells should detect DVI.

Most partial D antigens are produced by *RHD*, part of which has been replaced by the equivalent segment of an *RHCE* gene. For example, the common form of DVI is produced by an *RHD–CE–D* hybrid gene in which exons 4–6 have the nucleotide sequence of *RHCE*, and external loops 3 and 4 of the encoded hybrid protein have the amino acid sequence of an RhCe protein. Consequently, a protein is produced with a sequence similar enough to *RHD* to be stable in the membrane, but different enough to lack many epitopes of D. Some partial D antigens result from a single nucleotide change in an external loop of the RhD protein.

Other Rh antigens

Table 15.11 lists the antigens of the Rh system recognized by the International Society of Blood Transfusion. A few of these are described below.

C^w and C^x antigens (RH8 and RH9)

C^w and C^x occur in about 2% and 0.2% of white people, respectively, although substantially higher frequencies are found in Finns. They appear to have an allelic relationship, although C^w and C^x represent Gln41Arg and Ala36Thr substitutions in an RhCcEe protein respectively. Anti-C^w and anti-C^x have caused HDN but, on the rare occasions on which this occurs, it is usually mild.

G antigen (RH12)

With only rare exceptions, G is expressed when either D or C, or both, are present. Anti-G, therefore, recognizes a determinant common to the products of *RHD* and the *C* allele of *RHCE*. Anti-G usually occurs with anti-D (see p. 238) and it is essential

*Polymorphic = > 1%, < 99% in at least one major population.
†Only polymorphic in black people, low in other populations.

that anti-D typing reagents do not contain anti-G, which could lead to mistyping of Cde/cde women of childbearing age as D-positive.

VS and V antigens (RH20 and RH10)

VS and V have frequencies of about 40% and 10%, respectively, in Africans, but are rare in other ethnic groups. Both are associated with an *RHCE* mutation encoding Leu245Val, but only VS is expressed when a Gly336Cys mutation is also present. Neither anti-VS nor anti-V have caused HDN or an HTR.

Compound antigens

Antibodies to the compound antigens, anti-ce (-f, -RH6), -Ce (-RH7), -cE (-RH27) and -CE (-RH22), define pairs of CcEe antigens only when they are encoded by the same *RHCE* gene. For example, anti-Ce and -cE, will react with D+C+c+E+e+ cells of *DCe/DcE* genotype, but not *DCE/dce*, whereas the reverse applies to anti-ce and -CE.

Rh$_{null}$, Rh$_{mod}$ and D––

Rh$_{null}$ and Rh$_{mod}$

Rh$_{null}$ red cells lack all antigens of the Rh system and people with this rare phenotype can make an antibody, antiRh29, which reacts with all red cells except those of the Rh$_{null}$ phenotype. They also lack LW antigens, RhAG and Fy5 of the Duffy system, and have weakened expression of CD47 and of S, s and U antigens on glycophorin B. Rh$_{null}$ subjects have a chronic haemolytic stomatocytic anaemia, which is usually compensated but may require splenectomy, and probably arises from the CD47 deficiency.

There are two modes of inheritance of the Rh$_{null}$ phenotype.
1 The amorph type, the rarer of the two, results from homozygosity for a deletion of *RHD* (characteristic of most D-negatives) plus homozygosity for an inactivating mutation (frameshift or splice site) in *RHCE*. Consequently, neither Rh protein is produced. Both parents are heterozygous for the mutations and possess only one-half of the usual quantity of Rh antigens.
2 The regulator type arises from homozygosity for inactivating mutations (frameshift, splice site, missense) in *RHAG*, the gene encoding RhAG. In the absence of RhAG, no Rh antigens are expressed, despite the presence of normal Rh genes. Consequently, individuals with the regulator type of Rh$_{null}$ inherit normal Rh genes from their parents and pass them on to their offspring. These parents and offspring are heterozygous for the *RHAG* mutation and have apparently normal Rh antigens, although there may be some weakening of expression. The parents of both types of Rh$_{null}$ individuals are usually consanguineous.

Rh$_{mod}$ is similar to Rh$_{null}$ of the regulator type, but there is only partial inactivation of *RHAG*, caused by missense mutations, encoding single amino acid substitutions, and resulting in weakened expression of all Rh antigens. Rh$_{mod}$ individuals cannot make anti-Rh29.

D–– and related phenotypes

Homozygosity for a rearranged *RHCE* gene, together with an active *RHD*, results in a series of phenotypes, called D––, D••, Dc– and DC^w–, in which no E or e antigens and, in the case of D– and D••, no C or c, is produced. These phenotypes are very rare and have enhanced expression of D. If transfused, individuals with these phenotypes produce anti-Hr$_o$ (-RH17), an antibody that reacts with all red cells except for Rh$_{null}$ cells and cells with D–– and related phenotypes.

Antibodies of the Rh system

Naturally occurring antibodies

Generally, Rh antibodies are only produced following immunization by red cells. However, anti-E is often naturally occurring; about one-half may occur without a history of pregnancy or transfusion. Rarely, naturally occurring anti-D and anti-C^w are found and such antibodies react optimally with enzyme-treated cells.

Immune antibodies

The clinical importance of the Rh system lies in the readiness with which anti-D arises after stimulation with D-positive red cells by pregnancy or transfusion. Prophylaxis of Rh immunization with anti-D immunoglobulin has led to a significant decrease in the incidence of anti-D, but it still remains the most common immune antibody of clinical relevance detected in a routine blood transfusion laboratory. D is considerably more immunogenic than the other Rh antigens, which have the following order of immunogenicity: c > E > e > C.

About 20–30% of anti-D sera also appear to contain anti-C. Usually, this anti-C is not a separable antibody and is probably more correctly called anti-G (see p. 237). About 1–2% of anti-D sera also contain anti-E. Anti-C (and anti-G) in the absence of anti-D is very uncommon.

The incidence of other Rh antibodies is much lower, but together they are more common than the antibodies against K (Kell), which is the most immunogenic antigen after D. In routine screening, pure anti-E is the most common, followed by anti-c, although anti-c is a more common cause of HDN, which can be severe. This is probably because about one-half of the examples of anti-E are weak, naturally occurring antibodies. Anti-e, like anti-C, is very rare. The vast majority of Rh antibodies are IgG and do not fix complement. Anti-D may occasionally be partly IgA. IgM anti-D is very rare.

D immunization

The realization that D-negative women without anti-D who had just delivered a D-positive child could be protected from forming anti-D by the injection of IgG anti-D soon after delivery has been a powerful stimulus for experimental work on D-negative volunteers. About 90% of D-negative people will make anti-D after the transfusion of a large volume of D-positive

cells, and 70% will respond to repeated small volumes. Responders to D can usually be identified from survival curves after a single injection of ^{51}Cr-labelled D-positive cells. Serological methods are relatively insensitive for detecting very low levels of anti-D.

ABO-incompatible D-positive red cells are less likely to stimulate the production of anti-D than ABO compatible D-positive cells when injected into a D-negative recipient. Two explanations have been offered for this protection. First, it might be due to competition for the antigens so that the red cells are taken up by anti-A or anti-B-forming cells and are thus unavailable for anti-D-forming cells. Second, it might be that anti-A and -B bring about intravascular lysis with sequestration of the red cell stroma predominantly in the liver, which is an unfavourable site for antibody formation. Neither of these explanations is very satisfactory and the reason for the protection afforded by ABO-incompatible red cells remains uncertain. This protection is the basis of the lower incidence of maternal Rh sensitization when mother and infant are ABO incompatible.

It has been shown that 20 μg (100 IU) of anti-D immunoglobulin given intramuscularly will give complete protection from 1 mL of concentrated D-positive red cells (approximately 2 mL of blood). This figure is the basis for the standard dose of 100 μg (500 IU) anti-D Ig given post partum in the UK, as it will cover the vast majority of transplacental haemorrhages (TPH). A dose of 3.2–4.0 mg of anti-D Ig given intravenously will protect a D-negative recipient against the consequences of inadvertently transfusing a unit of D-positive whole blood (*c*. 200 mL of red cells).

The mechanism of protection by anti-D immunoglobulin is not really known. Two explanations have been suggested. The first is that the passively administered antibody leads to phagocytosis of antibody-coated red cells and their rapid destruction by macrophages in the spleen before they can combine with receptors of immunologically competent cells. The second is a central mechanism by which the Fc fragment of the antibody combined to antigen might give a suppressive or inactivating signal to the immunocompetent cells. It has been calculated that the amount of passive antibody needed to protect the recipient from antibody formation is less than that needed to cover all the D antigen sites on the injected Rh-positive cells.

Prior to the advent of Rh immunoprophylaxis, the first ABO-compatible, D-incompatible infant resulted in the primary immunization of about 17% of D-negative women. In about one-half of these women, the antibodies appeared within 6 months of delivery and, in the other half, the antibodies became detectable by the end of the second pregnancy.

Source of anti-D for immunoprophylaxis

Anti-D is usually obtained from volunteer men and from women unable to bear children, preferably if they have already been immunized by transfusion or pregnancy. Those with low levels of anti-D are deliberately restimulated with D-positive red cells. Plasma from these donors is harvested by apheresis and sent to a fractionation plant for processing. The possibility of using human monoclonal anti-D for prophylaxis might become a reality within the near future. Preliminary clinical trials look promising.

Detection of fetal red cells in the maternal circulation

Fetal red cells can be detected in a sample of maternal blood by the acid elution method of Kleihauer, which depends on the fact that fetal haemoglobin is more resistant to elution in an acid medium than adult haemoglobin. Thus, fetal haemoglobin is retained in the cell and the fetal red cell stains darkly with the counterstain, whereas adult haemoglobin elutes and the mother's red cells appear as ghosts. Fetal D-positive cells can be quantified in the maternal circulation by flow cytometry after fluorescent staining with anti-D, with as few as 0.05% of fetal cells being detected. This is the preferred method for the follow-up of large TPHs and also of the inadvertent transfusion of Rh-positive red cells to D-negative women. Rosetting techniques can be useful for the estimation of RhD-positive cells in an RhD-negative patient.

Fetal red cells can frequently be detected in the mother's circulation, particularly during the last trimester of pregnancy and after delivery. In about 85% of blood samples taken soon after delivery, the proportion of fetal cells to adult cells is less than 1 in 20 000 (equivalent to a TPH of less than 0.5 mL). In two to three samples per 1000 deliveries, the TPH will be of the order of 10 mL of whole blood (5 mL of red cells) or more. Such women, if delivering a D-positive infant, will not be protected by the standard UK anti-D Ig dose of 100 μg and additional protection should be given. All laboratories should standardize the conditions of the acid elution technique (or any other quantitative technique) in order to estimate the absolute amount of fetal red cells present in the maternal circulation.

Immunization by abortion, miscarriage and obstetric intervention

Abortion and miscarriage can induce the immunization of D-negative women; obviously the incidence is greater if the abortion is therapeutic and if it occurs in the second trimester rather than in the first. Amniocentesis, chorionic villus sampling, fetal blood sampling and other obstetric manoeuvres can also lead to immunization of D-negative women carrying a D-positive fetus.

Prediction of fetal Rh genotype by molecular methods

Knowledge of the molecular basis for D-negative phenotypes has made it possible to devise tests for predicting fetal D type from fetal DNA. This is valuable in determining whether the fetus of a woman with anti-D is at risk from HDN. Most methods involve

PCR tests that detect the presence or absence of *RHD*. For the PCR, it is important that primers are selected that distinguish between *RHD* and *RHCE*. Differences between the two genes in exon 7, the non-coding region of exon 10 and in intron 4 have usually been exploited for this purpose. It is also important to test for more than one region of *RHD*, so that hybrid genes responsible for partial D antigens do not give a false result, and to test for the *RHD*-pseudogene (*RHDψ*), so that this does not give rise to a false-positive result.

Until recently, the usual source of fetal DNA has been amniocytes, obtained by amniocentesis, with its inherent risk of fetal loss and feto-maternal haemorrhage. It is now possible to use sensitive PCR technology to determine fetal D type from the small quantities of free fetal DNA present in maternal plasma, as early as 12 weeks into the pregnancy. This non-invasive form of fetal D typing is now provided as a reference service in the UK and some other parts of Europe.

The MNS system

MNS was discovered by Landsteiner and his colleagues in 1927 and the MNS genes were the first blood group genes to be cloned, in 1986 and 1987. The MNS system now contains 43 antigens, but is relatively unimportant in clinical blood transfusion.

The antigens of the MNS system

M and N are inherited as codominant Mendelian traits, giving rise to three common genotypes *M/M*, *M/N* and *N/N*. The *Ss* locus, which is closely linked to *MN*, also consists of two codominant alleles, at least in Europeans and Asians, producing S or s antigens. In northern Europeans, haplotype frequencies are *MS*, 25%; *Ms,* 28%; *NS*, 8%; and *Ns*, 39%. The system also contains many variants. About 2% of black West Africans and 1.5% of African-Americans are S–S– and most of these lack the U antigen that is present when either S or s is expressed.

The MN antigens are carried on glycophorin A (GPA) (see Figure 14.1), which is encoded by the *GYPA* gene on chromosome 4. M and N differ by amino acids at positions 1 and 5 of the external N-terminus of GPA. There are about 1 million molecules of GPA per cell, yet their absence in the rare En(a–) phenotype does not affect red cell function or survival. The negative charge of the red cells is mainly due to the ionized COOH groups of sialic acid (neuraminic acid), which is mostly carried on the oligosaccharides of GPA and can be removed with neuraminidase. Hence, En(a–) cells have a reduced negative charge and behave serologically as if they have been neuraminidase treated. Glycophorin B (GPB; see Figure 14.1) carries the S and s determinants, which represent an amino acid substitution at position 29. GPB is encoded by *GYPB*, which is closely linked and homologous to *GYPA*. S–s–U– red cells lack GPB. The amino acid sequence at the N-terminus of GPB is identical to

that of N-specific GPA and accounts for the weak reactivity of *M/M* cells with anti-N, provided they are S+ or s+. The numerous MNS variants mostly result from amino acid substitutions in GPA and GPB and from the formation of hybrid GPA–GPB molecules, formed by intergenic recombination between *GYPA* and *GYPB*. GPA and GPB are exploited as receptors by the malaria parasite *Plasmodium falciparum*.

The antibodies of the MNS system

Anti-M is uncommon and reacts with about 80% of random samples. It is naturally occurring, more common in infants than adults, but can be immune and can very rarely cause HDN.

Anti-N is also rare and reacts with about 70% of random samples. It is nearly always a cold-reactive IgM antibody. Because of the 'N' activity of GPB, at low temperatures anti-N reacts with, and can be completely absorbed by, *M/M* cells, except those of the M+N–S–s– phenotype. Useful anti-N lectin can be prepared from the seeds of *Vicia graminea*.

A cold-reacting N-like antibody (anti-Nf) has been described in certain patients undergoing renal dialysis, regardless of their MN group. Although it may cause confusion in cross-matching tests, anti-Nf is usually of little clinical importance, but has been reported to cause hyperacute renal graft rejection. Nf arises from the effects of minute amounts of formaldehyde (used to sterilize the dialyser coil) on the patient's red cells; these changed cells stimulate anti-Nf.

Anti-S, the rarer anti-s and anti-U are usually immune, IgG, and can cause HDN. They have also been implicated in HTRs. Anti-U only occurs in S–s– black people and reacts with all cells that have the S or s antigens and up to 50% of cells that are S–s–. Finding compatible blood for a patient with anti-U may prove difficult.

The Lutheran blood group system

Lutheran is a complex system comprising four pairs of allelic antigens: Lu^a and Lu^b, Au^a and Au^b, Lu6 and Lu9, Lu8 and Lu14. These represent single amino acid substitutions in the Lutheran glycoproteins. There are another 12 antigens of very high frequency. The incidence of Lu^a and Lu^b phenotypes in the UK population is as follows:

Lu(a+b–)   0.1%;
Lu(a+b+)   7.5%;
Lu(a–b+)   92.4%.

The rare Lu$_{null}$ phenotype, in which no Lutheran antigens are expressed, has three genetic backgrounds: (i) homozygosity for an inactive Lutheran gene; (ii) heterozygosity for an unlinked dominant suppressor gene, *In(Lu)*; and (iii) hemizygosity in males of a recessive X-linked suppressor gene, *XS2*. Only individuals with the recessive type completely lack the Lutheran glycoproteins and can make anti-Lu3.

Lutheran antibodies are uncommon and are not generally considered clinically significant, although anti-Lu^b may have caused mild delayed HTRs. Lu^a may be omitted from antibody screening cells.

The Lutheran glycoproteins bind the extracellular matrix glycoprotein laminin and might function as adhesion molecules.

The Kell blood group system

The Kell system consists of one triplet and four pairs of allelic antigens – K and k; Kp^a, Kp^b, and Kp^c; Js^a and Js^b; K11 and K17; K14 and K2 – all of which represent amino acid substitutions in the Kell glycoprotein, plus 11 high-frequency and three low-frequency antigens.

The incidence of the K/k phenotypes, the most important clinically, is as follows:

K+k–   0.2%;
K+k+   8.7%;
K–k+   91.1%.

K is rare in populations other than those of white people. Js^a is present in about 20% of black people, but is extremely rare in other ethnic groups. The very rare null phenotype of the Kell system, in which no Kell system antigens are expressed, is called K_o, and results from homozygosity for a variety of inactivating mutations in the *KEL* gene.

The Kell antigens are located on a glycoprotein of 93 kDa, which crosses the cell membrane once and has a large, glycosylated, C-terminal extracellular domain, maintained in a folded conformation by multiple disulphide bonds. Reduction of these bonds by 2-aminoethylisothiouronium bromide (AET) results in loss of expression of all Kell system antigens. The Kell glycoprotein has sequence and structural homology with a family of neutral endopeptidases that processes biologically important peptides. The Kell glycoprotein cleaves the biologically inactive peptide big endothelin-3 to produce endothelin-3, an active vasoconstrictor. Whether Kell performs this function *in vivo* is not known.

The Kell glycoprotein is linked by a single disulphide bond to the Kx protein, which is produced by an X-linked gene, *XK*. Absence of Kx protein, resulting from hemizygosity in males of a deletion of *XK* or *XK* inactivating mutations, gives rise to the McLeod phenotype, in which there is no expression of Kx antigens and weak expression of all Kell system antigens. This rare phenotype is also associated with McLeod syndrome (MLS), a neuroacanthocytosis that is usually characterized by late onset muscular, neurological and, occasionally, psychiatric disorders, and abnormally shaped red cells. In some cases, an X chromosome deletion is large enough to encompass *XK* and *CYBB*, a gene for a subunit of flavocytochrome b_{558}, which leads to MLS and chronic granulomatous disease (CGD). If boys with MLS and CGD are transfused, they are liable to make anti-Kx, which can cause severe HTRs and makes compatible blood very difficult to find. If possible, transfusion of these patients should be avoided.

Anti-K is an important antibody in white populations; it is nearly always immune, IgG and complement-binding. It has been the cause of severe HTRs and HDN. K antigen stimulates the formation of anti-K in about 10% of K-negative people who are given one unit of K-positive blood. This makes K the next most immunogenic antigen after D. About 0.1% of all cases of HDN are caused by anti-K; most of the mothers will have had previous blood transfusions. HDN caused by anti-K differs from Rh HDN in that anti-K appears to cause fetal anaemia by suppression or erythropoiesis, rather than immune destruction of mature fetal erythrocytes. Kell antigen is expressed by erythroid cells at a very early stage of erythropoiesis and anti-K probably facilitates immune destruction of early erythroid progenitors, before they become haemoglobinized. Anti-K is best detected by the IAT; anti-K does not always agglutinate red cells treated with enzymes, or suspended in low-ionic-strength solution.

Anti-k is a very rare antibody, which reacts with 99.8% of random blood samples. It is always immune and has been incriminated in some cases of mild HDN. Most other Kell system antibodies are rare and best detected by the IAT.

The Duffy blood group system

The allelic antigens Fy^a and Fy^b represent a single amino acid substitution in the extracellular N-terminal domain of the Duffy glycoprotein. Their incidence in the UK is as follows:

Fy(a+/−)   20%;
Fy(a+b+)   46%;
Fy(a–b+)   34%.

About 70% of African-Americans and close to 100% of West Africans are Fy(a–b–). They are homozygous for an Fy^b allele containing a mutation in a binding site for the erythroid-specific GATA-1 transcription factor, which means that Duffy glycoprotein is not expressed in red cells, although it is present in other tissues. The Duffy glycoprotein is the receptor essential for penetration of *P. vivax* merozoites into erythroid cells and the Fy(a–b–) phenotype confers resistance to *P. vivax* malaria. In West Africa, where other forms of malaria are common, *P. vivax* does not occur and it is tempting to speculate that the high incidence of Fy(a–b–) arose by natural selection when the parasite was previously prevalent. An identical GATA mutation is found in an Fy^a allele in Papua New Guinea, where *P. vivax* is endemic.

The Duffy glycoprotein (also called Duffy-Antigen Chemokine Receptor, DARC) is a red cell receptor for a variety of chemokines, including interleukin 8. It might function as a 'sink' or scavenger for the removal of unwanted chemokines.

Anti-Fy^a is not infrequent and is found in previously transfused patients who have usually already made other antibodies. It is IgG, often complement-fixing and can cause HTRs, but seldom HDN. It is best detected by IAT and does not react with

red cells treated with the proteases papain and ficin. Anti-Fy^b is very rare and is always immune.

The Kidd blood group system

Kidd has two alleles, *Jk^a* and *Jk^b*, which represent a single amino acid change in the Kidd glycoprotein. Phenotype frequencies in the UK population are as follows:

Jk(a+b−)   25%;
Jk(a+b+)   50%;
Jk(a−b+)   25%.

A Kidd-null phenotype, Jk(a−b−), results from homozygosity for inactivating mutations in the Kidd gene, *SLC14A1*. It is very rare in most populations, but reaches an incidence of greater than 1% in Polynesians.

The Kidd glycoprotein is a urea transporter in red cells and in renal endothelial cells.

Anti-Jk^a is uncommon and anti-Jk^b is very rare, but they may both cause severe transfusion reactions and, to a lesser extent, HDN. Kidd antibodies have often been implicated in delayed HTRs; they are IgG and predominantly complement fixing, but may be difficult to detect because they tend to disappear and then reappear promptly in anamnestic responses. The antiglobulin test is the best method for detection; reactions will be enhanced if the cells have been protease-treated or if fresh serum is added as a source of complement. Patients who have made Kidd antibodies should always be given an antibody card.

The Diego blood group system

Diego is a large system of 21 antigens: two pairs of allelic antigens – Di^a and Di^b, Wr^a and Wr^b – plus 17 antigens of very low frequency. All represent single amino acid substitutions in band 3, the red cell anion exchanger. The original Diego antigen, Di^a, is very rare in white and black people, but relatively common in Mongoloid people, with frequencies varying between 1% in Japanese and 50% in some native South Americans. Anti-Di^a and -Di^b are immune and rare, but can cause HDN. Wr^a has a frequency of about 0.1%. Its high-frequency allelic antigen, Wr^b, is dependent on an interaction between glycophorin A and band 3 for its expression. Naturally occurring anti-Wr^a is present in approximately 1% of blood donors. Anti-Wr^a is often found in the serum of patients who have made other antibodies or who are suffering from autoimmune haemolytic anaemia. Very rarely, anti-Wr^a causes HDN.

The Dombrock blood group system

The allelic antigens Do^a and Do^b represent a single amino acid substitution on the Dombrock glycoprotein, a member of the ADP-ribosyltransferase family, which also expresses the high-incidence antigens Gy^a, Hy and Jo^a. Approximately 66% of northern Europeans are Do(a+). Gy(a−) red cells are also Do(a−b−) Hy$^−$ Jo(a−). Dombrock antibodies are extremely rare, immune and are best detected by IAT; they have been implicated in severe acute and delayed HTRs. Anti-Do^a and -Do^b reagents are rare and unreliable, so Dombrock typing is most easily achieved by molecular methods.

The Colton blood group system

Co^a and Co^b represent a single amino acid substitution in the water channel aquaporin-1. Colton phenotype frequencies in white people are:

Co(a+b−)   90.5%;
Co(a+b+)   9.0%;
Co(a−b+)   0.5%.

The extremely rare Colton-null phenotype, Co(a−b−), results from homozygosity for inactivating mutations in the Colton gene, *AQP1*.

Colton antibodies are very uncommon. Anti-Co^a has caused severe HDN, and has been implicated in acute and delayed HTRs.

Some other blood group systems

Yt^a and Yt^b of the Yt system represent a single amino acid change in red cell membrane acetylcholinesterase. Yt^a and Yt^b have frequencies of about 99.8% and 8% respectively. Anti-Yt^a and Yt^b are exceptional and most are of no clinical significance.

The Scianna system consists of five antigens: the allelic antigens Sc1 and Sc2 of high and low frequency respectively; the high-frequency antigens Sc3 and STAR; and the low-frequency antigen Radin (SC4). They are located on the adhesion protein ERMAP. Scianna antibodies are very rare and little is known of their clinical significance.

The Xg system comprises two antigens, Xg^a and CD99, encoded by separate, but homologous genes on the X chromosome; *CD99* is also expressed on the Y chromosome. The corresponding antibodies are rare and of no clinical significance.

The eight antigens of the Gerbich system – three of high frequency and five of low frequency – are located on glycophorins C and D, which are encoded by a single gene, *GYPC*. The 12 antigens of the Cromer system and eight antigens of the Knops system are carried on the complement regulatory glycoproteins decay accelerating factor (CD55) and complement receptor 1 (CD35) respectively. Antibodies of these three systems are not generally considered clinically significant. However, antibodies of the Knops system are relatively common and often obscure identification of other, clinically important antibodies, in the same serum. Once identified, Knops antibodies can be ignored from a clinical point of view.

Antigens with high or low frequency

There are many other antigens, of either very high or very low incidence, that have not been assigned to blood group systems. Anti-Vel, -Lan, -At[a], -AnWj and -MAM are examples of antibodies to high-frequency antigens (HFAs) that have caused HDN and/or HTRs. For those rare individuals who have formed antibodies to HFAs, the provision of compatible blood can be a problem; it is often necessary to approach the national or international panels of rare donors for compatible units.

Antibodies to low-frequency antigens (LFAs) are usually naturally occurring; they may occasionally give rise to unexpected incompatible cross-matches. Some antibodies to LFAs have caused HDN.

Polyagglutinable red cells

Erythrocyte polyagglutination is the agglutination of red cells irrespective of blood group by many sera from normal adults. Polyagglutinable red cells are not agglutinated by the patient's own serum. The abnormality is a property of the red cells, not of the sera, in contrast with panagglutination, which is the agglutination of most red cells by one serum.

There are two main categories of polyagglutination, acquired and inherited. The acquired forms can be subdivided into: (i) microbial, due either to the passive coating of red cells with bacteria or their products or to the action of microbial enzymes on red cell surface oligosaccharides (T, Tk, acquired B); and (ii) non-microbial, which is caused by somatic mutation (Tn). There are four types of inherited polyagglutination: Cad (a strong expression of Sd[a]), congenital dyserythropoietic anaemia type II (CDAII or HEMPAS), NOR and Hyde Park. Lectins are required for the diagnosis of the different types of polyagglutination (Table 15.12).

T activation

T activation occurs transiently in some patients with an obvious microbial infection, especially *Vibrio cholerae*, *Clostridium perfringens*, *Diplococcus pneumoniae*, various streptococci and the influenza virus. These microbes produce sialidases, which remove sialic acid (*N*-acetylneuraminic acid, NANA) from the oligosaccharides of membrane sialoglycoproteins (Table 15.13) to expose the hidden T antigen (galactose linked to *N*-acetylgalactosamine), with an accompanying loss of negative surface charge. For T polyagglutination to occur, microbial sialidases must be present in sufficient quantity to neutralize the enzyme inhibitors normally present in plasma; the same is true for other forms of enzymic polyagglutination.

Most adult sera contain naturally occurring, cold-reacting, complement-fixing, IgM anti-T. Most cases of T activation are detected by the discrepancy in results of cell and serum ABO grouping. The correct ABO group can be obtained from tests at 37°C.

T polyagglutination may be associated with (i) haemolytic anaemia, (ii) haemolytic transfusion reactions (especially in children) caused by anti-T in transfused plasma, although this is still questionable, (iii) haemolytic uraemic syndrome and (iv) neonatal necrotizing enterocolitis.

Peanut lectin, *Arachis hypogaea*, is the most effective tool for identification of T -activated cells (Table 15.12).

Tk activation

Tk activation, like T activation, is transient and associated with infection. Endo-β-galactosidases produced by *Bacteroides fragilis*, various clostridia or *Candida albicans* remove β-galactose from ABH polysaccharide chains, exposing *N*-acetylglucosamine (Tables 15.7 and 15.13), with the consequent depression of ABH expression, without affecting the quantity of sialic acid on the red cell. Tk cells are specifically agglutinated by BSII lectin,

Table 15.12 Some characteristics of T, Tk, Tn and Cad polyagglutinable red cells.

	T	Tk	Tn	Cad
MN antigens	↓	Normal	↓	Normal
ABH antigens	Normal	↓	Normal	Normal
Most normal sera	+	+	+	+
Glycine soja lectin	+	−	+	+
Arachis hypogaea lectin	++	+	−	−
Bandeiraea simplicifolia lectin	−	+	−	−
Salvia sclarea lectin	−	−	+	−
Dolichos biflorus lectin (other than group A$_1$)	−	−	+	+
Polybrene* solution	−	+	+mf	+

*Polybrene is a positively charged polymer that agglutinates cells with a negative charge and fails to aggregate sialic acid-deficient cells.

↓, reduced reactivity of MN or ABH antigens; mf, mixed field.

Table 15.13 Structure of T, Tn and Tk antigens.

O-linked oligosaccharide of GPA and GPB	
NeuNAcα2→3Galβ1→3GalNAc–Ser/Thr	Normal
6

A-, B- or H-active chains modified by endo-β-galactosidase	
GlcNAcβ1→3Galβ1→4GlcNAc–R	Tk

Gal = galactose; GalNAc = *N*-acetylgalactosamine; GlcNAc = *N*-acetylglucosamine; NeuNAc = *N*-acetylneuraminic acid (sialic acid); R = remainder of molecule; Ser/Thr = serine or threonine.

an extract from *Bandeiraea simplicifolia* (Table 15.12). These cells are also agglutinated by peanut lectin, probably due to the exposure of galactose, the next sugar in the chain.

Tn activation

Tn activation, unlike T and Tk, is a persistent abnormality caused by an abnormal clone of stem cells arising by somatic mutation. Tn is often associated with other haematological abnormalities, such as chronic haemolytic anaemia, leucopenia or thrombocytopenia, but may be present in healthy individuals. Somatic mutation leads to a deficiency of the galactosyltransferase that elongates the O-linked oligosaccharides on GPA, so that many of the O-glycans consist of only *N*-acetylgalactosamine, the immunodominant sugar of Tn (see Table 15.13). This loss results in a depression of M and N antigens, a loss of sialic acid and a negative charge similar to that found in T activation. Only some of the red cells are agglutinated by the anti-Tn present in all normal adult sera, giving a mixed field appearance in agglutination tests. Platelets also show two populations. *Salvia sclarea* lectin specifically agglutinates Tn-activated cells, and the exposed *N*-acetylgalactosamine molecules can be detected with *D. biflorus* lectin (but only in people who are not group A_1).

White cell and platelet antigens and antibodies

HLA and transfusion

The HLA system is covered in Chapter 23. Leucocyte reactive antibodies have in the past been reported, albeit transiently, in up to 96% of massively transfused patients. Complement-fixing lymphocytotoxic antibodies have been found in as many as 50% of patients receiving multiple transfusions of platelet concentrates over a 4-week period. This frequency is lower in immunosuppressed patients. In contrast, some patients never become HLA immunized, despite repeated transfusions, and are considered to be non-responders to HLA. Pregnancy can lead to HLA antibodies in approximately 15%, 25% and 35% of women after a first, second or third pregnancy respectively. Such antibodies are generally of class I specificity, with anti-HLA-B being approximately twice as prevalent as HLA-A antibodies.

HLA antibodies stimulated by pregnancy or transfusion are usually IgG, complement fixing; naturally occurring IgM antibodies produced without a known stimulus, usually HLA-B8 specific, can be found in about 1% of individuals. The clinical importance of HLA antibodies relates to their ability to mediate graft rejection. In pregnant women, IgG antibodies may cross the placenta but are not considered to be a cause of neonatal leucopenia or thrombocytopenia. HLA antibodies are the usual cause of immunological refractoriness to random donor platelet transfusions, but not all patients with HLA antibodies are refractory to platelet transfusions, and a small proportion of immunologically refractory patients have no detectable lymphocytotoxic antibodies. The management of patients who become immunologically refractory to platelet transfusions is described in Chapter 16.

Neutrophil-specific antigens and antibodies

Neutrophils carry not only class I HLA antigens, but also neutrophil-specific antigens, as shown in Table 15.14. The antibodies showing specificity to the following antigens are clinically important in: (i) alloimmune neonatal neutropenia (HNA-1a, -1b, -1c, -2a, -3a, -4a); (ii) febrile transfusion reactions (HNA-1a, -1b, -2a, and other unidentified antigens on FcRIIIb and CD18); (iii) transfusion-related acute lung injury, caused by the passive transfer of granulocyte-specific antibodies in donor plasma (HNA-1a, -1b, -2a, -3a, NB2, though less frequently than HLA); and (iv) autoimmune neutropenia, in adults or in infancy (ND and NE have only been defined by autoantibodies). The antigens of the HNA-1 system are expressed on neutrophil FcRIIIb.

In addition, neutrophils express polymorphic antigens that also occur on endothelial cells (EM antigens), monocytes (HMA antigens), monocytes plus lymphocytes (HNA-4, HNA-5), and granulocytes and lymphocytes (SL).

Working with granulocytes is cumbersome and typing, as well as antibody screening, should be left to specialized laboratories. The techniques used to detect neutrophil antigens and antibodies include EDTA-dependent granulocyte agglutination, immunofluorescence, cytotoxicity, opsonization, chemiluminescence, radioactive antiglobulin tests and the use of staphylococcal protein A. Of these, granulocyte agglutination and immunofluorescence antiglobulin techniques are the most widely

Table 15.14 Neutrophil antigens.

System	Antigen	Previous names	Frequency (%)*	Glycoprotein	Amino acid change
HNA-1	HNA-1a	NA1	61.2	FcγIIIb	Arg36, Asp65, Asp82, Val106

used; each can detect a different range of antigen specificities and both techniques should be used in parallel when investigating samples for neutrophil antibodies. Both techniques will detect HLA antibodies, including non-complement fixing ones that are not detectable by the lymphocytotoxicity test (LCT).

The discrimination of granulocyte-specific antibodies from granulocyte-reactive antibodies such as anti-HLA, which also react with other leucocyte subsets, requires access to large panels of HLA-typed granulocytes and lymphocytes, the application of tests that detect non-complement-fixing lymphocyte-binding antibodies (e.g. immunofluorescence by flow cytometry) and monoclonal antibody capture assays, known as MAIGA (monoclonal antibody immobilization of granulocyte antigens).

Neutrophil antibodies can be found in as many as 3% of pregnant women, especially if their serum is tested against their partner's neutrophils. However, neonatal alloimmune neutropenia is very rare and, as expected, associated with the presence of potent IgG antibodies. Neutrophil autoantibodies are also usually IgG, although some cold-reacting IgM antibodies have also been reported; these may be cytotoxic. Soluble IgG-containing immune complexes, rather than granulocyte-binding (auto)antibodies, may cause the neutropenia associated with Felty's syndrome. Autoimmune neutropenia may also be caused by antibodies that prevent neutrophil precursor maturation, rather than by destroying mature neutrophils and some drug dependent antibodies may also act by binding to neutrophil precursors.

Platelet-specific antigens and antibodies

Platelets carry ABH, Lewis, li and P antigens, as well as HLA class I and several so-called platelet-specific antigens. The HLA class I antigens are predominantly HLA-A and HLA-B; HLA-C is only weakly expressed on platelets. In some individuals, HLA-A and HLA-B are barely, or not at all, detectable on the platelet surface. HLA antibodies are the single most important cause of immunological refractoriness to random donor platelet transfusions although platelet-specific antibodies occur in 3–9% of cases, usually in association with HLA antibodies, and are also responsible for post-transfusion purpura (PTP) and neonatal alloimmune thrombocytopenia (NAIT) and, very occasionally, febrile transfusion reactions.

Over 20 antigens have been described as platelet specific, some of which are shown in Table 15.15. These include the antigens of the various HPA (human platelet antigen) systems, which are composed of a high-incidence 'a' allele (e.g. *HPA-1a*) and a low-incidence 'b' allele (*HPA-lb*).

Some of the HPA antigens are not truly platelet specific; the HPA-l antigens are also found on endothelial cells, which might contribute to the severity of NAIT and PTP caused by anti-HPA-1a. The HPA-5 antigens have been described on activated T cells and probably also on endothelial cells, on the very late antigen-2 (VLA-2) membrane protein.

The genetic location of the HPA alleles is known for all of the HPA systems. All represent single nucleotide polymorphisms (SNPs) encoding amino acid substitutions at different positions on the platelet glycoproteins GPIIIa, GPIb, GPIIb and GPIa (Table 15.15); except HPA14w, which is a frameshift deletion. Typing for platelet antigens by serology is difficult: sera with appropriate specificity are rare, usually contaminated by HLA antibodies, and generally lack the adequate potency required for reliable typing. However, serology can now be replaced by PCR-based DNA typing methods.

Three alternative strategies for PCR typing have been widely used. In the first, restriction fragment length polymorphisms (RFLP), the relevant HPA genes are amplified with appropriate primers, and the alleles encoded subsequently discriminated with allele-specific restriction enzymes. The restriction enzymes are chosen for their ability to recognize the nucleotide sequence of one of the two alleles and to cleave the PCR-amplified DNA product of that particular allele. The length of the DNA fragments produced on cleavage by the enzymes are analysed by polyacrylamide gel electrophoresis, and the observed RFLP determines which of the two alleles was present. This approach is also known as PCR-ASRE (allele-specific restriction enzyme) typing.

†In Japan.

In PCR with sequence-specific oligonucleotides (SSO), the amplified DNA is blotted onto nylon membranes, then hybridized with SSO probes under conditions of sufficiently high stringency to allow only the SSO probes complementary to the amplified allele to bind. The bound probe can then be detected with immunoenzyme conjugates, which recognize haptenylated deoxyribonucleotides incorporated into the SSO probes, or by autoradiography if ^{32}P-labelled probes are used. In PCR SSP, allele sequence-specific primers are used to amplify individual alleles and the PCR product is visualized after electrophoresis through agarose and staining with ethidium bromide. All three PCR typing methods use DNA extracted from lymphocytes, as platelets, being anucleate, lack DNA. Alternatively, platelet mRNA can be converted to cDNA with reverse transcriptase before PCR amplification.

Serological techniques for platelet antibody detection in patients' sera include the platelet suspension immunofluorescence test (PSIFT, the 'gold standard' recommended for routine platelet serology), solid-phase technology and an antigen-capture ELISA technique known by the acronym MAIPA (monoclonal antibody-immobilization of platelet antigens). In the PSIFT, HPA-typed platelets are incubated with the patient's serum, washed, and any bound immunoglobulin detected with a fluorescent anti-Ig conjugate is visualized by ultraviolet microscopy or flow cytometry. In the solid-phase method, platelets are anchored onto the bottom of U-well microtitre plates by a polyclonal rabbit–anti-human platelet serum. Following incubation with the patient's serum, platelet-bound IgG is subsequently detected using anti-human IgG-coated indicator red cells.

In the MAIPA assay, donor platelets are incubated successively with the patient's serum and a mouse monoclonal antibody that recognizes a specific platelet membrane glycoprotein complex (e.g. anti-GPIIb-IIIa, anti-GPIa-IIa or anti-GPIb-IX),

and then solubilized in a mild detergent such as Triton X-100. Immune complexes in the resulting supernatant are captured into the wells of an ELISA plate coated with goat–anti-mouse IgG. Any human antibody present in a captured monoclonal antibody–platelet glycoprotein trimolecular complex is detected with an anti-human Ig ELISA conjugate.

Other techniques that have been used for platelet serology, although much less frequently, include platelet agglutination, the platelet radioactive antiglobulin test, ELISA, ^{51}Cr release, monocyte chemiluminescence and complement fixation.

The platelet antibody specificity that most frequently causes PTP is anti-HPA-la, found in 85% of cases; anti-HPA-1b has been reported in 5% and anti-HPA-3a in 7% of cases in Europe. Similarly, anti-HPA-la is the most common cause of NAIT, having been reported in 80% of HPA-1a-negative mothers at the time of birth of an affected infant. Anti-HPA-5b has been found in 15% of NAIT cases, as have occasional examples of anti-HPA-lb and HPA-3a, in HPA-la-positive mothers in Europe. Approximately 85% of babies affected by NAIT are born to HPA-1a-negative mothers, making anti-HPA-la the major implicated antibody specificity.

Cross-matching for immunologically refractory patients

The major cause of immunological refractoriness to platelet transfusion is, by far, the presence of HLA-A and/or HLA-B antibodies in multitransfused patients. Quite often, such antibodies are found to react with the lymphocytes from the majority (and sometimes all) of the donors included in the panel. Platelet-specific antibodies may occur in 3–9% or less of refractory patients. Implicated specificities have included anti-HPA-la and anti-HPA-1b, as well as anti-HPA-3a, anti-HPA-2b, HPA-15b, and in this setting platelet-specific antibodies are usually accompanied by HLA antibodies.

Management of immunological refractoriness can often be accomplished by transfusion of platelets obtained by apheresis from HLA-matched donors. Some degree of mismatching of donor–recipient phenotypes may be permissible. 'HLA-B-matched' platelets, which differ by one or more antigens (Bl to B4 matches) within a serologically cross-reactive group of HLA-A or -B antigens, can often provide satisfactory increments in platelet counts; for example, by transfusing platelets from an HLA-A1-A1l-B8-B27 donor to an Al-A1l-B8-B7 patient (B7 and B27 are cross-reactive). The best matched platelets are theoretically from 'A-matched' donors, who do not express any HLA-A or -B antigens that are not present on the recipient's lymphocytes. Donors with apparently 'homozygous' HLA phenotypes (e.g. Al-X-B8-X) can often provide 'A-matched' platelets for a variety of recipients (e.g. Al-A2-B8-B44) who have an HLA haplotype in common with the homozygous donor. All matched donor platelets must be gamma irradiated before transfusion to prevent potentially fatal graft-versus-host disease.

Because the provision of HLA-matched platelets is an extremely expensive service, it is strongly recommended that their use is properly justified by taking post-transfusion platelet counts 1 h or 24 h after transfusion. If HLA-matched, cross-match (LCT or solid phase) compatible platelets still do not provoke satisfactory increments and the presence of platelet-specific antibodies has been excluded, then it is recommended to revert to the transfusion of platelets from random donors. In immunological refractoriness to platelet transfusions, the provision of HLA-matched platelets may not be sufficient per se for obtaining satisfactory post-transfusion platelet increments; it could be that a previously unrecognized HLA specificity, detectable by cross-matching the donor's lymphocytes by LCT, might be present, or that platelet-specific antibodies might be involved. If a patient does not show good increments when transfused with HLA-matched platelets that gave negative LCT cross-matches, then cross-matching the donor's platelets by a method such as the solid-phase technique could prove valuable in selecting compatible donors.

Plasma protein antigens and antibodies

Many components of human plasma can be antigenic when whole blood or plasma is transfused. Problems associated with such antibodies represent one of the less well-investigated areas in blood transfusion. Urticarial reactions following the transfusion of blood or plasma components are not infrequent, although the culprit proteins are only rarely disclosed and are most likely to be ingested haptens present in donor plasma (e.g. chocolate, drugs). Quite often the antibodies causing the reactions are IgE. Antibodies to factor VIII are not known to cause transfusion reactions, although they will cause inhibition of the activity of transfused factor VIII. Antibodies to IgA can lead to serious anaphylactic reactions. Antibodies to IgG determinants may cause problems in blood grouping, but their role in transfusion reactions is debatable.

Gm antigens are polymorphic antigens on the heavy chains of IgG (γ-chains), present mainly on the Fc fragment, although a few are on the Fd fragment. There are many different Gm antigens and they are inherited in haplotypes. IgG myeloma proteins have shown that different Gm antigens are associated with different IgG subclasses (e.g. IgG1 can carry four different Gm determinants, whereas IgG3 can carry 13 and IgG4 none).

Typing for Gm antigens is carried out with test serum to inhibit the agglutination of red cells coated with selected IgG Rh antibodies, of known Gm status, by Gm-specific antibodies.

Gm antibodies are found in: (i) the sera of patients with rheumatoid arthritis; (ii) the sera of women who have been pregnant; (iii) children between the age of 6 months and 5 years who are Gm incompatible with their mothers' IgG; and (iv) some normal adults. Gm antibodies are of no significance in transfusion medicine.

Clinical blood transfusion

16

Marcela Contreras, Clare PF Taylor and John A Barbara

Introduction

This chapter describes pretransfusion testing of the recipient's blood, complications and adverse effects of blood transfusion, appropriate use of components and, finally, a description of the features of haemolytic disease of the newborn. The first section deals with aspects of blood donation and collection, and the preparation and storage of blood components.

The blood donor (Tables 16.1 and 16.2)

Blood donation shall in all circumstances be voluntary. Financial profit must never be a motive for the donor or for those collecting the donation.

These statements sum up the attitude of the World Health Organization and the International Society of Blood Transfusion towards the principle of blood donation. However, in a number of countries worldwide, whole blood donation and apheresis plasma donation are remunerated. There are data suggesting that the microbiological safety of donations from paid donors is inferior, and stringent post-donation testing and viral inactivation are required to enhance blood safety.

In general, blood donors should be healthy adults between the ages of 17–18 and 65–70 years. These age limits vary slightly worldwide, but a lower limit is set to take account of the high iron requirements of adolescence. An upper limit is necessary because with age there is an increase in medical conditions that might make blood donation more hazardous, and increase the

Table 16.1 Measures to protect the donor.

Age 17–70 years (60 at first donation)

Weight above 50 kg (7 st 12 lb)

Haemoglobin > 13 g/dL for men, 12 g/dL for women

Minimum donation interval of 12 weeks (16 weeks advised) and
   three donations per year maximum

Pregnant and lactating women excluded because of high iron
   requirements

Exclusion of those with:
   Known cardiovascular disease, including hypertension
   Significant respiratory disorders
   Epilepsy and other CNS disorders
   Gastrointestinal disorders with impaired absorption
   Insulin-dependent diabetes
   Chronic renal disease
   Ongoing medical investigation or clinical trials

Exclusion of any donor returning to occupations such as driving
   bus, plane or train, heavy machine or crane operator, mining,
   scaffolding, etc. because delayed faint would be hazardous

Table 16.2 Conditions in the donor that lead to deferral.

All potential donors provided with information, so those at risk of HIV through lifestyle will refrain from donation (sexual practices, piercing, tattooing)

Donors with history of hepatitis deferred until 12 months after recovery

Exclusion of all potential donors who have themselves received a blood transfusion (due to risk of third party vCJD transmission)

Exclusion of those who have received pituitary-derived hormones or cadaveric dura mater or corneal grafts, and those with family history of CJD

Exclusion of those whose travel history places them at risk of malaria, Chagas' disease (unless antibody test available) and SARS

Permanent exclusion of any donor who has had filariasis, bilharzia, yaws or Q fever

Exclusion for varying time periods following vaccinations

Exclusion after known exposure to infectious illnesses such as varicella

Exclusion of anyone with a malignant condition except fully excised BCC of skin

Exclusion of those with diseases of unknown origin, e.g. Crohn's disease

Donor deferral for most drugs based on the underlying illness, e.g. cardiovascular, diabetes, malignancy, anaemia

Exclusion of those taking teratogenic drugs or those that accumulate in the tissues

probability that coincidental accidents may be attributed to the act of giving blood. Pregnant and lactating women are not accepted as donors of allogeneic blood, again because of high iron requirements.

As donors should be fit, healthy individuals, no donations should be accepted from those who have ever suffered from cancer, diabetes, or heart or kidney disease. Those with severe allergic disorders should not give blood because recipients may develop temporary hypersensitivity reactions due to passively transfused antibodies.

Minor red cell abnormalities

Donors with minor red cell abnormalities, such as thalassaemia trait, sickle cell trait and hereditary spherocytosis, are perfectly acceptable, providing that the haemoglobin (Hb) screening test excludes anaemia. Red cells containing HbS have a limited survival under conditions of reduced oxygen tension and so should not be transfused to newborn infants and patients with hypoxia or sickle cell disease. Red cells with HbS obstruct leucodepletion filters and it is therefore advisable, in the UK, to defer such people from blood donation. Blood from donors with G6PD deficiency survives normally, unless the recipient is given oxidant drugs.

Volume of blood taken

Modem blood collection packs are designed to hold 450 ± 45 mL of blood, mixed with 63 mL of citrate–phosphate–dextrose–adenine (CPD-A) anticoagulant. The ratio of anticoagulant to blood must be maintained at the optimal level, and donations of less than 405 mL or more than 495 mL of blood should not be issued for clinical use. Healthy donors can generally withstand the loss of 450 mL of blood without any ill effect, but vasovagal reactions become more common in those who weigh less than 47.5–50.0 kg (105–110 lb), as the standard donation represents a greater proportion of their total blood volume. In some countries, such as China and Japan, 'underweight', otherwise healthy, donors may donate smaller volumes (250 mL) of blood into specially designed packs containing the appropriate volume of anticoagulant. In several countries, including the UK, double doses of red cells are collected by apheresis from suitable large donors; such units are very useful to decrease donor exposure in multitransfused patients such as those with β-thalassaemia major.

Haemoglobin estimation

A test to exclude anaemia is performed before donation. A convenient and widely used method depends upon the specific gravity of a drop of blood, obtained by means of a finger prick. An estimate of the Hb value can be made, depending upon whether the drop of blood sinks in a copper sulphate solution of known specific gravity. The standard for male donors is generally a solution of specific gravity 1.055, approximating to a Hb level of 13.0 g/dL. The equivalent for females is 1.053 (Hb of 12.0 g/dL), although lower limits have been introduced in some countries. The copper sulphate method tends to underestimate the Hb value and may lead to unnecessary rejection of donors. However, the specific gravity of whole blood does not depend solely upon the Hb content of red cells and a pathological rise in plasma protein level or total white cell count (e.g. myeloma, chronic myeloid leukaemia) may lead to an anaemic donor passing the Hb test. Many transfusion services use an additional method of Hb determination on donors who fail the copper sulphate test, or as an alternative screening test. A relatively inexpensive portable haemoglobinometer can reduce the number of unnecessary rejections by up to 30%.

Donation intervals

A donation of 450 mL of blood contains approximately 200 mg of iron, which is lost to the body. Studies have shown depletion of iron stores in those who give three or four blood donations per year, but overt iron deficiency anaemia is uncommon except in female donors of childbearing age. In general, donors are bled two or three times per year in the UK (minimum interval 16 weeks), but some donors are able to donate more frequently without any significant iron depletion. When it is standard

practice to take donations at shorter intervals, appropriate monitoring and/or iron supplements are recommended. However, this is not a major problem in the UK, where the average annual donation rate is less than 1.5.

Hazards of blood donation

The most common hazard of blood donation is fainting, reported in between 2% and 5% of all donors, but being especially common in young people and in those donating for the first time, particularly if they are nervous or apprehensive. A sympathetic approach by blood collection staff, enforcement of an adequate rest period, and constant vigilance to detect warning signs of an impending vasovagal attack can help to avert this problem. Once a faint occurs, the standard treatment of rest in a horizontal position and elevation of the legs is usually sufficient. Delayed faints occurring after a donor has left the clinic are potentially hazardous and a contraindication to further donation. For this reason, those donors who are drivers, machine operators, scaffolders and so on should not return to work on the day of donation. Infection of the venepuncture site should be avoided by meticulous attention to skin cleansing and aseptic techniques. All blood collection packs are manufactured as integral sets, each needle is sterile, to be used only once. No pack should be reused (even on the same donor) if the initial venepuncture attempt fails. Bruising of the arm may occur, particularly when venous access has been difficult; firm pressure over the site for 2–3 min and an explanation to the donor are usually sufficient. In the very rare event of arterial puncture, elevation of the limb and firm pressure over the site for 10–15 min should be combined with prolonged rest if a whole donation has been taken, as the rate of blood donation under such circumstances is usually very rapid. Very occasionally, attempted venepuncture may result in trauma to the nerves in the arm, resulting in pain, paraesthesiae and numbness. Such symptoms generally resolve in a few days, but very rarely may take several months of recovery.

Hazards of allogeneic blood transfusion

A number of diseases have the potential to be transmitted by transfusion of blood or its components. Donor selection criteria and subsequent testing of all donations are designed to prevent such transmission (Table 16.3).

The viruses that pose the greatest potential risk for transmission by transfusion are those that have long incubation periods (often causing subclinical infection), and especially those that may be carried by asymptomatic individuals for many years, or even lifelong. Alternatively, some viruses that are transfusion tranmissible exhibit cell-associated latency. If the virus is latent in white blood cells, recrudescence of that virus stimulated by allogeneic transfusion can cause infection of the recipient.

More rarely, a few viruses causing acute infection can be transmitted in the short presymptomatic viraemic phase if this

Table 16.3 Measures to protect the recipient.

Donor selection
Donor deferral/exclusion
Microbiological testing of donations
Immunohaematological testing of donations
Stringent arm cleansing
Diversion of the first 20–30 mL of blood collected
Leucodepletion of cellular products
Post-collection viral inactivation steps, e.g. MB or SD treatment
Monitoring and testing for bacterial contamination
Pathogen inactivation, e.g. using psoralen technology
Safest possible sources of donors for plasma-based products

coincides with the time of blood donation. Such agents pose a risk only if recipients have not been previously infected and donors have become infected after visiting endemic countries.

Bacteria, especially skin contaminants and blood-borne parasites, are also potentially transmissible by blood transfusion.

The key transfusion transmissible agents are summarized in Table 16.4.

Hepatitis viruses
Donors with a history of hepatitis are deferred for 12 months.

When serum from an individual with hepatitis B virus is ultracentrifuged and examined with the electron microscope, three types of particle may be seen. The large (42-nm diameter) Dane particle is the actual virus with its central nucleocapsid core, which has its own antigenic constituent HBc. The core contains partially double-stranded DNA and DNA polymerase, and is surrounded by a lipoprotein coat carrying the surface antigen (HBsAg). The other two types of particles are 20-nm rods and spheres and represent overproduction of surface antigen material. The HBe antigen is in soluble form and is present in the incubation period, during acute infection and during the first years of the carrier phase. HBeAg is a marker of high infectivity. Dane particles are very rare in the plasma of low-infectivity carriers.

All donations are tested for the presence of hepatitis B surface antigen (HBsAg) by sensitive enzyme-linked immunosorbent assays (ELISAs) that can detect at least 0.2 IU/mL of HBsAg.

Hepatitis C virus (HCV) is recognized as the cause of the majority of cases of what was previously known as non-A non-B (NANB) hepatitis. Although electron microscopic visualization of HCV has not been verified, its genome has been cloned and ELISAs have been developed in which cloned and/or synthetic peptides can react with antibody to HCV.

Individuals with a history of jaundice may be accepted as donors, provided that they have been shown to be negative for markers of HBV and HCV. Clinical jaundice may be due to causes other than hepatitis B and C, including non-viral causes; also the majority of donors who are positive for HBsAg have no such history, so there is no sense in rejecting all people who give

Table 16.4 Transfusion-transmissible agents.

Agents		Characteristics related to transfusion
Viruses		
Hepatotropic	HAV	Very rarely transfusion transmitted; no carrier state; faecal-oral transmission
	HBV	2- to 6-month incubation period; carrier state; readily transmissible by blood
	HCV	Majority of cases asymptomatic; carrier state; readily transmissible by blood
Retroviruses	HIV1 and HIV2	Carrier state and latent in WBCs; readily transmissible by blood
	HTLV-I and HTLV-II	Latent in WBCs
Herpesviruses	CMV	50% UK adults have been infected; latent in WBCs
	EBV	Most UK adults have been infected (therefore already exposed pretransfusion); latent in WBCs
Others	Parvovirus B19	Generally mild or asymptomatic, posing no transfusion risk except for non-immune aplastic anaemia patients and fetuses
		Approximately two-thirds of UK adults have been infected
		Seasonal variation (and epidemic years) in incidence rate
	West Nile virus	Recently exhibiting epidemic rates of transmission in summer months in North America
Bacteria		
Endogenous	*Treponema pallidum*	Inactivated by storage at 4°C
		No transfusion transmissions reported in the past 15 years
	Yersinia enterocolitica	Very occasional transmissions, usually contaminated red cells transfused late in the storage period
Exogenous	For example, *Staphylococcus epidermidis; micrococcus, sarcina*	Mainly skin commensals or contaminants
		Most common cause of platelet contamination
Parasites	Malaria	Only five verified transfusion cases reported in UK in 25 years (all *Plasmodium falciparum)*
	Chagas' disease	No transmission of *Trypanosoma cruzi* by transfusion has been reported in UK
Prions	Abnormal PrP	Possible transfusion risk from vCJD; two UK cases potentially transfusion transmitted

a history of clinical jaundice. In the UK, the incidence of HBsAg in first-time blood donors is approximately 1 in 2000 and in established donors (i.e. new infections) less than 1 in 100 000. Hepatitis B surface antigen-positive subjects are permanently excluded from donation, and should be under specialist follow-up, as they have an increased risk of developing chronic liver disease and hepatocellular carcinoma.

Although the transmission of hepatitis B by blood and blood components has been virtually eliminated, HBsAg testing will not exclude all donors capable of transmitting HBV, as the sensitivity of presently available techniques may allow as many as 10^4–10^6 HBV genome copies per millilitre of plasma to remain undetected. The introduction of screening for anti-HBc and/or HBV DNA would reduce the very low risk of transmission of HBV yet further, but is not justified in the UK because of the striking rarity of reports of post-transfusion hepatitis B in recent years.

In the USA, before screening for anti-HCV was introduced, about 10% of transfusions caused significant increases in transaminase activity in recipients. There were also occasional cases of symptomatic hepatitis. Acute HCV infection is usually mild, but a proportion of patients do develop chronic liver disease, with a risk of hepatocellular carcinoma. Confirmed rates of HCV positivity in the UK are 1 in 2000 for new donors and < 1 in 100 000 for repeat donors. Methods of heat inactivation and solvent–detergent treatment of factors VIII and IX prevent transmission of HCV. Haemophiliacs who have received effectively inactivated factor VIII have proved negative for anti-HCV, in contrast with those who received untreated concentrate.

Hepatitis A virus is rarely transmitted by transfusion. Any donor who has been in close contact with a case (e.g. household contact), or developed hepatitis A is deferred for 12 months.

Human immunodeficiency virus (HIV-l and HIV-2)

The classical descriptions and the vast majority of the literature on AIDS refer to HIV-1; a second retrovirus capable of causing AIDS, HIV-2, mainly occurs in West Africa.

Human immunodeficiency virus (HIV) can be transmitted both in cellular and plasma components. Most of the patients infected by the transfusion of blood components were transfused before the introduction of the screening of blood donations for HIV antibodies. The majority of recipients of blood products who were infected in the past were transfused before 1985 with unheated, non-pasteurized pooled plasma products, mainly factor VIII and factor IX. Thus, HIV infection became an important sequel to transfusion of factor VIII concentrates to haemophiliacs in the early 1980s, before the introduction of heat treatment and other viral inactivation methods. HIV is more heat labile than HBV, especially when in solution. Prolonged heat treatment and other viral inactivation methods of plasma products are effective means of protecting haemophiliacs from infection, although too late for those who were receiving regular factor VIII therapy in the late 1970s and early 1980s.

Albumin solutions are pasteurized, and carry no risk of HIV transmission. Similarly, i.m. immunoglobulin preparations are rendered safe from HIV infectivity by their manufacturing processes.

Blood and all fresh blood components (platelets, white cells, single donor plasma, fresh-frozen plasma and cryoprecipitate) are capable of transmitting HIV. Certain behaviour patterns place individuals at greater risk of HIV infection. Accordingly, male homosexuals and bisexuals, intravenous drug users and prostitutes are permanently deferred from blood donation. The sexual partners of such individuals and of haemophiliacs treated with blood products are also excluded. In addition, large areas of sub-Saharan Africa and South-East Asia have a high incidence of HIV seropositivity in the general population. Inhabitants of these areas and their partners are also considered to be at greater risk of HIV infection than heterosexual non-drug users in other areas of the world. Donor education and encouragement of those whose behaviour may have exposed them to HIV to exclude themselves from blood donation are highly cost-effective methods for the prevention of transmission of HIV infection by blood transfusion. Systems for donor deferral should continue to be in place, even in the presence of sensitive assays for the detection of infectious donors.

In most HIV-infected subjects, antibody develops within 3–4 weeks and it coexists with the virus thereafter. Hence, HIV seropositivity is an indicator of infectivity. The tests that lend themselves most readily to the rapid mass screening required in blood transfusion are all ELISA based. As many of the commercially available kits have some false-positive reactions, due mainly to cross-reactivity, confirmatory tests using alternative methodologies are carried out before a positive result is reported.

Routine screening, combined with the well-established donor education and self-deferral schemes, has reduced even further the already small risk of the transfusion of a contaminated donation. There have been only three documented cases of HIV transmission by transfusion in the UK since screening began. The small residual number of HIV transmissions through screened blood will arise through donations given in the 'window period' of infectivity, i.e. soon after the donor has been infected but before anti-HIV has become detectable (as in the three UK documented cases referred to), or through system errors. With current combined antigen–antibody screening techniques, the window period has been estimated to be less than 2 weeks on average. The prevalence of HIV antibodies in repeat UK blood donors is less than 1 in 100 000, and is 1 in 25 000 in new donors; there is no doubt that energetic donor education has contributed to this very low rate by excluding high-risk individuals. In England and Wales, it is estimated that the residual risk of HIV infection by transfusion at present, per donation, is approximately 1 in 8 million. Although small, the risk of HIV transmission by transfusion is greater in the USA (approximately 1 in 500 000–1 million donations) than in the UK. In order to reduce the length of the window period even more, i.e. to about 2 weeks, the USA and other countries (such as Thailand) introduced screening for HIV antigen at a considerable cost. In the USA, this has been replaced by nucleic acid testing (NAT) for HIV RNA, which reduces the window period to approximately 1 week. However, in areas of low HIV incidence, the number of extra donors detected by such screening will be extremely small. In the UK, combined antigen–antibody serological testing has proved extremely effective, although NAT for HIV has been introduced in some parts of the country.

Human T-cell leukaemia viruses (HTLV I and HLTV II)

Human T-cell leukaemia viruses (HTLV I and II) are related retroviruses. The importance of HTLV II is not clear; it appears to be associated with intravenous drug use in the Western world and has no known association with any clinical condition. However, HTLV I is endemic in the Caribbean, parts of Africa, and in Japan, where 3–6% of the population are seropositive. Infection with HTLV I is associated with at least two distinct clinical conditions; it can lead to adult T-cell leukaemia (ATLL), with an incubation period of approximately 20 years and, on rare occasions, to tropical spastic paraparesis (also known as HTLV I-associated myelopathy), which appears to have a shorter incubation period. Only about 1% of patients who are seropositive develop T-cell leukaemia. Both HTLV I and HTLV II are cell associated and not transmitted in plasma. In highly endemic areas, transmission of HTLV I by transfusion was relatively common before mandatory screening was introduced. Both tropical spastic paraparesis and ATLL have been associated with transfusion-transmitted HTLV I.

In areas of low prevalence of HTLV I and II infection, the cost benefit of mandatory screening of blood donations has been debatable. Routine serological screening is by ELISA, but confirmation of positive results can still cause difficulties because other retroviruses may cross-react. In certain cases, it may also be difficult to differentiate between HTLV I and HTLV II in the laboratory, despite the quite different clinical consequences of the two infections. The prevalence of anti-HTLV in previously untested UK blood donors is roughly 1 in 50 000 and screening became mandatory in 2002.

Cytomegalovirus

Although most cases of post-transfusion cytomegalovirus (CMV) infection are subclinical, the syndrome of post-transfusion infectious mononucleosis-like illness is well recognized, especially after the transfusion of large amounts of blood. The infection is characterized by fever, splenomegaly and atypical lymphoid cells in the peripheral blood, with a negative Paul Bunnell test. The usually benign course of CMV infection in recipients has meant that there has been no necessity to screen all donors for evidence of past infection. However, immunosuppressed individuals are at great risk from potentially fatal pneumonitis or disseminated cytomegalovirus infection, and these recipients require special measures to prevent CMV transmission.

The groups at particular risk are: premature babies weighing < 1500 g, bone marrow and other organ transplant recipients and pregnant women (the fetus is at risk). In such cases, if the patient (and the tissue donor) or the mother (in the case of neonates) lacks evidence of past CMV infection, then anti-CMV free blood and blood components should be provided. This may cause logistical problems, especially with platelet supplies, as the incidence of anti-CMV in the UK adult population is 50–60%. Although only a small number of antibody-positive donors may be capable of transmitting the infection, there is no test for infectivity. Thus, all antibody-positive donors should be considered as having the potential to transmit CMV. As CMV is cell associated, leucodepletion should provide similar levels of safety as serological testing, but this has not been proven prospectively in well-controlled clinical trials.

Syphilis

Each donation is tested by a serological test for syphilis. Although *Treponema pallidum* does not survive well at 4°C and red cell preparations are likely to be non-infective after 4 days' refrigeration, storage does not affect the positive serology. Passive transmission of the antibody to a recipient could cause diagnostic confusion. The organism is more likely to be transmitted in platelet concentrates, due to their room temperature storage and short shelf-life. Any donation from an individual giving a positive result is discarded, and subjects with positive tests are permanently debarred from donation, even after effective therapy. In the past, syphilis testing was believed valuable as a surrogate marker for lifestyles known to be associated with high risk of HIV infection. Sensitive HIV assays have reduced this usefulness.

Malaria

Malarial parasites remain viable in blood stored at 4°C, and are readily transmissible by blood transfusion. In some endemic areas, all recipients are treated with antimalarial drugs. In non-endemic areas, there is a real risk of failure to recognize post-transfusion malaria owing to the rarity of the infection. This fact, combined with increasing travel to tropical areas, necessitates the careful vetting of blood donors by direct questioning and, in some centres, by tests for malarial antibodies. Visitors who have recently travelled to a tropical area are treated similarly for 12 months after the visit, unless malaria antibody testing is available. Such testing has recently become available in the UK.

Other infections

There are no other protozoal or microbiological diseases (for which tests are available) that pose a significant problem in the context of blood transfusion in the UK. However, diseases such as Chagas' disease cause significant problems for the blood transfusion services in Latin America, and potential exposure of UK donors necessitates specific serological testing of those individuals to exclude the possibility of infection.

Bacteria

Although rare in absolute terms (approximately three cases are reported and confirmed per year in the UK), bacterial transmissions by transfusion constitute two-thirds of all microbial transmissions by this route and often prove fatal. The vast majority of such cases are due to contaminated platelet preparations that are more than 3 days old, because bacteria (mostly skin commensals) will proliferate easily at room temperature. This risk is now far greater than viral risks because of the introduction of interventions such as NAT for HCV. UK blood services are in the process of introducing enhanced methods of donor arm cleansing, 'diversion' of the first 20 mL of the donation to reduce the risk from skin contaminants and are considering routine bacterial screening of platelet preparations.

Prions

Variant Creutzfeldt–Jakob disease (vCJD), the human form of bovine spongiform encephalopathy (BSE), is considered a potential threat to blood safety. This risk is at present only applicable to the UK, where nearly 150 cases of vCJD had been reported at the beginning of 2004. Therefore, plasma for fractionation (and fresh-frozen plasma for infants and children not exposed to the risk of BSE in food) is obtained from the USA. Appropriate donor exclusions and the introduction of leucodepletion of all blood components are other precautionary interventions. It has been shown experimentally that BSE acquired in sheep, by eating contaminated beef, can be transmitted by blood transfusion to other sheep. As it is not known how many people could be infected with vCJD and because of the recent reports of two possible cases of vCJD transmission by blood transfusion, recipients of blood have now been excluded as blood donors in the UK. It has not been possible to detect abnormal prion in the blood of patients with vCJD; hence no screening tests are yet available for blood donations.

Laboratory tests on blood donations (Table 16.5)

Samples for laboratory testing are taken at the time of donation, to avoid later entry into the sterile blood pack. The routine tests are automated if large numbers of donor samples are tested daily.

Table 16.5 Microbial testing in England and North Wales.

HIV	ELISA (combined HIV_1 Ag plus anti-HIV_1, and anti-HIV_2)
HBV	HBsAg ELISA
HCV	Anti-HCV ELISA plus NAT on pools of 48 samples
HTLV	Anti-HTLV ELISA (on pools of 48 samples)
CMV	Anti-CMV for immunosuppressed recipients only.
Malaria	Antibody screening of potentially exposed donors
Chagas' disease	Antibody screening of potentially exposed donors
Bacteria	All donations are tested for antibody to syphilis; the option to test platelet preparations by culture methods is under review

All blood donors in the UK are tested at each donation for syphilis, HBsAg, anti-HIV 1 and 2 and antigen, anti-HCV, HCV RNA, and anti-HTLV. ABO and RhD grouping is determined routinely on each occasion. Typing for other Rh antigens (C, E, c and e) and K is now routinely performed on most, although not all blood donations, in the UK. Matching for such antigens is only performed in special cases such as alloimmunized patients and sickle cell disease patients. Ideally, girls and women of childbearing age should be matched for c and K, as anti-c and anti-K are, after anti-D, the major causes of severe HDN in the UK.

All donations are also screened for the presence of atypical red cell alloantibodies by testing against group O red cells that are selected to bear the most common blood group antigens. The incidence of clinically significant red cell alloantibodies in blood donors is very low (0.3%) compared with the incidence in potential recipients (1.5–3.0%). Donations with potent clinically significant alloantibodies are not issued to hospitals. Group O blood for emergency or 'flying squad' use, which may be given, in exceptional circumstances, to ungrouped recipients, should be given as red cells in additive solution (e.g. saline–adenine–glucose–mannitol, SAGM) to avoid problems that might be caused by high-titre anti-A,B in donor plasma. As soon as the patient's group is known, group-specific blood should be given. If group O platelets have to be given to non-O recipients, donors with high-titre anti-A,B should be excluded as the providers of the plasma used to suspend the platelets, or platelet-additive solutions can be used to replace most of the plasma.

Some donations are screened for CMV antibodies for patients in need of CMV-negative blood. Units from donors at risk are screened for malaria antibodies, Chagas' disease antibodies and for HbS (sickle trait).

Residual microbial risk of allogeneic blood transfusion

The residual risks of microbial transmission are now so low in the UK that prospective studies to determine them would need to be too large to be practical. Risk is therefore calculated from the length of the 'window period' (prior to laboratory delectability of the infection) and the rate of new infections for specific viruses. The calculated residual risks per donation in England and Wales for HIV, HBV and HCV are approximately 1 in 8 million, 1 in 1 million and 1 in 30 million respectively. These calculations are consistent with 'haemovigilence' reports in the UK Serious Hazards of Transfusion (SHOT) scheme. Indeed, acute microbial transmissions now constitute a mere 3% of all reported hazards, with 'incorrect blood component transfused' being the major reported risk. The low microbial risk is a result of a series of incremental safety interventions becoming ever more complex and costly.

In this context, pathogen inactivation–reduction is likely to prove very cost-*ineffective*, unless existing safety interventions can be reduced, or discontinued, or 'emerging' microbial risks are considered to pose a sufficient threat. In any case, if pathogen inactivation techniques such as photochemical inactivation are introduced, we need to ensure that the blood product is not affected in its immunogenicity or efficacy, and that the benefits of their introduction outweigh the risks.

Storage of blood

When blood is stored in a liquid state there is a progressive loss of viability of the red cells, and of red cell ATP, and depletion of 2,3-diphosphoglycerate (2,3-DPG). The purpose of modern anticoagulants that are used for the collection of blood is to reduce these changes to a minimum.

Anticoagulants and solutions for red cell preservation

The addition of 'rejuvenating' agents or purine nucleosides (adenosine, inosine) to standard anticoagulant solutions has been shown to improve significantly the viability of red cells (e.g. CPD-AI). Adenosine is effective in restoring the ATP content of stored red cells, whereas inosine restores the 2,3-DPG content. Adenosine is potentially toxic, although rapidly deaminated to inosine in the circulation. Inosine catabolism can raise serum uric acid levels. Hence, neither compound is used in routine practice, but adenine has been found to have a beneficial effect similar to that of adenosine without its side-effects.

Optimal additive solutions (e.g. saline-adenine-glucose-mannitol, SAGM)

Optimal additive plasma replacement solutions have been developed to improve viability of plasma-depleted red cells on storage, by maintaining both ATP and 2,3-DPG levels. SAGM (as well as ADSOL and Nutricel) medium provides good red cell storage conditions and is now the most usual preservative solution for red cells in the UK. A multiple 'top and bottom' blood collection pack is used (Figure 16.1). The blood donation is taken into the main pack, which contains standard CPD anticoagulant. After centrifugation, plasma and buffy coat are separated and transferred into empty satellite packs. The latter is pooled with three other buffy coats and the plasma from one of those donations. After a further gentle centrifugation, the platelet-rich plasma is expressed into a special platelet pack and the remainder of the buffy coat is discarded (Figure 16.2). Platelet concentrates are then suspended in CPD-plasma; they can be resuspended in 2:3 platelet additive solution and 1:3 plasma, especially for patients in whom exposure to plasma is contraindicated or when the potency of anti-A,B in group O platelets needs to be reduced for non-O recipients. As a separate procedure, the red cells left at the bottom of the pack are added to 100 mL of SAGM medium, contained in another satellite pack (i.e. in a closed system). The resulting red cells have flow characteristics equivalent to plasma-reduced blood and a storage life of 35–42 days (35 in the UK). Using this method, maximal amounts of plasma can be removed from blood donations for the manufacture of factor VIII and albumin, thus helping to meet the self-sufficiency targets for plasma products. At the same time, both platelets and an improved red cell product can be obtained. As stated above, in the UK, in order to decrease the possible risk of transmission of vCJD by transfusion, plasma for fractionation is imported from the USA.

Other anticoagulants and additive solutions

Heparin is now rarely used, and it can only be useful for blood that is to be transfused within 12 h of collection. This is because heparin is gradually broken down in storage and the blood then clots. Heparinized blood for neonatal cardiac surgery and exchange transfusion has been replaced by citrate–phosphate–dextrose–adenine (CPD-AI) blood, less than 3–5 days old, with no untoward effects. Some neonatologists use SAGM red cells for newborn infants, with success. For intrauterine transfusion, irradiated, white cell-depleted red cells are used.

CPD-AI solution has a final concentration of 9.25 mmol/L adenine and a slightly higher dextrose content than standard CPD. Red cell viability is well maintained for up to 5 weeks. Acid–citrate–dextrose (ACD) solution, which preserves red blood cells for only 21 days, is not used any more for red cells. However, ACD-A is the anticoagulant of choice for routine use in all apheresis platelet collections. CPD is used when collecting plasma donations by apheresis.

Storage changes of blood

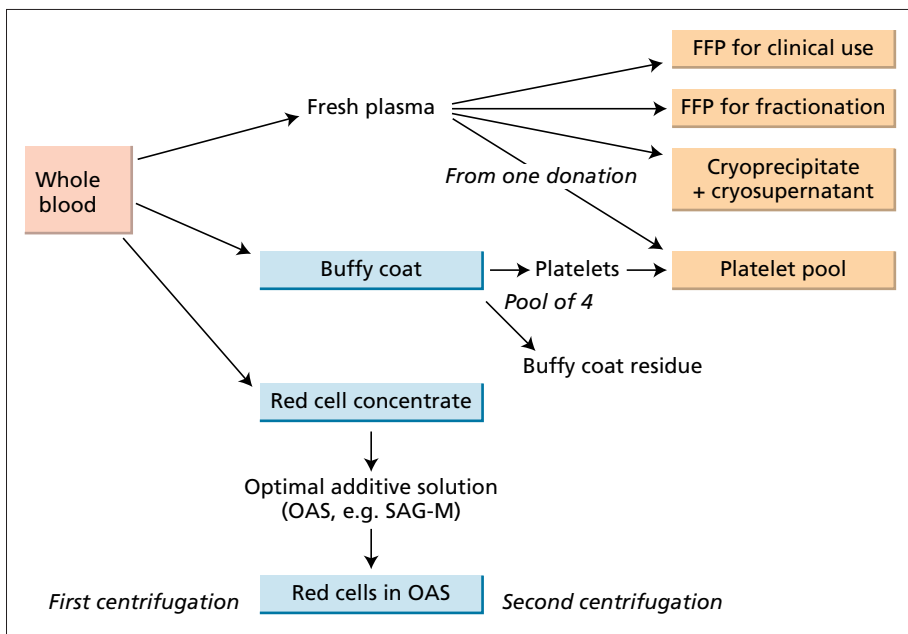
Loss of red cell viability is the most important practical consideration. Progressive loss of viability varies according to the anticoagulant used. The time limit for storage of blood is set taking this into consideration. After transfusion of stored red cells, a proportion are removed from the circulation within the first 24 h. The remainder appear to survive normally. With increased length of storage, a greater proportion of red cells are


Figure 16.1 Diagrammatic representation of the preparation of components from whole blood by the 'top and bottom' or 'buffy coat' method. Items in boxes represent final components. FFP, fresh-frozen plasma.
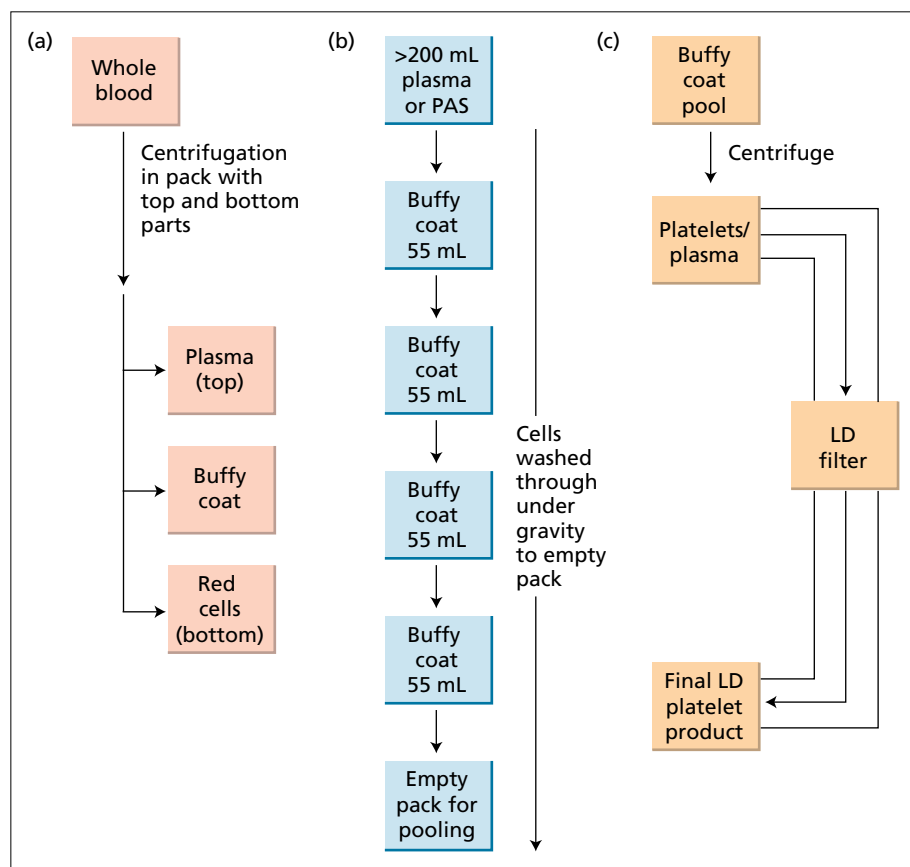

Figure 16.2 Preparation of leucodepleted pooled, buffy coat-derived platelet preparations. PAS, platelet additive solution; LD, leucodepletion.

removed within the first 24 h. The destruction at 24 h of more than 30% of the total number of cells transfused is considered unacceptable.

Depletion of ATP is progressive during storage of red cells, leading to changes in red cell shape (discs to spheres, loss of membrane lipid and increased rigidity). These changes can be partially reversed by incubation with purine nucleosides, and reduced by addition of adenine at the time of collection. ATP seems to be an important determinant of red cell viability, although not the only one.

Reduction in red cell 2,3-DPG during storage is less severe in CPD blood than in ACD: 2,3-DPG levels are normal in CPD and CPD-AI blood at 1 week. Reduced red cell 2,3-DPG levels increase the oxygen affinity of Hb, and the oxygen dissociation curve is shifted to the left, with less oxygen being given up to the tissues. The red cell 2,3-DPG level is restored to normal by approximately 24 h post transfusion. The clinical significance of the low 2,3-DPG level of stored red cells is only likely to be an important consideration in recipients with severe anaemia or coronary artery insufficiency. Even in massive transfusion of stored blood, depletion of red cell 2,3-DPG can probably be well tolerated if cardiac function is satisfactory.

Electrolyte changes are the result of equilibration of sodium and potassium levels across the cell membrane once active trans-

port has been halted by the cooling of blood to 4°C. There is rapid restoration of electrolyte levels after transfusion.

The pH of blood decreases rapidly with storage, but most recipients can handle the acid load during transfusion without ill effect.

Frozen red cells

Red cells can be stored for a prolonged period without damage if glycerol is added before freezing. Thawed red cells must be washed free of glycerol before transfusion. This method of storage is expensive and time-consuming but is invaluable as a means of storing red cells with rare phenotypes. National banks for frozen rare cells have been established for this purpose. Freezing, thawing and washing is also an efficient way of removing plasma, platelets and leucocytes from red cells.

Blood components

Preparation and storage of other separate blood components (Figures 16.1 and 16.2)

After initial centrifugation, three components can be obtained

from a whole blood donation: red cells, buffy coat and plasma (Figure 16.1). Fresh plasma is expressed from the top and red cells from the bottom of the pack, leaving the buffy coat in the original pack. The red cells are transferred to a pack containing an optimal additive solution (OAS) to preserve red cell function during storage. The plasma is then kept to resuspend the platelets, or frozen either for clinical use as fresh-frozen plasma (FFP) or it can be subjected to a fractionation process for the manufacture of IVIg, albumin, anti-D, specific antiviral immunoglobulins and coagulation factors. However, at present it is not permitted to use UK plasma for fractionation, owing to concerns over the possible transmission of vCJD by blood components.

The buffy coat layer contains most of the platelets, over 80% of the white cells and 5–10% of the red cells. This is pooled with three other buffy coats and > 200 mL of plasma from one of the donations, using a sterile connecting device (Figure 16.2). The pool undergoes a second gentle centrifugation step and the supernatant is used to produce a platelet preparation. The residue from the buffy coat pool, containing mainly white cells and some red cells, is then discarded.

The systems that enable the separation of buffy coats in a semiautomated manner are called blood separators, examples of which are Optipress and Compomat (Figure 16.2). Cellular components (red cells and platelets) and plasma may, at this stage, be individually filtered to leucodeplete to a level of $< 5 \times 10^6$ white cells per unit. The alternative is to use leucodepletion filters at the initial stage on whole blood, before separation of components. These two alternative methods are necessary because most whole blood filters also remove a significant number of platelets, making production of platelet concentrates from filtered whole blood impossible. In the UK, leucodepletion of all blood components has been mandatory since 1999.

Platelet preparations

Platelets do not survive well in stored blood. For all practical purposes, there are no viable platelets remaining in blood stored for 48 h at 4°C. Blood donations should be kept at room temperature after collection, and platelets separated as soon as possible. Although function is maintained when platelet preparations are stored at 4°C, post-transfusion survival is poor and any haemostatic effect is short lived. Storage at 20–22°C is therefore preferable. Platelets have a shelf-life of 5 days, in packs of plastics used for 'extended storage'. These allow the diffusion of oxygen into the pack, which, with constant gentle agitation, reduces the rate of fall of pH. The shelf-life of platelet preparations can be extended to 7 days, provided that systems are in place to monitor bacterial contamination.

Platelet pools provide an adequate adult dose of platelets and contain, on average 300×10^9 platelets, usually from four donations suspended in the plasma from one donation. White cell contamination should be reduced to a minimum in platelet concentrates, as this is the cause of non-haemolytic febrile transfusion reactions due mostly to the reaction of white cells with antibodies in the recipient and to cytokine release in storage. With leucodepletion, this is no longer a problem (Figure 16.2).

In the USA, platelets are prepared from individual donations by a method which leaves the platelet-rich plasma as a supernatant. Each platelet concentrate contains a minimum of 5.5×10^{10} platelets, suspended in 50 mL of plasma. An adult dose of platelets prepared in this way contains significantly more leucocytes than the platelet concentrates prepared by 'top and bottom' systems and which are considered to be leucocyte poor, even before leucodepletion.

The equivalent of two or even three adult doses of platelets (minimum 2.4×10^{11} each) may be obtained from one donor, with adequate platelet counts, by an apheresis procedure lasting approximately 90 min. At present, in the UK, approximately 40% of platelets are produced by this method, using Gambro, Baxter or Haemonetics cell separators. These preparations reduce donor exposure and are invaluable for the treatment of immunologically refractory thrombocytopenic patients requiring human leucocyte antigen (HLA)-matched platelets. However, they are expensive to produce and demanding on both staff and donors. A large HLA-typed donor panel is needed to provide HLA-compatible platelets. A proportion of apheresis platelet donors are also HPA typed.

Frozen platelets can be preserved in dimethyl sulphoxide (DMSO) or glycerol. The platelet recovery is significantly lower than with fresh preparations, but the post-transfusion survival is normal. Frozen platelets are very seldom used and are not available in the UK.

Granulocyte concentrates

Granulocytes are extremely labile; they must be separated from whole blood immediately after collection and transfused within hours of preparation. Granulocytes prepared from routine blood donations ('buffy coats') are heavily contaminated with red cells and platelets. Buffy coats from at least 10 donors are required to produce a therapeutic dose for an adult (at least 1×10^{10} granulocytes). Ten buffy coats also contain the equivalent of two units of red cells and 2.5 pools of platelets. Venesection of the recipient may therefore be required if daily buffy coats are indicated. Granulocyte concentrates prepared by apheresis are the only satisfactory means of achieving a therapeutic dose for an adult neutropenic patient. Sedimenting agents (gelatin, hydroxyethyl starch) must be added to the blood or given to the donor in order to obtain an adequate yield, unless the donor has chronic granulocytic leukaemia.

A directed donation from a suitable relative may sometimes be possible. Consent may then be obtained for the donors to have their counts boosted using steroids and granulocyte colony-stimulating factor (G-CSF), resulting in an excellent yield of granulocytes. In the UK, it is not permitted for non-directed volunteer donors to receive this medication. Average yields from unstimulated apheresis collections are 0.7×10^{10}; with the use of G-CSF and steroids, this can be increased to $5–10 \times 10^{10}$.

Fresh-frozen plasma

This plasma has been separated from whole blood (Figure 16.1) or obtained by apheresis, and frozen within 8 h, to a temperature that will maintain the activity of the labile factors V and VIII. FFP contains all coagulation factors and should be stored at –30°C or below for up to 24 months or even longer. When needed, the plasma is thawed rapidly at 37°C and then transfused without delay. A dose of 15 mL/kg is appropriate to correct abnormal coagulation in acquired coagulopathies when no concentrate is available. It may be used to reverse the effects of warfarin, and can be used to treat inherited coagulation factor deficiencies if the appropriate factor concentrates are not available.

Single units of FFP can be treated with methylene blue (MB) and exposed to visible light to inactivate pathogens that may be present in the plasma. If required, the MB can be removed before the plasma is rapidly frozen to –30°C. FFP can be pooled with around 1500 other units and treated with solvent–detergent (SD) in order to inactivate pathogens. Both these methods of viral inactivation reduce the levels of labile clotting factors in FFP. FFP or standard cryosupernatant are the products of choice for the treatment of thrombotic thrombocytopenic purpura (TTP) in the UK.

Cryoprecipitate

Cryoprecipitate is prepared from blood within 8 h of collection (Figure 16.1). Plasma is separated, frozen and allowed to thaw (classically at 4°C, overnight). After removal of the supernatant, the factor VIII:C, vW factor, fibrinogen, fibronectin and FXIII are left as a precipitate, which is then refrozen in approximately 15 mL of plasma, and stored at –30°C or below for up to 24 months. Each unit should contain a minimum of 70 IU of factor VlII:C and 140 mg of fibrinogen. Cryoprecipitate is now used mainly as a source of fibrinogen in cases of disseminated intravascular coagulation (DIC), hepatic failure and hypofibrinogenaemia. Where coagulation factor concentrate is not available, cryoprecipitate is effective in the management of von Willebrand's disease, but is not the product of choice. A standard adult dose of cryoprecipitate is 10 units, which are thawed at 37°C in about 10 min and should be used immediately.

Cryoprecipitate-poor plasma (cryosupernatant)

This term is used for the remaining plasma after the removal of cryoprecipitate. The main and specific indication for cryosupernatant is for plasma exchange in TTP. This is an immune-mediated condition in which there is an autoantibody directed against a vWF cleaving metalloproteinase. The resulting accumulation of high-molecular-weight (HMV) vWF multimers contributes to the pathophysiology of the condition with thrombosis in the microvasculature. Cryosupernatant supplies both more of the metalloproteinase, and lacks the HMW multimers, so it can be used to correct both abnormalities. It is stored frozen at –30°C or below for up to 24 months.

Table 16.6 Preoperative assessment.

Take a full history and examination, including previous surgical episodes and bleeding history

Arrange full blood count, group and antibody screen, routine chemistry, coagulation screen (if indicated) and tube for haematinics assessment (ferritin level for iron stores, vitamin B_{12} and folic acid), which can be put on hold pending full blood count (FBC) results

Consider autologous pre-deposit if patient is fit enough and greater than 50% likelihood of significant blood loss requiring transfusion or if rare atypical red cell antibodies are present

Consider using recombinant erythropoietin and/or intravenous iron sucrose, even with normal haemoglobin, at a dose of 600 IU/kg weekly for 4 weeks preoperatively

Prescribe iron and folic acid supplement if any suspicion of iron deficiency

Establish whether patient is taking regular aspirin, NSAIDS or warfarin and, whenever possible, make necessary arrangements to stop this drug 7 days preoperatively

The recipient (Table 16.6)

Preoperative assessment

Growing pressure on hospital beds and increasing use of day surgery means that a preoperative assessment should be performed before admission. This allows for efficient use of hospital resources and limits the number of cancelled operations. The key aims are to assess a patient's fitness to undergo surgery and anaesthesia, anticipate complications, arrange for supportive therapy to be available perioperatively and to liaise with the appropriate specialists regarding non-surgical management. This assessment needs to take place at a presurgical clinic at least 1 month before the planned date of surgery. After the clinic, it is imperative that the results are seen so that the necessary action can be taken for each patient.

Only a small proportion (1.0–1.5%) of potential recipients will have red cell alloantibodies other than anti-D; however, routine pretransfusion antibody screening will allow blood bank staff to identify those samples that need detailed investigation well in advance of the planned transfusion.

Laboratory tests

Pretransfusion group and screen

The ABO and RhD groups of all potential recipients should be determined before transfusion. No other blood groups are routinely tested or matched when selecting blood for transfusion. The need for blood is rarely so urgent that there is insufficient

time to perform the ABO and RhD groups before transfusion, as rapid testing need take only 5–10 min. The patient's serum should also be screened for the presence of atypical red cell antibodies using a sensitive indirect antiglobulin technique, with two or three individual (not pooled) group O red cells selected to express, between them, all the common red cell antigens. If a positive result is obtained, further investigation using a red cell panel of 8–10 cells is required to identify the antibody.

For patients who have preformed antibodies, an antibody screen using a panel of cells that are negative for the pertinent antigen(s) should be used (i.e. panel of rr cells in the case of pre-formed anti-D). Only 1–2% of patients have clinically significant red cell alloantibodies. About 75% of these antibodies have Rh and/or K specificity. Therefore, patients with haematological diseases who are likely to need repeated transfusion over many years should ideally be phenotyped for the major red cells antigens; if this is not possible, at least RhD, C, c, E, e and K typing should be performed. Blood that is compatible with the patient's Rh and K type should be transfused, as this reduces the probability that they will produce antibodies. Ideally, girls and women of childbearing age should be transfused with K-negative red cells, but K typing is not necessary as only 9% will be positive.

Red cells for transfusion are selected to be of the same ABO and RhD group as the recipient. If clinically significant red cell alloantibodies are present in the recipient, units of blood lacking the relevant antigens are selected for compatibility testing, even if the maximum surgical blood ordering schedule (SBOS, see below) only requires 'group and screen' for that surgical procedure.

Compatibility testing (cross-match)

The donor red cells are routinely tested against the recipient serum or plasma in order to detect any potential incompatibilities, i.e. to identify any antibodies in the recipient that are reactive with antigens on the red cells of the selected donor. This test will provide a means of checking the ABO compatibility of donor and recipient. If the antibody screen is negative, then the cross-match should be as simple as possible, for example an immediate spin or indirect antiglobulin test at 37°C. This will detect ABO incompatibilities resulting from clerical or technical errors such as sample switching or erroneous group in the bag, or the presence of antibodies missed in the screening. The antiglobulin test can be performed in low-ionic-strength solution (LISS) in tubes or using gel (column) techniques (see Chapter 14) that decrease the incubation time and increase the sensitivity for the detection of some antibodies. Tests should be carried out at 37°C, not at room temperature, otherwise clinically insignificant cold antibodies will be detected, especially when LISS is used. This may cause confusion and inconvenience to the recipient (e.g. cancellation of planned surgery). Any clinically significant antibody will react at 37°C (see Chapter 14), and the techniques chosen should take this into account.

A group and screen policy used in combination with a maximum (or standard) surgical blood ordering schedule (MSBOS) can reduce the number of compatibility tests performed. Each hospital should agree its own MSBOS among the blood bank, surgeons and anaesthetists, through the Hospital Transfusion Committee (HTC). It is based on a retrospective comparison of the number of units of blood cross matched, and the number actually transfused for each elective surgical procedure. Procedures that are likely to require blood have a ratio of cross-matched:transfused blood below 2.5:1.0. All patients awaiting surgery have blood samples taken for grouping and antibody screening. As long as no atypical alloantibodies are detected, cross-matching is reserved for those in whom the need for blood is fairly certain. Operations for which blood is not usually required (such as hysterectomy and cholecystectomy) are not covered by cross-matched blood. If blood is unexpectedly needed, an abbreviated cross-match (using an immediate spin technique to ensure ABO compatibility) may be used safely, with minimal risk to the recipient. If atypical antibodies are detected, antigen-negative blood should be cross-matched before surgery if there is any minimal likelihood of blood being required.

Electronic cross-match

A number of hospitals with suitable blood bank computing systems now use a so-called 'electronic cross-match' or 'electronic issue'. A patient has group and screen performed on two separate occasions. If both screen results on the laboratory's computer system are negative, and if no blood has been transfused during this period, ABO and Rh compatible blood is issued directly via the computer with no further wet testing being performed. This makes it possible to reduce the number of operations for which blood is issued in advance even further, as the electronic cross-match is very quick. It also saves laboratory time, which can then be dedicated to more complex problems.

Antenatal testing

All women should have blood samples taken at antenatal booking for blood grouping and antibody screening. If no clinically significant antibody is detected, further samples should be tested at 28 weeks' gestation (see p. 271). Much of the emergency compatibility testing for possible Caesarean sections can be avoided by performing another antibody screen and group at admission, using either an abbreviated or electronic cross-match should blood be required.

Repeated transfusions

Patients who require repeat transfusion after an interval of more than 72 h must have a new sample sent before the next transfusion to detect any clinically significant antibody that may have been stimulated in an anamnestic response by the recent trans-

fusion. Severe haemolytic transfusion reactions still occur due to failure to observe this simple rule; many could be avoided. In the case of an undetected haemolytic transfusion reaction, in addition to the antibody screen, a direct antiglobulin test (DAT) should be performed on the red cells of the new sample to detect any alloantibodies attached to donor red cells but not free in the serum.

Massive transfusion

If the total blood volume has been replaced within less than 24 h, compatibility testing becomes academic. In such patients, interdonor incompatibility is a possible problem, but all donor sera should have been screened at the transfusion centre for the presence of potent atypical antibodies. When a pretransfusion alloantibody screen on the recipient has not detected any atypical antibodies and blood has been cross-matched without a problem then continued compatibility testing may be omitted. If a pretransfusion screen reveals the presence of an atypical antibody, the blood selected should be negative for the relevant antigen. Once transfusion has commenced, the antibody will be 'diluted out' and compatibility testing may no longer be reliable, unless the original serum sample is used for all testing. In practice, once 10 units have been transfused there is no need to continue to cross-match red cells for further transfusions, or to select antigen-negative red cells, if these are scarce.

Transfusion in autoimmune haemolytic anaemia

Ideally, patients with this condition should not be transfused. However, if transfusion is imperative, special serological techniques such as elution and absorption should be used to exclude the presence of alloantibodies, which may be masked by autoantibodies. Blood should then be selected which is compatible with the alloantibody, if present, even though transfused red cells will be destroyed by the autoantibody at the same rate as the patient's own blood. Whenever possible, red cells should also be Rh- and K-compatible to reduce the possibility of further alloimmunization. Blood that does not express the antigen to which the autoantibody is directed against should be issued only when the autoantibody has restricted specificity and mimics an alloantibody such as anti-e. However, if the patient is a female of childbearing age and is RhD-negative, with an autoantibody mimicking anti-e, then R_2R_2 (*cDE/cDE*) cells should not be given because of the high risk of RhD immunization.

Neonatal 'top-up' transfusion

Premature infants are amongst the most widely transfused patients, with 'top-up' transfusions being very frequent. Only the first pretransfusion sample needs to be tested, with no further sample testing until 4 months of age, as infants are not cap-

able of making clinically significant antibodies in the first months of life. Ideally, the unit of red cells used for the first transfusion should be aliquoted into several (six to eight) satellite packs and used for the same infant until expiry, to decrease exposure to multiple donors. Measures should be in place in all neonatal units and their supporting laboratories to minimize the quantities of blood required for testing, by use of microsampling techniques and near-patient testing. Anaemia in this group is largely due to 'bleeding into the laboratory'. Erythropoietin has been extensively studied as an alternative to transfusion in the anaemia of prematurity but it does not consistently reduce the need for transfusion in this group.

Complications of blood transfusion

The frequency of the complications of blood transfusion will vary inversely with the care exercised in the preparation for, and especially in the supervision of the transfusion.

Although the majority of side-effects are mild, the overall incidence of complications is estimated at 2–5%. Immediate fatalities, although difficult to quantify accurately, are of the order of 1 in 100 000–500 000 patients transfused; 50% of these are caused by ABO incompatibilities, mainly due to failure to identify correctly the donor or recipient, at the time of sampling or at the time of transfusion. The wrong pack of blood, i.e. one intended for a different recipient, is reported to be given in 1 in 6000–30 000 transfusions. This is likely to be an underestimate due to underdetection and non-reporting of incidents. It follows that transfusions of blood and blood components should only be prescribed when there is a definite and appropriate clinical indication, when there are no feasible alternatives and when the benefits of transfusion are judged by the prescribing clinician to outweigh its short- and longer term risks.

The complications of blood transfusion can be conveniently divided into acute and delayed, immunological and non-immunological categories (Table 16.7).

Immunological complications

Sensitization to red cell antigens
As only the ABO and RhD antigens are routinely matched in blood transfusion; there is a constant possibility of sensitization to other red cell antigens. This is more likely in multitransfused patients. The consequences may be negligible but can lead to difficulty with compatibility testing, HDN and haemolytic transfusion reactions.

Haemolytic transfusion reactions
This is premature destruction of transfused red cells reacting with antibodies in the recipient. Red cell alloantibodies form in response to exposure, through previous transfusions or pregnancies, and are not naturally occurring. Such reactions may

Table 16.7 Hazards of transfusion

	Non-immune complications	Immune complications
Acute	Bacterial: acute sepsis or endotoxic shock	Febrile non-haemolytic transfusion reactions
	Hypothermia	Acute haemolytic transfusion reactions: intravascular (IgM), extravascular (IgG)
	Hypocalcaemia ($\downarrow Ca^{2+}$) in infants	Allergic reactions (urticarial)
	Air embolism rare	Anaphylactic reactions (anti-IgA)
		TRALI (transfusion-related acute lung injury)
Delayed (days to years after transfusion)	HIV	Delayed haemolytic transfusion reactions (due to anamnestic immune responses with red cell alloantibodies)
	Hepatitis C	
	Hepatitis B	Post-transfusion purpura (PTP)
	CMV	Transfusion-associated graft-versus-host disease (TA-GvHD)
	Others: parvovirus B19; hepatitis A; malaria; Chagas' disease; brucellosis; syphilis; vCJD?	Immune modulation

occur immediately after the transfusion, or may be delayed for anything up to 2–3 weeks.

Immediate haemolytic transfusion reactions

Immediate, intravascular destruction of recipient red cells should be avoidable. In practice, the main cause is error, when the incorrect blood component is transfused. The most severe reactions occur in major incompatibility, when a group O recipient with high-titre anti-A and/or anti-B, is transfused with group A, B or AB red cells. Less severe intravascular haemolysis occurs when group A red cells are transfused to a group B recipient, or vice versa, because group B and A subjects have less potent ABO antibodies than those of group O. More rarely, intravascular red cell destruction may occur when group O plasma is transfused, by mistake, to A, B or AB recipients. For this reason, group O blood should not routinely be used for non-O recipients; furthermore, this practice leads to unnecessary shortages of group O blood. If unavoidable, the group O blood must first be screened for the presence of high-titre haemolysins or be devoid of plasma.

In the UK, screening for high-titre ABO antibodies is routinely carried out at the blood centre and marked on the bag. ABO-compatible cryoprecipitate, FFP and platelet transfusions should be selected for all recipients, especially for children because of their smaller blood volume. Group A, B or AB plasma components are safe for group O recipients.

Occasionally, there is a laboratory error when antibodies in the recipient's plasma are not detected (or there is insufficient time to complete an antibody screen or compatibility test). In the UK haemovigilance system (SHOT), 30% of reported cases of incorrect blood components transfused were due to clerical or technical errors that originated in the hospital laboratory. The remainder of reports (70%) relate to clerical or admin-

istrative errors in the ward, collection of the blood from the blood bank, failure to confirm the identity of the patient when taking samples, mislabelling of the sample of blood or failure to perform proper checks before removing the units from the fridge or transfusing the blood. The serious consequences of such failures emphasize the need for set protocols for meticulous checks at all stages. If an identification mistake has been made, it is important to check, as a matter of urgency, that the units intended for the patient under study have not been misdirected to another recipient.

Intravascular red cell destruction is the most dangerous type of haemolytic transfusion reaction; it is associated with activation of the full complement cascade by IgM antibodies and is practically always due to ABO-incompatible blood transfusions (haemolytic anti-A,B, anti-A or anti-B present mainly in the recipient or, rarely, in the donor plasma). Most of these ABO incompatible transfusions are due to identification errors, and occur with an approximate frequency of 1 in 100 000 patients transfused. The mortality rate in such ABO-incompatible cases is 5–10%. In a further 10–15% of cases there is some morbidity.

The symptoms in the recipient are usually dramatic and severe; most are due to anaphylatoxins C3a and C5a that are liberated during complement activation (see Chapter 14), although the cytokines interleukin 1 (IL-I), IL-8 and tumour necrosis factor also play an important role. These molecules cause smooth muscle contraction, platelet aggregation, increased capillary permeability, and release of vasoactive amines and hydrolases from mast cells and granulocytes respectively. Typically, within less than 1 h of the start of the transfusion, when the reaction is symptomatic, the patient complains of heat or pain in the cannulated vein, throbbing in the head, flushing of the face, chest tightness, nausea and lumbar pain. These symptoms are

Table 16.8 Antibodies associated with haemolytic transfusion reactions.

Blood group system	Antibodies implicated in intravascular haemolysis	Antibodies implicated in extravascular haemolysis
ABO	A, B	
Hh	H (Bombay)	
Rh		All
Kell		K, k, Kp^a, Kp^b, Js^a, Js^b
Kidd		Jk^a, Jk^b, Jk^3
Duffy		Fy^a, Fy^b, Fy^3
MNS		M, S, s, U (some)
Lutheran		Lu^b (some)
Lewis	Le^a, Le^b, Le^{a+b}	
Cartwright		Yt^a (some)
Vel	Vel	Vel (some)
Colton		Co^a, Co^b
Dombrock		Do^a, Do^b

usually accompanied by tachycardia and hypotension. In severe cases, there is profound hypotension and collapse. Rigors and pyrexia usually follow. Intravascular destruction of red cells brings about liberation of thromboplastin-like substances that activate the coagulation cascade and lead to DIC. The bleeding diathesis and increased destruction of red cells (which may eventually involve the recipient's cells) further exacerbates the problem.

Intravascular destruction of red cells liberates Hb into the circulation. Once haptoglobins are saturated, Hb will also appear in the urine. If haemoglobinuria is very severe, haemosiderinuria may be seen. Renal complications consist of acute renal failure with oliguria and anuria, possibly the result of hypotension and/or the action of activated complement.

The initial symptoms may of course be modified or abolished in anaesthetized or heavily sedated patients, in whom evidence of DIC, hypotension or the presence of haemoglobinuria may be the first signs.

Haemoglobinaemia and haemoglobinuria may also be seen in severe extravascular haemolytic transfusion reactions (see below) and, occasionally, after the transfusion of lysed red cells. This may occur in the following circumstances: inappropriate warming and overheating of blood; exposure to extreme cold due to faulty storage conditions; lysis due to mechanical problems during administration; or due to the injection of 5% dextrose with the transfused red cells. Severe fulminant toxic symptoms leading to death, similar to those of intravascular haemolytic transfusion reactions, can be seen after the transfusion of bacterially infected blood, especially if it contains endotoxin-producing organisms (e.g. *Staphylococcus* and *Yersinia* species). Haemoglobinaemia and haemoglobinuria may also follow transfusion of blood to a patient with severe autoimmune haemolytic anaemia, due to an increase in the number of red cells in the circulation which will be subject to immune lysis.

Extravascular red cell destruction is mediated by IgG antibodies (Table 16.8). Mononuclear phagocytic cells have receptors for the Fc fragment of IgG1 and IgG3; the binding of IgG-coated cells to these receptors is inhibited by free IgG in plasma. There are no receptors for IgM on macrophages. Red cells sensitized with IgGI and/or IgG3 antibodies, may or may not activate complement up to C3b only. If they do not, they are removed extravascularly (phagocytosis or cytotoxicity) by mononuclear phagocytic cells, predominantly in the red pulp of the spleen, where the plasma is largely excluded and the IgG on the red cells can compete with free IgG in the plasma. However, cells coated with IgG antibodies, which activate complement up to C3b, adhere to the C3b receptor on macrophages and monocytes. The presence of C3b on red cells greatly enhances the extravascular destruction of IgG-coated cells. This is because the binding to C3b receptors is not inhibited as there is no native C3b in plasma and consequently IgG-/C3b-coated cells are destroyed by phagocytosis or cytotoxicity, predominantly in the liver, where there are abundant macrophages (Kupffer cells) and a generous blood flow. As C3b is rapidly inactivated by the actions of factors H, I and proteases, a proportion of the cells re-enter the circulation coated with C3dg and are resistant to further lysis (Figure 16.3). Red cells coated with potent IgG antibodies, especially if they are C3b-binding, are destroyed mainly by cytotoxicity. Very rarely, red cell alloantibodies too weak to be detectable by routine pretransfusion testing may destroy donor red blood cells carrying the corresponding antigen.

The features of an immediate haemolytic transfusion reaction vary according to a number of factors: whether the red cells are destroyed within the circulation or in the reticuloendothelial (RE) system; the strength, class and subclass of antibody; the nature of the antigen; the number of incompatible red cells transfused; and the clinical state of the patient. When antibodies are present in the circulation in low titres and a large volume
Figure 16.3 Mechanisms of extravascular destruction of red cells coated with IgG1 or IgG3 (± C3b). ADCC, antibody-dependent cell-mediated cytotoxicity.

of incompatible blood is given, all circulating antibody will bind to the incompatible red cells, coating them weakly without destroying them. There will then be no antibody detectable in the serum for a number of days until secondary antibody production is stimulated by the immune challenge. In the presence of an overloaded or poorly functioning RE system, large volumes of IgG-sensitized incompatible red cells can be present in the circulation with minimal or no premature removal, so the Hb level may be stable with little evidence of haemolysis. The DAT will be positive, but as there is no free antibody, elution techniques will be necessary for antibody identification.

Immediate extravascular destruction of red cells may be accompanied by hyperbilirubinaemia, occasionally haemoglobinaemia due to antibody-dependent cytotoxicity (in severe cases), fever and failure to achieve the expected rise in Hb level. The signs and symptoms are less severe and dramatic than in intravascular haemolysis and usually appear more than 1 h after the start of transfusion (Table 16.8). There may be no signs or symptoms at all. Renal failure is very rare, even when the antibody binds the earlier components of the complement cascade. The symptoms are attributed in a large degree to liberation of cytokines from mononuclear phagocytic cells after binding to

IgG-coated red cells and to liberation of C3a when complement is bound up to C3b. The mortality is extremely low, but, in an already sick patient, the added complication of destruction of transfused red cells may contribute to death.

The management of immediate haemolytic transfusion reactions should be to terminate the transfusion immediately the patient develops the appropriate signs or symptoms. The identity of the patient and the units transfused should be checked against the appropriate documentation. Blood samples must be taken for investigation as in Table 16.9.

The circulating blood volume should be restored and the blood pressure and urinary flow maintained using fluid challenges and furosemide (frusemide) infusion. Monitoring on a high-dependency unit may be required. The renal team should be involved early if urine output is poor (< 1 mL/kg/h) and haemofiltration may be necessary. Appropriate blood component therapy will be required if there is DIC.

All packs of transfused units should be returned to the blood bank. Pretransfusion samples should be tested in parallel. If no identification mistake is discovered immediately, a sample should be sent for bacteriological testing and all urine passed during the first 24 h should be measured and examined for Hb. Subsequent management depends upon awareness of the possible complications and prompt therapy if these occur. If the patient develops only a rise in temperature, unaccompanied by other symptoms, red cell incompatibility is unlikely and the transfusion should be slowed, under strict monitoring, but need not be stopped.

New technologies to prevent patient identification errors are under investigation in a number of countries. These generally involve bar-coded patient ID details on the patient's wristband and the use, both on the wards and in the laboratory, of a hand-held bar-code reader with all data collated by the transfusion computer system. These systems are likely to be developed in tandem with similar arrangements for pharmacy and drug prescriptions, as well as ordering of blood tests and other investigations for patients.

Delayed haemolytic transfusion reactions
Such reactions are neither predictable nor preventable. In the majority of cases, an individual has been previously sensitized to one (or more) red cell antigen(s) by previous transfusion or pregnancy. Antibody is not detectable in routine pretransfusion testing, but the transfusion of blood containing the antigens to which the recipient has been sensitized previously provokes a brisk anamnestic response that is characteristic of the secondary immune response. Within days, the antibody level rises and the transfused cells are removed from the circulation. The effects of the secondary immunization are usually seen about 5–10 days after the transfusion, when the recipient may already have left hospital.

The clinical features of this type of reaction are the triad of fever, hyperbilirubinaemia and anaemia. The degree of fall in

Table 16.9 Investigation of suspected acute haemolytic transfusion reaction.

Blood test	Rationale/findings
FBC	Baseline parameters, red cell agglutinates on film
Plasma/urinary Hb, haptoglobin, bilirubin	Evidence of intravascular or extravascular haemolysis
Blood group of patient and units transfused	Compare with retested pretransfusion sample, to detect ABO error. Unexpected ABO antibodies may arise from transfusion of incompatible plasma. Rechecking labels is often sufficient
DAT	Positive in majority. Compare with retested pretransfusion sample. May be negative if all incompatible cells destroyed
Compatibility testing	Repeat antibody screen and compatibility testing on pre- and post-transfusion samples. Elution of antibody from post-transfusion cells may aid antibody identification or confirm specificities in plasma in cases of non-ABO incompatibility
Urea, electrolytes and creatinine	Baseline renal function
Coagulation screen	Detection and monitoring of DIC
Blood cultures	In event of possible septic reaction caused by bacterial contamination of unit

Hb level will of course depend upon the number of incompatible units transfused.

The possibility of delayed haemolytic reactions underlines the importance of always taking fresh serum samples for antibody screening, direct antiglobulin test and compatibility testing if a transfusion has been given more than 72 h previously. Awareness of this complication may avoid unnecessary investigations to exclude infection when fever develops a few days after a transfusion. Most importantly, it will detect any alloantibody that will have been boosted by the transfusion, thus enabling the provision of compatible blood.

Reactions due to white cell and platelet antibodies

Febrile transfusion reactions
Febrile reactions are most frequently due to sensitization to white cell antigens and more rarely to platelet antigens. Together with urticaria, these are the most common type of immunological reaction to blood transfusion. Antibodies are directed usually against HLA antigens, or sometimes against granulocyte and platelet-specific antigens; they are stimulated by previous transfusions or pregnancies. Cytokines released from white cells during storage may also be pyrogenic. Characteristically, the onset of the reaction is delayed until 30–90 min after the start of the transfusion (depending upon the strength of antibody and the speed of transfusion). A rise in temperature may be the sole symptom, but the recipient may suffer chills, headache or rigors. There is no associated hypotension, lumbar pain or chest discomfort. These reactions are usually only troublesome rather than dangerous, except in very sick patients or in the presence of very potent lymphocytotoxic HLA antibodies.

The management of a simple, mild febrile transfusion reaction is to slow the rate of transfusion and treat the patient with an antipyretic such as paracetamol. Antihistamines are of no benefit. It is usually not necessary to discontinue the transfusion: more blood is probably wasted by premature termination of a unit due to a simple febrile reaction than for any other reason.

When a patient requiring repeated transfusions has a history of simple febrile reactions, the rate of transfusion should be kept slow and antipyretics should be prescribed prophylactically. If symptoms recur with repeated transfusions, buffy coat-poor red cells and platelets should be tried. If severe symptoms persist, tests for HLA antibodies (lymphocytotoxicity) should be carried out. If these are negative, platelet antibodies should be sought. Patients with troublesome symptoms in whom white cell antibodies have been demonstrated should be given white cell-depleted blood. Modern prestorage leucodepletion filters are highly efficient and can remove more than 98% of the white cells; the specification is that 99% of leucodepleted components should have $< 5 \times 10^6$ leucocytes. Red cells and platelets should be filtered as soon as possible after collection in the transfusion centre. In the UK, the incidence of febrile transfusion reactions has decreased significantly since the introduction of universal leucodepletion of blood components in 1999.

In countries where there is no universal leucodepletion policy, there is no need to administer white cell-depleted blood prophylactically, except in cases where prevention of sensitization to HLA and leucocyte/platelet antigens is essential (i.e. possible future consideration for bone marrow transplantation, especially in patients with aplastic anaemia).

Transfusion-related acute lung injury

Transfusion-related acute lung injury (TRALI) consists of pulmonary infiltrates on chest radiograph, accompanied by chills, fever, cough and dyspnoea with low oxygen saturation and low or normal central venous pressure. The clinical picture, depending on the severity, will be the same as acute lung injury (ALI) or acute respiratory distress syndrome (ARDS) due to other causes, and a differential diagnosis is essential. Symptoms develop very rapidly usually within 1–2 h, or up to 6 h after infusion of a plasma-containing component.

Management is essentially supportive, requiring high-dependency unit care, and careful attention to fluid balance. The reaction is due in most cases to passive transfer of leucoagglutinins (mostly anti-HLA class I or class II or granulocyte antibodies, i.e. anti-HNA) in donor plasma, leading to endothelial and epithelial injury, alveolar damage and inflammatory changes, mediated by cytokines and other inflammatory mediators. The donors are usually multiparous women; once identified as the source of a reaction, such donors should be removed from the panel, even although it is known that their plasma will not always lead to TRALI in recipients with the pertinent antigens. The incidence is unclear but may be in the region of 1 in 5000 transfusions. There appears to be a significant mortality rate from this condition.

Post-transfusion purpura

Post-transfusion purpura is a rare complication of blood transfusion, characterized by a sudden onset of severe thrombocytopenia 7–10 days after the transfusion of platelet-containing blood components, usually red cells. The patient always has a history of previous blood transfusions or pregnancies (thus it is far more common in women). The most frequent cause is the presence in the recipient of an antibody (anti-HPA-1a) against the platelet-specific antigen HPA-1a (PI^{A1}). It appears that the antigen–antibody reaction between the recipient's antibody and the donor platelets causes both transfused and autologous platelets to be prematurely destroyed, either by the formation of immune complexes (in a manner similar to the 'innocent bystander' mechanism) or by cross-reaction of the causative antibody with the patient's own platelets. The disease is self limiting but, in severe cases, or if bleeding occurs, prompt therapy with intravenous immunoglobulin or plasma exchange is indicated. Platelet transfusion is not recommended, as this may exacerbate the disease process.

Reactions due to plasma protein antibodies

Mild urticarial reactions without other symptoms are not uncommon during blood transfusion; they occur with an approximate incidence of 1% and are mediated by IgE antibodies, usually against plasma proteins or other allergens present in donor plasma. Mild urticarial reactions may be treated effectively with antihistamines, and do not always recur. There is no necessity to avoid transfusion of standard 'bank blood' unless symptoms are recurrent and severe. On the other hand, severe anaphylactic reactions accompanied by dyspnoea, wheezing, collapse and shock are rare and potentially fatal. Such reactions are associated with the presence of anti-IgA in an IgA-deficient recipient. These antibodies react with IgA in the transfused plasma and complement is activated, with the consequent liberation of anaphylatoxins C3a and C5a, leukotrienes and cytokines.

Milder reactions may be associated with anti-IgA of limited specificity. If an anaphylactic reaction occurs, the recipient should be treated promptly with adrenaline and tested for the presence of plasma protein antibodies. If anti-IgA is detected, plasma from IgA-deficient donors should be used in future, as well as well-washed red cells and platelets. Occasionally, washed cells may be indicated for patients with serious urticarial or severe hypersensitivity reactions due to non-IgA antibodies.

Non-immunological complications

Disease transmission

Reactions due to bacterial pyrogens and bacteria

The presence of bacteria in transfused blood may lead either to febrile reactions in the recipient (due to pyrogens) or to the far more serious manifestations of septic or endotoxic shock. Bacterial-transmitted infections are considerably more frequent than serious acute manifestations of virus-transmitted infections in countries such as the UK (see p. 255).

Bacterial pyrogens are rarely the cause of reactions with present-day methods of manufacture and the sterilization of fluids and disposable equipment. Infection of stored blood is also extremely rare, but has a very high mortality in recipients. Skin contaminants are sometimes present in freshly donated blood but many (e.g. staphylococci) do not survive storage at 4°C. However, they will grow profusely in platelet concentrates stored at 22°C. A number of Gram-negative psychrophilic, endotoxin-producing contaminants found readily in dirt, soil and faeces (pseudomonads, coliforms) may very rarely enter a unit and grow readily under the storage conditions of blood (and even more rapidly at room temperature).

Healthy individuals who are bacteraemic at the time of donation may also act as a source of infection. The majority of such cases relate to transmission of *Yersinia enterocolitica*, which grows well in red cell components due to its dependence on citrate and iron.

Transfusion of heavily contaminated blood will usually lead to sudden, dramatic symptoms, with collapse, high fever, shock and DIC with haemorrhagic phenomena. These symptoms resemble, and may be more severe than, those of ABO incompatibility. Prompt recognition of the cause and administration of broad-spectrum intravenous antibiotics, in conjunction with the treatment of shock, are vital. The diagnosis should be confirmed by direct microscopic examination of the blood, and blood cultures from the recipient and the blood bag.

Prevention of this potentially disastrous complication of blood transfusion rests on stringent observation of procedures for aseptic techniques in blood collection and in the manufacture of anticoagulant solutions and packs. Packs should never be opened for sampling, and the unit should be transfused within 24 h if any open method of preparation has been used (for example, washed red cells, frozen–thawed blood). Blood should always be kept in accurately controlled refrigerators (with alarms), maintained strictly at 2–6°C, and a unit of blood should never be removed and taken to the ward or theatre until it is required. The practice of obtaining multiple units of blood for the same patient, and leaving unused units at room temperature (or in uncontrolled ward refrigerators) until needed must not be tolerated. Bacteria may cause haemolysis or clotting of blood and all units should be inspected for these before transfusion. Platelets should be inspected for discoloration, foaming and absence of swirling.

Circulatory overload

All patients, except those who are actively bleeding or fluid depleted, will experience a temporary rise in blood volume and venous pressure after the transfusion of blood and/or plasma. In young people with normal cardiovascular function, this will not cause any embarrassment, providing the total volume given and the transfusion rate are not excessive. In contrast, pregnant women, patients with severe anaemia, and the elderly with compromised cardiovascular function will not tolerate the increase in plasma volume, and acute pulmonary oedema may develop. In view of this possibility, concentrated red cells should be given to these patients more slowly over 4 h. Patients with severe chronic anaemia and cardiac failure may require partial exchange transfusion. In less severe cases, diuretics (oral or intravenous furosemide) should be given at the start of the transfusion and only one or two units of concentrated red cells should be transfused in any 24 h period. The patient should be observed carefully for early signs of cardiac failure (raised jugular venous pressure, crepitations at the lung bases, and symptoms of pulmonary oedema, cough and breathlessness). For this reason alone, transfusions should be given during the day, when staff are able to monitor the patient closely. Overnight transfusions should be avoided for the patient's safety and comfort. If circulatory overload occurs, transfusion should be discontinued, the patient propped upright and intravenous diuretics given. Emergency venesection for fluid overload should not be necessary if all precautions have been taken.

Thrombophlebitis

Thrombophlebitis is a complication of indwelling venous cannulae, and not specifically related to blood transfusion.

Air embolism

This is now practically unknown, as blood and blood components are administered from plastic bags.

Transfusion haemosiderosis

Haemosiderosis is a very real complication of repeated blood transfusions, and is being seen more commonly as long-term blood transfusion therapy improves the survival of patients suffering from some chronic anaemias. It is most commonly seen in thalassaemic individuals, who commence transfusions in early childhood. Each unit of blood has approximately 200 mg of iron, whereas the daily excretion rate is about 1 mg: the body has no way of excreting the excess. Unless a patient is actively bleeding, and therefore losing iron, iron accumulation is inevitable. Significant iron overload is generally present after approximately 50 units of blood have been transfused to an average-sized adult. It is routine practice to give thalassaemic patients the parenteral iron-chelating agent desferrioxamine or the oral iron chelator deferiprone (L1) when available, or a combination of both. This does not completely overcome the iron load administered with blood, but has substantially delayed the onset of problems due to haemosiderosis (see Chapters 3 and 6).

Transfusion of neocytes, or young red cells, looked promising as a means of decreasing the frequency of transfusions and of reducing the iron load. However, this practice is expensive and time-consuming and the trial results were not as favourable as expected. Patients who are transfusion dependent should receive blood which is less than 1 week old, which may help to increase the transfusion interval and therefore reduce the overall number of units required.

Complications of massive transfusion

Massive transfusion is usually defined as the replacement of the total blood volume within a 24-h period. Although a number of different problems may result from changes that occur in stored blood, it should not be forgotten that any patient who needs a massive blood transfusion is by definition already seriously ill. Too much attention may be paid to the theoretical problems caused by metabolic changes in stored blood, and not enough to the underlying clinical condition. The coagulopathy problems derived from massive transfusion are different in trauma from those in elective surgery.

Although the transfusion problems encountered in cardiac surgery were in the past similar to those of massive transfusion, the volume of blood transfused to such patients is now insufficient to merit the routine administration of fresh blood or FFP. When post-operative bleeding occurs, this is usually due to platelet dysfunction and/or reduced numbers. Platelet transfusion is then indicated.

Replacement of the total blood volume will inevitably lead to some dilution of platelets. Blood effectively has no functional platelets after 48-h storage and once 8–10 units of blood have been given to an adult, thrombocytopenia will usually be seen. The severity will vary from patient to patient; in most elective surgery patients, the thrombocytopenia will reach a critical level only after 20 units of blood have been transfused. Bleeding due to a slightly low platelet count is uncommon, so that the routine

administration of platelets after a set number of units of blood is unnecessary. Regular monitoring of the platelet count in these situations is far more helpful; platelet administration may then be judged on the clinical condition and the platelet count. As a guide, platelet transfusion may be required if the platelet count falls below 80×10^9/L in the face of continued bleeding or surgical intervention. Red cell transfusion contributes to normal haemostasis by helping with the margination of platelets and responsiveness of activated platelets, so it is recommended to aim for Hb levels around 10 g/dL if possible.

Coagulation factors will also be diluted as stored blood is administered. Whole blood that has been stored for less than 14 days has adequate levels of most coagulation factors for haemostasis (whole blood is not available in the UK). Factors V and VIII are the most labile but, in conditions of patient 'stress', factor VIII is released from endothelial cells; deficiency of factor VIII sufficient to cause bleeding does not usually occur in these circumstances. If stored blood that is more than 14 days old is given, or if plasma-reduced blood or red cells in optimal additive solution have been used, replacement of coagulation factors may become necessary. Treatment should be monitored by coagulation studies and DIC screen; FFP and cryoprecipitate, as a source of fibrinogen, should be prescribed on the basis of results from the laboratory or near-patient testing. Disseminated intravascular coagulation associated with massive transfusion is most usually due to the underlying condition, such as trauma and/or prolonged shock, and not due to transfused blood per se.

Metabolic changes in stored blood include low pH, hypocalcaemia and hyperkalaemia. The reduced oxygen-carrying capacity of stored blood becomes significant only after 21 days' storage (for CPD-AI blood), and is due to low 2,3-DPG levels (see p. 256). Although excess citrate in transfused blood could cause toxicity theoretically, its metabolism in the liver is usually rapid. In practice, the only situations when citrate toxicity is a real problem is with extremely rapid transfusion (1 unit every 5 min), or in infants, especially if premature, having exchange transfusion with blood stored in citrate for longer than 5 days. Hypocalcaemia and hyperkalaemia are usually transient and rapidly corrected once the transfused blood is circulating. Acidosis is not usually significant, as citrate metabolism leads to an alkalosis. However, if a patient is severely shocked and undertransfused, acidosis may be a clinical problem. All these changes due to stored blood are exacerbated by hypothermia. Cardiac irregularities, in particular ventricular fibrillation, may result from transfusion of large quantities of cold blood. The optimal functioning of coagulation factors and of platelets is also temperature dependent and effectiveness is reduced by hypothermia. Thus, the use of a blood warmer and keeping the patient warm may be the most important measures to prevent the complications of massive transfusion. Unfortunately, this inevitably reduces the speed at which blood can be transfused, which may be a serious disadvantage when rapid transfusion is needed. When replacement therapy has failed, recombinant activated factor VII (rFVIIa) has been reported as successful in treating the coagulopathy of massive transfusion. However, more evidence is needed.

The most important consideration in massive blood transfusion is to replace blood loss quickly and adequately with maintenance of normal tissue perfusion. Too little blood too late has far more serious consequences than massive blood transfusion itself.

Haemovigilance and SHOT

The interest in transfusion-transmitted infections has meant that transfusion medicine has developed significantly and great emphasis has been put on quality, audit and good manufacturing practice (GMP). However, there were no surveillance systems in place to assess the incidence and prevalence of transfusion risks. France instituted the first system of national haemovigilance in 1994. Haemovigilance is defined as 'the set of procedures of surveillance organized from the collection of blood and its components to the follow-up of its recipients, with the purpose of collecting and evaluating information on the undesirable and unexpected effects resulting from the use of blood products and of preventing their occurrence'.

SHOT (Serious Hazards of Transfusion), the UK haemovigilance system was introduced in 1996 (Figure 16.4). SHOT receives reports of major adverse events surrounding the transfusion of single or small pool blood components supplied by the UK National Blood Services (red cells, platelets, FFP, methylene blue-treated FFP and cryoprecipitate). It does not cover complications of fractionated plasma products except for some incidents related to anti-D Ig administration. It is a confidential and anonymized scheme of voluntary reporting, though the
Figure 16.4 Cumulative data from 6 years of UK Haemovigilance (SHOT) reporting, 1996/97 to 2001/02. Completed questionnaires received, by transfusion incident, 1996/97–2001/02 ($n = 1630$).

European Directive will make reporting mandatory. Hospitals report events under the following categories:

• incorrect blood component transfused (IBCT), regardless of harm to recipients;
• acute transfusion reaction (ATR) within 24 h;
• delayed transfusion reaction (DTR) beyond 24 h;
• transfusion-associated graft-versus-host-disease (TA-GvHD);
• transfusion-related acute lung injury (TRALI);
• post-transfusion purpura (PTP);
• transfusion transmitted infection; (TTI) comprising
  – bacterial contamination;
  – post-transfusion viral infection;
  – other post-transfusion infection, e.g. malaria;
• 'Near miss' events (this has been introduced more recently).

Since 1996, the SHOT scheme has collected data on serious transfusion complications in the UK, from which to make firm recommendations for improvements in transfusion safety. The four UK Blood Services issue approximately 3.5 million blood components each year. Since 1996 there has been a year-on-year increase in the number of reports, with 405 eligible hospitals on the scheme. By the sixth year, participation was running at 93%. The increase in total reports is almost solely the result of an increase in 'incorrect blood component transfused' incidents.

Of 1630 fully analysed reports, the vast majority, i.e. 1045 (64.1%) were 'wrong blood' incidents. Of these, 193 were ABO-incompatible transfusions leading to 11 deaths and 41 cases of major morbidity, for example leading to intensive care unit admission; 92 were RhD incompatible, leading to possible RhD sensitization in females of childbearing potential.

Immune complications constituted 33.1% of reports, with 103 cases of possible TRALI, leading to 11 deaths that were definitely, or probably, related to transfusion, and a further 14 deaths possibly, making TRALI the second largest cause of transfusion-related mortality and morbidity after ABO incompatibility. A large proportion of cases reported as TRALI could not be confirmed in the laboratory.

TTI constituted less than 3% of reports. There were 36 confirmed TTIs of which the majority (22 cases) were of bacterial contamination (19 of platelets, three of red cells), resulting in six deaths.

The SHOT data demonstrate that in high-resource countries, microbiological, and especially virological, safety of the blood supply is advanced. Efforts should now be concentrated in preventing bacterial contamination and in other areas of transfusion medicine, such as the encouragement of appropriate use of blood, safe administration of blood components, accurate patient and sample identification, etc.

Appropriate use of blood and alternatives to allogeneic blood transfusion

In view of the inherent risks of blood transfusion and difficulties with donor recruitment due to escalating stringent donor selection criteria, blood components should only be transfused when the benefits outweigh the risks.

There are several reasons for aiming at reducing unnecessary allogeneic blood transfusion:
1 safety of the patient, by avoiding errors, as well as microbiological and immunological risks;
2 shortages of blood and increasing difficulties in the recruitment of blood donors;
3 cost containment;
4 high anxiety levels in patients that are disproportionate to the real residual risk of transfusion.

There are several alternatives to allogeneic blood transfusion, which can be classified as operational, biological and pharmacological, as listed below.

Operational alternatives

• Treatment of preoperative anaemia with haematinics, if appropriate, in a timely way at preassessment clinics.
• Autologous transfusion in all its forms. It seems that cell salvage is considerably more cost-effective than pre-deposit autologous transfusion. The value of preoperative haemodilution needs further assessment.
• Re-evaluation of transfusion triggers and algorithms for estimation of acceptable blood loss in surgery. Adherence to guidelines.
• Alternative fluid replacement (i.e. replace FFP with crystalloids or colloids when appropriate).
• Anaesthetic methods to reduce blood loss (e.g. hypotension).
• Enhancement of surgical haemostasis and new surgical technologies (e.g. water scalpels).
• Stopping aspirin, non-steroidal anti-inflammatory drugs (NSAIDS) and anticoagulants preoperatively.
• Post-operative haematinics.
• Near-patient testing in theatre.
• Miniaturizing blood sampling in intensive care units for premature babies and adults.
• Stem cell transplantation for transfusion-dependent patients (e.g. thalassaemia).

Biological alternatives

• Recombinant erythropoietin.
• Granulocyte colony-stimulating factor (G-CSF).
• Recombinant clotting factors.
• Recombinant activated factor (rVIIa).
• Fibrin glue in surgery.
• Probably in the future? Hb solutions and platelet substitutes.

Pharmacological alternatives

• Aprotinin in cardiac and liver surgery.
• Tranexamic acid infusion intra- or post-operatively.

- DDAVP® preoperatively in mild haemophiliacs.
- Intravenous iron, with or without recombinant erythropoietin (rEPO) preoperatively, especially in patients intolerant or unresponsive to oral iron.
- In the future? Oxygen carriers such as fluorocarbons.

Haemolytic disease of the newborn

Haemolytic disease of the newborn (HDN) is a condition in which the lifespan of the fetal/neonatal red cells is shortened due to maternal alloantibodies against red cell antigens inherited from the father. Maternal IgG can cross the placenta, thus IgG red cell alloantibodies can gain access to the fetus. If the fetal red cells contain the corresponding antigen then binding of antibody to red cells will occur. When the antibody is of clinical significance (e.g. anti-D, -c, -E, -K, -Jk^a), and of sufficient potency, the coated cells will be prematurely removed by the fetal mononuclear phagocytic system. The effects on the fetus/newborn infant may vary according to the characteristics of the maternal alloantibody.

The antibodies giving rise to HDN most commonly belong to the Rh or ABO blood group systems. The morbidity of Rh HDN is explained by the great immunogenicity of the D antigen; HDN due to anti-c is also important and its incidence comes second amongst the cases of severe HDN closely followed by the non-Rh antibody, anti-K. (The anaemia caused by anti-K is more properly called *alloimmune anaemia of the fetus and newborn* as it is due to direct inhibition of erythropoiesis by the antibody and haemolysis is not a feature.) Antibodies against antigens in almost all the blood group systems (e.g. Duffy, Kidd, etc.) and against the so-called 'public' and 'private' antigens, have also been responsible for HDN. However, IgM cannot cross the placenta and Lewis and P_1 antibodies, which occur frequently during pregnancy, are usually IgM and do not lead to HDN. Furthermore, the Lewis antigens are not fully developed at birth.

All women who have had previous pregnancies or blood transfusions may become immunized against 'foreign' red cell antigens. However, alloantibodies may be found in those with no such history, either because the antibodies are 'naturally occurring' or because a spontaneous abortion early in a previous pregnancy was unrecognized as such. Blood samples from all pregnant women must be tested early for the presence of atypical red cell antibodies (usually at 12–16 weeks, at the booking visit), and again at 28 weeks' gestation, even if no antibody was found at booking.

When anti-D, anti-c or anti-K are detected at booking, the strength of the antibody and the rate of rise (if any) in titre, or level in micrograms, during pregnancy must be carefully monitored by regular monthly blood sampling during the second trimester and fortnightly thereafter. If the level of any other clinically significant antibody is moderately high or high at 28 weeks, it should be monitored fortnightly until term. If the level

of anti-D is > 10 IU (2 µg) or anti-c > 20 IU, or if other antibodies have an IAT titre of 32 or greater, the fetus should be monitored by ultrasound/Doppler for evidence of anaemia and cardiac decompensation. At these levels, in the case of anti-D, -c or -K referral to a feto-maternal unit is advised. It should be noted that, in the case of potent anti-K, severe anaemia may occur relatively early during gestation.

Fetal and neonatal anaemia due to anti-D and anti-K tends to be more severe than that due to any other alloantibody. The next important in terms of severity is that due to anti-c. Anti-A,B is a common cause of HDN in group O mothers delivering group A or B infants (1 in 150 births), but the disease is usually mild; death *in utero* is unknown though exchange transfusion after birth may occasionally be required.

There are many significant differences between HDN due to ABO and Rh incompatibilities. The low incidence of infants requiring treatment for ABO HDN contrasts with the situation in Rh HDN. Furthermore, ABO HDN is found as frequently in the first pregnancy as in later pregnancies; subsequent infants may not be affected. In Rh HDN, a first pregnancy is usually unaffected (unless there has been prior immunization by abortion or transfusion), and subsequent Rh incompatible infants are affected to an equal degree or more severely. The majority of neonates affected with Rh HDN require some form of therapy.

Clinical features

In its least severe form, HDN manifests itself as mild haemolytic anaemia. The infant's red cells, coated with maternal IgG alloantibody, are removed prematurely from the circulation, causing slight jaundice (maximum on the second to third days of life) and mild anaemia during the second week of life. More severely affected infants show severe hyperbilirubinaemia in the neonatal period, a condition that was called *icterus gravis neonatorum.* Prompt treatment with exchange transfusion is necessary to prevent bilirubin impregnation of the basal ganglia and neurological damage, a condition known as *kernicterus*. This condition may be fatal, or lead to serious neurological deficit, with deafness, mental retardation, choreoathetosis and spasticity.

In the most severely affected cases, profound anaemia develops *in utero*, and intrauterine death may occur at any time from the eighteenth week of gestation. Affected fetuses are pale and oedematous, with marked ascites. The placenta is bulky, swollen and friable. This condition is known as *hydrops fetalis*, and had a high mortality rate until ultrasound-guided intravascular transfusions and improved intensive care facilities for very premature babies were introduced. The pathophysiology of hydrops is not fully understood, but extravascular haemolysis with fetal anaemia seems to play a major role by stimulating extramedullary erythropoiesis in the liver, with distortion of the hepatic circulation, leading to portal hypertension and impaired albumin production. Hypoalbuminaemia leads to ascites, oedema and pleural/pericardial effusions. In addition, the severe
Figure 16.5 Blood film of a fetus affected by HDN, showing polychromasia and increased numbers of normoblasts.

anaemia leads to cardiac failure and tissue hypoxia, which damages the endothelium, leading to fluid extravasation into the extravascular space.

The blood film of a fetus affected by HDN shows polychromasia and increased numbers of nucleated red cells (Figure 16.5). In most cases (except a few due to ABO antibodies), the direct antiglobulin (DAT or Coombs') test on the infant's cells is positive owing to IgG coating.

Rh haemolytic disease of the newborn

Until the early 1970s (when Rh immunoprophylaxis was introduced), 0.5–0.75% of all births gave rise to infants affected by Rh HDN. Anti-D accounted for over 90% of all cases. Although anti-D HDN has decreased significantly as a cause, it remains the most important. Of all infants affected by Rh HDN, 10–20% died *in utero* or in the early neonatal period before effective therapy was possible. The disease due to anti-D is more severe than that due to most other alloantibodies (e.g. anti-c, -E) except for some cases of anti-K. Early detection of maternal alloantibodies, regular fetal monitoring and assessment of rises in antibody titres are prerequisites to a successful outcome.

Antenatal assessment of maternal blood

Rarely, anti-D may develop in a first pregnancy in a woman who has had no previous transfusions. However, it is not common for the antibody to reach high levels, and it is not usually detectable before 28 weeks; most of such cases become apparent after delivery. Conversely, in women who have had previous pregnancies or transfusions with Rh-positive red cells, anti-D may be detected early in pregnancy; regular monitoring of the level is necessary in order to plan the best type and timing of intervention. At present, the most objective means of quantifying anti-D levels routinely is with an automated analyser or,

rarely, by flow cytometry and not by manual titration. More important than the anti-D levels in determining the severity of HDN is the obstetric assessment of the fetus.

The ABO, Rh groups and antibody screen should be performed in all pregnant women at booking (usually around 16 weeks' gestation). All women should have the testing repeated once more at about 28 weeks to confirm the Rh group and to detect the presence of atypical antibodies. If clinically significant antibodies are detected, more frequent testing will be required (see below). If the mother is RhD-negative with no anti-D by 28 weeks, routine antenatal prophylaxis should be given (see below). Following delivery, all RhD-negative women who are unsensitized for RhD should be given prophylactic anti-RhD immunoglobulin if the infant is RhD positive (Figure 16.6).

The level of anti-D in the serum correlates approximately with the clinical severity of the HDN, but this is also affected by factors such as IgG subclass, rate of rise of antibody, past history and presence of maternal blocking antibodies. As a rough guide, levels below 4.0 IU/mL (0.8 μg/mL) require no action, whereas a level of > 4 and up to 10 IU/mL (2.0 μg/mL) indicates moderate risk; 10–20 IU/mL indicates high risk of HDN and levels greater than 20 IU/mL indicate a high risk of hydrops. Anti-D, -c and -K should be monitored monthly to 28 weeks and 2-weekly thereafter. Other red cell antibodies reacting by IAT should be re-tested at 28 weeks, titrated and the maternal serum should be tested for the presence of kell alloantibodies. If the anti-D level is > 10 IU, anti-c > 20 IU, or, for other antibodies the IAT titre is > 32, the fetus should be monitored by the fetal medicine specialist for evidence of anaemia. The strength and trend in titre of other maternal alloantibodies should be reported to the obstetrician, for fetal monitoring as appropriate.

Antenatal assessment of disease severity and treatment of haemolytic disease

The severity of the haemolytic process may be assessed by fetal medicine specialists by clinical and ultrasound monitoring, including Doppler flow velocity. The systolic velocity of the fetal middle cerebral artery is a reliable indicator of fetal anaemia (Figure 16.7). Measurement of the bile pigments in the amniotic fluid by spectrophotometry from week 28 onwards is less commonly used now in the UK. The absorbance of normal amniotic fluid over the range of wavelengths 400–600 nm forms a smooth curve when plotted on semi-logarithmic graph paper. When there is an excess of bilirubin, the curve shows a greatly increased absorbance, with a peak at about 450 nm. The increase in density at this wavelength over the normal absorbance is the measurement of severity.

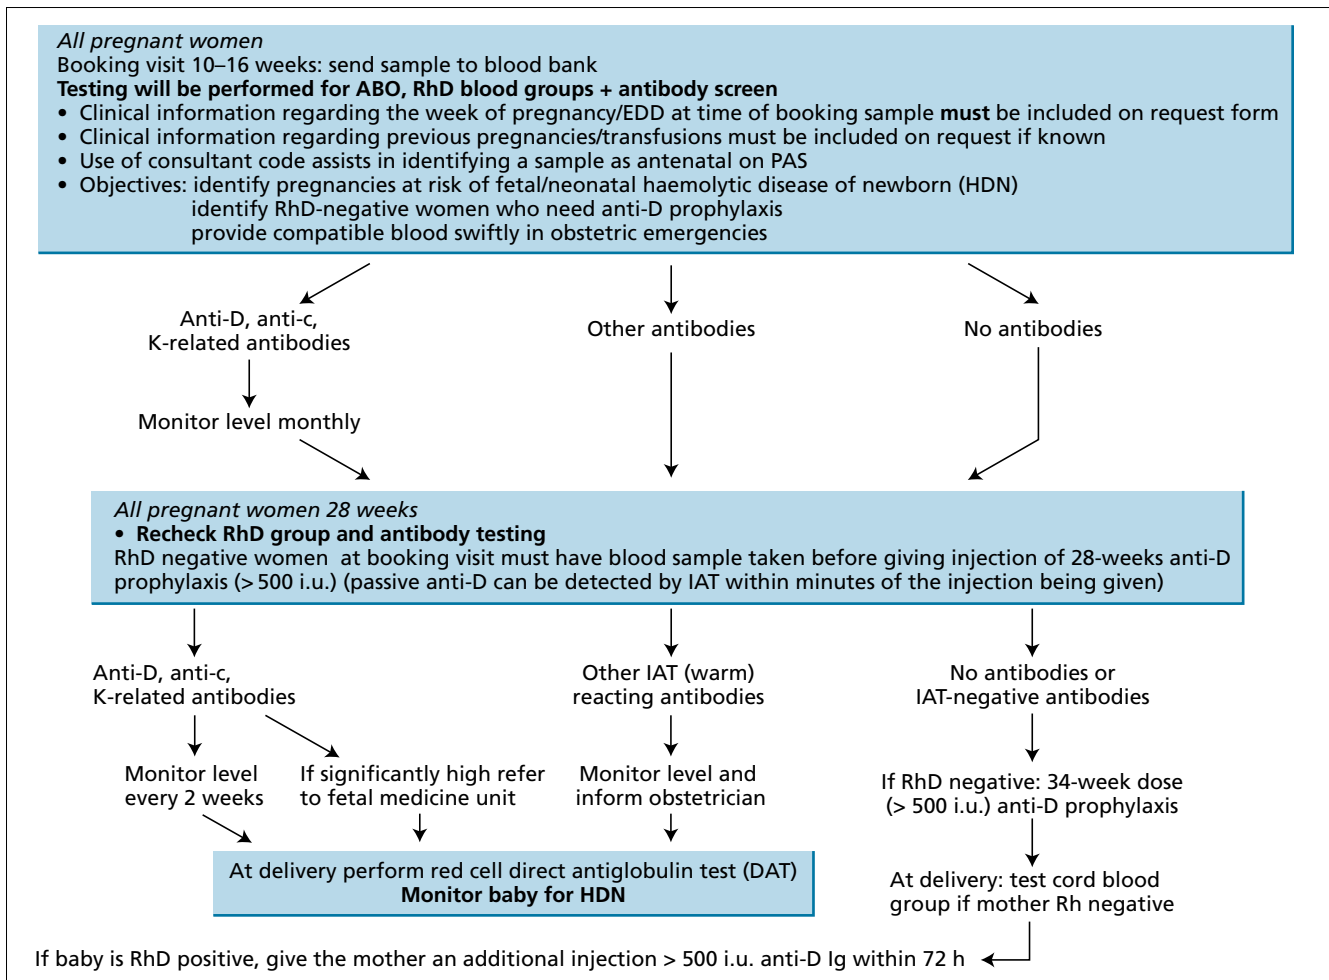
If the non-invasive parameters of severity indicate a severely affected infant, the fetal medicine specialist can perform ultrasound-guided fetal blood sampling (FBS), from 18–20 weeks onwards. The fetal Hb deficit is measured (Figure 16.8) and, if necessary, an intravascular transfusion with fresh (< 5 days


Figure 16.6 Blood group and antibody testing in pregnancy (source: *BCSH Guidelines for Blood Grouping and Antibody Testing During Pregnancy 1996*).

old) group O RhD-negative, CMV-negative, irradiated blood of the desired packed cell volume (PCV) can be administered. Such transfusions will be performed subsequently throughout pregnancy, with a frequency determined by the severity of the disease. Fetal blood sampling and amniocentesis carry a risk of immunizing a previously unsensitized RhD-negative woman carrying an RhD-positive fetus, due to leakage of fetal blood into the maternal circulation. Similarly, pre-existing low antibody levels may be 'boosted' by a new stimulus. Immunization to, or boosting of, other clinically significant red cell alloantibodies is not a rare occurrence. Although the risks of FBS are small in experienced hands, there are possible adverse effects on the fetus (e.g. bleeding through puncture of fetal vessels).

Intraperitoneal transfusion involves injection of antigen-negative donor red cells into the peritoneal cavity of the fetus (now rarely used). Blood with the same specification as used for intravascular transfusions, is used from 24 weeks of gestation. If ascites is already present, absorption of the red cells into the fetal circulation is slow and intravascular transfusion will continue to be the treatment of choice.

It is possible to determine the Rh genotype of the fetus from amniotic cells through DNA typing, thus avoiding further manipulations when the fetus is RhD negative. Fetal RhD genotyping is now possible by DNA extraction from maternal plasma from 16–18 weeks' gestation; this non-invasive technique is replacing amniocyte typing (see Chapter 15). If the partner is available, he too may be tested for the presence of the relevant antigen.

Premature delivery

Modern neonatal intensive care has dramatically increased survival rates of very premature infants born at 24–30 weeks' gestation. Nevertheless, morbidity is high and premature delivery is now, due to the success of intrauterine transfusions, rarely performed. It is sometimes considered at 36 weeks for
Figure 16.7 Middle cerebral artery Doppler. Peak velocity of systolic blood flow in the middle cerebral artery in 111 fetuses at risk for anaemia due to maternal red cell alloimmunization. Open circles indicate fetuses with either no anaemia or mild anaemia (≥ 0.65 multiples of the median Hb concentration). Triangles indicate fetuses with moderate or severe anaemia (< 0.65 multiples of the median Hb concentration). The solid circles indicate the fetuses with hydrops. The solid curve indicates the median peak systolic velocity in the middle cerebral artery and the dotted curve indicates 1.5 multiples of the median (courtesy of Professor Charles Rodeck).

Figure 16.8 Fetal Hb concentration of 48 hydropic (open circles) and 106 non-hydropic (closed circles) fetuses from red cell isoimmunized pregnancies at time of first blood sampling. Values are plotted on the reference range of fetal Hb for gestation. The individual 95% confidence intervals of the normal Hb for gestation define zone I and the individual 95% confidence intervals of the Hb for gestation of the hydropic fetuses define zone III. Zone II indicates moderate anaemia (courtesy of Professor Charles Rodeck).
fetuses suffering from haemolytic disease due to antibodies other than anti-D, -c or -K. When the previous obstetric history is poor, the mother starts with a high level of anti-D and the partner is homozygous for D, or the fetus is known to be D positive, IVIg is given to carry the pregnancy to 20 weeks, when intrauterine transfusions can be started. In several countries, IVIg is the mainstay of therapy throughout pregnancy.

Assessment of severity in the newborn

Cord blood samples should be taken at delivery. The DAT may be positive, but is not a useful indication of severity or need for therapy. The best simple criterion of severity is the cord Hb level; this is much more useful than a sample taken a few hours after birth, when rapid haemodynamic changes are occurring. The normal range of cord Hb levels is 13.6–19.6 g/dL. Most infants with levels in this range do not require therapy; more than 50% of affected babies have a level in the normal range. Where the cord Hb is below 12 g/dL, exchange transfusion will be necessary. It may also be indicated for a rising bilirubin level after birth, dependent upon the rate of rise and the maturity of the infant. Phototherapy may be given to reduce the rise in bilirubin levels but it is not a substitute for transfusion. Less severely affected infants may require small-volume transfusions of red cells at 2–3 weeks of age. In both of these instances, careful follow-up arrangements must be made as haemolysis may

continue, causing further rises in bilirubin or need for additional top-up transfusion.

The infant's RhD group should be determined on the cord blood sample of all infants born to D-negative mothers with no preformed anti-D, to give anti-D Ig prophylaxis if they type as D-positive. A DAT is only performed on cord bloods of mothers who have made anti-D; the cord bloods of women given antenatal Rh prophylaxis should not have a DAT done as it may be positive due to the passive anti-D given. If intrauterine transfusions have been given, the ABO and Rh groups may be those of the donor, and the DAT may be negative. A DAT should be performed on the cord blood of all women who have IAT-reactive antibodies. If the DAT is positive, the cord Hb should be checked and the clinical state, Hb and bilirubin of the infant monitored for signs of HDN for 1 month.

Exchange transfusion

Exchange transfusion is effective therapy for HDN, removing from the infant's circulation sensitized red cells and plasma containing both maternal antibody and bilirubin. It also treats the anaemia.

An exchange transfusion of one blood volume will replace approximately 75% of the infant's red cells. It is usual to exchange relatively large volumes of blood (e.g. 160 mL/kg) slowly, via an umbilical vein catheter. The donor blood should be ABO compatible with mother and infant, and lack the antigen against which the maternal antibody is directed. A compatibility test should be performed against maternal serum. Blood in CPD-A1 of less than 5 days old with a PCV of 0.5–0.6 is suitable for exchange transfusions, regardless of the ABO group of the infant. If group O blood is used in all exchange transfusions, it should be devoid of high-titre ABO antibodies. CMV Ab-negative donations should be used for infants of less than 1200 g in weight. If possible, the blood should be irradiated, but there should be no delay to the exchange on account of this. Irradiated blood must be given to infants who have been transfused *in utero*, because they are at greater risk of TA-GvHD.

ABO haemolytic disease of the newborn

In 20% of births, the mother is ABO incompatible with her fetus. In A and B subjects, the anti-B and anti-A are predominantly IgM and do not enter the fetus. ABO HDN is usually restricted to group O mothers possessing IgG anti-A,B. In 15% of all pregnancies of white mothers, a group O mother carries a group A or B fetus, but the overall incidence of ABO HDN requiring treatment is extremely low. In absolute terms, however, exchange transfusion may be required in up to 1 in 3000 infants.

The lack of severity of ABO HDN can be accounted for by the widespread occurrence of A and B antigens, not only on red cells but also in plasma and on other cells, which will partially neutralize maternally derived ABO antibodies. Furthermore,

the A and B antigens are not fully developed in the infant and the number of ABO sites is much smaller than in adults (see p. 227). Thus, only small amounts of the maternal antibody bind to infant red cells, and clinical sequelae are usually mild.

Serological findings

The mother is usually blood group O; IgG anti-A and anti-B can be demonstrated in her plasma after inactivating or inhibiting the IgM component with a reducing agent (2-mercaptoethanol or dithiothreitol, ZZAP). When infants are affected and require therapy, the maternal IgG anti-A or anti-B is almost always present in a titre greater than 64.

The infant will be group A or B and the DAT may be positive, only weakly positive or negative. In most cases, spontaneous agglutination will be observed if a drop of whole blood from the cord is rocked gently on a tile, especially if the cells are suspended in ABO-compatible plasma. Testing eluates from the red cells by IAT will reveal anti-A or anti-B specificity. Examination of the infant's blood film may show spontaneous agglutination of red cells, spherocytosis (not seen with Rh HDN), reticulocytosis, polychromasia and increased numbers of nucleated red cells.

Treatment

Severe anaemia is uncommon. Hyperbilirubinaemia is more often a problem which often subsides with phytotherapy, but may occasionally be serious enough to warrant exchange transfusion to prevent brain damage. Group O donor blood with low-titre anti-A,B should be used.

Haemolytic disease of the newborn due to other antibodies

After anti-D, the antibodies encountered most commonly as a cause of HDN are anti-c and anti-K (the former usually due to previous pregnancy and the latter usually due to previous maternal blood transfusions). The disease is generally less severe than that caused by anti-D, but may sometimes be serious enough to warrant early delivery and/or exchange transfusion, and occasionally requires treatment of the fetus. Anti-K of high titre may cause severe fetal anaemia. Assessment and treatment of the fetus and infant should be along the same lines as for anti-D. Blood that lacks the appropriate antigen should be given if intrauterine or exchange transfusion is required.

Although uncommon, practically all other red cell alloantibodies have been implicated in HDN requiring no therapy, small-volume transfusion or exchange transfusions.

Prevention of haemolytic disease of the newborn

The major success in HDN in the last 15 years is because of

the decrease in cases due to anti-D, so that other antibodies now account for a higher proportion of occurrences. This reduction has been achieved by the routine administration of 500 IU (100 μg) anti-RhD immunoglobulin to all RhD-negative mothers within 72 h of delivery of a RhD-positive infant. Extra doses of 50–75 IU (20–25 μg) per additional millilitre of red cells may be required for the small number of women (< 1%) who have a transplacental bleed greater than that covered by the standard dose (which covers 4 mL of packed cells). Anti-RhD immunoglobulin is also indicated after spontaneous or therapeutic abortion or threatened miscarriage and all procedures that might lead to a feto-maternal bleed (amniocentesis, external version, abdominal injury, chorionic villus sampling); the dose is 250 IU (50 μg) up to 20 weeks' gestation and 500 IU thereafter. It is critical that a Kleihauer acid elution test for detection and quantification of fetal red cells is performed on a maternal blood sample taken shortly after (within 1 h of) delivery and after each sensitizing event after 20 weeks. If the test shows > 4 mL of fetal cells, flow cytometry should be used to check the volume and give additional doses of anti-D as required. In several countries, and parts of the UK, the standard dose of anti-D Ig is 1250–1500 IU (250–300 μg).

Despite prophylaxis, new cases of sensitization to the D antigen still occur. Some may be due to an early unrecognized abortion and some to clerical and administrative errors (e.g. incorrect grouping of mother or child, or errors in the recording of groups). Failure of protection after delivery may result from omission of anti-D Ig (e.g. early discharge), an insufficient dose, or where primary immunization has already occurred during the pregnancy, now the most common cause of failure of conventional postnatal prophylaxis. Approximately 0.8–1.5% of Rh-negative women carrying a Rh-positive fetus become immunized during pregnancy.

To further reduce Rh immunization significantly, anti-RhD immunoglobulin should be given routinely during pregnancy to all RhD-negative women (usually 500 IU (100 μg) at 28 and 34 weeks, or a single dose of 1500 IU (300 μg) at 28 weeks). However, data from Canada suggest that a second dose of 300 μg may be needed for many women at 34 weeks, despite the larger dose at 28 weeks. The UK policy is to offer routine antenatal prophylaxis to all pregnant RhD-negative women, as it would significantly reduce the incidence of RhD sensitization in pregnant women. It is expected to offer D typing of the fetus from DNA extracted from maternal plasma before 28 weeks' gestation (see Chapter 15). This will avoid giving unnecessary routine antenatal Rh prophylaxis to women carrying RhD-negative fetuses.

The next most common causes of HDN requiring therapy are anti-c and anti-K. Any reduction in the cases due to anti-K could only be achieved by prevention of sensitization through transfusion of all women of childbearing potential with K-negative blood.

Phagocytes

Farhad Ravandi and Ronald Hoffman

Introduction

White blood cells have fundamental roles in defence against invading micro-organisms and the recognition and destruction of neoplastic cells as well as their role in acute inflammatory reactions. Furthermore, through their phagocytic function, white blood cells are influential in clearing senescent and apoptotic cells, hence allowing tissue repair and remodelling. Production of various cytokines by white blood cells influences the functions of other cells and affects processes such as cellular and humoral immunity, and allergic phenomena. The phagocytic actions of white blood cells can cause damage to the host tissue, leading to inflammation. This occurs either as a by-product of their microbial killing actions or as a direct attack on the host in autoimmune disorders.

Normal haemopoiesis, including generation of appropriate white blood cell number and constellation, is dependent upon intricately regulated signalling cascades that are mediated by cytokines and their receptors. Orderly function of these pathways leads to the generation of the normal constellation of haemopoietic cells, and their abnormal activation results in impaired apoptosis, uncontrolled proliferation and neoplastic transformation. Cytokines function in a redundant and pleiotropic manner; different cytokines can exert similar effects on the same cell type and any particular cytokine can have several differing biological functions. This complexity of function is a result of shared receptor subunits as well as overlapping downstream pathways, culminating in transcription of similar genes. Increased understanding of the role of cytokines and other growth factors in the control of normal haemopoiesis has led to better delineation of the pathogenetic events that affect the function and number of these cells.

In this chapter, we consider the normal production and function of white blood cells involved in phagocytosis and describe various disorders causing their altered number and activity.

Mechanisms of phagocyte function

Locomotion

Phagocytes are an important part of the innate host defence system, performing their function either as resident cells in tissues (e.g. macrophages) or as circulating defenders (e.g. neutrophils, eosinophils and monocytes). Phagocytosis of invading micro-organisms by both types of defender involves the synthesis of highly toxic derivatives of molecular oxygen by the respiratory burst NADPH oxidases and the delivery of stored antimicrobial proteases into the vacuoles containing microbes.

Circulating phagocytes such as neutrophils respond to spatial gradients of chemotaxin and move by alternating the extrusion and retraction of broad frontal lamellipodia that determine the direction of movement. As a result, the cell body elongates along the axis defined by the lamellar protrusion. As little as a 2% change in the concentration of the chemoattractant can be recognized by neutrophils. The signals generated by such gradients activate the cytoplasm of the cell for propulsive and retractive events. Movement of neutrophils is achieved by the contraction of an actin filamentous network in the cortical gel at the leading front. This dynamic network provides strength for the forming protrusions and serves as an anchor for adhesion molecules. ATP provides the energy for the movement of the cell.

Phagocytic cells possess a number of cell–cell adhesion receptors and ligands, which mediate their recruitment, migration and interaction with other immune cells (Table 17.1). These include members of the integrins, the immunoglobulin superfamily and the selectins. Migration of macrophages involves their adhesion to endothelial surfaces and their extravasation through to the extravascular space. This process is mediated by cytokine-regulated expression of intercellular adhesion molecules (ICAMs) on the surface of both phagocytes and endothelial cell. ICAMs share similar structure to the immunoglobulin (Ig)

Table 17.1 Phagocytic cell adhesion molecules.

Adhesion molecule	CD number	Cellular distribution	Ligand	Function
Integrin family				
Very late-acting antigens				
$\alpha_1\beta_1$ (VLA-1)	CD49a/29	Mo, EC	Collagen I, IV, laminin	Cell adherence to ECM
$\alpha_2\beta_1$ (VLA-2)	CD49b/29	Mo, EC, platelets	Collagen I, IV, laminin	
$\alpha_3\beta_1$ (VLA-3)	CD49c/29	Mo	Collagen I, laminin, fibronectin	Cell adherence to ECM
$\alpha_4\beta_1$ (VLA-4)	CD49d/29	Mo, eos, bas	Fibronectin, VCAM-1	Cell adherence to ECM and cell–cell adhesion matrix
$\alpha_5\beta_1$ (VLA-5)	CD49e/29	Mo, neut, EC	Fibronectin	Cell adherence to ECM
$\alpha_6\beta_1$ (VLA-6)	CD49f/29	Mo	Laminin	Cell adherence to ECM
Leucocyte integrins (LFA-1 family)				
$\alpha_D\beta_2$	–/18	Ma	?	
$\alpha_L\beta_2$ (LFA-1)	CD11a/18	Mo, Ma, granulocytes	ICAM-1, ICAM-2, ICAM-3	Cell–cell adhesion and cell–matrix adhesion
$\alpha_M\beta_2$ (CR3, Mac-1)	CD11b/18	Mo, Ma, granulocytes	ICAM-1, C3bi, fibronectin, factor X, microbial antigens	Endothelium adherence/extravasation
$\alpha_X\beta_2$ (p150,95)	CD11c/18	Mo, Ma, granulocytes	C3bi, fibronectin	Adhesion during inflammatory response
Cytoadhesins				
$\alpha_V\beta_3$ (vitronectin receptor)	CD51/61	Mo, EC	Vitronectin, fibronectin, collagen, thrombospondin, vWF	Cell adherence to ECM
$\alpha_R\beta_3$ (leucocyte response integrin)		Mo, granulocytes	Vitronectin, fibronectin, collagen, thrombospondin, vWF	Cell adherence to ECM
$\alpha_V\beta_5$	CD51/–	Mo	Vitronectin, fibronectin	Cell adherence to ECM
$\alpha_V\beta_7$	CD51/–	Ma	?	
Immunoglobulin superfamily				
ICAM-1	CD54	Mo, EC	$\alpha_L\beta_2$, $\alpha_M\beta_2$	Cell–cell adhesion
ICAM-2	CD102	Mo, EC	$\alpha_L\beta_2$	Cell–cell adhesion
ICAM-3	CD50	Mo, granulocytes	$\alpha_L\beta_2$	Cell–cell adhesion
VCAM-1	CD106	Ma, EC, dendritic cells	$\alpha_4\beta_1$	Recruitment
PECAM-1	CD31	Mo, EC, platelets	CD31, $\alpha_V\beta_3$	Transmigration
HCAM	CD44	Ubiquitous	Collagen I, IV, fibronectin	Extravasation
Selectin family				
L-selectin	CD62L	Mo, granulocytes	Carbohydrate determinants on EC	Migration, rolling on vessel wall
E-selectin	CD62E	Neutrophil, EC	Mo, neut, eos	Migration, rolling on vessel wall
P-selectin	CD62P	EC, platelets	Mo, neut, eos	Adhesion to activated platelets and EC

Bas, basophil; cd, cluster of differentiation; EC, endothelial cell; eos, eosinophil; ICAM, intercellular adhesion molecule; Mo, monocyte; Ma, macrophage; neut, neutrophil.

family and other Ig-like adhesion molecules such as VCAM-1, and serve as ligands for the β_2-integrins. The distribution and regulation of the three members of the ICAM family is different. ICAM-1 is expressed at a low level on endothelial cells; its expression is enhanced by the inflammatory cytokines such as interleukin 1 (IL-1), interferon-α (IFN-α) and IFN-γ. ICAM-2 is constitutively expressed on endothelial cells, with no response to the inflammatory cytokines. ICAM-3 is expressed by neu-

Table 17.2 Opsonic receptors mediating phagocytosis.

Receptor	Marker	Opsonic ligand	Binding affinity (Ka)	Cell type	Function
FcγRI	CD64	IgG1	High (50 nmol/L)	Monocytes, Macrophages, Neutrophils (after IFN-γ exposure)	Phagocytosis, Respiratory burst
FcγRII	CD32	IgG1 = IgG3≥ IgG4 = IgG2	Low (1 μM)	Neutrophils, monocytes, macrophages	Phagocytosis, Respiratory burst
FcγRIII		IgG1 = IgG3	Low (110 nmol/L)	Neutrophils, monocytes, macrophages	IIIB – Phagocytosis (requires CR1 or FcγRII)
IIIA	CD16a, 1 allotype NA1		Low (470 nmol/L)		
IIIB	CD16b, 2 allotypes NA1 and NA2				
FcαR	CD89 My43 IgM	IgA1, IgA2, secretory IgA1 and IgA2		Neutrophils, monocytes, macrophages, T- and B-cell subsets, NK cells, erythrocytes	Phagocytosis, Respiratory burst, Bacterial killing
CR1	CD35 4 alleles	C3b and C4b dimers	High (0.5 nmol/L)	All phagocytes, some T lymphocytes	Phagocytosis
CR3	CD11b/CD18 Mac1	C3bi	High (0.5 nmol/L)	All phagocytes, NK cells, γδ-T cells	Phagocytosis, Respiratory burst

CR, complement receptor; NK, natural killer.

trophils, monocytes and lymphocytes. Another member of the endothelial Ig superfamily, PECAM-1 (CD31), serves an important role in transmigration of neutrophils into mucosal or other body tissues.

The β_2-integrin family consists of three leucocyte restricted integrins, LFA-1 (CD11a/CD18), CR3 (MAC-1, CD11b/CD18) and p150/95 (CD11c/CD18). They share a common β-subunit, CD18, and three unique α-subunits, CD11a, CD11b, and CD11c. LFA-1 and ICAM-1 are both present on monocytes and mediate their attachment to endothelial cells and to lymphocytes bearing the corresponding receptor/ligand, thereby facilitating antigen presentation. Leucocyte adhesion deficiency (LAD) type I, described later in the chapter, is caused by the genetic deficiency of all three CD18 integrins. LAD-I neutrophils bind poorly to IL-1-stimulated endothelial cells and do not undergo transendothelial migration.

Selectins are expressed on all leucocytes (L-selectins) as well as post-capillary endothelial surfaces (E-selectins) and in platelet α-granules and endothelial cell Weibel–Palade bodies (P-selectins). Neutrophils, eosinophils, monocytes and macrophages constitutively express L-selectin. E- and P-selectins recognize oligosaccharide ligands on macrophages. Selectins are implicated in the early interactions of phagocytes and endothelium. The interaction of E- and P-selectins on cytokine-activated endothelial cells, and L-selectins on macrophages with their appropriate ligands, targets phagocytic cells to the endothelium at sites of vascular injury and initiates the rolling movement of leucocytes along the vessel wall. The ligands for selectins have a similar structure containing carbohydrate groups typically as terminal structures of glycoproteins and glycolipids. A major selectin ligand, a sialylated and fucosylated tetrasaccharide related to the sialylated Lewis X blood group, is heavily expressed on quiescent neutrophils and monocytes.

Phagocyte receptors

Phagocytes express a number of surface receptors that are able to recognize microbial surfaces as well as altered tissue components and apoptotic bodies (Table 17.2). Furthermore, non-specific components of the innate immune response, such as the components of the complement cascade, can tag and thereby identify invading micro-organisms, thus allowing their opsonization via another family of receptors, leading to the uptake of complement-coated micro-organisms. This complement fixation

can occur either via the classical pathway, which is activated by the prior binding of immune IgG or IgM to the organism or particle, or by antibody-independent activation of the alternative pathway. Similarly, other molecules such as matrix proteins (i.e. fibronectin and vitronectin) can act as opsonins allowing recognition and uptake by the phagocytic cells. Interestingly, in order to evade phagocytes, pathogenic bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Neisseria meningitidis* have developed strategies such as production of polysaccharide capsules, which provide a shield against complement binding and activation, and recognition by scavenger receptors.

Two types of complement receptors, CR1 (CD35) and CR3 (CD11b/CD18) have been described. The CR1 receptor is a glycosylated protein with a molecular weight of 160–250 kDa and can be identified as CD35. CR1 is present on all phagocytes as well as some T lymphocytes. CR1 mediates phagocytosis of particles opsonized by C3b and regulates complement activation. CR3 is a member of the β_2-integrin family and is designated CD11b/CD18. It is composed of two polypeptide chains, an α-subunit of 185 kDa and a β-subunit of 95 kDa. CR3 is expressed on all phagocytes as well as natural killer cells and some $\gamma\delta$-T cells. Monocytes and macrophages express high levels of CR3; neutrophils have lower level expression that can increase rapidly through release from intracellular stores. CR3 can bind particles opsonized with C3bi as well as determinants on unopsonized microbes. The avidity of CR3 is enhanced by an amphipathic anion lipid called integrin-modulating factor (IMF-1) as well as by bacterial peptide fragments, C5a, LTB4, and cytokines such as tissue necrosis factor (TNF), granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF). However, IFN-γ transiently decreases the binding capacity of both CR1 and CR3. Simultaneous cross-linking of two different receptor types also increases binding by CR3. For example, macrophages adhered to collagen ingest complement-coated particles less efficiently than macrophages adhered to fibronectin, which cross-links other integrin receptors. CR3 also plays a critical role in adherence dependent potentiation of the respiratory burst and secretory responses of neutrophils.

Phagocytes also express a number of receptors for the Fc portion of immunoglobulin molecules IgA, IgE, and IgG. They mediate opsonization of particles and micro-organisms enhancing their phagocytic uptake. The antigen binding site (Fab) of IgG binds to bacteria exposing the Fc binding site, which is in turn recognized by one of three classes of receptors, FcγRI, FcγRII or FcγRIII. FcγRIII is constitutively expressed in neutrophils with 100 000 to 300 000 copies per cell and is identified as CD16. Two isoforms, A and B, exist, which differ only with respect to their transmembrane and cytoplasmic domains. FcγRIIIB lacks both of these domains and is anchored by a glycosyl-phosphatidylinositol (GPI) protein and is therefore absent in patients with paroxysmal nocturnal haemoglobinuria. FcγRIIIB can trigger granule release but no associated respiratory burst.

However, FcγRIIIB and CR3, together with FcγRII, act synergistically to activate the respiratory burst. FcγRII (identified as CD32) is a constitutive low-affinity receptor with low expression (1000 to 4000 copies per cell) requiring dimeric IgG for binding. Cross-linking FcγRII stimulates oxygen radical production. FcγRI, identified as CD64, is not expressed on quiescent neutrophils but its expression is highly increased after exposure to IFNγ and a number of inflammatory mediators. It binds IgG1 and IgG2 with high affinity and promotes phagocytosis of bacteria opsonized by them. Polymeric IgA antibody can also function as an opsonin and is recognized by a specific IgA receptor (FcαR), which is widely distributed on the circulating haemopoietic cells but is more highly expressed in phagocytes found in secretions of the gut and the lung.

A number of miscellaneous receptors involved in phagocytosis have been described. The mannosyl/fucosyl receptors, otherwise known as the macrophage mannose receptors (MMR), are lectin-like molecules that bind mannose and fucose residues on the surfaces of yeasts, bacteria and parasites. These receptors are present only on the surface of macrophages and their expression is increased by IFN-γ. Their activation mediates endocytosis, phagocytosis and cytotoxicity by reactive oxygen intermediates. The receptors described to date are composed of eight and 10 contiguous C-type lectin domains. CD14 is the receptor for complexes of lipopolysaccharide (LPS)-binding protein with LPS, which coat Gram-negative bacteria and enhance phagocytosis. CD14 is constitutively expressed on monocytes and macrophages but its expression is modulated by cytokines. TNF, IL-1 and IL-6 increase its expression, whereas IFN-γ and IL-4 decrease it. CD14 expression can also be induced on neutrophils by various cytokines. CD14 is also a GPI-linked protein and is shed by monocytes.

Several receptors have also been implicated in the recognition and phagocytosis of apoptotic cells. Morphological changes in the apoptotic cells such as formation of characteristic membrane protuberances (blebs) lead to the exposure of phosphatidylserine (PS) and changes on surface sugars, which are recognized by phagocytic receptors. These include integrins of the $\alpha_v\beta_3$ or $\alpha_v\beta_5$ classes and the lipid scavenger receptors of both A and B classes. The membrane of apoptotic cells bind increased amounts of thrombospondin, a macrophage secretory product, that is recognized by both CD36 (thrombospondin receptor) and integrin $\alpha_v\beta_3$ (vitronectin receptor). Similarly, phagocytic lectin receptors bind carbohydrate determinants exposed on the surface of apoptotic cells. A specific receptor for PS, or PSR, has also been described, which acts alone or in association with CD36 to recognize the exposed PS. CD14 has also been reported to be involved in tethering of apoptotic lymphocytes via interaction with ICAMs.

Neutrophils also recognize the chemoattractant signals through receptors expressed on their cell surface. *N*-formyl-methionyl tripeptide receptors such as f-Met-Leu-Phe (FMLP) are similar to naturally occurring bacteria-derived factors. Each demonstrates

time-dependent saturable binding kinetics and a high-affinity dissociation constant (K_D) for the specific chemoattractant. Approximately 50 000 FMLP receptors per cell with a K_D of 20 nmol/L have been demonstrated on human neutrophils. Thrombospondin also has chemotactic activity and binds neutrophils via specific receptors linked to Gi2 proteins, a subpopulation of which is also associated with the FMLP receptors. Neutrophils also have a specific receptor for the chemotactic cleavage product of C5a with a receptor expression of approximately 50 000–100 000 per cell and a binding affinity of 2 nmol/L.

Chemokines are a family of proinflammatory cytokines with potent chemotactic activity. They are small proteins (8–10 kDa), characterized by a pattern of conserved cysteine residues. CXC chemokines such as IL-8 are specific to neutrophils and are distinguished by having their first two cysteine residues separated by an amino acid. Whereas CC chemokines, including macrophage inflammatory protein-1α (MIP-1α) have the first two cysteine residues adjacent, are inactive for neutrophils, but attract monocytes, basophils, eosinophils and T-lymphocytes. Monocyte migration is also directed by monocyte chemotactic proteins (MCP). Eosinophil migration is directed by MIP-1α and RANTES (regulation on activation normal T-cell expressed and secreted protein) in addition to the CC chemokine, eotaxin. Phagocytic cells in general have a high expression of the receptors for these chemokines enabling them to recognize and respond to the appropriate chemoattractants.

Phagocytic signalling

The complex process of phagocytosis is regulated by events related to the activation of various receptors such as the FcγRs. Such receptor activation results in initiation of downstream signalling events through immunoreceptor tyrosine-based activation motifs (ITAMs). As a result of cross-linking of these receptors under appropriate conditions, downstream effector functions are activated, resulting in phagocytosis, stimulation of the respiratory burst, degranulation of bactericidal proteins and activation of transcription factors, in turn leading to enhanced expression of genes encoding cytokines and other inducible proteins.

Members of the Src family of tyrosine kinases (e.g. Lyn, Fgr and Hk) associate with FcγRs and are probably responsible for their tyrosine phosphorylation. The tyrosine-phosphorylated ITAMs then serve as binding sites for downstream kinases such as Syk, which propagate signals important for phagocytosis. Downmodulation of Syk in monocytes using antisense oligonucleotides results in decreased ability of these cells to ingest IgG-coated particles. Furthermore, macrophages that lack Syk demonstrate a profound reduction in FcγR-mediated tyrosine phosphorylation of p85 subunit of PI-3 kinase, SHIP, Shc and other important signalling proteins.

Phosphorylation and activation of members of the Rho/Rac family of GTPases as well as the ARF6 family are probably involved in cytoskeletal remodelling necessary to trigger phagocytosis. For example, inhibition of Rac1 or Cdc42 in murine macrophage models leads to impaired focal actin assembly beneath bound IgG-coated particles and blocks subsequent ingestion without affecting particle binding. Cdc42 and Rac1 appear to control different steps in the phagocytic process, namely pseudopod formation for the former and phagosome closure for the latter. The role of phospholipase C-γ (PLC-γ) and protein kinase C (PKC) isoforms in actin assembly, and the role of PI3 kinase (PI3K) pathways in membrane remodelling during phagocytosis are under investigation. Treatment of macrophages with PI3K inhibitors such as wortmannin and LY 294002 results in the failure of pseudopods to extend around particles.

Degranulation and secretion

Degranulation and secretion are processes whereby the contents of phagocytic storage granules are released into the phagocytic vacuoles (degranulation) or into the extracellular space (secretion). Degranulation and secretion can be triggered by invading micro-organisms, immune complexes, cytokines, chemotactic factors, and adhesion to tissue surfaces and activation of ICAMs. The processes of degranulation and secretion begin with the onset of phagocytosis. A number of morphological changes occur within the granules and they translocate and fuse their membranes with those of the phagocytic vacuoles formed by the invagination of the plasma membrane.

Cytoskeletal proteins are essential for this process facilitating granule transfer to plasma membrane or phagolysosomes. The exact cause of membrane fusion is unknown but the process is likely to involve the activation of several phospholipases leading to altered lipid composition of granule–phagosome or granule–plasma membrane contact points. Actin polymers act like a barrier between plasma membrane and granules, and in order for the membrane fusion to occur the granules have to go through the physical barrier of such cytoskeletal elements in the cell periphery. Furthermore, the repulsive negative charge on the surface of both membranes, related to the negatively charged phospholipids phosphatidylserine and phosphatidylethanolamine, is a further barrier that needs to be overcome. A number of soluble molecules capable of provoking the release of granule content into the extracellular space have been described. They include many chemotactic factors such as C5a, fMLP, PAF, LTB4, as well as phorbol myristate acetate (PMA) and several non-chemotactic interleukins, cytokines and growth factors such as TNF-α, IL-1, IL-6, IL-4, IL-6 and GM-CSF. Importantly, phagocytes are capable of rapidly replenishing cellular stores of proteins and forming new granules, thus allowing repeated degranulation and secretion.

Regulation of granule release is mediated by a number of factors such as calcium, guanine nucleotides and G-proteins, which regulate changes in the cytoskeleton, resulting in actin polymerization and clearing of the cytoskeleton along the plasma
Figure 17.1 Components of the NADPH oxidase system. The components include a 47-kDa cytosolic protein (p47), a 67-kDa cytosolic protein (p67), a 40-kDa cytosolic protein (p40), cytosolic G-proteins (Rac1 and Pap1), and a membrane-bound cytochrome (*b*558). The cytochrome consists of haem containing p22-phox and gp91-phox. The gp91 subunit is a FAD-dependent flavoprotein shuttling electrons to molecular oxygen, forming O_2^-. The p47 component can be phosphorylated to various extents. In activated cells, the p40, p47 and p67 proteins translocate to membrane to form an activation complex with cytochrome *b*558. Similarly, the Rac1 and Rap1 proteins also translocate. The activated oxidase passes electrons from NADPH via FAD to oxygen, thereby generating superoxide.

membrane fusion site. These proteins include members of the annexin family, the calcium-binding protein calmodulin, protein kinase C and phospholipases.

Phagocytic killing – the respiratory burst

Activation of phagocytes is associated with a rapid and dramatic increase in oxygen consumption described as the respiratory burst. This process is non-mitochondrial and is mediated by the activation of a latent enzyme system referred to as NADPH oxidase, which transfers a single electron to molecular oxygen (O_2), forming the superoxide anion (O_2^-). The superoxide anion then dismutates to hydrogen peroxide (H_2O_2), a process occurring either spontaneously or through the catalytic function of superoxide dismutase. H_2O_2 then reacts with superoxide anion, forming the highly reactive hydroxyl radical (OH), which is highly microbicidal. This and other reactive oxidative products not only contribute to microbial killing but also activate metalloproteinases such as elastase and collagenase, leading to the surrounding tissue injury that often accompanies phagocyte activation.

The NADPH oxidase is a multicomponent enzyme, with several subunits located in various regions of the quiescent phagocytes (Figure 17.1). These subunits, called the phox (phagocyte oxidase) proteins, are identified by their molecular weight (e.g. p40

phox). In the quiescent neutrophil, p47 phox protein resides in the cytosol, along with p67 phox complexed with p40 phox. Activation of NADPH oxidase results from protein kinase C-mediated phosphorylation of p47 phox and the subsequent binding of the p47 phox phosphoprotein and the p67 phox–p40 phox complex to the membrane flavocytochrome b558 located primarily in the specific granules, gelatinase granules and secretary vesicles of neutrophils. The cytochrome *b*558 is the terminal component of the superoxide generating system allowing the efficient transfer of electrons from the cytoplasmic NADPH to the surface of phagolysosome or the extracellular surface, where oxygen is reduced to the superoxide anion. Other GTP-binding proteins such as Rap1A and Rac2, associate with the above molecules and regulate phagocyte activation and oxidase activity through their preferred substrate GTP (Figure 17.1).

Phagocytic killing – nitric oxide

Generation of reactive nitrogen intermediates through nitric oxide synthase (NOS) is another mechanism for phagocytic killing of microbes. Nitric oxide (NO) is the highly reactive free radical product of the oxidation of L-arginine in phagocytes during inflammation. Three distinct isoforms of NOS have been described in blood cells. Two are found in endothelial and neuronal cells and the third, the inducible NOS, is induced by

Phagocytes

cytokines, such as IFN-γ, in a number of cell types. Cofactors required for the activity of NOS include flavine adenine dinucleotide (FAD), flavine mononucleotide (FMN), NADPH and tetrahydrobiopterin. The calcium binding protein, calmodulin, is tightly bound to the macrophage NOS. The activity of NOS is also regulated by kinases and phosphatases and its production is influenced by other cytokines such as IL-4, IL-10, IL-8 and transforming growth factor β (TGF-β).

NO has an important role in the antimicrobial activity of both neutrophils and mononuclear phagocytes. In contrast to NADPH oxidase, which is active at the plasma and phagolysosome membrane, NOS is located in the cytoplasm and mediates defence against facultative intracellular pathogens, as well as other prokaryotic and eukaryotic pathogens. Its inhibitory effects are due to nitrosylation of proteins and interaction with transition metals at the active sites of enzymes. Furthermore, NO scavenges superoxide to form peroxynitrite ($OONO^-$), which can disrupt protein phosphorylation.

Phagocytic killing – antimicrobial proteins

Phagocytic cells such as neutrophils can kill micro-organisms using proteins present in various granules. The importance of such non-oxidative killing is evident in chronic granulomatous disease neutrophils that are still capable of killing many potent micro-organisms. Furthermore, this process is important for defence against organisms such as *Escherichia coli* and *Salmonella typhimurium*, which do not produce their own source of oxidants and are killed under anaerobic conditions. The contents of each phagocytic cell type are specific. Neutrophil antimicrobial proteins include defensins, serpocidins (including cathepsin G and azurocidin) and bacterial permeability-increasing protein (BPI). The antimicrobial proteins within neutrophils are summarized in Table 17.3.

These microbicidal proteins exert their killing effect through enzymatic means such as proteolysis or by non-catalytic mechanisms, and their combinations potentiate bactericidal activity. Cathepsin G is a serine protease that exerts its bactericidal action by binding to penicillin-binding proteins of bacteria and interfering with the synthesis of peptidoglycans. Azurocidin is another serine protease effective against a number of bacteria and fungi. Defensins constitute as much as 50% of neutrophil granule protein content and exert their cidal activity by inserting into hydrophobic channels, forming voltage-dependent ion channels in the lipid bilayer. BPI kills Gram-negative bacteria by binding to their LPS capsule and altering their bacterial

Table 17.3 Neutrophil microbicidal proteins.

Protein	Characteristics	Target organisms	Effects on target
Non-enzymatic proteins			
BPI	Highly cationic, neutralizes LPS, most potent cidal protein, not released from granule	Gram –ve bacteria	Binds lipid A region of LPS, increases bacterial membrane permeability, activates bacterial degradative enzymes
Defensins	Comprise 30% to 50% of azurophil granule protein	Gram +ve > –ve bacteria, fungi, viruses, mammalian cells	Increases membrane permeability
Lactoferrin	Cationic, stimulates hydroxyl radical formation	Gram +ve and –ve bacteria, fungi	Oxidative damage
Catalytic proteins and analogues			
Proteinase 3	Serine proteinase	*Escherichia coli, Streptococcus faecalis, Candida albicans*	Growth inhibition
Cathepsin G	Serine proteinase	Gram +ve and –ve bacteria, fungi	Inhibition of peptidoglycan synthesis
Azurocidin	Serine proteinase	Gram –ve bacteria	Non-catalytic mechanisms
Lysozyme	Cationic	Gram –ve bacteria, few Gram +ve bacteria	Potentiation of complement and H_2O_2 killing, cleavage of cell wall peptidoglycans
Elastase	No direct cidal activity		Co-active with lysozyme Potentiation of MPO–halide–H_2O_2 system

BPI, bacterial permeability inducing factor; LPS, lipopolysaccharide; MPO, myeloperoxidase.

membrane permeability to extracellular solutes. A mutant strain of *S. typhimurium*, which is resistant to BPI, has also been found to be resistant to neutrophil bactericidal activity under strict anaerobic conditions, demonstrating the importance of BPI in non-oxidative killing by neutrophils. Other neutrophil granule proteins include lactoferrin, which kills some Gram-negative bacteria by generating free radicals from iron bound to it, and lysozyme, which is involved in the digestion of killed bacteria in phagolysosomes of neutrophils. These antimicrobial proteins can also enhance the effects of other cidal mechanisms such as complement lysis and oxidative killing. Combinations of these proteins can also enhance their killing action, as seen with the combination of neutrophil lysozyme and elastase against Gram-negative bacteria. Some of the microbicidal proteins of the phagocytes have other effects at lower concentrations, such as stimulation of mast cell degranulation, release of proinflammatory molecules and monocytic chemotaxis, as well as regulation of phagocytosis and granulopoiesis.

Production, structure and dysfunction of phagocytes

White blood cells are produced from pluripotent stem cells located within the bone marrow. Development of white blood cells along different lineages is governed by external stimuli including cytokines, matrix proteins, and other cellular products within the marrow environment. The combination of specific cytokines and growth factors influence the maturation of white blood cell progeny along specific lineages. Although

there is significant overlap between these growth factors, certain cytokines have been found to be associated with specific maturation pathways. Some of these cytokines are now manufactured commercially and are in clinical use to influence the speed of recovery of white blood cells following administration of chemotherapy.

Neutrophils (Figure 17.2a)

Development and function

Neutrophils are the predominant white blood cells involved in phagocytic killing of bacteria and certain fungi. They are also referred to as polymorphonuclear or segmented, owing to their characteristic lobulated nucleus (their nucleus is segmented into two to five lobes, connected by thin chromatin strands). They are at the end stage of maturation (Figures 17.3 and 17.4) and generally uniform in size (13 μm in diameter), with pink cytoplasm and fine azurophilic granules. The production of neutrophil leucocytes involves the action of a variety of growth factors including granulocyte colony-stimulating factor (G-CSF), granulocyte–macrophage-colony-stimulating factor (GM-CSF), IL-3, and macrophage colony-stimulating factor (M-CSF). Other factors such as IL-11, stem cell factor (SCF) and FLT-3 ligand enhance clonal neutrophil expansion *in vitro*. GM-CSF induces neutrophil, eosinophil and macrophage colony expansion *in vitro*, but there is no evidence that it induces neutrophil differentiation in the absence of G-CSF.

Neutrophils contain four types of granules that can be identified by marker enzymes or proteins (Table 17.4). The lysozyme-like azurophil granules, otherwise known as primary

granules, present in the promyelocytes and all further stages of neutrophil differentiation and contain microbicidal proteins and acid hydrolases (such as myeloperoxidase, defensins, and lysozyme) involved in oxidative and non-oxidative killing of bacteria and fungi. These granules release their contents exclusively into phagocytic granules, with little discharge outside the cell except for release from disintegrating neutrophils. Specific or secondary granules are smaller than azurophil granules and contain other distinct hydrolases, as well as chemotactic,

opsonic, and adhesion protein receptors. They release their contents both into phagocytic vesicles and into the extracellular medium. Other granules, collectively known as tertiary granules, include secretory vesicles, which contain alkaline phosphatase, and gelatinase granules rich in gelatinase. Degranulation of neutrophils begins with the onset of phagocytosis and involves their translocation and fusion with phagocytic vacuoles created by invagination of the plasma membrane. Degranulation may also occur by reversed endocytosis as a result of the action of complement, aggregated immunoglobulin or certain cytokines. Although the release of granule contents is important for phagocytosis and bacterial killing, extracellular release can also lead to tissue injury and inflammation.

Neutrophils exist in one of three states: quiescent, activated or primed. They circulate in the blood in the quiescent state and react weakly to stimuli, thus limiting potential damage to vascular walls. Priming of neutrophils is a process that does not immediately stimulate an effector response but allows an exaggerated response upon later stimulation. Therefore, this is a mechanism whereby phagocytes are selectively activated upon recruitment to sites of infection and inflammation. Three main types of agonists are responsible for priming neutrophils, including chemotactic inflammatory mediators, serum immunoglobulin and complement opsonins, and inflammatory cytokines and growth factors. Upon neutrophil activation, a significant increase in oxygen consumption, termed respiratory burst, occurs leading to the production of reactive oxygen species responsible for microbial killing.

Figure 17.4 Neutrophil lifespan and stages of maturation. Of every 100 nucleated cells in the bone marrow, 2% are myeloblasts, 5% promyelocytes, 12% myelocytes, 22% metamyelocytes and bands and 20% mature neutrophils (i.e. about 60% developing neutrophils). The times indicated for the various compartments were obtained by isotopic labelling techniques. The ordinate shows the flux, and the abscissa the time, in each compartment. The stepwise increase in cell numbers through the dividing compartments represents serial divisions. Note that no mitoses occur after the myelocyte stage (reproduced with permisssion from Bainton DF, *Developmental Biology of Neutrophils and Eosinophils,* and Cronkite EP, Vincent PC, 1969, *Ser Haematology* 3: 3–43).
Table 17.4 Neutrophil granules and their contents.

Granule	Azurophilic (primary)	Specific (secondary)	Gelatinase (tertiary)	Secretory vesicles
Marker enzyme	Myeloperoxidase	Lactoferrin	Gelatinase	Alkaline phosphatase
Membrane	CD63, granulophysin, CD68, V-type H^+-ATPase	CD15, CD66, CD67, CD11b/CD18, Cytochrome b, fMLP-R, fibronectin-R, G-protein α-subunit, laminin-R, NB-1 antigen, 19-kDa protein, 155 kDa protein, Rap-1, Rap-2, SCAMP, thrombospondin-R, TNF-R, urokinase type plasminogen activator-R, VAMP-2, vitronectin	CD11b/CD18, cytochrome b, diacylglycerol-deacylating enzyme, fMLP-R, SCAMP, urokinase type plasminogen activator-R, VAMP-2, V-type H^+-ATPase	CD10, CD13, CD45, CD14, CD16, CD35 (CR1), CD11b/CD18, alkaline phosphatase, fMLP-R, SCAMP, urokinase type plasminogen activator-R, V-type H^+-ATPase, VAMP-2, C1q-receptor, decay activating factor
Matrix, microbicidal	Myeloperoxidase, nitric oxide (NO) synthase, lysozyme, BPI protein, defensins, serprocidins, elastase, cathepsins, proteinase 3, azurocidin (CAP 37)	Lactoferrin, lysozyme	Lysozyme	
Matrix, hydrolases	Acid β-glycerophosphatase, α-mannosidase, β-glucuronidase, β-glycerophosphatase, N-acetyl-β-glucosaminidase, sialidase	Gelatinase, collagenase, histaminase, heparanase, NGAL, sialidase	Gelatinase, acetyltransferase	
Matrix, other	Acid-mucopolysaccharide, heparin binding protein	β_2-microglobulin, urokinase-type plasminogen activator, vitamin-B_{12} binding protein	β_2-microglobulin,	Plasma proteins (including tetranectin)

Fmlp, f-Met-Leu-Phe; R, receptor; SCAMP, secretory carrier membrane protein; VAMP, vesicle associated membrane protein.

Neutrophils are the most numerous leucocytes comprising 65% of circulating phagocytes with a normal range in the peripheral blood of $1.5 - 7.7 \times 10^9$/L. The largest proportion of neutrophils is within the marrow (reserve pool), with circulating and tissue pools comprising smaller fractions (Figure 17.4). The circulating pool itself consists of a marginated pool of cells that are loosely adherent to the vascular endothelium and a freely circulating pool with the compartments in a constant state of dynamic equilibrium. Several factors including corticosteroids, exercise and infection can lead to an increase in the free circulating pool. Corticosteroids promote the release of neutrophils from the reserve pool into the circulation and prevent migration from the blood into the tissue pool. Endotoxin and some complement components (C5a) on the other hand, result in increased margination and reduction in the circulatory pool. The half-life of a circulating neutrophil is short (6–8 h) (Figure 17.4). In Figure 17.5, the variations in neutrophil morphology are shown. These include: (a) Barr body, a drumstick appendage to the neutrophils in females; (b) Pelger–Huët anomaly, with bilobed nuclei; and (c) Alder–Reilly anomaly. Also shown are May–Hegglin (d), toxic granulation (e), hypersegmented neutrophils (f) and Chédiak–Hegasin (g).

The May–Hegglin anomaly is a rare autosomal dominant condition. The neutrophils contain basophilic inclusions of RNA, resembling Döhle bodies (Figure 17.5). Giant platelets with thrombocytopenia are common, leukopenia less so.

Disorders of neutrophil function and number

Neutrophilia
Leucocytosis or increased white blood cell count may be either due to a primary (congenital or acquired) marrow disorder or secondary to a disease process, a toxin or a drug (Table 17.5). Neutrophil counts are high in neonates and decrease to normal adult levels with ageing. Secondary leucocytosis not associated with leukaemia but with a very high white blood cell count ($> 50 \times 10^9$/L) is often referred to as leukaemoid reaction and can be associated with presence of Döhle bodies and toxic

Table 17.5 Causes of neutrophilia.

Primary	Hereditary
	Chronic idiopathic
	Familial myeloproliferative disease
	Leukaemoid reaction associated with congenital anomalies
	Leucocyte adhesion deficiency (LAD) types I and II
	Familial cold urticaria and leucocytosis
Secondary	Infection
	Stress
	Chronic inflammation

	Non-haematological neoplasms
	Asplenia and hyposplenism
Neoplastic	Chronic myeloid leukaemia
	Other myeloproliferative disorders (myelofibrosis, PV, ET)

ET, essential thrombocythaemia; PV, polycythaemia vera.

granulation within the cytoplasm (Figure 17.5), as well as a 'left shift' (with presence in blood of myelocytes, metamyelocytes and band forms) and an elevated leucocyte alkaline phosphatase score (compared with a low score in chronic myeloid leukaemia, CML). In contrast with acute leukaemia, there is an orderly maturation and proliferation of all normal myeloid elements in the bone marrow. Leukaemoid reactions have been described in patients with osteomyelitis, empyema, septicaemia, tuberculosis, Hodgkin's disease, juvenile rheumatoid arthritis and dermatitis herpetiformis.

Leucocyte adhesion deficiency (LAD) is a congenital disorder, presenting with persistent leucocytosis, delayed separation of the umbilical cord, recurrent infections, impaired wound healing and defects of activation of neutrophils. The condition is caused by defects in adhesion of neutrophils to blood vessel walls. As a result, phagocytes do not migrate from the bloodstream to sites of infection. Two types of LAD have been described. In LAD-I, mutations of the gene encoding the β-subunit of the $β_2$-integrins (CD11b and CD18) have been detected. The molecular basis for the rare LAD-II is defective glycosylation of ligands on leucocytes recognized by selectin family of adhesion molecules. Clinical features in the two types are similar and, due to the defect in neutrophil migration, abscesses and other sites of infection are devoid of pus despite the striking neutrophilia. Treatment involves the use of prophylactic antibiotics and aggressive therapy of periodontal disease. Stem cell transplantation can be considered in patients with severe disease.

Hereditary neutrophilia has been described in a single family of four with leucocyte counts chronically in the range of

20×10^9/L to 70×10^9/L as well as splenomegaly, widened diploë of the skull, and a high leucocyte alkaline phosphatase but without serious medical problems. Neutrophil function and adhesion to vessel walls in these patients are normal and the condition appears to have an autosomal dominant inheritance.

Chronic idiopathic neutrophilia is an association of a chronically elevated neutrophil count (in the range of 11×10^9/L to 40×10^9/L) in healthy individuals without any associated clinical problems. In one series, several individuals were followed for up to 20 years without developing any disease.

Leukaemoid reactions have been described with congenital disorders such as amegakaryocytic thrombocytopenia, tetralogy of Fallot, dextrocardia with absent radii and in patients with Down's syndrome. The neutrophilia in Down's syndrome patients is transient but may be exaggerated in response to stress. A syndrome of growth retardation, hepatosplenomegaly and leucocytosis has been described as familial myeloproliferative disease with some affected individuals dying in early life and others remaining stable or even improving with time. These patients had low LAP scores and no detectable cytogenetic abnormality. Others have reported families with several generations of affected individuals with a variety of myeloproliferative disorders but without cytogenetic abnormalities.

Familial cold urticaria and leucocytosis is a syndrome of fever, urticaria, rash and muscle and skin tenderness on exposure to cold, which appears to be dominantly inherited. The onset of the disease is in infancy with urticaria, rash and leucocytosis generally occurring several hours after cold exposure. The skin rash is histologically characterized by intense infiltration by neutrophils.

Non-malignant causes of neutrophilia include acute infections with elevated counts in most bacterial infections. In cases of overwhelming infection, marrow depletion can occur, resulting in neutropenia rather than neutrophilia. Neutrophilia in chronic inflammatory processes is usually more modest in degree and can be accompanied by monocytosis. Modest elevation of neutrophil count is commonly seen in various forms of 'stress' such as exercise, adrenaline injection, myocardial infarction, post-operative period, post-ictal states and with emotional distress. This is probably due to the migration of neutrophils from the marginated pool to the circulatory pool. Mild neutrophilia has also been reported with unipolar depression. A number of drugs and drug reactions are commonly associated with increased neutrophil count. Steroids stimulate the release of neutrophils from the bone marrow and diminish their egress from the circulation resulting in chronic neutrophilia. This can be distinguished from neutrophilia due to infection by the distinct lack of band forms in the former. β-Agonists produce an acute neutrophilia by releasing neutrophils from the marginated pool. Other drugs known to produce neutrophil leucocytosis include lithium, which increases the production of CSF and potentiates its effects on myeloid colony formation, and tetracycline, which has been associated with counts as high as

80×10^9/L. Growth factors such as G-CSF, GM-CSF and Neulasta (a pegylated form of G-CSF that prolongs its half-life in circulation) are commercially available and are used commonly to reduce the duration of neutropenia associated with chemotherapy and to mobilize stem cells for transplantation. Their use in healthy individuals for the latter purpose is associated with significant neutrophilia and a left shift.

Neutropenia

Neutropenia can be due to impaired production by the bone marrow, shift from the circulating pool to marginated pool, increased peripheral destruction, or a combination of these (Table 17.6). It has been defined as an absolute neutrophil count

Table 17.6 Causes of neutropenia.

Decreased production	
Inherited	Reticular dysgenesis
	Dyskeratosis congenita
	Schwachman–Diamond–Oski syndrome
	Cyclic neutropenia
	Kostmann's syndrome
	Hyperimmunoglobulin-M syndrome
	Chronic idiopathic neutropenia
Acquired	Aplastic anaemia
	Bone marrow infiltration (leukaemia, lymphoma, tumours, tuberculosis, etc.)
	Severe infection
	Drug induced (cytotoxic chemotherapy, radiation, chloramphenicol, penicillins, cephalosporins, phenothiazine, phenylbutazone, gold, antithyroid drugs, quinidine, anticonvulsants, alcohol)
	Myelodysplastic syndrome
	Vitamin B_{12} or folate deficiency
	Pure white cell aplasia
	T-γ lymphocytosis and neutropenia
	Neutropenia associated with metabolic disorders
Increased peripheral destruction

	Stress

of more than two standard deviations below a normal mean value. There is a variation of neutrophil counts amongst different ethnic groups, with black people generally having slightly lower counts (lower limit of normal 1.2×10^9/L) compared with white people (lower limit of normal 1.5×10^9/L). The lower count in black population has been attributed to a relative decrease in the size of marrow storage pool. In patients whose neutropenia is related to decreased production, the propensity to develop infections is directly related to the degree and duration of neutropenia.

On the other hand, in patients whose neutropenia is to peripheral destruction or margination of neutrophils, there is no direct correlation between the degree of neutropenia and the propensity for infections. Conditions such as marrow failure states and neutropenia associated with chemotherapy can predispose patients to severe life-threatening infections, although this is more likely in patients with neutrophil counts below 0.5×10^9/L. Common organisms encountered in this setting are *Staphylococcus aureus, Pseudomonas aeruginosa, Escherichia coli* and *Klebsiella* species. On the other hand, patients with some congenital or immune forms of neutropenia can tolerate low counts for prolonged periods without any apparent increase in the incidence of infections.

Several well-defined inherited syndromes associated with neutropenia have been described. Moderate, asymptomatic neutropenia associated with specific ethnic groups such as American black people and Yemenite Jews has dominant inheritance. *Kostmann's syndrome or infantile agranulocytosis* is characterized by early onset of severe, recurrent infections, neutropenia and maturation arrest of myelopoiesis at the promyelocyte stage. Defects of granule production have been described in some patients. Both autosomal recessive and dominant inheritance, as well as sporadic cases, have been described. Recent studies have detected different inherited or spontaneous point mutations in the neutrophil elastase gene.

Other reported abnormalities include deficiency of antibacterial peptides, which correlates with the degree of periodontal disease. Development of additional genetic defects during the course of the disease, such as G-CSF receptor and *ras* gene mutations, and cytogenetic aberrations, indicates an underlying genetic instability. Progression to acute myeloid leukaemia (AML) and myelodysplastic syndrome (MDS) has been reported and may be associated with the mutations of G-CSF receptor gene. The majority of patients (over 90%) respond well to G-CSF, with a reduction in incidence of severe infections and use of intravenous antibiotics. It is plausible that G-CSF may accelerate the propensity for MDS/AML in the genetically altered stem and progenitor cells, especially in those with G-CSF receptor and *ras* mutations (82% and 50% of patients who transform, respectively). However, no association between the dose or duration of G-CSF therapy and malignant transformation has been identified and it is more likely that G-CSF may simply be an 'innocent bystander' that corrects neutropenia, prolongs patient

survival and allows time for the malignant predisposition to declare itself. Haemopoietic stem cell transplantation should be considered particularly in those with a poor response to G-CSF.

Cyclic neutropenia is a rare, dominantly inherited disorder with variable expression, which is characterized by repetitive episodes of fever, pharyngitis, stomatitis and other bacterial infections attributable to recurrent severe neutropenia occurring every 15–35 days. The nadir neutrophil count, usually between zero and 200×10^9/L, lasts 3–7 days and is frequently associated with monocytosis. Cycling of red cell and platelet production is also observed in some cases. The bone marrow is characterized by transient arrest at the promyelocyte stage before each cycle. Both childhood and adult onset have been reported. Recent studies have shown that autosomal dominant and sporadic cases of this disease are due to a mutation in *ELA2*, the gene for neutrophil elastase (a chymotryptic serine protease of neutrophil and monocyte granules), located at chromosome 19p13.3. This enzyme is synthesized in neutrophil precursors early in the process of primary granule formation. A hypothesis at present suggests that the mutant neutrophil elastase functions aberrantly within the cells to accelerate apoptosis of the precursors, resulting in oscillatory production. The disorder is effectively treated with G-CSF, and no transformation to AML or MDS has been in these patients, with or without G-CSF therapy.

Schwachman–Diamond–Oski syndrome is an autosomal recessive disorder characterized by exocrine pancreas insufficiency, metaphyseal dysostosis and bone marrow dysfunction. Recurrent severe bacterial infections and susceptibility to leukaemia are the major causes of morbidity and mortality, although many affected individuals have relatively few problems with infections. Neutrophil count is commonly less than 500×10^9/L and many patients are also anaemic and thrombocytopenic. Bone marrow is usually hypoplastic and a number of neutrophil functional disorders such as chemotactic defects may be present. A variety of physical anomalies including short stature, strabismus, syndactyly, cleft palate and microcephaly may exist. The propensity to develop leukaemia and aplastic anaemia suggests that a stem cell defect may be present. Treatment involves the use of G-CSF in patients with recurrent infections, and the use of pancreatic enzyme supplements for the gastrointestinal insufficiency and steatorrhoea. Some anaemic patients respond to steroids.

Reticular dysgenesis is associated with neutropenia, lymphoid hypoplasia, and thymic hypoplasia with normal erythropoiesis and megakaryopoiesis. Patients have a hypoplastic marrow and low levels of IgM and IgG and die from overwhelming infections usually in early infancy. Dyskeratosis congenita is a rare disease characterized by abnormal skin pigmentation, nail dystrophy and mucosal leucoplakia. More than 80% of the affected individuals develop bone marrow failure, which is the major cause of death. The disorder is caused by defective telomere maintenance in stem cells. The major X-linked form of the disease is due to mutations in the DKC1 gene located at Xq28 and coding for dyskarin, a nucleolar protein (see Chapter 12). Dyskerin is part of small nucleolar ribonucleoprotein particles involved in processing ribosomal RNA. It is also found in the telomerase complex, pointing to a possible link between these two processes. An autosomal dominant form is due to mutations in the RNA component of telomerase. Patients with this form of the disease are more severely affected in the later generations carrying the mutations, possibly due to the inheritance of shortened telomeres, and may be considered to have aplastic anaemia.

Neutropenia has been seen with immunological abnormalities such as hyper-IgM syndrome and X-linked agammaglobulinaemia. Hyper-IgM syndrome is an X-linked disorder characterized by lymphoid hyperplasia, low concentrations of IgG and IgA, but high concentration of IgM and severe neutropenia. A genetic defect in the T-cell CD40 ligand has been implicated as the cause of the disease. CD40 ligand is a 39-kDa protein expressed on the surface of activated CD4+ T cells, which delivers contact-dependent signals to CD40-expressing cells: B cells, monocytes, dendritic cells, epithelial cells, endothelial cells and fibroblasts. The loss of interaction between CD40 and its ligand results in an impairment of T-cell function, of B-cell differentiation and of monocyte function. Patients commonly die of overwhelming infections by the age of 5 years unless treated with intravenous immunoglobulin and long-term G-CSF.

Chronic benign neutropenia, *chronic idiopathic neutropenia and autoimmune neutropenia* are very similar in laboratory findings and differ only with regards to age of onset and association with other immune disorders. Chronic benign neutropenia commonly presents in older children or young adults. Patients are usually asymptomatic and have neutrophil counts in the range of $0.2–0.5 \times 10^9$/L. Bone marrow examination is commonly normocellular or occasionally moderately hypocellular. They usually have a peripheral monocytosis and often a benign course, although anecdotal cases progressing to acute leukaemia have been reported. Anti-neutrophil antibodies, detected in some patients, are not commonly present but antibodies to the stem cells or other precursors may be the inciting factor in these patients. As these patients generally have a benign course, treatment to increase neutrophil count should be reserved for those who have recurrent infections. Corticosteroids, splenectomy, cytotoxic agents and G-CSF have all been used successfully in this setting. Chronic benign neutropenia of infancy and childhood is probably a related disease, with the majority of patients presenting in the first year of life. There is no familial predisposition and anti-neutrophil antibodies are commonly detected. Furthermore, the neutropenia responds to immunosuppressive therapy, suggesting an immune mechanism. There is a compensatory increase in neutrophil precursors in the marrow. Some patients have a measurable defect of neutrophil mobility, otherwise described as 'lazy leucocyte syndrome'.

Infants of hypertensive mothers also commonly have

moderate to severe neutropenia lasting for several days. This is probably related to bone marrow suppression. Moderate to severe neutropenia can also occur in newborn infants as a result of transfer of maternal IgG anti-neutrophil antibodies in a manner similar to the rhesus haemolytic disease of the newborn. This isoimmune neutropenia develops antenatally and is due to maternal production of antibodies against antigens on fetal neutrophils.

Pure white cell aplasia is a rare condition associated with recurrent pyogenic infections and with thymoma in 70% of the affected patients. There is almost complete absence of myeloid precursors without any abnormality of erythroid or megakaryocytic precursors in the marrow. In the majority of patients, the marrow inhibitory activity is in the IgG and IgM fractions of serum but, in some, the inhibition is due to the lymphocytes. The immunoglobulin is directed against progenitor cells or myeloid precursors. The disorder has been associated with therapy with ibuprofen, certain natural remedies and chlorpropamide. If associated with thymoma, surgical removal of the thymus gland can partially correct the neutropenia. Other treatment options include corticosteroids, cyclosporin A, cyclophosphamide and intravenous immunoglobulin.

Humoral and cellular immune responses are responsible for the development of neutropenia in a number of settings. Autoimmune neutropenia due to circulating antibody can occur as an isolated condition or in association with other autoimmune disorders such as autoimmune thrombocytopenic purpura and autoimmune haemolytic anaemia. The antibodies may be directed at the mature neutrophils or morphologically identifiable myeloid precursors.

Inhibition of granulopoiesis by suppressor or cytotoxic T lymphocytes can occur in patients with collagen vascular disorders as well as in patients with T-γ lymphocytosis. Patients with T-γ lymphocytosis commonly present with recurrent infections at a median age of 55 years. There is a clonal proliferation of either CD3$^+$/CD56$^+$ T cells or CD3$^-$/CD56$^+$ natural killer (NK) cells. NK cells do not express CD5 and T-cell receptor (TCR) proteins, and their TCR locus is not rearranged, whereas CD3$^+$ large granular lymphocytes have rearranged TCR genes and are thought to represent *in vivo* activated cytotoxic T cells. The characteristic findings include peripheral blood lymphocytosis with most lymphocytes being large granular lymphocytes. Patients may also have lymphadenopathy and hepatosplenomegaly; the bone marrow is commonly normocellular with increased lymphocytes and arrested myelopoiesis at the myelocyte stage. The CD3$^+$ subset of the disease most commonly has an indolent course although most patients need treatment for recurrent episodes of life-threatening infections. G-CSF therapy is used in managing acute infections and methotrexate, prednisolone, cyclophosphamide or cyclosporin can be effective in improving neutrophil counts for sustained periods. In contrast, the CD3$^-$/CD56$^+$ NK-cell disorders are clinically aggressive, occurring in younger patients and presenting with fever, massive hepa-tosplenomegaly, jaundice and marrow infiltration with the abnormal clone. They typically have a rapidly progressive course unresponsive to combination chemotherapy.

Neutropenia is also associated with collagen vascular diseases such as systemic lupus erythematosus (SLE), and rheumatoid arthritis. IgG or IgM antibodies may be directed against mature neutrophils or their precursors. Recent advances have allowed better understanding regarding the mechanism of neutropenia and improved options for treatment. Target antigens for anti-neutrophil antibodies have been identified for both Felty's syndrome and for SLE. In Felty's syndrome, severe neutropenia is associated with rheumatoid arthritis, splenomegaly and leg ulcers. Therapy for neutropenia with methotrexate and cyclosporin A has been attempted with variable success. The efficacy of both GM-CSF and G-CSF in reversing neutropenia and decreasing the risk of infections in Felty's syndrome and SLE has been well documented. Of concern, however, have been flares of symptoms or development of leucocytoclastic vasculitis in some patients following the use of these cytokines. Recent results suggest that G-CSF should be administered at the lowest dose effective at elevating the neutrophil count above 1.0×10^9/L.

Drug-induced neutropenia is probably the commonest cause of isolated neutropenia. A thorough evaluation of the medication history of a patient with neutropenia is important for excluding drugs as the inciting factor. The mechanisms usually are by suppression of the bone marrow or immunological. The neutropenia commonly develops 1–2 weeks after initiation of the drug and resolves soon after discontinuation of the offending agent. Agents most commonly associated with this side-effect include antibiotics (such as penicillins, cephalosporins and chloramphenicol), anticonvulsants (e.g. carbamazepine and phenytoin), anti-inflammatory agents (e.g. gold, phenylbutazone), antithyroid drugs (e.g. carbimazole, methylthiouracil), hypoglycaemic agents (e.g. chlorpropamide), diuretics (e.g. hydrochlorothiazide, bumetanide) and phenothiazine. Cytotoxic agents used in cancer therapy are well known for this complication.

Other miscellaneous causes of neutropenia include viral infections (HIV, varicella, measles, rubella, infectious mononucleosis, influenza, hepatitis A and B, parvovirus and cytomegalovirus), overwhelming bacterial infections (by exhausting the neutrophil reserve pool), metabolic diseases (such as orotic aciduria, methylmalonic aciduria and glycogen storage disease type Ib), nutritional deficiency (deficiency of vitamin B$_{12}$, folate causing also hypersegmented nuclei – Figure 17.5 – or copper) and with hypersplenism.

Disorders of neutrophil function
A number of congenital and acquired conditions with abnormal neutrophil morphology (Figure 17.2a) and/or function have been recognized (Table 17.7). Some of these are associated with abnormal neutrophil numbers and were discussed earlier.

Table 17.7 Disorders of neutrophil morphology and/or function.

Functional defect	Congenital	Acquired
Minimal	Hereditary neutrophil hypersegmentation (AD)	Megaloblastic hypersegmentation
	Pelger–Huet anomaly (AD)	Mucopolysaccharidoses
	Alder–Reilly anomaly (AR)	
	May–Hegglin anomaly (AD)	
	Myeloperoxidase deficiency (AR)	
Adherence/migration	Leucocyte adhesion deficiency (AR)	Renal failure
	Neutrophil-specific granule deficiency (AR)	Diabetes
	Schwachman's syndrome (?AR)	Neonates
	Hyper-IgE syndrome	Malnutrition
	Job's syndrome (AR)	Leukaemia
	Familial Mediterranean fever (AR)	
Phagocytic killing	Chronic granulomatous disease	Malnutrition
	Papillon–Lefevre syndrome (AR)	Vitamin E deficiency
		Severe iron deficiency
		Neonates
		Diabetes
		Viral infections
		Sickle cell disease

AD, autosomal dominant; AR, autosomal recessive.

Chédiak–Higashi syndrome

Chédiak–Higashi syndrome is a rare autosomal recessive disorder characterized by oculocutaneous albinism, recurrent and severe bacterial infections, giant blue-grey granules in the cytoplasm of white blood cells (Figure 17.5f), a mild bleeding diathesis, progressive peripheral neuropathy and cranial nerve abnormalities. Morbidity results from patients succumbing to frequent bacterial infections or to an 'accelerated phase', a progressive lymphoproliferative syndrome. Patients eventually succumb to a profound pancytopenia. Neutrophils contain a highly inhomogeneous population of giant granules probably derived from coalescence of azurophil and secondary granules. The giant granules are seen more commonly in the bone marrow than peripheral blood, as many of the abnormal myeloid precursors are destroyed before release, leading to moderate neutropenia.

Neutrophils also have a deficiency of antimicrobial proteins as well as disordered degranulation and chemotaxis. Dysfunction of other elements of the immune system such as the cytotoxic T lymphocytes and natural killer cells contribute to the propensity for infection and the development of the accelerated phase of the disease. Mutations in the lysosomal trafficking regulator, or *CHS1/LYST* gene, located on chromosome 1q43, have been implicated as the cause of this disease. At present, treatment for the disorder is stem cell transplant, which alleviates the immune problems and the accelerated phase, but does not inhibit the development of neurological disorders that grow increasingly worse with age.

Chronic granulomatous disease

Chronic granulomatous disease (CGD) is an inherited disease characterized by severe and recurrent purulent bacterial and fungal infections, including pneumonia, lymphadenitis, hepatic abscesses and osteomyelitis. The majority of patients present in the first year of life with infections with catalase-positive organisms. Phagocytic cells of CGD patients are unable to produce superoxide anions, and their efficiency in bacterial killing is significantly impaired. In addition, a failure to switch off the inflammatory response leads to the formation of granules. All the subtypes of X-linked CGD are caused by mutations in the gene for the gp91-*phox* subunit of cytochrome *b* (CYBB) located at the XP21.1. There is a significant heterogeneity in the mutations in the gene, with most being family specific. This accounts for the clinical heterogeneity seen in the X-linked CGD. Other mutations in recessively inherited forms of the disease have also been described.

Diagnosis of CGD is suggested by failure of neutrophils to reduce nitroblue tetrazolium (NBT slide test). Diagnosis can be further established by directly measuring respiratory burst activity as oxygen consumption, O_2 production or H_2O_2 production. A severe deficiency of glucose-6-phosphate dehydrogenase (G6PD) in neutrophils, as seen in a rare X-linked disorder, can result in a greatly attenuated respiratory burst and a condition resembling CGD. Therapy involves prevention and early treatment of infections, aggressive parenteral antibiotic therapy for established infections, and use of prophylactic trimethoprim–

sulphamethoxazole. Recombinant human interferon-γ may augment the host defence and reduce the incidence of life-threatening infections by unknown mechanisms other than reversing the respiratory burst defect. Haemopoietic stem cell transplantation, if performed at the first signs of a severe course of the disease, is a valid therapeutic option for children with CGD having an HLA-identical donor.

Myeloperoxidase deficiency
Myeloperoxidase (MPO) deficiency is the most common inherited disorder of phagocytes and is inherited in an autosomal recessive manner. The gene encoding for MPO is located at 17q22–23 near the breakpoint of the translocation in acute promyelocytic leukaemia. Despite the key role of MPO in the microbicidal function of neutrophils, persons with MPO deficiency lack any clinical symptoms and therapy is not required except for incidences of fungal infections when aggressive antifungal therapy is indicated.

Neutrophil specific granule deficiency
Specific granule deficiency (SGD) is a rare congenital disorder characterized by recurrent bacterial and fungal infections of skin and lungs. The inheritance is autosomal recessive and, although the precise molecular defect has not been elucidated, recent data implicate functional loss of the myeloid transcription factor CCAAT/enhancer binding protein, C/EBP(epsilon), as important in the development of SGD. The neutrophils of these patients display atypical bilobed nuclei, lack expression of at least one primary and all secondary and tertiary granule proteins, and possess defects in chemotaxis, disaggregation, receptor upregulation and bactericidal activity. Similar neutrophil granule deficiencies have been described in some patients with leukaemia.

Papillon–Lefevre syndrome
This is a rare autosomal recessive disorder characterized by palmoplantar keratoderma and early-onset peridontitis. Pyogenic liver abscesses are an increasing recognized complication. Consanguinity is common and the disease is commonly manifested in the first 6 months of life, with early progressive loss of both primary and secondary dentition. A phagocytic defect in microbicidal activity and degradation of ingested material is thought to be present. This is attributed to loss of function mutations of the CTSC gene located on chromosome 11q14–q21, which encodes the protease, cathepsin G.

Eosinophils (Figure 17.2b)

Development and function
Eosinophils, which account for 5–10% of leucocytes $(0.2 \times 10^9/L)$ are similar to neutrophils morphologically except for the presence of a bilobed nucleus and numerous bright-orange cytoplasmic granules. There are three distinct granule popula-

tions including the round, uniformly electron-dense primary granules present mainly in the eosinophilic promyelocyte/myelocyte stages, secondary or specific granules, and the less well characterized small granules (Table 17.8).

Primary granules contain eosinophil peroxidase and Charcot–Leyden crystal protein. The eosinophil peroxidase is distinct from neutrophil myeloperoxidase and can mediate damage to micro-organisms and tissues and bronchoconstriction in asthma. Charcot–Leyden crystal protein is found in tissues and fluids in association with eosinophil inflammatory reactions and may have a role in respiratory disease.

The large specific granules contain the eosinophils' cytotoxic and proinflammatory proteins and account for more than 95% of granules in the mature eosinophils conferring the characteristic appearance of the cell. The eosinophil granules contain a number of enzymes similar to those in the neutrophil lysosomes, but lack lysozyme. Different cationic polypeptides are the major constituents of eosinophil granules and include the major basic protein (MBP), eosinophil cationic proteins (ECP) and eosinophil-derived neurotoxin (EDN). MBP is toxic to cells, including parasites and mammalian epithelial cells, and evokes release of mediators from basophils and mast cells. Eosinophils have a significant cytotoxic and proinflammatory function and play an important part in the pathogenesis of a number of allergic, parasitic and malignant disease processes.

Eosinophils are derived from bone marrow stem cell-derived, myeloid progenitors in response to a number of T-cell derived cytokines and growth factors including IL-3, GM-CSF and IL-5. Mast cells, macrophages, natural killer cells, endothelial cells and stromal cells also produce these cytokines. IL-5 is the most lineage-specific factor and plays an important role in regulation of terminal differentiation and post-mitotic activation of eosinophils. Therefore, IL-5 is a late-acting cytokine that is both necessary and sufficient for eosinophil development *in vivo*, a finding that has been confirmed by IL-5 transgenic and IL-5 knockout mice.

In normal individuals, eosinophils exist transiently in the circulation and localize specifically to certain tissues and organs exposed to the external environment. Eosinophils are recruited in response to early- and late-phase components of immediate hypersensitivity reactions as well as other immunologically mediated reactions. Their activation and recruitment involves the interaction of several adhesion pathways and chemotactic agents including the complement fragment C5a, platelet-activating factor (PAF), IL-3, IL-5, GM-CSF, IL-2, RANTES, eotaxins and the CD8[+] T cell-derived lymphocyte chemoattractant factor (LCF).

The specificity and intensity of the microbicidal function of eosinophils differ from those of other leucocytes; their bactericidal activity is less efficient than that of neutrophils, but not because any deficiency of specific enzymes. In fact, eosinophil peroxidase is more bactericidal than myeloperoxidase. However, the major protective role of eosinophils in host defence is the

Table 17.8 Contents of eosinophil granules.

Granule	Protein content	Comment
Primary granule (Charcot–Leyden crystal protein-containing granule)	Charcot–Leyden crystal (CLC) protein	Weak lysophospholipase, carbohydrate binding properties
Specific granule (secondary granule)	Eosinophil peroxidase	
	Major basic protein (MBP)	Toxic to parasites
	Eosinophil cationic protein (ECP)	Ribonuclease, bactericidal, toxic to parasites
	Eosinophil derived neurotoxin (EDN)	Ribonuclease, toxic to parasites
	Eosinophil peroxidase (EPO)	Antibacterial
	Lysophospholipase	
	Acid phosphatase	
	Arylsulphatase B	
	Phospholipase A_2 (secretory)	Antibacterial
	Bactericidal permeability-increasing protein (BPI)	LPS binding, antibacterial
	NAMLAA	Antibacterial

	Catalase	
	Urokinase	
	CD63	Tetraspanin
	Proteoglycan	
	α_1-Antitrypsin	
Small-type granule	Arylsulphatase B	Lysosomal hydrolase
Secretory vesicle	Cytochrome $b558$	NADPH oxidase component
	CR3	β_2-Integrin

FAD, flavin adenine dinucleotide; NAMLAA, N-acetylmuramyl-L-alanine amidase.

destruction of metazoan parasites. Eosinophils readily degranulate in response to stimulation by antigens, cytokines and complexed or secretory IgA, IgE, and IgG. Proteins released from eosinophils result in histamine release from basophils and mast cells, and amplify the inflammatory response. They are also powerful toxins towards host cells, leading to tissue injury. A further role of eosinophils is in tissue repair and remodelling through the regulation of the deposition of extracellular matrix proteins.

Disorders of eosinophils

Eosinophilia

Eosinophilia is considered as an absolute eosinophil count of 0.5×10^9/L or more. Blood and tissue eosinophilia can be seen in a number of parasitic, neoplastic, collagen vascular and allergic diseases (Table 17.9). In these disorders, a variety of abnormal stimuli lead to the increased production and tissue localization of eosinophils. When no underlying cause can be identified, the hypereosinophilic syndrome (HES) may be present. Several reactive pulmonary and cutaneous eosinophilic syndromes (such as Churg–Strauss syndrome, Loeffler's syndrome and eosinophilic lymphofolliculosis or Kimura's disease) as well as

an eosinophilia–myalgia syndrome have also been described. Eosinophilia–myalgia syndrome is related to metabolites and contaminants in preparation of the drug L-tryptophan and presents with peripheral blood eosinophilia, fatigue and severe myalgia. It responds slowly to the cessation of L-tryptophan therapy in a number of the patients.

Hypereosinophilic syndrome is characterized by sustained eosinophilia of 30–70% of total leucocyte count ($> 1.5 \times 10^9$/L) for longer than 6 months, absence of other underlying causes of eosinophilia and evidence of organ dysfunction due to eosinophilic tissue infiltration. Presenting features include anorexia, weight loss, fever, sweating, thromboembolic episodes, heart failure, splenomegaly, and skin and central nervous system disease. Peripheral blood eosinophils have a variety of cellular abnormalities and bone marrow eosinophils are increased (30–60%), but myeloblasts are usually not. It has been difficult to assess the clonality of the hypereosinophilic syndrome, but some cases are clonally derived, as demonstrated by clonal karyotypic abnormalities and X-inactivation assays.

In most cases of idiopathic hypereosinophilic syndrome, however, the eosinophils are independent of growth factors, and the condition has features of a myeloproliferative syndrome. In some cases, a monoclonal population of activated T cells,

displaying abnormal combinations of surface markers, produces large amounts of IL-5, the presumed cause of the eosinophilia. IgE levels in serum can be very high, perhaps because of other cytokines released by the T cells. Treatment of the HES attempts to limit organ damage by controlling the eosinophil count and includes prednisolone, hydroxyurea, IFN-α and cytotoxic chemotherapy. In most cases, however, the disorder is fatal. Recently, it was reported that nine out of eleven patients treated with imatinib mesylate, a tyrosine kinase inhibitor specific to

BCR-ABL, KIT and platelet-derived growth factor (PDGF) responded with a durable normalization of their peripheral blood and marrow eosinophil count. One of these patients had a complex chromosomal abnormality leading to the identification of a fusion gene, *FIP1L1–PDGFRα*, generated by an interstitial deletion on chromosome 4q12. The protein product of *FIP1L1–PDGFRα* has enhanced tyrosine kinase activity, may be pathogenic at least in some patients, transforms haemopoietic cells and is inhibited by imatinib.

Basophils and mast cells (Figure 17.2c)

Development and function

The functions of basophils and mast cells are similar but not identical. They express on their surface the receptor that binds with high affinity the Fc portion of IgE antibody (FcεIR) and they have large metachromatic (purple-black) granules rich in histamine, serotonin and leukotrienes. Basophils have a bilobed nucleus, in contrast to mast cells, which have a unilobed nucleus. More recent studies have demonstrated that despite their significant similarities, basophils and mast cells are terminally differentiated progeny of distinct bone marrow progenitors. Whereas basophils mature in the bone marrow and circulate in the blood, mast cells mature in the tissues. They both have significant roles in a number of allergic and inflammatory disorders as well as host defence mechanisms against parasites.

Mechanisms mediating the maturation of basophils and mast cells are different. Mast cells are derived from CD34+, c-Kit-positive progenitors and not monocytes or basophils. A complex array of cytokines, elaborated by T cells, macrophages and stromal cells, regulate the production of basophils and mast cells. The major growth and differentiation factor for basophils is IL-3, whereas the growth and development of mast cells requires the presence of stem cell factor (SCF).

Basophils are the least abundant leucocytes, accounting for less than 0.5% of bone marrow and peripheral blood leucocytes. Basophils arise from a common basophil–eosinophil progenitor cell, mature in the marrow over a period of 2–7 days and after release in the circulation last for up to 2 weeks. They are the key mediators of immediate hypersensitivity reactions such as asthma, urticaria and anaphylaxis. In addition, they have been implicated in delayed cutaneous hypersensitivity reaction. Basophils are stimulated by a number of mediators, such as IgE, IL-3, C5a, GM-CSF, insect venoms and morphine, to release the contents of their granules such as histamine.

The interaction between IgE and basophil/mast cell FcεIR and antigens bridging them results in basophil degranulation and initiation of their effects. The granules of basophils and mast cells contain sulphated glycosaminoglycans responsible for their intense staining as well as histamine, leukotriene D_4 (LTD_4), PAF, eosinophil chemotactic factor (ECF), and kallikrein responsible for type I immediate hypersensitivity reactions and chronic inflammation (Table 17.10). Histamine is derived from histidine by decarboxylation and is stored as a complex with heparin or chondroitin sulphate proteoglycans. The primary protease of mast cells, tryptase, is mainly released during the early phase of allergic response and is a marker of mast cell activation in chronic inflammatory diseases. Other neutral proteases such as carboxypeptidase B, chymase, and sulphatases are also released and degrade extracellular matrix proteins. Basophil and mast cell activation also leads to the elaboration of cytokines such as GM-CSF, TNF-α, IFN-γ, IL-3, IL-4 and IL-5, which serve to amplify the inflammatory response; TNF-α and GM-CSF recruit and prime neutrophils, IL-5 activates eosinophils and IL-4 enhances cell adhesion molecule expression on endothelial cells, recruits eosinophils into tissues and induces helper T cells to mediate IgE production by B cells.

Disorders of basophils and mast cells

High basophil numbers are commonly seen in patients with myeloproliferative disorders, in particular chronic myeloid leukaemia (CML). Basophil number can be strikingly elevated in patients with CML, accounting for over 20% of circulating leucocytes in the more advanced stages of the disease. They are a part of the neoplastic clone expressing the Philadelphia chromosome or the BCR–ABL fusion gene. In other myeloproliferative disorders such as myelofibrosis and polycythaemia vera, elevation of basophil numbers is usually more modest. Cases of AML with high levels of immature basophils have also been reported. Rarely, basophils may constitute over 80% of circulating leucocytes, a condition sometimes referred to as basophilic leukaemia. These patients may exhibit clinical features related to the release of histamine and other basophil granular contents, and their treatment can be difficult owing to the possibility of massive release of these mediators secondary to cellular lysis. Other causes of basophilia include ulcerative colitis, myxoedema, recovery from acute illness and drug allergies, although these conditions are usually associated only with modest elevations of circulatory basophils.

As discussed earlier, SCF or c-kit ligand is an important factor in mast cell development. Therefore, it is plausible that conditions leading to its excessive production and mutation of c-kit, leading to its constitutive activation, can cause mastocytosis. An increased number of tissue mast cells can be seen in a number of disorders, including atopy, parasitic diseases, Hodgkin's and other lymphoproliferative disorders, some neoplasms and rheumatoid arthritis.

Several conditions, ranging from isolated cutaneous mastocytomas to mast cell leukaemia, are associated with mast cell proliferation. Solitary mastocytomas generally regress spontaneously. The more common cutaneous mastocytosis or urticaria pigmentosa typically presents with multiple small round reddish-brown maculopapular lesions, which, when subjected to minimal trauma, lead to intense pruritus. In some patients, this disease progresses to the systemic variety, with involvement of bone marrow, spleen, liver and the gastrointestinal tract. Systemic mastocytosis can also occur without prior or concurrent cutaneous disease, and in association with haematological disorders, including leukaemias and lymphomas. Organ dysfunction may be secondary to the release of biochemical mediators by mast cells, such as peptic ulcer disease secondary to histamine release. Mast cell leukaemia, a rare condition, presents with circulating mast cells of abnormal morphology (accounting for up to 95% of circulating nucleated cells), peptic ulcer disease, constitutional symptoms, anaemia and

Table 17.10 Basophil and mast cell granules, and their contents.

Component	Function	Main physiological role	Other properties	Cell specificity
Protein				
Histamine	Binds to H_1, H_2, H_3 receptors	Hypersensitivity reactions and inflammation		Basophils, mast cells
Proteoglycan				
Heparin	Package of basic proteins into granules		Binds and stabilizes proteases	Connective tissue mast cells
Chondroitin sulphates	Package of basic proteins into granules		Binds and stabilizes proteases	Basophils
Enzymes				
Chymase	Inactivates bradykinin, activates angiotensin 1, activates precursor IL-1β	Affects microcirculation, modulates microcirculation, modulates skin, inflammation		Connective tissue mast cells
Tryptase	Cleaves C3 to C3a and C3b	Proinflammatory, stimulates neutrophil chemotaxis and adherence	Tetrameric when bound to heparin, monomer inactive, restricted substrate specificity, raised levels in mast cell disorders	Mast cells
	Activates metalloproteinase 3, inactivates fibrinogen Degrades calcitonin gene-related peptide	Regulates collagenase, attenuates fibrin deposition		
Cathepsin G-like protease				Connective tissue mast cell

Exoglycosidase				

hepatosplenomegaly. It should be distinguished from AML, which can develop in association with systemic mastocytosis.

Management of patients within all categories of mastocytosis includes careful counselling of patients and care providers, avoidance of factors triggering acute mediator release, treatment of acute and chronic mast cell mediator release, an attempt to treat organ infiltration by mast cells, and treatment of any associated haematological disorder. The agents and modalities commonly used in treating patients with mastocytosis include antihistamines, H_2-receptor blockers, adrenaline, steroids, cromolyn sodium, proton pump inhibitors, ultraviolet light with psoralen (PUVA), chemotherapy, radiation, IFN-α, cyclosporin, 2-chlorodeoxyadenosine and splenectomy. With increased availability of small-molecular-weight inhibitors of signal transduction, targeting of the constitutively active mutated c-kit has attracted more attention. Two classes of constitutive activating *c-kit* mutations have been reported. The more frequent occurs in the catalytic pocket coding region, with substitutions at

codon 816, and the other in the intracellular juxtamembrane coding region. Therefore, kinase inhibitors that block mutated c-*kit* activity might be used as therapeutic agents in systemic mastocytosis. Imatinib mesylate inhibits both wild-type and juxtamembrane mutant c-Kit kinase activity, but has no effect on the activity of the D816V mutant, commonly seen in patients with mastocytosis. Therefore, imatinib mesylate does not appear to be an effective therapy for this disease. However, activity of imatinib has been reported in a subset of patients with associated eosinophilia, who express the *FIP1L1–PDGFRα* fusion gene.

Monocytes and macrophages (Figure 17.2d and e)

The mononuclear phagocyte system has been defined as a family of cells comprising bone marrow progenitors, blood monocytes and tissue macrophages. Monocytes develop from a pluripotent stem cell in the bone marrow, termed colony-forming unit – granulocyte, erythrocyte, monocyte, megakaryocyte (CFU-GEMM) and the more committed CFU-GM. This stem cell can commit to both the neutrophil and monocytic pathways. Cytokines and growth factors, such as monocyte colony-stimulating factor (M-CSF), GM-CSF and IL-3, allow the commitment along monocytic pathways. M-CSF, also known as colony-stimulating factor-1 (CSF-1), is the most important factor in the development of monocytes and macrophages, and is necessary but not sufficient for their activation.

Following their release into the circulation, monocytes rapidly partition between the marginating and circulating pools. The circulating monocytes have a highly convoluted surface and a lobulated nucleus. They can be further characterized by non-specific esterase and contain a single type of nucleus with staining characteristics of lysosomes. After migration into tissues, they become larger and acquire the characteristics of tissue macrophages. Monocytes contain lysosomal hydrolases and the intracellular enzymes elastase and cathepsin. After transformation into tissue macrophages they produce predominantly metalloproteases and metalloprotease inhibitors, lose expression of hydrolases, and express macrophage-specific genes and products such as inducible nitrous oxide synthase (NOS) and IFN-γ. Tissue macrophages are long-lived and self-sustaining cells.

Macrophage activation is the acquisition of competence to perform specific and complex functions as a result of exposure to a constellation of cytokines and other factors in their environment, rather than achievement of a universal activated state. Physiological factors from the host such as cytokines and growth factors as well as environmental factors from micro-organisms constitute this constellation and their combined effect is synergistic. Macrophage activating factor (MAF), identified as IFN-γ, as well as IL-2, IL-4, M-CSF and GM-CSF are either directly or indirectly, through IFN-γ, responsible for macrophage activation. They stimulate monocyte/macrophage proliferation, increase adhesive receptor expression and stimulate the production of proteolytic agents responsible for pathogen clearance.

Whereas production of IFN-γ by the T helper 1 cells (Th1) results in a cytocidal macrophage state, IL-4 and IL-13 produced by the Th2 population of T lymphocytes stimulate the antigen-presenting cell (APC) state. These cytokines then enhance macrophage stimulation of T cells by inducing class II MHC antigen and co-stimulatory molecule expression. Activated macrophages, in turn, produce cytokines that stimulate both types of helper T cells.

Several cytokines including IL-4, IL-10, IL-13 and TGF-β can inhibit different aspects of macrophage function. Furthermore, prostaglandin E_2, elaborated by macrophages as well as corticosteroids can suppress various actions of macrophages. These provide a feedback loop mechanism for the control of the immune response.

Disorders of monocyte/macrophages

Monocytosis and monocytopenia
Chronic inflammatory conditions, both infectious and immune in nature, are associated with monocytosis (Table 17.11). These

include tuberculosis, bacterial endocarditis, syphilis, collagen vascular disease, sarcoidosis and ulcerative colitis. Monocytosis is also commonly seen in a number of haematological malignancies such as AML, Hodgkin's disease, non-Hodgkin's lymphomas, and histiocytosis. Decreased number of circulating monocytes has been reported with endotoxaemia, corticosteroid administration and hairy cell leukaemia.

Histiocytic disorders

As described above, bone marrow monocytes enter the circulation and transform into tissue-specific macrophages under the influence of the local environment thus becoming cells of the mononuclear phagocytic system (MPS). Dendritic cells also have their origin in the bone marrow and share common progenitors with macrophages. Progenitors of dendritic cells are released from the bone marrow and enter tissues in which they differentiate into functional, antigen-presenting dendritic cells. The ordinary tissue macrophages have IgG Fc receptors, whereas the tissue-based dendritic cells comprising the dendritic cell system (DCS), lack phagocytic capacity or Fc receptors, and are predominantly antigen-presenting cells. The dendritic Langerhans cells are found in virtually all tissues except the brain and are the major immunological cellular components of the skin and mucosa. Their racquet-shaped ultrastructural inclusions (Birbeck bodies) distinguish them from other tissue cells. They interact with and process antigen, then migrate to lymphoid organs, where, through interaction with T-cells, they generate cellular and humoral immune responses. This ability of dendritic cells to interact with T cells and other inflammatory cells contributes to the often varied clinical manifestations of the histiocytic disorders.

The histiocytic disorders comprise varied haematological disorders with cells of the MPS or the DCS involved in their pathogenesis. In general, disease associated with proliferation of histiocytes can be grouped into two different categories: inflammatory disorders and neoplastic (clonal) disorders (Table 17.12). In the more recent classifications by the World Health Organization Committee on Histiocytic/Reticulum Cell Proliferations, other disorders in which histiocytes are implicated such as storage diseases (Gaucher's and Niemann–Pick) have been excluded. Abnormal immune response mediated by cytokines has been proposed to be the inciting factor for the two more common disorders: Langerhans cell histiocytosis (LCH) and haemophagocytic lymphohistiocytosis (HLH). It is, however, unclear whether the histiocytes themselves or other immune cells are the defective cell population.

Langerhans cell histiocytosis

It has been recognized that the offending cells in the disorders previously referred to as 'histiocytosis X' (including eosinophilic granuloma, Letterer–Siwe disease and Hand–Sculler–Christian disease) have the characteristics of the epidermal Langerhans cells. These disorders, now collectively referred to as LCH, have

Table 17.12 Histiocytic disorders.

Disorders of varied biological behaviour
Related to dendritic cells
Langerhans cell histiocytosis
Juvenile xanthogranuloma and related disorders
Solitary dendritic cell histiocytoma

Related to macrophages
Haemophagocytic syndromes
    Primary – familial haemophagocytic histiocytosis
    Secondary – infectious, tumour associated, drug associated
      (e.g. phenytoin)
Rosai–Dorfman disease (sinus histiocytosis with massive
    lymphadenopathy)
Solitary macrophage histiocytoma

Clonal disorders
Related to monocytes
Leukaemia – FAB M4 and M5, acute myelomonocytic
    leukaemia, chronic myelomonocytic leukaemia,
    extramedullary monocytic tumours

Related to dendritic cells
Histiocytic sarcoma (malignant histocytosis) – localized or
    disseminated

Related to macrophages
Histiocytic sarcoma (malignant histocytosis) – localized
    or disseminated

variable clinical features depending on the organs infiltrated by the responsible Langerhans and accompanying cells. The true prevalence of these disorders is seven cases per million. The majority of cases occur in children under 15 years of age, but they can occur at any age.

The aetiology of these disorders is far from clear, but a number of clues from their biology and epidemiology are emerging. Associations with malignancies and an inherited predisposition based on studies in identical twins have been suggested. No seasonal variations or geographic or racial clustering has been reported, disputing the possibility of an infectious aetiology. Flow cytometry and chromosomal analysis of cells from LCH infiltrates as well as methods to assess clonality based on X chromosome inactivation have suggested the possibility of a clonal nature, although no consistent chromosomal alterations have been reported so far.

However, it is now clear that LCH is characterized by a clonal proliferation of CD1a+ cells. The Langerhans cells from the lesions of patients demonstrate several phenotypic changes that distinguish them from their normal counterparts. Differences in staining by the lectin, peanut agglutinin (PNA), expression of placental alkaline phosphatase (PLAP), expression of the

interferon-γ receptor, and expression of co-stimulatory receptors such as CD86 and CD80 have been reported between LCH lesional cells and their normal counterparts. There is extensive expression of GM-CSF, IL-1, IL-3, IL-4, IL-8, TNF and LIF in the LCH lesions, suggestive of activation of T lymphocytes as well as recruitment of macrophages, eosinophils and granulocytes. The accumulation of IL-1 and prostaglandin E_2 may explain the association of these lesions with bone loss. It is of note that such increases in immunostimulatory and tissue-damaging cytokines are at local sites, usually without high systemic levels.

The diagnosis of LCH is based on a biopsy of the involved organs with the key diagnostic feature being the presence of pathological Langerhans cells, which can be identified by demonstration of either CD1a surface antigen, or the presence of Birbeck granules on electron microscopy (Figure 17.5). Mitoses are usually not present and when found have no prognostic significance. Early lesions are generally cellular and locally destructive with abundance of essentially normal Langerhans cells. As the lesions mature, there are fewer Langerhans cells with occasional necrosis.

The lesions of LCH occur in skin, bone, lymph nodes, liver, spleen, bone marrow, lungs, the central nervous system and the gastrointestinal tract. Clinical features are varied and depend on the organs involved. It may involve single organs or be multisystem, and assessment of organ function is important as it can have prognostic significance. Initial investigations should include a full blood count, assessment of renal and hepatic function, a skeletal survey and a technetium bone scan; these latter studies are complementary with the latter being more sensitive for early lesions. Other investigations include a chest radiograph, and possibly magnetic resonance imaging (MRI) of the brain to rule out central nervous system (CNS) involvement. Additional testing for diabetes insipidus and other organ involvement should be carried out as indicated.

Solitary or multifocal eosinophilic granuloma (SEG or MEG) is found mainly in older children and young adults and accounts for the majority of cases of LCH. Hand–Sculler–Christian disease occurs in younger children (2–5 years) and often presents with exophthalmos due to a tumour mass in the orbital cavity. Letterer–Siwe disease is the rarest and often most severe form of LCH, typically presenting with a scaly, seborrhoeic, eczematoid and, occasionally, purpuric or ulcerative rash in infants younger than 2 years. Bone involvement in LCH can lead to a tender swelling (as a result of infiltration of adjacent tissues) and inability to bear weight. On radiography, lesions appear as 'punched out' holes sometimes with sclerotic edges. Other clinical manifestations include rashes, which may be maculopapular, nodular or vesicular, ear discharge, lymphadenopathy, diabetes insipidus due to the involvement of hypothalamus and the pituitary, respiratory symptoms with radiographic changes such as micronodular infiltrates due to lung involvement, hepatomegaly with laboratory evidence of liver dysfunction, splenomegaly, CNS

disease with ataxia, dysarthria, cranial nerve palsies and, rarely, gut involvement with diarrhoea, malabsorption and protein-losing enteropathy.

The prognosis of patients with LCH depends on age of onset, number of involved organs and degree of their dysfunction. In general, infants with multiorgan disease have the worst prognosis. There is also growing realization that multiple recurrences of the disease can occur indefinitely, and those patients with multisystem involvement can have long-term sequelae of their disease and/or its treatment. These include neurocognitive and psychosocial problems, neurological complications with a neurodegenerative pattern of CNS involvement, orthopaedic problems, hearing loss, and hypothalamic/pituitary axis deficiencies, leading to stunted growth and other endocrine problems.

Spontaneous resolution in a significant proportion of patients with LCH can occur and patients with a limited disease usually do not require systemic therapy. In contrast, patients with multifocal disease generally benefit from systemic therapy. Treatment options have included low-dose radiation for symptomatic single lesions, local injection of steroids, topical steroids, PUVA, non-steroidal anti-inflammatory drugs, high-dose systemic steroids, and systemic multi-agent chemotherapy regimens with agents such as prednisolone, vinblastine, vincristine, etoposide and 6-mercaptopurine. Other agents, that have been tested in patients with disease progression while on therapy include cyclosporin, antithymocyte globulin, 2-chlorodeoxyadenosine (2CDA), thalidomide, TNF inhibitors, anti-CD1a antibodies and haemopoietic stem cell transplantation.

Haemophagocytic lymphohistiocytosis

These disorders include primary (familial) and secondary (related to infections or malignancy) with the familial form affecting neonates and infants and occurring in 1–2 children per million white people per year. Males and females are equally affected and over two-thirds of cases occur in siblings. The familial form is an autosomal recessive disease without a well-defined genetic defect. Recently, several defects in genes important for immune functions have been reported in patients with familial HLH and include mutations in the genes for perforin, the γ-chain of IL-2 receptor and purine nucleoside phosphorylase.

It is hypothesized that the disease is caused by impaired lymphocyte-mediated cytotoxicity and defective triggering of apoptosis. Perforin, normally secreted by cytotoxic T cells and natural killer (NK) cells, can form cell death-inducing pores through which toxic granzymes may enter the target cell and trigger apoptosis. Mutations of the perforin gene have been reported in several patients with familial HLH and result in defective lymphocyte cytotoxic activity. The manifestations of the disease are thought to be mediated by such inflammatory cytokines as IFN-γ TNF-α, soluble IL-2 receptor, FAS ligand and GM-CSF. Such excess of proinflammatory cytokines results in tissue infiltration by lymphocytes and macrophages, leading to haemophagocytosis.

The secondary form of HLH is commonly precipitated by viral (particularly Epstein–Barr virus and other herpesviruses), bacterial, fungal and protozoan infections, often in an immunocompromised host. Other factors that have been associated with secondary HLH include malignancies (particularly lymphoproliferative disorders), autoimmune disorders, drugs (such as phenytoin) and Chédiak–Higashi disease. It is important to distinguish patients with the secondary form of the disease from individuals with familial HLH and a precipitant viral infection.

Clinical presentations of HLH commonly include fever, anorexia, malaise, irritability and vomiting. Hepatic and splenic enlargement, lymphadenopathy, pancytopenia, abnormal liver function, coagulopathy, and CNS signs and symptoms are also common. Other features include hypertriglyceridaemia, hypofibrinogenaemia, cerebrospinal fluid pleocytosis, and rashes. Marrow examination is often hyperplastic with increased numbers of haemophagocytic histiocytes. Histopathological features of lymph node or other involved tissue are often diagnostic, showing infiltration by lymphocytes and histiocytes and the characteristic prominent erythrophagocytosis and haemophagocytosis, which is essential for diagnosis. There are no specific diagnostic tests, but during the acute phase of the illness, the plasma concentrations of inflammatory cytokines IFN-γ, TNF-α, soluble IL-2 receptor and IL-6 are often markedly elevated.

Treatment of familial HLH has traditionally involved the use of corticosteroids, cyclosporin and etoposide. Although high initial responses are observed, disease recurrence within months is usual. Adequate control of CNS disease is important but the value of routine prophylaxis with intrathecal methotrexate is controversial. Patients are at high risk of opportunistic infections because of their underlying immune dysfunction and the effects of therapy. Age is an important prognostic factor with the higher likelihood of survival in children older than 2 years of age. Haemopoietic stem cell transplant from a matched sibling is the definitive treatment modality in patients with familial HLH.

Sinus histiocytosis with massive lymphadenopathy or Rosai–Dorfman syndrome is characterized as a benign, frequently chronic, painless lymphadenopathy involving the cervical nodes and less commonly other nodal areas. Other features may include fever, weight loss, extranodal disease in skin, soft tissues, orbits, upper respiratory mucosa, bone and other organs. Although the disease commonly occurs in the first two decades of life, all ages can be affected. Diagnostic evaluation of involved lymph nodes reveals infiltration by histiocytes and multinucleated giant cells associated with erythrophagocytosis. The proliferating histiocytes are morphologically distinguished from Langerhans cells of LCH by the absence of Birbeck granules on electron microscopy as well as their surface phenotype. Treatment is usually unnecessary and ineffective with the disease manifestations usually subsiding over several months to years.

Although monocytic leukaemias are included in the classification of histiocytic disorders, their discussion is beyond the scope of this chapter and will be dealt with elsewhere.

Haemopoietic growth factors

Jenny L Byrne and Nigel H Russell

18

Haemopoiesis

Stable haemopoiesis is maintained by the activity of pluripotential stem cells, which are capable not only of differentiating to form all three haemopoietic cell lineages, but also of retaining the ability for self-renewal. These pluripotential stem cells give rise to more differentiated lineage-committed stem cells that in turn differentiate into mature blood cells.

Initially, measurements of the stem cell content of human bone marrow could only be inferred by the growth of erythroid, myeloid and megakaryocytic cell colonies (BFU-E, CFU-GM and CFU-Meg) in culture. It has been estimated that there are 1×10^6 pluripotential stem cells in human marrow, and assays for these primitive cells have been developed, such as the long-term culture-initiating cell (LT-CIC) assay. In 1984, the expression of a specific antigen (now designated the CD34 antigen) on the surface of a small percentage of immature marrow cells was identified. This CD34$^+$ fraction of cells does, in fact, contain a number of committed stem cells, but it is also capable of restoring haemopoiesis following myeloablative chemotherapy, indicating that it also contains the pluripotential cell fraction. Expression of the CD34 antigen appears to be stage specific and is lost upon further maturation. Studies have shown that cells expressing high levels of CD34 are the most primitive, and those with a CD34^{bright}, Thy-1$^+$, CD38$^-$, CD45RO$^+$ and rhodamine^{dull} profile are representative of true pluripotential stem cells and account for less than 10% of the CD34$^+$ cell fraction.

The role of haemopoietic growth factors in normal haemopoiesis

The survival, differentiation and proliferation of haemopoietic progenitor cells *in vivo* and *in vitro* are dependent on the presence of small, hormone-like polypeptide molecules referred to as haemopoietic growth factors or colony-stimulating factors (CSFs). A large number of these factors have now been cloned and their effects have been studied. Their effects are exerted upon cells following interaction with specific growth factor receptors situated on the cell surface, which in turn activate signal transduction pathways. Different CSFs act on bone marrow cells at different stages of maturation (Table 18.1). Some influence immature progenitors and increase the production of cells of several lineages [e.g. interleukin 3 (IL-3) and stem cell factor (SCF)], whereas others act on more committed progenitors and thus have a specific effect, leading to an increased production of cells of a particular subtype, e.g. Epo and granulocyte colony-stimulating factor (G-CSF). The evolutionary importance of these molecules is indicated by the significant homology that exists between the species for these growth factors and their receptors and the common use of certain receptor subunits and signalling pathways.

In addition, there is considerable overlap between the functions of different CSFs, for example IL-3, granulocyte–macrophage colony-stimulating factor (GM-CSF) and G-CSF all stimulate the production of mature neutrophils. This redundancy may arise because different CSFs act on cells at different stages of differentiation. Furthermore, the actions of CSFs may be subtly different in that some may promote survival of cells by inhibiting apoptosis, whereas others act to induce proliferation of these cells. There is also evidence that the actions of CSFs may be synergistic in their effects upon haemopoietic progenitors; for example, the addition of SCF and GM-CSF results in an increase in both the number of colonies formed and the number of cells in each colony.

Growth factor receptors

Haemopoietic growth factors act by binding to specific receptor molecules on the surface of haemopoietic progenitors. The

Table 18.1 Haemopoietic growth factors and their receptors.

Growth factor	Location of gene	Receptor	Cell source	Cells produced	Clinical use
IL-3	5q23–31	Low-affinity α-subunit (70 kDa) and β-subunit (120 kDa) common to IL-3/5 receptors	Fibroblasts, mast cells, T cells, NK cells, endothelial cells	Granulocytes, monocyte/macrophages, eosinophils, basophils, mast cells (erythrocytes if Epo also present)	Not in clinical use
GM-CSF	5q23–31	Low-affinity α-subunit (70 kDa) and β-subunit (120 kDa) common to IL-3/5 receptors	Fibroblasts, T cell macrophages, marrow stroma, endothelial cells	Granulocytes, monocyte/macrophages, eosinophils, megakaryocytes	Stem cell mobilization; post chemotherapy/bone marrow transplantation, use in graft rejection
G-CSF	17q21–22	Low-affinity monomer, high-affinity oligomer	Fibroblasts, marrow stroma, endothelial cells	Granulocytes	Stem cell mobilization, post-chemotherapy/bone marrow transplantation
SCF	12q22–24	145-kDa transmembrane protein	Fibroblasts, marrow stroma, endothelial cells	Granulocytes, monocyte/ macrophages, erythrocytes, megakaryocytes	? Increase stem cell mobilization
Epo	7q21	166-amino-acid polypeptide	Kidney cells	Erythrocytes, megakaryocytes	Renal anaemia, MDS; anaemia secondary cancer
TPO	3q26–27	Product of c-*mpl* proto-oncogene	Liver and kidney cells	Megakaryocytes	Not in clinical use

molecular structure of a number of these growth factor receptors is now defined (Figure 18.1).

Some of the receptors have intrinsic tyrosine kinase domains that are activated upon ligand binding to the extracellular domain. Examples include the macrophage colony-stimulating factor (M-CSF) and SCF receptors.

The remaining CSF receptors all share a common Trp–Ser–X–Trp–Ser motif (where X can be any amino acid) near the transmembrane domain and are referred to as part of the cytokine receptor superfamily. Some of these receptors consist of a single chain, for example Epo and G-CSF receptors, whereas others are made up of two or more subunits, some of which are
Figure 18.1 Cytokine receptor superfamily.

common to several receptors, for example the common sub-unit of GM-CSF and IL-3 receptors. Following ligand binding, homo- or heterodimerization occurs and leads to the activation of intrinsic or extrinsic tyrosine kinases, resulting in signal transduction.

Mutations of various CSF receptors have been described which may have clinical sequelae. For example, deletion at the C-terminal end of the cytoplasmic domain of the erythropoietin receptor leads to the development of familial erythrocytosis in humans. Mutations of the gene encoding the thrombopoietin receptor have been identified in all patients with congenital amegakaryocytic thrombocytopenia, a rare disorder characterized by severe hypomegakaryocytic thrombocytopenia in infancy, which develops into pancytopenia in later childhood. In the case of congenital neutropenia, for example Kostmann's syndrome, mutations of the G-CSF receptor appears to be acquired in patients and heralds transformation to myelodysplastic syndrome (MDS)/acute myeloid leukaemia (AML).

Signal transduction by growth factor receptors

Following growth factor binding to its receptor, a number of signal transduction pathways are activated. The first step in these signalling pathways involves the activation of a tyrosine kinase, either the intrinsic tyrosine kinase domain such as in M-CSF and SCF or an extrinsic tyrosine kinase molecule.

Jak/STAT signalling

Members of the family of Janus or Jak kinases are known to be associated with activated growth factor receptors. This association may either be constitutive, for example Epo receptor, or occur only after ligand binding, for example IL-3 receptor. Heterodimerization of the receptors allows these kinases to be brought into close proximity, resulting in cross-phosphorylation and activation of their kinase domains. Following activation, Jak kinases are able to phosphorylate another family of proteins known as the STAT proteins (*s*ignal *t*ransducers and *a*ctivators of *t*ranscription). Phosphorylated STAT proteins are then able to enter the nucleus and bind to DNA acting as transcription factors, and leading to a cellular response.

Ras-dependent signalling

Activated Jaks can also phosphorylate the protein Shc, which, in turn, associates with the adaptor protein Grb2. The latter associates with the nucleotide exchange factor Sos, which controls the GTPase activity of a small membrane-bound protein termed 'Ras'. Activated Ras in the GTP-bound state can then induce signalling via a number of phosphorylation cascades, including the MEK–MAP kinase pathway and the phosphatidylinositol

3-kinase (PI-3 kinase) pathway, which, in turn, lead to gene induction and a cellular response.

Recombinant growth factors

Following the discovery of haemopoietic growth factors and their effects on haemopoiesis, the genes encoding these proteins were identified. This has enabled recombinant human growth factors to be produced, and several of these have now become established for clinical use. Growth factors that have been synthesized and used in this way include G-CSF, GM-CSF, SCF, IL-3, erythropoietin and thrombopoietin. A large number of studies have been published reporting on the use of these growth factors in a number of different clinical settings. In view of the high costs of these agents it is important to carefully evaluate their use in terms of both clinical efficacy and cost–benefit ratio. In this regard, a number of groups have attempted to rationalize the use of haemopoietic growth factors by issuing clinical guidelines that recommend specific indications when they should be considered.

Erythropoietin

Physiology of erythropoietin secretion
(see also Chapter 2)

Erythropoietin (Epo) is an 18-kDa protein consisting of a 166-amino-acid polypeptide chain linked by two disulphide bonds. Following translation, it is heavily glycosylated, resulting in a final molecular weight of 30.4 kDa. The glycosylation is essential for its biological activity *in vivo* as removal of the sialic acid residues decreases its half-life significantly. It is encoded by a gene on the long arm of chromosome 7. In adult life, the gene is largely expressed by the peritubular fibroblast-like interstitial cells of the kidney and, to a lesser extent, by hepatocytes. In embryonic tissues, the liver is the major source of Epo production. Epo production is stimulated by hypoxia, which is detected by a DNA-binding complex termed hypoxia-inducible factor 1 (HIF1). HIF1, a transcription factor complex, is a key mediator of oxygen homeostasis and is regulated by a ubiquitin-mediated oxygen-dependent destruction of the α-subunit of the complex. It controls the expression of many genes that are regulated by hypoxia, including erythropoietin. Activation of HIF1 by hypoxia results in the rapid synthesis and release of Epo into the bloodstream, increasing levels by up to 1000-fold. Other factors may regulate Epo levels, including the red cell precursor mass (as high serum levels are found in aplastic anaemia).

Epo is a true hormone that circulates to the bone marrow and binds to Epo receptors on erythropoietic cells within the bone marrow. Epo plays no role in determining the lineage commitment of haemopoietic cells but, rather, binds to receptors on committed erythroid progenitor cells (BFUe and CFUe) and stimulates their growth, survival and differentiation. Erythroid

progenitors, particularly CFUe, require continual exposure to Epo in order to survive, although their sensitivity to Epo varies widely, with only those progenitors requiring low Epo levels surviving and CFUe with high Epo requirements undergoing apoptosis during steady-state haemopoiesis when Epo levels are low. As Epo levels rise in response to tissue hypoxia, increasing numbers of erythroid progenitors are prevented from undergoing apoptosis, leading to an expansion of red cell production. An understanding of this is crucial to the appropriate use of Epo replacement therapy because when Epo levels are high nearly all available CFUe survive and, therefore, increased pharmacological doses of the drug cannnot lead to further expansion of erythropoiesis. Epo is not only a survival factor for erythroid progenitor cells but it also stimulates proliferation as well as RNA and protein synthesis in more differentiated erythroid cells.

The erythropoietin receptor is a member of the class 1 cytokine receptor family encoded by a gene on chromosome 19p13.3–p13.2. The binding of Epo to its receptor (Epo-R) induces receptor dimerization, which, in turn, induces phosphorylation of the pre-bound Jak2 kinase and hence phosphorylation of the Epo-R itself. The STAT5 protein is then able to bind to the phosphorylated Epo-R, leading to tyrosine phosphorylation of the STAT5 molecule. Phosphorylated STAT5 then disengages from the Epo-R, moving to the nucleus, where it activates Epo-inducible genes. Downstream events from this pathway lead to the upregulation of the anti-apoptotic protein bcl-xl, which promotes survival of erythroid progenitor cells.

Recombinant erythropoietin

Epo was the first haemopoietic growth factor to be cloned in 1985, and since then the use of recombinant erythropoietin (epoetin) has been shown to be effective in the management of the anaemia of chronic renal failure. At present, several different epoetin molecules are clinically available, including epoetin-α and epoetin-β, which vary in the number of sialic acid residues present and, more recently, darbepoetin-α. This is a modified, hyperglycosylated form of erythropoietin, which differs in five amino acids from the endogenous protein and has a threefold longer biological half-life than standard preparations and is suitable for weekly administration. More recently, other clinical uses of epoetin have emerged in the treatment of conditions in which defective endogenous Epo production can occur. These include the myelodysplasias, anaemia in patients with solid tumours and lymphoproliferative disorders, and anaemia associated with HIV infection, chronic disease and prematurity (Table 18.2).

The clinical uses of erythropoietin

The anaemia of renal failure

The use of recombinant Epo for the treatment of renal anaemia is a clearly established indication. Renal anaemia is an erythropoietin deficiency state and, although coexisting conditions, for example haematinic deficiency, blood loss or aluminium toxic-

Table 18.2 Clinical uses of erythropoietin.

Perisurgical uses

ity, can blunt the effectiveness of Epo therapy, nearly all patients with renal anaemia have a positive response, if adequate doses are given, resulting in an increase in haemoglobin (Hb) levels into the normal range. Most physicians accept a target Hb of 11 g as recommended by the European Best Practice guidelines. This can be achieved with an initial thrice-weekly loading schedule followed by a maintenance schedule of weekly subcutaneous therapy at a dose of 100 IU/kg. The use of epoetin and the correction of anaemia have been associated with an improved quality of life without evidence of a deterioration in renal function or dialysis efficiency. Furthermore, there is evidence for a reduction in mortality and morbidity in renal patients receiving optimal epoetin therapy.

For a decade, epoetin therapy has been considered safe. In 2002, however, a series of renal patients were reported who developed pure red cell aplasia due to the development of anti-erythropoietin antibodies. Serum from these patients was found to be inhibitory to erythroid colony formation *in vitro*. Almost all cases now reported have been associated with subcutaneous administration of epoetin-α, and in 2002 the prescribing information was changed to state that this preparation should no longer be given by this route in renal failure. Pure red cell aplasia (PRCA) due to epoetin therapy remains a rare event; however, it should be suspected in patients who have been on therapy for more than 3 months and who develop a sudden severe unexplained fall in their Hb, associated with reticulocytopenia, despite continuing epoetin treatment, and in whom no other cause of PRCA can be found. The diagnosis can be confirmed by the finding of low serum erythropoietin levels and the detection of anti-erythropoietin antibodies. Epoetin therapy should be withdrawn in favour of transfusions. Immunosuppression with cyclophosphamide has been reported to be of help in some patients, and correction of the anaemia has been reported following successful renal transplantation. Although this remains a rare complication, it has been recommended that monitoring of the reticulocyte count should now be a regular part of the monitoring of all patients receiving erythropoietin therapy.

Myelodysplasia

Anaemia is one of the commonest manifestation of myelodysplasia and repeat transfusions, which have been the major therapeutic

option for low-risk MDS such as RA and RARS, eventually lead to complications, particularly transfusional haemosiderosis. The anaemia particularly of low-grade MDS has been in part explained by increased apoptosis of haemopoietic cells in the bone marrow. Treatment of MDS patients with the cytokines G-CSF and Epo alone, or in combination, has been associated with reduced levels of imtramedullary apoptosis and enhanced haemopoiesis.

The efficacy of epoetin therapy has been explored both as a single agent and in combination with G-CSF. In one randomized double-blind placebo-controlled trial of 87 patients, 37% of the epoetin group responded with a 1–2 g rise in their Hb level compared with 11% of control subjects ($P = 0.007$). The subgroup of patients with RA had the highest response rate of 50%. Patients with low Epo levels of < 200 IU/L and who have low transfusion requirements have the highest response rate and guidelines produced by the British Committee for Standards in Haematology (BCSH) have suggested an 8-week trial of therapy in this subgroup. Most patients with MDS who are anaemic have appropriately high Epo levels, and it is unclear why a proportion have low levels. Dosage schedules of 10 000 IU three times per week have been recommended, although it has been suggested that a once-weekly dose of 40 000 IU may be as effective and may improve patient compliance.

A number of studies have combined G-CSF with epoetin in MDS patients with evidence of an enhanced effect. The synergy of these two cytokines is most pronounced in RARS, when responses are seen in approximately 50% of patients, whereas responses with epoetin alone are poor in this subgroup. A predictive model for response to epoetin has been developed based on steady-state erythropoietin levels (< 100, 100–500, > 500 IU/L) and monthly transfusion requirements (< 2 or > 2 units/ month). The model provides a predictive score for Hb response of high (74% response rate), intermediate (23%) and poor (7%), with the group with the low epo levels and low transfusion requirements having the high response rate.

A practical recommendation is to start epoetin therapy alone in RA patients and in RARS patients, with a high predicted response as outlined above. The trigger for starting epoetin therapy is a Hb of 10 g or less, or patients who are becoming transfusion dependent. Most patients will require doses of greater than 30 000 IU per week and treatment can therefore be extremely expensive. G-CSF can be added to non-responders in a weekly schedule at a dose adjusted to keep the neutrophil count in the normal range. A trial of therapy should continue for 2–3 months and in responding patients gradual dose de-escalation can be attempted.

Unfortunately, although responses are well described in low-risk MDS, the patients who one might wish to benefit most from epoetin therapy, i.e. those with severe anaemia and transfusion dependency, appear the least likely to respond. Furthermore, the durability of response is not always clear from the published studies. The risk of epoetin-induced PRCA must also be considered, although this is likely to be difficult to diagnose in the setting of MDS and the risk of this complication occurring is unclear.

Use of erythropoietin in anaemia associated with malignant disease

Anaemia is common in patients both with solid tumours and haematological malignancy, as a consequence either of the disease or of its treatment. A number of individual studies have shown response rates between 28% and 80% for patients with cancer-related anaemia and a Hb of < 10 g/dL. At present, guidelines produced by the American Society of Clinical Oncology (ASCO) recommend treatment with epoetin for this group of patients. Patients with lymphoproliferative disease, particularly chronic lymphocytic leukaemia (CLL) and myeloma, often develop anaemia for which blood transfusion is required. Most anaemic patients with myeloma have been shown to have low Epo levels, and there is evidence that they greatly benefit from epoetin therapy. In 1996, Osterborg and colleagues found an improvement in Hb level and elimination of transfusion requirements in 60% of epoetin-treated patients compared with 24% in the control group. These results have been confirmed in other studies and have also shown not only an improvement in Hb and haematocrit levels, but also significant improvements in patient-assessed quality of life. At present, there are no reliable indicators of response to therapy, but with an appropriate dosage more than 80% of myeloma patients show a Hb increment of > 1 g/dL after 4 weeks of treatment.

It seems reasonable to recommend a 6-week trial of epoetin in patients with a Hb of < 10 g/dL and for symptomatic patients with a Hb of 10–12 g/dL, provided that other possible correctable causes of the anaemia have been excluded. A dose schedule of 10 000 IU three times per week with dose escalation for initially unresponsive patients is appropriate. Recently, a weekly schedule of epoetin-β given at a dose of 30 000 IU was found to be equivalent to 10 000 IU three times per week in patients with lymphoproliferative disease who had serum epo levels of < 100 IU/L, with > 70% of patients responding.

The use of epoetin as an alternative to blood transfusion in patients with cancer-related anaemia is low in the UK at present compared with the USA and some other European countries. However, its use in this setting is likely to increase and is consistent with the objective of avoiding unnecessary blood transfusion, as outlined in the NHS Circular on Better Blood Transfusion.

Other uses of erythropoietin

The anaemia associated with HIV infection is multifactorial and involves a direct effect of the virus on haemopoietic progenitor cells, as well as anaemia of chronic disease and peripheral destruction of red cells and the involvement of the bone marrow by lymphoma and by infection. Furthermore, the drugs used in the treatment of HIV or it complications, such as

cytomegalovirus (CMV) infection, frequently cause marrow suppression. Several clinical trials have now demonstrated the benefit of epoetin therapy in some patients with HIV-associated anaemia. Improvements in Hb and a significant reduction in transfusion requirements have been seen in patients with an Epo level of < 500 IU/L, whether or not the patient is receiving anti-retroviral therapy.

Following allogeneic bone marrow transplantation (BMT), endogenous Epo production may be impaired, possibly related to the effect of cyclosporin. A number of studies have shown that epoetin can accelerate erythroid recovery and reduce transfusion requirements in the first few months post allogeneic transplant.

Epoetin has also been used perisurgically to enhance the collection of autologous blood pre-deposited before elective surgery and also to correct anaemia prior to surgery with the aim of reducing the requirement for donor blood. In a Canadian study, the use of Epo was found to reduce the need for transfusion in patients undergoing elective hip replacement surgery, whose initial Hb was < 13.5 g/dL, from 74% to 33%.

Granulocyte and granulocyte–macrophage colony-stimulating factors

Physiology of G-CSF and GM-CSF

G-CSF and GM-CSF are both glycosylated polypeptides in their natural form, which are the main regulators of granulocyte production. The gene for G-CSF is located on chromosome 17q, whereas that of GM-CSF is located on chromosome 5q. Both of these CSFs can be secreted by a variety of cell types, including monocytes/macrophages, T cells, endothelial cells and fibroblasts when appropriately stimulated *in vitro*. The levels of endogenous G-CSF can increase to detectable levels when there is a demand for increased granulocyte production such as in acute treatment-induced neutropenia, chronic neutropenic conditions and in acute infections in patients with or without underlying haematological disorders. G-CSF in peripheral blood is detected more often and in higher concentrations than GM-CSF, and there appear to be differences in their production and regulation. GM-CSF has more pleiotropic effects than G-CSF and stimulates the production of neutrophils, eosinophils and monocytes, although both have been primarily exploited for their effects on stimulating myelopoiesis. GM-CSF treatment results in the release of IL-1 and tumour necrosis factor from monocytes and hence its administration has been associated with fever.

Clinical uses of G-CSF and GM-CSF

Mobilization of peripheral blood stem cells

The use of CSFs for the mobilization of peripheral blood stem cells (PBSCs) from both patients and donors is recommended in both the BCSH guidelines and also the ASCO recommendations.

Mobilization of PBSC for autologous transplantation

It was first discovered in the 1960s that peripheral blood contains a small number of stem cells that can give rise to all three haemopoietic cell lineages. In the resting state, the number of these cells circulating in the peripheral blood is very low, whereas during haemopoietic recovery after myelosuppressive chemotherapy the number of circulating PBSC increases up to 100-fold. The administration of haemopoietic growth factors (G-CSF or GM-CSF) can also lead to a similar increase in the number of circulating PBSCs, and these can be readily collected by the use of continuous-flow cell separation and then used for autologous transplantation and to support high-dose therapy.

The combination of chemotherapy and subsequent administration of a growth factor (G-CSF or GM-CSF) appears to be synergistic and leads to a superior yield of PBSCs as enumerated by flow cytometric analysis of cells expressing the CD34 antigen. The minimum number of PBSCs required for complete and sustained haemopoiesis has been established at a level of 2×10^6 CD34+ cells/kg, with optimal haemopoietic recovery occurring at doses of around 5×10^6/L. Various stem cell mobilization regimens have been employed, either using cyclophosphamide alone in doses ranging from 2 to 7 g/m^2 followed by G-CSF, or using combination chemotherapy regimens plus G-CSF, which may give superior yields and also have the advantage of efficacy against the underlying haemopoietic malignancy. Although high doses of cyclophosphamide may be more effective for PBSC mobilization, they are now less frequently used because of the higher toxicity that is associated with them (Figure 18.2).

The rationale behind obtaining PBSCs for autologous transplantation is that a number of studies have confirmed that restoration of haemopoiesis occurs more rapidly using PBSCs as the source of haemopoietic progenitors than when using autologous marrow. The use of PBSCs for autologous transplantation leads to a significant acceleration of neutrophil and platelet engraftment, and this may result in shorter hospitalization and reduced toxicity of the procedure. One of the early studies by Sheridan *et al.* (1992) showed a highly significant acceleration of platelet engraftment compared with historical bone marrow controls of 15 versus 39 days. Furthermore, this benefit of PBSC transplantation over bone marrow transplantation in terms of faster haemopoietic reconstitution has been confirmed in a randomized study of lymphoma patients. As a result of these findings, the use of PBSCs for autologous transplantation has become widespread and has virtually replaced autologous marrow in order to achieve rapid restoration of bone marrow function after high-dose therapy.

The efficacy of G-CSF and GM-CSF for autologous mobilization has been reported to be equal in terms of median progenitor cell yield and time to haematological recovery following transplantation. However, in view of the better toxicity profile of G-CSF, its use has generally been favoured for PBSC mobilization. Mobilization of sufficient PBSCs for autografting is not always successful, and factors associated with a failure to mobilize
Figure 18.2 Mobilization of stem cells for autologous transplantation.

include heavy pretreatment with chemotherapy, especially alkylating agents, and also previous radiotherapy exposure. The use of additional growth factors for these patients, for example IL-3 and SCF, is being evaluated at present.

Mobilization of PBSCs for allogeneic transplantation
A number of randomized studies have also shown similar benefits of mobilized PBSCs compared with bone marrow for allogeneic transplantation. There are good data showing significant benefits for G-CSF-mobilized PBSC in terms of neutrophil and platelet recovery. One study has also reported a trend for improved survival and a significant increase in disease-free survival at 2 years for the PBSC recipients. Another has reported a shorter duration of hospitalization for those patients receiving G-CSF-mobilized PBSCs, resulting in a reduction in the total cost of the procedure.

One concern regarding the use of PBSCs for allogeneic transplantation was that there is a theoretical increased risk of graft-versus-host disease (GvHD) compared with the use of bone marrow, as unmodified PBSC grafts contain at least 1 log more T cells. However, this has not been apparent clinically, as a number of studies have not shown an increased risk of acute GvHD, although the incidence of chronic GvHD does appear to be raised.

The mobilization of PBSCs from normal donors has almost entirely been with G-CSF alone, which has an excellent safety record and low toxicity profile compared with GM-CSF, which tends to have more side-effects. In Europe, the usual schedule for G-CSF administration to normal donors has been 10 μg/kg per day given subcutaneously for four consecutive days. Higher doses of G-CSF have been used (12–16 μg/kg per day), which may result in a higher yield of progenitors, although this may result in greater toxicity. Using the standard dose of G-CSF of 10 μg/kg per day, the number of CD34+ cells in the peripheral blood peaks on days 5–6, reaching levels of between 20 and 140 μL before tailing off. The white cell count (WCC) usually peaks at between 30 and 65×10^9/L. There is no correlation between the WCC and the CD34+ cell count in the peripheral blood; however, a dose reduction of G-CSF is usually recommended if the WCC reaches levels of more than 70×10^9/L. With this regimen, leucapheresis is usually initiated on day 5 (i.e. the day following the fourth G-CSF injection), and the target of $> 4 \times 10^6$ CD34+ cells/kg recipient weight is usually achieved in one to two collections processing 2.5 times the blood volume (Figure 18.3). For the majority of donors, it is possible to collect PBSCs via the use of peripheral veins, although the use of long lines is occasionally necessary due to poor venous access.
Figure 18.3 Mobilization of stem cells – sibling donors.

The advantages of PBSC donation for the donor include the avoidance of general anaesthesia, the less invasive procedure and the lack of hospitalization. Using this dose of G-CSF, the procedure is generally well tolerated but it is not a completely risk-free procedure. The commonest side-effects reported include bone pain (83%), headache (39%), fatigue (14%) and nausea (12%), which resolve rapidly with cessation of G-CSF therapy. More serious adverse effects have been reported in small numbers of patients (often using higher doses of G-CSF), including splenic rupture, severe pyogenic infection, exacerbation of ischaemic heart disease and precipitation of vaso-occlusive crisis in a patient with Hb SC disease. A number of relative contraindications of PBSC mobilization have been agreed, which include a history of autoimmune, inflammatory or thrombotic disease. There do not appear to be any long-term sequelae of a short course of G-CSF for PBSC mobilization. Studies investigating the long-term effects of PBSC donation have revealed no significant abnormalities in the blood counts of donors, their general health, the risk of development of leukaemia or other malignancy or any effect on fertility.

Use of colony-stimulating factors following haemopoietic progenitor cell transplantation

The use of CSFs to accelerate haemopoietic reconstitution after autologous and allogeneic progenitor cell transplantation is recommended both by the BCSH guidelines (Table 18.3) and the ASCO recommendations (2000 update) (Figure 18.4 and Table 18.4).

Colony-stimulating factors post autologous transplantation

High-dose myeloablative chemotherapy followed by autologous transplantation is a highly effective treatment for a number of haematological malignancies and has been widely used. Apart from the risk of disease relapse, the major complication of this approach is the possibility of procedure-related toxicity. This includes the risks of major haemorrhage, life-threatening infection, delayed or incomplete engraftment and organ damage from the ablative regimen, all of which may lead to prolonged hospitalization and increased procedural cost. Measures to reduce any of these potential problems will clearly be of benefit in terms of improved survival and also the cost–benefit of this treatment

Table 18.3 BCSH guidelines on the use of colony-stimulating factors in haematological malignancies.

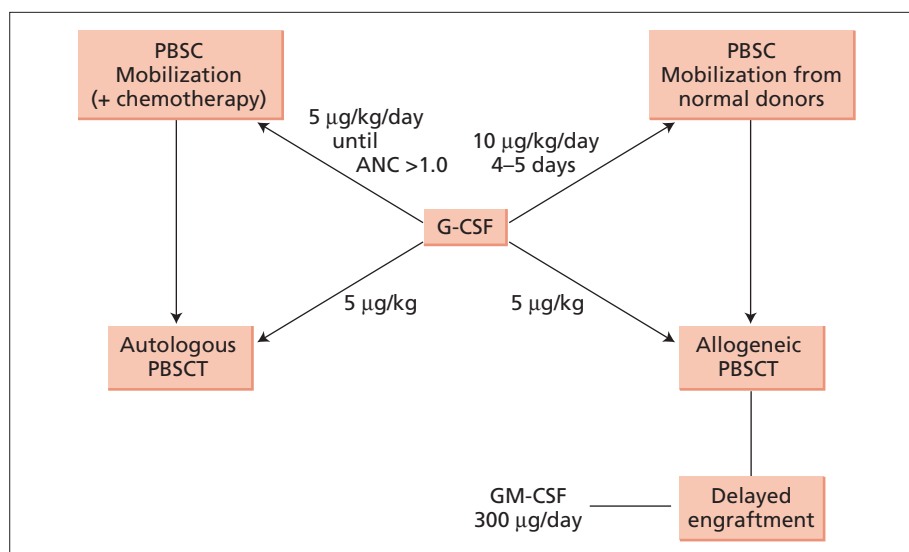
Primary prophylaxis	Not routinely recommended unless the expected incidence of febrile neutropenia is greater than 40% (level IIa, grade B)
Secondary prophylaxis	Not routinely justified but indicated for tumours when delay/dose reduction would compromise overall survival (level III, grade B)
Adjunctive treatment	Not recommended for patients with uncomplicated febrile neutropenia (level Ib, grade A) but should be considered in patients with poor prognostic factors (level IV, grade C)
AML	Routine use of CSF is recommended after consolidation chemotherapy (level Ib, grade A); CSF is recommended following induction if it reduces hospital stay or antibiotic usage
ALL	G-CSF is indicated to reduce the severity of neutropenia following intensive phases of therapy (level Ib, grade A)
MDS	CSFs are indicated to reduce the severity of neutropenia in patients receiving intensive chemotherapy (level 1b, grade A). CSFs are also recommended on an intermittent basis for neutropenic patients with infection (level IV, grade C) but continuous prophylactic use is not justified
Aplastic anaemia	There is insufficient evidence to make any recommendations and so patients should be given CSFs on an individual therapeutic trial basis (level IV, grade C)
Bone marrow failure	G-CSF is recommended when improvement of the neutrophil count is appropriate (level III, grade B)
Lymphomas	Evidence supports the routine use of CSFs to reduce infection, chemotherapy delay and hospitalization especially when the risk of neutropenia sepsis exceeds 40% (level 1a, grade A); there is also evidence of improved survival with G-CSF supported dose intensification in elderly patients with HG NHL (level Ib, grade A); at present this cannot justify a change in policy for all lymphoma patients but elderly patients may benefit from G-CSF support
PBPC mobilization	CSFs are indicated for the mobilization of PBPCs
PBPC transplantation	CSFs are indicated to accelerate reconstitution after allogeneic and autologous transfusion


Figure 18.4 Role of haemopoietic growth factors in progenitor cell transplantation.

Table 18.4 Summary of ASCO recommendations (2000 update).

Primary prophylaxis	Routine use of CSFs not recommended; consider CSFs in high-risk patients, including the elderly
Secondary prophylaxis	Use of CSFs should be considered in patients with complicated febrile neutropenia
Chemotherapy AML	CSF treatment after induction therapy should be used if cost–benefits can be shown; CSFs for priming is not recommended outside the setting of clinical trials; CSFs are recommended after consolidation chemotherapy
ALL	G-CSF administration begun after completion of the first few days of chemotherapy of the initial induction or first post-remission course is recommended
MDS	Intermittent use of CSFs may be considered in patients with severe neutropenia and recurrent infection; prolonged or continuous treatment with CSFs is not recommended
AA	No specific recommendations
Lymphomas	No specific recommendations
PBSC mobilization	Use of CSFs is recommended for both patient and donor
	PBSC mobilization; higher CSF doses may be useful
Post HSC transplantation	Use of adjunctive CSFs is recommended post PBSC transplantation and after autologous and allogeneic BMT

approach. The administration of haemopoietic growth factors following autologous transplantation has therefore been introduced in an attempt to shorten the neutropenic period, decrease the frequency and severity of neutropenic septic episodes, and hence reduce the duration of hospitalization and thereby reduce the overall cost of the procedure. A number of randomized controlled trials have confirmed that the use of CSFs after autologous transplantation are beneficial in significantly shortening the duration of neutropenia and hospitalization. This did lead to a mean cost saving in at least one of the studies.

Both G-CSF and GM-CSF have been shown to be effective in hastening haemopoietic recovery following autologous transplantation. No large-scale prospective comparative studies have been performed addressing the relative efficacy of these two CSFs. In addition, the optimal timing, duration and dose of CSFs following autologous transplantation remains to be established.

The ASCO guidelines support the use of G-CSF at a dose of 5 μg/kg per day and 250 μg/m² per day for GM-CSF, and the commencement of CSFs up to 5 days after progenitor cell reinfusion. This dose should then be continued until the absolute neutrophil count (ANC) exceeds a minimum of 1×10^9/L. Further modifications to the dosage and scheduling of these growth factors may be possible to reduce costs without impairment of the beneficial clinical effects.

Colony-stimulating factors post allogeneic transplantation
The major complications of allogeneic transplantation are similar to those of autologous transplantation with the additional problems of GvHD and graft rejection. Therefore, as for autologous transplantation, the rationale for administration of growth factors following allogeneic transplantation is to accelerate myeloid recovery and reduce the incidence of infection, number of febrile days, antibiotic usage and duration of hospitalization. Available data from a number of studies have confirmed a clinical benefit in terms of neutrophil engraftment kinetics using either G- or GM-CSF following allogeneic transplantation from either sibling or unrelated donors. The degree of acceleration of neutrophil recovery, however, is also influenced by other factors, including the GvHD prophylaxis used and the source of haemopoietic progenitors infused, i.e. G-CSF-mobilized PBSCs versus bone marrow.

It is still not clear whether the enhanced haemopoietic reconstitution seen in patients receiving CSFs post transplant translates into improved transplant-related mortality rates and survival, although this has been suggested by some studies.

Initial concerns about the use of growth factors in the allogeneic setting leading to an increased risk of GvHD or to an increase in relapse rates for AML have proved to be unfounded despite the effects of growth factors on cytotoxic T cells and myeloid blast cells *in vitro*. As with autologous transplantation, the optimal cost-effective dose and schedule for the administration of CSFs following allogeneic transplantation remains to be established.

The problem of bone marrow graft failure or delayed haematological recovery (ANC < 0.2×10^9/L by day +28) after transplantation is a problem mainly seen after allogeneic transplantation using unrelated donors, especially when a low cell dose has been infused. When this occurs, it usually results in prolonged hospitalization, increased treatment costs and a higher treatment-related mortality, mainly as a result of infective deaths. Few studies have examined the use of growth factors for the treatment of delayed engraftment, although there are some data to suggest that GM-CSF may be of benefit in this setting. The updated ASCO guidelines recommend a trial of CSFs for patients who experience delayed or inadequate neutrophil engraftment after PBSC transplantation, and suggest using a dose of GM-CSF 250 μg/m² per day for 14 days, followed by a 7-day break. This can be repeated for up to three courses if there is no effect with a dose escalation to 500 μg/m² per day for the third course.

Use of colony-stimulating factors to support standard chemotherapy
Neutropenia and neutropenic sepsis are the main dose-limiting complications of chemotherapy, with the risk of infection being directly related to the severity and duration of neutropenia. Although the mortality from neutropenic sepsis is low, such episodes require hospitalization and treatment with broad-spectrum antibiotics. They may also lead to the delay or dose reduction of subsequent courses of chemotherapy, which may have a deleterious effect on the response to treatment.

Primary prophylaxis
Although the addition of CSFs following chemotherapy has been shown to reduce the incidence of febrile neutropenia, this appears only to be cost effective for highly myelosuppressive dose-escalated regimens in which the incidence of febrile neutropenia reaches 40%. Routine use of CSFs for primary prophylaxis in patients receiving standard outpatient chemotherapy regimens is not recommended except in high-risk patient populations (e.g. the elderly, patients with AIDS-related non-Hodgkin's lymphoma, patients with pre-existing neutropenia or decreased immune function or patients with active infections).

Secondary prophylaxis
The use of CSFs in patients who have already experienced an episode of febrile neutropenia following a previous course of chemotherapy is justified in order to prevent further infection and also to maintain the delivery of full-dose chemotherapy on schedule.

Use of colony-stimulating factors for neutropenia
The routine use of haemopoietic growth factors in patients rendered neutropenic following standard chemotherapy but who remain afebrile cannot be justified. Although the duration of neutropenia may be reduced in patients treated with CSFs, this has not been shown to be of any clinical benefit as in general the neutropenia observed in such patients is profound but short. Even in the presence of neutropenic fever, there is only limited evidence that the addition of growth factors improves clinical outcome in terms of duration of hospitalization and antibiotic use despite a consistent reduction in the duration of neutropenia. Thus, current ASCO and BCSH guidelines recommend the use of CSFs only in febrile neutropenic patients who have adverse prognostic factors such as pneumonia, hypotension, multiorgan failure or invasive fungal infection or who are elderly.

Use of colony-stimulating factors in haematological disorders
A number of studies have investigated the role of haemopoietic CSFs in the treatment of patients with a number of haematological disorders in an effort to maintain chemotherapy dose intensity and to reduce the incidence of neutropenic sepsis.

Use of colony-stimulating factors in AML therapy
Randomized trials have shown that the administration of CSFs following acute myeloid leukaemia (AML) induction chemotherapy has consistently reduced the neutropenic period, with concurrent benefits in terms of hospitalization and antibiotic use. Some of these studies have also shown additional benefits in terms of clinical response rate, disease-free or overall survival, although this has not been consistently observed. Importantly, no adverse effects have been observed on the stimulation of leukaemic cell growth or drug resistance in any of these studies despite the fact that CSF receptors may be expressed on myeloid blasts. Elderly AML patients are most at risk from death from neutropenic sepsis, and recommendations at present are that this group should certainly be considered for CSF therapy. The use of CSFs for other AML patients can also be justified if it is considered that the reduction in hospitalization outweighs the cost of the CSF treatment. Comparative studies of G- and GM-CSF have not been performed, but available data seem to suggest that both CSFs are effective in this setting. Delaying the commencement of CSF 2–3 days following the completion of chemotherapy does not appear to reduce the efficacy and may be associated with some cost savings.

Similarly, the use of CSFs in a similar way following consolidation chemotherapy can also be justified as their use in this setting appears to result in a marked reduction in the duration of neutropenia and hospitalization.

The use of CSFs to 'prime' leukaemic blasts in an attempt to enhance their sensitivity to S-phase-specific cytotoxic agents has been investigated. The best-known AML chemotherapy regimen utilizing this approach is the 'FLAG' chemotherapy protocol, which combines fludarabine, cytosine arabinoside and G-CSF. In this case, G-CSF is given before and during the chemotherapy to sensitize the blast cells, and the fludarabine, being scheduled before the cytosine arabinoside, acts synergistically to increase the rate of accumulation of Ara-CTP in the blasts and lead to enhanced killing of these cells. No clear benefit in terms of response rates or survival has, however, been demonstrated using such an approach, and at present it is recommended that the use of CSFs in this setting should be restricted to clinical trials.

Myelodysplastic syndromes
Many patients with myelodysplasia suffer from chronic severe neutropenia, and among such patients the incidence of serious infections is high. Studies have demonstrated that administration of CSFs alone to such patients may be effective in improving neutrophil and also eosinophil counts and is well tolerated. Thus, the intermittent use of CSFs in patients with severe neutropenia and recurrent infection can be recommended. Indeed, the combination of CSFs together with erythropoietin may also be of benefit in MDS patients who are also anaemic owing to a synergistic effect on Hb. Furthermore, for patients with high-risk MDS who are receiving systemic chemotherapy, the administration of CSFs results in a shortening of neutropenia and reduction of the interval between induction and consolidation courses. The theoretical increased risk of transformation to overt AML has not been observed but, in view of this, prolonged or continuous use of CSFs cannot be recommended.

Acute lymphoblastic leukaemia
There is good evidence from randomized trials that G-CSF is effective in reducing the duration of neutropenia by up to 8 days in both adults and children receiving ALL induction chemotherapy. This was associated with a reduction in the number of infections and duration of hospitalization in some of the studies but had no effect on overall or disease-free survival. On the basis of these findings, it has been recommended that G-CSF is commenced after the first few days of induction or first post-remission course of chemotherapy.

Aplastic anaemia
There is limited evidence from clinical trials regarding the use of CSFs for patients with aplastic anaemia. There have been a number of sporadic reports of responses to G- and GM-CSF, especially in less severe cases. It also does not appear that the addition of prophylactic CSFs to immunosuppressive therapy reduces the number of infections developing in such patients. Therefore, it is suggested at present that the use of these agents for patients with aplastic anaemia should be restricted to clinical trials. The efficacy of a number of other haemopoietic growth factors is being evaluated at present, both alone and in combination with stem cell factor (SCF), erythropoietin, flt3-ligand and thrombopoietin. The data from these studies are awaited with interest.

Severe chronic neutropenia
Severe chronic neutropenia is defined as an absolute neutrophil count below 0.5×10^9/L lasting for months or even years. Causes include cyclic, idiopathic and congenital neutropenias, and G-CSF has been shown to be effective in all these categories, leading to durable responses in the neutrophil counts. In the case of inherited bone marrow failure syndromes such as Kostmann's syndrome, Schwachman–Diamond syndrome, Fanconi anaemia and dyskeratosis congenita, G-CSF may be effective in improving neutrophil counts in up to 90% of cases and may also reduce infections and improve survival; these infants previously suffered from severe pyogenic infections and had a median survival of less than 3 years. Adverse effects include mild splenomegaly, mild thrombocytopenia, osteoporosis and possibly malignant transformation.

The fact that some responders with congenital neutropenia have developed myelodysplastic syndromes or AML raises the possibility that G-CSF may play a role in the pathogenesis of these disorders in these patients. The issue is complicated because many of these disorders have a propensity for transformation into AML/MDS as part of their natural history. One

registry study revealed a rate of AML/MDS of 12.5% after 8 years of treatment, with no significant relationships found between the age of onset of AML/MDS, patient gender, G-CSF dose or duration of G-CSF therapy. However, the cumulative acquisition of genetic aberrations was observed in the bone marrow cells from patients with Kostmann's syndrome who transformed, including *ras* mutations, the appearance of clonal cytogenetic abnormalities and the presence of G-CSF receptor mutations. It has been shown in murine models that G-CSF receptor defects may lead to the development of a hyperproliferative response to G-CSF, confer resistance to apoptosis and hence enhance cell survival.

It remains unclear whether G-CSF directly accelerates the propensity for transformation to AML/MDS in the genetically abnormal progenitor cells in these patients with inherited forms of bone marrow failure, especially those with G-CSF and *ras* mutations, or whether G-CSF simply prolongs patient survival and allows time for the malignant predisposition to declare itself. It is, however, noteworthy that G-CSF has also been shown to be effective in the management of patients with cyclic and idiopathic neutropenia, and in these patients there have been no cases of AML/MDS. Nevertheless, only careful follow-up of these patients will resolve this issue.

Hodgkin's disease and non-Hodgkin's lymphoma
Several studies have shown that the addition of G- or GM-CSF as primary prophylaxis in patients receiving chemotherapy for various lymphomas reduces the incidence of neutropenia, neutropenic sepsis, chemotherapy delays and duration of hospitalization. Furthermore, G-CSF has been used to permit a reduction in the interval between cycles of CHOP chemotherapy from 3-weekly to 2-weekly, which may translate into improved disease responses and survival. Overall, there is currently insufficient evidence to justify routine addition of CSFs for all patients with non-Hodgkin's lymphoma, but it may be considered in elderly patients.

Use of colony-stimulating factors in the paediatric population
Chemotherapy protocols for the treatment of paediatric malignancies are often considerably myelotoxic, and infants are particularly susceptible to neutropenic sepsis because of the immaturity of their immune systems. In addition, as many childhood cancers are potentially curable, there is a perceived higher cost–benefit ratio for the use of CSFs to support these chemotherapy regimens. As a result, there is generally a higher usage of CSFs for primary and secondary prophylaxis than in the adult population. The use of CSFs for patients with congenital neutropenias has already been discussed, and there are some data to support the use of CSFs in neonatal sepsis. Otherwise, the indications for the use of CSFs are similar to those for adults, and it appears to be that G-CSF is better tolerated than GM-CSF.

Use of GM-CSF as an adjunct to antifungal therapy
Invasive fungal infections have emerged as a cause of serious mortality and morbidity to immunocompromised patients. Host defences including appropriate cytokine responses and intact phagocyte function are necessary to combat opportunistic fungal infections such as candidiasis and aspergillosis. Bronchoalveolar macrophages, which are derived from peripheral blood monocytes, have a particularly important role in this regard, but this mechanism may be severely impaired in patients who are cytopenic following cytotoxic chemotherapy or who are treated with steroids (e.g. dexamethasone) that have a suppressive effect on macrophage function.

A number of CSFs have been investigated and studied *in vitro* for activity against fungal pathogens. The most promising results have been seen with GM-CSF, which has been shown to augment the antifungal activity of monocytes and macrophages. The main effects of GM-CSF on macrophages and monocytes are to enhance their phagocytic and metabolic functions, including increased synthesis and release of superoxide anions that are directly toxic to microbes, and to release other proinflammatory cytokines. This results in the inhibition and/or killing of *Candida albicans*, *Aspergillus hyphae*, *Cryptococcus*, *Pneumocystis*, *Leishmania* and *Mycobacteria* as well as other intracellular pathogens. GM-CSF has also been shown to block the ability of dexamethasone to suppress the activity of bronchoalveolar macrophages.

There have been several reports on the successful use of GM-CSF in conjunction with antimicrobial therapy in the management of patients with these opportunistic infections. This supports the clinical value of CSFs in this situation, although controlled trials are needed for full evaluation of their efficacy.

The role of G-CSF in the harvesting of granulocytes for transfusion
The development of bacterial and fungal infections continues to be a major complication for neutropenic patients. Despite the use of modern antibiotics and the use of haemopoietic growth factors to reduce the period of post-treatment neutropenia, infection remains a major cause of morbidity and mortality in these patients. The transfusion of normal granulocytes is a logical approach to the treatment of serious infections in neutropenic patients. Before the introduction of CSFs, initial studies of granulocyte transfusions in the 1960s using buffy coats were disappointing owing to difficulties in collecting adequate numbers of functional granulocytes from donors to raise the ANC in adult recipients by more than a few hundred cells per litre. This dose of cells is probably inadequate to treat an established infection.

More recently, it has been shown that the combined administration of dexamethasone and G-CSF to donors prior to leucapheresis can increase the yield of granulocytes collected up

to 10×10^9/L in a single 2- to 3-h procedure using hydroxyethyl starch as a sedimenting agent. These cells appear to be functionally normal by both *in vitro* and *in vivo* measurements. This dose of cells can increase and maintain the blood neutrophil count at $0.5–1.0 \times 10^9$/L for up to 24 h after transfusion, and several reports have indicated a significant improvement in established infections. Adverse effects experienced by recipients are mainly febrile transfusion reactions, although there are theoretical concerns regarding pulmonary toxicity and HLA sensitization. G-CSF administration to donors is generally well tolerated. Further studies are required to determine the exact role for granulocyte transfusions in neutropenic patients with severe infection.

Exogenous production of colony-stimulating factors by tumours

Tumour-related leucocytosis is a paraneoplastic syndrome that has been reported occasionally in a number of different non-haematological malignancies, including lung carcinoma, mesothelioma, transitional cell carcinoma of the bladder, and renal and hepatocellular carcinomas among others. Autonomous production of haemopoietic CSFs such as G-CSF, GM-CSF and IL-6 by these tumours has recently been demonstrated. Although the mechanism for this aberrant expression of G-CSF m-RNA remains unclear, it appears that in the case of lung cancer this phenomenon is associated with a poor outcome.

Long-acting haemopoietic growth factors

Haemopoietic growth factors such as G-CSF and GM-CSF are highly effective at shortening the period of neutropenia following cytotoxic chemotherapy and hence reducing the incidence of infections. Although they are safe and effective, they have a short half-life, being rapidly cleared from the body predominantly through the kidneys. As a result, daily subcutaneous administration is required often for periods of 7–14 days. Attempts have therefore been made to modify these agents to increase their half-life and reduce the frequency of injections. The successful engineering of a sustained-duration G-CSF has now been achieved by the addition of a polyethylene glycol moiety to the G-CSF molecule (pegfilgrastim). This longer-acting cytokine binds to the same receptor and stimulates the proliferation and differentiation of neutrophils by the same mechanism as its shorter-acting counterpart. However, it is minimally cleared by the kidneys and has a much longer serum half-life. Furthermore, its clearance is neutrophil dependent and is therefore self-regulated. Initial clinical trials have shown that a single subcutaneous dose of the pegylated G-CSF per cycle of chemotherapy is sufficient and as effective as its shorter-acting derivative in reducing the neutropenic period. The safety profile and tolerability of pegylated G-CSF is also similar.

Thrombopoietin

Thrombopoietin (TPO) is an essential growth factor for stem cell maintenance and proliferation, although its major role is to enhance platelet production and function. It is the ligand for the receptor c-mpl, which is a member of the cytokine receptor superfamily and is expressed on megakaryocytes, platelets and also on pluripotential stem cells. TPO is mainly synthesized in the liver, and its levels are regulated by clearance through platelet binding. The effect of TPO in culture is to increase the number of CD34$^+$ stem cells, colony-forming units and long-term culture-initiating cells (LT-CIC) (repopulating cells). Indeed, TPO alone can be used to maintain bone marrow cells in culture for several months without loss of the primitive phenotype and with sustained high-level production of both megakaryocytic and non-megakaryocytic cells. Knockout mice lacking TPO or c-mpl expression are not only thrombocytopenic, but also have a serious deficiency in stem cell numbers.

Early hopes that TPO administration after myelotoxic treatment would lead to accelerated platelet recovery were borne out by animal studies. In non-human primates, a single dose of TPO given shortly after cytotoxic therapy was sufficient to alleviate thrombocytopenia and also appeared to potentiate the action of G- or GM-CSF by accelerating CD34$^+$ reconstitution. However, the dose and scheduling were important. Unfortunately, clinical trials with TPO in humans were less successful partly because of problems in scheduling the drug and also because of problems with platelet aggregation. Furthermore, the pharmaceutical development of a pegylated truncated thrombopoietin, termed *megakaryocyte growth and development factor* (MDGF), was halted because of the development of neutralizing antibodies in some patients who received the agent. These antibodies were able to cross-react with endogenous TPO, leading to profound thrombocytopenia. As a result, there are no growth factors with the ability to stimulate platelet production in use at present.

Stem cell factor

Stem cell factor (SCF) is an essential growth factor with both proliferative and anti-apoptotic functions and exerts its influence on both primitive and committed haemopoietic progenitors. It has been mainly used in conjunction with G-CSF due to the apparent synergy between these two CSFs. For example, this combination has been used in the laboratory to enhance the long-term expansion of human primitive haemopoietic cells and clinically to increase the yield of peripheral blood progenitor cells during mobilization. A randomized study comparing the efficacy of G-CSF alone and G-CSF combined with SCF in stem cell mobilization from heavily pretreated patients with non-Hodgkin's lymphoma and Hodgkin's disease showed that the combination led to a superior CD34$^+$ cell yield.

The SCF receptor, termed c-Kit, has an intrinsic tyrosine kinase domain and may be abnormally expressed in haemopoietic malignancies and other tumours (e.g. gastrointestinal stromal tumours, GIST). Recent advances have identified molecules that are able to target and inhibit specific tyrosine kinase inhibitors. This may represent an emerging modality for the treatment of AML, as activated endothelial cells have been shown to secrete haemopoietic growth factors such as SCF and GM-CSF, which may be necessary for leukaemic cell survival in a paracrine fashion. AML blasts themselves have been shown to express SCF (c-Kit) receptors in approximately 50% of cases. These receptors may be responsible for AML blast proliferation and resistance to apoptosis as these cells may respond to growth stimuli provided by endothelial cells from the bone marrow microenvironment. Therefore, therapy directed at blocking SCF signalling might prove to be an effective therapy for the treatment of AML. Studies of different tyrosine kinase inhibitors in this regard are ongoing.

Interleukin 3

Interleukin 3 (IL-3) is a multipotential growth factor produced by activated T cells, monocytes/macrophages and stromal cells. It stimulates all haemopoietic lineages and induces proliferation, maturation and proliferation of pluripotential haemopoietic stem cells and also committed myeloid, erythroid and megakaryocytic cells. Human IL-3 was cloned in 1986 and recombinant IL-3 has been used in various clinical trials to speed haemopoietic recovery following cytotoxic chemotherapy. Initial phase I/II studies gave promising results with apparent faster regeneration, but this was not confirmed in phase III studies. Furthermore, the use of IL-3 alone in the treatment of patients with aplastic anaemia and myelodysplasia has been disappointing. The potential of IL-3 in conjunction with other growth factors to increase the yield of PBSCs for harvesting is being evaluated. Owing to the problems of toxicity and inflammatory side-effects induced by IL-3, it is no longer in clinical use. Instead, attention has switched to the development of synthetic chimeric growth factor receptor agonists that have greater *in vitro* biological activity and fewer side-effects.

Chimeric haemopoietic growth factors

The shared properties of haemopoietic growth factors and their receptors has enabled the construction of genetically engineered synthetic cytokines with higher affinities, increased biological activity and more favourable toxicity profiles. Synthokine (a high-affinity IL-3 analogue), myelopoietin (an IL-3 and G-CSF chimera) and promegapoietin (an IL-3 and thrombopoietin chimera) are all multilineage haemopoietic growth factors that are being evaluated in clinical trials. The advantage of these compounds is their potential ability to enhance platelet recovery in addition to their effect on neutrophil recovery.

Lysosomal storage disorders

19

Atul B Mehta and Derralynn A Hughes

Introduction

Lysosomes

A vital feature of eukaryotic cells is the presence of internal membranes subdividing the interior of the cell and compartmentalizing cellular processes into organelles.

Lysosomes are membrane-bound intracellular organelles representing the major degradative compartment of mammalian cells. They are morphologically heterogeneous and are distinguished from other organelles by an operational definition that describes them as membrane-bound acidic organelles containing mature acid-dependent hydrolases and lysosome-associated membrane proteins (LAMPS) but lacking receptors for mannose 6-phosphate residues. Lysosomal hydrolases, active at acidic pH, catalyse the degradation of macromolecules imported from the cytoplasm by chaperones or derived from endocytosis, pinocytosis, phagocytosis or autophagocytosis. More than 50 different soluble hydrolases are responsible for the breakdown of lipids, proteins, nucleic acids, glycosaminoglycans and oligosaccharides.

The lysosomal membrane is also vital to protect the cytoplasmic components from the acid hydrolases. Protection against cell digestion is thought to be accomplished by LAMP proteins. These are transmembrane proteins with highly glycosylated intralysosomal domains, among the most densely *N*-glycosylated proteins so far reported. The lysosomal membrane is also involved in fusion with other organelles, in maintenance of an acidic intralysosomal pH and in the efflux of amino acids and mono- and oligosaccharides produced by the lysosomal hydrolases.

Soluble lysosomal enzymes are synthesized on the rough endoplasmic reticulum and acquire *N*-linked oligosaccharide side-chains in the Golgi apparatus. Here, asparagine-linked high-mannose residues are phosphorylated at position 6. This modification is specific for lysosomal enzymes and is essential for the routing of the enzymes to the lysosomal compartment via mannose 6-phosphate receptors (Figure 19.1). The receptor–lysosomal enzyme complex is translocated to a prelysosomal compartment where the complex is dissociated by the low pH. The mannose 6-phosphate receptor recycles back to the Golgi, whereas the enzyme accumulates in the lysosomes. The small proportion of newly synthesized enzyme that does not bind to the receptors is secreted into the interstitial fluid, where it may bind mannose 6-phosphate receptor located on the plasma membrane. This enzyme is then recovered by receptor-mediated endocytosis and transported to the lysosome. Trafficking signals for lysosomal membrane glycoproteins probably reside in the cytosolic tails of the proteins and differ from those of lysosomal enzymes. Knowledge of the sorting mechanism for lysosomal enzymes has been exploited in the development of enzyme replacement therapy of lysosomal storage disorders.

Pathophysiology of lysosomal storage disorders

In most lysosomal storage disorders, an inherited deficiency of a specific lysosomal enzyme results in the accumulation of undegraded substrates within the lysosome. In others, accumulation of storage product results from the deficiency or malfunction of activator proteins, transport proteins or enzymes responsible for the processing of other lysosomal macromolecules. The involvement of over 40 different genes has been characterized, with many exhibiting a large number of different mutations. The resulting diseases are grouped according to the major stored substance, for example mucopolysaccharidoses (MPS), sphingolipidoses and glycoproteinoses. Storage product within the lysosomes causes disruption of cellular organization and disturbance of normal function. Different lysosomal storage diseases have characteristic organ distribution patterns of the abnormal metabolites and therefore recognizable pathological manifestations. For example, in MPS III (Sanfilippo disease) there is accumulation of heparan sulphate, an essential component of the neuronal membrane. This results in mental retardation. In contrast, in MPS IV (Morquio disease) accumulation of keratan

Figure 19.1 Routes of lysosomal enzyme cycling. Extracellular enzyme binds to the plasma membrane via mannose 6-phosphate receptors and is internalized by a clathrin-coated vesicle into an early endosome. As the early endosome acidifies to become a late endosome, the enzyme dissociates from the mannose 6-phosphate receptor, which recycles to the plasma membrane. The late endosome fuses with a primary lysosome derived from the Golgi apparatus to form a secondary lysosome, which may remain in the cell as a residual body or fuse with the plasma membrane in the process of exocytosis of digested products.
sulphate results in severe skeletal deformities. However, even within a discrete storage disorder there are often wide-ranging clinical manifestations. Individual mutations of the relevant enzymes give rise to variable levels of residual enzyme activity. This may result in different sites of storage and rates of accumulation producing clear genotype–phenotype correlations. More often, however, the genotype–phenotype relationship is unclear, with even siblings known to have the same mutation exhibiting disparate disease manifestations. This suggests that genetic or environmental factors other than residual enzyme level impacts upon the disease phenotype. Although knowledge of the genetics and biochemistry of the disorders has recently improved substantially, little is known of the pathological processes that actually result in end-organ damage. The enormous variability in symptom severity cannot be explained simply by differences in the overall burden of storage product but suggests a complex host reaction to abnormal cells. This may result in cytokine secretion, cellular proliferation, enhancement of other enzyme levels, and effects on metabolites and energy expenditure. In Gaucher's disease (GD), where storage cells are macrophages that play an essential role in host physiology and pathogenesis of inflammatory and immunological responses, a wide variety of enzymes, cytokines and coagulation factors are perturbed (Table 19.1). Interleukin 1 (IL-1), IL-6, IL-10 and tumour necrosis factor (TNF) have been implicated in GD pathogenesis. Elevated serum levels of IL-6, which is produced by macrophages, endothelial cells, fibroblasts and T cells, have been found to correlate with an index of severity in GD patients, and may be instrumental in the pathogenesis of B-cell dysregulation and

bone disease. IL-10, which in general inhibits the synthesis of other inflammatory cytokines, is also elevated and may represent an abnormal state of immune activation.

Prevalence

Few data are available on the frequency of lysosomal storage disorders. This is partly due to their rarity and the long observation period required to collect sufficient cases but also to incomplete ascertainment of cases. This is both because patients with minimal symptoms such as homozygotes for the Gaucher N370S mutation may not come to medical attention and also because of misdiagnosis of multisystem disorders such as Fabry disease. Studies in Europe, the USA and Australia suggest an overall birth prevalence of 1 in 5000–8000. In a study performed in the Netherlands, lipidoses were the most frequent as a group followed by mucopolysaccharidoses. Mucolipidoses and oligosaccharidoses were very rare. Metachromatic leucodystrophy, Krabbe's disease and Gaucher's disease were the most frequent individual disorders (Table 19.2).

Diagnosis

In the absence of an informative family history, diagnosis of lysosomal storage disorders requires a high degree of clinical suspicion. Levels of lysosomal enzymes may be measured in plasma or leucocytes using commercially available synthetic or naturally occurring labelled substrates. Storage product may be identified within biopsy specimens, plasma or urine. Once

	Elevated	Reduced
Plasma	Glucosyl ceramide	Total plasma cholesterol
	Apolipoprotein E	Low-density lipoprotein
	Transcobalamin II	High-density lipoprotein

a candidate enzyme is identified analysis of the corresponding gene may identify a specific mutation and facilitate rapid screening of other family members. As effective treatment becomes available for a larger number of disorders it is increasingly important that patients should be diagnosed as early as possible as presymptomatic individuals may be candidates for early intervention.

Therapy

Effective treatment of lysosomal storage disorders self-evidently involves reduction of the stored compound and prevention of its reaccumulation. This has been achieved by replacement of the missing protein by stem cell transplantation and by infusion of the missing enzyme (enzyme replacement therapy, ERT). Many

patients with Gaucher's disease, metachromatic leucodystrophy, Krabbe's disease and mucopolysaccharidosis type I have undergone stem cell transplantation. Donation of stem cells has largely been from HLA-identical siblings but, as the highest level of enzyme activity will be supplied by donor cells from non-carriers, cord blood from unrelated donors has recently been used with good results.

Enzyme replacement therapy is now available or under investigation for several lysosomal storage disorders (Table 19.2). Recombinant human enzyme is produced in Chinese hamster ovary cells or human fibroblasts, chemically modified, purified and prepared for home infusion. ERT is effective in reducing the non-neuronopathic manifestations of a number of disorders, including Gaucher's type I and Fabry's disease. However, because enzyme does not cross the blood–brain barrier, it has not been

demonstrated to prevent the onset and progression of neurological symptoms. Even attempts to administer missing enzymes into the spinal canal of patients with Tay–Sachs disease have failed, probably as a result of the limited access to the neuronal cells. Therefore, the effectiveness of ERT would appear to depend on the accessibility of the site of the pathology to exogenous enzyme and the ability of affected cells to internalize the enzyme.

Most recently, the strategy of decreasing the rate of synthesis of the stored component, so-called substrate reduction therapy (SRT), has been evaluated. The principle is to reduce the rate of substrate synthesis to approximately equal the rate of degradation using low-molecular-weight enzyme inhibitors. This may be especially effective in individuals with later onset forms of the diseases with detectable levels of residual enzyme activity. Furthermore, SRT may have therapeutic utility in crossing the blood–brain barrier. In addition, because low levels of enzyme may arise from misfolding or abnormal transport, the ability of pharmacological chaperones to rescue misfolded or unstable enzymes is under investigation at present. Low-molecular-weight analogues, receptor agonists and receptor antagonists diffuse into the cell and bind site-specifically to folding intermediates of the mutant protein and rescue it from degradation. Such enhancement of residual galactosidase A activity by galactose infusion has been used in the cardiac variant of Fabry's disease.

Finally, gene therapy is under investigation in animal models of lysosomal storage disorders and has been reported as an adjunct to ERT in Gaucher's disease.

Prognosis

The clinical course of infants diagnosed with a lysosomal storage disorder usually follows a predictable path of loss of learned skills and neurological deterioration until death results from infection and progressive organ damage. When onset is later, in adolescents and adults, the clinical course is more varied and the prognosis depends on the major organ systems affected.

Clinical manifestations

The key clinical features of the major lysosomal storage disorders are presented in Table 19.3. In view of recent advances in therapy, Gaucher's disease and Fabry's disease are presented in greater detail below.

Gaucher's disease

Gaucher's disease (GD) is due to deficiency of the enzyme glucocerebrosidase (GC), a lysosomal enzyme that hydrolyses glucosylceramide to glucose and ceramide (Figure 19.2). It is an autosomal recessive condition arising as a result of mutation within the GC gene. Affected individuals have a mutant enzyme with reduced activity, resulting in accumulation of the substrate (glucosylceramide) in lysosomes of reticuloendothelial (RE) cells. It is one of the commonest lysosomal storage disorders, with an estimated incidence of 1: 60 – 80 000 individuals.

Table 19.3 Lysosomal storage disorders: clinical features.

Category	Disease	Clinical features
Mucopolysaccharidoses	MPS I	Hurler's disease: developmental delay, ENT infections, coarse facial features, macrocephaly, thick skin, corneal clouding, hepatosplenomegaly, bony deformity including large skull, pelvic dysplasia, deformed vertebrae and shortened tubular bones (dysostosis multiplex)
		Scheie disease: mild skeletal abnormalities, stiff joints, corneal opacities, carpel tunnel syndrome, cardiac valvular abnormalities and respiratory infections
	MPS II	Like MPS I but without corneal clouding
	MPS III	Loss of acquired skills, aggression, hyperactivity, coarse hair, hirsutism, seizures, may become tetraspastic
	MPS IV	Disproportionate dwarfism, joint contractures, kyphoscoliosis, corneal clouding
	MPS VI	Like Hurler's disease but without neurological involvement
	MPS VII	Skeletal disease, hepatosplenomegaly, lethal hydrops, normal
Mucolipidoses	ML I	Early psychomotor retardation, hypotonia, truncal ataxia, upper motor neuron signs, corneal clouding
	ML II	Like Hurler's, mild corneal clouding and hepatosplenomegaly, prominent gum hypertrophy, severe dysostosis multiplex
	MLIII	Progressive arthropathy, bone lesions, low intelligence, cardiac valvular lesions, corneal clouding
	ML IV	Like ML 1

Table 19.3 (*cont'd*)

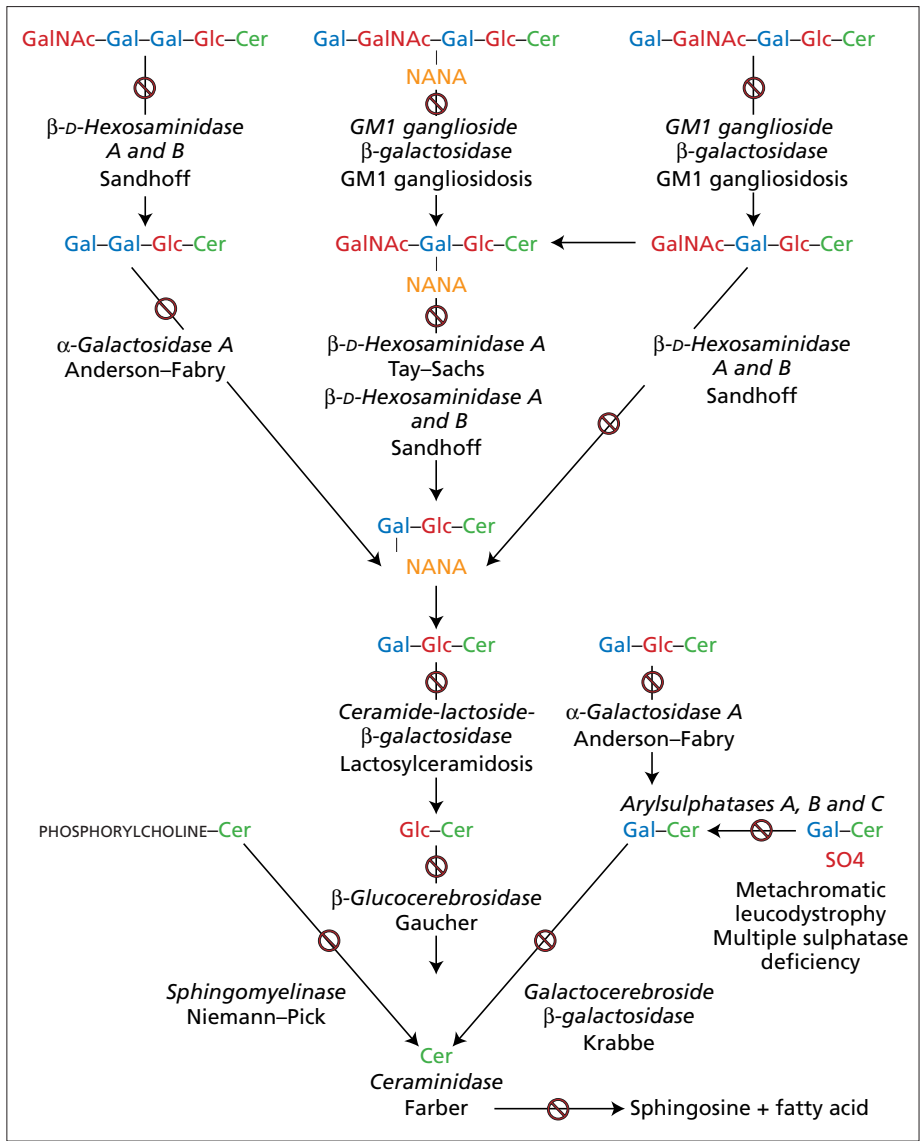
Category	Disease	Clinical features
Sphingolipidoses	GM1 gangliosidosis	Infantile: coarse features, seizures, progression to decerebrate rigidity and spastic quadriplegia by 2 years
		Juvenile: psychomotor and neurological degeneration over 2–10 years
		Adult: progressive cerebellar impairment, spasticity and intellectual impairment
	GM2 gangliosidosis	Tay–Sachs: motor weakness, psychomotor retardation, blindness, lapsing into vegetative state with decerebrate rigidity
		Sandhoff disease: like rapidly evolving Tay–Sachs disease
	Globoid cell leucodystrophy	Developmental delay and progressive neurological degeneration aged 3–9 months
	MLD	Flaccid paresis, lack of coordination and hyporeflexia, psychomotor retrogression, juvenile and adult forms have later onset, intellectual deterioration
	Fabry's disease	Left ventricular hypertrophy, renal impairment, angiokeratoma and acroparaesthesia
	Gaucher's disease	Type 1: hepatosplenomegaly, skeletal disease and pancytopenia
		Type 2: death from neurological complications by 2 years
		Type 3: slowly progressive neurodegenerative disorder
	Farber's disease	Hoarse cry, painful arthropathy, pulmonary infiltration, cherry-red spot, mental handicap, thickened heart valves
	Niemann–Pick	A: Hepatosplenomegaly, lymphadenopathy, neurological regression, epileptic seizures, macular cherry red spot
		B: Hepatosplenomegaly and pulmonary infiltration
		C: Psychomotor delay and regression
Oligosaccharidoses	α-Mannosidosis	Mild skeletal deformity, coarse facial features and moderate to marked mental retardation
	β-Mannosidosis	Hearing loss and swallowing difficulties
	Fucosidosis	Neurological degeneration, neurological impairment, seizures, angiokeratoma and mild skeletal dysplasia
	Aspartylglucosaminuria	Progressive psychomotor retardation, coarse facial features and mild skeletal dysplasia
	Schindler's disease	Progressive psychomotor retardation, blindness and seizures
Glycogen Lipid	Pompe's disease	Cardiomegaly, hepatosplenomegaly, muscular weakness and macroglossia
	Wolman's disease	Failure to thrive, malabsorption, adrenal gland enlargement and calcification, fatal by 1 year
	Cholesterol ester storage disease	Hypercholesterolaemia and premature atherosclerosis
Monosaccharide amino acids and monomers		
	ISSD	Visceral involvement, skeletal dysplasia, psychomotor retardation and early death
	Salla disease	Mental retardation, ataxia and near normal lifespan
	Cystinosis	Polyuria, thirst, failure to thrive, renal tubular acidosis, rickets, photophobia and hypothyroidism
	Cobalamin F disease	Stomatitis, glossitis, convulsions and developmental delay
	Danon disease	Cardiomyopathy, myopathy, variable mental retardation
Peptides	Pycnodysostosis	Short stature, osteosclerosis, short fingers, open fontanelle, hypodontia
Ceroid lipofuscinosis	CLN	Mental impairment, seizures, loss of vision and motor skills
Multiple enzyme deficiencies	Multiple sulphatase deficiency	Resemble a combination of MLD and Hurler's disease
	Galactosialidosis	Hypotonia, coarse features with facial oedema, retinal cherry-red spot


Figure 19.2 Biochemistry of lysosomal storage disorders.

Clinical features

Clinical manifestations are due to cellular and tissue damage consequent upon accumulation of abnormal RE cells in various tissues. Three main clinical phenotypes are observed (Table 19.4), determined in large part by the residual activity of the mutant enzyme. All three types are progressive disorders. The residual enzyme activity in type II is so low that abnormal cells accumulate in the central nervous system (CNS). This is the acute neuronopathic form of the disease, which presents with neurological complications in early infancy and usually leads to death before the age of 2 years. Type III GD is the subacute neuronopathic form that leads to a slowly progressive neurodegenerative disorder. Type I is the commonest form of GD and typically does not cause neurological disease. It is particularly common among

Table 19.4 Clinical manifestations of Gaucher's disease.

Manifestation	Type 1	Type 2	Type 3
Onset	1 year	< 1 year	2–20 years
Hepatosplenomegaly	++	+/−	+
Bone disease	++	−	+/−
Cardiac valve disease	−	−	+
CNS disease	−	+++	+/−
Oculomotor apraxia	−	+	+/−
Corneal opacities	−	+/−	+/−
Age at death	60–90 years	< 5 years	< 30 years

subjects of Ashkenazi Jewish origin; within this community, as many as 1 in 15–20 subjects are carriers, and approximately 1 in 800–1000 subjects are homozygous. Type I GD is a heterogeneous disorder that may present in childhood or in late adult life (> 60 years old). It is likely that many subjects are asymptomatic. Symptomatic individuals have hepatosplenomegaly, skeletal disease and bone marrow infiltration, leading to pancytopenia. Rarer manifestations of type I GD include renal involvement, pulmonary disease and skin involvement. Patients with type I GD have an increased incidence of malignancy generally and an increased incidence of haematological malignancies, especially B-lymphocyte disorders (myeloma, monoclonal gammopathy of undetermined significance) and myelodysplasia.

Laboratory features

Affected individuals have mutations within the GC gene; more than 300 different mutations have been described. The commonest mutation causing type I disease is a single basepair substitution in codon 370 (N370S), which accounts for approximately 70% of mutant alleles in affected Ashkenazi Jewish subjects. A basepair substitution in codon 444 (L444P) is the commonest mutation underlying neuronopathic GD. Diagnosis is confirmed by enzymatic assay of GC activity in leucocytes, fibroblasts and urine. However, enzymatic assay does not always identify heterozygote subjects and measured enzyme activity correlates poorly with clinical severity.

Splenic enlargement and marrow infiltration frequently lead to anaemia, leucopenia and thrombocytopenia.

Changes in serum immunoglobulins are frequent. Polyclonal hypergammaglobulinaemia is found in more than one-third of patients, and monoclonal gammopathy of undetermined significance (MGUS) is seen in up to 20%. Liver function tests are often abnormal, reflecting infiltration of the liver by Gaucher's cells leading to necrosis, fibrosis and, occasionally, even frank cirrhosis. There is an increased incidence of gallstones. The serum cholesterol level is typically lowered. GD is associated with a bleeding diathesis, attributable to abnormal platelet function and thrombocytopenia. Factor XI deficiency is commonly observed and is largely due to co-inheritance of other genetic abnormalities that are also common among Ashkenazi Jews.

The abnormal lipid-laden macrophages are readily detected on tissue biopsy (e.g. bone marrow aspirate, Figure 19.3), although biopsy is no longer considered necessary to make the diagnosis. The serum levels of ferritin, angiotensin-converting enzyme (ACE) and acid phosphatase are typically elevated. The enzyme chitotriosidase is derived from macrophages and is typically grossly elevated in untreated GD, and declines progressively with treatment. Levels may be as high as 30 000 units/L (normal range < 150 units/L); values below 1000 units/L generally indicate stable disease, and with prolonged (> 7 years) enzyme replacement therapy, values may even come down into the normal range (Figure 19.4). However, up to 6% of the population are deficient in this enzyme owing to a 24-basepair
Figure 19.3 Gaucher's cells in the bone marrow.
Figure 19.4 Clinical course in Gaucher's disease.

duplication in the chitotriosidase gene. These individuals cannot be monitored by measurement of plasma chitotriosidase activity. A new surrogate marker, pulmonary activation-regulated cytokine (Parc) (CCL18), is also elevated in plasma of patients with GD and may be useful for monitoring those patients with chitotriosidase deficiency. Parc is a member of the C-C chemokine family and its overexpression may be relevant to some of the pathophysiological features of GD such as abnormalities in neutrophil chemotaxis.

Treatment

All patients with GD should be evaluated by experienced physicians. Recombinant enzyme is made in Chinese hamster ovary (CHO) cells and additional mannose residues are added to the surface of the enzyme to facilitate uptake of the enzyme via the macrophage mannose receptor. This process allows treatment to be targeted to the RE system. GD is the first lysosomal storage disorder to be treated by enzyme replacement therapy (ERT), which has become the 'gold standard' of therapy for type I GD. Indications for ERT include significant pancytopenia (e.g. Hb < 10 g/dL, platelets < 100×10^9/L), skeletal disease and significant hepatosplenomegaly. High-dose ERT (> 100 units/kg every 2 weeks) is under evaluation at present for type II GD. The recombinant enzyme does not cross the blood–brain barrier and, although hepatosplenomegaly improves, ERT has little discernible impact on CNS disease.

However, ERT has recently (2003) been licensed for patients with type III GD, who typically have milder CNS abnormalities (e.g. ophthalmoplegia) in association with advanced systemic changes. ERT is administered by intravenous infusion (typically in the patient's home) every 1–2 weeks. The dose of therapy is titrated against the severity of clinical and laboratory changes. Type I patients with extensive bony disease and hepatosplenomegaly require 30+ units/kg every 2 weeks (60+ units/kg for type III), and these high doses should be continued for 2–3 years or more. Patients are monitored regularly with blood tests (the chitotriosidase assay is particularly helpful) and an annual skeletal MRI. Some patients with advanced type I and III disease may benefit from more frequent infusions (e.g. weekly) for the first year or more. The dose of ERT is gradually lowered as the disease burden declines. Patients with less advanced disease may require lower doses (e.g. 5–10 units/kg every 2 weeks), and some patients may only require monthly infusions. ERT is well tolerated and has been available for over 10 years. A small proportion of patients (< 10%) develop antibodies, but these are not usually neutralizing and do not affect treatment efficacy. Infusion reactions are rare and easily managed.

An oral form of therapy (Miglustat, Zavesca®) has recently been developed, and is licensed for mild to moderate type I disease. It is a form of SRT (see above). It is a small molecule that reduces the amount of substrate (glucosylceramide) being produced within lysosomes, such that patients with reduced residual enzyme activity will benefit. It is being evaluated at present in

Figure 19.5 MRI scan showing skeletal changes in Gaucher's disease.

other lysosomal storage disorders (LSDs) (e.g. Tay–Sachs disease, Niemann–Pick type C) as its administration leads to reduction of a range of substrates in addition to glucosylceramide. SRT does cross the blood–brain barrier and is being evaluated in type III GD and in other LSDs affecting the CNS (e.g. Tay–Sachs).

Supportive therapy is frequently required. The skeletal disease in GD (Figure 19.5) is painful and patients may require analgesia. Prior to the use of ERT, patients frequently developed acute 'bone crisis' – episodic, severe pain, typically in the limbs and often precipitated by dehydration. Bisphosphonate therapy is under evaluation for its potential to reduce pain and rate of progression of skeletal disease. Blood component therapy may be required for pancytopenic patients. Splenectomy should be avoided if possible as splenectomized subjects are more likely to develop tissue infiltration in other organs (e.g. liver, lungs, skeleton). Allogeneic stem cell transplantation is a curative modality of therapy, and has a definite role in carefully selected children with neuronopathic GD.

Fabry's disease

Fabry's disease (or Anderson–Fabry disease) is an X-linked lysosomal storage disorder due to mutation within the gene for α-galactosidase A (αGal A) (Figure 19.2). The resulting inability to catabolize glycosphingolipids leads to progressive accumulation of the substrate globotriasylceramide (Gb_3) in a range of tissues. In contrast to GD, the lipid accumulation in Fabry's disease affects a range of cells (e.g. endothelial cells, epithelial cells, myocytes) within a broad range of tissues and organs, particularly the kidneys (leading to renal failure), heart (causing ventricular hypertrophy and conduction disturbances) and vasculature of the CNS. It is one of the commonest lysosomal storage disorders, with an incidence of approximately 1 in 100 000. It is panethnic.

Diagnosis

Diagnosis is by assay of αGalA activity in leucocytes and detection of molecular abnormalities within the αGalA gene. More than 200 different mutations have been described, and most lead to complete loss of enzyme activity. Tissue diagnosis is by renal, skin or cardiac biopsy.

Clinical features

Clinical features are legion. Although females are heterozygous, they are usually symptomatic and may be as severely affected as males. A skin rash (angiokeratoma) and pain in limbs (acroparaesthesia) are early symptoms (under 10 years old). In late childhood, reduced sweating, abdominal symptoms and lymphoedema are characteristic. Renal failure, cardiac failure, stroke, epilepsy and CNS/sensory organ involvement are later features. Life expectancy is 40–50 years for men and 50–65 years for most women.

Treatment

ERT for Fabry's disease has been available since 2001. Two formulations are available: a recombinant galactosidase that is translated in CHO cells and mannose terminated (agalsidase, Genzyme Corporation, MA, USA) and an enzyme of identical amino acid sequence that is translated in a human fibroblast cell line wherein post-translational modification is performed within the human cell itself (Transkarcytic Therapies, MA, USA). The infused enzyme in Fabry's disease must be taken up by lysosomes within cells in diverse organs and tissues; hence, targeting is of crucial importance. No direct comparative data on the two formulations are available, but in randomized placebo-controlled trials both preparations appear to be well tolerated and to have clinical efficacy. Intravenous infusions are administered every 2 weeks and have been shown to reduce substrate levels in plasma, urine and tissue biopsy. Beneficial clinical effects of ERT have been observed in renal and cardiac function, pain, hearing loss and gastrointestinal symptoms.

At present, protocols advise commencement of ERT in any Fabry sufferer – male or female – with pain, renal or cardiac disease, neurological abnormalities or significant vascular disease. It is clear that ERT will not reverse significant organ damage (e.g. renal failure) but may slow progression. In Fabry's disease, as in many other LSDs, the key to successful ERT may be prevention of substrate accumulation by early intervention in childhood.

CHAPTER 20

Normal lymphocytes and non-neoplastic lymphocyte disorders

20

Mark T Drayson and Paul AH Moss

Introduction

The immune system has evolved in order to provide protection against infection. Its potential role in defence against malignant disease is also under investigation. The functions of the adaptive/specific immune system are mediated by lymphocytes, which circulate through a number of anatomical structures comprising *primary* and *secondary* lymphoid tissues.

The anatomy of the immune system

Lymphocytes are cells of the haemopoietic system and most derive ultimately from the haemopoietic stem cell in the bone marrow. The myeloid and lymphoid lineages diverge at an early time-point during differentiation, and this correlates with identification of a common myeloid progenitor (CMP) and common lymphoid progenitor cell (CLP). There are three classes of lymphocyte – B cells, T cells and NK cells – and these have different developmental pathways. T cells are generated in the thymus following the migration of prothymocytes from bone marrow to thymus followed by a complicated selection

process involving negative and positive selection of thymocyte precursors. Over 95% of thymocytes die in the thymus, but the minority population emerges from the thymus as single positive CD4+ or CD8+ T cells and enter the lymphoid system as naive precursors that can survive for many years.

Most B cells are generated from within the bone marrow, the 'B' in their name referring to an obscure avian structure called the bursa of Fabricius in which the B cells of birds develop. Naive mature B cells enter the lymphoid circulation but, if triggered by antigen in the periphery, a proportion of cells will return to the bone marrow as long-lived plasma cells that secrete immunoglobulin. Natural killer (NK) cells similarly appear to develop from within the environment of the bone marrow.

The bone marrow and thymus are therefore the sites of lymphocyte development and are known as the *primary* lymphoid organs. However, immune responses are initiated when lymphocytes encounter antigen and this occurs primarily in *secondary* lymphoid tissues such as lymph nodes and the spleen.

Lymphocytes circulate around the body tissues via the blood and lymphatic vasculature. Lymphatic vessels drain extravascular spaces and lymph nodes are collections of lymphoid tissue in lymphatic vessels, which are organized to optimize encounters

between lymphocytes and antigen. Afferent lymph drains into the lymph nodes, bringing circulating lymphocytes and populations of antigen-loaded dendritic cells from regional tissue. Efferent lymph returns lymphocytes to the bloodstream, where naive cells continue this circulatory pattern in a continuing quest for antigenic encounter. Antigen-experienced lymphocytes migrate to a variety of tissues in order to mediate their effector functions. The pattern of homing is largely determined by the chemokine receptor profile on the lymphocyte.

Lymphocytes

B lymphocytes are the precursors of antibody-producing cells. Each B cell produces and expresses on its surface immunoglubulin (Ig) with a distinct specificity for antigen. The specificity of the Ig is determined by the way the Ig variable-region genes are rearranged during B lymphopoiesis. B cells that bind antigen through their surface Ig have to obtain accessory signals if they are to proliferate and differentiate into antibody-secreting cells. These can be provided by helper T cells, which recognize antigen that has been taken up and presented by the B cell.

T cells are functionally diverse. Their receptors for antigen – the T-cell receptor (TCR) – exist only as cell-surface molecules and are not secreted. T cells function by: (i) providing signals that help induce T cells and B cells to proliferate and differentiate; (ii) specifically deleting virally infected cells or foreign cells; and (iii) activating macrophages to enhance cellular cytotoxicity.

NK cells are able to kill cells that fail to express major histocompatibility complex (MHC) class I molecules on their surface. Many intracellular viral infections are able to downregulate surface MHC class I expression as a mechanism of immune evasion. Surface expression is also frequently reduced on malignant cells.

<div style="background:#cde">

The nature of the antigen-specific receptors on T and B cells

</div>

B-cell surface immunoglobulin

In the 1960s, Gell and Sell provided indirect evidence that the surface receptor for antigen on B cells was immunoglobulin, and this was confirmed in 1970 by a number of workers using fluorescent anti-Ig antibodies. In 1984, the TCR was identified by the use of subtraction libraries comparing cDNA expression between T and B cells. There are approximately 20 000 to 100 000 antigen-specific receptors on a lymphocyte and all the receptors on a single T cell or B cell are identical.

However, although the antigen receptors on a single cell have homogeneous antigen-recognition structures, they are different from the receptors on other B or T lymphocytes. During lymphoid development, a repertoire of billions of B and T cells is generated and all have slightly different antigen receptors on their surface. At the initiation of an immune response, only a few
Figure 20.1 The structure of the antigen-specific receptor of B cells (BCR). Antibody (Ig) molecules on the surface of B cells provide their antigen-specific receptors. The green structures are the heavy (H) chains and the orange the light (L) chains. The antigen-combining – variable – regions are shown as open circles; the locations of the antigen-combining sites are indicated by arrows. The binding of antigen by B cells through their surface Ig can lead to antigen being internalized and can result, indirectly, in proliferation by the B cell and its differentiation to become an antibody-secreting cell or a memory cell. Signals delivered to the B cell when the surface Ig binds antigen are delivered through the α and β CD79 transmembrane signalling molecules and other surface Ig-associated molecules, including the complex of CD21 and CD19 with TAPA. CD21 binds the complement component C3d, which is derived from C3, and attaches to bacterial and other cell membranes; when CD21 and the surface immunoglobulin are cross-linked the stimulus for B-cell activation is considerably more than that delivered through the surface Ig alone. All B-cell surface Ig, such as plasma IgG and IgA, has two heavy and two light chains per molecule; IgA secreted from the body is a dimer and most IgM found in body fluids a pentamer of this basic four-chain structure.

of these cells are able to recognize the antigen and these are then expanded during their differentiation into effector cells. This is the basis of the *clonal selection* theory of immunology. The mechanisms that generate this great diversity of antigen receptors on lymphocytes are described in the next section. Figure 20.1 shows the structure of surface immunoglobulin on B cells.

T-cell receptors

T cells recognize peptides presented in association with MHC molecules. In humans, the MHC molecules are also known as human leucocyte antigens (HLAs) and there are two classes of MHC molecule. MHC class I molecules (Figure 20.2) are expressed by all nucleated cells except germ cells. They are not expressed by erythrocytes but are found on the surface of
Figure 20.2 T cells recognize peptides held in MHC molecules. A class I MHC molecule is depicted on the left and a class II MHC molecule on the right. Some of the protein produced within each cell is broken down to peptides, which are presented on the cell surface in the peptide-binding groove of MHC molecules, usually class I (Figure 20.3). Extracellular molecules are taken up by antigen-presenting cells, broken down within the cell and presented on the cell surface in the peptide-binding groove of MHC molecules, usually class II (Figure 20.3). There are three isotypes of class II molecules, known as DP, DQ and DR, and three main class I isotypes, A, B and C. All of these are encoded within the MHC gene complex at 6p21.3. The genes encoding the peptide-binding grooves of each of these isotypes show extraordinary variability within the human population – 'allelic polymorphism' (Figure 20.5). The range of peptides that can be held by different MHC molecules varies. Consequently, this polymorphism is reflected in differences between individuals in the ability to recognize specific peptides. Any one TCR will only recognize a particular peptide within a particular groove structure. β_2-Microglobulin is a non-polymorphic Ig-like domain that is non-covalently associated with HLA class I MHC molecules; it stabilizes peptide binding and is essential for the expression of class I on the cell surface.

erythroblasts. The peptides seen by T cells in association with class I MHC molecules are, in most circumstances, derived from proteins produced from within the cell. This places MHC class I molecules in an excellent position to present peptides derived from viral proteins following intracellular viral infection (Figure 20.3). It is now clear that antigen-presenting cells are also able to take up proteins from outside the cell and process them such that peptides gain access to the MHC class I presentation. This process is called *cross-presentation* and may be particularly important in generating CD8+ T cell responses to tumour-associated proteins.

MHC class I antigen presentation starts with the intracellular breakdown of proteins by a multimolecular proteolytic complex

known as a *proteasome*. These peptides are actively transported by TAP (transporter associated with antigen processing) proteins into the endoplasmic reticulum, where empty MHC class I molecules are being assembled. The nascent MHC molecules are able to 'fold' around the peptides, which make non-covalent interactions with the peptide-binding groove at the top of the molecule. This complex is then stabilized by the association of β_2-microglobulin before being transported to the cell surface. In this way, the cells are continuously advertising the peptide composition of the proteins that they are producing.

The selection of T cells during their development in the thymus involves the processes of *negative selection* and *positive selection*. T cells that have high affinity for self-peptides held in the groove of a self MHC molecule are deleted by apoptosis in a process known as *negative selection*. T cells with lower affinity for self peptide–MHC complexes are positively selected and survive to become peripheral T cells. T cells that recognize peptide presented by MHC class I molecules express a molecule CD8, which binds to the α3 domain of the MHC class I molecule (Figure 20.4). When any cell in the body presents immunogenic peptides, these may be recognized by a cytotoxic CD8 T lymphocyte that can then kill the target cell. This is most likely to occur as the result of virus infection when virus-encoded proteins are produced; it may also occur following the acquisition of a genetic mutation within a cell.

The other class of MHC molecule, MHC class II (Figure 20.2), is less widely expressed. The only cells that constitutively express large amounts of this class of MHC molecule are: (i) specialized antigen-presenting cells collectively known as dendritic cells; (ii) B lymphocytes; and (iii) thymic epithelial cells. Dendritic cells are derived from haemopoietic stem cells and codevelop with monocytes; they can be derived from blood mononuclear preparations by culture with granulocyte–macrophage colony-stimulating factor (GM-CSF) and interleukin 4 (IL-4). They migrate to many tissues, particularly epithelia, where they remain until activated by local tissue injury. On activation, they take up fluid and particles from their surrounding environment (Figure 20.3).

The pinocytotic activity in these cells can be induced by IL-1 and tumour necrosis factor (TNF) released at sites of injury. The pinocytotic vesicles fuse with an antigen-presenting endosomal compartment; proteolytic enzymes within this compartment are activated and proteins are broken down to peptides by the action of lysosomal enzymes. Class II molecules with peptide-binding grooves sealed by invariant chain (CD74) are inserted into the endosome wall. The invariant chain is digested and this allows peptides within the compartment to associate with MHC class II molecules. The MHC class II–peptide complex is then taken to the cell surface.

The scrutiny of antigen-presenting cells by T cells starts when dendritic cells have moved from peripheral tissues to the T cell-rich areas of adjacent secondary lymphoid organs. In that site they are known as interdigitating dendritic cells (IDCs),
Figure 20.3 Antigen processing and presentation in association with MHC molecules. Left: Antigen presentation of proteins produced within cells is mainly the property of class I MHC molecules. A proportion of proteins (black ribbons) produced within a cell on ribosomes (yellow) are broken down to peptides (black fragments) within a cytoplasmic molecular complex known as a proteasome. The resulting peptides are actively transported by TAP proteins (blue) through the wall of specialized endoplasmic reticulum (ER) that has MHC class I molecules blue in its wall. The peptides and β_2-microglobulin associate with class I molecules and are then expressed on the cell surface (detailed in Figure 20.2). Right: Antigen presentation in association with class II MHC molecules involves pinocytosis of antigen (black ribbon) and fusion with an antigen-processing endosome, which has class II MHC molecules (magenta and blue) inserted in its wall. The antigen-presenting grooves of the class II MHC molecules are kept empty by the association with invariant chain (CD74). Fusion of the pinosome with the endosome heralds the activation of proteolytic enzymes; the invariant chain and the ingested proteins are broken down to peptides. The resulting peptides (black fragments) are assembled into the antigen-presenting groove of class II MHC molecules that are held in the endosomal wall. The HLA class II molecules with bound peptides are then carried to the cell surface (detailed in Figure 20.2).

which express increased amounts of MHC class II and constitutively express other molecules associated with T-cell activation such as CD40, CD80 (B7.1) and CD86 (B7.2). They also have markedly reduced capacity for pinocytosis. In the T zones of secondary lymphoid organs CD4+, and to a lesser extent CD8+, recirculating T cells are constantly migrating to the surface of IDCs, which they appear to scrutinize for the presence of an MHC–peptide complex to which they can bind with their T cell receptor. In this way, the T cells continually screen for the presence of peptides derived from both extra- and intracellular antigens (see section on immune responses).

The T-cell receptor (TCR) (Figure 20.4) has certain similarities to immunoglobulin in that it is made up of two non-identical polypeptide chains that have constant and variable regions. In addition, as described in the next section, the genes that encode for TCR and immunoglobulin are remarkably similar. The TCR has only one antigen binding site per molecule, as opposed to the two antigen binding sites of immunoglobulin.

There are two types of TCR. The most common is composed of a heterodimer of an α-chain and a β-chain. The minority population of γδ TCRs is less well characterized, but they appear to recognize antigen in a different way from αβ TCR. A number of different molecules are associated with the two TCR polypeptide chains in order to generate the TCR complex. This transmembrane signalling complex of molecules is collectively known as CD3 (detailed in Figure 20.4) and is linked to 'second messenger' signalling molecules, whose expression varies between different T-cell subsets and at different stages of T-cell differentiation. CD4 or CD8 molecules are closely associated with the CD3 complex and determine the class of MHC molecule to which the TCR can bind.

The polymorphism of major histocompatibility complex molecules

There is extensive polymorphism of the major histocompatibility complex (MHC) class I and class II molecules (Figure 20.5).
Figure 20.4 The αβ T-cell receptor complex. The αβ TCR is composed of two polypeptide chains, each with a variable (open ovoid) and constant (closed ovoid) domain. Peptide plus MHC is recognized by the combined variable regions. The TCR is surrounded by the CD3 complex of transmembrane signalling molecules. This is composed of four types of polypeptide chain, γ, δ, ε and ζ that are present as three pairs: ε with δ, ε with γ and a pair of ζ-chains or ζ plus η (a splice variant of ζ with a longer intracellular tail). Most monoclonal antibodies against CD3 are directed against antigenic determinants on CD3ε. Most peripheral T cells express CD4 or CD8 with their TCR. In the thymus, the TCR is first expressed on thymocytes that express both CD4 and CD8, allowing the possibility for selection on the basis of either class II or class I-recognizing properties (see section on T-cell development).

These were first recognized as targets for allograft rejection and the allelic forms of the MHC molecules differ in the fine structure of their MHC-binding grooves. This is reflected in differences in the range of peptides that different MHC alleles can present to T cells. Crossover during meiosis is relatively rare; consequently. the alleles on each chromosome 6 are usually inherited *en bloc* and are named the MHC haplotype of that chromosome. It follows that approximately one in four siblings share the same MHC haplotype on both chromosomes. For the purposes of stem cell transplantation, the patient and donor must usually be fully matched for HLA alleles and thus only 25% of siblings are appropriate for donation.

Highly inbred strains of mice have the same MHC haplotype on both chromosomes and accept grafts from each other. Analysis of the immune response of such mice indicates that some strains of mice are poor responders to certain antigens, whereas other strains produce high responses to the same antigen. Analysis of the response to different antigens does not necessarily show the same pattern for high and low responders. Cross-breeding experiments show that strains of mice responding well to a certain protein have an MHC allotype that is particularly good at presenting a peptide from the antigen to T cells. It is possible to rank the capability of particular alleles to present specific peptides to TCR.

Certain MHC alleles are associated with relative protection against specific infections. Conversely, some alleles, or combinations of alleles, are associated with a greater chance of developing autoimmunity. Many diseases, including diabetes mellitus, Graves' disease and ankylosing spondylitis, are distinctly more common in individuals with a particular MHC allele or MHC haplotype. It seems logical that in evolution most alleles have been retained because they have certain advantages without too many disadvantages. The advantages of an allele might relate to a particular infection that is prevalent in one part of the world, but almost unknown in another; for example, the HLA-B53 allele has a high prevalence in West Africa and is associated with relative protection from a potentially lethal form of malaria.

The generation of antigen-specific receptors on T and B lymphocytes

The genes that encode the antigen-combining or variable (V) part of the antigen-specific receptors of both B cells and T cells show marked similarities, which indicate that the gene complexes have evolved from a common precursor gene during the process of evolution. Both the immunoglobulin and TCR variable-region genes have to undergo a process of *gene rearrangement* from their germline configuration before they can encode an antigen recognition structure. This process is a key element in
Figure 20.5 MHC polymorphism. This is a simplified diagram of the main genes that encode MHC class I and MHC class II molecules and their exceptional polymorphism.

Table 20.1 The variable region genes of human T- and B-cell antigen receptors.

Gene complex	Chromosomal location	Gene segments	
		Type	Approximate number
Ig heavy chain	14q32.3	V_H	51
		D_H	~27
		J_H	6
		C_H	10
Ig kappa light chain	2p12	V_κ	40
		J_κ	5
		C_κ	1
Ig lambda light chain	22q11	V_λ	~29
		J_λ	4
		C_λ	4
TCR alpha chain	14q11.2 (contains TCR δ locus)	V_α	~70
		J_α	61
		C_α	1
TCR delta chain	14q11.2 (between Vα and Jα of TCR α)	V_δ	~4
		D_δ	3
		J_δ	3
		C_δ	1
TCR beta chain	7q32.5	V_β	52
		D_β	2
		J_β	13
		C_β	2
TCR gamma chain	7p15	V_γ	12
		J_γ	5
		C_γ	2

C, constant regions; D, diversity segments; J, joining segments; V, variable sements.
Where the number of functional gene segments is uncertain, this is denoted by '~'. There are many non-functional gene segments (pseudogenes); these are disregarded in this table. Because TCR α- and δ-genes are encoded in the same gene complex on chromosome 14, successful rearrangement of the TCRα genes inevitably results in looping out of the δ-genes so that α- and δ-genes cannot be co-expressed.

the differentiation of lymphocytes from haemopoietic stem cells. The location and composition of the B- and T-cell receptor gene complexes and the details of their variable regions are given in Table 20.1. Although there are considerable differences in the organization of the gene complexes, the mechanism of variable-region gene rearrangement appears to be similar.

The genetic organization of the variable-region genes and the way in which they are rearranged can generate a huge diversity of antigen recognition structures for subsequent display on the surface of mature B and T lymphocytes. For T cells, this is the only way in which diversity of V region structure is achieved. In B cells, there is an additional mechanism that increases the variable-region gene repertoire. This is a *somatic hypermutation* mechanism that is activated during B-cell maturation in germinal centres and which introduces mutations into the rearranged immunoglobulin variable-region genes. It is discussed in detail in the section on antibody responses.

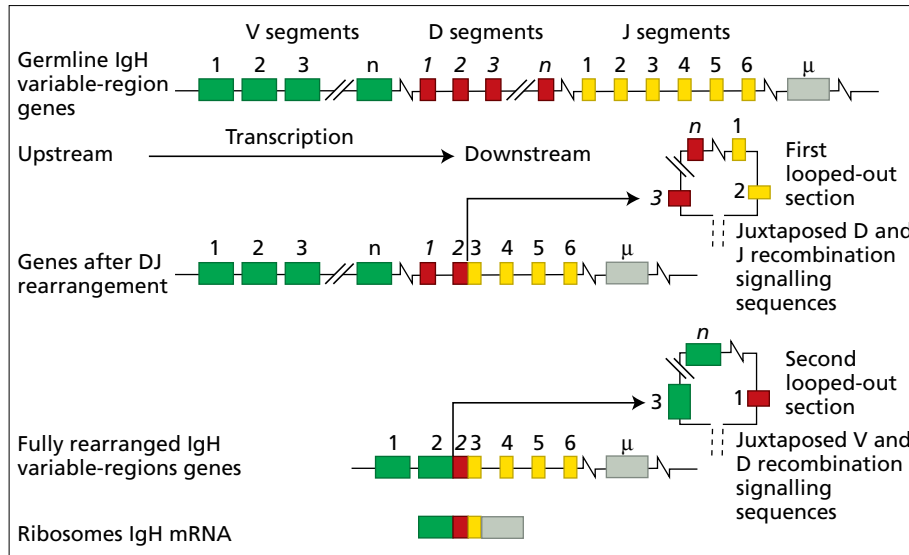
There are six pairs of genes that encode antigen-specific receptors – three for immunoglobulin (κ and λ light chains, and heavy chains) and three for TCRs (β, γ and a combined α and δ locus – see Table 20.1). Each has variable-region and constant-region gene segments and, before comparison of the individual members, the structure of the variable-region gene segments that encode immunoglobulin heavy chain and the way in which these are rearranged during B-cell development will be described to exemplify the common features.


Figure 20.6 Immunoglobulin heavy-chain variable-region genes and their rearrangement. The germline structure of the variable-region gene complex is shown in the top line. The genes are present in this form in haemopoietic stem cells. The approximate number (n) of V_H, D_H and J_H segments are given in Table 20.1. The constant-region genes are downstream of the V region genes. The first of these, μ, encodes the IgM heavy chain constant-region domain. This is followed in sequence by δ, γ3, γ1, a non-functional pseudo-ε gene, α1, γ2, γ4, ε and α2. The boxes represent exons and lines introns. During rearrangement, first one of the J segments becomes aligned with one of the D segments and the intervening sequences are deleted; DJ rearrangement is always attempted on both chromosomes 14. The aligned DJ pair on one chromosome 14 then becomes linked to one of the V segments on that chromosome, and again intervening sequences are deleted. If this V to DJ rearrangement is able to encode a variable region then there is no V to DJ rearrangement on the other chromosome; if it has been unsuccessful (e.g. the rearrangement is out of frame) the cell goes on to attempt to rearrange a V segment to the DJ on the other chromosome. The D to J and V to DJ alignment is made possible by the presence of recombinase signalling sequences that flank (i) the upstream end of each J segment and the downstream end of each D segment and (ii) the upstream end of each D segment and the downstream of each V segment. Additional diversity at the junctions between the rearranged V, D and J segments results in part from imprecise splicing and partially through the insertion of additional non-encoded (N) basepairs at the D to J and V to DJ junctions through the action of terminal deoxynucleotidyl transferase (tdt).

Rearrangement of immunoglobulin heavy chain variable-region genes

The heavy chain gene is located at 14q32.3 and the germline organization of the part of the gene that encodes for the variable region of IgH is shown at the top of Figure 20.6. The variable-region component of the immunoglobulin heavy chain gene is divided into three types of *gene segment*: V segments, D segments and J segments. A large number of individual V gene segments are encoded within the genome. The V gene segments are longer than J or D segments and encode much of the framework of the variable-region domain, together with the first and second hypervariable regions (known as the complementarity-determining regions – CDR1 and CDR2). The CDR1 and CDR2 regions encode two out of the three parts of the variable region that determine the antigenic specificity of the heavy-chain V region.

There are fewer D and J gene segments. The third hypervariable region (CDR3) is encoded at the site of joining of one of the functional D segments with any one of the functional J segments and includes the downstream end of one of the V segments. Heavy-chain rearrangement involves two looping-out manoeuvres (Figure 20.6). In the first of these, one of the J segments becomes spliced to one of the D segments and the intervening sequences are deleted. Next, one of the two rearranged D–J pairs becomes linked to one of the V segments and again the intervening sequences are deleted. The association of segments appears to occur at random and the theoretical number of different variable region genes that might be generated in this way is the product of the number of functional V, D and J segments, i.e. ~8262. In practice, D to J and V to D–J joining is not exact and additional random nucleotides may be added at the point where the gene segments join. This results in very much greater diversity, which is seen only in CDR3 and which includes both the D to J and V to D–J junctions.

The diversity of CDR1 and CDR2 is therefore much less than that of CDR3. Junctional diversity in CDR3 is sufficiently
Figure 20.7 Outline of the main stages of B lymphopoiesis. The central process in B-cell formation is the rearrangement of Ig variable-region genes. For rearrangement of V-region genes to occur in either T or B cells, recombinase-activating genes (RAG) 1 and 2 have to be expressed. Absence of these genes totally blocks further differentiation towards B or T cells. After a successful heavy-chain VDJ has been made, a B cell must express the heavy chain with the surrogate light chain composed of V–pre-B and λ5 if further differentiation is to occur. Cells that fail to make either a productive heavy- or light-chain rearrangement destroy themselves by apoptosis.

great to allow the conclusion that B cells with the same CDR3 sequence are almost certainly derived from the same clone and this fact is used widely to identify the origin and relationship of malignant B cells. Further details about the process of rearrangement are given in the legend to Figure 20.6.

B lymphopoiesis

Sites of B lymphopoiesis

B-cell production starts in the fetal liver at the end of the first trimester of pregnancy and normally ceases at this site later in pregnancy. Subsequently, B cells are also produced in the bone marrow and production in this tissue continues throughout life such that approximately 2% of adult marrow mononuclear cells are B-cell progenitors. Some differences in the nature of

B-cell production occur during ontogeny; these are discussed at the end of this section.

Early signs of commitment of haemopoietic cells towards the B lineage

The events that occur as cells differentiate towards B cells are summarized in Figure 20.7. The associated phenotypic changes are set out in Table 20.2. The earliest signs associated with differentiation of haemopoietic cells towards the B lineage are the expression of CD19, CD24 and MHC class II molecules on the cell surface and CD22 inside the cell. These changes are followed by the expression of molecules such as recombinase-activating genes (RAG) 1 and 2, which are involved in immunoglobulin gene rearrangement. These genes act in both immunoglobulin and TCR gene rearrangement, and their absence totally blocks further differentiation towards B or T cells.

Table 20.2 Phenotypic changes during B-cell lymphopoiesis.

	Surface CD34	Cytoplasmic CD22 with surface CD19 and 24	Nuclear tdt	Surface CD10	Surface CD20	Cytoplasmic μ	Surface IgM
Pro-B cell	+	+	+	−	−	−	−
Early pre-B cell	+	+	+	+	−	−	−
Late pre-B cell	−	+	−	+	+	+	−
Virgin B cell	−	+	−	−	+	+	+

Almost always, heavy-chain rearrangement precedes light-chain gene arrangement. The first rearrangements to occur are in the joining of one of the J segments to one D segment, with the looping out of the intervening sequences (see previous section for details). The rearrangement or attempted rearrangement of D to J is completed on both chromosomes 14 before an attempt is made to rearrange the D–J to a V segment on one of the chromosomes. If this is successful, the rearranged V–D–J sequence will be transcribed together with the genes encoding the μ constant region. After translation of this transcript, the cell has cytoplasmic μ heavy chain and is known as a pre-B cell. During all the preceding stages of B lymphopoiesis cells showing differentiation towards B cells are known as pro-B cells.

When intact μ heavy chain is expressed, an essential further step has to take place if the B cell is to proceed to light-chain rearrangement. The μ chain is expressed on the cell surface at low level with a 'surrogate' light chain that is composed of two peptides, V–pre-B and λ5. If this surface expression does occur, the pre-B cell receives a signal for further differentiation to proceed, exits cell cycle and starts light-chain gene rearrangement. On the other hand, if the first attempt to rearrange V to D–J is not successful and no μ V–pre-B–λ5 complex is expressed at the surface, an attempt is made to rearrange a V segment to D–J on the other chromosome 14. If this also fails and the cell is still unable to express μ V–pre-B–λ5 at its surface, it will die by apoptosis. When the second heavy-chain rearrangement is successful, the cell proceeds, as above, towards light-chain gene rearrangement. The first expression of IgM on a B-cell surface marks the transition from pre-B cell to a newly produced virgin B cell.

Extensive analysis of variable-region genes in pre-B cells of mice has failed to identify cells with two functional VDJ rearrangements. One functional VDJ rearrangement can only be seen with a non-functional VDJ rearrangement or a D–J rearrangement. This *allelic exclusion* of antigen receptor genes means that only one functional antigen-binding protein is expressed on the surface of the cell.

The enzyme terminal deoxytransferase (TdT) is expressed during variable-region gene rearrangement and introduces non-encoded (N) sequences at the junctions of V to D–J and D to J. The enzyme is expressed both in pro-B cells in the marrow and in cortical thymocytes during TCR gene rearrangement. The expression of tdt is much greater in the bone marrow than in the fetal liver and, as a result, junctional diversity is less marked in the first B cells that are produced. These are mainly B1 cells, which are described later. The enzyme tdt is not expressed in late pre-B cells at the time of light-chain gene rearrangement and N sequences are not a feature of light chain V–J junctions. Normally, B cells will express only light chains encoded by one of their four light-chain gene complexes, i.e. they express either a κ-chain or a λ-chain. The ratio of κ-expressing B cells to λ-expressing B cells is closely regulated and in humans is close to 60:40. Major deviation from this ratio has been observed only in B-cell neoplasia, when there is massive expansion of a neoplastic

clone of B cells. Disturbance of the κ/λ B cell ratio to > 10:1 or < 0.1:1 can therefore be taken as a reliable indicator of the presence of a neoplastic clone.

Intact heavy chains can be exported to the surface of a B cell only if they are complexed with light chain or surrogate light chain. This does not apply to free light chains, which are able to pass out of B cells and plasma cells. Physiological light chain production is always greater than that required to complex all the available heavy chain, and measurement of serum free light chain is now a useful tool in the management of paraproteinaemia. The heavy chains that are secreted in heavy chain disease get out of the cell only because they are truncated heavy chains.

There is a high death rate among B cell progenitors. In part, this reflects failure to pass essential landmarks during the process of immunoglobulin gene rearrangement. Sometimes this results from the generation of non-productive variable-region gene rearrangements. In other circumstances light chains may be produced that will not combine with the heavy chains available in a cell as not all light and heavy chains are compatible.

T-cell production and selection in the thymus

Although the earliest progenitors of T cells are produced in the bone marrow, the development and selection of most mature immunologically competent T cells occurs in the thymus. The thymus is an encapsulated gland that is organized into lobules by capsular septa. Within each lobule, there is a complex meshwork of epithelial and other cells that are responsible for regulating the development of prothymocytes into mature T cells. The subcapsular region of the thymus is divided into the more peripheral cortex and the deeper medulla. The lymphocytes of the cortex are more densely packed than those of the medulla, many in the outer cortex are in division and a high proportion of cells throughout the cortex are dying by apoptosis.

It has been estimated that 95% of all thymocytes die within the thymus either as a result of failure to rearrange their TCR genes in an expressible form or as a consequence of elimination during the T-cell selection process. During the development from prothymocytes to mature lymphocytes, T cells pass from the outer cortex, through the inner cortex and on through the medulla before emerging as immunocompetent T cells in the peripheral circulation. T cells whose TCR molecules fail to engage with MHC–peptide complexes within the thymus die by neglect, whereas those whose TCR can interact with these complexes are subject to *positive* and *negative selection (see below)*. The individual regions of the thymus play differential roles during the generation and selection of the T-cell repertoire.

The accessory cells of the outer and inner cortex are different. In the outer cortex, large epithelial cells called 'nurse cells' can be seen and there is massive proliferation of thymocytes in

this part of the cortex, which is followed by TCR rearrangement. The epithelial cells of the deep cortex have branched dendritic processes rich in MHC class II molecules. These cells interconnect through cell junctions (desmosomes) that create a network through which cortical lymphocytes pass on their way to the medulla. There is now strong evidence that these thymic epithelial cells are critical in the positive selection of thymocytes, which have moderate affinity for MHC–peptide complexes. The boundary of the cortex and medulla is populated by macrophages (often called sentinel macrophages) that phagocytose cells undergoing apoptosis.

The medulla contains some epithelial cells and a number of bone marrow-derived IDCs that have broader processes than the cortical epithelial cells and express MHC class I and II antigens. It is here that the process of negative selection is mediated, in which T cells with high affinity for self MHC–peptide complexes are deleted. Structures known as 'Hassall's corpuscles', which are whorled aggregates of epithelial cells, can also be seen in the medulla. The function of these cells is obscure.

T-cell receptor gene rearrangements and phenotypic changes

Bone marrow-derived T-cell progenitors (prothymocytes) seed the subcapsular region of the thymic lobule (Figure 20.8). At this stage of ontogeny the cells have not started to rearrange their TCR genes, do not express the mature T-cell markers CD3, CD4 or CD8, and may not be irreversibly committed to the T-cell lineage. They may be identified by expression of CD7 and CD34. Interaction with the thymic stroma is accompanied by proliferation and expression of CD2, soon followed by cytoplasmic expression of CD3 genes. By this stage, the cell is committed to the T-cell lineage and TCR gene rearrangement is under way.

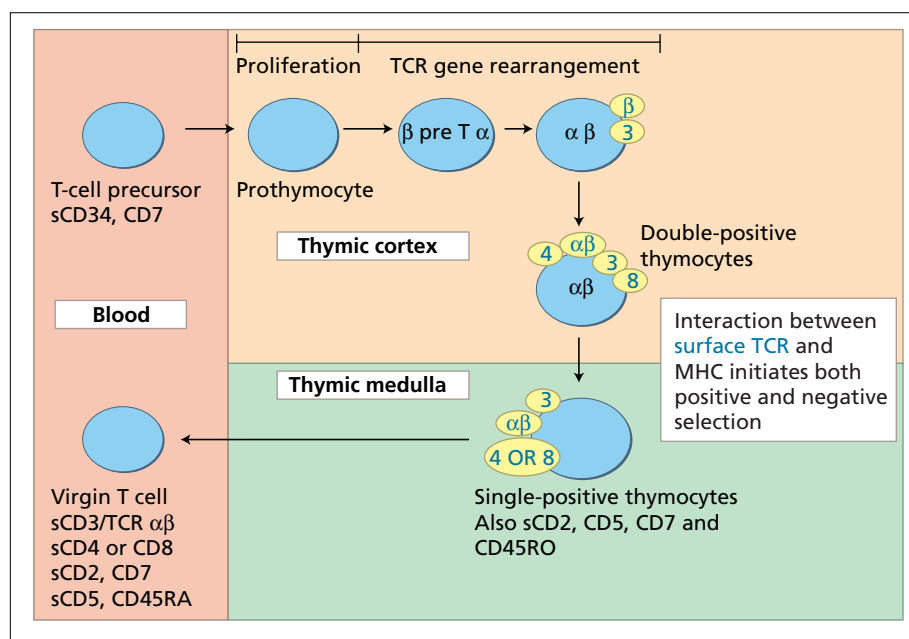
The configuration of the TCR and its genes is discussed in the section on antigen-specific receptors on T and B cells and is summarized in Figure 20.4 and Table 20.1. During early fetal development, the first cells to leave the thymus as mature T cells have successfully rearranged their γ and δ genes and express the γδ form of the TCR. Many γδ T cells do not express CD8 or CD4,


Figure 20.8 T-cell maturation in the thymus. Molecules within cells (red) or on a cell's surface (blue) are depicted without the prefix CD. T-cell progenitors enter the thymus from the marrow or other primary lymphoid site to become a prothymocyte. At this stage their TCR genes are in germline configuration. The proliferative potential and lack of commitment of prothymocytes is reflected in the ability of a single prothymocyte to populate an entire thymic lobe and generate a full T-cell repertoire. Prothymocytes proliferate in the outer cortex. Towards the end of the proliferative phase, TCR rearrangement starts: first β-chain genes are rearranged, then these are expressed with a surrogate α chain – pre-T α–. After this, α-chain genes rearrange. As with B

cells, these rearrangements require *RAG1* and *RAG2* genes to be expressed, and junctional diversity is increased by the addition of N sequences using tdt. Selection occurs at the double-positive stage when the full TCR complex is expressed with CD3 and both CD4 and CD8. These cells are selected on their ability to recognize self peptide presented by a self MHC molecule at low avidity. Those cells recognizing peptide with class I go on to become single-positive CD8 expressors; those recognizing peptide with class II continue to express CD4 without CD8. Cells recognizing self peptide at high avidity and cells failing to recognize a self MHC molecule are deleted.

suggesting they may not be interacting with antigen in association with MHC class I or class II molecules. During fetal development of mice, sequential waves of γδ T cells populate different epithelial surfaces with different and restricted Vγ gene usage. This does not appear to be the case in humans, although considerably less is known about the ontogeny and function of γδ T cells in humans. Some γδ T cells develop in congenitally athymic animals and are probably thymus independent and may have different functions from those of thymus-processed cells. During later stages of human fetal development and throughout the rest of life, 85–98% of T cells that leave the thymus have undergone successful α and β-gene rearrangement and express the αβ TCR.

Rearrangement of the gene encoding the TCR β-chain occurs first with D to J rearrangements followed by V to D–J rearrangements. Successful rearrangement leads to low-level expression of the β-chain at the cell surface in a complex with CD3 and a surrogate α-chain analogous to λ5–V–pre-B in B-cell development. It is at this stage that the cell starts to express low levels of both CD4 and CD8; further β-chain gene rearrangement is halted and α-chain gene rearrangement starts (Figure 20.8). TCR α-chain gene rearrangement may involve sequential rearrangements of V–J pairs, which enables the cell to express different TCR α-chains until a successful TCR αβ heterodimer is generated. Unlike B cells, αβ T cells do not show allelic exclusion of TCR α-chains and approximately 30% of peripheral T cells have two functional TCR α-chain rearrangements. Both may be expressed at the cell surface such that a small proportion of T cells may express two different antigen receptors.

Selection of the TCR αβ T-cell receptor repertoire

CD8 and CD4 thymocytes are selected on the basis of their potential to recognize peptides held in association with either MHC class I or MHC class II molecules respectively. Immature αβ TCR thymocytes are subject to two selection processes – positive selection, which allows cells that have the potential to recognize foreign peptide in association with self-MHC to mature to functional T cells, and negative selection, which removes T cells that recognize self-peptides in association with a self-MHC molecule. As with B cells, exhaustion of this process without successful rearrangement results in cell death by apoptosis. Generation of a rearrangement that is positively selected by interaction with self-MHC is accompanied by cessation of further gene rearrangement, loss of RAG1, RAG2 and tdt expression and cessation of expression of the redundant CD4 or CD8 molecule. Although the selection forces that are imposed on αβ T cells are well defined, it is still unclear whether those γδ T cells that develop in the thymus undergo a similar selection process.

Overt and hidden self peptides

It is now clear that negative selection in the thymus does not cover all the peptides produced from proteins within the body. This applies particularly to intracellular proteins and to extracel-lular proteins in tissues that do not normally allow the egress of macromolecules, such as the anterior chamber of the eye. These proteins may therefore be immunogenic if administered systemically in an appropriate form.

Peripheral B cells

Two lineages of B cells are recognized. The B cells that are produced in haemopoietic tissues in red bone marrow throughout life are termed conventional B cells. The other lineage appears to originate during ontogeny in the fetal liver and this population is known as B1 B cells.

B1 B cells

Studies of B cell ontogeny in mice indicate that B cells produced in fetal liver differ from those subsequently produced in the bone marrow. These B cells produced in the liver persist in adults and are found particularly in the peritoneal cavity. The surface glycoprotein CD5 is associated with many of these cells in mice and the term B1 B cell has been suggested for these cells. Other B cells are termed conventional B cells. A number of features distinguish B1 B cells from conventional B cells:

1 B1 B cells are the predominant B cell type that is produced in fetal life and in humans during the first year after birth, whereas after this they are outnumbered by conventional B cells.
2 Unlike virgin B cells produced in adults, B1 B cells are capable of antigen-independent self-renewal in the periphery. Conventional B cells proliferate in response to antigen but otherwise do not enter the cell cycle.
3 B1 B cells can readily be restored to irradiated mice by transfer of fetal liver or B cells from the peritoneal cavity, but cannot be renewed from stem cells derived from adult bone marrow.
4 The antigen-binding specificity of the antibodies produced by these cells tends to have broad reactivity including autoreactivity. These features seem to result from selection at the B-cell level rather than selective rearrangements to particular V-region gene segments. N sequences at the D to J and V to DJ regions are not usually found. This reflects a lack of tdt expression in fetal liver.

The function of B1 cells and the background IgM antibody they produce is still far from clear. It has been suggested that they may produce play a regulatory role in immune responses and selection of the B cell repertoire and they certainly seem to have been conserved during the evolutionary divergence of rodents and primates.

Conventional B cells

The B cells produced in the marrow after the first year of life fall into this category. Three stages of conventional B cell differentiation can be identified:

Table 20.3 Differences between the three main types of human B cell found in adults.

	B-cell type		
	Marrow IgM⁺, IgD⁻	*Recirculating*	*Marginal zone*
Diameter		~8 μм	~10 μм
Chromatin	Condensed	Condensed	Open
Cytoplasm volume/basophilia	Scanty/little	Scanty/little	Moderate/moderate
Proliferating	No	No	No
Lifespan	About 3 days	4 or more weeks	3 or more weeks
Antigen-independent movement	Migrate from marrow to 2° lymphoid tissue	Migrate between the 2° lymphoid tissues	Remain in the marginal zones
Surface Ig	IgM	IgM and IgD	IgM or IgG or IgA
Memory or virgin	All virgin	Almost all virgin	Variable mixture of virgin and memory
Ig V-region mutations	None	Not present	Present in memory cells
Molecules expressed on the cell surface			
CD19, 20, 37, 40 and class II MHC	+ve	+ve	+ve
CD21, 39	−ve	+ve	+ve
CD5	−ve	some +ve	−ve
CD23	−ve	+ve	−ve
CD25	−ve	−ve	+ve
CD38	−ve	−ve	−ve
Capacity to respond to different classes of antigen			
Bacterial cell wall lipopolysaccharide	+	+	+
Bacterial capsular polysaccharide	−	−	+
Protein-based antigens	+	+	+

IgM⁺, IgD⁻ cells of the marrow are representative of newly produced virgin B cells.

1 newly produced virgin B cells;
2 recirculating B cells;
3 marginal zone B cells.

These three cell types do not represent different cell lineages, as recirculating cells are derived from newly produced virgin B cells and marginal zone cells mature from recirculating cells. Most newly produced virgin B cells die without becoming recirculating cells, and only some recirculating cells mature to become marginal zone cells. The three types of conventional B cell differ in phenotype (Table 20.3), which reflects marked differences in the signals that influence their survival and induce them to proliferate and differentiate. *Recirculation* is a process by which cells migrate continually between the follicles of secondary lymphoid tissues via blood and lymph. Most recirculating B cells are virgin cells, whereas the B cells of the marginal zones do not recirculate and are a mixture of virgin and memory cells. In some lymphoid organs that are regularly exposed to antigen, such as the palatine tonsils and Peyer's patches, most marginal zone cells are memory cells.

Newly produced virgin B cells

These cells are produced in the bone marrow in large numbers throughout life and represent the only way the recirculating pool can be replenished, as recirculating B cells do not proliferate unless they are activated by antigen. Antigen-driven proliferation of recirculating cells can generate memory cells, but most of these become marginal zone memory B cells.

If a newly produced virgin B cell encounters self antigen expressed on a cell surface, it may enter apoptosis within the marrow and in this way some, but by no means all, autoreactive B cells are eliminated. Soluble autoantigens binding to the antigen receptor of a newly produced virgin B cell may be taken up and processed, and the resulting peptides are presented on the cell surface in association with MHC molecules (Figure 20.3). These cells become programmed to seek cognate interaction with primed T cells, but die after 3 days without proliferating or secreting antibody if this interaction is not made. As most autoreactive T cells have been eliminated during thymic education, it follows that B-cell tolerance is heavily dependent on

T-cell tolerance. The consequences of a successful interaction between B cells that have taken up antigen and primed T cells are discussed later.

Recirculating B cells

These cells are small, non-dividing virgin B lymphocytes that are classically surface IgM$^+$ and IgD$^+$. They are in a constant state of migration between the follicles of secondary lymphoid organs. On their way to the follicles, they migrate through the T cell-rich zones that contain antigen-presenting cells and have an average lifespan of 4 or more weeks.

Marginal zone B cells

These cells were first identified as a major B-cell population in the spleen, where most of the cells are IgM$^+$, IgD$^-$. Some of these cells express surface IgG or IgA. Almost all of these cells in the tonsils and Peyer's patches have features of memory B cells as they have undergone immunoglobulin class switching and somatic hypermutation of their immunoglobulin variable-region genes.

Marginal zone cells respond to capsular polysaccharides

Marginal zone cells, like recirculating B cells, respond to T cell-dependent antigens and to bacterial cell wall lipopolysaccharides (thymus-independent type 1, TI-1, antigens). Unlike recirculating B cells, they will also respond to bacterial capsular polysaccharides. Capsular polysaccharides are thymus-independent type 2 (TI-2) antigens. These antigens do not evoke antibody responses until several months after birth, and levels of antibody produced in response to these antigens do not reach adult levels until 5 years of age. Antibodies to the capsular polysaccharides of *Streptococcus pneumoniae*, *Haemophilus influenzae* B and *Neisseria meningitidis* are important in eliminating these pathogens from the body. Infection with these encapsulated bacteria is a particular problem in patients with hypogammaglobulinaemia. They have been estimated to cause some 5 million deaths worldwide per year in infants under 5 years of age, mostly after the first 3–6 months of life, when antibody transferred from the mother has been lost.

It is quite unclear why immune responses against TI-2 antigens should be delayed for so long during ontogeny, whereas TD and TI-1 responses can occur before birth. It cannot simply be that antibodies against these antigens are harmful in early life, for they are present in the perinatal period as the result of maternal Ig transfer across the placenta. (See Figure 20.12 for responses to conjugate vaccines made up of capsular polysaccharide and an immunogenic protein.)

Peripheral T cells

The majority of peripheral T cells express αβ TCR. When these αβ T cells leave the thymus, most express either CD4 or CD8 on their surface and are restricted to the recognition of peptides in the context of MHC class II or class I molecules respectively. A minority of T cells express a γδ TCR.

CD4$^+$ and CD8$^+$ T cells and their functions

CD4$^+$ T cells can have one or more of a variety of functions:
1 the provision of signals, during immune responses, that induce proliferation or differentiation of T or B cells, generally known as *T-cell help*;
2 selection of B cells in germinal centres, which have undergone hypermutation in their Ig V-region genes;
3 activation of macrophages as is seen in delayed hypersensitivity reactions;
4 class II-restricted cytotoxic activity.
  CD8$^+$ T cells include:
1 a large majority of HLA class I-restricted cytotoxic T cells;
2 a relatively small proportion of cells that can provide help; in this case, following activation by peptide presented with class I MHC molecules.

Although αβ T cells are selected to become CD4$^+$ or CD8$^+$ in the thymus, much of the functional diversity of these cells results from signals delivered when they are activated in the periphery. Virgin T cells have to undergo a process known as *priming*, which requires interaction with specialized antigen-presenting cells in the T zone of secondary lymphoid organs.

Cytotoxic T cells

Cytotoxic T cells kill target cells that present peptides they recognize in association with MHC molecules. The recognition and killing stages of T cell-mediated cytolysis require direct cell-to-cell contact, and only targets that are recognized through the TCR are killed. As with helper cells, cytotoxic T-cell precursors require antigen-specific priming before they acquire the ability to migrate into non-lymphoid tissues and kill cells that they recognize through their TCR.

There are two main killing mechanisms; in both of these, the target cell is induced to die by apoptosis without the effector cell being killed. The effector cells can go on to kill further targets. In one of the mechanisms, enzymes known as *granzymes* and pore-forming molecules termed *perforins* are transferred from the T cell to the target cell. Granzymes and perforins are present in granules that stain crimson and are easily seen against the featureless pale cytoplasm of cytotoxic T cells and NK cells in Jenner–Giemsa preparations. These features have given rise to the term large granular lymphocyte. This is misleading, for cytotoxic cells are generally no more than intermediate-sized lymphocytes (~10 μm in diameter). Similar granules are present in NK cells.

The second cytotoxic mechanism involves the expression of the Fas ligand (FasL) by the effector cell. The resulting engagement of Fas on the target cell induces the target to undergo apoptosis. Fas is a member of the TNF receptor family and FasL is an analogue of TNF-α and -β. Secreted TNF-β, sometimes termed lymphotoxin, will also induce some cells to enter

apoptosis but is not targeted to a single cell, and in other situations it acts as a signal to induce differentiation or proliferation.

Expression of CD45R isoforms by T cells

The CD45 family of cell-surface glycoproteins is known collectively as *leucocyte common antigen*. Two of its isoforms, CD45RO and CD45RA, are expressed differentially on T cells. High relative expression of CD45RO appears to relate to whether the cells have been activated recently by antigen.

The lifespan of peripheral T cells

Once the peripheral T-cell pool is established, it can maintain itself without further input from the thymus. Even neonatal thymectomy in humans during cardiac surgery does not cause clinically noticeable immunodeficiency. This indicates that T-cell clones can be very long-lived and this certainly applies to CD45RA^{high} virgin T cells. Unlike the peripheral pool of recirculating B cells, which cannot replenish itself when depleted, small numbers of transferred recirculating T cells will proliferate to fill a depleted peripheral T-cell pool in a process known as *homeostatic proliferation*. Some experiments suggest that memory T-cell clones persist only if there is periodic restimulation by antigen, but other experiments indicate that in some instances this is not required.

Natural killer cells

NK cells are cytotoxic lymphocytes that lack expression of a T-cell receptor and whose primary function is to kill cells that have downregulated expression of MHC class I molecules. NK cells express a range of inhibitory and activating receptors and it is the balance of signals received through these molecules that determines whether or not the target cell will be killed.

The inhibitory signals include: (i) killer inhibitory receptors (KIRs) that bind to HLA-C or HLA-B alleles on the surface of the target cell and (ii) CD94–NKG2 heterodimers that bind to HLA-E. Activating receptors include: (i) activating forms of KIR molecules, whose ligands are uncertain at present; (ii) NKG2D, which binds to proteins such as MICA and ULBP expressed on cells under physiological stress; and (iii) the immunoglobulin receptor (FcR) CD16.

HLA class I expression is often downregulated on the surface of cells following viral infection and is also a common feature of malignant cells. This provides some protection from recognition by CD8$^+$ T cells but renders the cell susceptible to lysis by NK cells (Figure 20.9). Thus, CD8$^+$ T cells and NK cells can be viewed as having complementary recognition systems based on the level of HLA class I on the target cell. The ability of NK cells to recognize ligands such as MIC-A, which are expressed on the surface of damaged or stressed cells, demonstrates that NK cells may also have the ability to target cells at site of inflammation, irrespective of HLA class I expression level.
Figure 20.9 Mechanism by which NK cells kill target cells that fail to express HLA class I. NK cells express two classes of receptors which either activate (b) or inhibit (a) NK cell killing. The activatory receptors can bind to a range of ligands on the target cell whose expression is often constitutive. In contrast, the major forms of inhibitory receptor bind to HLA class I molecules. If HLA class I expression is downregulated on the target cell, no inhibitory signal is delivered to the NK cells and the target cell is killed.

The lytic mechanisms of NK cells seem to be the same as those used by cytotoxic T cells. NK cells proliferate in the presence of IL-2 and their activity can be augmented by exposure to interferon-γ. They characteristically express a range of receptors such as CD56 (NCAM) and CD57 but these are also expressed on a subset of T cells.

NKT cells

Natural killer T cells represent a small (< 1%) population of peripheral blood T cells and appear to be positioned somewhere

between conventional T cells and NK cells in that they express a TCR but also a range of receptors typically associated with NK cells. Moreover, the TCR is invariant, with the same Vβ11Vα24 heterodimer being expressed on all cells. NKT cells recognize lipid antigens presented on the surface of CD1d molecules, CD1d being a protein with homology to MHC class I. It appears that NKT cells are activated very early in an immune response although their functional significance is uncertain.

Immune responses

The previous sections have indicated that antigen-driven T- and B-cell activation leading to antibody production or the generation of effector T cells requires a complex series of interactions between cells. In most primary immune responses this will occur only within secondary lymphoid tissue. The lymph nodes, mucosal lymphoid tissues and spleen contain the bulk of secondary lymphoid tissue. The outward appearance of the various secondary lymphoid tissues is markedly different, but their fine structure has many common features. In this section, the way in which immune responses occur in the different compartments of lymphoid tissues are considered.

There are two main sites of T-cell activation and T cell-dependent B-cell activation. These are the T zones and follicles. The general structure of a lymph node (Figure 20.10) is given first to provide a context for the detailed description that follows of the sites where immune responses occur and the molecular basis of T- and B-cell activation.

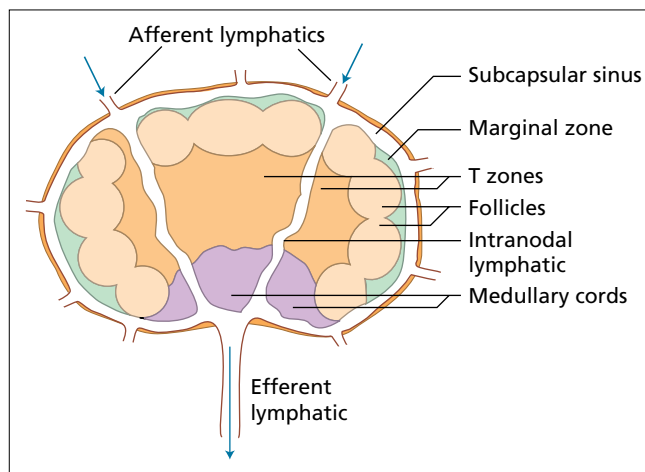
Lymph nodes have an afferent lymphatic supply that is fed by lymph draining the extravascular tissue spaces. This lymph


Figure 20.10 The main compartments of a lymph node. Note that the size of the marginal zone is variable; although it is often obvious in mesenteric lymph nodes, it may not be obvious in small nodes such as the popliteal nodes, particularly if these have not been sites of recent immune responses.

provides the main source of antigen for the node. Langerhans cells activated by local disturbance take up and process antigen, and then pass through afferent lymph into lymph nodes (Figure 20.11). The afferent lymph passes into the subcapsular sinus, which forms a lake of lymph that covers the cortical surface of the node. From the subcapsular sinus, lymph passes through intranodal lymph sinuses that surround and separate the cone-like segments that make up the solid tissue of the node. The intranodal lymphatics, as they pass the follicles and T zone, are difficult to see as they are crossed by fibrous cords. Attached to these and the walls of the tissue cones are macrophages and other poorly defined cells. Increased numbers of these cells in the intranodal lymph sinuses and similar cells in the subcapsular sinus are described by histopathologists as *sinus histiocytosis*. The intranodal lymph sinuses passing the medullary cords contain fewer fixed cells and are easier to identify. In the medulla, the intranodal lymph sinuses feed into the efferent lymphatic vessel that returns the lymph to the venous blood supply; in the case of the gut and lower half of the body, via the thoracic duct to the left subclavian vein.

The solid tissue of the node is made up of variable numbers of roughly cone-like segments (Figure 20.10). The base of each cone abuts onto the subcapsular lymph sinus in the cortex of the node and the apex is in the medulla. These cones fit together, but are separated by the intranodal lymphatic sinuses, to form the roughly kidney-shaped structure of lymph nodes. The cones have three main zones: the follicles in the cortex, the T zones and the medullary cords. The medullary cords form a convoluted apex to the cone. The contents and functions of each of these zones are described in detail in subsequent sections. The blood supply to the node enters and leaves the node through the medulla, and the specialized high endothelial venules through which recirculating B and T cells and newly produced virgin B cells enter the node are located in the T zones.

T zones – the primary sites of T- and B-cell recruitment into antibody responses

These zones are packed with migrating cells:
1 Interdigitating dendritic cells (IDCs) (Figure 20.11), permeate all parts of this zone. On their surface are processed peptides held in the antigen-presenting grooves of MHC molecules. IDCs enter the T zones of lymph nodes from the intranodal lymphatics. Those in mucosal lymphoid tissues probably come directly from local epithelia. IDCs in the spleen enter via the blood and include cells that have migrated from internal organs.
2 Virgin B and T cells and some memory cells enter the T zone by passing across specialized small blood vessels. In most T zones, these take the form of *high endothelial venules* that express a series of molecules that have ligands carried by recirculating and newly produced virgin B cells. Interaction between these pairs of molecules causes the lymphocytes to adhere to and
Figure 20.11 T-cell priming and T-cell-dependent B-cell activation in a lymph node. Local disturbance induces dendritic cells in the tissues to take up material from their surroundings. Ingested proteins are processed to peptides inside the cell (Figure 20.3). Dendritic cells that have taken up antigen migrate through afferent lymphatics to draining lymph nodes or through the blood to the spleen. By the time they reach a T zone, they have differentiated into interdigitating cells, which are specialized at presenting antigenic peptides, held in MHC molecules, to recirculating T cells. Virgin T cells migrating through the T zones move over the surface of the interdigitating cells and are activated if they meet antigen they recognize. As the result of this priming process, they move to the outer T zone and become targets for B cells that have taken up

and processed antigen. The primed as opposed to virgin T cells are able to deliver co-stimulatory signals via CD40 and B7.1 and B7.2 to B cells that specifically engage their TCR. B cells activated in this way migrate to extrafollicular foci of B-cell proliferation – the medullary cords in lymph nodes – where they generate short-lived plasma cells. Other B cells migrate to follicles where they may form germinal centres. T cells, after a brief period of proliferation in the T zone, either leave the node as effector cells/recirculating memory T cells or migrate to follicles, where they proliferate further and participate in the selection of B cells that have mutated the Ig variable-region genes in germinal centres (Figure 20.14). The consequences of this cognate T cell–B cell interaction are described in more detail in the text.

cross the venules into the T zones. Migration of these cells to the T zone in the spleen occurs after adhesion to the marginal zone blood sinusoids.

3 Primed T cells locate towards the edges of the T zones. These cells are very efficient at interacting with B cells that have taken

up and processed antigens. About one-half of the primed T cells have preformed CD40 ligand in granules in their cytoplasm. The presence of this preformed B-cell coactivation molecule is not characteristically found in recirculating memory T cells.

4 All B-cell types, including marginal zone memory B cells,

migrate to the outer T zones if they have taken up and processed antigen. Unlike recirculating B cells, they stay in the outer T zone until they make cognate interaction with a T cell, but those failing to make this encounter die within 3 days.

Responses to protein-based antigens in T zones

The series of stages leading to T-cell-dependent B-cell activation in the T zones is shown in Figure 20.11. T lymphocytes entering the T zone 'inspect' peptides held in MHC molecules of local IDCs and this interaction involves intimate contact between the two cells. If a T cell is able to recognize a peptide–MHC complex, it is activated through TCR signalling. Costimulation is provided by interaction between molecules such as CD80 and CD86 expressed on the IDCs and CD28, which is constitutively expressed by T cells. The effect of this interaction is to bring about changes in the T cell that are collectively called *T-cell priming*. These include the ability to express CD40 ligand and CTLA-4, a high-affinity ligand for CD80 and CD86. B cells cannot prime virgin T cells but are able to interact with primed T cells in the T zone (Figure 20.12).

Cytokines are produced by the T cell following this interaction and the nature of the cytokines produced in different situations is considered later. Short-term proliferation of the T and B cells is also induced, and most B cells migrate to local sites of antibody production. In the spleen this is the red pulp, and in lymph nodes the medullary cords. The lifespan of most of these plasma cells is 3 days. The extent of immunoglobulin class switching will depend on the conditions of dendritic cell activation and T-cell priming. In *primary* antibody responses, the plasma cells generated by B-cell activation in T zones do not have somatic mutations in their Ig V-region genes. On the other hand, in *secondary* responses, marginal-zone memory B cells that have somatic mutations in their V region genes can be induced to migrate to T zones on contact with antigen and give rise to short-lived plasma cells.

The other pathway of migration of T and B cells activated in T zones is to the follicles. Both antigen-specific B blasts and T blasts migrate to the follicles at an early stage in T-zone responses and give rise to *germinal centres*. This process is described in the section on follicular responses.

Responses to conjugate vaccines

Polysaccharides on bacterial cells are often poorly immunogenic but represent an important target for immune protection. One approach to overcoming this problem is to attach the polysaccharide to a carrier protein that elicits a strong T-cell immune response. The Hib conjugate vaccine provides an example of a large carbohydrate molecule that cannot elicit the help of thymus-processed T cells by itself. When conjugated to diphtheria toxoid, an aggregated glycoprotein, T-cell help can be obtained.
Figure 20.12 Surface molecules involved in T-dependent B-cell activation in T zones. B cells take up antigen that they bind specifically through their surface Ig. This is internalized, broken down to peptides and the peptides are presented on the B cell surface, held in the peptide-binding grooves of MHC class II molecules (Figure 20.3). Cross-linking of surface Ig by antigen induces the endocytosis of the antigen–antibody complex and signals upregulation of CD40 expression and *de novo* B7.1 and B7.2 expression. If this B cell interacts with a primed T cell that recognizes the peptide complex with class II MHC molecules, there will be costimulation through the molecule CD28, which is constitutively expressed by CD4 T cells, and this can result in further signalling through co-stimulatory molecules that are transiently expressed on the T cell surface; CD40 ligand exemplifies these transiently expressed signalling molecules. These interactions can lead to B- and T-cell proliferation and differentiation and may also induce cytokine secretion by the cells. Cytokine receptor expression by the B cell and the T cell is initiated or upregulated. The arrows indicate that TCR engagement induces CD40 ligand expression and that engagement of these molecules by their counterstructures on the B cell delivers further signals to the T cell. CD40 ligation induces Ig class switching in the B cell and migration as indicated in Figure 20.11.

After administration, the polysaccharide is bound by B cells with surface immunoglobulin that can recognize it and the conjugate molecule is internalized. The protein is broken down into peptides in the antigen-processing endosome and diphtheria toxin-derived peptides are presented on the cell surface. This

Figure 20.13 Processing of a conjugate vaccine between diphtheria toxoid (magenta) and the polyribosyl ribose phosphate of the capsule of *Haemophilus influenzae* B (green). A B cell with specificity for the capsular polysaccharide binds the conjugate vaccine with its surface Ig (black). The complex is endocytosed and the protein components are broken down to peptides (Figure 20.3). Peptides derived from the diphtheria toxoid are subsequently presented on the B-cell surface in association with class II MHC (blue and pink).
enables a Hib-specific B cell to obtain T-cell help from a diphtheria toxoid-specific T cell (Figure 20.13).

The follicles of secondary lymphoid tissues and germinal centres

These B-cell-rich areas are permeated by a dense network of follicular dendritic cells (FDCs). In follicles where no antigen-dependent activation is taking place, small recirculating B cells fill the spaces in the FDC network. In the first 3 weeks of T-dependent antibody responses, there is massive clonal expansion of B cells in follicles. This is associated with germinal centre formation. In the later stages of responses to protein antigens, small numbers of memory B blasts continue to proliferate in follicles for months or even a few years.

FDCs have the capacity to take up antigen in the form of antigen–antibody complexes and retain it for periods of many months. FDCs hold the antigen on their surface in a non-degraded form. In this respect they are completely different from Langerhans cells, IDCs and B cells, which process and present protein-based antigens to T cells. It seems likely that the antigen retained by these cells provides the drive for maintaining B-cell activation and indirectly T-cell activation during the months of the established phase of T-cell-dependent antibody responses.

Germinal centres – sites of antigen-driven clonal expansion of B cells that undergo mutation in their Ig V-region gene

Germinal centres are present in the first 3 weeks after immunization with protein-based antigens. Figure 20.11 indicates that some of the B blasts generated after cognate interaction with primed T cells migrate to follicles. Some of the antigen-specific T cells also migrate to the follicles. On arrival in the follicles, there is massive clonal expansion of the B cells such that the spaces in

the FDC network become filled with blasts. At this stage, changes occur in which the classical germinal centre structures of dark and light zones develop. The dark zone is formed by the blasts moving to the edge of the FDC network next to the T zone. These blasts, now termed centroblasts, activate the somatic hypermutation mechanism that acts on their rearranged immunoglobulin V-region genes. Centroblasts, like their precursors, have a cell cycle time of 7 h, but their numbers remain relatively constant. The hypermutation mechanism is specifically directed against the immunoglobulin V-region genes but is random in other respects.

The result is that the affinity of surface immunoglobulin for the original antigen may be either decreased or increased. Centroblasts continually give rise to centrocytes, non-dividing cells that migrate into the FDC network that forms the light zone of the germinal centre. Centrocytes either leave the light zone within 12 h or die *in situ*. They can leave the light zone only if they receive antigen-specific selection signals. The probable sequence of events occurring in fully developed germinal centres is shown in Figure 20.14.

Centrocytes pick up antigen from FDC. Their ability to do this will be determined by the affinity of their surface immunoglobulin for the antigen. In addition, they require signals from local T cells so they must process the antigen they have taken from FDCs and present the resulting peptides with class II MHC molecules to T cells. The T cells in the germinal centre are concentrated in the outer part of the light zone. They are antigen specific in that they were driven to enter the follicle after specific interaction with peptide on B cells in the T zone. This requirement for the B cells to receive T-cell help in the germinal centre protects against potential autoimmune responses, as those B cells that have developed reactivity against autoantigens are unlikely to receive selection signals from germinal centre T cells.

Centrocytes that survive selection within germinal centres leave the light zone as either plasmablasts or memory B cells. The plasmablasts migrate to distant sites of antibody production.
Figure 20.14 Selection of cells that have undergone Ig V-region gene hypermutation in germinal centres. The hypermutation mechanism is active in centroblasts, which are the rapidly dividing cells of the dark zone that give rise to centrocytes. Centrocytes die by apoptosis unless they (i) pick up and process antigen held on FDC and (ii) find a T cell in the germinal centre that recognizes the peptides from this antigen presented on centrocytes in association with self-class II. The T cell-dependent selection mechanism makes it unlikely that centrocytes with mutated Ig V-region genes that encode self-reactive antibody will be selected. Most B cells that are selected leave the germinal centre (i) to migrate to distant sites of antibody production, the gut or bone marrow, where they differentiate to become plasma cells and (ii) to differentiate into memory B cells. Some selected cells remain within the germinal centre and return to the dark zone as centroblasts.

Plasmablasts from follicles in the spleen or peripheral lymph nodes migrate to the bone marrow. Those activated in the gut or respiratory tract or the lymph nodes that drain these tissues migrate to the corresponding mucosal surfaces. In the bone marrow or the lamina propria of the gut, the plasmablasts differentiate into plasma cells. Unlike the plasma cells generated in T zones, most of these plasma cells have a lifespan of about 1 month.

Immunoglobulin class switching

Most, but not all, of the plasma cells and memory cells generated in follicles have undergone *switch recombination*. This is a pro-

cess by which the rearranged V-region genes become linked to heavy chain genes downstream from IgD. This process is similar to immunoglobulin variable gene rearrangement, with the DNA forming loops between complementary switch region genes that lie upstream of each set of heavy chain gene exons. The order of the heavy chain constant-region genes that encode the different heavy chain isotypes is located downstream from the variable-region genes: μ, δ, γ3, γ1, a non-functional pseudo-ε gene, α1, γ2, γ4, ε and α2. Thus, switching to γ2 involves looping out μ, δ, γ3, γ1, pseudo-ε and α1.

IgM and IgD are co-expressed on recirculating B cells. In this case, IgD is expressed without deletion of the μ-chain genes; this is achieved by differential splicing at the RNA level. The extent to which expression of other Ig isotypes can occur without μ and δ deletion is not clear, although this has been shown to occur in some neoplastic B-cell clones.

Class switching is triggered during interactions between T and B cells in the T zone of secondary lymphoid organs. It also occurs to a lesser extent during cognate interactions between centrocytes and T cells. The importance of interactions between CD40 and CD40 ligand to signalling class switching became apparent when X-linked hyper-IgM syndrome was mapped to mutation of the gene encoding CD40-ligand. Children affected by this mutation make antibody responses to protein antigens, but the antibody produced is all IgM and no germinal centres are formed. Interestingly, they do produce IgG in response to T-cell-independent antigens. Considerable evidence *in vitro* and some *in vivo* shows that cytokines can induce class switching. The best-characterized of these effects is the ability of IL-4 to induce switch recombination, first to γ1 and then ε. This will be discussed further in the section on T-helper subsets and cytokines.

Functional maturation of T cells during immune responses

T-cell priming

CD4 and CD8 cells can be primed in the T zones and undergo IL-2-dependent proliferation. This increases the number of antigen-specific T cells and alters the phenotype of the T cell. The level of adhesion molecules changes, as LFA-1 (CD11a, CD18 heterodimer), VLA molecules (heterodimers of CD29 and CD49) CD44 and CD2 are among those that may be upregulated. At the same time there is downregulation of some receptors such as CD62L (L-selectin), which is required for the entry of recirculating B and T cells from the blood to secondary lymphoid organs. The important effect of these changes is the expression of surface molecules that allow primed T cells to enter non-lymphoid tissues, particularly those that drain lymph into the lymphoid organs where their precursors were primed.

Figure 20.15 Maturation pathways of CD4$^+$ T helper cells. CD4$^+$ T cells that have been activated by antigen acquire the capacity to produce cytokines. The cytokines that they produce depends on the environment in which they are activated. Two main types of cytokine-producing T$_H$ cell are recognized – T$_H$1 and T$_H$2 cells. The cytokines produced by T$_H$1 cells tend to promote further T$_H$1 cell formation and inhibit T$_H$2 cell formation, and IL-4 produced by T$_H$2 cells promotes further differentiation towards T$_H$2 cells. T$_H$1-promoting cytokines are also produced by activated macrophages, dendritic cells and NK cells, whereas mast cells produce IL-4.

Differentiation of primed T cells into effector cells

Most CD8$^+$ T cells differentiate into cytotoxic effector cells. Differentiation of primed CD4$^+$ cells is directed into one of two pathways (Figure 20.15). T$_H$1 cells produce cytokines that are associated with macrophage activation, granuloma formation and delayed hypersensitivity. These cytokines are principally IL-2, interferon-γ and TNF-β. In contrast, T$_H$2 cells produce cytokines associated with antibody production, particularly IL-4, IL-10 and, in some instances, IL-6, although the last of these is mainly produced by macrophages and osteoclasts. This bifurcation in the differentiation pathway for CD4$^+$ T cells is preceded by an uncommitted stage (T$_H$0).

The nature of antigen, its route of entry to the body, the cells that process and present the resulting peptides, and the genetic polymorphism of MHC molecules are some of the factors that may influence the way that CD4$^+$ T cells differentiate. CD4$^+$ T cells stimulated in the presence of IL-12, which is produced by macrophages, and dendritic cells are more likely to differentiate into T$_H$1 cells. Interferon-γ secreted by NK cells or T$_H$1 cells themselves has a similar effect, which is in part attributable to inhibition of differentiation towards T$_H$2 cells. In contrast, IL-4 produced either by NKT cells or T$_H$2 cells promotes production of T$_H$2 cells and inhibits T$_H$1 cell formation.

A feature of antigen-experienced T cells is that effector function can be evoked without co-stimulatory signals from a specialized antigen-presenting cell, such as those delivered via CD28 and CD40 ligand. This reflects an increased surface expression of the adhesion molecules LFA-1 and CD2 and a change in the isoform of CD45 from a high-molecular-weight form (CD45RA) to a low-molecular-weight form (CD45RO), which increases the efficiency of signal transduction through the TCR. Most T-effector cells have a short lifespan – probably 95% die by apoptosis within a few days without having encountered specific peptide on a target cell. Others survive to become memory T cells. Table 20.4 lists the main cytokines that have been reported to be produced by lymphocytes, together with actions attributed to these cytokines.

Inflammatory (T$_H$1) CD4 T cells

Macrophages work in concert with T$_H$1 cells to provide a major mechanism by which mycobacteria and other pathogens are destroyed. Inflammatory CD4$^+$ T cells enhance this activity through

Table 20.4 The cytokine and cytokine receptor families.

Cytokine family	Members of family	Type of receptor
β-Trefoil	IL-1α, IL-1β	Ig family
Haematopoietins	IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-13, IL-15, GM-CSF	Class I cytokine receptor
	IL-10, interferons	Class II cytokine receptor
Tumour necrosis factor	TNF-α, TNF-β	Nerve growth factor receptor family
Cysteine knot	NGF	Nerve growth factor receptor family
	TGF-β	Serine threonine kinase
Chemokines	IL-8, MIP-1α, MIP-β, I-309, MCP1, MCP2, MCP3, γIP-10	Rhodopsin family

the action of cytokines following recognition of peptides presented by MHC class II molecules on macrophages.

Unlike cytotoxic T cells, effector functions activated in macrophages require hours or days to be accomplished.

Some T_H1 T cells have cytolytic potential and can kill infected macrophages by granzyme and perforin release or expression of Fas ligand. Recently, it has been shown that they can also kill by ADP release – this cytotoxic pathway has been found recently to result in the death of mycobacteria ingested by macrophages.

The balance between T_H1 and T_H2 cells

It is probably an unreasonable oversimplification to conclude that selective activation of inflammatory CD4 T cells (T_H1) leads to cell-mediated immunity, whereas selective activation of helper CD4 T cells (T_H2) leads to humoral immunity. In practice, there is unlikely to be a simple split between these two extremes, and intermediate effector cells probably exist. Tuberculoid leprosy exemplifies apparent dominance of a T_H1 response, and atopic disease seems to reflect an imbalance towards T_H2. Whether these extremes are due to the way the T cells were induced to differentiate or to a defect in the responsiveness of the T cells, or a combination of both of these, has to be determined. Nevertheless, manipulation of these cytokine networks provides a potential means of modifying established immune responses to avoid the complications associated with overactivity of either T_H1 or T_H2 cells.

Regulatory CD4$^+$ T cells

Immunological tolerance is mediated by a number of mechanisms, including deletion of self-reactive B and T cells in the bone marrow and thymus respectively. In addition, it is now clear that a specialized population of T lymphocytes can actively suppress immune responses. These cells have been termed 'regulatory T cells' (Treg) and have a phenotype of CD4$^+$ CD25$^+$. Naturally occurring regulatory CD4$^+$ T cells express high levels of CD25, the IL-2 receptor α-chain, and have been shown to suppress CD4 and CD8 T cells' responses to a range of stimuli, both *in vitro* and *in vivo*. In mice, CD4$^+$ CD25$^+$ regulatory T cells (Treg) are involved in maintenance of peripheral T-cell tolerance to self antigens and protection against autoimmunity. Human Treg appear to enrich within CD4$^+$ CD25^{high} T cells and constitute approximately 1–5% of peripheral blood CD4 lymphocytes. *In vitro*, Tregs are cytokine independent and require cell contact to mediate suppressive action. However, Tregs are able to induce other conventional CD4$^+$ CD25$^-$ T cells to develop cytokine-dependent regulatory function, termed 'infectious tolerance', and this observation may in part explain the complex discrepancy between *in vitro* and *in vivo* observations regarding the role for cytokines in Treg function. The role of Treg in a range of human diseases is being explored at present.

Cytokines and their classification

Cytokines are soluble proteins produced by leucocytes and other cells that influence the behaviour of cells that carry cytokine receptors. Many are secreted, but others, such as TNF-α, are cell membrane proteins that are active when bound to the cell that produced them but also have activity as a soluble protein. The potency of cytokines *in vivo* has been exemplified clearly by the dramatic effects of recombinant granulocyte colony-stimulating factor (G-CSF) in inducing accelerated recovery of neutrophil counts after the administration of myelotoxic therapy and the effect of interferon-α in the management of haematological malignancies. It seems likely that many cytokines act only at very short range and some appear to be more potent as membrane-bound forms than as released proteins.

Analysis of the genes that encode cytokines and their receptors show that many of these are related. This is dramatically exemplified in the case of the common γ-chain that forms part of many of the class I cytokine receptors for the haematopoietin family of cytokines, including the receptors for IL-2, IL-4, IL-7, IL-9 and IL-15. Deficiency of this polypeptide is one of the causes of severe combined immunodeficiency (SCID). The families of cytokines are summarized in Table 20.4, and a fuller description of the known cytokines that act on cells of the immune system is given in Table 20.5.

Chemokines and their classification

Chemokines are a class of cytokines with chemoattractant properties and are all related in sequence. There are two groups, the CC chemokines, which have two adjacent cysteine residues in their sequence, and CXC chemokines, in which these two cysteine residues are separated by another amino acid. Chemokine receptors are integral membrane proteins linked to G-proteins and have seven membrane-spanning domains. They are classified according to the type of chemokine that they bind, i.e. CCR1–9 and CXCR1–5. Cells that express chemokine receptors are attracted towards an increasing concentration of chemokine molecules, and these interactions are critical to many functions of the innate and adaptive immune response (Table 20.5). Some chemokines are expressed in a constitutive fashion, whereas others are released in response to inflammation.

Interpretation of blood lymphocyte counts

Blood provides the most accessible view of the lymphoid system but it must be remembered that peripheral blood contains only around 2% of total body lymphocytes. The cells that are in the blood are in transit and many are recirculating T and B lymphocytes that will pass rapidly into secondary lymphoid organs in less than 30 min. Some memory T cells also recirculate, and

Table 20.5a The major chemokines within the CXC subgroup.

Chemokine	Production	Receptors	Cells that are attracted	Effects
Il-8	Monocytes Macrophages Fibroblasts	CXCR1 CXCR2	Neutrophils T cells	Inflammation Angiogenesis
β-TG	Platelets	CXCR2	Neutrophils	Inflammation
GROα,β,γ	Monocytes Endothelium	CXCR2	Neutrophils T cells Fibroblasts	Inflammation Angiogenesis
IP-10	Endothelium Monocytes T cell Fibroblasts	CXCR3	T cells NK cells Monocytes	Promotes T_H1 immunity Immunostimulation
SDF-1	Stromal cells	CXCR4	Stem cells Lymphocytes	Stem cell homing Haemopoiesis

Table 20.5b The major chemokines within the CC subgroup.

Chemokine	Production	Receptors	Cells that are attracted	Effects
MIP-1α	Monocytes T cells Fibroblasts	CCR1, 3, 5	Monocytes NK and T cells Dendritic cells	T_H1 immunity
MIP-1β	Monocytes Macrophages Neutrophils Endothelium	CCR1, 3, 5	Monocytes NK and T cells Dendritic cells	T_H immunity
MCP-1	Monocytes Macrophages Fibroblasts Keratinocytes	CCR2B	Monocytes NK and T cells Dendritic cells	T_H2 immunity
RANTES	T cells Endothelium Platelets	CCR1, 3, 5	Monocytes NK and T cells Dendritic cells	Inflammation T-cell activation
Eotaxin	Endothelium Monocytes Epithelium	CCR3	Eosinophils Monocytes T cells	Allergy

some memory B cells circulate in the blood without entering secondary lymphoid tissues unless activated by antigen. Effector T cells pass through the blood on their way to the tissues, and plasmablasts migrate via the blood to mucosae and bone marrow.

The numbers of different lymphocyte subsets that are normally found in the blood in different age groups is given in Table 20.6. These numbers are derived from studies in which whole blood was labelled by fluorescent dye/monoclonal antibody conjugates, followed by red cell lysis and flow cytometry. When this method is used to measure the proportion of lym-

phocytes that belong to different subsets, much of the interlaboratory variation in calculating absolute numbers of subsets can be attributed to the method of measuring the total WCC and the percentage of lymphocytes.

A wide range of results is to be expected between different individuals. The most consistent variation is seen in childhood, but from adolescence onwards age-related changes are small. Differences between the sexes are small and, excluding physiological lymphopenia, there is little difference between ethnic groups.

Table 20.5c The main cytokines that have been described as having activity on cells of the immune system.

Cytokine	Molecular family, M_r (kDa)	Cytokine produced by	Family and size of receptors	Receptors expressed by	Immunological actions
IL-1α	β-Trefoil (M_r 17.5 kDa)	Macrophage, epithelia	Ig superfamily; type I (CD121a, M_r 80 kDa) type I (CD121b, M_r 60–68 kDa)	Very broad, including T, B, and NK	Activates T, macrophage, is pyrogenic
IL-1β	β-Trefoil (M_r 17.3 kDa)	Macrophage, epithelia	As IL-1α	As IL-1α	Activates T, macrophage, is pyrogenic
IL-2 (TCGF)	Haematopoietin (M_r 15–20 kDa)	T_H0 and T_H1	CKR class I; α (CD25, M_r 55 kDa) +β (CD122, M_r 70–75 kDa) + $γ_c$ (M_r 64 kDa)	Activated T, some B, NK, macrophage	Induces T growth and differentiation; also induces growth and differentiation of some B
IL-3 (multi-CSF)	Haematopoietin (M_r 14–30 kDa)	T, thymic epithelium	CKR class I; α (CD123, M_r 70 kDa) + $β_c$ (KH97, M_r 120 kDa)	Haemopoietic, B, macrophage	Apart from effect on haemopoiesis, induces growth and differentiation of some B
IL-4	Haematopoietin (M_r 15–19 kDa)	T_H2, mast, marrow stroma	CKR class I; α (CD124, M_r 140 kDa) + $γ_c$	Activated B and some T, others	B growth, switch to IgG4 and IgE
IL-5	Haematopoietin (M_r 45 kDa)	T, mast, eosinophil	CKR class I; α (CD125, M_r 60 kDa) + $β_c$	Eosinophil and basophil	Eosinophil growth and differentiation; growth and differentiation of mouse but not human B
IL-6	Haematopoietin (M_r 26 kDa)	T, macrophage, some B, osteoclast, others	CKR class I; CD126 (gp80) + CD130 (gp130)	Activated B, plasma, T, macrophage, others	Inflammatory, cytokine induces acute phase reaction, plasmacytoma growth factor, influences T and B activity
IL-7	Haematopoietin (M_r 20–25 kDa)	Bone marrow and thymic stroma	CKR class I; CD127 (M_r 68 kDa) + $γ_c$	T and B progenitors, mature T	Pre-B and thymocyte growth, some action on mature T
IL-8	Chemokine, (M_r 7 kDa)	Lymphocyte, macrophage, granulocyte, endothelia, others	Rhodopsin family; CDw128 (M_r 40 kDa)	Neutrophil, basophil, some lymphocyte	Chemoattractant neutrophil basophil, inflammatory and angiogenic
IL-9	Haematopoietin (M_r 35 kDa)	T_H2	CKR class I; IL-9R (M_r 64 kDa) may associate with $γ_c$	T_H, macrophage	Growth T, erythroblast, mast and megakaryoblastic leukaemia lines
IL-10	Haematopoietin (M_r 35–40 kDa)	T_H0, T_H2, mφ	CKR class II; (M_r 90–110 kDa)	B, T	Suppresses macrophage activation by T_H1 and NK, with TGF-β induces B switch to IgA
IL-11	Haematopoietin? (M_r 23 kDa)	Fibroblasts	Unassigned; IL-11R (M_r 151 kDa)	Plasmacytoma, haemopoietic	Plasmacytoma, megakaryocyte and macrophage precursor growth factor

Cytokine	Structure	Cell source	Receptor	Target cells	Actions
IL-12	Unassigned (M_r 35 + 40 kDa)	B, macrophage	CKR class I? IL-12R (M_r 180 kDa)	T, NK	Differentiation T_H0 to T_H1, promotes NK cytotoxic activity, induces IFN-γ secretion
IL-13	Haematopoietin (M_r 132 kDa)	T	CKR class I; (IL-13R may share components with IL-4R)	?	Growth and differentiation of B, like IL-4, suppresses production of IL-1-β, IL-6, TNF-α by activated macrophage
IL-14	Unassigned (M_r 60 kDa)	T, some B	Unassigned; IL-14R	B	B growth factor, inhibits Ig synthesis
IL-15	Probably haematopoietin (M_r 14 kDa)	Epithelial, macrophage	CKR class I; includes IL-2R-β and $γ_c$ but not CD25	?	Actions like IL-2
GM-CSF	Haematopoietin (M_r 22 kDa)	T cells, macrophage	CKR class I; α (CDW116) + $β_c$	GM series, Langerhans, others	GM precursor growth and differentiation, some plasmablasts
IFNγ	Haematopoietin (M_r 40–70 kDa)	T, NK	CKR class II; CDw119	Leucocyte, others	Macrophage and NK activation, expression MHC class I raised
IFNα	Haematopoietin, many isoforms (M_r 16–21 kDa)	Leucocytes	CKR class II; complex includes CD118	Most cells	Growth, differentiation of some B, expression MHC class I raised
NGF	Cysteine knot (M_r 26 kDa)	Nervous system, prostate	NGFR; (M_r 70–75 kDa)	Neurones, B, macrophage	Apart from role in nervous system, growth and differentiation B
TNFα	TNF family (M_r 52 kDa)	Activated mφ, NK, T, B, fibroblast	NGF family; type I CD120a, gp55; type II CD120b, gp75	Type I most cells, not resting T or red, type II haemopoietic	Induces apoptosis of some transformed cells synergizing with IFN-γ, inflammation, lymphocyte growth synergy with IL-6
TNFβ (lymphotoxin)	TNF family (soluble M_r 25 kDa)	Activated T and B	NGF family; as TNF-αRs		Induces apoptosis of some cells, inflammation, fibroblast growth factor
TGF-β	Cysteine knot, M_r 25 kDa × 2, there are three isoforms	Platelet, T, macrophage, others	Serine/threonine kinase; type I and II high and type III low affinity (M_r 53, 65 and 250–350 kDa) act in concert	Most	Inhibits cell growth, involved in wound repair and bone remodelling

This list is not comprehensive and some of the information about the function of these molecules is based upon studies *in vitro* that will not necessarily be found to be relevant to activity *in vivo*.

$β_c$ and $γ_c$, common receptors shared by more than one of the class I cytokine receptor family; CKR, cytokine; receptor family; CSF, colony-stimulating factor; 'growth', used to mean proliferation of cells; GM, granulocyte macrophage, IFN, interferon; Ig, immunoglobulin; IL, interleukin; kDa, kilodaltons; M_r, molecular ratio; NGF, nerve growth factor; R, receptor; TCGF, thymus cell growth factor; TGF, transforming growth factor; T_H, helper T cell; TNF, tumour necrosis factor. The word cell has been omitted, e.g. T for T cell.

Table 20.6 Normal ranges for lymphocyte subsets in the blood.

	Cell types	0–2 months		2–3 months		4–8 months		1–2 years		2–5 years		5–12 years		Adults	
Percentile		5	95	5	95	5	95	5	95	5	95	5	95	5	95
Total lymphocytes		3.2	8.5	2.9	8.8	3.6	8.8	2.2	8.3	2.4	5.8	1.8	5.8	1.0	3.4
CD3$^+$	All αβ and γδ T cells			2.1	6.5	2.3	6.5	1.5	5.4	1.6	4.2	0.9	2.6	0.60	2.5
CD4$^+$	Class II MHC-restricted αβ T cells	1.2	5.3	1.4	5.6	1.4	5.7	1.0	3.6	0.9	2.9	0.5	1.4	0.35	1.5
CD8$^+$	Class I MHC-restricted αβ T cells some γδ T cells and NK cells			0.7	2.5	0.7	2.5	0.6	2.2	0.6	1.9	0.4	1.2	0.23	1.1
CD4/CD8 ratio		1.1	4.5	1.1	4.4	1.1	4.2	1.0	3.0	0.9	2.7			0.66	3.5
CD3$^-$CD57$^+$ or CD56$^+$	NK cells					0.3	0.7			0.2	0.6			0.20	0.70
CD19$^+$ or sκ$^+$ or sλ$^+$	Total B cells					0.5	1.5			0.5	1.3			0.04	0.70

There is considerable variation in the normal ranges reported from different studies and this table is only intended to be illustrative.

Alteration of lymphocyte counts can result from the redistribution of lymphocytes, an absolute increase of lymphocyte numbers or a loss of lymphocytes. Redistribution of lymphocytes accounts for much of the marked differences in lymphocyte subset numbers found in serial measurements within a healthy individual. Some of these changes in lymphocyte numbers follow a diurnal pattern with peak levels at night and nadir in the morning; accordingly, time of sampling should be taken into account.

Increased numbers of effector cells in the blood usually reflects an active immune response. Analysis of the phenotype of these effector cells provides some information on the type of immune response, especially in differentiating between cytotoxic and inflammatory CD4$^+$ T cells. Particularly in viral infections, this response may be of sufficient magnitude to cause a lymphocytosis. Some non-malignant causes of lymphocytosis are given in Table 20.7.

Redistribution of lymphocytes is probably the cause of the lymphocytosis seen in *Bordetella pertussis* infection. Although lymphocytosis is uncommon in bacterial infections, in children over the age of 6 months the second and third weeks of infection with pertussis are usually associated with a lymphocytosis $> 10 \times 10^9$/L (in some cases $> 50 \times 10^9$/L). The lymphocytosis consists of small lymphocytes and is believed to be due to redistribution – a protein toxin from *B. pertussis* preventing migration across endothelium.

Acute infectious lymphocytosis is a benign disease, usually of children. In most cases there are no symptoms, but in some there is fever and in a small proportion gastrointestinal symptoms. Increase in the size of secondary lymphoid organs, anaemia and thrombocytopenia are rare. There is an increased number of small lymphocytes, persisting for 3–7 weeks, with an average peak level of $30–40 \times 10^9$/L. This is usually associated with an eosinophilia (average of 2×10^9/L), but the aetiology of the condition is unknown.

Table 20.7 Non-malignant causes of lymphocytosis.

Viral infections
Infectious lymphocytosis; infectious mononucleosis; cytomegalovirus infection; occasionally rubella, hepatitis, adenoviruses, varicella, HIV, human herpesvirus 6, mumps, chickenpox, dengue

Bacterial infections
Pertussis; occasionally healing tuberculosis, brucellosis, secondary and congenital syphilis, cat scratch fever, typhoid fever, diphtheria

Protozoal infections
Toxoplasmosis; occasionally malaria

Other conditions
Serum sickness; allergic drug reactions; splenectomy, dermatitis herpetiformis; metastatic melanoma; hyperthyroidism; congenital adrenal hyperplasia

Causes of primary lymphopenia have already been addressed in the section on primary immunodeficiency. Some lymphopenias predominantly reflect redistribution rather than a depletion of total body lymphocyte numbers. A dramatic short term lymphopenia is induced by corticosteroids. This causes the retention of lymphocytes in secondary lymphoid organs but these are released again after about 2 days and the blood lymphocyte counts return to near normal levels. Endogenous secretion of corticosteroids during acute illnesses may in part be responsible for the lymphopenias often seen in conditions such as heart failure or pneumonia. In many other conditions, lymphopenia reflects an increased rate of death of lymphocytes and/or a reduction in their rate of formation. Some of the causes of secondary lymphopenia are listed in Table 20.8. A normal absolute

Table 20.8 Causes of secondary lymphopenia.

Infections
Influenza; occasionally other viral infections, colorado tick fever, miliary tuberculosis, pneumonia, septicaemia, malaria, HIV

Loss of lymphocytes
Intestinal lymphangiectasia, Whipple's disease, severe right-sided heart failure, rarely inflammatory bowel disease, lymphatic fistula

Therapeutic procedures
Radiotherapy, anti-lymphocyte globulin, corticosteroids, cytotoxic drugs, purine analogues

Neoplastic conditions
Metastatic carcinoma, advanced Hodgkin's disease

Nutritional/metabolic
B_{12} or folate deficiency, zinc deficiency, uraemia

Other conditions
Systemic lupus erythematosus and other collagen vascular diseases, myasthenia gravis, aplastic anaemia, graft-versus-host disease, pancreatic necrosis, sarcoidosis, idiopathic

lymphocyte count can belie an underlying deficit of one or more lymphocyte subsets. This is often seen in HIV infection, when a severe deficit of $CD4^+$ T cells may be disguised by expansion of $CD8^+$ T cells.

Infectious mononucleosis

Infectious mononucleosis (IM) is caused by Epstein–Barr virus (EBV), which infects B lymphocytes. EBV enters B cells via CD21, a surface receptor for the C3d component of complement and, after the acute infection has been resolved, a lifelong subclinical infection is maintained, with a low frequency of infected B cells and detectable virus in the saliva – a main vehicle for contagion.

EBV infection of children usually results in immunity without developing typical clinical manifestations of IM. This immunity can be detected serologically and is associated with lifelong protection. Usually only after the age of 10 years is infection by EBV associated with the clinical manifestations of IM. In developing countries, the rate of seroconversion before the age of 10 years can be so high that clinically evident IM is rare. IM has its highest prevalence in young adults. It is uncommon after the age of 30 years and rare after the age of 40 years.

Clinical features of infectious mononucleosis

The symptoms of IM usually develop abruptly, with fatigue, malaise and feverishness after an incubation period of up to 7 weeks. These symptoms last for about 3 weeks. Sore throat occurs in over 80% of cases and is usually accompanied by anorexia and nausea. The sore throat develops in the first week and subsides in the second week, rarely generating severe symptoms or massive tonsillar/pharyngeal oedema. Sharply defined, red spots at the junction of the soft and hard palates are of diagnostic value. Positive throat swabs for β-haemolytic streptococci are frequently found. Bilateral, non-inflammatory cervical lymphadenopathy is almost invariable, and inguinal and axillary lymphadenopathy is usual. The spleen is palpable in more than one-half of cases, although only occasionally does it extend to the iliac crest. These secondary lymphoid organs increase in size in the first week and subside slowly after the second week. Slight hepatomegaly and jaundice occurs in about 10% of cases. Fever is present in most cases but of no characteristic type and may be transient. A few patients develop a fine macular rash, but rashes are more usually found as temporary reactions to penicillin and especially ampicillin.

Blood picture in infectious mononucleosis

In most patients, IM is associated with a leucocytosis; this peaks in the second and third weeks and usually persists for 1–2 months (the first week is occasionally associated with a leucopenia). In two-thirds of patients, the leucocytosis is from 10 to 20×10^9/L but in some cases may substantially exceed these levels. The leucocytosis is attributable to an absolute increase in numbers of both normal small lymphocytes and of activated T cells (atypical lymphocytes). Most of the activated cells are $CD8^+$ T cells but they also include $CD4^+$ T cells and $CD3^-$ NK cells. Most of these activated lymphocytes are cytotoxic for virus-infected cells and target viral peptides presented on MHC class I molecules. Although infection of B cells by EBV stimulates their proliferation, this appears to be controlled by the T-cell response such that the proportion of blood mononuclear cells that is EBV infected rarely exceeds 0.1%.

A peripheral neutrophilia may be seen early in the disease, but a neutropenia is equally common and eosinophilia is not unusual. Thrombocytopenia may occur and is occasionally severe. Anaemia is rare and then usually associated with anti-i antibodies. EBV infection may trigger a haemophagocytic syndrome in rare cases.

Serological changes in infectious mononucleosis

Three categories of antibody are produced as a result of EBV infection: (i) virus specific; (ii) heterophile; and (iii) autoimmune. The first virus-specific antibodies to appear are directed against the EBV capsid antigen (VCA). IgM anti-VCA antibodies probably develop during the incubation period and they peak in the second week of the illness followed by a rapid decline. IgG anti-VCA antibodies peak in the second to third weeks and

persist for life. Most patients also have a transient response to EB early antigen (EA), which peaks in weeks 2–3. Antibodies to Epstein–Barr virus nuclear antigen (EBNA) do not develop until some weeks into the illness but are present lifelong in all patients by 6 months. Serological diagnosis of acute IM is most accurately made by the presence of IgM anti-VCA and anti-EA antibodies and the absence of anti-EBNA antibodies.

Paul and Bunnell demonstrated that patients with IM have serum agglutinins directed against sheep erythrocytes (heterophile antibodies) and that a serum titre in excess of 1:112 is highly suggestive of IM. Similar agglutinins are found in low titre in healthy individuals (directed against Forssman antigen) and in some leukaemias and lymphomas as well as serum sickness. However, in these conditions the heterophile antibody can be absorbed out on guinea pig red cells. Formalin-treated horse erythrocytes appear to be agglutinated exclusively by heterophile antibodies of IM, and this forms the basis of the *monospot test*. Heterophile antibodies provide the routine serological test for IM but are commonly negative, particularly in children and in patients over the age of 25 years. EBV-specific serodiagnostic tests should be applied in cases with a strong clinical suspicion but negative heterophile antibodies. Total serum immunoglobulin levels increase around 4 weeks following onset of symptoms, and raised levels may persist for many months. The greatest proportional increase is in IgM, but IgG may also be raised. The specificity of most of these Igs is unknown but a variety of autoantibodies may be found, including: cold-reactive anti-i antibodies; Donath–Landsteiner cold haemolysins; and, occasionally, antibodies against smooth muscle, thyroid, stomach, rheumatoid factors and antinuclear antibodies (ANAs).

Differential diagnosis and treatment of infectious mononucleosis

The diagnosis and course of IM are usually uncomplicated. Signs of significant respiratory, cardiovascular, intestinal, urinary or joint disease make consideration of other diseases mandatory; some of these other diseases are listed in Table 20.7. Perhaps the commonest problem is when the patient is heterophile antibody negative. In this situation, other viral infections, particularly cytomegalovirus (CMV), should be considered, with assay for CMV-specific IgM. Primary EBV infection is rare in older patients and there may not be conspicuous lymphadenopathy. Occasionally, the blood picture may raise the suspicion of a leukaemia, in which case immunophenotyping of the blood mononuclear cells may be appropriate. Persistent lymphadenopathy beyond a few weeks suggests the need for diagnostic biopsy, particularly if heterophile antibodies are negative, but also the possibility of a false-positive Monospot test should be considered. Virus-specific serology may be helpful in both these situations.

There is no specific therapy for IM. In patients with severe fever or lymphadenopathy, corticosteroids produce prompt lysis of fever and reduction of lymph node hyperplasia. Steroids may be indicated in management of associated haemolytic anaemia, thrombocytopenia, progressive neurological complications and incipient airway obstruction. Patients should be advised of the small risk of splenic rupture from minor abdominal trauma and contact sports should be avoided for several months.

X-linked lymphoproliferative syndrome (XLP; Duncan's syndrome) is a rare inherited X-linked condition in which there is a specific immunodeficiency against EBV. These individuals may die as a result of primary infection or the subsequent development of an EBV-driven B-cell lymphoma. Patients receiving immunosuppressive therapy for allografts and who are carriers of EBV can develop proliferations of B lymphocytes that carry the EBV genome. These cases of *post-transplant lymphoproliferative disease* are heterogeneous, and B-cell proliferations vary from a polyclonal diffuse B-cell hyperplasia to monoclonal B-cell lymphomas. There is evidence for a causal role by EBV in the development of Burkitt's lymphoma, in association with both HIV infection and in the form endemic in African children. In less than 20% of sporadic cases of Burkitt's lymphoma, EBV-associated DNA can be demonstrated in the lymphoma cells.

The spleen

S Mitchell Lewis

The spleen has important diverse roles in homeostasis. Its normal functions are affected in a number of primary blood diseases as well as in other clinical disorders when its dysfunction may, in turn, give rise to haematological abnormalities. These haematological effects may be a minor phenomenon but in some cases they may come to dominate the clinical presentation. In such patients, especially those with a primary blood disorder, an assessment of spleen function is important in diagnosis, staging and clinical management. This is often useful for elucidating an abnormal blood picture.

Evolution of the spleen

The spleen is derived from a mesenchymal stem cell, which appears in the yolk sac of the embryo within 2 weeks of conception. The mesenchymal cell differentiates into reticulum cells, pluripotent stem cells and colony-forming units. Together with the liver, the spleen has a transient role in haemopoiesis from the third month, continuing until birth. From about 20 weeks, the bone marrow becomes a site of haemopoiesis, and this increases rapidly in the marrow during the last trimester of pregnancy, in both amount and extent of differentiation, while haemopoietic activity in the spleen disappears (Figure 21.1). There is no evidence of a specific inhibitor and the spleen remains a potential site for haemopoiesis, as the appropriate microenvironment is present, especially for the maintenance of erythropoiesis. The mechanisms for extramedullary haemopoiesis after birth are described below.

Structure and function

The normal spleen weighs about 150–250 g, but there is considerable variation between normal individuals and at various times in the same individual. At puberty, it weighs about 200–300 g, and after the age of 65 years its weight decreases to 100–150 g or less. In the adult, its length is 8–13 cm, its width is 4.5–7.0 cm, the surface area is 45–80 cm^2 and its volume less than 275 cm^3. A spleen greater than 14 cm long is usually palpable (see later). It enlarges in a wide range of diseases, up to a massive 2 kg or more in weight in some blood disorders.

The spleen has a complicated structure and several different functions. Essentially, it consists of a connective tissue framework, vascular channels, lymphatic tissue, lymph drainage channels and cellular components of the haemopoietic and reticulo-endothelial systems. There is white pulp, red pulp and an intermediate marginal zone, which lies at the periphery of the white pulp, blending into the red pulp.

The red pulp: splenic blood flow

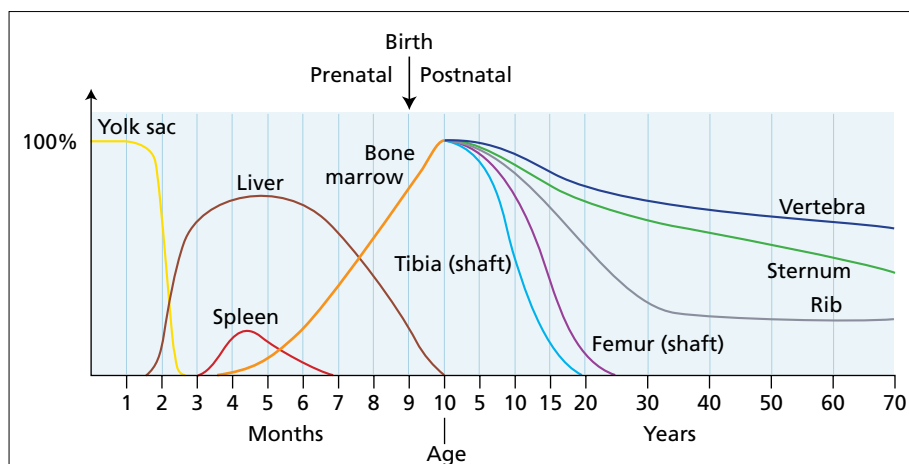
The circulation within the spleen is illustrated in Figure 21.2. Blood is brought to the spleen via the splenic artery, and then, through its branches (the trabecular arteries), into the central arteries, which are sited in the white pulp. These central arteries run in the central axis of periarteriolar lymphatic sheaths; they give off many arterioles and capillaries, some of which terminate in the white pulp whilst others go on to enter the red pulp. In the red pulp there are sinuses, 20–40 μm in diameter, and connecting cords (Bilroth cords). The sinuses are lined by endothelial and adventitial cells with a basement membrane. The cords consist


Figure 21.1 Site of erythropoietic tissue in fetus and throughout life.
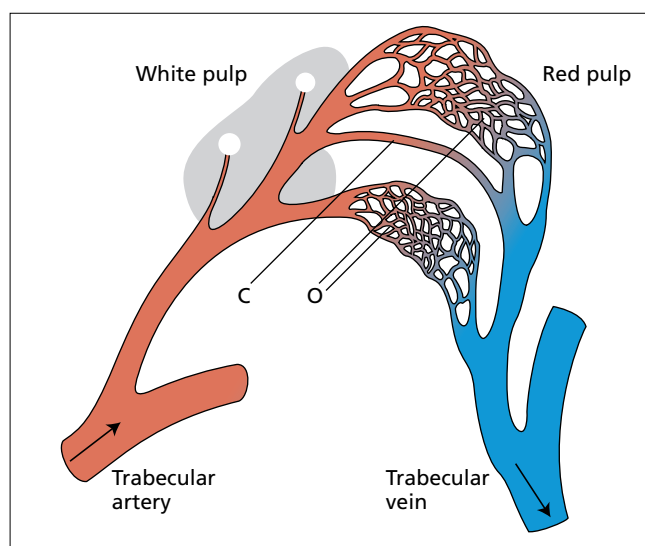

Figure 21.2 The circulation of the spleen. O, open system; C, closed system (see text).

of a fibroblast-like reticular meshwork containing numerous macrophages and erythrocytes. The cords and sinuses communicate by narrow inter-endothelial spaces in the sinus wall (open system).

A few arteries enter the sinuses directly and connect via the collecting vein to the trabecular vein (closed system).

There is thus both a rapid and a slow transit component in the splenic circulation. The rapid transit is of the order of 1–2 min; the slow mixing, which occurs notably when there is splenomegaly (see later), has a circulation time of 30–60 min or even longer. In normal subjects, the blood flows through the spleen as rapidly as through other organs, at a rate of about 5% of the blood volume per minute, so that each day the blood has repeated passages through the spleen. During the flow, by a process of plasma skimming, the plasma and the leucocytes pass preferentially to the white pulp, while the red cells remain in the axial stream of the central artery. The passage of cells into the sinuses is controlled by their ability to squeeze through the interendothelial spaces, assisted by contraction of the reticular cells.

The red cells are normally flexible, whereas cells with abnormal membranes, or with inclusions that render them relatively inflexible, remain in the cords where they either become conditioned for later transit or are destroyed.

Phagocytosis and sequestration

Three mechanisms are involved in the action of the spleen: sequestration, phagocytosis and pooling. Sequestration is a reversible process whereby cells are temporarily trapped by adhesion to the reticular meshwork of the cords on their passage through the spleen. Phagocytosis is the irreversible uptake by macrophages of particulate matter, non-viable cells and viable cells which have been damaged by prolonged sequestration or by antibody coating. Pooling is the presence of an increased amount of blood in the spleen in continous exchange with the circulation.

The red cells are subject to a further hazard: as the blood passes through the spleen, the plasma flows freely, whereas the red cells which are trapped in the reticular meshwork have reduced velocity. This leads to a rise in the intrasplenic haematocrit with increased viscosity, resulting in slower flow.

In the presence of metabolically active macrophages, the densely packed red cells are deprived of oxygen and glucose. This stress increases membrane rigidity and reduces the natural deformability of the biconcave cell. This occurs especially as a result of excessive reaction to stress (e.g. because of an underlying abnormality of the red cell metabolic system, or because the cells are already spherical or antibody coated, or are fragmented or misshapen in other ways); they remain trapped in the cord space and there undergo phagocytosis.

359

Siderotic granules, Howell–Jolly (DNA) bodies, nuclear remnants and Heinz bodies are removed (culling or pitting) during temporary sequestration; after removal of the inclusions, the red cells return to the circulation. Sequestration of reticulocytes has been shown to occur in both humans and in experimental animals. In humans, reticulocytes may be retained in the splenic cords for a considerable proportion of their 2–3 days' maturation time, while they lose their intracellular inclusions, alter the lipid composition of their surface and become smaller in size. It is not clear whether the spleen has any special role at the other end of the life of the red cell in the normal process of elimination of senescent cells; it seems more likely that such cells are removed by the general reticuloendothelial system, including the spleen to some extent, and especially in the marrow.

Blood pooling

The normal red cell content of the spleen is 30–70 mL, or less than about 5% of the total red cell mass. When the spleen is enlarged, expansion of the vascular bed occurs. This results in a considerable pool with a high haematocrit and only a slow exchange of red cells with the general circulation. In myelofibrosis, hairy cell leukaemia and prolymphocytic leukaemia, as much as 40% of the red cell mass may be pooled in the spleen. This pooling will functionally exclude a relatively large volume of red cells from the main arteriovenous circulation, and thus be an important cause of anaemia. In such cases, it should be noted that the red cell mass, as measured by a radionuclide labelling technique, may give a misleadingly normal result, whereas the peripheral blood packed cell volume will give a more reliable measurement of the effectively circulating red cell mass. In splenomegaly due to cellular infiltration, the pool is less prominent. Conversely, in the congestive splenomegaly of portal hypertension, spleen size with an increased red cell pool is a dominant feature.

The normal spleen contains a reservoir of granulocytes, which is in dynamic equilibrium with the circulating granulocytes. It is 30–50% of the body's total marginating pool, with a mean transit time through the spleen of about 10 min. Splenic sequestration of granulocytes is thought to be responsible for the neutropenia that often occurs in patients with splenomegaly. Platelets have also been shown to have a significant reservoir in the spleen, and are rapidly interchangeable with the circulation. In normal subjects, 20–40% of the total platelet mass is pooled in the spleen and the platelets spend up to one-third of their lifespan there. The pool increases when the spleen is enlarged. This pooling and temporary sequestration must be distinguished from destruction of platelets in the spleen, which occurs in many cases of thrombocytopenia.

Plasma volume is controlled by a neurohumoral mechanism which affects distribution of water between intravascular and extracellular fluid compartments across the capillary wall. Under physiological conditions, the red cell volume is fairly constant, while the plasma volume undergoes continual transient vari-

ations that trigger off the necessary adjustments which ensure that the total blood volume remains constant. There is no evidence that the normal spleen is involved in this mechanism, but when the spleen is enlarged it does play a role; splenomegaly is frequently associated with an increased plasma volume, which may lead to a dilutional pseudo-anaemia. Possible mechanisms that have been suggested to explain expanded plasma volume in splenomegaly include the following:

1 The enlarged organ, acting as a large arteriovenous fistula, requires an expansion of blood volume to fill the additional intravascular space; in conditions where marrow erythropoietic activity is reduced, as in myelofibrosis, it may not be possible to maintain the normal red cell: plasma ratio and the additional volume is provided by plasma alone.

2 As splenomegaly increases, flow-induced portal hypertension may cause activation of the neurohumoral mechanism, augmented renal sympathetic nerve activity and secondary renal sodium retention with consequent fluid imbalance.

3 Protein alterations, especially increased globulin levels with reduced albumin, result in an alteration in colloid cellular osmotic pressure. This has been suggested as a factor in tropical splenomegaly and in cirrhosis.

In blood dyscrasias, the increase in plasma volume is directly proportional to the size of the spleen, less so in cirrhosis.

The white pulp: immunological function

The spleen is the largest single accumulation of lymphoid tissue in the body. It contains 25% of the T-lymphocyte pool and 10–15% of the B-lymphocyte pool. T cells are found predominantly in periarteriolar lymphatic sheaths, and B cells in germinal centres in the white pulp. These cells do not appear to arise in the spleen but to have migrated there from other sites of origin, such as the bone marrow and thymus. There is a constant flow of both T and B cells through the spleen; T cells are the more mobile cells and stay in the spleen for a few hours, while B cells settle in the follicles, where they release immunoglobulins. T-cell interaction with the corresponding B cells takes place mainly when they are juxtaposed in the periarteriolar sheath.

During the primary immune response $CD8^+$ T cells act in association with macrophages to stimulate removal by phagocytosis of blood-borne bacteria as well as antigenic material such as damaged erythrocytes. Secondary stimulation with the antigen enhances antibody production, usually IgG. The antibody-coated cells come into contact with macrophages which have Fc receptors that enable immune-complex binding to occur.

The circulating immune complexes are then dealt with in two phases. Larger aggregates are removed by macrophage phagocytosis in the red pulp and marginal zone, while smaller aggregates are transported by B cells to the germinal centres. B cells produce immunoglobulins with antigen specificity and there is stimulation of immune response to soluble antigens as well as to particulate material. These are important mechanisms for protection against

bacterial sepsis, especially from *Streptococcus pneumoniae*, *H. influenzae* type b and *Neisseria meningiditis*. The spleen also appears to acts as a defence against viral infections and intra-erythrocyte parasitic infections such as Plasmodium and Babesia.

The coated red cells lose pieces of their membrane, becoming more spherical and less flexible each time they traverse the endothelial pores and thus are trapped. Apart from the type of antibody, several other factors also influence the role of the spleen in immune red cell destruction (e.g. the number of macrophages present and the rate of splenic blood flow). Increased haemolysis results in an increased number of phagocytes accumulating in the splenic cords, with consequent increasing lysis in a spiralling system. Conversely, however, phagocytic action may be reduced, at least temporarily, as the damaged red cell load blockades the reticuloendothelial cells.

Coagulation factors

The spleen has a role in haemostasis and thrombosis. Experimental studies demonstrated increased factor VIII activity in haemophilic dogs after spleen transplantation, and reports of the successful treatment of haemophilia by splenic transplantation adds weight to the view that the spleen is an important organ for production and storage of factor VIII.

The spleen has not been identified as a site of production of other coagulation factors except, possibly, the lupus anticoagulant. It does, however, have a significant role in bleeding disorders, as its platelet pool is a source of platelet reserve so that patients with moderate thrombocytopenia are at risk of bleeding in the absence of normal splenic function. In immune thrombocytopenias, when the spleen is the focal organ of platelet destruction, splenectomy may induce remission but also removes the platelet pool as a reserve to protect the patient in the event of a recurrence of the thrombocytopenia.

Extramedullary haemopoiesis

Total haemopoiesis in the spleen has been described above. The potential for splenic haemopoiesis remains after birth and recurs in two circumstances:
1 compensatory erythroblastic hyperplasia when there is a haematological stress of severe anaemia, as in chronic haemolysis, megaloblastic anaemia and thalassaemia major;
2 in myelofibrosis, and occasionally in patients with secondary carcinomatosis and myeloid leukaemia, when there is myeloid metaplasia.

A number of theories have been postulated. Committed progenitor cells of all series have been demonstrated in the spleen, but it is not clear whether they arise from a pluripotential stem cell which is present in the spleen (as in the marrow), but normally dormant in the spleen, or whether they derive from the bone marrow, having escaped into the blood and become trapped in the splenic red pulp. In haematological stress, this may occur as a mechanical process when the marrow expands beyond its confines as a result of increased cellularity (as in severe anaemia). In myelofibrosis and myeloid metaplasia, the cause may be inadequate cell to cell interaction with the stroma, or injury to the endothelial cells of the bone marrow sinuses.

The activation of cytokines or other factors required for haemopoiesis may take place in the spleen in pathological conditions in which structural changes may produce a microenvironment more amenable to cell growth, or the cells themselves may alter their character as a result of dysplasia and develop a predilection to growth outside the marrow.

Splenomegaly and hypersplenism

Spleen size

An enlarged spleen is a frequent and important clinical sign. It is thus essential to have a reliable picture of the presence and extent of splenomegaly. The dimensions of the normal sized spleen are given on p. 358. In the adult, an enlarged spleen is usually palpable when its length exceeds 14 cm. However, the measurement of spleen size by means of a physical examination of the abdomen is unreliable, as minor enlargement is often undetected by palpation and even a grossly enlarged spleen may be missed in an obese person.

Conversely, a lax phrenic–colic ligament or loss of tone of abdominal wall may give rise to a wandering spleen, which will be palpable, as will one that is pushed downwards by a flattened diaphragm in obstructive airways disease.

Traditional radiographic imaging may also be misleading and difficult to interpret. However, in modern practice, reliable information is obtained by ultrasonic imaging, nuclear magnetic resonance imaging (MRI) and computerized tomography (CT) scan, all of which give an accurate representation of the anatomy of the spleen and its position in relation to adjacent organs (Figure 21.3). The major advantage of CT scanning is the excellent structural detail that it provides, but it gives no insight into splenic function, whereas the advantage of MRI is that it demonstrates comparatively fine detail of structure and is also capable of identifying function-related parameters that are sensitive to pathological changes.

Another method of scanning the spleen is by means of a scintillation camera following injection of radio isotope-labelled red cells after they have been manipulated by a procedure which ensures that they are removed from the circulation by the spleen. The most effective method is by exposing the red cells, which have been labelled with ^{51}Cr, ^{111}In or ^{99m}Tc, to a temperature of 49.5°C for precisely 20 min (Figure 21.3b). As this procedure is laborious and the images obtained are relatively crude, it has been largely overtaken by MRI and CT scanning; however, it has a major advantage in that it provides information on the functional size of the spleen. Functional asplenia or atrophy is
Figure 21.3 Imaging of the spleen by various methods. (a) Scan of spleen after administration of ^{111}In-labelled autologous red cells showing red cell pool in the spleen; the scan also shows blood flow in the heart. (b) Scan of the same patient as in (a) after administration of labelled heat-damaged red cells which have been taken up exclusively by the spleen. (c) Computerized tomography: transverse section showing liver (left) and spleen (right). (d) MRI: Coronal (longitudinal) section showing liver, spleen and kidneys. (e) Ultrasound scan of enlarged spleen.

well demonstrated by this procedure. It is also useful in diagnosing space-occupying lesions such as splenic cysts and tumour deposits, in determining whether an upper abdominal mass is of splenic origin, and in identifying abnormally positioned and accessory splenic tissue.

From the radionuclide image, the area (A) of the spleen can be obtained from the linear measurements. Several formulae have been proposed for estimating the volume of the spleen from these measurements. The following appears to be fairly reliable:

$$[\text{Spleen volume (mL)} = 9.9A - 540]$$

A method has been developed which combines tomographic imaging and conventional radionuclide scanning by means of single photon emission tomography (PET scan); this has potential value for detecting deep-seated functional lesions. It also provides an accurate three-dimensional measurement of spleen volume.

Causes of splenomegaly

Enlargement of the spleen may occur as a result of various pathological factors:
1 reactive increase of white pulp in inflammation and infection;
2 congestive expansion of the red pulp compartment;
3 increased blood pool;
4 increased macrophage function;
5 proliferative cellular infiltration;
6 extramedullary haemopoiesis;
7 storage disease;
8 cysts;
9 solid tumours.

Splenomegaly is thus a frequent and important clinical sign. The diseases in which it occurs are listed in Table 21.1.

The relative incidence of the cause of splenomegaly is subject to geographical variation. In Western countries, the leukaemias, malignant lymphomas, myeloproliferative disorders, haemolytic anaemias and portal hypertension account for most cases. Infective endocarditis is also relatively frequent. In tropical countries, however, the incidence of these haematological causes of splenomegaly is swamped by the great preponderance of splenic enlargement caused by the parasitic tropical infections: malaria, leishmaniasis and schistosomiasis. Malaria demonstrates how several pathogenetic mechanisms may be involved in splenomegaly. There are reactive lymphoid changes and the red pulp sinuses dilate with expanded microcyte phagocytic activity; this latter function removes intercellular parasites, leaving the red cells intact but with loss of membrane, thus causing the cells to sphere. These spherical cells are then sequestered by the mechanism described earlier, and the spleen increases further in size. Portal hypertension is an important cause of splenomegaly in most tropical countries but it is especially prevalent in north-eastern India and southern China. The 'tropical splenomegaly syndrome' is seen in large numbers of patients in New Guinea and Central Africa. Splenomegaly is also associated with haemoglobin C disease in West Africa, with haemoglobin E disease in the Far East and with thalassaemia syndromes, which have a wide distribution throughout the tropics. Because of the multiplicity of factors responsible for splenomegaly in such countries, more than one pathology may contribute to an increase in splenic size in a particular patient. The prevalence of malaria is thought to explain the anomaly of splenic enlargement in African adults with homozygous sickle cell disease. In haemoglobin S/C and haemoglobin S/β thalassaemia syndromes, the spleen remains enlarged in adults.

The role of the spleen in myeloproliferative disorders is described in Chapters 37 and 46 and in lymphoproliferative disorders in Chapters 38 and 45. In primary proliferative polycythaemia, the increase in spleen size is mainly due to vascularity, with expansion of the red pulp and an increased red cell pool. In myelofibrosis, the red cell pool is remarkably increased and the spleen size is further augmented by myeloid metaplasia and expansion of the reticular elements. In contrast, in chronic myeloid leukaemia and lymphoproliferative disorders the increase in size is attributed mainly to cellular infiltration, while vascularity and red cell pooling have only a minor influence.

Primary splenic tumours are rare; the usual primary tumours are melanoma and carcinoma of breast and lung. Metastatic carcinoma is also a rare event.

Hypersplenism

Hypersplenism is a clinical syndrome; it does not imply a specific causal mechanism. It has the following characteristic features:
1 enlargement of the spleen;
2 reduction in one or more of the cell lines in the peripheral blood;
3 normal or hyperplastic cellularity of the bone marrow, often with orderly maturation of earlier stages but paucity of more mature cells;
4 premature release of cells into peripheral blood, resulting in reticulocytosis and/or large immature platelets;
5 increased splenic red cell pool, decreased red cell survival and increased splenic pooling of platelets with shortening of their lifespan.

The diagnosis of hypersplenism is ultimately confirmed by the response to splenectomy, although an immediate remission may be followed in the longer term by partial relapse.

Most of the diseases listed in Table 21.1 can give rise to secondary hypersplenism. In these conditions, the haematological features of hypersplenism may be obscured or dominated by the primary disease, especially if it involves the marrow. Hypersplenism also occurs as a primary event, due to an unknown pathogenetic stimulus. It is sometimes termed primary splenic hyperplasia, splenic neutropenia or splenic anaemia, and it includes those cases of non-tropical primary splenomegaly in which there is no firm evidence for an underlying lymphoma.

Table 21.1 Causes of splenomegaly.

Haematological
Acute leukaemia
Chronic myeloid leukaemia*
Chronic lymphocytic leukaemia
Malignant lymphomas (some cases present as 'non-tropical primary splenomegaly')*
Chronic (primary) myelofibrosis*
Polycythaemia vera
Thrombocythaemia (some cases)
Hairy cell leukaemia*
Gaucher's disease*, Niemann–Pick disease, Langerhans cell histocytosis X*
Primary splenic hyperplasia
   'Non-tropical splenomegaly'
   Splenic anaemia/neutropenia
Thalassaemia
Sickle-cell disease, HbSC disease and other haemoglobinopathies
Haemolytic anaemias

Minor
Acute anaemia
Megaloblastic anaemia

Systemic
Acute infections: septicaemia, typhoid, infectious mononucleosis, cytomegalovirus
Subacute and chronic infections: tuberculosis, syphilis, brucellosis, subacute bacterial endocarditis, AIDS
Tropical parasitic infections (tropical splenomegaly*): malaria*, leishmaniasis*, schistosomiasis*, trypanosomiasis
Collagen diseases: systemic lupus erythematosus, rheumatoid arthritis (Felty)
Sarcoidosis
Amyloidosis
Cysts
Haemangiomas
Carcinoma (rare)
Congestive splenomegaly
   Portal hypertension
   Cirrhosis
   Splenic/portal/hepatic vein obstruction
   Congestive cardiac failure

*Common causes of splenomegaly.

Splenectomy

Surgical excision of the spleen has been a standard treatment for the diagnosis and management of a number of disorders associated with a hyperactive spleen and also when a normal spleen has an effect on an extrasplenic defect such as: an heredit-

ary spherocytosis, when there are inflexible red cells that cannot readily traverse the red pulp cord; or in autoimmune acquired haemolytic anaemia, where removal of a major site for phagocytosis of antigen–antibody complex or damaged cells allows them to survive better in circulation.

Concern about the risks post splenectomy including sepsis in both children and adults has led to a search for alternative procedures for controlling hypersplenism while preserving some degree of splenic function. These include: (1) partial arterial embolization; (2) partial surgical amputation in selected patients in whom some splenic function may be preserved; (3) localized irradiation; and (4) immunosuppressive and cytotoxic drugs.

Apart from the removal of the spleen because of traumatic rupture or to facilitate surgery on contiguous organs, splenectomy is most commonly performed as a first choice in some hereditary haemolytic anaemias. In autoimmune haemolytic anaemias and thrombocytopenias, splenectomy or possibly splenic irradiation should be considered only after a course of immunosuppressive therapy; the results of spleen function studies (see later) may be helpful in supporting a clinical judgement. The role of splenectomy in myelofibrosis, lymphomas and other haematological conditions is discussed in the relevant chapters. When splenectomy is contemplated for any reason, the preoperative evaluation of the patient requires close cooperation between the surgeon and the haematologist; it is important to check liver function, to carry out ultrasound, CT, MRI or radionuclide scans, and to evaluate the hepatic and portal blood flow by means of Doppler ultrasound examination.

Complications of splenectomy

Immediate postoperative complications
These are bleeding, particularly when there is thrombocytopenia and subphrenic abscess. Haemorrhage usually comes from the peritoneal and diaphragmatic surfaces rather than from identifiable blood vessels. Frequently, no specific bleeding source is found at re-operation.

The incidence of subphrenic abscess is variable, and appears more likely to occur when adjacent organs are injured either by trauma or during surgery. Infection is also liable to occur following embolization.

Delayed complications
These include overwhelming post-splenectomy infection and a tendency to develop thrombocytosis with a risk of thromboembolic incidents.

Thrombocytosis

In the immediate postoperative period in uncomplicated splenectomy patients, the platelet count rises steeply to a maximum of usually $600-1000 \times 10^9$/L, with a peak at 7–12 days. In a number of patients, the thrombocytosis persists indefinitely

after splenectomy. This usually appears to be a consequence of continuing anaemia with a hyperplastic marrow; an inverse relationship exists between the severity of the anaemia and the height of the platelet counts. Although a reactive thrombocytosis is not usually associated with thromboembolic problems, the high platelet counts may have contributed to the serious and sometimes fatal episodes of pulmonary embolism that have occurred following splenectomy. Mesenteric infarction secondary to partial vein occlusion is more common in patients with myeloproliferative disorders who undergo splenectomy. Postoperative prophylaxis with heparin is usually needed. It is advisable to give antiplatelet therapy (e.g. aspirin 75 mg daily) as long as thrombocytosis is present.

Overwhelming postoperative infection

This may occur in adults as well as in children but it is in children, especially in the first few years of life, that splenectomy is more frequently associated with overwhelming bacterial infections. *Streptococcus pneumoniae* (pneumococcus) is the most common cause of infection but while *H. influenzae* type B, *Neisseria meningitidis* (mengococcus), *E. coli* and *Pseudomonas* are much less common, they are also associated with serious infection. Death is usually due to septicaemia or meningitis. The vulnerability of young children and their dependence on the spleen to deal with blood-borne infection can be explained by the general immaturity of their lymphoreticular systems. In the absence of the spleen, the defective reticuloendothelial clearance of an encapsulated rapidly growing organism such as pneumococcus may lead to a dangerous bloodstream concentration in too short a time for immunological defence to be mounted. Splenectomy should therefore be postponed until after the age of 5 if possible.

When splenectomy is being planned, the patient should be immunized against pneumococcal pneumonia, *H. influenzae* type B (HIB) and meningococcal infection. However, while pneumococcal vaccine contains antigens to a number of strains of *Streptococcus pneumoniae* it does not give complete protection because some strains are not covered and antibody response to the different antigens is variable. To obtain the maximum immune response, patients should, if possible, be immunized 2 to 3 months before splenectomy, and a booster dose should be given 5 years later. Most children will have received HIB vaccine but this should be checked; booster doses are not necessary for those who received the full course of three injections. Meningococcal vaccines are effective against types A and C but not against type B, the most prevalent in the West. The patient should also receive meningococcal C conjugate vaccine at a 6-month interval as this gives a higher and more lasting immunization against type C organism. Influenza vaccine is also recommended for asplenic or hyposplenic patients.

Postoperatively, lifelong prophylactic antibiotics should be advocated in all cases, but if this is not possible, antibiotics should be administered at least for the first 2 years after splenectomy, for all children up to 16 and when there is underlying impaired immune function. Oral penicillin 250 mg b.d. is usually recommended and patients who are allergic to penicillin should be offered erythromycin 250 mg b.d. When away from home, patients not allergic to penicillin should take a supply of amoxycillin to be used immediately if infective symptoms (pyrexia, malaise, shivering) develop; and penicillin-sensitive patients should increase their dose of erythromycin or change to a broader spectrum preparation. In all such cases, the patient should seek immediate medical help. When travelling to tropical areas, asplenic patients should be advised of the increased risk of severe Plasmodium infection and they must adhere scrupulously to antimalarial prophylaxis. *Neisseria meningitidis* and *H. influenzae* type B vaccines are also recommended for those travelling abroad. Education of patients or parents is perhaps the most important aspect of management, to ensure that they are alert to the possibility of infection, and know how to react. A card indicating that a splenectomy has been carried out should be carried.

Recurrence of symptoms

Accessory splenic tissue may be overlooked at operation; after splenectomy, it may enlarge and cause a recurrence of the symptoms for which the original operation was carried out. The haematological features of hyposplenism (see below) such as Howell–Jolly bodies and increased pitting, may be absent; CT and radionuclide scanning (Figure 21.4) will demonstrate the presence of a 'splenuncule' and identify its location for subsequent surgical removal should this be required.

Hyposplenism

Hyposplenism (excluding that induced by medical or surgical intervention) occurs in a wide range of conditions.

In some disorders such as sickle cell disease, gluten-induced enteropathy (coeliac syndrome) and dermatitis herpetiformis, hyposplenism occurs frequently; it is seen less frequently in Crohn's disease, ulcerative colitis and essential thrombocythaemia, and it occurs only occasionally in the other conditions listed in Table 21.2. Congenital absence of the spleen is rare and may be associated with organ transposition and with severe malformations of the heart and lungs.

After the age of 65–70 years, there is evidence of a decrease in splenic function. In old age, there is a rapid decrease in the weight of the spleen, together with increasing atherosclerotic vascular obstruction and fibrosis.

Patients with functional hyposplenism have impaired immunity to blood-borne bacterial and protozoal infections, and persistent thrombocytosis. Management is similar to that required post-splenectomy. It includes prophylactic antibiotics and vaccines (see above) and advice to the patients to seek

(a) (b)
Figure 21.4 Demonstration of residual splenunculus by a scan of heat-damaged isotope-labelled red cells: (a) anterior view; (b) posterior view. Uptake is predominantly in the liver.

medical attention immediately in the event of illness or fever. Antiplatelet therapy is advisable when the platelet count is high.

Haematological effects of splenectomy or splenic atrophy

Characteristic blood changes occur following splenectomy. Similar changes are seen with atrophy of the spleen to less than 20% of normal size and when there is functional asplenia, with or without reduction in the size of the organ.

Red cell changes

The changes in red cell morphology include the presence of Howell–Jolly bodies and siderotic granules in some of the cells and target cell vacuoles due to pitting may be seen (see below). In a proportion of subjects, irregularly contracted or crenated, acanthocytic forms are also a feature (Figure 21.5). There is usually an increase in the number of reticulocytes in the circulation and occasionally isolated erythroblasts are seen. There is, however, no alteration in red cell survival.

As a rule, only some of the red cells leaving the marrow will contain siderotic granules and Howell–Jolly bodies. As the number of cells containing siderotic granules is related to the sideroblastic percentage in the bone marrow, the siderocyte count in the peripheral blood will be low in hyposplenism if there is no marrow pathology. In patients suffering from haemolytic anaemias, thalassaemia and sideroblastic anaemia, a major proportion of the circulating red cells may contain siderotic granules. The number of Howell–Jolly bodies is also variable and is most marked in conditions characterized by dyserythropoiesis.
Figure 21.5 Blood film showing features of hyposplenism: Howell–Jolly bodies, target cells and contracted cells.

Other red cell inclusions may be prominent in the hyposplenic state: Heinz bodies are found following oxidative injury by drugs and in patients who have glucose-6-phosphate dehydrogenase deficiency or an unstable haemoglobin; precipitated α-chains are found in β-thalassaemia; and crystalline deposits of haemoglobin C in HbC disease.

Leucocyte changes

After splenectomy, there is a rise in the total leucocyte count. A neutrophil leucocytosis in the immediate postoperative period is, in the majority of subjects, later replaced by a significant and permanent increase in both lymphocytes and monocytes. After a few weeks, the neutrophil count returns to normal or near normal

Table 21.2 Causes of hyposplenism.

Congenital aplasia syndrome

levels. Minor increases in blood eosinophils and basophils have been noted after splenectomy but this is not a regular feature.

In response to infection, splenectomized subjects produce a much greater leucocytosis than persons with intact spleens. Often there is a marked left shift in the differential leucocyte count, with myelocytes and occasionally more primitive cells.

Platelet changes

As indicated above, the thrombocytosis post splenectomy is usually transitory and falls to normal or near normal values over the following 1–2 months. However, even if the platelet count has returned to normal values, occasional large and bizarre platelets can be seen in the blood films of many splenectomized subjects. Their presence suggests that these particular platelets are normally removed by the spleen.

Immunological effects

The spleen plays an important role in immunoglobin synthesis; a fall in the IgM fraction of the serum immunoglobulins is commonly found post splenectomy. IgG levels do not change while IgA and IgE increase. The removal of an organ with a unique ability to recognize and phagocytose circulating particulate antigens would be expected to have serious consequences. Despite these facts, splenectomy in adults without complicating disease is not usually associated with a substantially increased incidence of infection. It must be assumed, therefore, that an increase in activity of other lymphoreticular organs compensates for any defects in the immunological defence mechanisms that result from this operation.

Investigation of splenic function using radionuclides

The investigations described in this section are sometimes of clinical value; more frequently they have been undertaken to provide a better understanding of the pathophysiology of splenic function. Imaging techniques, especially when used in quantitative methods, allow a more extensive assessment of the various splenic mechanisms responsible for the production of anaemia. In hypersplenism, there may be thrombocytopenia and neutropenia as well as anaemia. There have been a number of studies of the role of the spleen using labelled platelets and white cells, as well as *in vivo* studies with red cells.

Apart from visualization of the spleen by ultrasound, MRI, CT scanning or radionuclide scanning, factors that may require elucidation are: the extent of splenic red cell and platelet destruction by the spleen; the degree of red cell pooling; the relative amounts of functioning and non-functioning tissue within the spleen; and the presence of extramedullary erythropoiesis. In cases of splenomegaly, it is possible to distinguish increased reticuloendothelial activity causing cell destruction from increased red cell content due to a large splenic pool, and from enlargement of the organ due to tumour infiltration. However, in practice, all three mechanisms may act at the same time.

Sites of red cell destruction

In vivo surface counting during survival studies with ^{51}Cr-labelled red cells provides a means for determining the sites of red cell destruction. The principle is that the destruction of red cells in an organ is manifested by an increase in radioactive

counts over that organ relative to the count rate over other organs and in the blood. By this means, it is possible to identify the principal site of red cell sequestration and destruction, and to determine the relative activities of the spleen and liver in a haemolytic process. Four patterns of surface counting occur: (1) excess accumulation in the spleen alone; (2) excess accumulation in the liver alone; (3) no excess accumulation in either organ; and (4) excess accumulation in both organs. Some congenital haemolytic anaemias (hereditary spherocytosis and hereditary elliptocytosis) generally fall into group (1); autoimmune haemolytic anaemias into group (1) or (4); hereditary non-spherocytic haemolytic anaemia into group (3); and paroxysmal nocturnal haemoglobinuria and cases of intravascular haemolysis into group (3) or (4). In patients with haemolytic disease, the results taken in conjunction with the clinical details of the patients have some value in deciding whether splenectomy should be undertaken. A good response can be expected mainly in patients who show the first pattern. Although this test is no longer often used, from published reports and personal data, it appears to give a 90% positive prediction that there will be at least a partial response to splenectomy and a 70% prediction of a full response.

Measurement of splenic phagocytic and immunological function

Irreversible trapping of particulate matter is a function of the reticuloendothelial system. Colloid particles 1 μm in size or less will be taken up by the liver, larger particles by the spleen. There is a well-established relationship between splenic reticuloendothelial function and the rate at which heat-damaged red cells are removed from the circulation. The half-clearance time in normal subjects is about 8–16 min. Post splenectomy, the time is increased to 60–120 min or longer and significantly increased times also occur in conditions associated with splenic hypofunction (see Table 21.2).

In these conditions, a slow clearance rate may identify splenic hypofunction before the blood film shows Howell–Jolly bodies and other morphological features. This test also provides a reliable functional assessment of residual splenic tissue after splenectomy for immune thrombocytopenic purpura or autoimmune haemolytic anaemia, thus indicating the extent to which the splenuncule can be incriminated for the occurrence of relapse. Faster than normal clearance times have been observed in patients with haemolytic anaemia and in some patients with splenomegaly.

The curve of the clearance time is complex, as it comprises three overlapping components, namely, intrasplenic cell transit, sequestration and phagocytosis or irreversible extraction. These may be interpolated from the curve which shows blood flow, cell transit time and extraction ratio (Figure 21.6). There is also a rapid uptake of some of the labelled material by the liver. When the spleen is functioning normally, transit time is 5–10% per
Figure 21.6 Curve of disappearance from circulation of heat-damaged red cells. The components of the curve reflect sequential transit pooling, sequestration and irreversible trapping of the cells. 1, blood flow; 2, cell transit time; 3, extraction rate.

minute, with extraction of 20–50% of the labelled cells. Using red cells coated with IgG (anti Rh(D)) antibody, splenic Fc-receptor phagocytic function can be measured.

Identification of platelet sequestration

When ^{51}Cr-labelled platelets are administered, combined measurements of radioactivity in the liver and spleen and in the blood show that normally about one-third of the platelets are promptly extracted from circulation by the spleen and are released later, with a subsequent monoexponential equilibration with the circulating platelets. A small fraction of the labelled platelets is taken up rapidly and irreversibly by the liver; this is assumed to be due to their being damaged by the labelling process. Splenomegaly is associated with a marked increase in splenic pooling; in contrast, in asplenia, nearly 100% of the labelled platelets are recovered in circulating blood. Surface counting and quantitative scanning have been used to identify the role of the spleen in thrombocytopenia. The clinical usefulness of such data in predicting the results of splenectomy in such patients is, however, debatable, as there is both sequestration and destruction of platelets in the spleen; sequestration is, as a rule, a temporary phase, which does not necessarily mean subsequent destruction, as with red cells.

Splenic red cell pool

A similar procedure to that for visualizing the spleen, but with undamaged, labelled red cells, provides a relatively simple

method for measuring the splenic red cell volume. By quantitative imaging, the fraction of the administered radionuclide present in the spleen is measured 20–30 min after injection. Normally, the spleen contains 5% or less of the red cell volume (about 60 mL), and there is general correlation between splenic red cell volume and the physical size of the spleen. There is a proportionately greater pool in certain disorders; in these, the pool may be a major cause of splenomegaly. Discrepancies between the volume of the spleen and of the red cell pool suggest that the splenomegaly is due, at least in part, to cell or tumour infiltration. The extent of the splenic red cell pool should be taken into account when assessing the significance of anaemia; it also makes it possible to predict the degree to which anaemia will improve following splenectomy.

Plasma volume

Splenomegaly is often associated with an increased plasma volume and splenectomy is usually followed by a reduction in plasma volume. This means that in splenomegaly the blood count may give an exaggerated impression of anaemia, so that measurement of red cell and plasma volumes must be included in clarifying the cause of anaemia in conditions associated with splenomegaly.

Immunodeficiency diseases

A David B Webster

This chapter describes the clinical presentations and mechanisms of the immunodeficiency diseases, focusing on those disorders that affect lymphocytes and complement. Defects in neutrophils are dealt with in Chapter 17. Immunodeficiency is either primary or secondary to other diseases, transplantation and various drugs. Although the first description of a patient with primary immunodeficiency (PID) was half a century ago, it is only in the last decade that significant advances have been made in our understanding of the molecular mechanisms. Over 50 separate genetic defects in lymphocytes or monocytes/macrophages are now known, mostly very rare and presenting in infants and young children. However, the majority of patients with PID do not yet have a defined condition and are 'classified' as having 'common variable immunodeficiency – CVID'. This disorder, as well as many of the known single-gene defects causing PID, is associated with autoimmunity to blood cells and lymphoma, and affected patients are often referred to haematologists.

Primary immunodeficiency: introduction

Patients with PID can be broadly divided into three clinical groups: (i) those who present in infancy or early childhood with severe life-threatening infection (severe combined immunodeficiency, SCID); (ii) those presenting at any age with a defect predominantly affecting antibody production; and (iii) those with inherited complement deficiency. The first is a paediatric emergency, while those in the last group often remain undiagnosed for many years owing to the insidious onset of symptoms. In addition, there are rare inherited disorders affecting multisystems in which the immunodeficiency has a major influence on survival. There is a network of specialist centres in the UK for the diagnosis and management of PID, and most patients need referral. An

important role for general practitioners and specialists such as haematologists is to recognize the characteristic clinical features of PID, have facilities to screen for the most common disorders and to have a working collaboration with a local immunologist who can provide specialized diagnostic tests.

Severe combined immunodeficiency

The majority of patients with SCID present with severe persistent infection in infancy or early childhood. A typical scenario is failure to thrive during the first 2 years of life, episodes of protracted diarrhoea and persistent cough due to an opportunistic fungal respiratory infection (Figure 22.1). However, there are many exceptions to this 'classical' presentation, some patients having features that are not directly related to infection, such as skin rashes, severe autoimmune phenomena, lymphadenopathy and hepatosplenomegaly. The associated antibody deficiency leads to a susceptibility to bacterial infection, particularly with *Haemophilus influenzae*, pneumococci and enteric pathogens such as *Campylobacter jejuni*. The cellular immunodeficiency leads to chronic fungal infections that are often difficult to diagnose and treat, such as *Pneumocystis carinii*, *Aspergillus fumigatus* and *Candida albicans*; chronic viral infection is also common, particularly rotavirus enteritis and life-threatening varicella or cytomegalovirus infection. Chronic intestinal parasitic infections can occur, particularly in patients living in underdeveloped countries.

A few patients present later in childhood and, occasionally, as adults with a more insidious development of persistent opportunistic infection, the first manifestation in adults often being severe cutaneous warts caused by papillomaviruses. Such patients may remain undiagnosed for many years, with no easy explanation as to how they have survived through childhood

Clinical features

Typical signs

Chronic/recurrent respiratory infection
Interstitial pneumonitis (often fungal)
Failure to thrive and diarrhoea
Oral/perineal candidiasis

Occasional signs

Erythroderma
Lymphadenopathy
Hepatosplenomegaly
Absent hair
Warts (usually after infancy)

Laboratory features

Lymphopenia (not always)
Hypogammaglobulinaemia (difficult to assess in infants)
T cells fail to proliferate *in vitro* with PHA or anti-CD3/28

Lymphocyte subset analysis (FACS)

Surface molecule defects (often normal lymphocyte count)	**T⁻ B⁻ NK⁻**	**T⁻ B⁻ NK⁺**	**T⁻ B⁺ NK⁻**	**T⁻ B⁺ NK⁺**
CD4 – p56lck	Reticular dysgenesis	Rag 1 and 2	cγ chain	IL-7Rα
CD8 – ZAP-70	ADA deficiency	Artemis – radiation	jak3	CD45
CD8α chain		sensitivity		Partial Rag defect (Omenn's syndrome with eosinophilia and high IgE)
MHC 11 – C11TA, RFX (after activation)				PNP deficiency
CD25 – IL-2Rα chain				Thymic aplasia – 22q11 defect
				Winged helix nude defect (alopecia)

Figure 22.1 Clinical and laboratory features of severe combined immunodeficiency. The subclassification based on the presence of B or NK cells is used only as a guide to potential molecular defects.

without significant infection. Nevertheless, having presented as adults, the prognosis is poor and most die from opportunistic infection within 5 years.

Prevalence and initial diagnosis

Severe combined immunodeficiency is rare, estimated to occur in about 1 in 30 000–100 000 live births. Haematologists will usually play some part in the diagnosis as lymphopenia is a characteristic but not consistent feature. It is important that haematology laboratories provide normal age-related ranges for lymphocyte counts and that paediatricians appreciate that these are different to adult ranges. Most infants and young children with SCID are lymphopenic, so a full blood count is a valuable initial diagnostic aid. A family history suggesting autosomal or X-linked inheritance, such as early deaths from severe infection in family members, may support the diagnosis. Although it may be useful to identify deficiencies of lymphocyte subsets using fluorescence-activated cell sorter (FACS) analysis, most suspected cases should be urgently referred to a paediatric immunology centre with facilities to make a definitive molecular diagnosis and proceed to bone marrow transplantation (BMT). No time should be lost in trying to treat a current infection before referral to a specialist centre, as the earlier BMT is performed the better the outcome.

Subclassification of severe combined immunodeficiency

Infants and young children with SCID can be conveniently subclassified into those patients who lack both T and B lymphocytes (T⁻ B⁻ SCID) and those who retain B lymphocytes (T⁻ B⁺ SCID). Additional clues to the molecular diagnosis can be provided by the presence or absence of natural killer (NK) cells (Figure 22.1). This is only a guide to a molecular defect, and is less reliable in patients presenting later in life.

The most common molecular defects involve the recombinase-activating genes (*RAG1* and *RAG2*) and the genes coding for adenosine deaminase or the γ-chain shared by receptors for a number of cytokines involved in growth and development of lymphocytes. The clinical phenotype of *RAG* gene defects is particularly variable, ranging from a typical presentation with severe lymphopenia and infection when there is no *RAG* gene expression, to Omenn's syndrome, with lymphadenopathy, hepatosplenomegaly, autoimmune blood dyscrasias, severe skin rashes and eosinophilia when there is partial expression. The pattern of T-lymphocyte subset deficiency can be a useful guide to the molecular diagnosis. For example, a selective deficiency of CD8⁺ T cells suggests one of the rarer SCIDs caused by mutations in the genes coding for CD8α or ZAP-70. A few SCIDs can be diagnosed relatively easily; deficiency of adenosine deaminase

and purine nucleoside phosphorylase can be diagnosed by measuring the enzymes in erythrocytes in a specialized laboratory; MHC class II deficiency can be diagnosed by the absence of these molecules on lymphocytes using FACS systems.

Thymic aplasia (DiGeorge's syndrome) is usually associated with hemizygous microdeletions in chromosome 22q11, and occasionally 10p, the underlying genetic mechanism not being understood. Although this is a relatively common cytogenetic abnormality, the consequences, which affect the embryonic development of the third and fourth pharyngeal pouch, are diverse and include cardiac defects, abnormal facies, thymic hypoplasia, cleft palate and hypocalcaemia due to parathyroid hypoplasia, the syndrome being referred to by the acronym 'CATCH 22'. Only a few of the affected infants and children have a significant immunodeficiency, and very few require either thymic transplantation or BMT. Circulating T-cell numbers often rise during childhood in those with severe lymphopenia in infancy, but about 50% of patients have lifelong minor defects in humoral immunity, often with low serum IgM levels.

Molecular diagnosis

A detailed family history is important because it may suggest an X-linked or autosomal recessive type of SCID, thus narrowing down the possibilities. The knowledge that a previous relative has suffered from a defined molecular defect clearly makes the diagnosis relatively straightforward, and if the mutation is known then the genotype can be confirmed within a few weeks in a specialized laboratory. Genetic counselling can be offered to the family and fetal diagnosis may be possible. However, most SCIDs are sporadic, and with facilities available at present it may take many months before the molecular defect is found. Routine rapid sequencing of potentially affected genes should soon be available in the UK, providing a specific diagnosis in most patients before long-term management decisions are taken.

Treatment

As for all patients with severe T-cell deficiency, patients should be immediately given prophylactic cotrimoxazole to prevent *Pneumocystis carinii* pneumonia, and immunoglobulin replacement therapy for the associated antibody deficiency. Some centres use antifungal prophylaxis while waiting for more definitive treatment. Blood transfusions should be irradiated to avoid graft-versus-host disease (GvHD) and all live vaccines are contraindicated.

Bone marrow or stem cell transplantation is the only curative option for most SCIDs. The various protocols used will not be discussed here, but the success rate for a complete HLA-matched sibling donor is more than 95%, with about 75% for a matched unrelated donor or haplo-identical sibling donor. In contrast to other indications for BMT, myeloablation is not required. There is usually split chimerism after transplanta-

tion, with the T cells being donor and the B cells being of recipient origin. Except for an identical related match, either a stem cell or whole marrow transplant followed by *in vivo* T-cell depletion is used to avoid GvHD. There is usually a period of some months before normal B-cell function is achieved, with about 20% of patients having persistent antibody deficiency requiring regular immunoglobulin replacement therapy. BMT is less successful in adolescents or adults because of thymic atrophy, and engraftment is less consistent in those retaining NK cells.

For those with ADA deficiency, enzyme replacement therapy with pegylated bovine ADA will often partially correct the immunodeficiency. However, this is usually inadequate, and there are additional problems with the production of antibodies to bovine ADA that neutralize the replaced enzyme. The most exciting curative development has been gene therapy, with complete restoration of immunity following transfection of the γc gene into the stem cells of infants with X-linked SCID. Unfortunately, the random nature of proviral integration into the host genome caused acute lymphoblastic leukaemia in two children associated with aberrant expression of LMO-2. This has led to a temporary cessation of gene therapy in the pioneering Paris centre, although other centres are continuing treatment with different vectors on selected patients, and are extending it to other types of SCID.

Combined immunodeficiency

A number of rare inherited defects significantly compromise both humoral and cellular immunity but do not usually lead to early death from severe infection (Table 22.1). These include defects in CD40 ligand (HIM-1), ataxia telangiectasia (AT) and other defects in DNA repair systems, and the Wiskott–Aldrich syndrome (WAS). A predisposition to cancer, particularly lymphoma, occurs in many of these syndromes. In WAS, the clinical features range from thrombocytopenia alone to a severe disease characterized by recurrent infection, severe eczema and B-cell lymphoma at an early age. Patients with ataxia telangiectasia usually die before the third decade from progressive ataxia and/or tumours, often compounded by recurrent infections due to an associated antibody deficiency. The mutated gene (ATM) is involved in cell cycle regulation and also appears to be a tumour suppressor, as it is frequently deleted in prolymphocytic and chronic lymphocytic leukaemia (CLL) cells. Another gene involved in DNA repair causes the Nijmegen breakage syndrome, affected patients also having progressive neurological disease and antibody deficiency, but having distinctive dysmorphic features.

Dysregulation of cytotoxic – and/or NK-cell function – can cause tissue damage during infection, often with bone marrow failure. For example, the dramatic expansion of CD8 cytotoxic T cells in X-linked lymphoproliferative syndrome (XLP) during Epstein–Barr virus (EBV) infection may cause acute liver failure,

Table 22.1 Combined immunodeficiency.

Designation	Genetic defect	Cellular abnormality	Specific features
Disorders of cytotoxic T cell/NK function causing acute organ damage after viral infections			
X-linked lymphoproliferative syndrome (XLP) (X)	SAP	Excessive CD8 T-cell expansion	Burkitt's-like lymphoma
Chediak–Higashi syndrome	Lyst	Deficient CTL and NK	Giant lysosomes in leucocytes
Griscelli syndrome	Myosin 5a or RAB27A		Encephalopathy in severe cases
Familial haemophagocytic syndrome	Perforin		
T-cell receptor defects			
Class 1 transporter defect	TAP 1 or 2	Absent Class 1 expression	Midline granulomas
CD3 receptor defects	CD 3γ or ε	CD3 signalling defect	
Disorders of DNA repair with chromosomal instability and sensitivity to X-radiation			
Ataxia–telangiectasia	ATM	Cell cycle checkpoint defect	Lymphomas, severe ataxia
Ataxia + immunodeficiency	Mre 11		Moderate ataxia
Nijmegen breakage syndrome	Nibrin	Cell cycle checkpoint DNA double-strand break–repair defect	Microcephaly
Ligase deficiency	Ligase 1 or 4		Growth retardation, lymphomas
Multisystem disorders			
Wiskott–Aldrich syndrome (X)	WASp	Defect in cytoskeletal integrity	Thrombocytopenia, small platelets lymphomas, vasculitis
Immune dysregulation polyendocrinopathy, enteropathy, X-linked syndrome (IPEX) (X)	FOXP3		Early onset diabetes, severe skin disease
Autoimmune polyendocrinopathy and ectodermal dysplasia	AIRE		Chronic mucocutaneous candidiasis
WHIM (waits, hypogammaglobinaemia infections, myelokathexis)	CXCR4	Chemokine receptor defect	Severe warts

These disorders are associated with variable patterns of immunoglobulin deficiencies and T cell abnormalities.
X, x-linked.

and the failure of a cytotoxic response to viruses in familial haemophagocytic lymphohistiocytosis and Chediak–Higashi syndrome can lead to uncontrolled viral replication and a massive acute phase response. The best explanation for the high incidence of midline granulomas in TAP (transporter associated with antigen processing) deficiency is that the failure to express MHC class 1 inhibitory molecules allows activated NK cells in the nasopharynx to damage adjacent tissues.

Secondary defects in cellular immunity

Chronic malnutrition is the most common cause of secondary T-cell deficiency worldwide, often exacerbated by AIDS in many underdeveloped countries in Africa. This explains the pandemic of tuberculosis at present in these countries and the very high mortality in children during epidemics of measles and other common viruses. Zinc, vitamin A and selenium have been em-phasized as being important for normal immunity, with some evidence that maintaining adequate levels reduces mortality.

In developed countries, immunosuppressive and cytotoxic drugs used for autoimmune disease, malignancy and after transplantation are the main causes of T-cell defects, although only a minority of treated patients develop clinically significant immunodeficiency. An example is the increased EBV replication and development of EBV-triggered post-transplant lympho-proliferative disease (PTLD). Major trauma and surgery has a transient inhibitory effect on T-cell function and can rarely lead to fatal reactivation of cytomegalovirus.

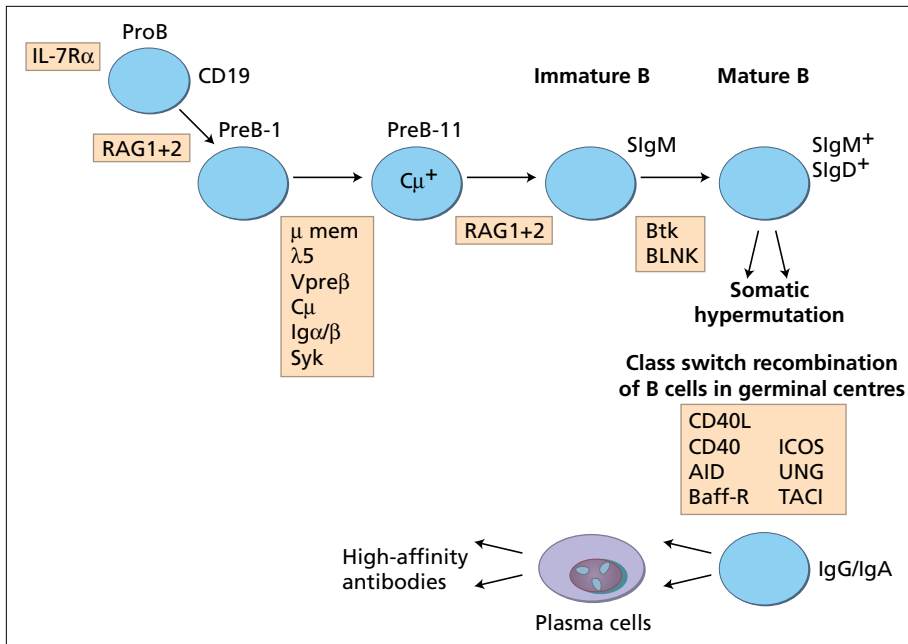
Except in AIDS, and more recently in PTLD, clinicians usually make no attempt to regularly screen for T-cell defects in those taking immunosuppressive drugs or in malnourished elderly people. A simple circulating CD4$^+$ T-lymphocyte count is probably a sufficient screening procedure, with counts of < 150/μL raising the alarm and prompting referral to an immunologist.


Figure 22.2 The stages in B-cell development. Genetic defects in molecules associated with arrest at various stages are shown in the coloured boxes. RAG, recombinase activating gene; μ mem, membrane-associated μ chain; Cμ, cytoplasmic μ expression; Btk, Bruton's tyrosine kinase; BLNK, B cell linker protein; ICOS, human *in*ducible *co-s*timulator; AID, activation-induced cytidine deaminase; UNG, uracil–DNA glycosylase; BAFF-R, B-cell activation factor from the tumour necrosis factor family; TAC-I, transmembrane activator and calcium modulator and cyclophilin ligand interactor.

Primary antibody deficiency

This is the most common PID, affected patients having either a severe or partial failure to produce antibodies, usually with low levels of one or more of the main immunoglobulin classes. Most patients with severe primary antibody deficiency (PAD) present as adolescents or adults, although a carefully taken history will uncover a susceptibility to infection in about 20% during childhood. The most common of these disorders is a selective complete deficiency of immunoglobulin A (IgAD), this having a prevalence of about 1 in 700 white people. Most affected individuals are asymptomatic, and the defect may be recognized only during population surveys or during routine investigation of an unrelated problem. However, there is a raised incidence of IgAD in patients with various autoimmune disorders, particularly coeliac disease. Family studies show that IgAD is often genetically linked to a more severe antibody deficiency called *common variable immunodeficiency* (CVID). Furthermore, many patients with subtle defects in immunoglobulin production (i.e. IgG subclass defects, low serum IgA and/or deficiencies in producing IgG-specific antibodies), appear also to have a disorder genetically linked to CVID and IgAD.

A variety of rare single-gene defects cause severe antibody deficiency as a result of failure of development of B lymphocytes within the bone marrow. The best known is X-linked agammaglobulinaemia (XLA), caused by a defect in Bruton's tyrosine kinase (btk), an intracellular signalling molecule whose precise role in B-cell development is still unknown. Other rarer defects involve surface ligands or intracellular signalling molecules involved in the differentiation of B cells (Figure 22.2). Recent work has identified a number of molecules critical for immunoglobulin class switching and somatic hypermutation, these processes being necessary for the generation of antibody diversity. The germline configuration of immunoglobulin genes on chromosome 14 consists of 'variable' V-region genes linked to the 'constant' region genes by a D–J segment. During the later stages of B-cell development in the bone marrow, functional immunoglobulin genes are assembled by recombination to produce a repertoire of IgM antibodies with low affinity. When these B cells encounter antigen, there is rapid proliferation to form the germinal centres in the secondary lymphoid apparatus, during which there is intense hypermutation in and around the rearranged V gene segments. Class-switch recombination occurs at this stage, a critical requirement being a signal within B cells stimulated via CD40-ligand expressed on the surface of activated T cells and CD40 on the B cell. Activation-induced cytidine deaminase (AID) is another molecule involved in class switching, its role being to deaminate doxycytidine to uracil, which then has to be excised and repaired for the immunoglobulin gene segment to be functional. Uracil–DNA glycosylase (UNG) is the most important molecule for this excision/repair step.

Genetic defects in any of these four molecules are very rare and characterized by a raised serum IgM, and usually very low IgG and IgA (hyper-IgM syndromes: HIM 1–4). However, each has some special features, for example defects in CD40 ligand cause susceptibility to opportunistic infection, particularly with cryptosporidia, and to unexplained sclerosing cholangitis and

Typical features	Occasional features
Chronic/recurrent bronchitis	Autoimmune disease, e.g. haemolytic anaemia,
Sinusitis/otitis media	neutropenia, thrombocytopenia, vitiligo
Pneumonia/septicaemia	Enteropathy
	Arthritis (usually mycoplasmal)
	Meningoencephalitis (usually enteroviral)
	Lymphoma

Diagnosis

Stage 1	Serum immunoglobins (+ serum immunoelectrophoresis)
	Baseline functional antibodies → if low, immunize and check response
	e.g. to tetanus toxoid
	pneumococcal polysaccharides
	IgG subclasses if total IgG <11 g/L

Stage 2	Consider secondary causes:
	1 Drugs – anti-inflammatory
	anticonvulsant
	immunosuppressive
	2 Increased loss –
	nephrosis
	enteropathy
	lymphangiectasia
	3 Lymphoma

Stage 3	Lymphocyte subsets – absence of B cells suggests Btk, μ-chain defect, etc.
	Family history – XLP, X-HIM and XLA need to be excluded in males
	Exclude thymoma in those > 40 years (lateral chest radiograph)
	Most patients with B cells will be 'labelled' as having
	common variable immunodeficiency

Figure 22.3 Clinical features and diagnosis of antibody deficiency.

liver cancer at a young age; the AID and UNG defects cause lymphadenopathy with expanded germinal centres filled with IgM-committed B cells, a feature sometimes confused with follicular lymphoma. Only three patients with UNG defects have so far been described, but they may be prone to B-cell lymphoma as this is a frequent complication in the knockout mouse model.

Presenting features of antibody deficiency

Nearly all patients with severe PAD present with infection, although in a minority the hypogammaglobulinaemia is discovered during investigation of autoimmune or inflammatory bowel disease (Figure 22.3). There is usually a gradual escalation of bacterial infection in the respiratory tract, with recurrent bronchitis, persistent nasal catarrh and sinusitis, and otitis media in children. The organisms most commonly isolated are nontypeable *Haemophilus influenzae*, pneumococci and *Moraxella catarrhalis*.

A few patients present with an acute, life-threatening septicaemia, sometimes with meningitis caused by pneumococci, capsulated *H. influenzae* and occasionally meningococci. A minority are susceptible to chronic enteroviral infection, particularly with echoviruses, that cause an insidious meningoencephalitis and sometimes a dermatomyositic-like condition and/or myocarditis. Immunization with live attenuated vaccines is contraindicated, particularly with oral polio vaccine (OPV),

because some patients have subsequently developed paralytic poliomyelitis. About 10% of patients are prone to chronic mycoplasma infection, usually manifesting as arthritis or urethritis, but sometimes as deep abscesses in the lungs or elsewhere. As only a minority of patients are prone to enteroviral or mycoplasmal infection, it is likely that they lack additional protective factors for these specific organisms. In the bowel, campylobacter or giardia infection is common and often difficult to eradicate with standard therapy.

Individuals with IgAD are usually healthy and need take no special precautions with vaccines. However, they often make anti-IgA antibodies, which in a small minority are of sufficiently high titre and affinity to cause anaphylactic reactions during blood or blood product infusion. There is no consensus among immunologists on whether IgAD individuals should be routinely monitored for anti-IgA antibodies, mainly because there is very poor correlation between the level of these antibodies and severe reactions.

Common variable immunodeficiency

This is a diagnosis of exclusion, but typically patients present with infections after adolescence and have very low levels of serum IgG and IgM and unrecordable IgA. Some rare inherited single genes defects have recently been shown to cause the CVID phenotype [e.g. a defect in human *i*nducible *co-s*timulator

(ICOS), X-linked lymphoproliferative syndrome (XLP), BAFF-R and TAC-I], but the majority appear to have a complex genetic disorder associated with increased production of inflammatory cytokines, particularly IFN-γ. This helps to explain the high incidence of inflammatory bowel disease and granulomatous infiltration of organs such as the spleen, liver and lungs, and the splenomegaly that often prompts a search for lymphoma. The incidence of stomach cancer and lymphoma is raised in CVID, the former probably due to *Helicobacter pylori* gastritis. There are some similarities between CVID and XLP, in that both are associated with a relative expansion in numbers of circulating $CD8^+$ T cells with restricted clonality, which in XLP are mainly committed to EBV peptides. Although XLP is a very rare disorder, the diagnosis should be excluded in male patients presenting with hypogammaglobulinaemia, particularly if they develop an EBV-related lymphoma. Hypogammaglobulinaemia associated with thymoma can mimic CVID at presentation but is classified separately because the prognosis is often poor due to a gradual deterioration of T-cell function.

There is evidence that at least 20% of CVID patients have an inherited dominant condition with a major susceptibility locus in the MHC region on chromosome 6, probably involving class II genes. However, the phenotype in affected family members varies from a mild subclinical selective deficiency of IgA (IgAD), to low IgG or IgG subclass deficiencies, with only the rare individual developing CVID with very low or absent serum levels of all immunoglobulin classes. Interestingly, IgAD is rare in Japanese people (1:80 000 of the population) but is relatively common in white people (1:700), with very few cases of CVID being reported in Japan. This geographical distribution suggests some selective advantage for the IgAD/CVID genotype, one possibility being that the associated upregulation of inflammatory cytokines has provided some protection during pandemics of infection with intracellular organisms such as mycobacteria.

Differential diagnosis of primary and secondary antibody deficiency

Figure 22.3 shows the procedures for investigating patients with suspected antibody deficiency. The family history may suggest an inherited defect. The pattern of the serum immunoglobulin deficiency can be helpful, with complete agammaglobulinaemia and absence of circulating B lymphocytes suggesting a B-cell maturation/differentiation defect. The presence of a normal or raised serum IgM, with very low IgG and IgA, suggests one of the HIM syndromes, whereas low IgG, unrecordable IgA and very low IgM suggests CVID. Some inherited 'single-gene' defects can be diagnosed easily by Western blot analysis of the relevant protein in lymphocytes and/or monocytes (e.g. XLA, XLP), but many patients remain undiagnosed because of the cost and the time it takes to search for mutations. The diagnosis of more subtle defects in antibody production relies on measuring specific antibodies before and after immunization. The problem here is

that there is very poor correlation between a specific failure to respond to various types of antigen (e.g. bacterial polysaccharides) and clinical symptoms and signs.

Secondary antibody deficiency must be excluded, being relatively common nowadays with many patients being treated with immunosuppressive and cytotoxic drugs. A variety of anti-inflammatory and anticonvulsant drugs have been associated with low serum immunoglobulins, and nearly 10% of patients treated for vasculitis with combinations of cyclophosphamide and steroids develop hypogammaglobulinaemia. The increasing use of combination therapy for malignancy and anti-B lymphocyte therapy for autoimmune disease is likely to be associated with an increase in the numbers of patients with secondary antibody deficiency. The mechanism for this complication is not known but is likely to be complex and involve polymorphisms in enzymes that metabolize specific classes of drugs. Other causes of secondary antibody deficiency such as increased loss from the kidney (nephrotic syndrome) can be easily eliminated, but protein loss from the bowel may be more difficult to confirm, particularly if the serum albumin is maintained (e.g. lymphangiectasia in the bowel due to tumours or venous congestion).

Hypogammaglobulinaemia is common in CLL, but usually the immunoglobulin levels are only moderately low and the clonal lymphocytosis confirms the diagnosis. Myeloma is often associated with profound depression of useful antibodies and, apart from the paraprotein, low immunoglobulin levels. Therefore, immunoelectrophoresis should be routine for all initial serum samples sent to the laboratory for immunoglobulin levels. Tests on urine for Bence Jones proteins may also be necessary to exclude atypical myeloma, particularly in patients presenting after 50 years of age. Some patients present with severe hypogammaglobulinaemia associated with malignant lymphoma, with uncertainty as to whether the patient has a primary antibody deficiency (e.g. CVID) with secondary lymphoma or a lymphoma with secondary immunodeficiency. Fortunately, such confusion does not alter management, and in most cases the sequence of events cannot be resolved.

Management of antibody deficiency

Most patients with suspected PID should be referred to a clinical immunologist with access to modern immunological tests. For severely affected patients, a combination of immunoglobulin replacement and periodic or prophylactic antibiotics (e.g. ciprofloxacin or a rotating regimen of amoxycillin, doxycycline and a quinolone) are required, but mild cases can often be managed with antibiotics alone. Most severely affected patients are given monthly intravenous immunoglobulin (400 mg/kg) or weekly subcutaneous infusions (100 mg/kg), the latter being recommended for infants and young children with difficult venous access. Morbidity and life expectancy depend on the type of immunodeficiency and the degree of organ damage at diagnosis; for example patients with XLA diagnosed early before there is

lung damage will have an excellent prognosis if they are compliant with treatment. In contrast, CVID patients frequently develop chronic inflammation with granulomas in their lungs and livers, and a minority may have severe unexplained enteritis or autoimmune thrombocytopenia that can severely affect their quality of life. Other rarer PADs are associated with special complications, such as cholangitis and liver cancer in patients with CD40 ligand deficiency, and EBV-induced lymphoma in those with XLP. Protocols for management and follow-up therefore need to be tailored to the genetic defect.

In secondary antibody deficiency, prognosis depends on the primary disorder, but there is often recovery of antibody production if the offending drug is discontinued or the underlying disease remits. There is no consensus on the use of prophylactic immunoglobulin in CLL or myeloma, with many centres preferring to use prophylactic antibiotics for those prone to infection. Nevertheless, there are patients who benefit from prophylactic immunoglobulin therapy, particularly in the winter months.

Primary defects in innate immunity (IL-12/IFN-γ and NFκB pathways)

Experimental mouse models have clearly demonstrated the importance of IL-12 and IFN-γ and their corresponding receptors in protection against infection with intracellular pathogens, particularly mycobacteria. This work led to a search for defects in these proteins in rare cases of infants and young children presenting with chronic mycobacterial disease, including persistent local disseminated BCG infection following vaccination. Families have been reported with autosomal inherited defects involving the IFN-γ receptor, STAT-1, which is critical in the signalling pathway for this receptor, and in IL-12 and its receptor. Affected patients usually present with chronic atypical mycobacterial infection at an early age and are also prone to chronic *Salmonella* infection. A defect in NEMO (NFκB modulator) causes a rare X-linked severe immunodeficiency with ectodermal dysplasia. Defects in IRAK-4 (interleukin-1 receptor-associated kinase 4) have been found in patients prone to recurrent pneumococcal pneumonia.

Patients with IFN-γ receptor (R) defects either fail to express the R1 chain or partially express either the R1 or R2 chain. Partial expression allows signalling by high concentrations of IFN-γ, and affected patients may respond to IFN-γ therapy. The heterozygous dominant form of partial expression is the most common, the abnormal chains interfering with the signalling via Jak-1 and STAT-1 following binding of IFN-γ to the receptor complex (so-called 'dominant negative' effect). Patients with complete deficiency of the p40 chain shared by both IL-12 and IL-23, and of the IL-12β1 receptor can be helped by IFN-γ therapy, but the few patients described with STAT-1 deficiency do not respond.

Defects in complement components

Inherited defects in nearly all of the complement components have been reported since the first description of a patient with very low haemolytic complement activity in 1960. Complement is important for localizing infection with encapsulated bacteria during the first few hours and preventing blood-borne dissemination. This is achieved mainly by activation of the 'classical' pathway through immune complexes activating C1q, but also by direct activation of the 'alternative' pathway by microorganisms, sometimes amplified by plasma collectins such as mannose-binding lectin (MBL). The alternative pathway, triggered by the production of nascent C3b, acts as an amplification system for the classical pathway (Figure 22.4). The importance of inhibitors at various stages to prevent persistent activation and unwanted bystander damage to tissues is demonstrated by inherited deficiencies of C1 esterase inhibitor, which causes attacks of severe angioedema: another example is haemolytic anaemia caused by deficiency of decay accelerating factor (DAF). As defects in these 'control' systems are not associated with infection they will not be discussed here.

Most patients with inherited defects are homozygous for the mutated allele; these are very rare except for C2 deficiency, which affects about 1:10 000 white people. Defects in the early components of the classical pathway (C1, C2, C4) predispose to recurrent bacterial infection, but the main problem for affected patients is a susceptibility to immune complex disease such as systemic lupus erythematosus (SLE), glomerulonephritis and vasculitis. The rare patients with complete C3 deficiency suffer from severe bacterial infections from an early age, but are also prone to vasculitis and glomerulonephritis. Defects in the late components, which include the membrane attack complex, are associated with recurrent meningococcal and gonococcal infection, except for C9 deficiency, which is common in Japanese people and only occasionally predisposes to meningococcal meningitis. Recurrent meningococcal disease is a feature of complete deficiency of alternative pathway components (i.e. factors B, D, I, H and properdin); those with factor H deficiency have an additional susceptibility to vasculitic renal disease. The clinical significance of MBL deficiency is controversial, but there is good evidence that severe deficiency predisposes to sepsis in infants, possibly in those with inadequate antibody production. About 5% of white people have severe MBL deficiency, and there are many reports linking both complete and partial deficiency with a wide variety of infections.

Diagnosis and treatment of complement deficiencies

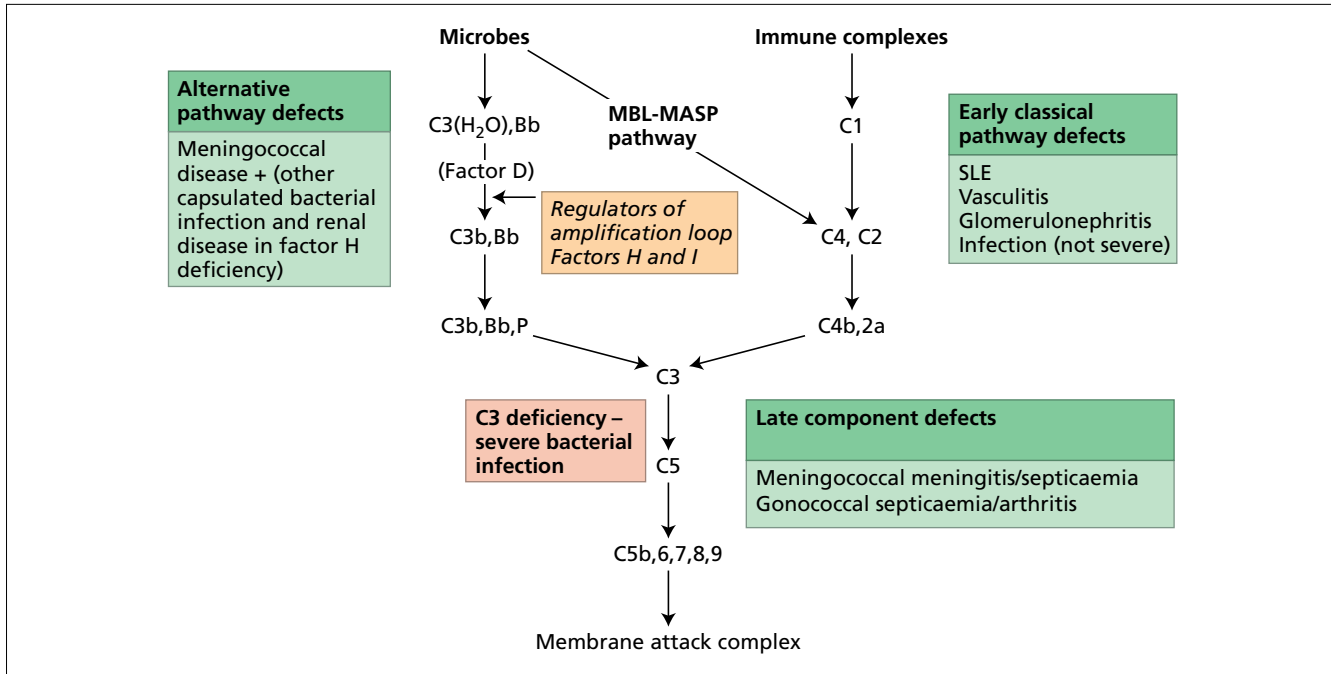
Functional assays of classical and alternative pathway haemolytic activity are available in most immunopathology laboratories as an initial screening test. Distinguishing primary from secondary


Figure 22.4 Diagram showing the sequential activation of the components of the classical and alternative complement pathways. Genetic defects in the various components are associated with the clinical complications shown in the adjacent coloured boxes.

hypocomplementaemia can sometimes be difficult during episodes of complement consumption, for example in active SLE, but the haemolytic activity rarely falls below 5% of normal, which is usual for primary defects. A specialized laboratory will measure individual components and search for the mutation, sometimes assisted by the type of inheritance (e.g. X-linked in properdin deficiency). Potentially affected family members should be screened. Regular replacement therapy for specific complement component deficiencies is not feasible but is theoretically possible on a temporary basis during an infection (compare with C1 inhibitor concentrate for hereditary angioedema). In practice, fresh-frozen plasma can be given, although it is not clear whether this adds any benefit to antibiotics that are clearly life-saving. Careful attention to maintaining protective levels of antibodies to pneumococci and meningococci by vaccination is sensible, and patients should be encouraged to take antibiotics as soon as they experience symptoms of infection; these prophylactic measures are best managed by an immunologist.

Haematology in HIV disease

Christine Costello

Acquired immunodeficiency syndrome

Viral structure

There are two subtypes of human immunodeficiency virus, HIV-1 and HIV-2. Infection with both viruses usually causes acquired immunodeficiency syndrome (AIDS), although those infected with HIV-2 tend to progress at a slower rate. HIV-1 and HIV-2 are retroviruses of the lentivirus subfamily and are sufficiently alike to be considered as one in terms of viral properties. Like all retroviruses, HIV replicates by forming a DNA provirus using the viral enzyme, reverse transcriptase. Retroviruses contain RNA in two subunits and have three genes central to their action: *gag* (group-specific antigen), coding for proteins within the viral particle; *pol*, coding for reverse transcriptase, which converts the RNA into DNA within the host cell; and *env*, which codes for envelope glycoproteins. In addition to these genes, the HIV genome contains several regulatory genes that modulate the rate of viral gene expression and the infectivity of the virus. The *tat* and *rev* genes act in positive feedback to enhance the processing and translation of RNA encoding the structural genes and proteins, whereas the *nef* gene appears to downregulate HIV replication.

It has been known for some years that different laboratory strains of HIV show considerable diversity of nucleotide sequence, which may result in antigenic variation, providing a means whereby the virus can escape humoral and cellular immune control. Using the polymerase chain reaction method for the amplification and subsequent analysis of viral genomes, it is now apparent that HIV genomes *in vivo* are even more diverse than those in laboratory strains.

Viral transmission

HIV transmission usually occurs by sexual contact, blood or blood products. It has been suggested that infected lymphocytes and macrophages are particularly effective at transmission but the infection of haemophiliacs given contaminated factor VIII demonstrates that extracellular viruses are potent.

Over one-half of patients in the UK with severe haemophilia have been infected with HIV, and of these two-thirds have died. No new cases of HIV infection from virally inactivated blood products have been detected since 1986. AIDS has been a new cause of death in thalassaemia major patients who have been regularly transfused. The risk is much lower in patients with sickle cell disease, as the frequency of transfusion is lower.

Latency

Although some cells are lysed directly by replicating HIV, the virus remains latent in others and so cannot be recognized by the immune system. Once a latently infected T cell is activated, however, viral replication begins and cell death follows.

Target cells

HIV produces its dominant effects on CD4$^+$ T cells, which are lysed or form syncytia with adjacent CD4$^+$ cells. CD4$^+$ antigen-presenting cells can harbour and release high titres of active virus. The CD4 antigen is the main receptor for HIV and CD4 antibodies and free CD4 antigens can block infection. However, CD4 alone is not sufficient for infection (e.g. mouse cells transfected with human CD4 will not necessarily become infected), and second receptors (CCR4 or CCR5) are required. CD4$^-$ cells,

including brain cells and haemopoietic cells, may also be infected using such alternative receptors.

Clinical effects of human immunodeficiency virus

The outcome of HIV infection is divided into four stages (or groups) according to the Centers for Disease Control (CDC) (Table 23.1), and it is not yet clear what factors determine whether (or how rapidly) movement occurs from one stage to the other.

After the initial seroconversion, which is often associated with a febrile mononucleosis-like illness, patients who are HIV antibody-positive enter either group 2 (chronic asymptomatic infection) or group 3 (persistent generalized lymphadenopathy).

Persistent generalized lymphadenopathy, or extended lymphadenopathy syndrome, should be diagnosed only if enlarged lymph nodes in at least two extrainguinal sites have been present for 3 months. There is no evidence that progression into group 4 is different in these patients from those without node enlargement. Biopsy is not now routinely undertaken but may be necessary to exclude lymphoma or Kaposi's sarcoma in a node that suddenly enlarges or, occasionally, in pyrexia of unknown origin, to exclude infection with acid-fast bacilli.

Three histological patterns have been described in biopsies of lymph nodes from HIV antibody-positive patients. Type I is the most common pattern seen in persistent generalized lymphadenopathy in which there is follicular hyperplasia with or without paracortical hyperplasia. The germinal centres are greatly expanded and may show necrosis and haemorrhage (Figure 23.1a). There is a variable loss of surrounding mantle zone lymphocytes. Type II is also seen in persistent generalized lymphadenopathy but is less common and may herald the development of AIDS. There is diffuse lymphoid hyperplasia with loss of germinal centres. Type III pattern, seen in patients with established AIDS, is marked by the absence of lymphoid follicles and severe depletion of both T and B lymphocytes (Figure 23.1b).

Haematological changes

Infection with HIV is associated with a range of haematological abnormalities. The mechanisms for these changes are multiple: quantitative and qualitative marrow defects and immune cytopenias are a direct result of HIV infection, whereas the effects of opportunistic infections, lymphoma and a myriad of drugs against infection, malignancy or HIV itself play an important role. With such a varied assault on the haemopoietic system it is not surprising that peripheral blood and bone marrow abnormalities are common in HIV infection and increase in frequency with advancing disease.

Haemopoiesis

Cytopenia is common in HIV disease and is often associated with morphological abnormalities in peripheral blood and bone

marrow cells suggestive of myelodysplasia. It is likely that HIV directly affects marrow production either by direct infection of precursor cells or by infecting stromal or accessory cells, thereby inducing altered production of regulatory cytokines.

Studies of purified haemopoietic progenitors (CD34+), as well as haemopoietic colonies obtained from semisolid culture, have yielded conflicting results with respect to the presence of HIV DNA, although HIV infection of monocytes/macrophages, promonocyte cell lines, megakaryocytes and eosinophils has been demonstrated as well as infection of bone marrow-derived fibroblast cell lines. Although susceptibility of marrow progenitor cells to infection by HIV *in vitro* has been demonstrated, the extent to which progenitor cell infection *in vivo* contributes to

*Denotes AIDS diagnosis. A CD4 count < 200 without an AIDS defining illness is considered as an AIDs diagnosis in the USA (but not in Europe).
Number in brackets is the diagnosis code.

(a)

(b)
Figure 23.1 Lymph node biopsy in HIV disease. (a) Type I pattern, showing florid follicular hyperplasia with large irregular germinal centres; (b) type III pattern, showing marked depletion of T lymphocytes and lack of lymphoid follicles with germinal centres (courtesy of Professor K Henry).

abnormal haemopoiesis is uncertain, and it is likely that the effect of HIV on stromal or accessory cells is more important. Infection of marrow accessory cells, T lymphocytes, macrophages, fibroblasts and dendritic cells with HIV leads to overproduction of cytokines, such as tumour necrosis factor (TNF), interleukin 1 (IL-1) and interferons, which have inhibitory effects on marrow progenitor cells. *In vitro* infection of stromal cells leads to impaired colony growth. T-cell depletion of marrow enhances marrow colony production in HIV-infected patients and, when T-cell-depleted marrow is cocultured with increasing concentrations of circulating or marrow T cells, an inverse correlation of T cells with progenitor colony growth is observed. This inhibitory effect of T lymphocytes is not seen in patients who are not infected with HIV.

Cell cultures of bone marrow from patients with HIV infection show a normal response to recombinant growth factors but colony formation is suppressed when anti-HIV antibodies are added to the culture system. This effect is not seen in marrow cultures from seronegative donors, suggesting that anti-HIV antibodies exert a suppressant effect directly on HIV-infected progenitor cells or indirectly on HIV-infected marrow accessory cells.

Thrombocytopenia

Thrombocytopenia is common at all stages of HIV disease and may be the presenting feature. In many patients, an immune basis is strongly suggested by the presence of normal or increased numbers of megakaryocytes in the bone marrow, by the presence of platelet-associated IgG and complement in a high proportion of patients studied, and by the response to conventional treatment for immune thrombocytopenic purpura (ITP). However, thrombocytopenia in HIV disease may also result from marrow impairment, toxic drug effects or the effects of splenomegaly.

The specific mechanism of platelet autoimmunity remains unclear. Higher levels of platelet-bound IgG and complement are seen in HIV-related ITP than in classic ITP, and circulating immune complexes capable of binding normal platelets can be found in the serum. In contrast with classic ITP, the eluates of the platelet-associated immunoglobulins in HIV-associated ITP react against normal platelets in only a minority of patients. In HIV patients, unlike patients with classic ITP, platelet counts are not inversely related to platelet-bound IgG, although it is likely that the deposition of immune complexes leads to increased peripheral destruction of platelets by phagocytic cells. The nature of the immune complexes has been extensively studied. They lack HIV antigen and proviral DNA but contain anti-HIV gp120 and anti-antibodies directed against the anti-HIV antibodies. In some patients cross-reactivity of antibodies against HIV gp120/gp160 with platelet glycoprotein GPIIb/IIIa has been demonstrated.

Platelet kinetic measurements suggest that, in addition to peripheral platelet destruction, ineffective thrombopoiesis is a factor in producing thrombocytopenia in HIV-infected patients, and this may result from the deposition of immune complexes on megakaryocytes, invasion of megakaryocytes by HIV or thrombopoietic inhibitors induced by HIV. The commonly observed dysplastic changes in the megakaryocyte series suggest that dysplasia is an important cause of ineffective platelet production and may be the dominant factor in the thrombocytopenia of advanced HIV disease.

Thrombotic thrombocytopenic purpura has been described in HIV disease and responds to conventional treatment with plasma exchange. The pathophysiology is unclear, although it has been postulated that immune complex damage to platelets and endothelial cells is contributory.

Management of HIV-related ITP

Immune thrombocytopenia in HIV disease does not increase the risk of progression to AIDS so should not be viewed as an indicator of poor prognosis. The response to conventional

treatment for ITP does not differ from classic ITP, although the approach to treatment is affected by the presence of HIV infection. Prednisolone is not satisfactory as a first-line treatment because of the risk of potentiating or reactivating infections. If other treatments fail, then prednisolone therapy should be covered with prophylactic antimicrobials against *Pneumocystis carinii* and mycobacteria, at least in patients with significantly reduced CD4 counts. Intravenous immunoglobulin is effective in HIV-related ITP and should probably be the first-line treatment, although the effect is usually only transient. Many patients, however, do not need active treatment and a conservative approach is justified, with intervention only if bleeding occurs, if an invasive procedure is planned, or if the platelet count is judged to be perilously low. Platelet transfusion may permit an adequate, if short-lived, increment sufficient to allow an investigative procedure such as endoscopic biopsy or lumbar puncture.

Splenectomy improves the platelet count in the majority of patients, but may not be justified in a person with advanced HIV disease. It does, however, have a role to play in the management of severe and troublesome ITP in the earlier stages of HIV disease, and there is no evidence that splenectomy contributes to the development of AIDS.

Some patients with HIV-associated thrombocytopenia respond to antiretroviral therapy. This effect was first described using zidovudine, but other agents may have a similar effect. It is likely that antiretroviral treatment exerts its effect by permitting more effective platelet production rather than by decreasing peripheral platelet destruction, thereby emphasizing the two mechanisms involved in HIV-associated thrombocytopenia.

Intravenous anti-D immunoglobulin is effective in a high proportion of RhD-positive patients with ITP and is generally well tolerated, with significant immune haemolysis being uncommon. The mode of action is likely to be Fc receptor blockade by anti-D-coated red blood cells. Patients who have been splenectomized have a much lesser chance of response as the spleen is the primary site of removal of antibody-coated cells.

Other treatment options in HIV-related ITP include danazol, vincristine, interferon-α and extracorporeal immunoabsorption; all have limited success.

Neutropenia

Neutropenia increases in incidence as HIV disease progresses, although it may be present in asymptomatic individuals. Impaired haemopoiesis, as discussed above, is the major factor, although in some patients immune neutrophil destruction may contribute. Antineutrophil antibodies have been detected in some HIV antibody-positive patients by using a granulocyte immunofluorescence technique, but there is poor correlation with the neutrophil count.

In general, neutropenia is well tolerated in HIV-positive individuals, although the risk of infection increases once the neutrophils fall to below 0.5×10^9/L, especially if a central venous catheter is *in situ*.

The responsiveness of HIV patient bone marrow culture to recombinant growth factors *in vitro* has led to the clinical use of recombinant granulocyte–macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) to reverse neutropenia. Following the administration of recombinant GM-CSF, a rapid dose-dependent increase in neutrophils, bands, eosinophils and monocytes is observed, although there is no increase in haemoglobin or platelets. The effect is reversed when GM-CSF is discontinued. G-CSF is the treatment of choice as it is better tolerated, and reports suggest that doses as low as 100–200 μg are capable of significantly elevating the neutrophil count, although conventional doses are more frequently used. Therapy with marrow-suppressant drugs such as ganciclovir or chemotherapeutic agents may thereby be continued.

There are no convincing studies to suggest that GM-CSF or G-CSF increase HIV-p24 antigenaemia.

Anaemia

The degree of anaemia increases with progression of HIV disease irrespective of other factors, including drug therapy (especially zidovudine), reticuloendothelial iron block, intercurrent infections, especially with atypical mycobacteria, marrow infiltration with lymphoma and haemophagocytic syndrome. It is unlikely that autoimmune haemolysis contributes, although a positive direct antiglobulin reaction is seen in 6–43% of HIV antibody-positive patients and may result from IgG or complement on the surface of the red cells. Although specific antibodies directed against a phospholipid antigen on the red cell could account for the positive antiglobulin test, in many patients this results from non-specific deposition of circulating immune complexes.

Reduced vitamin B_{12} levels have been reported in 10–35% of patients infected with HIV and, although many of these patients have gastrointestinal symptoms or late-stage HIV disease, reduced levels are also described in early, asymptomatic disease. The serum transcobalamin II cobalamin-binding capacity is significantly raised in asymptomatic patients with HIV infection, regardless of the vitamin B_{12} level; this suggests a stage of negative cobalamin balance.

The most likely mechanism underlying the reduced serum cobalamin in HIV disease is malabsorption. Malabsorption of cobalamin assessed by a Schilling test has been demonstrated in some patients with AIDS, and colonic and duodenal biopsies show chronic inflammation within the lamina propria. *In situ* hybridization of the specimens shows HIV to be present within mononuclear cells. Partial villous atrophy in the absence of enteropathogens has been shown in patients at all stages of disease, and HIV antigen p24 is present within the intestinal mucosa of patients presenting with gastrointestinal complaints. There is also some evidence that damage occurs to the gastric

mucosa in patients with HIV disease, resulting in a reduced ability to secrete acid and enzymes, which may cause difficulty in releasing cobalamin from protein-binding in food. This might explain the observation that in some HIV patients with reduced cobalamin levels, the Schilling test, in which cobalamin unattached to food is presented to the intestine, is normal.

Cobalamin levels tend to fall along with CD4 cell counts in those patients progressing to AIDS and thus falling serum cobalamin levels are a predictor of disease progression.

Anaemia in HIV disease is not usually due to or compounded by vitamin B_{12} deficiency and would not be expected to improve with vitamin B_{12} therapy.

The major cause of anaemia in HIV disease is impaired erythropoiesis secondary to marrow dysfunction and impaired response to erythropoietin. The anaemia has the characteristics of the anaemia of chronic disease, usually being normochromic, normocytic with a low or normal reticulocyte count. As with other cytopenias, inhibitor cytokines play a central role. In addition, there is an inappropriately low serum level of erythropoietin for the degree of anaemia. Treatment with recombinant erythropoietin may be helpful in patients with an endogenous erythropoietin level of < 500 IU/L. For most patients with severe anaemia, however, management is with red cell transfusions when clinically indicated. An occasional patient develops chronic red cell aplasia following parvovirus infection and may be helped by infusions of intravenous immunoglobulin.

Drugs may cause or exacerbate anaemia, the main culprits being zidovudine, ganciclovir and chemotherapeutic agents, all of which lead to marrow suppression; primaquine and dapsone may provoke oxidative haemolysis in patients with glucose-6-phosphate-dehydrogenase deficiency and even, in high dose, in patients with normal enzyme levels.

Bone marrow changes

Myelodysplasia

Abnormalities in the bone marrow are very common at all stages of HIV disease (Table 23.2), increasing in frequency as the disease progresses. The most common abnormal finding is of dysplasia affecting one or more of the cell lines. In general, the more advanced the disease, the more marked the dysplasia, and, although erythroid dysplasia is the most common finding, being recognized in over 50% of HIV-infected patients, abnormal granulocytic and megakaryocytic development is encountered in approximately one-third of patients.

Dyserythropoiesis may be manifest by florid megaloblastic change. This is unrelated to serum cobalamin and folate levels, or to drug therapy with zidovudine or folate antagonists, although these drugs may accentuate it. Erythroblasts are often bi- or multinucleated, with an irregular nuclear outline and basophilic stippling (Figure 23.2). Abnormal sideroblasts including ringed forms may be present. The frequently observed reticuloendothelial iron block is likely to be secondary to concurrent infection or chronic disease. Erythropoiesis appears disorganized on trephine biopsy with poorly formed erythroid islands.

Dysplastic features in megakaryocytes are common, occurring in over one-third of marrows and including nuclear hypolobulation and micromegakaryocytes (Figure 23.3). On trephine biopsy, megakaryocyte hyperplasia and clustering may be very pronounced. Increased numbers of naked megakaryocytic nuclei are a consistent feature.

Granulocytic dysplasia may be apparent at all stages of maturation, with giant metamyelocytes, nuclear abnormalities including detached nuclear fragments and Pelger cells reflecting

Table 23.2 Features of bone marrow in HIV disease.

Dysplasia	70% of marrows show some dysplastic features
	Erythroid dysplasia 60%
	Granulocytic dysplasia 30%
	Megakaryocytic dysplasia 40%
Cellularity	Increased in over 50%
	Hypocellular 15%
Fibrosis	Seen in 20–50% of trephines and may make aspiration difficult
Reticuloendothelial iron block	Common manifestation of chronic disease
Histiocytes	Increased and may show haemophagocytosis
Plasma cells	Increased and may be atypical
Opportunistic infections	Culture or examination of slides may show acid-fast bacilli (AFB), leishmania, histoplasma, pneumocystis, cryptococcus
Granulomas	Seen in infection with AFB and cryptococcus
Lymphoid aggregates	Reactive nodules
AIDS-related lymphoma (ARL)	20% of patients with ARL have bone marrow involvement
Figure 23.2 Erythroid dysplasia in HIV disease.
Figure 23.3 Dysplastic megakaryocytes in HIV disease.

Figure 23.4 Bone marrow trephine biopsy in HIV disease, showing hypercellularity and increased numbers of dysplastic megakaryocytes.
Figure 23.5 Bone marrow trephine biopsy in HIV disease, showing increased fibrosis.

dysfunctional nuclear maturation. On trephine biopsy, the atypical localization of immature precursors, a feature that has been highlighted in primary myelodysplastic syndrome, is sometimes observed in HIV marrows. Apoptosis is increased. In non-HIV patients, granulocytic dysplasia may precede acute leukaemia. Although several HIV antibody-positive patients with acute myeloid leukaemia have been described, the role of myelodysplasia in the evolution of acute leukaemia in HIV disease is uncertain. Its rarity and the failure to detect chromosomal abnormalities in patients with marked dysplastic changes suggest that myelodysplasia in the setting of HIV disease is not generally a pre-leukaemic state, thus differing from the classic myelodysplastic syndrome. The term 'HIV-related myelodysplasia' has been coined to describe the changes in HIV disease.

Ultrastructure studies of bone marrow cells from patients infected with HIV have shown abnormalities in erythroid cells, marrow granulocytes, plasma cells and stromal cells, which were attributed to a direct effect of HIV infection. No definite viral particles were detected at electron microscopy level, although the presence of incomplete virus particles was not excluded. The abnormalities in stromal cells lend credence to the hypo-thesis that disturbances in the microenvironmental regulation of haemopoiesis may contribute to cytopenias.

Cellularity

Marrow from HIV-infected patients is sometimes difficult to aspirate and the trails are of decreased cellularity. The true marrow cellularity is better appreciated on trephine biopsy, which is hypercellular in a majority of patients (Figure 23.4). The difficulty in aspiration may in part be due to the increased reticulin fibrosis seen especially in hypercellular marrows (Figure 23.5). Hypercellularity of the marrow in the face of peripheral cytopenia is a very common finding in HIV disease and is likely to reflect myeloid dysplasia and ineffective haemo-poiesis. Indeed, there is a correlation between observed marrow dysplastic changes and the peripheral blood findings of anaemia and leucopenia.

Red cell hypoplasia has been described in patients with HIV disease and may be associated with infection with B19 parvovirus

and disseminated *Mycobacterium avium intracellulare.* Severe erythroid hypoplasia has also been described in patients receiving therapy with zidovudine.

Gelatinous transformation (serous fat atrophy) is common in marrow from HIV patients and has been described previously in patients with severe malnutrition and weight loss.

Histiocytes

Increased numbers of histiocytes are often seen in the bone marrow and in many patients haemophagocytosis is striking. Reactive haemophagocytosis has been described in patients suffering from a wide variety of viral, bacterial, fungal and parasitic infections and is more common in immunosuppressed patients. In many of the patients with HIV infection who show increased numbers of marrow histiocytes, there is no obvious infective cause and it is likely that HIV itself is the trigger to histiocyte proliferation and phagocytosis, probably by initiation of cytokine production, resulting in macrophage stimulation. It is likely that as a result of HIV infection the marrow produces a histiocytic reaction, which varies from increased numbers of histiocytes to a full-blown haemophagocytic syndrome with severe pancytopenia.

Plasma cells

Plasma cells are often strikingly increased in the marrow of HIV-infected patients. They may represent a physiological response to antigenic stimulation by viruses or other infective agents, or may be secondary to dysregulated B-cell proliferation due to HIV. The marrow plasmacytosis is not confined to those patients with advanced HIV disease in whom opportunistic infections could be implicated, but is seen also in patients at an early stage who have no concurrent infections. The plasma cells are often morphologically abnormal and may appear in clusters. A polyclonal increase in gammaglobulins occurs in most HIV patients. Paraproteinaemia occurs in approximately 9% of homosexual HIV antibody-positive men without AIDS. This is much higher than the incidence of paraproteins in healthy people of similar age and may result either from changes in T-cell regulation or from the activation of B lymphocytes directly infected by HIV. The prognostic significance of paraproteinaemia in HIV antibody-positive patients is unknown. It does not appear to be more common in patients developing non-Hodgkin's lymphoma (NHL), although this also occurs in the setting of clonal B-cell activation. Some of the paraproteins have activity against HIV *gag* and *pol* gene products and may represent a vigorous immune response to HIV infection.

Multiple myeloma has been described in a few patients with HIV disease and occurs at a much younger age than in the general population.

Lymphoid aggregates

Lymphoid aggregates are identified in one-third of trephine biopsies and are likely to be benign manifestations of infection with HIV rather than a response to opportunistic infections or a herald of malignant lymphoma.

Opportunistic infections

Bone marrow examination and culture have a contribution to make to the diagnosis of opportunistic infections. Trephine biopsy may yield histochemical evidence of acid-fast bacilli or fungal organisms (Figure 23.6). Acid-fast bacilli (both *Mycobacterium tuberculosis* and atypical mycobacteria) may be cultured from the bone marrow of patients with disseminated infection. The bone marrow may be the only site of culture, despite culturing of blood, induced sputum and bronchoalveolar lavage.

Disseminated infection with *Leishmania donovani-infantum* and *Histoplasma capsulatum* may be diagnosed on the basis of marrow examination (Figures 23.7, 23.8 and 23.9). Clinically, these infections may be atypical in immunosuppressed patients and serological tests are not always helpful. Marrow aspirate and trephine biopsy material, as well as marrow culture, are useful in the monitoring of response to treatment.
Figure 23.6 Acid-fast bacilli in trephine biopsy in HIV disease.

Figure 23.8 Leishman–Donovan bodies in trephine biopsy of patient with AIDS.

(a)

(b)

Figure 23.9 (a and b) *Histoplasma capsulatum* in macrophage in bone marrow of patient with AIDS.

Cryptococci and *P. carinii* have been demonstrated in marrow aspirates and trephine biopsies in patients infected with HIV. Patients in whom opportunistic organisms are present in the bone marrow are profoundly immunosuppressed, as manifest by very low CD4 cell counts. This is in keeping with the observa-

Figure 23.10 Bone marrow trephine biopsy from a patient with AIDS, showing well-defined granuloma.

tion that the major risk factor for infection with *Mycobacterium avium–intracellulare* is the level of immune dysfunction.

Granulomas (Figure 23.10) may be seen in marrows of patients secondarily infected with mycobacteria and have also been described in cryptococcal infection. Well-formed granulomas are not often associated with atypical mycobacteria and, when associated with *M. tuberculosis*, caseation is usually conspicuously absent.

Clinical value of bone marrow examination
Examination of the bone marrow is useful in the diagnosis and staging of AIDS-related lymphoma, marrow infiltration being seen in approximately one-fifth of patients; in some patients the marrow represents the initial evidence of lymphoma. Kaposi's sarcoma is extremely rare in the bone marrow.

Culture of marrow aspiration and careful examination of slides from aspirate and trephine biopsy are of value in the diagnosis of opportunistic infections and in the monitoring of treatment.

Immune thrombocytopenia can be suspected on the evidence of plentiful megakaryocytes in the marrow, along with peripheral thrombocytopenia. The value of marrow examination in elucidating the cause of anaemia and leucopenia is less obvious but has occasionally yielded an unexpected diagnosis of disseminated leishmaniasis or histoplasmosis in patients with pancytopenia.

The clinical value of bone marrow examination is in:
1 microbiological culture in patients with fever of unknown cause;
2 exclusion or staging of lymphoma;
3 diagnosis of immune thrombocytopenic purpura;
4 elucidation of cytopenias (value less clear).

Lupus anticoagulant

The lupus anticoagulant has been described in patients infected with HIV. This circulating anticoagulant is an IgG or IgM

immunoglobulin, which inhibits *in vitro* activity of the pro-thrombin activator complex, thus prolonging the partial thromboplastin time and, to a lesser extent, the prothrombin time.

Thrombotic events in patients with AIDS are rare when compared with patients with the lupus anticoagulant in other settings, where thromboembolic phenomena are common. Patients with a prolonged partial thromboplastin time secondary to a lupus anticoagulant do not appear to be at increased risk of bleeding.

The pathophysiological basis for the development of the lupus anticoagulant in HIV disease is not understood, but an association with active opportunistic infection, especially with *P. carinii* has been suggested.

Anticardiolipin antibodies have also been described in HIV disease but do not correlate with the presence of a lupus anticoagulant.

Figure 23.11 Diffuse large-cell lymphoma (courtesy of Professor K Henry).

AIDS-related lymphoma

It has long been recognized that patients with both inherited and acquired abnormalities of cellular immunity have an increased incidence of non-Hodgkin's lymphoma. The incidence of lymphoproliferative disorders in patients with primary immunodeficiency diseases, such as ataxia telangiectasia or the Wiscott–Aldrich syndrome, is approximately 100 times greater than expected; NHL in allograft recipients has an incidence 60 times that of the general population. In a similar way to these patients, individuals infected with HIV have defective cellular immunity and are thus at risk of developing B-cell malignancy, which is recognized as an AIDS-defining diagnosis. Both systemic and cerebral NHL occur in this population with the relative risk being approximately 100-fold higher than that expected in the general population.

The introduction of combination highly active anti-retroviral treatment (HAART) in the late 1990s has led to a reduction in AIDS-defining illnesses, including NHL. Adjusted incidence rates show a decline in incidence of AIDS-related lymphoma (ARL) from 1992 to 1996, and from 1997 to 1999, with a relative risk ratio of 0.58. This decline is most marked for cerebral lymphoma but is also significant for systemic disease. There remains, however, a significant risk among patients on HAART, and a higher risk in those who do not have access to HAART, either because of economic restrictions or because they are unaware of their HIV status. Overall, it is estimated that approximately 10% of HIV-infected individuals will develop NHL.

Histopathology

Over 90% of systemic ARL are high-grade B-cell tumours and within the WHO/REAL classification approximately two-thirds are diffuse large cell lymphomas (20% of which are confined to the central nervous system), whereas one-third are Burkitt's
Figure 23.12 Burkitt's lymphoma: small non-cleaved lymphoma with scattered macrophages giving characteristic 'starry-sky' appearance (courtesy of Professor K Henry).

lymphoma (Figures 23.11 and 23.12). The incidence of T-cell lymphoma is also increased but only five- to tenfold. In addition, two uncommon lymphoproliferative disorders that are associated with human herpesvirus 8 are seen in this population: primary effusion lymphoma (PEL) or body-cavity lymphoma and multicentric Castleman's disease. Histologically, PEL is a CD30⁻(Ki-1)-positive anaplastic large cell lymphoma.

Occasionally, low-grade B-cell lymphomas are reported in HIV patients but there is no epidemiological evidence that these cases have increased in parallel with the AIDS epidemic and no evidence that these patients respond differently to treatment when compared with non-HIV-infected individuals. A few patients with B-cell acute lymphoblastic leukaemia (FAB L3) in HIV disease have been described, and it is likely that these cases represent peripheral blood involvement with Burkitt's lymphoma.

Aetiology

In all groups of immunosuppressed patients it seems that malignant lymphoma arises in the setting of polyclonal B-cell proliferation secondary to impaired T-cell surveillance. Reactivation of latent Epstein–Barr virus (EBV) infection is likely to play a significant role in this proliferation. Following primary infection with EBV, some B cells appear to switch to a latency 1 pattern expressing only EBNA-1, a nuclear antigen, and these cells may escape destruction by cytotoxic T lymphocytes and persist, thus permitting reactivation of EBV, long-term stimulation and proliferation of B lymphocytes resulting in the development of NHL.

Some B-cell lymphomas from patients with ataxia telangiectasia have been shown to contain the EBV genome and several studies have documented its presence in the vast majority of B-cell lymphomas from allograft recipients. The EBV genome is a uniform finding in endemic African Burkitt's lymphoma, although it is uncommon in the sporadic type. The precise role of EBV in the development of ARL is controversial; EBV genomic sequences or EBV proteins have been demonstrated in fewer than one-half of HIV-associated Burkitt's lymphoma, although they have been shown in the majority of systemic and primary cerebral lymphomas.

HIV itself is unlikely to be directly involved in the malignant transformation of B-lymphocytes. No HIV sequences have been detected in B-lymphoma tissues and they are not detected in the reactive B-cell hyperplasia commonly seen before the evolution of lymphoma. HIV may, however, indirectly encourage the development of lymphoma by initiating the release of cytokines such as IL-1, IL-6, IL-10, TNF and B-cell growth factors, which stimulate B-cell proliferation.

The continuous stimulus to B lymphocytes may permit mutations in critical oncogenes or tumour-suppressor genes, eventually resulting in malignant transformation. The development of multiple clonal rearrangements of immunoglobulin genes within the reactive lymphadenopathy lesions of HIV-infected patients may represent precursors to the development of lymphoma.

Specific chromosomal translocations have been described in endemic, sporadic and HIV-related Burkitt's lymphoma in which t(8;14), t(8;22) or t(8;2) are commonly found. These translocations permit deregulation of the c-*myc* oncogene, which might encourage malignant transformation.

Some data suggest that the HIV diffuse large cell lymphomas are primarily driven by rearrangements of the oncogene *bcl 6*. In addition, mutations in the *p53* cancer-suppressing gene have been found in about 40% of cases of ARL, mostly Burkitt's.

In summary, it is likely that lymphoma in HIV disease arises from the chronic stimulation of B lymphocytes by EBV or cytokines that are produced as a result of HIV infection. In the setting of defective cellular immunity, this stimulation of B lymphocytes may lead to mutation in critical oncogenes or tumour-suppressor genes, permitting c-*myc* activation, clonal selection and the development of malignant lymphoma.

Clinical picture

In more than one-half of the patients with ARL, this is the presenting feature of AIDS. Data from the CDC relating to patients in whom lymphoma was the AIDS-defining diagnosis suggest that Burkitt's lymphoma is seen at a younger age than diffuse large cell lymphoma, the incidence of which increases with age. Primary cerebral lymphomas occur equally in all age groups and are of the immunoblastic type.

The majority (up to 98%) of patients with systemic ARL present with extensive disease and systemic (B) symptoms. Extranodal lymphoma is very common, occurring in the majority of patients at presentation: frequently, the disease is exclusively extranodal. The most common extranodal sites of lymphoma in HIV patients are gastrointestinal tract, liver, meninges (up to 20%), lung, bone marrow (approximately 20%) and oropharynx. Lymphoma in unusual sites such as the heart, adrenals, kidneys, skin, testes, mouth, muscle, soft tissue, anus and rectum occur more frequently in HIV-infected patients.

Primary cerebral lymphoma can be difficult to distinguish from cerebral toxoplasmosis and magnetic resonance imaging (MRI) may be more sensitive than computerized tomography (CT) in making the distinction, although only brain biopsy can make a definitive diagnosis. In practice, however, a trial of anti-toxoplasma therapy is fully justified, with brain biopsy being only rarely indicated. The presence of EBV, detected by polymerase chain reaction in cerebrospinal fluid, may give a clue to the diagnosis without recourse to biopsy in many patients with HIV-associated primary cerebral lymphoma.

Management

Patients with HIV disease are already at risk of opportunistic infections as a result of HIV-related immune suppression; chemotherapy would be expected to increase this risk. Furthermore, the bone marrow in AIDS patients is frequently impaired and likely to be seriously compromised as a result of marrow-toxic chemotherapeutic agents. The immunosuppressive effects of chemotherapy may precipitate acceleration of the HIV disease itself. Management therefore poses considerable problems with this group of patients.

However, the advent of HAART, improved prophylaxis against opportunistic infections and intrathecal prophylaxis support a more aggressive approach to treatment for systemic ARL, with better outcomes being reported. Many units now use standard-dose chemotherapy and are reporting response rates and overall survival that approach those in the immunocompetent. The prognosis for primary cerebral lymphoma remains very poor such that palliative treatment is usually the only option.

Table 23.3 Features of AIDS-related non-Hodgkin's lymphoma.

Histopathology (%)	Diffuse large cell (DLC)	65 (including primary cerebral lymphoma)
	Small cell non-cleaved (Burkitt's)	33
	Primary effusion lymphoma	2
EBV implicated (%)	Burkitt's	< 50
	Systemic DLC	80
	Primary cerebral lymphoma	100
	Primary effusion lymphoma	100
*Prognosis features for AIDS-related NHL**		
Major adverse prognostic factors	Prior AIDS diagnosis	
	CD4 count < 100/μL	
	ECOG performance status > 2	
	Primary cerebral origin	
Minor adverse prognostic factors	Bone marrow involvement	
	Extranodal disease	
	Raised serum LDH	
	Age > 35 years	

*Good prognosis defined by less than two major adverse prognostic factors; poor prognosis is defined by more than one major adverse prognostic factor.

In centres without access to HAART, a prognosis-stratified approach to the management of ARL may be taken. Patients falling into the poor prognosis group (Table 23.3) may be treated with palliative intent using a combination of prednisolone, vincristine and bleomycin, with radiotherapy for localized symptomatic lesions. The life expectancy for these patients is 3–6 months. Patients with a better prognosis may be treated with combination chemotherapy such as CHOP (cyclophosphamide, doxorubicin, vincristine and prednisolone) or mBACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine and dexamethasone), perhaps with the support of granulocyte colony-stimulating factor. Complete remission rates are approximately 60%. The role of rituximab (a monoclonal antibody directed against CD20) in ARL is under investigation.

Following chemotherapy, 40% of the patients with good prognostic features will remain in remission until another AIDS-related illness such as opportunist infection occurs. Recent studies show higher median survivals with little change in response rate for ARL, suggesting that the improved duration of survival is related to reduced deaths from opportunistic infections in the HAART era among patients who have durable remissions of their ARL.

The concomitant use of antiretroviral agents with chemotherapy is generally accepted practice with the possible exceptions of zidovudine, which significantly adds to the myelosuppression of combination chemotherapy, and didanosine, which may worsen the peripheral neuropathy caused by vincristine. Little is known about the pharmokinetic interaction of protease inhibitors and non-nucleoside reverse transcriptase inhibitors with chemotherapy.

It is routine practice to instigate prophylaxis against pneumocystis, *M. avium intracellulare* and toxoplasmosis in individuals receiving chemotherapy for ARL.

As there is a high rate of meningeal involvement in systemic ARL, intrathecal chemotherapy should be given to patients with meningeal disease or at high risk of cranial disease by virtue of Burkitt's histology or extensive paranasal sinus and base of skull disease. Most centres also recommend prophylactic chemotherapy for patients with bone marrow involvement.

A recent development in ARL chemotherapy has been the introduction of infusional therapy with CDE (cyclophosphamide, daunorubicin and etoposide) or EPOCH (etoposide, prednisolone, vincristine, cyclophosphamide and daunorubicin). In a recent study by Little and co-workers, a dose-adjusted EPOCH regimen with suspension of HAART achieved a complete remission in 74% of patients and at 53 months median follow-up, disease-free and overall survival were 92% and 60% respectively. A multicentre trial is under way to confirm these results.

The dose-adjusted strategy was developed to reduce haematological toxicity while maintaining maximum drug doses. *In vitro* studies have shown that tumour cells are relatively less resistant to prolonged low-concentration exposure compared with brief high concentration exposure. In addition, infusional therapy is more effective against highly proliferative tumours such as ARL.

The question is raised as to whether treatment with HAART alters the biology of the tumour, making it less resistant to

chemotherapy. Low BCL-2 and high CD10 expression are observed, both implying a germinal centre origin, a feature associated with good-prognosis disease. The high expression of p53 indicates a highly proliferative tumour, but in HAART-treated patients this is not associated with a poor outcome.

In Little's study, discontinuing HAART during chemotherapy led to increases in viral load, which fell below baseline within 3 months of resuming treatment, and decreases in CD4 cells, which recovered within 4 months of reintroducing HAART. This suggests that withholding antiretroviral treatment does not significantly worsen the AIDS prognosis while avoiding the potentially adverse effects on lymphoma treatment.

Hodgkin's disease

The incidence of Hodgkin's disease is increased up to eightfold in HIV-infected individuals and is strongly associated with EBV. Most patients present with advanced disease and extranodal involvement with poor prognosis subtypes – mixed cellularity or lymphocyte depleted. The outcome of therapy is poor with opportunist infections and poor marrow reserve, making treatment difficult.

Drugs used in HIV disease

Inevitably, in a disease that results in opportunistic infections and opportunistic malignancies, multiple drug therapy is common, especially in patients with advanced disease. These are the very patients who commonly have compromised bone marrow function, and thus it is not surprising that marrow-toxic antiretroviral, antimicrobial and antimitotic drugs may have profound effects on their blood picture.

The introduction of HAART has transformed the prognosis in HIV infection with dramatic reductions in opportunistic infections and mortality. Long-term survival now seems possible, although deaths from HIV-associated liver disease and lymphoma are increasing as patients survive longer. At present, guidelines recommend initiating treatment when the CD4 count falls below 350 cells/μL or when the viral load (plasma HIV RNA) is in excess of 30 000 copies/mL in asymptomatic individuals. Patients who present with clinical manifestations of HIV should also receive treatment.

Antiretroviral agents

Antiretroviral drugs fall into three groups:
1 Nucleoside analogues, such as zidovudine, are phosphorylated within cells to their active triphosphate metabolites, which are incorporated into nucleic acids. They prevent the formation of double-stranded DNA from viral RNA by reverse transcriptase. Nucleotide analogues, for example tenofovir, have recently become available and work by a similar mechanism.

2 Non-nucleoside reverse transcriptase inhibitors prevent the same process; they are not incorporated into nucleic acids but bind directly to reverse transcriptase.
3 Protease inhibitors inhibit the viral protease that is responsible for cleaving precursor proteins, thereby preventing formation of fully formed infectious viral particles.

HAART usually comprises three or more drugs in combination. The usual starting combination is two nucleoside analogues, together with either a protease inhibitor or a non-nucleoside reverse transcriptase inhibitor. Treatment failure as determined by viral load, CD4 cell count or clinical progression requires a new regimen, with substitution or addition of at least two new agents. Newer agents including attachment inhibitors, fusion inhibitors, coreceptor antagonists and integrase inhibitors are undergoing clinical trials at present.

Prophylaxis against opportunistic infections

The timing of institution of primary prophylaxis differs according to the infective agent. In the prevention of *P. carinii* infection, a CD4 cell count of less than 200 cells/μL indicates a requirement for prophylactic treatment, for *Toxoplasma gondii*, less than 100 cells/μL, and for *M. avium*, less than 50 cells/μL.

Haematological toxicity of drugs used in HIV disease

Antiretroviral agents

Haematologically the most toxic antiretroviral agent is the nucleoside analogue, zidovudine. This was the first drug shown to be inhibitory to HIV and was initially used in larger doses than employed at present. Anaemia was the most common haematological toxic effect and repeated blood transfusions were frequently necessary, especially in patients with advanced disease. Marrow hypoplasia was often severe. New combination treatments with antiretroviral agents now permit smaller doses of zidovudine to be used with consequent reduced toxicity. Other nucleoside analogues such as didanosine (ddI), zalcitabine (ddC) and lamuvidine (3TC) have a low incidence of marrow toxicity. Protease inhibitors such as saquinavir, ritonavir and indinavir do not appear to suppress haemopoiesis.

Antimicrobial agents

Cotrimoxazole
Cotrimoxazole is effective both in the treatment and prevention of *P. carinii* pneumonia (PCP). A high proportion of HIV-infected patients, however, experience adverse effects from this drug combination, thus limiting its use. The most common problem is nausea, although this is less troublesome with intravenous administration. Skin reactions are commoner in the

HIV-infected population and the Stevens–Johnson syndrome is a potentially life-threatening complication. The dose of cotrimoxazole used in the treatment of PCP is high, and bone marrow toxicity is common due to the effects on folic acid metabolism and possibly to the suppression of DNA synthesis of marrow cells. Treatment with folic acid or folinic acid does not reduce the severity of marrow suppression and its attendant pancytopenia.

Pentamidine

Pentamidine isethionate is very effective against *P. carinii* but has major toxic side-effects of hypotension, hypoglycaemia, renal damage and bone marrow suppression, although the latter is less frequent than with cotrimoxazole. Nebulized pentamidine is less toxic and can be used in the treatment of mild or moderate PCP or in prophylaxis.

Dapsone

Dapsone is used as an agent for PCP prophylaxis and in combination with trimethoprim for the treatment of PCP but can cause haemolytic anaemia at high dosage and special care must be taken to exclude glucose-6-phosphate dehydrogenase deficiency in susceptible individuals.

Fansidar

This combination of sulphadoxine and pyrimethamine has been shown to be an effective prophylactic combination against PCP and may also provide effective prophylaxis against toxoplasmosis. In a twice-weekly regimen, haematological side-effects are uncommon, but long-term administration may lead to cytopenias, especially if other folate inhibitors such as cotrimoxazole are also administered. Fansidar is rarely used now because of severe skin rashes.

Ganciclovir

Ganciclovir (dihydrophosphoguanine) is a derivative of acyclovir and is effective when given intravenously in serious cytomegalovirus (CMV) infection, including CMV retinitis. It produces severe bone marrow suppression, especially neutropenia, in a high percentage of patients and this is probably worsened by concurrent administration of zidovudine. Valganciclovir, an oral prodrug of ganciclovir, has recently been shown to be as effective for induction treatment of CMV retinitis as ganciclovir, and has a similar degree of haematological toxicity. Oral ganciclovir is less marrow toxic than the intravenous preparation but is ineffective as treatment of CMV though may be useful for prophylaxis.

Antimitotic agents

Kaposi's sarcoma

The vinca alkaloids vinblastine and vincristine are both effective agents against Kaposi's sarcoma. Vinblastine is more toxic to the bone marrow than vincristine, especially when used in combination with doxorubicin. Bleomycin, also effective in Kaposi's sarcoma, does not usually lead to marrow suppression, whereas etoposide, another very effective agent, can lead to severe neutropenia. The suppressive effects of antimitotic agents are more pronounced in advanced HIV disease when the marrow is already compromised by the effects of HIV and, possibly, by concurrently administered antimicrobial or antiretroviral agents.

AIDS-related lymphoma

The problems of chemotherapy in NHL associated with HIV infection have been discussed earlier. As in Kaposi's sarcoma, the more powerful combinations of chemotherapeutic agents are significantly immunosuppressive and run the risk of precipitating opportunistic infections at the same time as provoking serious bone marrow suppression.

Hepatitis C in HIV disease

Hepatitis C virus (HCV) is especially common among haemophiliacs and intravenous drugs users, most of whom carry both viruses. As deaths from HIV disease are declining as a result of HAART, liver disease has become an increasing cause of morbidity and mortality. The immunodeficiency associated with HIV infection accelerates the course of HCV infection and the hepatotoxicity of anti-HIV drugs poses particular problems.

HIV antibody-positive patients who fulfil standard criteria for chronic hepatitis C (persistent elevated aminotransaminase levels, detectable serum HCV-RNA and necroinflammatory activity with portal or bridging fibrosis in the liver biopsy) respond less well to combination treatment with interferon-α and ribavirin than HIV antibody-negative patients, although this is linked to the degree of immunosuppression. Slow-release interferon-α, covalently bound to polyethylene glycol (pegylated form) can provide continuous exposure to interferon-α with a single weekly injection. Ribavirin can cause haemolytic anaemia, although this is not usually severe. Care should be taken when it is prescribed along with other nucleoside analogues (especially zidovudine) that cause bone marrow suppression and ddI, which causes severe mitochondrial toxicity.

Histocompatibility

Ann-Margaret Little, Steven GE Marsh and J Alejandro Madrigal

24

The major histocompatibility complex and human leucocyte antigens

In the 1950s, three independent scientists, Jean Dausset, Rose Payne and Jon van Rood, described the presence of alloantibodies in the sera of individuals exposed to genetically non-identical tissues such as the fetus in pregnancy and/or blood cells after transfusion. These alloantibodies were subsequently shown to react against protein antigens, encoded by a genetic region called the major histocompatibility complex (MHC). The MHC had also independently been identified in animal models of skin transplantation and tumour immunology, when genetically different strains of mice were shown to reject transplants from one another. Genetically identical mice could accept such transplants without rejection.

These observations led to theories of self–non-self discrimination, and the elucidation of the genetics of the MHC genes encoding the protein 'histocompatibility' (or transplantation) antigens. Analysis of the structure and function of histocompatibility antigens has led to the establishment of routine transplant protocols for both solid organ and haemopoietic stem cells between genetically disparate individuals.

The MHC in humans is located on the short arm of chromosome 6 (6p21.3). This region of the genome has been studied extensively and fully sequenced as part of the human genome project (www.sanger.ac.uk/HGP/Chr6/). The MHC is an extremely gene-dense region of the genome and it can be divided into 'three' subregions, based on the type of genes found.

The genes encoding histocompatibility antigens are located within the MHC class I and II regions (Figure 24.1). These genes are called HLA genes (defined as human leucocyte antigens – although originally called human locus-A). HLA genes found in the class I region differ in structure from those found in the class II region and, as a result, the encoded proteins also differ. HLA class I genes encode a polypeptide of ~340 amino acids. This polypeptide is found as a cell-surface transmembrane glycoprotein and is associated with the soluble protein β_2-microglobulin (β_2m) encoded by a gene on chromosome 15.

There are three classical class I genes: HLA-A, HLA-B and HLA-C. Their encoded proteins are expressed on virtually all nucleated cells within the body and also on platelets. The expression of HLA class I proteins varies for different types of tissues. For example, expression is high on lymphocytes but low on hepatocytes and tissues constituting the nervous system. In addition, there are class I genes encoding non-classical class I molecules called HLA-E, HLA-F and HLA-G. The tissue distribution of these molecules is more restricted than that of HLA-A, B and C, and this is a reflection of their differing function. These molecules are not considered as transplantation antigens.

HLA class II molecules are overall similar in structure to HLA class I molecules. They are also composed of two polypeptide chains (α and β); however, both are encoded by MHC genes. HLA class II molecules, unlike class I, have a restricted tissue distribution. They are expressed on haemopoietic cells such as B cells, dendritic cells, macrophages and also activated (but not resting) T cells. There are three classical class II molecules: HLA-DR, HLA-DQ and HLA-DP. In addition, there are other non-classical class II molecules encoded by the HLA-DM and HLA-DO genes. These non-classical class II molecules are not transplantation antigens, but do contribute to the antigen-presenting function of class II molecules.

The class III region of the MHC does not contain any HLA genes. This region contains genes encoding proteins with various different functions, including proteins involved in the immune response such as TNFα and -β and complement components C2, C4 and Bf.
Figure 24.1 The major histocompatibility complex. Approximate location of HLA-A, -B, -C, -DRA, -DRB, -DQA, -DQB, -DPA and -OPB genes are indicated. Other related genes are also present.

Structure of HLA proteins

The X-ray crystallographic structure of the extracellular domains of several HLA class I and II proteins has been obtained. The structures are divided into four domains, as illustrated in Figure 24.2. The two most membrane-distal domains, α_1 and α_2 for HLA class I and α_1 and β_1 for HLA class II, form a β-pleated sheet, surrounded on both sides by two α-helices. In both class I and II structures, a short peptide was found bound in the cleft formed. Thus, both class I and class II proteins can be considered as trimolecular proteins consisting of three subunits: HLA heavy chain, β_2-microglobulin and peptide form class I molecules, and HLA α- and β-chains and peptide form class II molecules.

Antigen processing and presentation

Peptide binding to HLA class I and II proteins plays an important role in the function of these molecules. The way in which peptides are derived and the binding procedure differs for the two classes of molecules, and this is reflected in the different function of these molecules.

HLA class I molecules are assembled within the endoplasmic reticulum (ER). The heavy chain is directed to the ER via a leader peptide sequence. Within the lumen of the ER, the extracellular domains of the heavy chain associate with β_2-microglobulin. This association is mediated by ER-resident chaperones including calnexin and calreticulum.

Association with peptide also occurs within the ER. Peptides are derived from the cytoplasmic degradation of molecules that takes place in the proteasome, a multicatalytic protein complex. Peptides produced by the proteasome are actively transported into the ER via a transmembrane peptide pump called TAP (transporter associated with antigen processing). Association between HLA class I heavy chain–β_2-microglobulin complex and peptide is catalysed by another ER resident chaperone called tapasin.

Once the class I trimolecular complex is formed, the molecule can leave the ER and complete its journey to the cell surface via the Golgi apparatus.

The journey of a class II molecule differs from that of a class I

Figure 24.2 HLA class I and II molecules showing protein domains and bound peptide.

molecule. Both α- and β-chains are directed to the ER, where a complex of three αβ chains and three invariant chains is formed. The invariant chain (Ii) is also a transmembrane protein. Association of HLA class II molecules with Ii effectively blocks the peptide binding site on the class II molecule, thus preventing association of ER-resident peptides. Invariant chain cytoplasmic tail sequences direct the class II molecule through the Golgi apparatus, but, unlike class I molecules, the class II molecules make a detour to endosomal vesicles before arriving at the cell surface. The non-classical HLA-DM and HLA-DO molecules are located within endosomal vesicles, and it is here that the Ii chain is cleaved, leaving a peptide, called CLIP, to block the class II peptide binding cleft. Specific peptide binding is catalysed by HLA-DM, and may also be aided by HLA-DO. The peptides that bind to class II molecules are derived either from internalization of cell surface or from extracellular proteins. Thus, the antigen presentation pathway for HLA class II molecules differs from that of HLA class I molecules by directing the class II molecules to a location where they can bind peptides that differ from those presented by class I molecules.

HLA function

Once presented at the cell surface, HLA molecules are subjected to surveillance by circulating T cells and natural killer (NK) cells. Both of these cell types possess receptors that can recognize and interact with HLA molecules. Typically, T cells expressing the CD4 molecule recognize HLA class II molecules, and T cells expressing CD8 recognize HLA class I molecules. The specificity of interaction is determined during development of T cells within the thymus, such that circulating T cells should not interact with HLA molecules presenting peptides derived from normally expressed self proteins. However, the presentation of non-self peptides, for example peptides derived from viral or bacterial proteins, or aberrant expression of tumour antigens, can initiate activatory signals mediated by the T-cell receptor, resulting in the generation of an immune response against infected cells.

The interactions between HLA molecules and NK cell receptors play an important role in the function of NK cells. NK cells primarily function in innate immune responses. These cells express a range of receptors that can elicit either activatory or inhibitory signals. It is the balance between the two opposing signals that determines the action of an NK cell. Typically, interaction between HLA molecule and corresponding NK receptor resulting in a negative signal will outweigh any activatory signals; thus, the NK cell will not attack the cell expressing the HLA molecule. However, if a cell has lost expression of HLA molecules such as after malignancy or virus-induced downregulation, then the absence of the inhibitory signal will result in the activatory signal being dominant and allow NK cell-mediated attack on the target cell.

HLA nomenclature

The naming of HLA specificities falls under the remit of the WHO Nomenclature Committee for Factors of the HLA System. The Committee names HLA genes, alleles and serologically defined antigenic specificities. The names of the antigens, which were originally defined using either serological or cellular techniques, are a combination of letters that indicate the gene encoding the antigen and numbers assigned in chronological order of their description. An example of an individual's HLA type determined by cellular and serological methods is A1, A2; B7, B13; Cw6, Cw7; Dw1, Dw13; DR1, DR4; DR53; DQ5, DQ8; DPw1, DPw4.

The numbering of antigens encoded by HLA-A and -B genes is in a single series for historical reasons, as these antigens were originally believed to represent the products of a single gene. The use of a lower case 'w' between the gene name and antigen number to indicate a provisional specificity has been used, although in most cases these have been removed. The exceptions are Bw4 and Bw6, which represent public epitopes rather than distinct antigens, HLA-C antigens (e.g. Cw1), to distinguish them from complement factors, and the HLA-D and HLA-DP antigens defined by cellular techniques.

Many HLA antigens have been characterized by serological methods into two or more subtypes, which are called 'splits', with the parent antigen called 'broad'. Thus, both A23 and A24 are splits of the broad antigen A9. It is convention to indicate the broad antigen specificity in parentheses following the designation of the split, for example A23(9) or A24(9). A full listing of all the serologically and cellularly defined HLA antigens is given in Table 24.1.

Since 1987, the WHO Nomenclature Committee for Factors of the HLA System has assigned official names to HLA allele sequences. It was recognized that a single antigenic specificity, such as HLA-A2, defined by serology could be subdivided still further by DNA sequencing. Each allele is given a numerical designation that may be up to eight digits in length. The gene name is followed by an asterisk (*) and then the numerical designation; the first two digits indicate the allele group, which often corresponds to the broad serological antigen encoded by the allele. The third and fourth digits are used to list subtypes, numbers assigned in the order in which the DNA sequences have been determined. Alleles whose numbers differ in the first four digits must differ in one or more nucleotide substitutions that change the amino acid sequence of the encoded protein. The fifth and six digits are used to name alleles that differ only by synonymous nucleotide substitutions (also called silent or non-coding). The seventh and eighth digits are used to name alleles that differ in either intron, or 3′- or 5′-regions of the gene. Lastly, an allele may have a suffix indicating an aberrant expression; for example an N indicates that it is a null allele with no protein being expressed, an L indicates low cell-surface expression, and an S indicates that the molecule is expressed only in a soluble form.

	B67						

Broad specificities are indicated in parentheses.
Figure 24.3 The increase in number of HLA alleles identified by year.

For example, the A*24020101 and A*24020102L alleles differ only by a single nucleotide that lies within an intron at a splice site. A*24020101 is expressed at normal levels on the cell surface; however, A*24020102L is expressed at very low levels on the cell surface due to the splice mutation.

Many new HLA alleles are reported each year (Figure 24.3). Details of the most recent advances in HLA nomenclature can be found in the latest WHO Nomenclature Committee for Factors of the HLA System Report or by accessing the IMGT/HLA Sequence Database, the official database of the Nomenclature Committee (www.ebi.ac.uk/imgt/hla).

HLA polymorphism

The outstanding feature of HLA genes and the proteins encoded by the genes is the extensive polymorphism exhibited. At each of the genes, there are multiple possible variants (Tables 24.2 and 24.3). These variants are called alleles. The nucleotide sequence differences between HLA alleles at a given locus can be translated into the protein sequence and analyses of the polymorphism has demonstrated that most variation exists within the peptide-binding domains. Experimental data support this by showing that different HLA proteins can bind peptides with different sequences. Thus, one of the functions of HLA polymorphism is to allow the presentation of different peptides to the immune system. As there are six antigen-presenting 'classical' HLA molecules (HLA-A, -B, -C, -DR, -DQ, -DP), and most individuals are heterozygous for these loci; one can see that potentially each individual has 12 different HLA molecules, each of which can bind thousands of different peptides. The existence of a polymorphic polygenic antigen-presenting system gives each individual the capacity to elicit immune responses against a wide variety of protein antigens.

HLA polymorphism also varies within different populations.

Table 24.2 Number of HLA alleles and serologically defined antigens, by June 2003.

HLA gene	No. of alleles	No. of antigens
A	282	24
B	540	49
C	136	9
DRA	2	–
DRB1	342	20
DRB3	39	1
DRB4	12	1
DRB5	17	1
DQA1	20	–
DQB1	55	7
DPA1	20	–
DPB1	106	–

Variation in climate, geography and infectious agents are all factors that are considered to have influenced the evolution of HLA polymorphism, therefore it is not surprising to find that different ethnic groups display different HLA types.

Thus, HLA polymorphism functions as an advantage both at the level of an individual and population. The extreme diversity found makes it extremely likely that that someone somewhere should possess an HLA molecule that can be effective in generating an immune response against any infectious agent.

HLA associations with disease

As both HLA class I and class II molecules control the positive and negative selection of T-cell receptors in the thymus, it is not surprising to find many associations between HLA loci and

Table 24.3 Complete listing of defined HLA alleles and serological specificities, by June 2003.

HLA-A alleles	HLA-A antigen specificity	HLA-B alleles	HLA-B antigen specificity	HLA-C alleles	HLA-C antigen specificity	HLA-DR alleles	HLA-DR antigen specificity	HLA-DQ alleles	HLA-DQ antigen specificity	HLA-DP alleles	HLA-DP antigen specificity

immune system disorders such as autoimmune disease. The first strong association described is that of HLA-B27 with ankylosing spondylitis and related spondylarthropathies, where over 95% of affected individuals possess an HLA-B*27 allele. Despite tremendous effort to discover the immunological basis for the association between B27 and AS, the answer is still unknown. HLA type has also been associated with susceptibility to and protection from infectious diseases. Individuals possessing HLA-B*5301, an allele prevalent within African populations, are more likely to be resistant to severe malaria. This association is supported by experiments showing the B53 allotype can present a peptide derived from the malaria parasite.

HLA class II molecules are restricted in their tissue distribution. However appropriate stimulation can induce the expression of class II molecules on tissue where they are not normally expressed. This aberrant HLA class II expression may contribute to an autoimmune reaction by providing HLA/peptide complexes not encountered during T-cell receptor education in the thymus. Amongst the many associations between HLA class II molecules and autoimmune and/or inflammatory disease is rheumatoid arthritis and HLA-DR4. This association has been linked to the presence of an epitope contributed by residues 67, 70, 71 and 74 of the β-chain that contributes to a pocket (P4) in the peptide-binding site, thus supporting the role of peptide binding in the disease.

For other associations between HLA and disease, the answer has been found. Haemochromatosis has been associated with haplotypes possessing HLA-A*03. Genetic mapping has identified the gene, *HFE*, responsible for this association. Thus associations between HLA and disease may not be directly related to the HLA allotype but may be due to the presence of other genes that are closely linked or are hitch-hiking within particular HLA haplotypes.

More recently, associations between HLA type and hypersensitivity to drugs have been reported. A high number of patients receiving abacavir, an inhibitor of HIV-1 reverse-transcriptase, who subsequently demonstrated life-threatening hypersensitivity have been found to possess haplotypes containing HLA-B*5701 and HLA-DRB1*0701. The mechanism for such association is currently not known.

HLA matching in transplantation

The benefits of HLA polymorphism in allowing the generation of immune responses against a wide range of antigens is completely negated when transplantation of organs and cells between genetically disparate individuals is considered.

Typically, an individual will possess T cells capable of reacting against a foreign antigen at a frequency of 1 in 10^4–10^5. However, if cells from two HLA disparate individuals are mixed, the frequency of responding cells can be as high as 1–10%. These responding cells are called alloreactive cells.

Alloreactions are responsible for the inability to transplant organs and cells between genetically different individuals. To overcome alloreactivity, it is necessary to define the HLA type of donor and recipient, and to select an HLA-matched donor wherever possible. In solid organ transplantation, HLA matching is encouraged for kidney transplants, where outcome data support a beneficial role of HLA matching. However, immunosuppressive therapy is extremely effective in renal transplantation, and this allows for imperfect matching to be performed, yet it is critical to avoid transplantation of mismatched donor kidneys possessing HLA types against which the patient may have raised alloantibodies as a result of a previous mismatched transplant, pregnancy or blood products. The presence of such alloantibodies can lead to hyperacute rejection. HLA matching for other solid organs such as liver and heart and lung is not usually performed. The liver appears to be an immunoprivileged site that tolerates HLA mismatches, whereas heart and lung transplants are usually performed on patients for whom no other chance of life is possible thereby not allowing for selection of HLA-matched donors. Alloreactions mediated following solid organ transplants are usually only directed at the transplanted organ.

Patients receiving blood products, for example random pooled platelets, can produce antibodies against the HLA molecules present on the transfused platelets. The presence of anti-HLA antibodies can lead to platelet refractoriness, and for these patients it is advised to seek HLA-matched platelet donors.

Alloreactions occurring after haemopoietic stem cell transplantation can result in the failure of the graft to engraft or graft-versus-host disease (GvHD), in which donor cells mediate attack on various tissues within the host's body. The risks of graft rejection and GvHD are reduced significantly if the donor cells are histocompatible with those of the patient. The perfect donor is an identical twin. However, this will only be the case for very few patients. The chances of finding an HLA-matched sibling as a potential donor for a patient is theoretically 1 in 4 (25%). Therefore, again, the majority of patients will not be able to find a suitable donor within their family.

Another source of HLA-matched donors are the various volunteer donor registries that exist throughout the world. The first volunteer donor register, The Anthony Nolan Trust, was established in London in 1974 at a time when unrelated donor transplants were viewed as experimental. Since this time, the success of unrelated donor transplants has increased and the use of unrelated volunteer donors is acceptable practice. There are now over 50 volunteer donor registers throughout the world. In addition, the successful use of cord blood derived stem cells for transplantation has driven the establishment of cord blood banks in many countries. In total there are 8.5 million potential donors/cord blood units registered worldwide. Details on both volunteer donor and cord blood registries can be found on www.bmdw.org.

Histocompatibility testing procedures

Detection of HLA polymorphisms can be performed by either targeting the DNA sequence of the HLA gene or by analysis of the encoded protein directly.

Serology

Serology describes the use of antibodies to detect epitopes on target antigens. HLA polymorphism results in the presence of different antigenic epitopes on the protein molecule. Antibodies used to define these antigenic epitopes can be found in multiparous women, and can also be created using monoclonal antibody technology. The latter has the advantage of being available in unlimited supply. Serology involves the incubation of peripheral blood mononuclear cells (PBMCs) or separated B cells for class II typing, with serum containing antibodies of known anti-HLA specificity. If the PBMCs express the appropriate HLA molecules then binding between the antibodies in the serum and the PBMCs will occur. This binding will result in lysis of the PBMCs after the addition of complement components. The cells can be stained in order to detect which cells are alive (no reaction) and which cells are dead (positive reaction). The pattern of positive and negative reactions is then interpreted to give an HLA type.

In order to obtain a full tissue type, panels of antisera have to be screened to cover the range of recognized HLA specificities. Despite the number of serological reagents that have been analysed, there are many HLA class I and II polymorphisms that remain undetected by serology (Table 24.2). Many of these polymorphisms are not present on the surface of the HLA molecules, but are found within the peptide binding site, and could alter the peptide binding specificity of the HLA molecule and hence the antigen presentation function of the molecule.

DNA methods

The introduction of polymerase chain reaction (PCR) methodologies for analysis of DNA has led to the establishment of rigorous DNA-based methodologies that can be applied for genetic diagnostics. DNA-based methods are now used routinely for histocompatibility typing.

The most frequent HLA class I antigen in populations of caucasoid Europeans, and the first HLA antigen to be defined, HLA-A2, encompasses three serological variants. Sequencing analyses have shown that at least 70 alleles encode the HLA-A2 specificity. Of these 70 alleles, 59 differ by substitutions that are predicted to influence the antigen-presentation function of the HLA-A2 molecule, and four alleles (A*0215N, A*0232N, A*0243N and A*0253N) contain mutations that prevent expression of the HLA-A2 antigen.

For HLA class I molecules, the polymorphism is mostly localized within the $\alpha1$ and $\alpha2$ domains, which are encoded by exons 2 and 3, respectively, of the class I gene. For HLA class II, the $\alpha1$ domain of the β-chain, encoded by exon 2, is most polymorphic for DRB1, whereas for DQ and DP, the polymorphism extends to both the $\alpha1$ and $\beta1$ domains. Thus, DNA methods for HLA class I typing focus predominantly on exons 2 and 3, whereas for HLA class II, exon 2 is targeted.

Sequence-specific oligonucleotide and sequence-specific primer methods

The most widely used DNA-based methods for HLA typing are PCR sequence-specific primers (PCR–SSP) and PCR sequence-specific oligonucleotide probing (PCR–SSOP). Both methods use DNA primers (sequence-specific primers, SSPs) or probes (sequence-specific oligonucleotides, SSOs) that react with polymorphic sequence motifs present within the nucleotide sequence of HLA alleles. The presence of a positive reaction indicates that the polymorphism defined by the primer or probe is present in the DNA sample, whereas a negative reaction defines the absence of that particular sequence polymorphism. For PCR-SSO typing, the target DNA molecule is amplified by locus (e.g. all HLA-A alleles are amplified in one PCR) or group-specific PCR. The PCR product (amplicon) is immobilized directly onto a nylon or nitrocellulose membrane, such that multiple amplicons from different individuals can occupy each membrane.

Most procedures utilize a 96-well plate format or multiples thereof; thus, this approach is ideal for the laboratory with a large-scale throughput such as screening of potential donors for bone marrow donor registries. Each membrane is subsequently incubated with a labelled (e.g. digoxigenin) oligonucleotide probe. If the amplicon contains the DNA sequence that is complementary to the probe sequence then the probe will anneal to the amplicon and remain bound to the membrane. Probes that do not bind will be lost after washing of the membrane. Bound probes are identified by a chemiluminescent secondary reaction using, for example, an alkaline phosphatase-labelled anti-digoxigenin antibody. After identification of the positive reactions, the HLA type can be assigned usually with the help of computer software.

Alternatively, in the reverse dot-blot assay, the probes are pre-immobilized onto a membrane support and a single amplicon (from one individual) is incubated with the membrane.

PCR–SSP typing utilizes multiple PCR primer pairs, all used independently on the same sample of DNA (Figure 24.4). The primer pairs are designed such that the 3′ end defines the specificity of the primer with the target sequence. To obtain a full HLA type requires numerous primer pairs that have been designed to operate under identical PCR amplification conditions. If the target sequence for a primer pair is present in the sample DNA, a PCR product will be produced, whereas if the target sequence is not present, there will be no PCR product. The presence and absence of PCR products can be visualized after agarose gel electrophoresis.
Figure 24.4 Example of PCR–SSP test. An ethidium bromide-stained agarose gel containing electrophoresed PCR products. In this example, 24 PCR primer mixes have been utilized to determine HLA-DRB1*11 subtype. Each lane on the gel contains the product from amplification of a non-polymorphic region of the genome. The presence of this product indicates successful amplification. A second band is observed in lanes 1, 3, 6 and 9, where specific amplification of a polymorphic region from an HLA gene is achieved. If no second band is present then the individual being tested does not possess the complementary HLA polymorphism. The pattern of positive and negative reactions (presence and absence of second bands) is interpreted to give the HLA type (courtesy of Franco Tavarozzi, the Anthony Nolan Trust).

The resolution of the typing results obtained by SSO and SSP methods can vary depending on the number of probes or primer mixes utilized, with an increasing number required for higher resolution.

Regardless of the number of typing reagents used with SSP and SSO methods, the end result is the presence or absence of a reaction between a probe or primer of a known sequence, with the target HLA sequence. Thus, the data generated can be directly related to the DNA sequence of the HLA alleles possessed by an individual.

Direct sequencing

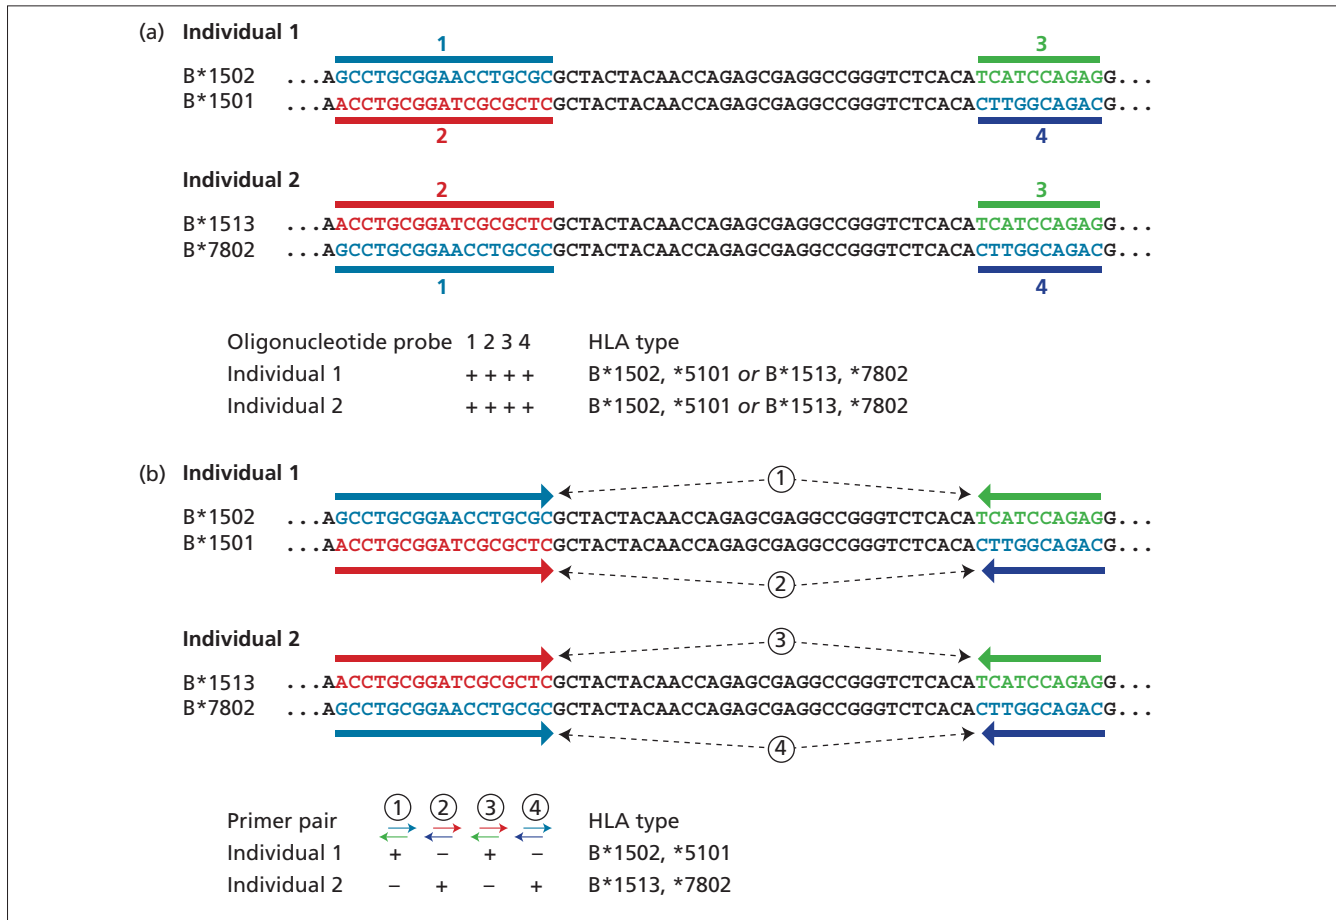
The generation of a database of known nucleotide sequences of HLA alleles has had a tremendous impact on the transfer of methodologies from serology to DNA-based techniques. Improvements with automated instrumentation for DNA sequencing has also made this methodology an affordable alternative technique for HLA typing. The sequencing techniques utilized for HLA typing involve PCR amplification and direct sequencing of the PCR product. The strategies developed have focused on the amplification of DNA fragments containing the polymorphic exons, which, for the majority of class I alleles, extends to a fragment containing exons 2 and 3 (and exon 4 for increased resolution) and usually exon 2 is targeted for class II analysis. HLA-DQB1 benefits from analysis of both exon 2 and exon 3. As most loci are heterozygous, assignment of HLA type is dependent on the use of software that is capable of assigning heterozygous positions. In addition, an up-to-date database of all known HLA sequences is required (Figure 24.5).
Figure 24.5 Electropherogram of sequencing results from analysis of a heterozygous locus. The sequence is read from left to right. For this short stretch of nucleotides, many different results are possible. Heterozygous positions are given appropriate IUB codes. First heterozygous position (marked 1): CC or CT, continuing to second heterozygous position (marked 2): CCC or CCT or CTC or CTT, continuing to third heterozygous position (marked 3): CCCG or CCCT or CCTG or CCTT or CTCT or CTCG or CTTT or CTTG, continuing to fourth heterozygous position (marked 4): CCCGG or CCCGC or CCCTG or CCCTC or CCTGG or CCTGC or CCTTG or CCTTC or CTCTG or CTCTC or CTCGG or CTCGC or CTTTG or CTTTC or CTTGG or CTTGC, etc. (courtesy of Steven T Cox, the Anthony Nolan Trust).


Figure 24.6 Example of SSO ambiguities. (a) The use of oligonucleotide probes to detect complementary DNA sequences. As HLA alleles share sequence motifs, two different heterozygous loci in two individuals can give the same pattern of reactivity with oligonucleotide probes. (b) The use of PCR primer pairs allows linkage of cis motifs (on same haplotype) and resolves the ambiguity.

The advantages of DNA based methods over serology are numerous and include the ease with which typing reagents (primers, probes) can be synthesized and the interpretation of the data as directly relating to nucleotide sequence, whereas the data obtained utilizing polyclonal antisera requires an extensive knowledge of cross-reactivities of sera with different HLA antigens. In addition, the storage of material is simplified for DNA typing, as live cells are not required.

Ambiguities

SSO and direct sequencing methods can generate ambiguous results as both alleles in a heterozygous combination are analysed together. Therefore, it can be difficult to determine whether a sequence motif is in the cis or trans orientation as compared with a different motif (Figure 24.6). This problem can be overcome by performing allele-specific amplification on samples with ambiguities prior to analysis by SSO or sequencing. Fewer ambiguities are obtained using PCR–SSP.

Conformational methods

An alternative approach for the definition of HLA polymorphism is to directly analyse differences in DNA conformation as detected by their differential mobilities in polyacrylamide gel electrophoresis (PAGE). Conformational methods offer the advantage of utilizing a minimum number of reagents. Both single- and double-stranded DNA molecules can be analysed by conformational methods. The limitations of single-strand conformation polymorphism (SSCP) is that only DNA fragments of 200–400 nucleotides in length can be analysed. With heteroduplex analysis, longer DNA fragments can be analysed. The major limitations of both SSCP and heteroduplex analysis are in the complexity of the banding patterns that are visualized by

Figure 24.7 Reference strand-mediated conformational analysis (RSCA) methodology (see text for details).
conventional polyacrylamide electrophoresis. The lane-to-lane and gel-to-gel variations inhibit such approaches for direct HLA typing, and these methods have been most widely utilized for subtyping of HLA types and for donor–patient matching analyses.

Improvements with conformational methods for direct HLA typing have been aided by the use of sensitive detection systems and automated analysis software. Reference strand-mediated conformational analysis (RSCA) is a method that can be used to achieve high-resolution results without the ambiguities seen by direct sequencing.

RSCA begins with PCR to produce DNA from the locus of interest, for example HLA-A. The PCR product is hybridized with a locus-specific fluorescent labelled reference (FLR) DNA fragment. Heating the DNA mixture causes the double-stranded DNA molecules to separate. Subsequent cooling allows reformation of the original DNA molecules (homoduplexes) and, in addition, heteroduplexes can form (Figure 24.7). The resulting mixture of heteroduplexes and homoduplexes is separated by non-denaturing PAGE in an automated DNA sequencer. Only those duplexes containing a fluorescent duplex will be detected. The mobility of each fluorescent duplex is measured and comparisons are made with control duplexes analysed in the same gel, and control markers within each lane, allowing the assignment of a value indicative of HLA type. For a heterozygous locus, one homoduplex and two heteroduplex signals are detected. RSCA has been applied for the typing of class I and class II loci, and has also been used as a quick and effective method for assessing histocompatibility for HLA loci between donor and patients.

Cellular assays

Cellular methods for assessing potential alloreactivity between patient and donor can also be utilized for the selection of the most appropriate haemopoietic stem cell (HSC) donor. The mixed lymphocyte culture (MLC) assay has been used since the 1960s. MLC measures the reactivity of donor T cells against alloantigens expressed by patient cells, i.e. graft-versus-host direction. By mixing both donor and patient cells together, any allo-reactions that occur will cause the responding donor cells to proliferate and incorporate [^{3}H]thymidine, which can be measured. The patient cells are prevented from proliferating by being gamma irradiated prior to the mixing of cells. However, since the introduction of DNA-based methods for HLA class II typing, the MLC reaction is infrequently utilized. Indeed, studies have indicated that positive MLC reactions in the absence of detectable HLA class II mismatches are not indicators of the development of GvHD post BMT.

More sensitive cellular assays have been developed to measure HLA disparity. The cytotoxic T-lymphocyte precursor (CTLp) assay uses limiting dilution analysis (LDA) to measure the frequency of donor CTL responding to predominantly HLA class I mismatches on patient cells. High frequencies of CTLp have been shown to be strongly associated with HLA class I mismatches, which may have escaped detection by the conventional low to medium level of resolution typings, which, until recently, were widely used for class I matching. Similarly, the helper T-lymphocyte precursor (HTLp) assay measures the HTL response of the donor to HLA class II mismatches, with HLA-DR mismatches associated with high HTLp frequencies with no apparent contribution from HLA class I mismatches. Both CTLp and HTLp assays can be combined in a single LDA, thus minimizing the use of often valuable material.

The drawback of cellular assays is that they take up to 2 weeks to perform, and they require viable cells from both donor and patient. With more widespread use of high-resolution HLA typing techniques, the number of laboratories performing cellular assays has decreased significantly.

Other genetic polymorphisms

HLA polymorphisms clearly play an important role in determining the outcome of a HSC transplant. There are also other genetic polymorphisms that have been demonstrated to influence outcome. Minor histocompatibility antigens (mHA) are also alloantigens that are capable of initiating an immune response when their genes are mismatched for patient and donors, despite the presence of HLA matching. Minor histocompatiblity antigens are peptides derived from normal self-proteins that possess polymorphisms. A donor and patient may share HLA type, but differ in the polymorphism found in the mHA gene. Several human mHA have been defined, for example HA1, HA2, HA3, etc. The genes encoding several of these mHA have been described, and this has allowed the development of typing procedures for these genes using techniques such as PCR–SSP.

There is therefore a choice in techniques that may be utilized for optimum donor selection for patients requiring a HSC transplant. Each methodology has its advantages and disadvantages. It is now accepted practice that DNA-based typing should be performed on all related and unrelated donors and patients. Serology and cellular assays may be used to complement the outcome of the DNA typings. A major challenge for the future of histocompatibility typing for HSC transplantation will be to acquire a greater understanding of what types of mismatches are acceptable in that they do not result in adverse alloreactions, and also to know which mismatches are detrimental. It is likely that more sensitive and reproducible cellular assays may play a role in determining these mismatches. The use of ELISPOT (enzyme-linked immunospot) assay and real-time PCR methods for detecting low numbers of cytokine-producing cells may become additional tools for the histocompatibility laboratory in the future.

Stem cell transplantation

Charles Craddock and Ronjon Chakraverty

Introduction

The demonstration in the 1950s that infused bone marrow cells possess the ability to reconstitute the haemopoietic system of lethally irradiated recipients formed the basis for the development of stem cell transplantation (SCT) as a treatment for leukaemia and bone marrow failure. After decades of refinement, transplantation of allogeneic and autologous haemopoietic stem cells has become an increasingly safe and effective procedure and now plays a major role in the management of malignant and non-malignant haematological disorders. It was initially postulated that the curative potential of SCT simply reflected the ability to deliver myeloablative chemo/radiotherapy without the risk of permanent marrow aplasia. Although this is undoubtedly the case in recipients of autologous transplants, there is now conclusive evidence of an additional immunologically mediated graft-versus-leukaemia (GvL) effect after transplantation of allogeneic stem cells. This has permitted the introduction of non-myeloablative transplant regimens and, together with increased donor availability, has markedly increased the number of patients eligible for allogeneic transplantation. Taken together, these developments have resulted in a dramatic expansion in the numbers of stem cell transplants performed over this period in Europe and worldwide (Figure 25.1 and Table 25.1).

Immunological basis of stem cell transplantation

The major complications of allogeneic SCT are caused by the immunological responses triggered by the infusion of donor haemopoietic progenitors and lymphocytes into an immunosuppressed host. These can either take the form of a host-versus-graft (HvG) or a donor-derived graft-versus-host (GvH) response. Clinically, the HvG response can result in graft rejection, whereas a GvH response may manifest itself either as graft-versus-host disease (GvHD) or as a GvL reaction. It is now possible to blunt the HvG reaction by optimizing the immunosuppressive properties of the conditioning regimen and, consequently, graft rejection is rare in most clinical settings. In contrast, GvHD and disease relapse are still major complications of allogeneic transplantation and novel approaches that manipulate the GvH response to therapeutic advantage are needed. By contrast, autologous SCT, in which the patient serves as his/her own stem cell donor, is an immunologically unremarkable event.

Antigens and cellular effectors

The antigens against which HvG and GvH responses are directed include the products of highly polymorphic genes lying within the major human leucocyte antigen (HLA) complex and minor histocompatibility antigens (minor H antigens) encoded by genes lying outside the HLA system. These antigens and the methods employed to identify them have been reviewed in Chapter 20. In very general terms, the degree of difference or 'incompatibility' between the donor and recipient will define the risk of graft rejection and/or GvHD. Thus, in situations where the donor is genetically identical to the recipient (syngeneic transplantation), graft rejection or significant GvHD are not observed.

If the donor and recipient are mismatched for either class I or II HLA antigens, immune responses may be generated against
Figure 25.1 Numbers of allogeneic (a) and autologous (b) stem cell transplants performed within Europe 1900–2002 (EBMT data courtesy of Professor A Gratwohl).

HLA antigens or minor H antigens. Single class I or class II mismatches are in general well tolerated, but greater degrees of mismatch are associated with increased rates of graft rejection or GvHD. At present it is not known whether it will be possible to define 'permissive' mismatches that have no impact on clinical outcome, although such information would clearly be of value in guiding the choice of unrelated donors.

If both recipient and donor are HLA identical, immune reactivity is limited to minor H antigens. These are polymorphic antigens, which include proteins such as HA-1, HA-2 and HA-8. In addition, the protein H-Y is coded for by a gene on the Y chromosome and is therefore only expressed on male cells. Female donors, specifically multiparous individuals, may have been primed against such antigens and, as a consequence, have circulating T-cells that can recognize host cells expressing these proteins. This is likely to underlie the increased risk of GvHD in male recipients of female grafts. The tissue specificity of minor H antigen expression influences the clinical presentation of the GvH response and it is of interest that minor H antigens such

as HA-1 and HA-2 are expressed exclusively on haemopoietic cells.

The most important cells with the capacity to recognize these antigenic differences and mount an injurious immune response are CD4+ and CD8+ T cells. A central role for donor-derived T cells in both GvHD and GvL is demonstrated by the observation that, although depletion of T cells from the donor stem cell inoculum reduces the risk of GvHD, this comes at the price of an increased risk of disease relapse. In the setting of class I HLA disparity, natural killer (NK) cells may also be important cellular effectors. NK cells express receptors termed killer immunoglobulin-like receptors (KIRs), which can interact with HLA class I molecules. KIR activation produced by interaction with a cognate class I ligand may inhibit NK alloreactivity. Conversely, NK-mediated lysis will be triggered if the appropriate inhibitory KIR ligand is not presented on the target cell. Consequently, NK-mediated killing of host targets is determined by their expression of HLA class I ligands.

Graft-versus-host disease

GvHD is a complex immunological disorder in which donor T cells with specificity for recipient antigens not expressed in the donor initiate tissue damage. The recipient, as a result of immunosuppression or immunodeficiency, is incapable of rejecting the T cells mediating the alloreactive response. Conditioning induced tissue injury leads to the release of proinflammatory cytokines and altered chemokine or adhesion molecule expression. These changes impact upon the developing GvH response, leading to cytokine dysregulation and enhanced trafficking of cellular effectors to GvHD target organs. Induction of GvHD (Figure 25.2) requires the interaction of donor T cells with host antigen-presenting cells (APCs), most probably dendritic cells within secondary lymphoid organs, such as lymph nodes and gut-associated lymphoid tissue.

Host APCs are activated by proinflammatory cytokines, such as TNF-α or IL-1β, which are released following tissue damage induced by the conditioning regimen. APCs upregulate the surface expression of co-stimulatory molecules and HLA molecules loaded with peptides derived from host antigens and, in addition, secrete inflammatory chemokines (e.g. MIP-1α). Donor CD4+ and CD8+ T cells with anti-host specificity interact with host APC, become activated, expand and develop effector functions that lead to the secretion of activating cytokines (e.g. TNF-α, interferon-γ) or the induction of perforin or Fas ligand pathways required for cellular cytotoxicity. Altered expression of homing molecules (e.g. the integrin $\alpha4\beta7$) permits trafficking of alloreactive T cells from secondary lymphoid tissue to damaged non-lymphoid tissues (especially skin, gut and liver).

T cells aid recruitment of other cellular effectors such as neutrophils, eosinophils, macrophages and NK cells, which together cause the epithelial injury characterizing the clinical manifestations of GvHD. Importantly, GvHD at its initiation is

an antigen-specific adaptive immune response but, as the immune response develops, it becomes less specific so that cells lacking the relevant antigens are targeted in the ensuing response. It follows that efforts designed to prevent or treat GvHD are likely to be more successful prior to or at the point of induction of the alloreactive response.

Graft-versus-leukaemia effect

The importance of an immunologically mediated GvL effect in contributing to the curative effect of allogeneic SCT is supported by the observations that T-cell depletion (TCD) increases the risk of relapse and that patients who develop GvHD have a lower risk of disease relapse. Conclusive evidence was provided by the demonstration that infusion of donor lymphocytes can produce durable remissions in patients who have relapsed after allogeneic SCT. It has subsequently been shown that donor lymphocyte infusion (DLI) is a remarkably effective salvage therapy in chronic myeloid leukaemia (CML), with > 80% of patients achieving a sustained molecular remission. Durable responses can also be achieved in patients with acute leukaemia, myeloma and lymphoma albeit at a much lower rate.

As would be predicted, DLI can be complicated by the development of GvHD although the risk of this life-threatening complication is reduced if donor lymphocytes are infused using an escalating dose schedule rather than in a single 'bulk' infusion.

Experimental data suggest that CD8$^+$ T cells are the major effectors of GvL, although there is increasing evidence that other cells, including CD4$^+$ and NK cells, play a role. The identity of the antigens recognized in a GvL reaction remains an area of conjecture. Candidates include ubiquitous or haemopoietic specific minor H antigens (e.g. HY and HA-1 respectively), leukaemia-specific antigens such as product of the BCR–ABL fusion gene or proteins that are overexpressed on leukaemic cells such as proteinase 3 or WT1.

Immune reconstitution

Allogeneic SCT is followed by a prolonged period of cellular and humoral immunodeficiency while donor-derived immune reconstitution occurs. This is exacerbated by T-cell depletion of the graft, coexisting GvHD or prolonged immunosuppressive therapy. Thymic function is reduced in adults and may be further compromised by the effects of chemoradiotherapy and chronic GvHD. As a consequence, the number of naive donor T cells generated from CD34$^+$ progenitors within the thymus in the first months after transplantation is low. The T-cell repertoire as a consequence is limited and mostly dependent upon expansion of donor memory T cells.

Significant HLA mismatching between donor and recipient may also lead to 'holes' within the T-cell repertoire due to a failure of thymocytes or mature T cells to interact with peptides
Figure 25.2 Pathophysiology of GvHD. APC, antigen-presenting cell; CD40L, CD40 ligand; FasL, Fas ligand; LPS, lipopolysaccharide; MAdCAM-1, mucosal addressin cell adhesion molecule-1; MIP-1α, macrophage inflammatory protein-1α.

presented in the context of 'foreign' host HLA molecules. Quantitative B-cell deficiency is present in virtually all patients in the first months post transplant, and may persist for a number of years as a consequence of reductions in the number of marrow B-cell precursors. This defect in B-cell production is often multifactorial; causes including damage to the bone marrow stroma, the deleterious effect of inflammatory cytokines and the lympholytic effects of glucocorticoid therapy.

Stem cell engraftment

Biology of stem cell engraftment

Restoration of haemopoiesis after myeloablative therapy is dependent on the transplantation of long-term reconstituting cells (LTRCs). These cells are defined by their capacity for self-renewal as well as their ability to differentiate into all

haemopoietic lineages. Their proliferative capacity is such that transplantation of as few as 100 LTRC can restore haemopoiesis in a lethally irradiated mouse. The cell-surface glycoprotein CD34 is widely used at present as a stem cell marker in clinical transplantation, and is expressed on both committed haemopoietic progenitors as well as LTRCs.

Durable engraftment of allogeneic stem cells is augmented by graft-facilitating donor CD8$^+$ T cells, which usually overcome any residual HvG response generated by host T cells that have survived the conditioning regimen. Thus, the major factors determining engraftment are the intensity of host immunosuppression delivered by the conditioning regimen, the numbers of donor T cells in the stem cell inoculum and the degree of genetic disparity between donor and host.

It was previously assumed that engraftment of allogeneic cells was dependent upon the creation of 'space' within the bone marrow cavity. However, the demonstration that durable engraftment can be achieved using a non-myeloablative dose

Table 25.2 Comparison of cellular composition of typical bone marrow harvest compared with G-CSF-mobilized PBSC (after two aphareses).

of total body irradiation (TBI) (200 cGy) has challenged this concept and emphasized the critical importance of pretransplant immunosuppression in securing donor engraftment. The other major determinant of engraftment is the number of stem cells transplanted (see below). The use of granulocyte colony-stimulating factor (G-CSF)-mobilized peripheral blood stem cells (PBSCs) makes it possible to transplant significantly higher stem cell doses than is possible if harvested bone marrow is used. Consequently, PBSCs now play a critical role in optimizing engraftment in settings when T-cell depletion or HLA disparity are present.

Incorporating these principles into clinical practice has markedly reduced the risk of graft failure such that it occurs in less than 1% of patients undergoing an HLA-identical sibling allograft, and less than 5% of those transplanted from an unrelated donor providing a myeloablative conditioning regimen is used. In autologous SCT, when a HvG reaction is absent, graft failure is very rare providing that an adequate stem cell dose is used.

Stem cell dose and source

In allogeneic transplants the size of the transplanted stem cell inoculum plays an important role in determining outcome in recipients of both matched sibling and volunteer unrelated donor (VUD) transplants. This effect is predominantly mediated through a reduction in transplant-related mortality (TRM), consequent upon accelerated immune reconstitution in recipients of a higher stem cell dose; 2×10^6 CD34 cells/kg (2×10^8 mononuclear cells/kg if bone marrow is being used) is considered the lowest acceptable stem cell dose but, as outcome is improved with higher doses, most centres aim for a dose in the region of 4×10^6 CD34 cells/kg. Reports of an increased incidence of chronic GvHD if more than 8×10^6 CD34 cells/kg are transplanted suggest that $4-8 \times 10^6$ CD34 cells/kg should be regarded as the desirable stem cell dose.

There remains considerable debate concerning the optimal source of stem cells in allogeneic transplants. The use of PBSCs is associated with earlier neutrophil and platelet engraftment and, in patients with advanced leukaemia, this may translate into a lower TRM. However, transplantation of PBSCs results in an increased incidence of chronic GvHD, reflecting the five- to ten-fold greater dose of T cells transplanted if mobilized cells are used in preference to bone marrow-harvested cells (Table 25.2).

Thus, the use of PBSCs has become commonplace in patients being allografted for advanced leukaemia, when TRM is a major cause of treatment failure, but bone marrow is still preferred in diseases such as aplastic anaemia, when chronic GvHD is an important cause of treatment failure. The increasing use of PBSCs has obvious implications for allogeneic stem cell donors. G-CSF in the doses used for stem cell mobilization (10–15 μg/kg × 4–6 days) is in general well tolerated (Chapter 18). However, the attendant side-effects in the form of myalgia, bone pain, headache coupled with a 2–5% chance a bone marrow harvest being required because of failure to mobilize sufficient progenitors makes careful counselling an essential part of the donor work-up.

In the past decade, umbilical cord blood (CB) cells, harvested at the time of delivery, have been used as a source of allogeneic stem cells. CB is rich in LTRCs and haemopoietic progenitors, and durable engraftment can be reliably obtained in infants and children. Moreover, the incidence of severe acute GvHD is significantly lower with mismatched CB than would be expected using a comparable unrelated donor. It is theoretically possible that the lower numbers and naive phenotype of T cells contained in CB collections will be associated with a reduced GvL effect but no increase in relapse risk has yet been reported in CB transplants.

Given the difficulties which can be experienced in obtaining stem cell collections from unrelated donors, the relative ease of access to CB banks has resulted in this becoming an increasingly important stem cell source in paediatric transplantation. However, in older patients delayed engraftment is commonly observed because of the lower cell doses (per kilogram of body weight) transplanted and this has limited their use in adults. Therefore, approaches that improve engraftment, such as *ex vivo* expansion of haemopoietic progenitors or the use of more than one donation, will be needed before CB is widely used in adult transplantation.

In patients undergoing autologous transplantation PBSC are now almost universally used in preference to bone marrow harvests. The accepted minimum number of PBSC required for engraftment after autologous SCT is 2×10^6 CD34^+ cells/kg. Although increasing the stem cell dose hastens neutrophil and platelet engraftment, there is little evidence that transplantation of more than 5×10^6 CD34^+/kg is beneficial and there remain concerns that higher stem cell doses may be associated with an increased risk of tumour contamination.

Stem cell manipulation

Characterization of the stem cell phenotype has permitted the development of strategies by which PBSC grafts can be manipulated *ex vivo*. By using CD34-specific antibodies conjugated with magnetic beads, highly efficient enrichment of CD34$^+$ cells can be achieved. This technology also allows, as a consequence of passive depletion of CD34$^-$ cells, efficient depletion of either contaminating malignant cells in autologous grafts or donor T cells in allogeneic stem cell harvests. The former is of potential importance, although so far unproven, in reducing relapse rates in recipients of autologous transplants, whereas the latter is an effective form of GvHD prophylaxis in allogeneic transplant recipients.

Conditioning regimens: basic principles

The combination of drugs and radiotherapy that is administered before stem cell infusion is termed the conditioning or preparative regimen. In the setting of allogeneic SCT, the conditioning regimen serves two purposes: host immunosuppression to prevent graft rejection and myeloablation in order to achieve tumour eradication. Considerable experience has been gained over the past three decades in the design and delivery of myeloablative conditioning regimens. However, they are still associated with significant toxicity, which precludes their use in patients older than 50–55 years old (45–50 years for recipients of VUD transplants).

The recent demonstration that durable donor engraftment can be reliably achieved using a non-myeloablative preparative regimen, coupled with increased awareness of the potency of the GvL reaction, has led to the development of a range of reduced-intensity conditioning (RIC) regimens. These protocols are associated with a markedly reduced TRM than that which would be observed using a myeloablative regimen. As a result, allogeneic transplantation can now be safely performed in many patients in whom it would previously have been contra-indicated on the grounds of age or comorbidity (Chapter 26). Experience with RIC regimens is limited, however, and longer follow-up is needed before their ability to produce long-term disease-free survival can be accurately assessed.

In autologous SCT when there is no alloreactive response, myeloablative conditioning regimens are better tolerated, allowing autografting to be safely performed in patients up to the age of 70.

Myeloablative conditioning regimens in allogeneic stem cell transplantation

The two commonest myeloablative conditioning regimens used in allogeneic SCT utilize combinations of cyclophosphamide (Cy) and either TBI or busulphan (Bu).

Cyclophosphamide/total body irradiation (Cy/TBI)

Cyclophosphamide is an alkylating agent which, when administered in the doses routinely used in myeloablative conditioning regimens (120–200 mg/kg), has both immunosuppressive and anti-leukaemic properties. It is a prodrug that must be metabolized by the P450 system in the liver to produce metabolically active derivatives, principally phosphoramide mustard, which exert their cytotoxic activity through the production of inter-strand DNA links. The two major complications of cyclophosphamide at the doses employed in allogeneic transplantation are haemorrhagic cystitis and cardiac toxicity. The former results from the toxic effects of a cyclophosphamide metabolite, acrolein, upon the uroepithelium and can be reduced by the use of the thiol sodium 2-mercaptoethanesulphonate (Mesna); the latter is very rare at doses of cyclophosphamide below 150 mg/kg.

TBI also has immunosuppressive and anti-leukaemic properties when administered in myeloablative doses (typically 12–14 Gy). The degree of immunosuppression produced by TBI-containing regimens is related to the total dose of irradiation delivered. The use of higher TBI doses is therefore an effective method of optimizing engraftment in settings such as TCD or unrelated donor transplantation when the risk of graft failure might otherwise be increased. Haematological malignancies are highly radiosensitive and the risk of disease relapse can be reduced if a higher dose of TBI is used. Early complications associated with the use of TBI include nausea, vomiting, diarrhoea and parotitis, which can usually be managed symptomatically. More seriously, TBI increases the risk of both pneumonitis and venoocclusive disease (VOD) of the liver. Long-term complications include cataract formation, hypothyroidism, infertility and, in children, growth retardation. Radiobiological principles predict that the toxicity of TBI can be reduced by either decreasing the overall dose of radiation administered or, as is now common, by giving it in a fractionated form over a number of days (e.g 14.4 Gy divided into eight fractions over 4 days).

Busulphan/cyclophosphamide (Bu/Cy)

Bu/Cy is a myeloablative preparative regimen which has the advantage of not requiring the presence of irradiation facilities on site. Busulphan is an oral alkylating agent with potent activity against leukaemic progenitors and is widely used in both allogeneic and autologous transplantation. Major complications associated with the use of high-dose busulphan (14–16 mg/kg) are VOD, infertility and pulmonary and CNS toxicity. There is considerable interpatient variability in busulphan pharmacokinetics, which is of clinical importance given the increased risk of VOD in patients who develop high plasma busulphan levels. Measurement of busulphan levels during the course of its administration allows appropriate dose adjustment and safer use of this agent. Seizures, a complication associated with the administration of high dose of busulphan, can be prevented by the use of prophylactic phenytoin or diazepam.

In non-malignant disorders such as aplastic anaemia, cyclophosphamide alone can be used as a conditioning regimen and is sufficiently immunosuppressive to permit engraftment of allogeneic stem cells, provided that an adequate stem cell inoculum is transplanted.

Comparisons of myeloablative conditioning regimens

The two central questions in the design of myeloablative conditioning regimens are: 'is there any survival benefit to be gained from intensifying the conditioning regimen?' and, secondly, 'are Cy/TBI and Bu/Cy equally effective preparative regimens'? In patients receiving a Cy/TBI allograft, prospective studies have failed to demonstrate any improvement in survival if an increased dose of TBI is used. Although the use of a higher TBI dose reduces the risk of leukaemic relapse, this benefit is offset by a concomitant increase in TRM. Similarly, there is no evidence that addition of busulphan to a Cy/TBI regimen has any impact on disease-free survival.

The decision whether to use Cy/TBI or Bu/Cy as a conditioning regimen has been examined in a number of randomized studies. Although both regimens appear equally effective for patients undergoing a sibling allograft for CML in first chronic phase, there appears to be some benefit attached to the use of a TBI-based regimen in patients with advanced leukaemia. The optimal conditioning regimen in patients who are being transplanted using an unrelated donor has not been determined. The greater degree of HLA disparity results in a higher risk of graft failure than that observed using an HLA-identical sibling and many groups therefore elect to use a TBI-based regimen. It should be noted, however, that equivalent results have been reported by a number of groups using a Bu/Cy regimen.

Strategies for graft-versus-host disease prophylaxis

The commonest method of GvHD prophylaxis utilizes post-transplant immunosuppression in the form of intravenous cyclosporin (2.5–5 mg/kg per day) and methotrexate (e.g. four doses of 10 mg/m^2 administered on days 2, 4, 8 and 12 post transplant). Cyclosporin and other related agents, such as tacrolimus, decrease T-cell activation by inhibiting the calcineurin-dependent secretion of IL-2. Increasing the intensity of immunosuppression reduces the risk of GvHD but is also associated with a higher rate of disease relapse consequent upon a decreased GvL effect.

Depletion of T cells from the donor stem cell inoculum is also an effective form of GvHD prophylaxis. TCD can be achieved *ex vivo* by manipulating the stem cell inoculum or *in vivo* by administration of T cell-depleting antibodies such as anti-thymocyte globulin (ATG) or alemtuzumab (a humanized monoclonal antibody which recognizes CD52). Although a highly effective method of GvHD prophylaxis, TCD is associated with an increased risk of relapse and graft failure, and delays immune reconstitution increasing the risk of post-transplant infections such as CMV. It is therefore difficult to show any overall benefit of TCD on patient survival. Alternative approaches that allow the selective depletion of T cell subsets (CD4$^+$ or CD8$^+$) are being explored and are of interest in terms of defining approaches that may permit dissociation of GvHD and GvL.

Clearly, the form of GvHD prophylaxis used for any particular patient should be selected with their individual risk of both GvHD and relapse in mind. Thus, it may be desirable to avoid the use of TCD in patients with advanced leukaemia in whom the risk of relapse is high. In contrast, patients with a low risk of disease recurrence may benefit from more intensive GvHD prophylaxis. It should also be remembered that patients receiving a TCD graft require a more intensely immunosuppressive conditioning regimen in order to overcome the increased risk of graft rejection.

Conditioning regimens in autologous stem cell transplantation

Conditioning regimens in autologous SCT are designed with dose intensification in mind, and are limited mainly by considerations of extramedullary toxicity. High-dose melphalan (200 mg/m^2) is the standard conditioning regimen in myeloma autografts. BEAM (BCNU 300 mg/m^2, etoposide 800 mg/m^2, cytosine arabinoside 1600 mg/m^2 and melphalan 140 mg/m^2) is widely used in patients with lymphoma. Both Bu/Cy and Cy/TBI are effective preparative regimens for patients with acute leukaemia. A number of other drug combinations incorporating melphalan, busulphan and thiotepa are used in solid tumours. The major extramedullary toxicities of these regimens (in addition to those described already for Cy/TBI and Bu/Cy) are mucositis and gastrointestinal toxicity. Disappointingly, there are little prospective randomized data on which to base the choice of conditioning regimens in autologous SCT. In myeloma, a randomized comparison between a TBI-containing regimen and high-dose melphalan alone demonstrated no benefit associated with the use of TBI. There are, however, no large randomized studies of preparative regimens in lymphoma.

Management of patients undergoing stem cell transplantation

The use of PBSCs coupled with improved supportive care has decreased the mortality of autologous transplantation to 1–3% in most centres. The morbidity and mortality of allogeneic SCT has also continued to fall over the last two decades, largely thanks to more accurate tissue typing and advances in the detection and management of infectious complications. Nonetheless, organ toxicity, GvHD and infections consequent upon delayed

immune reconstitution mean that this procedure remains associated with a TRM in excess of 10%, even in the most favourable of circumstances. There also remain significant long-term complications after allografting, which can significantly compromise a patient's quality of life.

Practicalities of stem cell infusion and supportive care

Stem cell products are infused in the same way as other blood products, except that on-line blood filters should not be used. They must not be irradiated. Cryopreserved products are usually defrosted in a water bath at the bedside and then infused without delay. The most common side-effect of the DMSO cryopreservative is nausea but, as it is excreted by the lungs, a garlic-like odour is also observed for 2–3 days after stem cell infusion. Damage to red blood cells releases free haemoglobin, which can precipitate acute renal failure, and thus patients should be adequately hydrated and their urine output monitored closely. The supportive care of patients with neutropenia is discussed extensively in Chapter 36 and will not be repeated here.

Appropriate and timely use of blood products is required during the period of myelosuppression post transplant. All cellular blood products should be irradiated using 25 Gy prior to administration in order to prevent transfusion-related GvHD. This should be commenced 6 weeks prior to transplant and is continued for 6 months after an autograft or indefinitely for allogeneic transplants. In patients undergoing allogeneic SCT, where there is a major ABO incompatibility between donor and recipient (for example, a group O recipient receiving group A bone marrow), the graft must be depleted of red cells prior to administration unless PBSCs are being transplanted, in which case red blood cells are effectively depleted during leucapheresis. The subsequent choice of blood group for platelets or red cells depends upon the precise nature of the ABO incompatibility, the time from SCT and the results of blood grouping. Delayed erythroid engraftment or haemolysis, caused by continuing synthesis of isohaemagglutinins by host lymphocytes, may occur several weeks after stem cell infusion and is associated with the presence of a positive direct antiglobulin test and anti-donor red cell antibodies in serum or red cell eluates.

Complications of allogeneic stem cell transplantation

Early complications (day 0–90)

Graft failure

Primary graft failure is defined as the failure to achieve a neutrophil count $> 0.5 \times 10^9$/L within 28 days of stem cell infusion, and most commonly occurs as a consequence of graft rejection. It is rare except in the setting of TCD or where there is marked donor–host HLA disparity, such as that seen using a mismatched unrelated or family donor. Investigations in patients with suspected graft failure should include a bone marrow aspirate and trephine (which should be urgently processed) and chimerism studies. Patients with evidence of donor chimerism, whose bone marrow examination demonstrates engrafting myeloid and erythroid progenitors, may benefit from G-CSF support. However, patients with no evidence of engraftment or absence of donor chimerism are candidates for urgent intervention in the form of a second transplant from the same donor or an infusion of cryopreserved autologous stem cells.

The mortality of primary graft failure is in excess of 50%, and it is therefore important to consider performing an autologous harvest in patients, such as unrelated donor recipients, where there is a significant risk of graft failure. Secondary graft failure occurring after initial evidence of engraftment occurs in up to 5% of mismatched or unrelated donor transplants but is extremely rare after a sibling allograft. The aetiology of secondary graft failure is often complex, but causes that need to be considered include late graft rejection, drugs (cotrimoxazole and ganciclovir), viral infection (CMV and parvovirus), disease relapse and, rarely, hypersplenism.

Acute graft-versus-host disease

Acute GvHD occurs at or near the time of engraftment in 40–70% of patients undergoing allogeneic SCT and is characterized by the presence of rash, diarrhoea or abnormal liver function tests. Risk factors for the development of acute GvHD include increased recipient age, HLA mismatch and the use of a female donor. Children and recipients of cord blood transplants have a lower risk of acute GvHD.

Skin GvHD typically presents as a maculopapular rash involving the face, neck, palms and soles, but may extend to involve the whole body (Figure 25.3). In the worst cases, it progresses to erythroderma, with bullae formation and painful blistering. Histology shows apoptosis at the base of dermal crypts, dyskeratosis, and evidence of lymphocytes in a perivascular distribution or adjacent to dyskeratotic keratinocytes. Gastrointestinal involvement presents with nausea, vomiting, secretory diarrhoea and/or abdominal pain. In patients with more severe gastrointestinal GvHD, abdominal pain and distension in association with voluminous, occasionally bloody, diarrhoea may occur. Gastric, antral and rectal biopsies have a high diagnostic yield with diagnostic features including the presence of apoptotic cells in the base of crypts and a lymphocytic infiltrate. A well-defined manifestation of upper gut GvHD is the development of anorexia and nausea – both of which usually resolve rapidly if treated with low-dose methylprednisolone (1 mg/kg). A rising bilirubin and raised alkaline phosphatase are the initial features of liver GvHD, which typically develops later than skin or gut GvHD. Liver histology is diagnostic and demonstrates a portal tract lymphocytic infiltration, pericholangitis and bile duct loss.

Accurate and early diagnosis of acute GvHD is essential for effective management of this potentially life-threatening dis-

order. When possible, diagnostic biopsies should be taken both to confirm the presence of GvHD and to assist in the exclusion of other aetiologies. It is also important to stage GvHD accurately and the criteria devised by Glucksberg are widely used (Table 25.3). This staging system is a reliable indicator of prognosis and guides the intensity of treatment required. Grade 2–4 acute GvHD should be treated with high-dose methylprednisolone (typically 2 mg/kg daily) which is tapered according to response. In the setting of limited skin GvHD and upper gut GvHD topical or oral steroids (1 mg/kg) coupled with optimiza-

tion of cyclosporin levels may be sufficient to control symptoms. Approximately 70% of patients will improve significantly with oral or intravenous corticosteroid therapy, but a number will either fail to respond or relapse when immunosuppression is tapered. Individuals with steroid refractory acute GvHD have a poor prognosis and require second-line therapy using equine or rabbit anti-thymocyte globulin (ATG). Although a proportion of patients will respond to second-line therapy, steroid refractory acute GvHD remains associated with a non-relapse mortality in excess of 80%. Prophylactic administration of antimicrobial and antifungal agents is essential in all patients receiving high-dose steroids for treatment of GvHD.

Infectious complications

The organisms responsible for infectious complications after allogeneic SCT depend primarily on the time from stem cell infusion (Figure 25.4). Active steps should be taken to prevent the risk of infection and patients should be cared for in single rooms, preferably with laminar air flow or high-efficiency particulate air filtration. A number of effective prophylactic strategies have been developed in allograft patients. Evidence supports the use of triazole antifungals, for example fluconazole (100–400 mg daily), as an effective means of reducing *Candida* infection. Aciclovir (200–400 mg q.d.s.) is administered to prevent herpes simplex virus (HSV) reactivation. Quinolone antibiotics (e.g. ciprofloxacin 500 mg b.d.) are used by some units to reduce the risk of severe Gram-negative infections, although the evidence supporting this measure is inconclusive and practice should be guided by advice from local microbiologists concerning the prevalence and sensitivity of drug-resistant organisms. Patients should receive cotrimoxazole (480 mg b.d. three times per week) upon recovery from aplasia (neutrophils $> 1.0 \times 10^9$/L) to prevent *Pneumocystis carinii* infection. If allergic to cotrimoxazole, nebulized pentamidine (300 mg monthly) can be substituted.

Allogeneic recipients, particularly recipients of TBI-containing regimens, continue to be at long-term risk from infections by encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* and require lifelong penicillin prophylaxis (250 mg b.d.) or erythromycin (250 mg b.d.) if allergic to penicillin. Antibody titres to diseases for which childhood vaccination is performed decline after SCT. Revaccination is therefore recommended, particularly in allograft recipients, and most centres commence such a programme 12 months post transplant.

Cytomegalovirus infection and disease

Human cytomegalovirus (CMV) is a ubiquitous herpesvirus that infects up to 60% of healthy adults. CMV reactivation occurs commonly after allogeneic SCT, giving rise either to an asymptomatic infection or, less commonly, to end-organ damage (CMV disease) and death. Patients at the highest risk of CMV reactivation are seropositive recipients, especially those who

(a)

Stage	Skin	Liver bilirubin	Gut
+	Maculopapular rash < 25% body surface	34–51 µmol/L	Diarrhoea, 500–1000 mL/day or persistent nausea
++	Maculopapular rash 25–50% body surface	51–102 µmol/L	Diarrhoea, 1000–1500 mL/day
+++	Generalized erythroderma	102–255 µmol/L	Diarrhoea > 1500 mL/day
++++	Desquamation and bullae	> 255 µmol/L	Pain with, without ileus

Figure 25.4 Infectious complications occurring after allogeneic SCT.

receive TCD or unrelated donor grafts and patients who develop GvHD, requiring steroid therapy. Primary infection of seronegative patients may occur as a result of the infusion of stem cell or blood products from a CMV-positive donor but is rare. Nonetheless, all seronegative transplant recipients should receive CMV-negative or leucodepleted blood products to limit the possibility of primary infection.

CMV reactivation occurs in 40–80% of at-risk patients and, until recently, a substantial number of such patients progressed to develop CMV disease. As a result, CMV was the commonest cause of infectious death after allogeneic transplantation. It is now possible to detect low levels of CMV infection post transplant, using either polymerase chain reaction (PCR)-based detection of CMV nucleic acids or detection of pp65 antigen in peripheral blood leucocytes (CMV antigenaemia). The introduction of these sensitive diagnostic techniques, coupled with the development of effective antiviral drugs, has markedly reduced the incidence of CMV disease. Nonetheless, CMV remains a significant cause of mortality in recipients of unrelated donor and T cell-depleted transplants. The most common manifestation of CMV disease is pneumonitis, which presents as progressive dyspnoea and hypoxia 30–80 days post transplant. CMV related gastrointestinal ulceration, hepatitis and retinitis are seen only rarely after SCT.

Prevention of CMV disease in at-risk patients (all CMV seropositive patients and any patient with a seropositive donor) has relied on the use of ganciclovir (5–10 mg/kg), a nucleoside analogue that inhibits viral thymidine kinase. The major side-effect of ganciclovir is myelosuppression, which is especially problematic after SCT. Two strategies have been devised to reduce the risk of CMV disease and death in allograft recipients. The first is based on pre-emptive treatment of patients who develop evidence of CMV infection. Ganciclovir therapy is continued until patients have a sustained period without evidence of CMV viraemia. Using this 'pre-emptive approach', ganciclovir use is restricted to patients who reactivate CMV and, consequently, a proportion of patients will not require ganciclovir therapy, thereby avoiding its attendant toxicities. Randomized studies have confirmed that this approach reduces the risk of CMV disease and death after sibling allogeneic transplantation.

Alternatively all at-risk patients can receive ganciclovir prophylactically from the time of engraftment until a defined time

post transplant (usually 90 days), regardless of whether there is evidence of CMV infection. Although this approach is effective in reducing the incidence of both CMV infection and disease post transplant, it increases patient exposure to ganciclovir and is associated with a greater risk of neutropenia and bacterial and fungal infection. For this reason, a pre-emptive approach to prevention of CMV disease is generally preferred. The effective treatment of CMV infection delays the development of an immune response to CMV and as a result late (beyond 100 days post transplant) CMV reactivation and disease is increasingly observed.

Two other agents are valuable in the management of CMV infection and disease. Foscarnet, a DNA polymerase inhibitor, has less myelotoxicity than ganciclovir and is effective as part of a pre-emptive approach, although it is associated with significant nephrotoxicity. Cidofovir is also an effective agent that has the ability to salvage patients with ganciclovir-refractory CMV disease (particularly pneumonitis), although it is nephrotoxic and not recommended in patients with significant renal impairment. High-titre CMV immunoglobulin may also be of value in the treatment of CMV pneumonitis.

Other members of the herpesvirus family have the potential to cause significant morbidity after allogeneic SCT. The incidence of HSV, which used to be very common in the first 30 days after SCT, has been sharply reduced by the use of prophylactic aciclovir. Reactivation of varicella zoster virus (VZV) occurs in up to 50% of at-risk patients after allogeneic SCT, and typically presents as shingles with severe pain and a dermatomal vesicular eruption. Less commonly, VZV reactivation presents with atypical pain (headache or undiagnosed abdominal pain) in the absence of a rash. Prompt treatment of VZV infections with high-dose intravenous aciclovir is indicated after allogeneic SCT, both to prevent dissemination but also to reduce the severity of post-herpetic neuralgia. HHV-8 is also increasingly being reported in association with a syndrome variously associated with delayed engraftment, encephalitis and hepatitis.

Fungal infections

Fungal infections remain a major complication of SCT, reflecting the absence of accurate diagnostic tests and the inadequacy of therapies available at present. A high index of clinical suspicion is therefore required in transplant patients, particularly allografts, and most units administer systemic antifungal therapy early in the course of the management of neutropenic fever. Risk factors for the development of fungal infection include prolonged neutropenia after SCT, the use of high-dose corticosteroids for treatment of GvHD and a history of prior fungal infection.

Effective strategies exist for the prophylaxis and treatment of infection with yeasts (*Candida* spp.) but are lacking for moulds such as *Aspergillus* spp. *Candida* infections typical manifest as oral thrush and, less commonly, as oesophageal candidiasis. Hepatosplenic candidiasis is seen occasionally, presenting with

high spiking fevers at the time of engraftment in association with abnormal liver function tests. Ultrasound or computerized tomography (CT) imaging of the liver and spleen will confirm the diagnosis. Prophylactic use of fluconazole (100 mg daily) has proved effective in reducing the incidence of both superficial and invasive candidiasis. Patients who develop either hepatosplenic candidiasis or candidaemia should be treated with systemic antifungals, usually amphotericin B and any indwelling catheter must be removed.

Clinical features of *Aspergillus* infection develop before or shortly after engraftment usually manifesting as an antibiotic-resistant fever in association with a markedly elevated CRP. End-organ infection, most commonly invasive pulmonary aspergillosis (IPA) or, rarely, cerebral or hepatosplenic aspergillosis, can develop rapidly over a period of days. Accurate diagnosis of *Aspergillus* infections remains problematic as spores are only rarely cultured from lavage fluid or infected tissues, and the sensitivity and specificity of other diagnostic techniques are low. Contradictory results have been obtained using galactomannan detection assays and the initially encouraging results with PCR technology have not been confirmed by all groups. In practice, many units base management decisions on the results of a chest CT, which should be obtained in all patients with a neutropenic fever that has persisted for more than 72 h. Although the characteristic radiographic features of peripheral nodular shadows, with or without evidence of cavitation or a 'halo' sign, may take weeks to develop, the presence of any significant pulmonary infiltrate substantially increases the likelihood of *Aspergillus* infection and is an indication for the commencement of high-dose amphotericin therapy. Conversely, the likelihood of developing IPA in a patient with a normal chest CT is low.

Many patients fail to tolerate treatment with conventional amphotericin because of infusion reactions or nephrotoxicity. Liposomal preparations (Abelcet®, Ambisone®), although significantly more expensive, are much better tolerated and also allow dose escalation in patients in whom there is a high degree of clinical suspicion of fungal infection. Newer drugs such as voriconazole and caspofungin, used alone or in combination with liposomal preparations of amphotericin, are likely to improve therapeutic options in this population of patients, but their precise role remains to be established.

Organ toxicity

Gastrointestinal toxicity

Mucositis is universally observed in patients transplanted using a myeloablative conditioning regimen. It typically develops in the first few days after stem cell infusion and peaks approximately 8 days post transplant. The severity of mucositis is closely correlated with both the intensity of the conditioning regimen and the use of methotrexate as GvHD prophylaxis. Patients with severe mucositis should receive adequate (often opiate) analgesia and be monitored for evidence of airway obstruction.

Table 25.4 Causes of abnormal liver function tests after allogeneic SCT.

Precipitant	Clinical presentation
Veno-occlusive disease	Hyperbilirubinaemia associated with weight gain, ascites and painful hepatomegaly
Drugs	Cyclosporin (hyperbilirubinaemia), fluconazole (raised AST)
Haemolysis	Fall in Hb associated with unconjugated hyperbilirubinaemia and positive Coombs' test
Biliary obstruction	Dilated biliary tree associated with gall bladder 'sludge' or cholelithiasis
Infection	Viral hepatitis, fungal infection (disseminated aspergillosis or candidiasis), cholangitis lenta

Allogeneic SCT recipients may require parenteral nutritional support during this period. In patients who develop symptoms of severe oesophagitis, the possibility of superadded infection with *C. albicans* or HSV must be considered, the latter typically being associated with intractable vomiting. Nausea, vomiting and anorexia are common complications associated with cytoreductive therapy. Given the range of underlying conditions that may be associated with these symptoms, upper gastrointestinal endoscopy is strongly recommended in patients, providing that their mucositis has resolved sufficiently to allow the procedure to be performed safely.

Diarrhoea and/or abdominal pain are common manifestations of conditioning toxicity. Alternative causes of diarrhoea in the first few weeks post transplant include enteritis due to *Clostridium difficile*, rotavirus or CMV, acute GvHD and pancreatitis. VZV reactivation can occasionally present with severe abdominal pain, usually in association with markedly deranged liver function tests.

Liver toxicity
Abnormal liver function tests are commonly observed after allogeneic SCT, and causes include VOD, drugs, infectious-related complications, cholelithiasis and acute GvHD (Table 25.4). VOD is a clinical syndrome characterized by a triad of hyperbilirubinaemia (> 34 μmol/L), weight gain (> 5% baseline) and painful hepatomegaly. It is associated with evidence of damage to sinusoidal endothelial cells and hepatocytes, and subsequent damage to the central veins in zone 3 of the hepatic acinus. In severe cases, hepatic venular occlusion and widespread zonal disruption may lead to portal hypertension, hepatorenal syndrome, multiorgan failure and death. Risk factors for the development of VOD include the use of conditioning regimens containing busulphan or higher doses of TBI, pretransplant abnormalities of liver function tests, previous abdominal irradiation and recent exposure to the anti-CD33 antibody gemtuzumab ozogamicin (Mylotarg).

A diagnosis of VOD is most commonly made on clinical criteria. Doppler studies demonstrating evidence of reversal of portal flow support the diagnosis. Definitive diagnosis requires transjugular venous liver biopsy. which has a significant morbidity in the early post-transplant period and is therefore often avoided. It is important to exclude other causes of hyperbilirubi-

naemia, particularly cyclosporin toxicity, haemolysis (typically consequent upon donor, recipient ABO mismatch) and the hepatitis of sepsis (cholangitis lenta). Management is supportive, consisting of careful fluid balance, the judicious use of diuretics and, where necessary, haemofiltration. There is now convincing evidence that defibrotide can effectively treat up to 40% of patients with severe VOD.

Renal toxicity
Impairment of renal function is frequently observed after allogeneic SCT unless careful attention is paid to fluid balance and the nephrotoxic potential of drugs commonly used during SCT, especially cyclosporin, amphotericin B, aminoglycosides and loop diuretics. Cyclosporin-related renal toxicity is usually easily reversible by temporary omission and dose reduction. Occasionally, cyclosporin toxicity manifests itself as a microangiopathic haemolytic anaemia with features of thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome. Withdrawal of the drug is mandatory and plasmapheresis may be required.

Pulmonary infections and non-infectious complications
A variety of non-infectious pulmonary complications can occur after allogeneic SCT. Pulmonary oedema is common in the first few weeks after transplant, consequent either upon increased capillary hydrostatic pressure caused by fluid overload or upon increased capillary permeability due to irradiation or sepsis. Idiopathic pneumonia syndrome, defined as diffuse lung injury occurring after SCT for which no infectious or non-infectious aetiology can be identified, typically occurs 30–50 days post transplant. The classic presentation includes dyspnoea, non-productive cough, hypoxaemia and non-lobar infiltrates on chest radiograph, which can progress rapidly to acute respiratory distress syndrome. Treatment is supportive but frequently unsatisfactory, and steroids have little effect upon outcome. Diffuse alveolar haemorrhage is seen predominantly in patients undergoing autologous SCT, but can also be seen in allogeneic recipients. This complication usually occurs within the first 2–3 weeks of transplantation and presents with dyspnoea, haemoptysis and hypoxaemia. Radiographic changes include interstitial or alveolar shadowing. Definitive diagnosis requires bronchoscopy, which shows fresh blood on repeated lavage. Recognition

of this disorder is essential as early intervention with high-dose steroids may significantly improve survival.

A range of pulmonary infections occur after allogeneic SCT. In the first month, post-transplant bacterial and fungal pneumonias are common. Viral infections such as CMV, respiratory syncitial virus (RSV) and parainfluenza are important causes of pneumonitis and typically occur in the first 90 days post transplant. PCP infection and toxoplasmosis infection are still seen occasionally in the first few months post transplant in patients who do not receive or are not compliant with cotrimoxazole prophylaxis.

Intensive care support

The outcome of patients admitted to the intensive care unit after allogeneic SCT is very poor, and consultation with intensivists at an early stage in their care is essential. Interventions such as non-invasive ventilatory support, if used early, may reduce the requirement for mechanical ventilation. Patients with isolated respiratory failure requiring mechanical ventilation have a mortality in the range 80–95%, although a significant proportion of those who can be weaned from the ventilator may become long-term survivors. The development of combined hepatic and renal dysfunction in patients who are ventilated is associated with an extremely gloomy prognosis. It is therefore important that the complex decisions regarding the appropriateness or otherwise of intensive support in SCT patients are based on a realistic assessment of the probability of long-term survival.

Late complications of allogeneic stem cell transplantation

As the results of allogeneic SCT have improved, its long-term complications have come to be better recognized and represent an increasingly important cause of morbidity in patients who might otherwise be considered to be cured of their underlying disease.

Chronic graft-versus-host disease

Chronic GvHD refers to a complex syndrome occurring more than 100 days after allogeneic SCT and is its commonest long-term complication. Registry data show an incidence of chronic GvHD of approximately 33% in patients undergoing transplantation from HLA-identical siblings, rising to 66% in patients receiving grafts from unrelated donors. Risk factors for the development of chronic GvHD include increased recipient age, the use of PBSC or an unrelated or HLA-mismatched donor as a stem cell source, and the presence of prior acute GvHD. Chronic GvHD may develop directly from acute GvHD (progressive), after the resolution of an episode of acute GvHD, or *de novo* in patients with no history of chronic GvHD. The clinical manifestations are summarized in Figure 25.5 and are characterized by features of both immunodeficiency and 'autoimmunity'. At present, chronic GvHD is classified as limited or extensive (Table 25.5), although the utility of this staging system is under
Figure 25.5 Clinical manifestations of chronic GvHD.

review. Patients with progressive-type onset, extensive skin involvement, a platelet count $< 100 \times 10^9$/L and a poor performance status have a particularly poor prognosis. Current treatment is unsatisfactory and involves immunosuppression with cyclosporin or prednisolone, which are continued for approximately 6 months prior to a gradual reduction in responding patients. Second-line therapies include tacrolimus, mycophenolate mofetil, thalidomide and extracorporeal photopheresis.

Secondary malignancies

The incidence of solid tumours in recipients of allogeneic SCT is increased compared with control populations and includes a higher rate of skin or buccal cavity squamous cell carcinoma and melanoma. In the largest study to date, the cumulative incidence of all solid tumours was 2.2% at 10 years and 6.7% at 15 years, although the latter figure may represent an overestimate. Risk factors for the development of secondary malignancies include the use of TBI in the conditioning regimen and the presence of chronic GvHD. Post-transplant lymphoproliferative disorder (PTLD) includes a spectrum of Epstein–Barr virus (EBV)-driven B-cell hyperproliferative states that range from polyclonal benign proliferations to life-threatening neoplastic disease. Most cases of PTLD involve EBV-seropositive donors and present with lymphadenopathy and fever. In contrast to the PTLDs that develop following solid organ transplants, the majority of cases after SCT are of donor origin and arise as a result of inadequate T-cell control of proliferation of EBV-infected B-cells. Risk factors for the development of PTLD include T-cell depletion, HLA disparity and ATG therapy. Treatment involves cessation

Limited chronic GvHD

Either or both

of immunosuppressive therapy, donor lymphocyte infusion or anti-CD20 monoclonal antibody (Rituximab®).

Growth, puberty and fertility

Retarded growth is seen predominantly in children who have received irradiation, particularly cranial irradiation. Growth retardation is multifactorial and, although growth hormone levels may be diminished as a consequence of hypothalamic or pituitary irradiation, this does not entirely account for the observed reduction in height. Gonadal failure (both testicular and ovarian) is a common consequence of myeloablative conditioning regimens, particularly those which contain TBI or busulphan. Although prepubertal girls receiving cyclophosphamide alone (as for transplantation in severe aplastic anaemia) are likely to experience a normal puberty, most receiving other preparative regimens will fail to regain normal ovarian function and will require sex hormone replacement therapy for the induction of puberty. Thereafter, sex hormone replacement is indicated to maintain the menstrual cycle and normal bone turnover/mineralization, but the optimal duration of therapy and the potential long-term risks of hormone replacement therapy in this setting is unknown. Although ~10% of women who receive TBI-containing regimens may have some recovery of gonadal function, the overall incidence of pregnancy is very low. In males, cryopreservation of sperm should be performed at diagnosis.

Complications of autologous stem cell transplantation

The major toxicities of autologous SCT relate to immediate or delayed organ failure caused by the conditioning regimen (Table 25.6) or complications consequent upon neutropenia or thrombocytopenia. Late complications are rare but include

Organ	Complications
Lung	Diffuse alveolar haemorrhage; interstitial pneumonitis especially in recipients of bleomycin or TBI-containing regimens
Gastrointestinal	Mucositis, nausea, diarrhoea
Hepatic	Asymptomatic elevations of bilirubin or AST; veno-occlusive disease (especially in recipients of Bu-containing regimens)
Renal	Prerenal acute renal failure; renal toxicity, nephrotoxic antibiotics interstitial nephritis
Cardiac	Arrhythmias; cardiac failure (cyclophosphamide)

Table 25.6 Immediate complications of autologous stem cell transplantation.

pulmonary fibrosis in patients who have received busulphan and BCNU, and gonadal failure particularly in recipients of TBI- or busulphan-containing regimens. Female but not male recipients of BEAM chemotherapy may recover some gonadal function. The development of myelodysplasia and acute myeloid leukaemia (AML) is a well-recognized late complication. It appears that prior chemotherapy is the most important factor in the development of t-MDS or t-AML, as the leukaemia-associated cytogenetic abnormality can frequently be detected in the infused stem cell inoculum.

Management of relapse

Disease relapse after allogeneic SCT indicates resistance of cells within the malignant clone to the conditioning regimen, coupled with an ability to evade tumour surveillance by the donor immune system. Possible mechanisms for tumour evasion include downregulation of HLA class I or II expression, absence of co-stimulatory molecules or location of residual cells in privileged sites such as the central nervous system or testes. Relapse after autologous SCT is caused either by failure of the conditioning regimen to eradicate malignant haemopoiesis or infusion of contaminating tumour at the time of transplantation.

The management of relapse after allogeneic SCT has been transformed by the use of donor lymphocytes. DLI is remarkably effective in patients who have relapsed after allografting for CML, and up to 80% of patients treated in cytogenetic relapse will achieve a durable molecular remission. Responses to DLI are less commonly observed in patients who have relapsed after an allograft for acute leukaemia (AML or acute lymphoblastic leukaemia, ALL), myeloma or lymphoma, although durable responses can occur particularly if donor lymphocytes are administered after cytoreductive therapy. The major complications of DLI are myelosuppression and GvHD. Myelosuppression is most commonly observed in patients with overt haematological relapse and may require treatment with G-CSF and, occasionally, transfusion of donor PBSC. In early studies, DLI was administered as a single 'bulk' infusion and associated with a significant risk of severe GvHD. However, the recognition that the use of an escalating schedule of administration substantially reduces the risk of severe GvHD without compromising its efficacy has markedly reduced the toxicity of DLI.

Patients who relapse after autologous SCT may respond to further conventional chemotherapy, although this will only rarely result in long-term disease-free survival. In a small group of patients, allogeneic SCT may be indicated, although this will be associated with an increased TRM. Patients with myeloma in whom the duration of response to the first transplant was greater than 2 years may benefit from a second autograft.

Donor choice

An HLA-identical sibling donor is identifiable in only one-third of patients eligible for allogeneic SCT. Thanks to the rapid expansion of unrelated donor registries, approximately 8 million volunteer unrelated donors (VUDs) are now registered worldwide. As a result, it is possible to identify a suitable unrelated donor in up to 60% of Caucasians, although this figure is lower in other ethnic groups. Initial results with unrelated donor transplantation were characterized by a high TRM and an increased incidence of severe GvHD. In the last decade, there has been a marked improvement in outcome of unrelated donor SCT. Instrumental in this improvement in outcome has been the development of more accurate tissue typing techniques. In patients undergoing unrelated donor SCT, the availability of molecular typing at class I and II loci of the HLA complex has transformed the process of donor selection, since it is now clear that the presence of multiple disparities at class I or class II loci is associated with a worse transplant outcome. As yet, we lack sufficient information to allow us to identify whether specific allelic mismatches are of particular clinical significance.

Recent improvements in outcome using haploidentical donors make this an increasingly attractive alternative to unrelated donor transplantation. Until recently, haploidentical transplants have been associated with unacceptable rates of graft failure and GvHD. However, the ability to maximize the stem cell dose, using GCSF-mobilized progenitors, coupled with the development of efficient methods of TCD, has significantly improved outcome particularly in children.

Predicting outcome after allogeneic SCT is an imprecise science but analysis of registry data has allowed the identification of a number of risk factors that have been used to construct a robust prognostic score for patients allografted for CML (Table 25.7). The general principles encapsulated in this approach are also applicable to other diseases such as acute leukaemia where similar factors have been shown to affect outcome. In unrelated donor transplants patient CMV status also has a significant impact on outcome, with a marked increase in TRM in CMV-positive patients.

Table 25.7 Predictors of transplant outcome in patients undergoing allogeneic SCT for CML (Gratwohl *et al.*, 1998).

Patient age
Donor match (sibling versus unrelated donor)
Donor sex (female–male associated with worse outcome)
Disease stage
Time from diagnosis to transplant (applies for patients with CML first CP)
Patient CMV serostatus (if undergoing VUD transplant)

Future developments in stem cell transplantation

Autologous stem cell transplantation

The commonest cause of failure after autografting is disease recurrence. Attempts to decrease disease relapse revolve around reducing the risk of contamination of the stem cell inoculum or the use of more effective conditioning regimens. By incubating stem cell harvests with a retrovirus, it is possible to 'tag' infused cells and demonstrate that cells within the transplanted stem cell inoculum do indeed contribute to disease relapse. However, attempts to decrease the risk of relapse using purging techniques have yielded disappointing results. Thus, although it is possible achieve up to a four-log reduction in the number of contaminating plasma cells, randomized studies have shown this does not reduce the relapse rate in patients autografted for myeloma.

The inability of conditioning regimens to eradicate malignant haemopoiesis at present is underlined by the observation that relapse rates remain high in CML and myeloma, even if syngeneic donors are used. Most of the drugs contained in preparative regimens are already administered at close to the limit of extramedullary toxicity and therefore there is little room for further dose escalation. Reducing the risk of relapse will depend either on altering the mode of delivery of agents used at present or the development of new therapies. The scope for optimizing drug delivery is demonstrated by the recent development of an intravenous preparation of busulphan, which results in a more predictable pharmacokinetic profile. Preliminary studies suggest that this approach may decrease the risk of VOD. Haematological malignancies are radiosensitive and there is interest in the possibility of increasing the effective dose of irradiation delivered to the marrow without increasing organ toxicity using radiolabelled immunoconjugates. Early-phase clinical studies using β-emitters (e.g. ^{131}I or ^{90}Y) conjugated to myeloid-specific antigens, such as CD45 or CD66, demonstrate that such an approach is feasible, and phase II studies in myeloma and lymphoma are ongoing.

Allogeneic stem cell transplantation

Major factors limiting the successful application of allogeneic SCT include regimen-related toxicity, GvHD, infectious complications and disease relapse. The use of RIC regimens to reduce the toxicity of allografting is discussed elsewhere. TCD remains the most highly effective method of GvHD prophylaxis, particularly when unrelated donors are used. A major limitation in the effective use of TCD is the increased rate of infectious complications associated with this manoeuvre. The possibility of accelerating immune reconstitution after allogeneic SCT by transfer of antigen-specific cytotoxic T lymphocytes to viruses such as CMV and EBV is being explored at present. Such cells can be generated either by culturing donor lymphocytes with candidate antigens or by direct selection from donor blood using HLA tetramers. Alternatively, infusion of donor lymphocytes from which alloreactive T cells have been depleted may hasten immune reconstitution without incurring a risk of GvHD. In one approach, alloreactive T cells are depleted from the stem cell inoculum by incubating them *ex vivo* with recipient APCs. Activated T cells, defined by the expression of CD25, are then removed using magnetic selection techniques or an immunotoxin. Alternatively, blockade of APC-mediated costimulation (for example, using CTLA-4–Ig or antibodies to B7) may induce anergy or deletion of alloreactive T cells. Co-infusion of naturally occurring or *ex vivo* expanded CD4$^+$ CD25$^+$ regulatory T cells may also inhibit conventional T cells from inducing GvHD. These strategies are all under intense investigation at the present time.

Reducing the risk of relapse after allogeneic SCT can be achieved either by increasing the intensity of the conditioning regimen or by optimizing the GvL effect. Incorporating radioimmunotherapy into the preparative regimen shows promise in the setting of allogeneic SCT and may prove of value in patients with advanced leukaemia, in whom relapse is the most important cause of treatment failure. Alternatively, patients judged to be at a high risk of relapse may benefit from prophylactic DLI, administered with the aim of boosting a GvL response. Such an approach is limited by the fact that administration of donor lymphocytes within the first 12 months of SCT is associated with a high rate of GvHD, particularly if an unrelated donor has been used. Consequently, there is great attraction in the use of donor lymphocytes that recognize residual host leukaemia. Early clinical studies examining the use of lymphocytes generated against minor H antigens or leukaemia-specific antigens such as WT1 and proteinase 3 are recruiting at present. If successful, such an approach, coupled with a TCD transplant, may offer the possibility of disassociating GvHD from GvL.

Introduction

Conventional allogeneic transplantation

In patients with haematological malignancy, bone marrow transplantation from an allogeneic donor has become a well-established mode of treatment for selected patient groups.

The rationale behind this therapeutic procedure is that conditioning treatment is administered in doses designed to ablate the host haemopoietic tissue and, with it, the remnants of the malignancy. The incoming donor graft is then introduced, in the face of minimal resistance from the depleted endogenous immune system, to repopulate the empty marrow and rescue the patient from death due to aplasia. This then largely mimics the technique of high-dose therapy with autologous stem cell rescue (autograft), with the additional benefit of guaranteed tumour-free replacement stem cells.

The disadvantages of this allografting technique, however, relate both to the formidable toxicity of the radio- and chemotherapy used in the conditioning regimens and to the morbidity and mortality ascribable to graft-versus-host disease (GvHD) – the immunological consequence of engrafting an allogeneic immune system – and its treatment.

These effects can be marked in certain groups, for example in older patients, such that allogeneic transplants have conventionally been utilized only in those under the age of 50–55 years, in the absence of concomitant medical problems. As most haematological malignancies peak in presentation after the age of 50, the majority of affected patients have not been considered for allogeneic transplantation. In addition, the procedure-related mortality for certain patient cohorts (e.g. those with Hodgkin's lymphoma, multiple myeloma) when treated with conventional allografts has historically been particularly high – whether because of the pattern of prior treatments, disease-related end organ damage, or other host/disease factors – and clinicians have therefore tended not to offer this line of therapy in such situations.

There is, however, considerable evidence supporting the existence of a graft-versus-malignancy (GvM) effect, whereby an immune response, mediated by T lymphocytes from the incoming allograft, is directed at the host-derived residual tumour cells. Evidence in support of this concept first emerged over 20 years ago, with the observation of an association between the occurrence of graft-versus-host disease and a reduction in relapse rates, and has been further supported by the finding of similarly reduced relapse rates when allogeneic donors are compared with syngeneic donors, and when T cells are not depleted from the incoming graft. Most recently, there has also been the observation that durable disease responses can be obtained, in patients in whom relapse has occurred post allograft, by the direct infusion of additional donor lymphocytes. The disease in which this has been most comprehensively demonstrated is chronic myeloid leukaemia. Not only has the donor lymphocyte infusion (DLI) responsiveness of this disease been shown, it has also been noted that the graft-versus-leukaemia (GvL) effect can be separated from the GvHD effect by incremental increase in CD3 doses, administered at increasing times from transplant. This concept that a therapeutic window exists in which an optimal T-cell dose infused at an appropriate time following allograft will result in an isolated anti-tumour effect has been of particular interest to those attempting to manipulate the donor allogeneic effect in the context of reduced-intensity conditioning.

Reduced-intensity conditioning

Principles

As a potential solution to the problems of excessive regimen-related toxicity, the reduced-intensity or non-myeloablative allograft, was introduced in the mid-1990s.

Table 26.1 Advantages/disadvantages of reduced-intensity conditioning relative to conventional myeloablative regimens.

Advantages	*Disadvantages*

Transplants available in
  Older patients
  Those with comorbid conditions
  Patients with prior autograft
  In non-malignant conditions in which
    feasibility relies on minimal TRM
	Curative potential of myeloablation is lost
	Reliance on GvL effect risks continuing
	  morbidity/mortality from associated GvHD

Some regimens allow outpatient transplantation.

Here, the conditioning regimens are designed principally to immunosuppress the host sufficiently to allow donor engraftment, cure of disease being delivered subsequently by the allogeneic GvL effect. Although the regimens contain varying degrees of anti-tumour activity in order to control the malignancy until the incoming lymphoid compartment is sufficiently reconstituted to exert such a GvL effect, the aim of the conditioning therapy is no longer principally to eradicate disease, and thus toxicity is significantly reduced. In this way, the benefits of allogeneic transplantation can potentially be extended to patients who would generally not be considered candidates for conventional myeloablative transplant regimens (Table 26.1). Although all the regimens devised are broadly grouped together as 'reduced-intensity' or 'mini-' transplants, there is significant disparity in the relative degree of immunosuppression and myelosuppression involved (Figure 26.1). With minimally myelosuppressive or truly non-myeloablative regimens, patients can be conditioned such that donor neutrophil engraftment occurs in the absence of recipient granulocyte aplasia, and this preservation of circulating

Figure 26.1 Comparing the relative myelosuppressive and immunosuppressive properties of various reduced-intensity conditioning regimens. Abbreviations: TBI, total body irradiation; flu, fludarabine; cy, cyclophosphamide; FLA/Ida, fludarabine, cytarabine, idarubicin; mel, melphalan; bu, busulphan; ATG, anti-thymocyte globulin; BEAM, carmustine, cytarabine, etoposide, melphalan.

granulocyte numbers thus reduces the risks of serious bacterial sepsis, so the treatment can even be delivered in an outpatient setting. Conversely, the more myelosuppressive or 'reduced-intensity' regimens cause observable aplasia and carry greater toxicity but have the advantage of greater debulking of residual disease, which may be of importance in those malignancies which are aggressive and propagate rapidly.

To facilitate durable engraftment, the host has to be adequately immunosuppressed in order that the incoming stem cells are not rejected. This is often achieved by using the purine analogue, fludarabine, in combination with either low-dose total body irradiation (TBI) or alkylating drugs such as cyclophosphamide, melphalan or busulphan. Some regimens incorporate, in addition, anti-T-cell serotherapy with either alemtuzumab or anti-thymocyte globulin (ATG) to reduce the incidence of GvHD, although this must be balanced against the need for T cells to facilitate engraftment, contain viral infection and mediate subsequent GvL effects.

Finally, it is important to note that the kinetics of engraftment are significantly altered in non-myeloablative transplantation, although, once again, this is regimen dependent. Given that non-reversible myeloablation is not the aim, host haemopoiesis remains potentially functional, although suppressed, to varying degrees depending on the conditioning approach. This gives rise to a situation of mixed chimerism, whereby assays can detect cells of both recipient and donor origin in peripheral blood. In general, the more intensive regimens – those rendering the host temporarily aplastic – tend to lead to rapid full donor reconstitution, although mixed chimerism can re-emerge subsequently, whereas the minimally myelosuppressive regimens tend to result in a state of initial mixed chimerism. In this situation, a graft-versus-host haemopoiesis effect is required to gradually convert to full donor haemopoiesis. Once again, depending on the underlying condition being treated, rapidly eradicating host haemopoiesis and thus potentially residual malignancy may be a priority. The techniques available for detecting chimerism are usually either cytogenetic, e.g. fluorescence *in situ* hybridization (FISH) to detect sex chromosomes where there is a donor/recipient gender mismatch, or molecular, commonly a polymerase chain reaction (PCR)-based method utilizing microsatellite disparities.

Regimens

Initial reports from Giralt *et al.* (1997) demonstrated that conditioning with fludarabine, idarubicin and cytarabine in 15 patients with acute myeloid leukaemia (AML)/myelodysplastic syndrome (MDS) could result in successful engraftment and complete remission, in some cases of reasonable duration (Table 26.2). This regimen, however, proved insufficiently immunosuppressive to support consistent engraftment in chronic myeloid leukaemia (CML). The same group went on to demonstrate successful engraftment and encouragingly long-lived disease responses in a cohort of 86 patients with haematological malignancies using a purine analogue and melphalan combination, albeit with 34% of patients developing grade II–IV acute GvHD, and with a transplant-related mortality (TRM) at 2 years of 45%. This study also examined the use of a cladribine/melphalan combination, which proved unacceptably toxic.

Other centres were experimenting with radiotherapy-containing regimens, in the expectation that minimizing myelosuppression while providing sufficient immunosuppression to facilitate engraftment would lessen treatment toxicity and even allow transplantation to occur in the outpatient setting. The regimens implemented built on pre-existing data from canine models using MHC-identical littermates which had demonstrated the threshold doses required, first, for causing lethal aplasia and, second, for allowing donor stem cell engraftment. Subsequently it was shown that similar engraftment could also be achieved with incremental reductions in TBI doses if immunosuppressive drugs were additionally administered, the TBI required varying with the drugs chosen.

These findings were then translated into a clinical model of low-dose TBI-based conditioning in HLA-matched related transplants for patients with haematological malignancies, with the majority of transplants being performed in the outpatient setting. The conditioning consisted of a single fraction of 2 Gy TBI given on the day of stem cell return, with immunosuppression thereafter by cyclosporin A (CyA) and mycophenolate mofetil (MMF). Although initial engraftment occurred in all patients, with most avoiding severe cytopenia, 20% of the first 45 rejected following discontinuation of their immunosuppression. The protocol was adjusted to include fludarabine in the conditioning, and rejection was seen thereafter in only 3%. Acute GvHD grade II–IV occurred in 46%, and, of the total 192 patients, 59% were alive at a median follow-up of 289 days. Transplant-related mortality was 22% and the remaining 18% died of their underlying disease, with 2-year overall survival and progression-free survival estimates of 50% and 40% respectively.

Given these results, this regimen was then used in a study of 77 HLA-matched unrelated donor allografts. Sustained engraftment was seen in 78% of patients, with rejection more common in those patients whose stem cell source was bone marrow (7/17; 41% rejected) rather than peripheral blood (10/60; 17%). Data are also available for a cohort of 52 patients with both matched and mismatched unrelated donors; with a median follow-up of 19 months, overall survival and progression-free survival figures were 35% and 25% respectively. Further studies are ongoing with peripheral blood stem cells (PBSC) only as stem cell source, and with modifications to post-transplant immunosuppression in an attempt to reduce late rejection events.

Each of the above regimens involves reinfusing an unmanipulated T-replete graft. As discussed in the previous section, although there are reasons for preferring this approach, it does confer significant risks of acute and chronic GvHD, with the attendant morbidity and mortality. The alternative involves a degree of T-cell depletion of the incoming stem cells, and, in the non-myeloablative setting, this has tended to be done by the use of anti-lymphocyte antibodies *in vivo*. These antibodies are given as part of the conditioning and thus fulfil a dual role, immunosuppressing both host and, as a result of their persistence *in vivo*, incoming donor T cells. The antibodies most commonly used are (ATG) or alemtuzumab (Campath-1H), the former being a mixed product with wide-ranging specificities including T lymphocytes, and the latter an anti-CD52 monoclonal antibody, which targets a variety of cell-types, including T cells, B cells and monocytes.

Slavin *et al.* reported the use of ATG, busulphan and fludarabine, first in 26 patients with either haematological malignancies or genetic disease and subsequently in a further 23 patients, all of whom had lymphoma. This regimen has incorporated subsequent donor lymphocyte infusions (DLIs) to compensate for the T depleting effect of *in vivo* ATG, and disease-free survival was 81% at median follow-up 240 days for the former group and 43% at 675 days for the latter group. Subsequent results have been particularly encouraging for patients with chronic myeloid leukaemia.

Finally, several groups have used regimens containing alemtuzumab (Campath-1H) or, less commonly, Campath-1G. While the most prevalent approach is to combine alemtuzumab with fludarabine and an alkylating agent, many other combinations are under investigation, and the optimal antibody and chemotherapy schedule remains to be established. Kottaridis *et al.* reported a series of 44 patients with haematological malignancies conditioned with alemtuzumab, fludarabine and melphalan, and observed sustained engraftment in 42 of the 43 evaluable patients. Only two patients developed grade II GvHD, with no grade III–IV, and, at a median follow-up of 9 months, progression-free survival was 75%. Other approaches include the use of alemtuzumab, fludarabine and busulphan in MDS in a series of 23 patients, which resulted in 2-year actuarial disease-free survival of 39%, and the use of Campath-1G with BEAM (carmustine, etoposide, cytarabine, melphalan) chemotherapy in lymphoid malignancies, following which 57% of 30 patients studied were disease-free at a median follow-up of 1.3 years.

One of the most striking features of the alemtuzumab-containing regimens is the reduction in GvHD rates. As mentioned above, grade II–IV GvHD has been reported to affect < 5% of

Table 26.2 Reduced-intensity conditioning regimens.

patients receiving matched related allografts, and even in the unrelated setting a series of 47 patients, 20 of whom were mismatched for HLA class I and/or class II alleles, yielded grade II–IV GvHD in 21%, with grade III–IV in only 6%. This compares extremely favourably to those regimens that lack T-cell depletion, with the use of an unrelated donor in the fludarabine and melphalan study described earlier leading to a 25% mortality from acute GvHD.

Infections

A major cause of morbidity and mortality in allogeneic transplantation is infection. There has been some speculation that the use of reduced-intensity conditioning may alter the incidence and characteristics of such infection, for example by using regimens in which mucositis is reduced and by avoiding the lung injury associated with high-dose radiotherapy. Predictably, the profile of infection varies according to the conditioning regimen employed, with those minimally myelosuppressive regimens causing little or no neutropenia (e.g. fludarabine and low-dose TBI) resulting in less risk of early bacterial and fungal infection. Regarding the risk of opportunistic infection, particularly post-engraftment viral infection, this varies with the degree of immunosuppression inherent in the protocol. For example, lymphoid reconstitution is delayed in patients conditioned with regimens including T-cell-depleting antibodies such as alemtuzumab, with its *in vivo* T-depleting effect on the incoming allograft. This results in a high rate of cytomegalovirus (CMV) reactivation, although, with appropriate surveillance and prompt treatment, no excess of disease. This rate of reactivation, however, is not significantly different from similar T-depleted myeloablative regimens, and perhaps the only difference that is suggested between myeloablative and non-myeloablative regimens in the context of viral infection is a reduction in mortality following early respiratory virus infections in the latter group, presumably as they lack the pulmonary toxicity of myeloablative doses of TBI.

Finally, as would be expected, those protocols which contain no T-cell depletion result in significantly higher rates of acute and chronic GvHD, with the concomitant excess of infection that this entails.

In summary, therefore, the risks of infection appear to relate to the degree and length of neutropenia, degree of T depletion and incidence of GvHD – which vary considerably between reduced-intensity protocols – and are similar to those seen in myeloablative protocols, if matched for these risk factors. The possible exception to this seems to be a reduced mortality from respiratory infection in the absence of ablative doses of TBI.

Graft rejection/source of stem cells

Both bone marrow and granulocyte colony-stimulating factor (G-CSF) mobilized PBSCs have been used extensively in reduced-intensity conditioning transplants. The experience with myeloablative regimens would suggest that the use of PBSCs results in more rapid engraftment and in higher rates of chronic GvHD.

There are few specific data in the reduced-intensity setting that address rates of GvHD/engraftment with differing stem cell source, although the Seattle group – using a minimally myelosuppressive regimen – did describe significantly increased rejection when the source of stem cells used was bone marrow rather than PBSCs. Further studies with this protocol therefore have been carried out with only PBSCs as the stem cell source. In addition, the earliest regimen used by this group contained low-dose TBI only, and gave rejection rates of 20%, a figure reduced to 3% by the addition of fludarabine to provide further host immunosuppression.

The more intensive regimens have been associated with significantly less graft rejection, irrespective of stem cell source, with one alemtuzumab-based regimen resulting in rejection in < 3% using PBSCs from sibling donors and 6% using bone marrow from unrelated donors.

Donor type/graft-versus-host disease

Regarding donor type, the early experience with reduced-intensity conditioning using sibling donors has been successfully extended to unrelated donors, either HLA-matched or 1–2 allele mismatched. As expected, the rates of GvHD increase with the use of unrelated, and particularly mismatched, donors, with substantially greater rates of GvHD when the regimens are T-cell replete. For example, the low-dose TBI-based regimens give acute (grade II–IV) GvHD rates of ~45% and ~60% in the sibling and unrelated setting respectively, whereas a T-deplete alemtuzumab-based regimen gives acute (grade II–IV) GvHD rates of 5% and ~20% in the sibling and unrelated settings. Chronic GvHD rates follow a similar pattern.

It had been proposed that the absence of the inflammatory response induced by myeloablative doses of TBI or chemotherapy would lead to generally less acute GvHD in reduced-intensity transplants when compared with the myeloablative setting, but this has not been confirmed.

It would be fair to conclude that there do not appear to be any particular characteristics of GvHD incidence intrinsic to reduced-intensity conditioning, rather that there are substantial differences seen depending on the degree of T-cell depletion in the non-myeloablative regimen used, and that these incidences are similar to those seen in myeloablative transplantation.

Disease-specific outcomes

Multiple myeloma

For the vast majority of patients, multiple myeloma is currently an incurable disease.

Standard treatment involves initial cytoreductive chemotherapy preceding high-dose therapy, with autologous PBSC rescue. While this strategy can result in several years of progression-free survival, there is a continual decline in disease-free survival (DFS), and relapse is generally considered inevitable.

The only prospect for long-term DFS has been allogeneic transplantation with conventional ablative conditioning. However, only a small number of patients are eligible for this treatment for reasons of age/comorbidity/donor availability, and the combination of TRM and disease relapse remains formidable, even in those deemed suitable. Although the historical reported TRM rates are now improving, with advances in supportive care, such non-relapse mortality remains usually in excess of 30%, even in highly selected younger patients with HLA-matched sibling donors. There is, however, evidence for a GvM effect, with demonstration of responses following donor lymphocyte infusion for relapse following conventional allograft, in the order of 40–60%.

The combination, therefore, of allogeneic transplantation as the only demonstrably curative treatment, evidence for a GvM effect, and a high attrition rate from transplant-related causes when conventional conditioning is used, makes this disease an attractive candidate for reduced-intensity conditioning regimens (Table 26.3).

Peggs et al. reported a series of 20 patients (12 HLA-matched related donors, eight unrelated donors) conditioned with alemtuzumab, fludarabine and melphalan. As expected in this setting of T-cell depletion, GvHD rates were encouragingly low, with only 3/20 patients developing grade II acute GvHD and none developing grade III or IV. Unfortunately, the disease responses post transplant presumably also reflect the degree of donor T-cell depletion, with only two patients in complete remission (CR) at 6 months, four in partial remission (PR) and two with minimal response. Donor lymphocytes in escalating doses were given to 14 patients, with seven demonstrating further disease responses – mostly but not exclusively those who also developed GvHD – but these responses were once again not durable, with a 2-year progression-free survival of only 30%.

This and other early experience in myeloma would suggest that debulking of disease to a minimum prior to the allograft, and certainly to a stable plateau, may be necessary to minimize the chance of early progression post transplant, and several groups have addressed this question, with protocols including high-dose chemotherapy with autologous stem cell rescue prior to the allogeneic procedure.

Maloney et al. reported a series of 54 patients treated with induction chemotherapy followed by high-dose melphalan and autologous stem cell rescue. At a median of 62 days later, patients were then conditioned with 2 Gy TBI and stem cells from HLA-matched related donors were returned, with CyA and MMF given as additional immunosuppression. Overall survival at a median follow-up of 552 days was 78%, with a TRM of 17% and extensive chronic GvHD in 46%. Of the 48 patients not in CR at study entry, 25 (52%) subsequently achieved CR and, of those patients (plus the six who entered the study in CR), only three have relapsed. Outcome, in terms of both TRM and disease response, was better in those transplanted with chemoresponsive disease, and the overall progression-free survival at 2 years was estimated at 55%.

A similar tandem approach has been reported by Kroger et al. in 17 patients (nine with HLA-matched related donors) with non-progressive myeloma, who received a melphalan autograft as above, and then were conditioned with fludarabine, melphalan and ATG, prior to stem cell infusion. Complete remission occurred in 72% post procedure, exclusively in those with proven chemosensitive disease, and the estimated progression-free survival at 2 years was 56%.

The follow-up in these studies is currently relatively short, and a true assessment of efficacy is not yet possible, but the early experience suggests that cytoreduction with an autograft may be obligatory if allogeneic transplantation with reduced-intensity conditioning is to be successful in this disease. In addition, the responses in these studies have usually been associated with the presence of GvHD, and there is currently little evidence for a GvM effect occurring in the absence of such GvHD.

Non-Hodgkin's lymphoma

Low-grade non-Hodgkin's lymphoma

This group of conditions, although indolent and frequently consistent with lengthy survival from the time of diagnosis, remain incurable with conventional chemotherapy. High-dose chemotherapy has been used in association with autologous stem cell rescue, and can generate prolonged DFS, but there is a continuing risk of relapse, and a plateau is not apparent on DFS curves.

Where allogeneic transplantation has been employed, the familiar pattern of reduced relapse risk offset by a significant risk of procedure-related mortality has proved prohibitive in the majority of patients. Treatment toxicity is particularly pronounced in the presence of a preceding autograft, and increases with increasing age, rendering the majority of patients with low-grade non-Hodgkin's lymphoma (NHL) ineligible, given the predominance of older patients in the affected cohort.

This has therefore been a particularly attractive setting for transplantation with reduced-intensity conditioning, and several groups have reported series of patients treated in this way, many of whom have relapsed following previous autograft procedures, and some of whom have chemorefractory disease (Table 26.3).

Encouraging results have been reported in a cohort of 20 patients conditioned with cyclophosphamide and fludarabine, nine of whom also received rituximab. Although numbers are relatively small, and 12 of the patients were in complete remission already at the time of transplant, all patients achieved a durable complete remission post procedure, with no disease relapses at a median follow-up of 21 months. In addition, of the six patients who were tested for minimal residual disease by

Corradini *et al.* (2002)	10 (45 all diagnoses)	Flu/cy/thiotepa	Acute (grade II–IV) 47%	Median follow-up 385 days 70% CR
Spitzer *et al.* (2003)	20	Cy/ATG or anti-CD2/TI	Acute (grade II–IV) 45%	Follow-up 13–52 months DFS 25%

Abbreviations: flu, fludarabine; CR, complete remission; OS, overall survival; mel, melphalan; TRM, transplant-related mortality; DFS, disease-free survival; TBI, total body irradiation; NRM, non-relapse mortality; RR, relapse rate; ATG, anti-thymocyte globulin; alem, alemtuzumab; BEAM, carmustine, Ara-C, etoposide, melphalan; PFS, progression-free survival; cPFS, current progression-free survival; NRM, non-relapse mortality; ritux, rituximab; cy, cyclophosphamide; EFS, event-free survival; CR, complete remission; TI, thymic irradiation; bu, busulphan.

PCR for the *Bcl*-2 gene rearrangement before transplant, all subsequently achieved molecular remission. This gave a 2-year actuarial DFS of 84%, although with a cumulative incidence of chronic GvHD of 64%.

The use of T-depleting regimens has also been reported. Morris *et al.* conditioned 46 patients with low-grade NHL [31 follicular NHL, 12 chronic lymphocytic leukaemia (CLL)] with alemtuzumab, melphalan and fludarabine. Most were in partial remission at the time of the transplant, and 25% had had prior autograft procedures. The TRM at 3 years was 10%, with 4-year actuarial overall survival of 69% and progression-free survival of 65%. Eleven patients received DLI for residual disease or disease progression, of whom six responded. Thus, this regimen can be given to relatively heavily pretreated patients with an extremely low incidence of GvHD and a respectable procedure-related mortality. Although the infused graft is T depleted by the alemtuzumab *in vivo*, the conditioning regimen has cytoreductive capacity which appears, so far, to protect from the potential relapse risk conferred by the loss of alloreactive T cells in the initial post-transplant period.

Another T-depleting regimen (fludarabine, busulphan and ATG) was described in 13 patients with CLL, of whom 12 were alive at a median follow-up of 652 days, and 10 of whom were disease-free, as assayed by flow cytometry for minimal residual disease in bone marrow.

The combination of alemtuzumab with BEAM has also been employed with low TRM in patients with lymphoma. Faulkner *et al.* reported a cohort of 51 patients with low-grade lympho-proliferative disease (including five with Hodgkin's lymphoma), conditioned with BEAM-Campath, whose actuarial event-free survival (EFS) at 2 years was 69%, with a relapse rate of 10%. Rituximab has also been added to this schedule to maximize cytoreduction, and preliminary results have been encouraging, with three out of five patients alive in molecular remission at a median follow-up of 521 days.

In addition, data on 77 patients with CLL collated by the Chronic Leukaemia Working Party of the European Bone Marrow Transplant group, albeit with heterogeneous conditioning regimens, showed a 1-year TRM of 18% and event-free and overall survival at 2 years of 56% and 72% respectively.

Therefore, it can be seen that this approach shows promise in the management of the low-grade lymphomas. There is some evidence supporting the presence of a GvL effect, the regimens have relatively low procedure-related mortality, and, although disease control pre-transplant is important, the indolent nature of the disease makes the risk of relapse in the period immediately post engraftment, before the generation of an effective anti-tumour allogeneic, less of an issue than in some of the other haematological malignancies discussed. The very indolence of the disease, however, means that it is still too early to comment on the efficacy of any of these regimens in effecting cure, and data emerging as these cohorts mature will be critical.

High-grade non-Hodgkin's lymphoma

Overall, high-grade NHL is curable in approximately 40–50% of affected individuals, a proportion of whom have relapsed and been salvaged by second-line treatment followed by autograft as consolidation. Almost inevitably, therefore, those patients who have up until now been considered for allogeneic transplantation with conventional conditioning have failed a previous autograft and been in, at best, a third complete remission. Transplant-related mortality in this situation has been reported from around 30% to in excess of 50%.

Several groups have therefore explored the use of reduced-intensity conditioning regimens (Table 26.3).

Morris *et al.*, in the cohort described above, also reported 47 patients with high/intermediate-grade NHL. Most were again in partial remission at the time of transplant, and 70% had had a prior autograft. The TRM at 3 years was 37%, with actuarial overall survival and progression-free survival at 4 years of 35% and 29% respectively. Seven patients received DLI, of whom three responded.

The BEAM–Campath regimen has also been used in high/

intermediate-grade NHL, with a less encouraging event-free survival than in low-grade disease (17% at 2 years), and a correspondingly high relapse rate (68% at 2 years). Responses to DLI given for disease progression were poor, and this group now plan to reduce post-transplant immunosuppression in an attempt to combat early relapse.

Corradini *et al.* described 10 patients with high-grade NHL who received conditioning with thiotepa, fludarabine and cyclophosphamide before reinfusion of a T-replete graft. Non-relapse mortality was relatively low and, at the time of reporting, seven of the patients were alive in complete remission.

In addition, Spitzer *et al.* reported a series of 20 patients with diffuse large B-cell lymphoma, 17 of whom had chemorefractory disease, who were conditioned with cyclophosphamide, ATG or anti-CD2 antibody and thymic irradiation. Eight patients had a disease response, and, of these, five were alive and progression free at 13–52 months' follow-up (25%). Four of these five patients had chronic GvHD.

There have been many other reports of the use of different conditioning regimens on small numbers of patients with high-grade disease. In general, the data on high-grade disease are less encouraging than on low-grade disease, with usually higher procedure-related mortality and poorer disease response rates, although progression-free survival with 1–2 year follow-up is certainly being seen in a proportion of these otherwise incurable patients.

The generally inferior disease responses seen may partly reflect the more rapid tempo of disease growth when compared with low-grade disease, meaning that the risk of early relapse or progression is relatively higher during the period post transplant prior to the development of a significant allogeneic effect. Furthermore, donor lymphocyte infusions may be unable to exert a sufficiently robust GvL effect within the timescale needed, if administered in the presence of relapsing disease.

In an attempt to maximize disease reduction prior to allogeneic transplantation, and therefore minimize the risk of progression/relapse prior to the establishment of an allogeneic GvL effect, cytoreduction with high-dose chemotherapy plus autologous stem cell rescue prior to allogeneic transplantation is also being explored.

Hodgkin's lymphoma

In Hodgkin's lymphoma, significant numbers of patients who relapse following standard first-line therapy can be salvaged by reinduction treatment and then consolidation with autologous stem cell rescue. There is, however, a cohort that subsequently relapses, and in whom allogeneic transplantation with conventional conditioning has proved effective in reducing relapse rates but at a prohibitive cost in terms of procedure-related mortality, resulting in no increase in overall survival.

Once again, reduced-intensity conditioning has been attempted in this cohort with reasonable early results (Table 26.4). Using

an alemtuzumab-containing regimen, Peggs *et al.* describe results in 41 patients. Transplant-related mortality was 9%, and 16 patients received donor lymphocyte infusions for residual/progressive disease post-transplant. Of those, nine had demonstrable responses, giving a current progression-free survival at 4 years of 42%, and demonstrating the existence of a therapeutically beneficial GvL effect.

The strategy described previously using preceding high-dose chemotherapy with autologous stem cell rescue has also been used in patients with high-risk Hodgkin's lymphoma. Carella *et al.* described 17 patients treated with a BEAM autograft, followed by fludarabine/cyclophosphamide conditioning and stem cell return from HLA-matched sibling donors. Responses were seen in 11 patients (CR in nine), and 11 were alive (six in ongoing CR) at a median follow-up of 566 days. Of note, the best disease responses were seen in those patients who achieved full

donor status and in whom GvHD developed, again suggesting the presence of an allogeneic graft-versus-lymphoma effect.

Chronic myeloid leukaemia

As CML is the disease in which response to allogeneic donor lymphocyte infusion was first and most comprehensively demonstrated, it is an obvious candidate for the reduced-intensity conditioning approach (Table 26.4).

Or *et al.* described 24 patients transplanted in first chronic phase, using fludarabine, busulphan and ATG. The incidence of significant acute GvHD was 54%, and, at a median follow-up of 42 months, 21 of the 24 patients remained well, and in complete molecular remission, giving an actuarial 5-year DFS of 85%.

Elsewhere, use of a similar regimen, involving fludarabine plus busulphan as conditioning, was described in 44 patients

Table 26.4 Disease-specific outcome according to regimen.

Reference	No. of patients	Conditioning	GvHD	Outcome
Hodgkin's lymphoma				
Carella *et al.* (2001)	17	(BEAM autograft first) Flu/cy	Acute (grade II–IV) 24%	Median follow-up 566 days OS 65%, DFS 35%

Sayer *et al.* (2003)	113	Flu/bu or TBI	–	Median follow-up 12 months RM 26%, NRM 26%

Abbreviations: flu, fludarabine; ida, idarubicin; bu, busulphan; cy, cyclophosphamide; CR, complete remission; OS, overall survival; 2-CDA, 2-chlorodeoxyadenosine; TRM, transplant-related mortality; DFS, disease-free survival; TBI, total body irradiation; NRM, non-relapse mortality; RM, relapse mortality; ATG, anti-thymocyte globulin; alem, alemtuzumab; BEAM, carmustine, Ara-C, etoposide, melphalan; PFS, progression-free survival; cPFS, current progression-free survival; CP, chronic phase.

with CML, with 34 patients also undergoing T-cell depletion via ATG. Again, acute GvHD occurred in a significant proportion, and at a median follow-up of 562 days TRM was substantial, at 34%, with 50% of the patients transplanted in chronic phase alive and disease free at 2 years. This form of transplantation is therefore a viable option in patients with CML in first chronic phase, with ample capacity for inducing disease responses by the administration of donor lymphocytes.

Acute myeloid leukaemia/myelodysplastic syndrome

Giralt *et al.* first demonstrated the feasibility of the non-myeloablative approach in a group of 15 patients with refractory or relapsed AML/MDS who were conditioned with either fludarabine/cytarabine/idarubicin or cladribine/cytarabine prior to infusion of stem cells from sibling donors (Table 26.4). Toxicity was acceptably low, and eight patients achieved remission post transplant, although responses were short-lived, as expected, in this high-risk group, and relapse occurred in all but two by a median follow-up of 100 days. The same group reported on the use of fludarabine and melphalan in these patients, and found that the additional cytoreduction conferred by this regimen resulted in improved DFS.

Following this, Parker *et al.* evaluated a fludarabine, busulphan and alemtuzumab-containing regimen in 23 patients with MDS. Early TRM was 9%, with a 2-year actuarial overall survival of 48% and DFS of 39%. Thus, transplantation with reduced-intensity conditioning was deemed a feasible approach for those patients considered inappropriate for conventional conditioning because of age or comorbidity, yielding similar results to those found in patients fit for the fully conditioned regimen. Of note, those individuals who fared best were those with good- or intermediate-risk cytogenetics and a low or intermediate International Prognostic Scoring (IPS) system score.

In those with high-risk MDS, Kroger *et al.* reported on 12 patients conditioned with fludarabine, busulphan and ATG. The results were consistent with the above observation regarding outcome-related to overall risk status, with a 2-year actuarial DFS of 12%, treatment toxicity and disease relapse both contributing to the generally poor outcome.

Furthermore, the same group subsequently published a study of 37 patients with MDS or secondary AML, in half of whom the donor was related, who were ineligible for conventionally conditioned transplants. The group received fludarabine, busulphan and ATG as reduced-intensity conditioning. The overall TRM was 27%, with significantly higher mortality in those with poor-risk cytogenetics (75% vs. 29%) or with an HLA-matched unrelated donor (45% vs. 12%). Thirty-two per cent of patients relapsed, and actuarial DFS at 3 years was 38%, with a median follow-up of 20 months. One further observation was that the development of chronic GvHD conferred a relative protection from disease relapse (15% vs. 70%).

Eighteen patients with AML (*de novo* 13, secondary 5) in first CR who had a sibling donor but were ineligible for conventional conditioning were reported by Feinstein *et al.* in 2003. Reduced-intensity conditioning was performed with fludarabine and 2 Gy TBI (8) or 2 Gy TBI alone (10). With a median follow-up of 766 days, 10 of the 18 patients (56%) had died, seven of whom had suffered a relapse. Of the eight survivors, seven were in continuing CR.

Finally, Sayer *et al.* reported on 113 patients with acute myeloid leukaemia ineligible for conventional transplants who were receiving reduced-intensity conditioning, consisting of fludarabine and busulphan or TBI. Apart from once again demonstrating the feasibility of such conditioning in these patients, this study identified certain poor prognostic factors. These included low Karnofsky performance scores and the presence of unrelated donors, but the most striking association was that between the level of residual disease at the time of transplant and subsequent outcome. With a median follow-up of 12 months, the probability of EFS was 49% for patients in morphological remission on bone marrow examination, 24% in patients with 5–20% blasts, and 14% in patients in whom > 20% blasts remained.

Thus, reduced-intensity conditioning shows some promise in those patients with AML/MDS ineligible for transplantation using conventional regimens, although follow-up is generally relatively short. Furthermore, outcome is significantly affected by the presence of poor-risk features such as high-risk cytogenetic changes, chemorefractory disease, unrelated donors and low IPS and Karnofsky performance scores. These factors should be considered when selecting patients for such procedures. In addition, there seems to be, in common with other malignancies, a beneficial effect conferred by the presence of chronic GvHD on the risk of disease recurrence.

In conclusion, although allogeneic transplantation with conventional conditioning should still be considered the procedure of choice in AML/MDS, if patients are ineligible for such treatment, reduced-intensity conditioning is a viable alternative.

Non-haematological malignancy

Reduced-intensity conditioning also has potential application in the treatment of solid tumours, where an allogeneic GvM effect may also be inducible (Table 26.5). Renal cell carcinoma is an attractive candidate for such immunotherapy, as some patients respond to immunomodulatory cytokines, and spontaneous regression of metastatic disease is occasionally seen. Childs *et al.* reported on 19 patients with refractory metastatic renal cell carcinoma conditioned with cyclophosphamide and fludarabine, a regimen with no anti-tumour effect. Disease responses with reduction in metastatic lesions were seen in 10 (53%) of the cohort, with three complete responses. All three remain in CR at a median follow-up of 402 days, and only two of the patients with PR have progressed within that time.

Table 26.5 Disease-specific outcome according to regimen.

Reference	No. of patients	Conditioning	GvHD	Outcome
Non-haematological malignancy				
Childs *et al.* (2003)	19	Flu/cy	Acute (grade II–IV) 53%	Median follow-up 402 days OS 43%, DFS 16%
Ueno *et al.* (2003)	23	Flu/mel	Acute (grade II–IV) 39% Chronic 43%	Follow-up 19–1119 days NRM 22% Disease response 45%
Inherited defects				
Horwitz *et al.* (2001)	10	Flu/cy/ATG	Acute (grade II–IV) 30%	Median follow-up 17 months Engraftment, reduced infection in 8/10 patients
Amrolia *et al.* (2000)	8	Flu/mel/ATG	No acute (grade II–IV)	Median follow-up 12 months Good immune function in 75%

Abbreviations: flu, fludarabine; cy, cyclopsosphamide; OS, overall survival; mel, melphalan; DFS, disease-free survival; NRM, non-relapse mortality; ATG, anti-thymocyte globulin.

The median time to disease response was 4 months, and evidence for a GvM effect was the occurrence of responses only following withdrawal of immunosuppression and conversion to full donor status, in addition to the association between GvHD and disease regression.

Given the observation that conversion from mixed chimerism seemed a necessary precondition for response, other groups have experimented with regimens yielding rapid full donor status, for example a fludarabine/melphalan combination, where only donor haemopoiesis was detected by 30 days post transplant, and responses were subsequently shown in 8 out of 15 (57%) of patients with metastatic renal cell carcinoma.

There has also been considerable interest in reduced-intensity conditioning in transplantation for treating breast cancer, following the earlier observations that an allogeneic effect occurred in some patients with regression of liver deposits following conventional myeloablative conditioning. The same fludarabine/melphalan regimen mentioned above was also administered to eight patients with refractory metastatic breast cancer, with three of the eight (37%) showing responses, two of which were complete. Once again, responses were associated with the withdrawal of immunosuppression or the development of significant GvHD.

Other solid tumours are also being studied, including colon carcinoma, hepatocellular carcinoma, and sarcomas of varying origin, and this is clearly an area with considerable potential but where definitive benefit remains to be demonstrated.

Inherited defects

A further group of disorders in which non-myeloablative transplantation has potential utility is in treating congenital defects of the lymphohaemopoietic system (Table 26.5). In this situation, the aim is to produce a state of mixed chimerism sufficient to provide a source of the defective gene product. There is usually no requirement for the incoming graft to completely supplant recipient haemopoiesis, as adequate function can be restored with only partial reconstitution of the defective cell population, and in addition there is no requirement for a graft-versus-host effect other than the relatively minor degree of graft-versus-lymphohaemopoietic effect necessary to ensure stable engraftment. While conventional conditioning has been used in these conditions, the procedure-related mortality and morbidity has proven prohibitive in many instances, which is not surprising given that the majority of these conditions are compatible with relatively lengthy lifespans when compared with the malignancies that constitute most candidate diseases for allogeneic transplantation.

Allogeneic transplantation has been shown to be curative in sickle cell disease, and there are anecdotal case reports of success using reduced-intensity conditioning regimens in this disease. In addition, transplantation with conventional conditioning has been demonstrated to be an effective intervention in other haemoglobinopathies, such as the thalassaemias, although toxicity becomes limiting where significant pretransplant end-organ damage is present, thus making this another attractive patient group for the reduced-intensity approach.

Regarding enzyme defects, a series of 10 patients with chronic granulomatous disease conditioned with cyclophosphamide, fludarabine and ATG has been reported, with 33–100% of neutrophils being of donor origin in eight of the recipients (graft rejection occurred in two) at a median follow-up of 17 months. A concomitant clinical response was seen, with only four episodes

of significant bacterial infection in those eight patients post engraftment.

Amrolia *et al.* reported a series of eight patients with congenital immunodeficiencies (two CD40L deficiency, one X-linked lymphoproliferative disorder, one adenine deaminase deficiency, four unclassified severe or combined immunodeficiencies) who underwent conditioning with fludarabine, melphalan and ATG. One patient died of relapsed disease, while six of the remaining seven were evaluable at median follow-up of 1 year, and all showed improvement in phytohaemagglutinin stimulation indices. In addition, the patients with CD40L deficiency both show increased expression of the affected receptor, and the patient with adenine deaminase deficiency has increased levels of the appropriate metabolites.

Other conditions

First, it is important to mention aplastic anaemia, the condition in which, arguably, reduced-intensity conditioning became first established. Conditioning for HLA-matched sibling allografts with cyclophosphamide alone was introduced in 1969. Graft rejection was high, however, and ATG was added to the regimen in the late 1970s. Although various regimens have been employed since then, the use of a non-myeloablative approach has remained both popular and successful in transplantation for this condition.

Reduced-intensity conditioning has also been studied in patients with acute lymphoblastic leukaemia. Results so far have been modest, with high procedure-related mortality and little chance of effective salvage unless the patient is in a stable complete remission.

Treatment of myelofibrosis has also been attempted via non-myeloablative conditioning, with encouraging results, although numbers are small and follow-up preliminary.

There exist anecdotal reports of resolution of pre-existing autoimmune diseases such as psoriasis and ulcerative colitis in individuals who have undergone conventional allografts because of other pathology. There has also therefore been some interest in the use of reduced-intensity conditioning in autoimmune conditions such as systemic lupus erythematosus (SLE), although it must be remembered that chronic GvHD can manifest with syndromes resembling autoimmune diseases, and that complete removal of recipient lymphopoeisis may well be necessary to induce complete remission.

In addition, animal modelling has demonstrated that donor-specific tolerance to a solid organ allograft can be induced by preceding or concomitant stem cell transplantation. This is demonstrated in a report documenting the successful acceptance of a donor kidney in two patients with myeloma and end-stage renal failure who underwent combined bone marrow and renal transplantation following reduced-intensity conditioning. Post-transplant immunosuppression was tapered rapidly, and despite donor chimerism being lost by 100 days post procedure, a state of lasting tolerance to the solid-organ allograft was established.

Conclusion

It can therefore be seen that allogeneic transplantation with reduced-intensity conditioning can be successfully performed in individuals with a wide variety of different diseases. Procedure-related toxicity has proven significantly less of a problem than in conventional conditioning, and has provided a means of delivering potentially curative treatment in many situations where this has previously not been possible. Longer follow-up and greater numbers are clearly required to delineate the exact potential for cure in the various different diseases, but encouraging results have been published thus far.

The major challenges for this field remain the identification of the optimal conditioning regimen for particular disease groups and, crucially, the manipulation of the allogeneic effect so as to promote GvM while avoiding undesirable GvHD. While GvM responses are often seen following the development of GvHD, some disease responses have been observed in the absence of GvHD, and attempts are being made to target, for example, overexpressed/abnormal tissue antigens or haemopoietic minor histocompatability antigens which may be relevant for such anti-tumour activity. If, for example, appropriate T-cell clones can be generated and expanded *ex vivo*, or generated *in vivo* by vaccination of donors, transplantation with non-myeloablative conditioning could provide an ideal platform for subsequent adoptive cellular therapy.

Gene therapy of haemopoietic disorders

27

Raphaël F Rousseau and Malcolm K Brenner

Introduction

Somatic cell gene transfer may be used to correct a deficit in a cell, to enhance or inhibit its pre-existing function, or to provide the cell with an entirely new capacity. This broad range of actions means that gene transfer may in principle contribute to the therapy of almost every disease in haematology. For principle to be turned into practice, however, investigators will need to overcome a formidable array of regulatory and technical barriers. The delay in the introduction of successful gene therapeutics that followed the initial hyperbole has led many to conclude that the entire field is devoid of clinical relevance. While this nihilistic viewpoint may yet be proven correct, it is more likely that the power of gene transfer will allow it to make essential contributions to otherwise intractable haematological problems. It is the purpose of this chapter to describe potential applications, current problems and future solutions.

For gene transfer to be of benefit, a number of criteria need to be met. First, the transferred gene's function should be understood. If, for example, a gene is active only during fetal development, there may be little purpose in attempting gene therapy for an adult. Similarly, genetic disorders in which the abnormal gene produces a transdominant effect (for example sickle cell anaemia) cannot be corrected simply by transferring a normal gene. Second, it will be necessary to have vectors that transfer the genes efficiently, safely and (ideally) in a targeted fashion, so that the correct cells are transduced. Moreover, for many applications the products of the transgenes need to be regulated, in terms of the quantity and timing of the material produced. While many gene transfer techniques are available, none meets these needs in full, and many fall far short of the desired goals. Hence,

the practice of gene therapy has to a large extent consisted in a careful selection of disease entities and treatment strategies that can exploit the limited strengths of current vectors, while avoiding their very substantial weaknesses. Undoubtedly, as our capacity to prepare safe, efficient, targeted and regulatable gene transfer vectors improves, the range of disorders that will be amenable to such treatment will grow. But, for the moment, ambition must be tempered by ability. Fortunately, for haematological diseases in general, and for malignant haematological diseases in particular, even current vectors provide us with opportunities to explore worthwhile clinical applications.

Gene transfer vectors for haemopoietic cells

A prerequisite for gene therapy for haematological diseases is successful transduction of target cells, which may include a malignant cell population, haemopoietic stem cells (HSCs), cells of the immune system or (for haemophilia) the cells of other organ systems (Table 27.1). The aim of transducing malignant cells is to reduce tumorigenicity or enhance immunogenicity, while the aim of transducing normal cells is to correct functional defects, or (in malignant disease) to permit cytotoxic drug dose escalation and to improve the outcome of stem cell transplant procedures. The major constraints for gene transfer strategies are the efficiency of gene delivery to target cells and the safety of the vectors used, in terms of immediate toxicity and the induction of mutational events following transgene integration; the importance of each is dependent on the vector system used.

449

Table 27.1 Advantages and disadvantages of vector systems.

Vector	Advantages	Disadvantages	Current uses
Retrovirus	Stable integration into dividing cells Minimal immunogenicity Stable packaging system	Low titre Only integrates in dividing cells Limited insert size Risk of silencing Risk of insertional mutagenesis	Marker studies Gene therapy approaches using haemopoietic stem cells or T cells Transduction of tumour cells
Adeno-associated virus (AAV)	Integrates into dividing cells Infects wide range cell types	No stable packaging cell line Very limited insert size	Gene therapy approaches using haemopoietic stem cells
Lentivirus	Integrates into dividing cells Integrates into non-dividing cells	No stable packaging system Complex safety issues	No approved trials as yet
Adenovirus	Infects wide range cell types Infects non-dividing cells High titres High level of expression Accepts 12- to 15-kb DNA inserts	Highly immunogenic Non-integrating	Direct *in vivo* applications Transduction of tumour cells
Herpesvirus	High titres Transduces some target cells at high efficiency Accepts large DNA inserts	No packaging cell lines Non-integrating Difficult to scale up for human use May be cytotoxic to target cell	Transduction of tumour cells Neurological disorders
Liposomes and other physical methods using naked DNA	Easy to prepare in quantity Virtually unlimited size	Very inefficient entry into target cell Non integrating	Topical applications Transduction of tumour cells

Retroviruses

Murine retroviruses, particularly the Moloney murine leukaemia virus (MoMuLV), have been used extensively as gene delivery systems, especially in gene marking studies. They are single-stranded RNA viruses that are transcribed by reverse transcriptase into double-stranded DNA that can integrate into host DNA. In a clinical vector, the packaging signal and long terminal repeats (LTRs) are retained, while the structural and replicative genes (*gag*, *pol* and *env*) of a murine retrovirus are replaced by one or more genes of interest, driven either by the retroviral promoter in the 5′-LTR or by an internal promoter, leaving room for up to 5 kb of transgene. The retroviral constructs are made in cell lines in which the missing retrovirus genes are present in *trans* and thus reproduce and package a vector that is not replication competent. After production of viral particles and infection of target cells, the vector is uncoated in the cytosol and the RNA is transcribed via reverse transcriptase into DNA, which integrates into the host genome. Thus, the transferred gene not only survives for the entire lifespan of the transduced cell, but is also present in that cell's progeny.

The host range of MoMuLV viruses is determined by the gp70 envelope protein, which interacts with their cellular receptors, and the genetic information they convey is integrated into the host cell DNA. Hence, these vectors are ideal for transferring genes into rapidly dividing cell populations, such as haemopoietic stem cells or lymphocytes. However, retroviral vectors have several disadvantages. Because expression of the transferred gene requires viral integration of the genome, and hence a population of dividing cells, the efficiency of transfer to many types of cell may be low. It is possible to increase efficiency by bringing vector particle and target cell into close physical apposition, for example by performing transduction on substances such as fibronectin, but, even then, overall levels of transfer leave much to be desired. *In vivo* gene transfer in many clinical studies has been disappointingly low, perhaps because the cytokines used to induce target cells into cycle also commit them to differentiation. Further, because the integration events themselves occur largely at random in the host cell DNA, regulatory genes could conceivably be damaged, contributing to oncogenesis. This hypothetical concern became reality with the development of T-cell leukaemias in two children with X-linked common gamma-chain severe combined immunodeficiency who were treated by retrovirus-mediated gene transfer of the absent cytokine receptor gene. Both had proviral integration sites proximate to the *LMO-2* gene, which is critical for T-cell growth and has been implicated in other spontaneous leukaemic transformations. Finally, retroviral vectors are not well suited for use *in vivo*, since they are generally unstable in primate complement, and as yet they cannot be targeted to specific cell types.

The development of pseudotyped particles, in which a retroviral vector genome is incorporated into an envelope derived all or in part from a different virus, may improve the *in vivo* stability of retroviral vectors and alter their target cell range.

Adenoviruses

In approaches in which short-term gene transfer may be adequate (for example the generation of anti-tumour vaccines), adenoviral vectors are an alternative delivery system. First-generation adenoviral vectors are *E1* (early protein) deletion mutants and therefore are not replication competent. These vectors infect a wide range of cell types and, unlike retroviruses, can transfer cDNA sized up to 10 kb even into non-dividing cells. The vectors are reasonably stable *in vivo* and can be used to infect cells *in situ*. Examples include gene transfer into respiratory epithelium (the *CFTR* gene in cystic fibrosis) or liver (genes encoding factor VIII and factor IX in haemophilia A or B). However, adenoviral vectors are generally non-integrating, so that the gene products are expressed from episomal DNA. The episome is often lost after cell division and can be inactivated or lost even in a non-dividing cell. Thus, adenoviral vectors are unsuited for any application that requires long-term expression in a rapidly turning over cell population. A more important limitation is that most adenoviral vectors are immunogenic. Immune responses are generated against the vector proteins themselves (often preventing readministration of the vector), as well as against low levels of adenoviral proteins, expressed even when cells are transduced by defective viruses. Moreover, concurrent expression of adenoviral genes appears to increase the probability of developing an immune response to the transgene product. Even before these adaptive immune responses are generated by adenoviruses, vector entry into many cell types triggers an innate immune response, with the release of cytokines, such as interleukins 6 and 8 and the development of a potentially highly destructive local inflammatory response. Finally, adenoviral damage to vascular endothelium and to other organ systems may cause a potentially lethal disseminated intravascular coagulopathy, or a more chronic hepatocyte hypertrophy and hepatic fibrosis. Since deletion of the E1 region alone does not prevent these toxicities, subsequent generations of adenovectors have been prepared that lack more than one set of adenoviral genes. Although showing less immunogenicity and toxicity and more durable transgene expression in some studies, such modified vectors produced little or no benefit in others, at least in part because of the persistent induction of innate immunity. Indeed, administration of an *E1/E4*-deleted vector has been linked to the death of a patient with ornithine transcarbamylase deficiency after adenoviral gene transfer via the hepatic artery.

The ultimate attenuated adenovector is the helper-dependent or 'gutless' vector, in which virtually all of the adenoviral genes have been removed and replaced with the gene of interest and its promoter, together with irrelevant DNA to allow packaging in the viral envelope. In this system, one virus (helper) contains all viral replication genes and the other contains only the therapeutic gene sequence, the viral inverted terminal repeats (ITRs) and the packaging recognition signal. Helper-dependent vectors have shown a much higher therapeutic index than conventional adenovectors in several different models. Importantly, they also seem to be much less immunogenic, so that transduced post-mitotic cells (muscle or liver, for example) may secrete vector-derived proteins over many months, a prime consideration in the treatment of many deficiency disorders. However, the manufacture of these viruses is currently difficult to scale up and there is a continued problem with contaminating helper virus, although the amounts may be less than 0.1%.

Adeno-associated viruses

Adeno-associated viruses (AAVs) are human parvoviruses that normally depend on a helper virus (adeno- or herpesvirus) for productive infection. Structurally, AAV is a DNA parvovirus, containing two palindromic-inverted terminal repeats (ITR). When linked with two gene products from the *rep* gene region, these repeats favour site-specific integration of chromosome 19 by the AAV. Thus, AAVs, like retroviruses, should persist for the entire life of the host cell and its progeny. Because genomic integration by AAVs is relatively site specific, the risk of oncogenesis is theoretically low. Moreover, AAVs may integrate the genomes of non-dividing cells and become permanently expressed even in resting or post-mitotic cells. Vectors based on AAVs have been developed as gene transfer vehicles able to transduce a wide variety of cells including non-dividing cells. There is no known disease associated with AAVs and, since the AAV vector genome lacks viral coding sequences, the vector itself has not previously been associated with toxicity or inflammatory responses, although data from a study in haemophilia, described below, have led to questioning of this dogma. AAVs may certainly generate neutralizing antibodies that may limit repeat administration although the availability of additional AAV vector serotypes may overcome this problem and allow additional cell types to be targeted. The major limitations of the AAV vectors are the small size (ca. 3.5 kb) of insert and the labour-intensive large-scale production required for clinical trials, caused in part by difficulty in developing high-titre producer cell lines free of contaminating helper adenoviruses.

Herpes viruses

Vectors derived from herpes simplex viruses (HSVs) can be used to transduce neuronal cells in a variety of preclinical models, and in some rodent tumour cell lines. Herpes-based vectors have a number of potential advantages over alternative systems in terms of their titre, the size of the gene insert, and their safety. Herpes-based vectors lack essential genes for toxicity and/or infectivity (such as glycoprotein H or gH), but can be grown to

high titre in a complementing cell line. In non-complementing cell lines that are permissive for herpesvirus growth, these vectors are restricted to a single cycle of replication, leading to the release of non-infectious virus. Improvements of this vector platform include the development of amplicons, in which plasmids are packaged as large tandemly repeated DNA in place of the wild-type HSV genome. Amplicons retain the outstanding transducing abilities of the original vector while reducing the risk of immunization and increasing the probability of generating stable transfectants of normal and malignant haemopoietic cells. Further enhancements include combination with other vectors and the generation of hybrid vectors with stable integrating capabilities into the genome of the host cell. These vectors have yet to be used for gene therapy of haemopoietic disease.

Human immunodeficiency viruses and other lentiviral vectors

Human immunodeficiency virus (HIV) vectors efficiently transduce primitive haemopoietic progenitors and primary acute leukaemia cells. HIV also infects and integrates into non-dividing and post-mitotic cells using as yet unidentified viral components. Technical problems remain before lentiviruses can readily be used for clinical application. For example, the toxicity of some HIV proteins has made generation of stable packaging cells difficult. In addition, there are safety concerns with these vectors – in particular the use of HIV-derived vector systems raises the possibility that wild-type or mutant infectious HIV may be generated during vector production. Efforts to increase safety include the development of third-generation, self-inactivating (SIN) lentiviral vectors in which the parental HIV-1 enhancer and promoter sequences from the lentivirus 3′-LTR have been deleted. When the SIN vector infects the target cells, they are incapable of transcribing vector-length RNA, and are thus incapable of further replication, reducing the likelihood of generating replication-competent retroviruses. SIN vectors should be regarded as the lentiviral vectors of choice for clinical trials and exploration of their value – initially in the treatment of AIDS – has begun.

Liposomes and other physical gene transfer methods

Clinical experience with the available physical methods of gene transfer has primarily involved cationic liposome–DNA complexes which fuse with the cell membrane and enter the endosomal uptake pathway. DNA released from these endosomes may then pass through the nuclear membrane and be expressed. The main advantage of liposomes is that they are non-toxic and can be given repeatedly. In some cell types, high levels of gene transfer have been obtained by this method. Liposomes are rather unstable *in vivo*, but liposomal transfer by local injection of human melanoma cells *in situ* has resulted in the expression of a new gene (HLA-B7). However, the DNA transferred by liposomes does not integrate the genome and, despite the incorporation of a variety of ligands into the liposome–DNA complex, the ability to target these vectors is still quite limited.

Successful gene transfer *in vivo* has also been reported with use of a bio-ballistic ('gene gun') technique in which DNA coated onto colloidal gold particles is driven at high velocity by gas pressure into the cell. It is not yet clear whether this approach can be used to transduce normal or malignant haemopoietic progenitor cells with sufficient efficiency to allow therapeutic application in humans. Localized electroporation of plasmid DNA using microelectrodes has also proved to be highly effective for *ex vivo* and *in vivo* transduction of cells from muscle and skin and may be followed by significant transgene expression.

Hybrid vectors

None of the vectors currently available is suitable for every potential application of gene transfer in haematological disease, and none is free of significant limitations and adverse effects. Ultimately, therefore, entirely new synthetic or semisynthetic vectors will have to be developed. Possibilities include the generation of hybrid viral vectors, which may combine, for example, the *in vivo* stability of adenoviruses and the integrating capacity of retroviruses. Alternatively, fully synthetic vectors will be developed by combining components from multiple different viruses, allowing safe, efficient and specific gene transfer and regulation. In the meantime, gene therapy protocols for haematological disease will require investigators to circumvent the limitations of current vectors and choose their agents on the basis of the most important feature required. For example, a requirement for long-term gene expression by the progeny of haemopoietic stem cells dictates an integrating vector such as a retrovirus, whereas a protocol specifying transient expression of differentiated malignant cells and their transduction *in vivo* would favour adenoviral vectors.

Targeting

To target viral vectors to specific cells or organ systems, it is usually necessary not only to add a targeting ligand to provide the new specificity, but also to disrupt pre-existing ligands ('detargeting') so that the new specificity replaces, rather than adds to, the old. Moreover, the new ligands should allow the virus to enter the cells by membrane fusion or active transport, through the same intracellular pathway as the native vector. For adenoviruses in particular, retargeting may also be an important means of limiting virus-induced toxicity to vulnerable organs. Type 5 adenoviruses, from which most human adenovectors have been derived, bind to at least two molecules on their target cells – the Coxsackie adenovirus receptor (CAR) and cell-surface integrins (usually $\alpha v\beta_3$ or $\alpha v\beta_5$). Domains on the adenoviral knob protein mediate binding. Since the sequence and crystal

structure of this protein is known, one can identify new ligand sequences and incorporate them into positions that disrupt pre-existing patterns of binding and establish new ones. The complexity of the process has hampered efforts to effectively retarget viral vectors. Retargeting may be much simpler with liposomal vectors, whose intrinsic targeting capabilities are limited, so that simple addition of a ligand could secure the desired effect. Despite the appeal of these retargeting strategies, the only *in vivo* success reported to date has been infection of liver cells through directed binding to the asialoglycoprotein receptor.

Regulation of transgene expression

Most effective gene therapies will require regulation of the transgene. Two approaches are available. The first relies on endogenous regulatory elements, by replacing the defective sequence with an inserted wild-type sequence – the process of homologous recombination. Several approaches have been suggested by which this may be accomplished, but as yet none have had a high enough efficiency for clinical use. Nonetheless, in animal models of several diseases (Crigler–Najar disease or UDP-glucoronysyl transferase deficiency, α_1-antitrypsin deficiency and the factor IX deficiency of haemophilia B) these approaches have produced promising results.

For most disorders, regulatory elements may need to be introduced with the transgene. Several regulatory structures are being developed with the intention of using small molecules to control transgene expression. The three systems closest to clinical use are regulated by rapamycin or tetracycline and their analogues, or by the anti-progestin agent mifepristone (RU486). By modifying a given DNA-binding domain, it is possible to alter the target sequence that is bound, allowing a repressor and an inducer to be present in the same cell. Similarly, by modifying the receptor for the small molecule regulator it is possible to use two different oral agents, one to upregulate and one to down-regulate production. This provides a lower background than an inducible system alone, and a higher level of maximum expression than a repressor alone. Alternatively, the system could be used to turn on two separate genes. None of these systems has yet entered clinical study.

Applications of gene transfer (Table 27.2)

Haemoglobinopathies

Sickle cell disease and thalassaemia have both attracted considerable interest as disease targets for gene transfer approaches, as the available treatments are unsatisfactory and the molecular basis of the diseases is well characterized. To date, most emphasis has fallen on thalassaemia, which also has the distinction of being the earliest disease for which gene therapy was attempted.

Table 27.2 Examples of early clinical trials for the treatment of malignant haemopoietic disorders approved by the Recombinant Advisory Committee of the National Institutes of Health (USA).

Target cell	Approach	Institution	Investigators
Leukaemia cells	Transduce with CD40L	Baylor College of Medicine UCSD	M Brenner, R Krance, H Heslop Thomas Kipps
Donor T cells after allogeneic BMT	Mark EBV-specific CTLs to prevent EBV lymphoma after transplant	St Jude Children's Research Hospital, Baylor College of Medicine	H Heslop, M Brenner, C Rooney
	Transduce donor T cell used to treat relapse with Tk	Human Gene Therapy Research Institute, Northwestern University	C Link, R Burt, A Traynor
	Transduce donor T cell used to treat relapse with Tk	Fred Hutchinson Cancer Research Institute	M Flowers, S Riddell
	Transduce donor T cell used to treat relapse with Tk	University of Washington, City of Hope	W Bensinger, P Parker, J Henslee
		National Medical Center, University of South Carolina, MD Anderson Cancer Center, Indiana University, University of Alabama	Downey, S Abhyanker, S Giralt, K Cornetta, M Carabasi
	Transduce donor minor antigen specific clones used to treat relapse with Tk	Fred Hutchinson Cancer Research Institute	E Warren
Marrow mononuclear cells in autologous transplantation	Mark marrow to ascertain source of relapse	St Jude Children's Research Hospital	M Brenner, J Mirro, C Hurwitz, V Santana, J Ihle
	Mark marrow to compare purging regimens	St Jude Children's Research Hospital	M Brenner, R Krance, H Heslop, V Santana, J Ihle

Tk, thymidine kinase; CTLs,: cytotoxic T lymphocytes; BMT, bone marrow transplantation; EBV, Epstein–Barr virus.

The ensuing furore about the unethical conduct of this first study in Israel and Italy in the 1970s was a major contributor to the establishment of the regulatory environment, which now encumbers the field. Since that time, the feasibility of effective gene therapy for thalassaemia has greatly increased based on an improved understanding of the normal regulation of the β-globin gene and the increased efficiency of vector systems. Initial studies showed that murine retroviral vectors expressing the β-globin genes could transduce murine and human haemopoietic stem cells, but levels of expression were low. As described in Chapters 2 and 6, it then became apparent that regulation of the β-globin locus depended on a 25-kb sequence termed the locus control region (LCR), which was located ~60 kb upstream of the adult β-globin gene. Retroviral vectors composed of functional fragments of the LCR fragments and globin gene sequences were generated but were found to rearrange on integration in target cells, apparently as a result of cryptic splice sites that resulted in internal deletions in the LCR/globin minigene. This problem, coupled with a low efficiency of gene transfer into human stem cells by murine retroviral vectors, led many to abandon the approach altogether. More recently, however, it has been shown that lentiviral vectors, which can package much longer sequences than murine retroviruses, could contain larger fragments of the LCR together with the globin locus. These vectors could integrate unrearranged LCR/globin genes at high efficiency in human stem cells. Pseudotyping these vectors allowed them to transduce murine stem cells and their use in β⁰-thalassaemic heterozygote and then homozygous mice resulted in long-term clinical improvement, including increased haemoglobin and haematocrit and a drop in the reticulocyte count.

Similar success with this vector system has been reported in sickle cell mice that received stem cells transduced to express an anti-sickling β-globin variant. Up to 48% of total haemoglobin originated from the transgene. If preclinical data continue to support this lentiviral approach, efforts will undoubtedly be made to bring it into the clinical setting. For thalassaemic and sickle cell disease patients, however, adequate engraftment of gene-modified cells will almost certainly require drug- or radiation-mediated ablation of uncorrected marrow progenitor cells. Such treatment will invariably have a finite risk of severe morbidity and mortality, so that the increase in safety of gene therapy over allogeneic transplantation may not be as striking as had been hoped: the cure rate in otherwise healthy thalassaemic patients transplanted from MHC-identical siblings is already more than 90%.

Haemophilia

Haemophilia is an attractive target for gene therapy, since production of even modest quantities of factor VIII or factor IX may be sufficient to improve levels in the blood and hence disease phenotype. For a similar reason, direct measurement of transgenic factor levels in the blood is an excellent marker of the success of the treatment and allows rapid analysis of outcome.

The availability of both small and large animal models of the disease has facilitated preclinical investigation and ensured that this disorder has been one of the most popular non-malignant disorders for a gene therapy approach. Because the factor VIII gene is large, most clinical studies of haemophilia A have focused on B-domain deleted mutants of the gene. For haemophilia B, the much smaller factor IX gene fits comfortably into most vector systems.

Of note, the target cell for gene therapy of haemophilia has not so far been of haemopoietic origin. Instead, fibroblasts, hepatocytes and muscle cells have all been genetically modified for treatment of the disease, using a range of vector systems including plasmids, retroviruses, AAVs and adenoviruses.

Clinical trials

Plasmid
The first clinical trial used a plasmid carrying a selectable marker and a B domain-deleted factor VIII cDNA, and introduced it by electroporation into patients' cultured skin fibroblasts. After *ex vivo* selection and expansion, cells were implanted into the patients' omenta. The first patients had a reduced frequency of spontaneous bleeds and of factor infusions. However, although factor VIII activity was above baseline in three out of six patients, it rarely reached the target level of > 2% required for major clinical benefit. After several months, the benefits and the factor VIII disappeared, presumably due to death or destruction of the transduced cells. It is not clear if this highly labour-intensive approach will ever be suited to widespread exploitation.

Adeno-associated viral vectors
Two widely reported subsequent clinical studies for haemophilia used adeno-associated viral vectors and targeted either skeletal muscle or liver. As described in the 'Vector systems' section above, AAV vectors have a limited size capacity for transgenes and have so far only been used clinically to treat factor IX deficiency. It is of note, however, that preclinical studies suggest that factor VIII can be delivered by AAV vectors in portions by using two vectors that subsequently concatemerize as DNA in the nucleus, or that encode separate protein subunits that assemble in the cell or even by using a dwarf promoter in a single vector. The first trial of AAV-mediated factor IX gene transfer used intramuscular injections and was based on successful preclinical studies in mice and haemophilic dogs. AAV–factor IX was administered at intramuscular sites in the legs and arms in a dose escalation design, although the highest doses administered $[2 \times 10^{12}$ virus particles (vp)/kg] were well below those required for efficacy in animal studies. Production of factor IX was hampered by the low efficiency of the required post-translational modifications in skeletal muscle, and by the propensity for inhibitory antibody formation as the dose per site was raised, which meant that dose escalation required injection of progressively larger numbers of intramuscular sites. Muscle biopsies

showed gene transfer and expression of factor IX in 8/8 subjects. Unfortunately, circulating levels remained < 1%.

Infusion of AAVs into the portal vein results in high-level expression of factor IX in mice and in haemophilic dogs. Compared with muscle as a target tissue, there is more than a log difference in the amount of factor IX produced for a given dose of virus, probably because hepatocytes more efficiently secrete factor IX into the circulation. The clinical study encountered problems early on when vector sequences were detected in semen from treated subjects, raising the spectre of germline transmission. After it was shown that vector sequences were cleared from the semen over time, the study restarted. High and collaborators report that the third dose (5×10^{12} vp/kg) resulted in circulating levels of factor IX around 10% for 4–5 weeks after infusion, but this was followed by a gradual reduction in levels to the pretreatment baseline (< 1%). Accompanying the fall was a transaminitis, indicating hepatocyte damage, perhaps by an immune response. The study has now been halted.

Adenoviral vectors

Adenovectors transduce hepatocytes at high efficiency, are roomy and express large quantities of transgene product. Unlike AAVs, they are easy to make in large quantities. All these features make them attractive for haemophilia gene therapy. However, they are also hepatotoxic, immunogenic and generally produce short-term expression, which in general has deterred investigators from using them to treat genetic disorders. The development of helper dependent 'empty' adenoviral vectors with lower hepato-toxicity and prolonged expression (in some models) inspired efforts to use them to treat factor VIII deficiency in humans, particularly since experiments in non-human primates had yielded circulating levels of 3–8% of normal. Sadly, if predictably, a phase I dose escalation study of a helper-dependent adenoviral vector for haemophilia A failed at the lowest (subtherapeutic) dose level, when the first subject experienced transient thrombocytopenia and transaminitis, probably as a result of toxicity from adenovector capsid proteins. Since these were the same problems experienced by patients prior to the first fatality from adenoviral vector treatment, there was little tolerance for these types of adverse events in patients with a genetic disorder, and the study was abandoned. Additional preclinical studies will be required to determine whether helper-dependent adenoviral vectors will ever be of value in the treatment of genetic disease, or whether this vector system will essentially be confined to applications in malignant disease, in which adverse events are a more accepted aspect of treatment.

Retroviral vectors

A phase I study conducted in 13 patients with haemophilia A used a retroviral vector derived from the classical Moloney murine leukaemia virus rendered replication deficient and carrying a B domain-deleted gene encoding for human factor VIII. While this vector has been extensively used in gene therapy clinical tri-

als using *ex vivo* gene transfer, the originality of this study resides in the choice of an intravenous route of administration. Safety monitoring indicated that this route of administration was safe and well tolerated. Tests performed at regular intervals demonstrated the absence of replication-competent retroviruses (even though one patient's semen tested positive by PCR). There was no exacerbation of pre-existing viral diseases, such as HIV or HCV. No factor VIII inhibitors were detectable after retrovirus administration but non-neutralizing antibodies to murine leukaemia virus developed in all subjects. PCR for retroviral sequences tested positive in 90% of the peripheral blood mononuclear cell (PBMC) samples after 29 weeks. At 1 year, 75% of the PBMC samples remained positive by PCR, even in subjects who had received the lowest retrovirus dose. Unfortunately, factor VIII activity unrelated to exogenous treatment remained low (1.1–19%) and transient, with nine subjects having factor VIII higher than 1% on at least two occasions 5 or more days after infusion of exogenous factor VIII. Of note, pharmacokinetic parameters of exogenously administered factor VIII showed an increased half-life and area under the curve compared with prestudy values. Bleeding frequency may have been lowered in five patients. As for many approaches using retroviral constructs, the long-lasting detection of retroviral sequences by PCR is counterbalanced with the loss of transgene expression, a finding as yet not fully elucidated. Alas, the recent insertional mutagenesis event observed in the French study conducted in patients with X-SCID does not incite optimism in getting approval for gene transfer approaches using retroviral vectors.

Therefore, for the moment, gene therapy of haemophilia is promising but will likely only become a clinical reality when safer and more efficient and longer lasting gene delivery systems can be developed.

Treatment of haemopoietic malignancies

Several approaches may use gene transfer as part of the clinical arsenal against haemopoietic malignancies:
• *modification of tumour cells,* by repairing genetic defects thought to be responsible for the malignant proliferation, for example by restoring genes controlling cellular division or that induce programmed cell death (apoptosis);
• *sensitization of normal tissues or malignant cells in order to modify their therapeutic index,* by introducing into the malignant cells genes encoding for an enzyme that can transform a non-toxic prodrug into an active drug; or by introducing into normal tissues genes that can protect them against the effects of anti-tumour toxic drugs;
• *modulation of tumour invasiveness,* by delivering genes that can inhibit the growth of new blood vessels in order to impede nutrient supply to the tumour cells (inhibition of neoangiogenesis);
• *enhancement of the anti-tumour immune response,* either by inducing the recognition of tumour cells by the host's immune system, or by enhancing the cytotoxic function of immune effectors;

• *gene marking*: even though gene marking is not *per se* a therapeutic intervention, this approach has helped investigators understand the behaviour and outcome of transduced cells once administered back to the patient.

Tumour correction

Many of the molecular aberrations leading to cancer alter key regulatory, survival and differentiation steps in the cell cycle; others lead to the production of abnormal fusion products, with subsequent gain or loss of critical functions of the cellular cycle.

In theory, gene therapy could be used to replace an inactive gene with an active one, or to neutralize an abnormal function gained by a mutated gene. While the introduction of genetic material into haemopoietic cells, either to correct or to block a defect involved in malignant transformation, is appealing, it is also technically extremely challenging. Not only is highly efficient transduction of target cells required, but also many of the mutations leading to cancer are effectively dominant, and simple introduction of a wild-type gene would not be of benefit. Under these circumstances, the abnormal gene product must be silenced. Several strategies for silencing are being evaluated, including antisense molecules that are oligonucleotides specifically designed to interfere with DNA or mRNA and prevent transcription or translation, and ribozymes that are RNA molecules that specifically cleave mRNA and intrabodies obtained by modifying genes encoding antibodies so that the antigen-binding domain is expressed intracellularly. More recently, RNA interference, for example with siRNA (small interfering RNA), has proven to be an extremely potent means of diminishing gene expression. All these approaches, however, still suffer from the key limitation of poor delivery to the tumour cell, a particular concern for haematological malignancy, in which broad, multiorgan distribution is essential.

These challenges notwithstanding, several clinical and many preclinical studies have attempted to correct the function of haematological malignancies. Synthetic oligonucleotides complementary to the junction transcripts of *BCL–ABL* fusion gene have been shown to block *in vitro* proliferation of Philadelphia-positive leukaemia cells without impairing the growth capabilities of normal bone marrow progenitors. Antisense-treated mice with severe combined immunodeficiency (SCID) injected with Philadelphia-positive leukaemia cells confirmed the capability of *BCR-ABL* antisense oligonucleotides to temporarily suppress the progression of the disease and to significantly enhance survival of the treated animals. A DNA–RNA hybrid ribozyme designed to cleave *BCR–ABL* mRNA was incorporated into a liposome vector and transfected into EM-2 cells, a cell line derived from a patient with blast crisis of chronic meyeloid leukaemia (CML). The ribozyme decreased levels of detectable *BCR–ABL* mRNA in these cells, inhibited expression of the *BCR–ABL* gene product, p210BCR–ABL, and inhibited cell growth.

Ribozymes against the multidrug resistance gene *MDR1* RNA have been shown to overcome retinoic acid (RA) resistance in acute promyelocytic leukaemia cells. Expression of *MDR1* transcripts was decreased in HL60 cells expressing the *MDR1* RNA ribozyme, allowing RA to inhibit cellular proliferation and induce differentiation of HL-60 cells in a dose-dependent manner, suggesting reversal of drug resistance in HL-60 cells by the *MDR1* ribozyme. Other antisense oligonucleotides are targeted to transcriptional products from proto-oncogenes (such as *myb* and *myc*) known to induce proliferation and/or downregulation of differentiation of normal haemopoietic progenitors. Several clinical studies have been reported using antisense oligonucleotides targeting the c-*myb* or the *p53* genes, either as marrow-purging agents for chronic- or accelerated phase CML patients or intravenously in patients with refractory acute myeloid leukaemia (AML) or CML in blast crisis. There have been no toxicities but no significant clinical responses. More encouragingly, an antisense *Bcl-2* oligonucleotide has also been administered in patients with refractory non-Hodgkin's lymphoma, with objective clinical and biological responses.

The above results emphasize that effective exploitation of a tumour correction strategy using gene transfer will require significant improvements in vector efficiency and targeting. Until these come to pass, the tumour correction strategy will probably be dominated by the development of novel rationally targeted small molecules.

Sensitization of normal tissues or tumour cells

Prodrug-metabolizing enzyme (PDME)

Introduction of a gene encoding an enzyme that metabolizes an otherwise inert molecule into a cytotoxic agent has frequently been used in anti-tumour gene therapy. Although the herpes simplex thymidine kinase–ganciclovir system has been the most widely used, in fact more than 20 such PDME systems are currently in various stages of development and/or clinical trials. For all of these, the concept is that the gene encoding the prodrug-metabolizing enzyme is expressed in the cancer cell, and metabolizes a small molecule to an active moiety, which then kills the tumour cell directly. The molecule may also diffuse either through intercellular gap junctions or in the extracellular space and destroy adjacent tumour cells. In this way, transduction of even a small proportion of tumour cells can produce a large 'bystander' effect on adjacent tumour tissue. This in turn, compensates for the low efficiency of transduction achieved by currently available vectors and may help to destroy a large tumour burden.

Initially, brain tumours were the target for this approach. A number of paediatric and adult clinical studies have been performed using retroviral and subsequently adenoviral vectors encoding herpes simplex thymidine kinase (HSV-Tk) or cytosine deaminase, which converts fluorocytosine to fluorourosil.

In haemopoietic malignancies that lack gap junctions and are

widely distributed, the lack of any potential bystander effect has essentially precluded direct cytotoxicity mediated by PDME *in vivo*. Instead, PDME has been used as a means of controlling T-cell immunotherapies. For example, graft-versus-host disease (GvHD) may occur when donor T cells are given to patients after allogeneic stem cell transplantation in an effort to treat relapse of leukaemia or lymphoma (graft versus tumour effect) or post-transplant infections. Several groups have infused donor T cells transduced with the HSV-Tk gene and reported successful abrogation of unwanted GvHD by treating the patients with ganciclovir. More recently efforts have been made to induce expression of the death signal Fas in donor T cells. An inducible construct is used in which Fas expression occurs only in the presence of a small molecule (chemical inducer of dimerization) that dimerizes two individually inactive components of a Fas transcriptional regulator, leading to expression of the Fas receptor and cell death on exposure to the ligand.

If T-cell immunotherapy for haematological malignancy becomes more widespread and more effective, these suicide mechanisms will become extremely important in ensuring that the regimens are acceptably safe.

Transfer of drug resistance genes to haemopoietic stem cells (HSC)

The transfer of drug resistance genes to haemopoietic cells has been used to protect these cells from the myelosuppression associated with chemotherapy and as a strategy for the *in vivo* selection and amplification of genetically modified cells. Several drug resistance genes have been evaluated in preclinical studies, including *MDR*, dihydrofolate reductase, nitrobenzylmercaptopurine riboside and methylguanine DNA methyltransferase. Of these, the human multidrug resistance 1 (*MDR1*) gene has been evaluated in clinical trials. The *MDR1* product, P-glycoprotein, functions as a drug efflux pump and confers resistance to many chemotherapeutic agents, thereby allowing 'dose-intensive' therapy with little marrow suppression. Early clinical studies showed minimal transfer, little expression and no protection, but with new-generation retroviral vectors and the use of stromal support elements, transduction efficiency of the HSC has improved. While it has been possible to show modest *in vivo* selection of gene modified cells after chemotherapy, as yet no convincing protection of human stem cells *in vivo* has been observed. Concerns about this approach include the risk of transferring drug resistance genes to neoplastic cells in the HSC graft, thus promoting a drug-resistant relapse, and the possibility of inducing myeloproliferation.

Modification of the tumour environment with anti-angiogenesis gene therapy

Because angiogenesis is a prerequisite for the development of metastatic disease for solid tumours, and probably for leukaemias and lymphomas as well, inhibition of new blood vessel formation may impede the spread of disease. A number of different large and small molecule inhibitors are currently under study, and some of these are suitable for a gene therapy approach. For example, endostatin, a 20-kDa fragment of collagen XVIII, can efficiently block angiogenesis, but the recombinant protein is difficult and expensive to produce and is somewhat unstable. Delivery of endostatin in murine tumour models by several different vector systems has been able to overcome this limitation. Similarly, angiostatin, a fragment of plasminogen, also functions as a large-molecule inhibitor of vessel growth and impedes metastatic tumours. This too can be transferred (for example by adeno-associated virus vector) to produce benefit in animal models of malignant brain tumours.

Much remains to be learned about the most appropriate route and cell of delivery of angiogenesis inhibition, but, as with any protein-based therapeutic, gene transfer should allow a continuous delivery of the drug rather than the peak and trough concentrations that result from most forms of injection, and may thereby produce a more sustained and effective response.

Gene modification of the immune response

Immunotherapy represents one of the most appealing of new anti-tumour approaches for haematological malignancy. Identification of antigens expressed on tumour cells and the improvements made in gene transfer techniques, together with a better understanding of the molecular and cellular mechanisms involved in the immune response against cancer, have given investigators tools to manipulate the immune system to induce an efficient immune response in the tumour-bearing host.

Tumour cell-based vaccines against haematological malignancies

Autologous tumour cells isolated from the patient's own tumour and treated (for example by irradiation) so that they no longer grow *in vivo* have long been tried as tumour vaccines, with limited success. Interest was greatly revived, however, when it was shown that genetic modification of tumour cells could increase their immunogenicity and induce an effective response not only against the gene-modified tumour, but also against unmodified tumour cells elsewhere in the individual. Tumour cells may be transduced with cytokine or co-stimulatory molecule genes, or with foreign major histocompatibility complex (MHC) molecules.

For applications in haemopoietic malignancies, particularly leukaemia and myeloma, transduced autologous cell lines are often difficult to prepare because the cells are either difficult to obtain from the patient or do not grow or survive *ex vivo*. Where autologous tumour cells cannot be obtained, a standardized immunogenic allogeneic tumour cell is a possible alternative. One potential drawback of the allogeneic approach is that the tumour antigens present in the host may be absent in the tumour line. The use of polyvalent tumour cell preparations

may overcome this limitation. Another problem is that shared antigens may not be expressed in the context of the patient's own MHC, making them unrecognizable by the host immune system. This problem may be overcome if the tumour cell antigens are taken up, processed and presented by host professional antigen-presenting cells (APCs). Finally, the immune response to the allogeneic MHC molecules will likely be more potent than to the weaker tumour antigens, and the gene-modified tumour cells may be lysed before tumour-reactive T cells are recruited. However, the highly immunogenic foreign MHC molecules might also act as an immune adjuvant and thereby enhance the anti-tumour immune response.

Clinical experience with gene-modified tumour cells

Among the many immunomodulatory gene products tested to date, vaccination with irradiated cells engineered to secrete GM-CSF (granulocyte–macrophage colony-stimulating factor) has been shown to induce the most potent, specific and long-lasting immunity in several murine tumour models. In patients with melanoma and renal cell carcinoma, local and systemic immune delayed-type hypersensitivity and transient tumour regressions were induced by GM-CSF-expressing autologous tumour cells. IL-2 and IL-12 have also emerged as potent immunomodulatory molecules in several murine and human tumours. In patients with several types of tumour including melanoma, renal cell carcinoma, glioblastoma, colon carcinoma and neuroblastoma, phase I trials of IL-2-gene transduced tumour cells showed no toxic effect of IL-2 production *in vivo*. Furthermore, preliminary results in these studies showed a positive effect of IL-2 on the specific immune response.

In haematological malignancy, considerable recent interest has focused on the CD40/CD40L system. CD40, a cell-surface receptor of the tumour necrosis factor (TNF) receptor family, was identified as a molecule expressed during all stages of B-cell development and differentiation. The ligand for CD40 (CD40L or CD154) is mainly expressed on activated CD4$^+$ T cells and on professional APCs. The interactions between B-cell CD40 and T-cell CD40L play an important role in T-cell-dependent activation of B cells and in the processing of antigen by B cells. Moreover, CD40 ligation induces B7 expression by leukaemic B cells and enhances the ability of B cells to act as APCs. Preclinical experiments in mice with CD40-positive B-cell leukaemia have shown tumour reduction and a significant benefit in survival when animals received a vaccine consisting of tumour cells admixed with syngeneic fibroblasts engineered to secrete CD40L and IL-2. This approach is currently being tested in a phase I trial in patients with acute lymphoblastic and myeloid leukaemia and is producing high levels of immunity. Recent administration of human B-chronic lymphocytic leukaemia cells expressing murine CD40L has provided evidence that this approach may also enhance anti-tumour immunity *ex vivo* and *in vivo*, with evidence also of tumour responses. Other immunomodulatory molecules, such as IL-2, IL-4, IL-12, TNF-α, GM-CSF and B7.1

(CD80), have similarly induced anti-leukaemia activity in several preclinical vaccine models.

Gene modified dendritic cells

'Professional' APCs such as dendritic cells (DCs) may be modified to express candidate tumour antigens by gene transfer using viral or non-viral vectors. The advantage of these cells over whole tumour cell vaccines is their expression of high levels of co-stimulatory molecules that may enable them to recruit T-cell responses even to weak tumour-associated antigens. Most clinical studies have used peptide-, protein- or mRNA-derived antigens or tumour cell lysates and apoptotic bodies to load the DC with tumour-associated epitopes. However, gene transfer can also be used to directly transfer a validated tumour-associated gene intended to be the target for an immune response. For example, DCs can be transduced to express the Epstein–Barr virus (EBV) latency gene *LMP-2*, and generate cytotoxic T cells that are highly specific for this weak tumour-associated antigen, present on the malignant cells of EBV-positive Hodgkin's disease and nasopharyngeal carcinoma.

These *LMP-2*-specific T cells are being evaluated in a series of clinical studies described in the following section.

Cancer therapy with gene-modified T cells

Several studies have suggested the feasibility and apparent clinical efficacy of adoptive transfer of cytotoxic T lymphocytes (CTLs) directed at viral or tumour antigens. Gene transfer offers the potential for improving these approaches. The earliest modifications simply used genetic markers (e.g. *neo*) transferred by retroviral vectors, enabling investigators to determine the survival and homing of virus-specific T cells infused in patients with EBV-associated post-transplant lymphoproliferative disorder (PTLD), or Hodgkin's disease or nasopharyngeal carcinoma, and to discover if they mediated any adverse effects.

More recently, the approach has been used to protect T cells against tumour-induced downregulation. While clinical studies using infusions of CTL against EBV-related malignancies have been promising, with some complete tumour responses, most patients with aggressive relapsed EBV-positive Hodgkin's disease ultimately progress. This may in part be due to the lack of specificity of the EBV-specific CTLs for the subdominant LMP1 and LMP2 antigens that are present on the Hodgkin's tumour cells and may be overcome using gene-modified dendritic cells as described above. In addition, however, many haematological malignancies, including EBV-positive Hodgkin's disease, secrete immunosuppressive cytokines and chemokines that affect CTL function and APC activity.

Gene transfer can be used to overcome both types of problems. In Hodgkin's disease, for example, dendritic cells transduced with adenoviral vectors encoding either LMP2 or a mutated LMP1 will generate CTL with high cytolytic activity *in vitro* to LMP2- or LMP1-positive cancer cells. These effectors can then be made resistant to the immunosuppressive cytokines secreted
Figure 27.1 EBV-specific T cell redirected towards leukaemia-specific antigens by means of a chimeric TCR leukaemia scFv-specific.

by the Hodgkin Reed–Sternberg cell. The cytokine which has the most devastating effects on CTL proliferation and function is transforming growth factor beta (TGF-β). This cytokine is secreted by many haematological malignancies and allows the leukaemia/lymphoma to escape the immune response. Effector cells can be transduced with a retrovirus vector expressing a dominant-negative TGF-β type II receptor (DNR), which prevents formation of the functional tetrameric receptor. Cytotoxicity, proliferation and cytokine release assays showed that exogenous TGF-β has minimal inhibitory effects on DNR-transduced CTLs. This combination of tumour-specific and tumour-resistant CTLs may prove highly effective for therapy.

Chimeric receptor-expressing cytotoxic T cells for tumour therapy

One can generate chimeric T/B cell receptors by joining the heavy- and light-chain variable regions of a monoclonal antibody to form a single-chain Fv (scFv) and coupling this in turn to the T-cell receptor (TCR) ζ-chain (Figure 27.1) or Fc-γ immune receptor domain. When these chimeric receptor genes are introduced into T cells, antigen stimulation of the extracellular component of the chimeric receptor results in tyrosine phosphorylation of immune receptor activation motifs present in the cytoplasmic domain, initiating T-cell signalling to the nucleus.

Primary T cells genetically modified to express chimeric receptors derived from antibodies and specific for tumour or viral antigens have considerable therapeutic potential. Chimeric T-cell receptors allow the recognition specificity of T lymphocytes to extend beyond classical T-cell epitopes and can therefore be applied to every malignancy that expresses a tumour-associated antigen for which a monoclonal antibody (MAb) exists. Unlike conventional T-cell receptors, these chimeric receptors will be active even if the tumour cells are MHC class I negative. Chimeric receptor transduced T cells have numerous advantages over immunotherapies based on monoclonal antibodies or T lymphocytes alone. As there is no need to select and expand tumour-specific antigens from scanty precursors, large populations of antigen-redirected T lymphocytes can be obtained in a matter of weeks. Moreover, chimeric T-cell receptors are MHC unrestricted, so that tumour escape by downregulation of MHC class I molecules and defects in antigen processing are bypassed. As both CD4+ and CD8+ T cells can express the same chimeric receptor, the full network of T-cell function is directed against tumour cells. The presence of chimeric TCR-mediated effector function may be more likely to produce tumour cell lysis than humoral immune responses alone.

The perforin/granzyme killing mechanism may be effective against cells that are relatively resistant to antibody and complement, while cytokine secretion upon T-cell activation by tumour antigen recruits additional components of the immune system, amplifying the anti-tumour immune response. Furthermore, unlike intact antibodies, T cells can migrate through microvascular walls, extravasate and penetrate the core of solid tumours to exert their cytolytic activity. Finally, a single T lymphocyte can sequentially kill a multiplicity of target cells.

Adoptively transferred chimeric receptor-transduced cells have been protective in murine tumour models and many investigators have succeeded in expanding human peripheral blood T cells expressing similar receptors. Among these have been cells targeted to the pan-B-cell markers CD19 and CD20. In the presence of CD80 and interleukin 15 (IL-15), these chimeric peripheral T cells can persist in tumour-bearing SCID Beige mice and eradicate disseminated intramedullary B-cell tumours. Similarly, CD20 chimeric receptor-transduced T cells from patients with chronic lymphocytic leukaemia (CLL) effectively lyse autologous tumour cells. While CD19 and CD20 are expressed on normal B cells which would then also become the targets of chimeric receptor-expressing T cells, this cross-reactivity would not be considered an absolute contraindication to their use in patients with advanced B-cell malignancies. Other targets for the treatment of haemopoietic malignancies include anti-CD33-specific chimeric constructs.

Though promising *in vitro* and in mice, in humans *in vivo*, chimeric receptor-expressing T cells have so far proved clinically disappointing, as they are short-lived or rapidly inactivated in the circulation. Clearance of modified T-effector cells by immune effector mechanisms may be delayed by humanization of currently available hybridoma antibodies or by the generation of fully human single-chain antibodies by phage display technology. But optimally sustained function may require chimeric receptor molecules that are coupled to the enhanced intracellular signalling mechanisms associated with co-stimulator molecules, such as CD28, or that are transferred into virus-specific T cells with established *in vivo* activity. Clinical trials adopting these approaches are imminent.

Conclusion

We have far to go before gene transfer will have any measurable impact on haematological diseases. But as we continue to make incremental advances in the application of this complex but potent methodology, we can expect to see gene therapies increasingly supplement, and perhaps ultimately supplant, many conventional therapies in haematology.

The molecular basis of leukaemia and lymphoma

28

Peter J Campbell, Anthony J Bench and Anthony R Green

Introduction

The average human produces many billions of red cells and neutrophils each day. This process is exquisitely responsive to physiological stresses such as infection and blood loss, and is able to increase output by up to 10-fold at such times. The haemopoietic system maintains such a prodigious yet appropriately balanced output through tight control of stem cell proliferation, lineage commitment and differentiation. It is corruption of these processes that results in haematological malignancy.

Studies of leukaemia and lymphoma have led the way in providing paradigms of general relevance to cancer biology. Present models posit a 'multiple-hit' process in which critical cellular pathways are corrupted by accumulating genetic damage, resulting in an autonomous, proliferating stem cell clone. The phenotype of the malignancy is determined by the particular pathways that are corrupted, often in a quite stereotypic fashion. Thus, specific tumour types are associated with particular genetic alterations that are not seen in other haematological malignancies.

This chapter will review what we understand of the molecular pathogenesis of leukaemia and lymphoma. The first section describes several basic principles germane to the pathogenesis of haematological malignancies, including aspects of clonality and clonal evolution, the concept of the 'leukaemic stem cell' and genotype–phenotype correlations. The second section covers the nature of acquired gene alterations associated with haematological malignancies, including chromosomal rearrangements, point mutations and epigenetic effects. In the third section, we illustrate the consequences of such alterations. It is beyond the scope of the chapter to provide an exhaustive list of causative mutations and pathways in all haematological malignancies: instead we illustrate the underlying principles by describing five

specific examples of malignancies with corruption of distinct cellular processes: tyrosine kinase signalling (the myeloproliferative disorders); intracellular signal transduction (juvenile myelomonocytic leukaemia); regulation of gene transcription (acute myeloid leukaemia); cell cycle control (mantle cell lymphoma); and apoptosis (follicular lymphoma).

Basic concepts of haematological neoplasia

Clonality

Studies of haematological malignancies have led the way in establishing the clonal origins of tumours. This is mainly because normal and malignant haemopoietic cells are readily accessible, can be grown in culture and have been well-characterized at a molecular level. Three main lines of evidence suggest that haematological tumours each arise from a single ancestral cell and thus are 'clonal'.

First, in almost all lymphoproliferative disorders and a minority of acute myeloid leukaemias, the tumour population carries a unique rearrangement of either an immunoglobulin (*IGH*) or TcR gene, the exceptions being very primitive acute lymphoblastic leukaemia (ALL) and lymphoma. In contrast, non-malignant disorders causing proliferation of lymphocytes are characterized by a polyclonal pattern of antigen receptor rearrangement. This is persuasive evidence for a clonal origin of lymphoid malignancies and suggests that a key transformation event occurred at or after gene rearrangement.

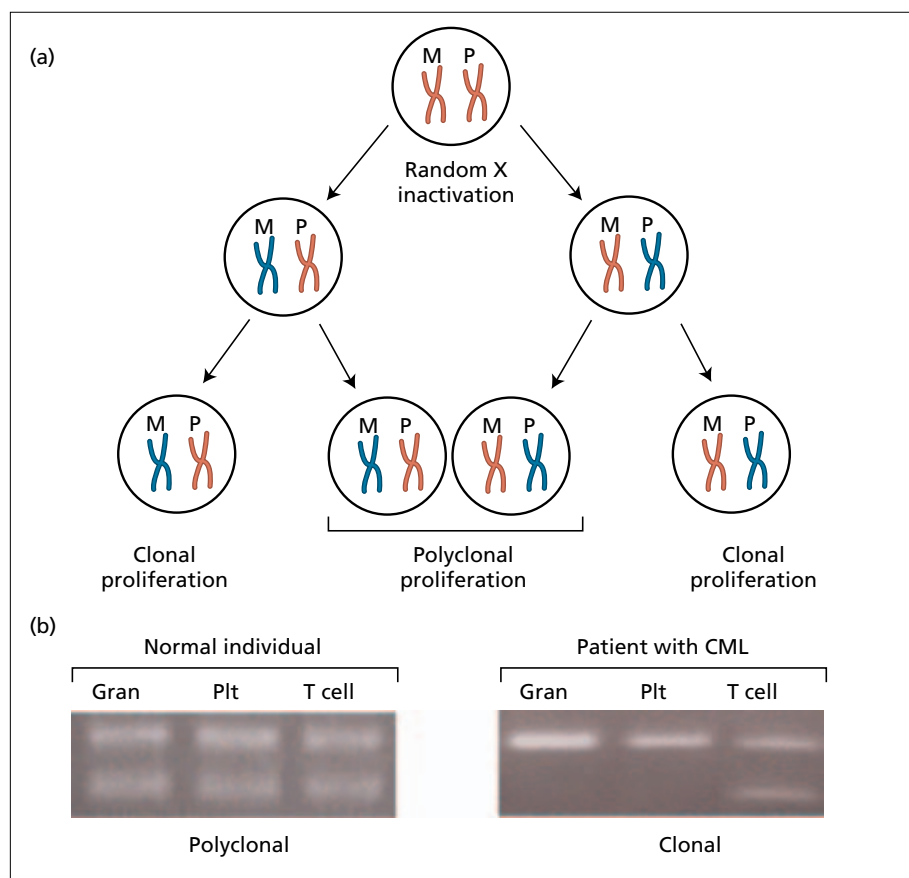
Second, evidence for clonality also derives from studies of X-chromosome inactivation patterns from female patients


Figure 28.1 X-chromosome inactivation patterns. (a) X-inactivation patterns in clonal and polyclonal proliferations. Early in female embryogenesis, each cell randomly inactivates either the maternal or paternal X chromosome. The pattern of X inactivation is faithfully passed on to all progeny cells and, as a result, women are mosaic with respect to X inactivation. As a clonal proliferation arises from a single cell, all of the proliferating cells will carry the same inactive X chromosome. By contrast, a polyclonal proliferation will be mixed, with some cells carrying an inactive maternal X chromosome, and others carrying an inactive paternal X chromosome. (b) Reverse transcription polymerase chain reaction (RT-PCR) analysis of X-chromosome inactivation patterns. Transcripts from the polymorphic X-linked *IDS* gene were amplified by RT-PCR from granulocytes (gran), T cells and platelets (plt) obtained from a patient with CML, and a normal individual. Note that two products (representing the maternally and paternally derived X chromosomes) are obtained in cells from the normal individual and in T cells from the patient. By contrast, only one allele is active in granulocytes and platelets from the patient.

(Figure 28.1). The process of X-chromosome inactivation is random and occurs early in fetal development. In women, a polyclonal proliferation therefore contains a mixture of cells, some of which carry an active maternal X chromosome, whereas others contain an active paternal X chromosome. By contrast, a clonal proliferation contains cells that carry either an active maternal or an active paternal X chromosome. Unfortunately, the diagnostic utility of such studies is limited by the fact that many normal women develop, as they age, a skewed pattern of X inactivation in their blood cells.

Third, acquired cytogenetic or molecular changes that arise during the development of a malignancy can also be used as clonal markers. For example, in chronic myeloid leukaemia (CML) the Philadelphia (Ph) translocation can be found in multiple different blood cell types, including neutrophils, monocytes, basophils and B cells, suggesting that the disease arises in a multipotent stem cell.

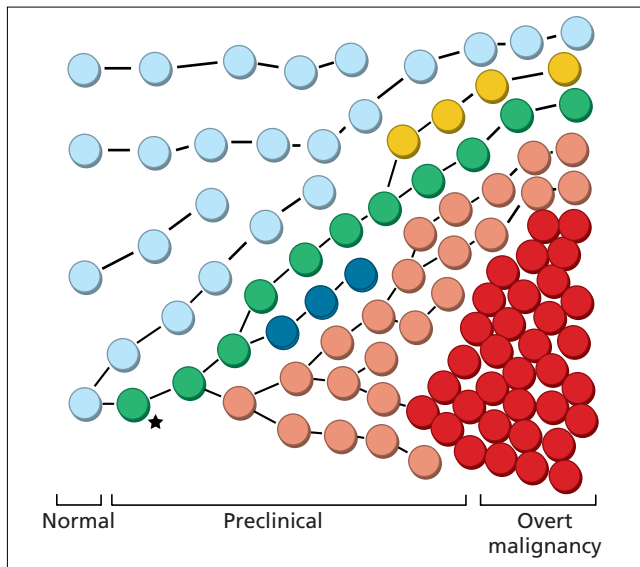
If it is accepted that lymphoma and leukaemia are clonal disorders, in which the vast number of autonomous malignant cells that are present at diagnosis all derive from a single cell, several questions are immediately prompted. How does this single cell acquire sufficient genetic damage to become so disordered? What is the nature of the ancestral cell? Is the phenotype of the malignancy determined by the genetic changes, by the characteristics of the ancestral cell in which they occurred or by both? These questions will be addressed in turn.


Figure 28.2 Clonal evolution of malignancy. The process starts in a single green cell (*) that acquires a mutation providing a slight selective advantage. Subsequently, the progeny of this cell acquire further mutations (blue, pink and red). Some mutations may be deleterious, and the corresponding clone dies out (blue). With time, a clone can acquire further mutations, leading to increasingly aggressive behaviour. Note that the overt malignancy is heterogeneous and contains a dominant subclone (red) as well as other less prevalent subclones (green and pink), which carry overlapping but distinct sets of mutations.

Clonal evolution

Most malignancies are thought to be the result of several mutations, acquired sequentially and randomly, rather than one single catastrophic mutation (Figure 28.2). Conceptually similar to the Darwinian natural selection, malignancy starts with a change in the genetic material of an ancestral cell that provides a slight selective advantage. Descendants of that abnormal cell subsequently acquire additional mutations, further increasing the selective advantage, and so the abnormal population expands until it eventually results in clinically overt disease. As the mutations are random events, some of them will be deleterious and may result in extinction of the corresponding subclone. Many different subclones, all deriving from the same original ancestral cell, will exist within the tumour population, and subtle differences in, for example, proliferative capacity or drug resistance may be evident. The several mutations that occur in a given tumour often occur in genes involved in interlinked or cooperating pathways, a theme developed in more detail later in this chapter.

Several lines of evidence demonstrate that more than one mutation is necessary for full malignancy. In both cell culture assays and murine models used to assess translocations found in

leukaemia, the fusion gene alone is usually insufficient to induce a leukaemic phenotype. In mouse studies, transplantation of haemopoietic stem cells transformed by a fusion gene often result in leukaemia only after a long latency, suggesting that further events are required for neoplasia. Consistent with this concept, the latency can be shortened by the administration of mutagenic agents such as nitrosourea.

In humans, there is also evidence that a single mutation is not sufficient for the full malignant phenotype. First, individuals who inherit a mutated *RUNX1* gene in all their cells develop a clonal leukaemia (i.e. from only one of their cells) in later life, suggesting that additional events are needed to cooperate with the *RUNX1* mutation. Second, translocations associated with childhood leukaemia can be detected at birth, several years before the leukaemia develops. In children who develop acute leukaemia associated with the t(12;21) and t(8;21) translocations, testing of DNA extracted from the Guthrie blood spot taken just after birth has demonstrated that cells carrying the same translocation were present in the first few days of life. Third, it has been observed that normal individuals may harbour very low levels of fusion transcripts that are normally associated with leukaemia, such as the BCR–ABL transcript of CML or PML–RARα of acute promyelocytic leukaemia. These results suggest that cells carrying these translocations need further events to transform them or that the mutation occurred in a cell incapable of sustaining a long-term self-renewing malignancy.

The model of clonal evolution also proposes that a population of malignant cells contains subclones that have acquired distinct secondary changes, and which may therefore exhibit different biological characteristics. Drug resistance serves as a paradigm for this observation. In studies of CML patients who initially respond to the tyrosine kinase inhibitor imatinib, but subsequently become resistant, the resistance is often mediated by point mutations that affect the imatinib binding site of the BCR–ABL fusion protein. These mutations can be found in samples taken before the patients started imatinib thus demonstrating that the drug provided a selective advantage to a pre-existing subclone of leukaemic cells. Similarly, patients who relapse after intensive chemotherapy for acute leukaemia will sometimes be found to harbour an apparently new cytogenetic or molecular abnormality that in retrospect was present as a low level subclone in samples from the original presentation.

The 'malignant stem cell'

Myeloid malignancies

A central feature of haematological and other malignancies is a capacity for malignant cells to self-renew. Self-renewal is also a feature of normal stem cells, and this has resulted in the suggestion that tumours result from transformation of a stem cell, a concept that would also explain how the original transformed cell and its progeny survive long enough to allow the acquisition

Figure 28.3 The cell of origin for haematological malignancies. (a) AML arises in a haemopoietic stem cell. Primary human AML samples contain a small number of leukaemia stem cells (red) with surface markers similar to normal haemopoietic stem cells (i.e. CD34$^+$, CD38$^-$). Transplantation of leukaemic stem cells but not the majority of leukaemia cells (orange) recapitulates the leukaemia in immunodeficient mice. (b) B-cell lymphomas may arise in committed B-cell progenitors. Normal maturation of B cells involves rearrangement and class switching of immunoglobulin genes. Mistakes occurring during these recombination events can result in leukaemogenic chromosome translocations. Analyses of sequences adjacent to the translocation breakpoints suggest that translocations occur at different stages of differentiation in distinct B-cell lymphomas.
of secondary mutations. An alternative hypothesis is that the original mutation does occur in a more mature cell, normally destined to differentiate and die, but the initiating event is sufficient to confer the ability to self-renew. It may well be that these different models operate in distinct types of malignancy.

Studies of myeloid malignancies have provided the first experimental evidence to support the existence of tumour stem cells. In patients with CML, cells representing multiple different haemopoietic lineages carry the *BCR–ABL* fusion gene and its protein product. Moreover, the fact that CML blast crisis can be either myeloid or lymphoid suggests that the original transformed cell had both myeloid and lymphoid potential (see also Chapter 37).

In AML, a leukaemic stem cell has been identified following transplantation of primary human AML cells into immunodeficient mice (Figure 28.3a). Leukaemic stem cells are relatively rare (most of the cells in a given leukaemia represent partially differentiated progeny), have the same surface markers as normal haemopoietic stem cells and are the only cells from the primary leukaemia capable of generating leukaemia in recipient mice.

These properties of leukaemic stem cells have significant implications for the treatment of malignant haematological disorders. A curative strategy must eliminate all malignant cells with the ability to self-renew and hence the capacity to regener-

ate the malignancy. Moreover, a fraction of leukaemic stem cells, like their normal counterparts, are metabolically inactive and in G_0, and so many conventional cell cycle-specific cytotoxics will be ineffective.

Lymphoid malignancies
In contrast to the myeloid malignancies, most lymphoid malignancies do not appear to result from transformation of a haemopoietic stem cell. Instead, lymphoid tumours arise from cells already committed to lymphoid differentiation, perhaps reflecting in part the fact that lymphocytes retain the potential for self-renewal and proliferation following exposure to antigen. Translocations associated with lymphoid tumours frequently reflect mistakes that occur during the normal process of antigen receptor rearrangement. During normal B-cell development, the *IGH* locus sequentially undergoes V(D)J rearrangement, somatic hypermutation and class switching. In B-cell malignancies, the timing of an associated translocation can therefore be inferred from analysis of the immunoglobulin locus sequence adjacent to the breakpoint (Figure 28.3b).

The cell of origin for mantle cell lymphomas and follicular lymphomas may well be pregerminal and germinal centre B cells undergoing immunoglobulin gene rearrangement. The breakpoints of the t(11;14) and the t(14;18) translocations tend to occur between the D and J segments of the *IGH* locus, suggesting

that they arise from mistakes of DJ recombination. In Burkitt's lymphoma, the c-*MYC* gene is frequently juxtaposed with a fully V(D)J rearranged and hypermutated *IGH* variable region in the t(8;14) translocation. Breakpoints are found clustered in the VJ sequences that are particular targets for somatic hypermutation, suggesting that the double-stranded DNA breaks effected during hypermutation may cause the translocations. Class switch recombination appears to be responsible for many of the translocations that occur in multiple myeloma, because the breakpoints are found in immunoglobulin heavy-chain switch regions.

These observations provide evidence that the translocations associated with different B-cell malignancies occur at distinct times within B-cell ontogeny. However, two caveats should be emphasized. First, *IGH* translocations may not represent initiating events. It remains formally possible that an unknown earlier lesion precedes the translocation and occurs in a more primitive cell. Second, transformed cells undergo partial differentiation even after acquiring an *IGH* translocation. For example, follicular lymphoma cells have both the histological appearances and gene expression signatures of germinal centre cells. For this continued differentiation to occur, the pregerminal centre cell with the t(14;18) translocation must have been able to participate in an antigen-driven germinal centre response. Consistent with this idea, there is evidence for on-going somatic hypermutation within the tumour clone.

Phenotype–genotype correlations

One of the most striking properties of leukaemias and lymphomas is the close relationship between certain cytogenetic or molecular abnormalities and unique morphological and clinical features. For example, the cells of Burkitt's lymphoma are characterized by a very distinctive morphological appearance and are almost universally associated with translocations involving the *MYC* gene. Similar strong associations occur between acute myelomonocytic leukaemia with abnormal eosinophil precursors (M4Eo AML) and the inv(16) abnormality, acute promyelocytic leukaemia and the *PML–RARα* fusion gene, and mantle cell lymphoma and the t(11;14) translocation.

There are two potential explanations for such associations. The nature of the chromosome rearrangement may determine the phenotype of the resultant leukaemia. Alternatively, a specific chromosome rearrangement may only occur in, or provide a selective advantage for, progenitor cells committed to a particular lineage. Both models may well be correct. For example, different subtypes of AML associated with distinct translocations, and which appear very different morphologically, contain leukaemic stem cells that appear identical in their pattern of cell surface markers. Thus, it seems that in AML it is the acquired genetic alterations that determine distinct phenotypes, and not the characteristics of the target cell. By contrast, several translocations involving the *IGH* or *TCR* loci are thought to be restricted to lymphoid tumours because sequences adjacent to the oncogenes mimic sequences involved in *IGH* rearrangement. The translocations may therefore only occur in cells at particular stages of lymphoid differentiation.

Nature of acquired genetic abnormalities

Translocations

The best-understood genetic abnormalities in haematological malignancies are chromosomal translocations. Balanced translocations involve a reciprocal exchange of genetic material between two chromosomes and may result in aberrant function of genes adjacent to the breakpoint (see also Chapter 30). Two common mechanisms have been described (Figure 28.4).

First, a fusion gene may be generated and encode a fusion protein with oncogenic properties. This mechanism is seen in many of the translocations associated with myeloid malignancies and some associated with ALL. Fusion proteins contain a combination of functional modules donated by the two partner proteins. As a consequence, the fusion protein is endowed with novel functions. For example, in fusion proteins that involve a tyrosine kinase, the partner protein invariably contributes a dimerization domain that allows the fusion protein to form oligomers spontaneously, thus resulting in constitutive activation of the kinase.

A fusion gene can also result from an interstitial deletion (such as deletion of chromosome 4 giving rise to the *FIP1L1–PDGFRA* fusion gene in chronic eosinophilic leukaemia) or inversion of
Figure 28.4 Recurrent translocations may result in fusion gene formation or transcriptional dysregulation of an intact target gene.

part of a chromosome (such as inversion 16 in the M4Eo subtype of AML).

The second category of translocations results in a structurally intact gene being placed next to regulatory elements from a gene on the partner chromosome. This scenario is frequently observed in lymphoid malignancies in which the normal process of antigen receptor rearrangement goes awry and results in translocations involving immunoglobulin or *TCR* loci. For example, in some B-cell tumours, genes such as *MYC* and *BCL2* are aberrantly expressed in B-cell precursors because they have been placed under the control of enhancers from one of the immunoglobulin loci. Similarly, in some cases of T-cell ALL, the *SCL* and *HOX11* genes are ectopically expressed in T-cell precursors when they relocate next to enhancers from the *TCR* loci. In addition, transcriptional dysregulation can occur as a consequence of deletions, such as chromosome 1 deletions resulting in dysregulation of the *SCL* gene (also known as *TAL1*) in T-ALL.

All balanced translocations give rise to two abnormal chromosomal products, one of which is usually implicated as the pathogenetic culprit. However, it is increasingly recognized that the other chromosomal product may also influence tumorigenesis. For example, in CML associated with the t(9;22) translocation, it is clear that the Philadelphia (derivative 22) chromosome carries the *BCR–ABL* fusion gene, which is central to the development of this leukaemia. However, in a subset of patients, the derivative 9 chromosome also carries a deletion that spans the translocation breakpoint. These deletions are thought to arise at the time of the Ph translocation and are associated with a particularly poor prognosis, perhaps reflecting the loss of one or more tumour-suppressor genes.

Similarly, in acute promyelocytic leukaemia, the t(15;17) translocation results in production of a *PML–RARα* fusion transcript from the derivative 15 chromosome, and considerable evidence supports a pivotal role for this transcript in the genesis of this form of leukaemia. However, in 70–80% of patients, the derivative 17 chromosome also expresses an *RAR–PMLα* transcript, which encodes a fusion protein that has functional domains capable of binding the p53 protein, and which influences the development of leukaemia in a mouse model.

What causes translocations to occur in the first instance? In the case of lymphoid tumours, chromosomal rearrangements and mutation are a feature of normal lymphocyte development. Rearrangements of immunoglobulin genes and the *TCR* genes require a series of double-stranded DNA breaks, with loss of intervening sequence and religation, and oncogenic translocations are likely to represent rare mistakes that arise during this process. There may be several reasons why certain genes are preferentially involved in these translocations. First, motifs similar to those recognized by the immunoglobulin or *TCR* recombinase have been found adjacent to the *BCL2* and *SCL* genes, which are involved respectively in the t(14;18) translocation of follicular lymphoma and the t(1;14) associated with T-ALL. Second, it is probable that dysregulation of only

certain genes will confer a selective advantage on B- or T-cell progenitors. Third, physical proximity may play a role, as partner genes of *IGH* translocations are more likely to collocalize with the *IGH* locus in the same spatial zone of the interphase nucleus.

For myeloid cells, the mechanism of translocation is poorly understood. Central to most models is a double-stranded break in genomic DNA. These breaks occur spontaneously, but can be increased in frequency by exposing marrow cells to ionizing radiation or other DNA-damaging agents, known risk factors for leukaemia. Normal repair mechanisms, such as homologous recombination or non-homologous end joining, then attempt to join the broken ends of DNA. However, these mechanisms are not infallible, and it is conceivable that they could misrepair two simultaneous breaks on different chromosomes to generate a translocation. Germline mutations in DNA repair genes (such as the ataxia telangiectasia gene) certainly increase the frequency of chromosome rearrangements and the incidence of many cancers, including leukaemias. It may also be relevant that Alu repeat sequences appear to cluster at or near translocation breakpoints in CML and other malignancies, as it has been suggested that the Alu core sequence acts as a binding site for proteins mediating homologous recombination and DNA repair.

Consensus sites for topoisomerase II binding may play a role in some translocations, particularly those involving the *MLL* locus. Topoisomerase inhibitors, such as etoposide and anthracyclines, are well-recognized causes of therapy-related leukaemia, often associated with translocations involving the *MLL* gene on chromosome 11q23. Topoisomerase II creates double-stranded breaks during execution of its function of relaxing overwound DNA, and it appears that topoisomerase II inhibitors may stabilize complexes that are formed between the enzyme and free DNA ends, thus increasing the likelihood that those ends might participate in a translocation.

Deletions and aneuploidy
